Advanced Bedside Neuromonitoring

Jovany Cruz Navarro, Samantha Fernandez Hernandez, and Claudia S. Robertson

INTRODUCTION

Little can be done to reverse the primary brain damage caused by an insult; however, one of the major factors influencing outcome in patients with acute brain injury is the additional brain damage that occurs from secondary brain injury processes.[1] These secondary insult processes entail a combination of inflammatory, biochemical, and excitotoxic changes,[1,2] making it challenging for the clinician to detect which processes are most important to monitor in order to obtain the most favorable outcome.[3] In addition, secondary ischemic insults of extracerebral origin (e.g., arterial hypotension, hypoxemia) can be prevented or treated before they become severe enough.[4] The main purpose of advanced monitoring of the brain in the intensive care unit (ICU) is to detect these secondary insults, allowing for a more informed, individualized approach to treatment.[3–5]

MONITORING NEUROLOGIC STATUS

The clinical approach to a patient with a neurologic problem requires the physician to have a specialized anatomic and physiologic knowledge of the nervous system. Daily evaluation of neurologic and mental status should be included in the neuromonitoring protocol. Neuromonitoring should include the Glasgow Coma Scale (GCS) score, function of pyramidal and extrapyramidal systems, status of cranial nerves, function of the cerebellum and spinal cord whenever possible, and any changing trend in the neurologic status. In critically ill patients, such a complete neurologic evaluation can sometimes be unreliable or impossible because of the use of sedatives and the need for intubation and ventilatory support as part of the medical treatment of the neurologic problem. However, in the nonsedated patient, the Full Outline of UnResponsiveness (FOUR) score, which measures ocular and limb responses to commands and pain, pupillary responses, and respiratory pattern,[6] may provide a more complete assessment of brainstem function. The FOUR score has been shown to perform equally well as the GCS in critically ill patients after brain injury,[7] possessing a similarly predictive power of outcome and the capability of being assessed in intubated patients.[8,9] Current evidence suggests that both the GCS and FOUR score provide useful and reproducible measures of neurologic state and can be routinely used to chart trends in clinical evaluation.

Pupillary evaluation is a strong predictor of outcome that must be integrated into the daily GCS evaluation. However, poor interrater reliability exists among practitioners when it comes to pupillary assessment. Devices like the handheld pupillometer provide objective measurement of pupillary response and diameter, but more clinical experience is needed to determine if they should be included as a standard of care.[10]

Along with neurologic examination, information about vital signs and key laboratory values should be immediately available in a 24-hour record sheet or electronic medical record. Assessment of pain and sedation can be challenging in the context of brain injury. Evidence recommends the use of validated and reliable scales such as the Sedation-Agitation Scale (SAS) and Richmond Agitation-Sedation Scale (RASS),[11] as these provide workable solutions in some patients.

"Wake-up tests" in patients with intracranial hypertension pose significant risks[12] and show no proven benefits in terms of duration of mechanical ventilation, length of intensive care unit (ICU) and hospital stay, or mortality rate in patients with neurologic disorders.

The Glasgow Outcome Scale (GOS) has been the standard outcome tool for neurocritical care. However, other tools, such as the Neurological Outcome Scale for TBI (NOS-TBI), have been adapted for traumatic brain injury (TBI) patients from the National Institutes of Health Stroke Scale (NIHSS).[13] This scale has demonstrated adequate predictive validity and sensitivity to change compared with gold-standard outcome measures and may enhance the prediction of outcome in clinical practice and research.[14]

INTRACRANIAL PRESSURE AND CEREBRAL PERFUSION PRESSURE

The threshold that defines normal or raised intracranial pressure (ICP) is uncertain, but normal resting ICP in an adult is considered to be less than 15 mm Hg, and a sustained ICP >20 mm Hg is considered pathologic.[3,15] In the 2016 Guidelines for the Management of Severe TBI, an ICP threshold >22 mm Hg was adopted as a level IIb recommendation to initiate treatment to reduce ICP in order to reduce mortality.[16] The necessity of ICP monitoring was questioned by the BEST-TRIP trial[17]: the researchers found no significant difference in outcome when management of patients with severe TBI was guided by either (1) ICP monitoring or (2) neurologic examination and imaging. However, the results of this trial are research oriented and highlight the necessity for further studies and may not be generalizable to other populations. First, the study was conducted on two developing countries where prehospital resuscitation might be less developed, resulting in higher episodes of secondary insults such as hypotension and hypoxia, and severely injured patients may not survive long enough to reach the hospital. Thus the study population may have had less severe brain injury than comparable ICUs in developed countries. Finally, 6-month survival was confounded by increased mortality after ICU discharge, possibly related to limited resources to receive rehabilitation and prolonged medical care.[18] In the most current Brain Trauma Foundation Guidelines (BTFG) for severe

TBI, monitoring of ICP is recommended in the management of severe TBI patients to reduce in-hospital and 2-week postinjury mortality, and the previous 2007 BTFG recommendations are no longer valid because of lack of supporting evidence.[16] Moreover, the Milan consensus does not recommend ICP monitoring in a comatose patient in the setting of normal imaging.[19] Treatment of ICP is important, and in circumstances where adequate resources are available, such treatment is advised.

Cerebral perfusion pressure (CPP) is the difference between the mean arterial blood pressure (MAP) and ICP. Under normal physiologic conditions, a MAP of 80–100 mm Hg and an ICP of 5–10 mm Hg generate a CPP of 70–85 mm Hg.[20] Cerebral blood flow (CBF) is determined by both CPP and cerebrovascular resistance (CVR) according to the formula CBF = CPP / CVR.

Under normal circumstances, the brain is able to maintain a relatively constant CBF of approximately 50 mL per 100 g/min over a wide range of CPP (60–150 mm Hg).[21] After injury, the ability of the brain to pressure autoregulate can be impaired, and CBF is often dependent on CPP.

The recommendations for an adequate CPP have changed over time and may in part be associated with the variability in how MAP is measured[22] and the autoregulatory function status. The 2007 BTFGs recommend targeting CPP values within the range of 60–70 mm Hg.[16] CPP values <60 mm Hg increase the risk of cerebral ischemia and hypoperfusion, whereas therapies required to maintain CPP >70 mm Hg such as intravenous fluids administration have been associated with an increased risk of acute respiratory failure.[16]

INTRACRANIAL PRESSURE MONITORING DEVICES

The current gold standard for ICP monitoring is the ventriculostomy catheter, or external ventricular drain (EVD), which is a catheter inserted in a lateral ventricle, usually via a small right frontal burr hole. This ventricular catheter is connected to a standard pressure transducer that must be maintained at a specific level. The reference point for ICP is the foramen of Monro, although in practical terms, the external auditory meatus is often used as a landmark.[23] Advantages of EVDs include the ability to measure global ICP and to perform periodic in vivo external calibration and therapeutic cerebrospinal fluid (CSF) drainage and sampling. However, intraventricular catheters are also associated with the highest rate of infection among the ICP monitors.[1] Several microtransducer-tipped ICP monitors are available for clinical use (e.g., Camino ICP monitor, Codman microsensor, Hummingbird ICP, and Neurovent-P ICP monitor). These catheter-based transducers can measure pressure directly in the brain parenchyma. Although there are fewer risks of infection and intracranial hemorrhage with these catheters,[1] the main disadvantage of these probes is that they cannot be calibrated in vivo. Also, after preinsertion calibration, they may exhibit zero drift (degree of difference relative to zero atmospheres) over time.[24]

Noninvasive ICP monitoring devices have been developed to reduce the risk associated with invasive monitors. Such technologies include displacement of the tympanic membrane,[25] optical detection of cerebral edema,[26] transcranial Doppler pulsatility index, and magnetic resonance of the optic nerve sheath, among others.[23] So far, none of these methods has provided sufficient accuracy to replace invasive monitors.

ICP WAVEFORMS

The normal ICP waveform consists of three arterial components superimposed on the respiratory rhythm. The first arterial wave is the percussion wave, which reflects the ejection of blood from the heart transmitted through the choroid plexus in the ventricles. The second wave is the tidal wave, which reflects brain compliance, and the third wave is the dicrotic wave that reflects aortic valve closure. Under physiologic conditions, the percussion wave is the tallest, with the tidal and dicrotic waves having progressively smaller amplitudes. When intracranial hypertension is present, cerebral compliance is diminished. This relationship is reflected by an increase in the peak of the tidal and dicrotic waves exceeding that of the percussion wave (Fig. 42.1).

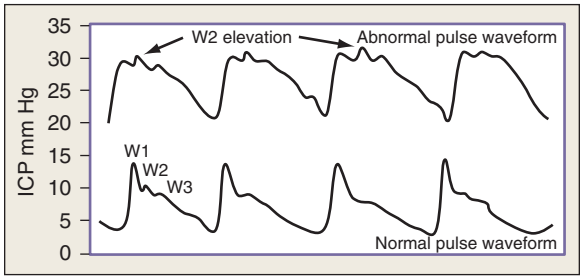

Fig. 42.1 *(Upper tracing)* Normal intracranial pressure (*ICP*) waveform and its components: W1 (percussion wave), W2 (tidal wave), and W3 (dicrotic wave). *(Bottom tracing)* As ICP increases, distinctive waveform changes occur (e.g., elevation of the second pulse wave and "rounding" in the ICP waveform).

COMPLICATIONS

Among the complications related to ICP monitoring, intracranial hemorrhage and infections are the most common.[1,23] Less frequent complications are malfunction, malposition, and obstruction. Although these complications generally do not produce long-term morbidity in patients, they can cause inaccurate ICP readings and may increase hospitalization costs by requiring replacement of the monitor.

The incidence of infection is reported to range from 0% to 22%,[27] depending on the type of device. Several other factors have been identified that may affect the risk of EVD infection: the use of prophylactic parenteral antibiotics, the presence of other concurrent systemic infections, the presence of intraventricular or subarachnoid hemorrhage (SAH), duration of monitoring, open skull fracture (including basilar skull fractures with CSF leak), leakage around the ventriculostomy catheter, and repeated flushing of the EVD.[28] Prophylactic antibiotic-impregnated catheters may be used in order to reduce EVD-associated infections; however, more trials should be conducted to evaluate the beneficial effect on clinical outcome. Placement of ICP monitors should be done under the most sterile possible conditions, minimizing excessive manipulation and flushing. The second most common complication related to ICP monitoring is postprocedural intracerebral hemorrhage (<1%).[27]

JUGULAR VENOUS OXYGEN SATURATION

Placement of a jugular venous oxygen saturation ($SjvO_2$) catheter involves retrograde insertion into the internal jugular vein of a catheter equipped with an oxygen sensor at the tip. The catheter is similar to the type used for CVP monitoring but is directed cephalad into the jugular bulb.[29] The tip of the catheter must be placed above the C1–C2 vertebral bodies to avoid contamination with blood coming from the facial vein. Correct positioning of the catheter can be confirmed with a lateral skull x-ray (Fig. 42.2). The incidence of complications related to the $SjvO_2$ catheter is low but includes carotid artery puncture, hematoma formation, infection, thrombosis, and increased ICP that may arise during catheter insertion or with prolonged monitoring.

SIDE OF JUGULAR CATHETERIZATION

The International Consensus on Multimodal Monitoring in Neurocritical Care recommends that the catheter site placement be based on the diagnosis, the type and location of brain lesions, and technical

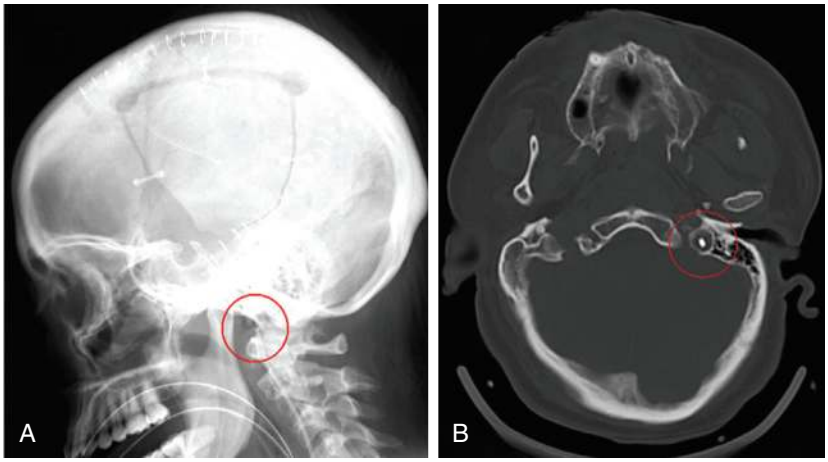

Fig. 42.2 A, Lateral skull x-ray confirming adequate $Sjvo_2$ catheter placement at the C1–C2 level. **B,** Head computed tomography scan showing the catheter tip correctly placed at the jugular venous bulb level.

feasibility.[30] If the strategy is to use $SjvO_2$ as a monitor of global oxygenation, then cannulating the dominant jugular vein is logical because it is most representative of the whole brain. The dominant internal jugular vein is the larger of the two internal jugular veins, as determined by ultrasound imaging.

NORMAL JUGULAR VENOUS OXYGEN SATURATION

$SjvO_2$ reflects the global balance between cerebral oxygen delivery (supply) and the cerebral metabolic rate of oxygen (demand). When arterial oxygen saturation, hemoglobin concentration, and the hemoglobin dissociation curve remain stable, $SjvO_2$ generally parallels changes in CBF. Normal $SjvO_2$ values range from 55% to 75%,[31] and jugular venous desaturation has been associated with worse outcomes post-TBI.[1] Current guidelines recommend maintaining $SjvO_2$ >50% in order to improve outcomes in the TBI population (level III recommendation),[16] acknowledging the fact that $SjvO_2$ >75% has also been associated with poor neurologic outcomes.[1,31] $SjvO_2$ provides only information of a global state of cerebral oxygenation, and focal ischemic areas are not evaluated with this technique. Multiple pathologic clinical scenarios may cause an increase or decrease in $SjvO_2$ values (Table 42.1).

TRANSCRANIAL DOPPLER FLOW VELOCITY AND FLOW VOLUME

Transcranial Doppler (TCD) ultrasonography is a noninvasive monitoring technique that measures blood flow velocity in one of the major arteries at the base of the brain. A 2-MHz pulsed ultrasound signal is transmitted through the skull (usually through the temporal bone) and, using the shift principle, measures red cell flow velocity. Flow volume is directly proportional to flow velocity and can be calculated by multiplying the velocity by the cross-sectional area of the vessel insonated. Cerebral vasospasm after aneurysmal SAH and traumatic SAH is a major cause of disability, with a similar incidence among both groups.[32] Angiography remains the gold standard for diagnosing posttraumatic vasospasm,[33] but TCD ultrasonography gives a noninvasive alternative for daily bedside monitoring of the CBF dynamics. Current literature suggests a high level of suspicion for posttraumatic vasospasm when velocities are above 200 cm/sec per TCD examination.[33] The Lindegaard ratio (middle cerebral artery–to–extracranial internal carotid artery flow velocity ratio) helps in differentiating vasospasm from hyperemia; vasospasm is considered to be present if the Lindegaard ratio index is greater than 3, and severe vasospasm when it is greater than 6.[34] In hyperemia, the flow velocity for both intracranial and extracranial vessels increases, whereas in vasospasm, high-flow velocity is seen only in intracranial vessels, resulting in a high ratio.

Vasospasm after TBI or SAH has an impact on morbidity and mortality. Frequently, the first clinical sign is a deterioration in the neurologic examination, which occurs too late to reverse the process. TCD ultrasonography may identify changes in flow velocity that can precede these clinical findings and may lead to further diagnostic assessment and therapy. The major drawback of TCD ultrasonography is that it is operator dependent, though color-coded TCD provides improved accuracy of measurement.

TCD studies have high specificity as a supporting tool for the diagnosis of brain death.[35] Brief systolic forward-flow spikes with reversed or absent diastolic flow found bilaterally or in three different arteries are accepted TCD criteria to support the diagnosis of brain death. TCD should not be used as a sole brain death diagnostic tool.[36]

TABLE 42.1 Clinical Conditions Associated With Alterations in $SjvO_2$ Values

Increased $SjvO_2$	Restricted oxygen diffusion or extraction resulting from neuronal infarction or inflammation Decreased cerebral metabolism Hyperemia
Decreased $SjvO_2$	Local or systemic hypoperfusion (e.g., intracranial hypertension, shock or prolonged hypotension, vasospasm) Decreased systemic oxygen supply (e.g., low PaO_2) Increased cerebral metabolism or oxygen extraction (e.g., seizures, fever) Anemia

BRAIN TISSUE OXYGEN PARTIAL PRESSURE

A major limitation of $SjvO_2$ technology is that regional ischemia cannot be identified. After TBI, regional differences in CBF are commonly seen. Brain tissue oxygen partial pressure ($PbtO_2$) is a tool that measures local brain oxygen partial pressure levels. It has proven to be the most reliable cerebral oxygenation monitoring technique to date.[1]

$PbtO_2$ is measured using a polarographic Clark-type electrode at the tip of a catheter placed in the brain parenchyma. The Clark electrode polarographic probe has a semipermeable membrane covering two

electrodes. In the presence of dissolved oxygen crossing the membrane, an electric current is generated and then transferred to a monitor for interpretation. Temperature is also needed to calculate the oxygen tension—brain temperature rather than core temperature is preferred for this purpose, as a sensor is incorporated into the $PbtO_2$ catheter.[37]

Normal values for $PbtO_2$ range from 20 to 40 mm Hg[1,5,30,38]; levels below 20 mm Hg are indicative of compromised brain oxygen, and intervention should be considered. The likelihood of poor outcome after severe TBI increases with long periods of $PbtO_2$ below 20 mm Hg. It has been reported that low $PbtO_2$ values after a severe TBI are present within the first few days postinjury in up to 70% of patients.[38]

Correct probe placement and depth into the region of interest are key for successful monitoring of $PbtO_2$. Two general strategies have been used for placement of this probe. Some recommend placement of the probe into relatively normal brain tissue so that the PO_2 values reflect global brain oxygenation.[5] Changes in $PbtO_2$ correlate well with changes in $SjvO_2$ when the sensor is inserted into noncontused areas of the brain. Others recommend placement of the probe into penumbra tissue so that PO_2 values reflect oxygenation in the most vulnerable areas of the brain.[1] Regardless of the strategy used, the $PbtO_2$ values must be interpreted with the understanding that the values measure only the local tissue surrounding the catheter. $PbtO_2$ monitoring is safe and provides accurate data for up to 10 days and can be used to guide pharmacologic, hemodynamic, or respiratory therapy.[30] Along with ICP monitoring, $PbtO_2$ assessment has been incorporated into an overall management strategy of patients suffering from severe TBI. A recently completed two-arm, single-blind, prospective, randomized controlled multicenter phase II trial (BOOST-II) showed that ICP + $PbtO_2$–guided management in severe TBI compared with ICP alone was associated with reduced mortality and improved outcomes 6 months postinjury.[38] BOOST-II demonstrated that ICP + $PbtO_2$–guided management is not only safe but nonfutile, laying the foundation for BOOST-3, which is a phase III trial that will assess the impact of ICP + $PbtO_2$–guided management in severe TBI on neurologic outcome.

Treatment for a reduced $PbtO_2$ should be first directed at any underlying causes of inadequate cerebral oxygen delivery. Such corrections might include increasing CPP (reducing ICP, increasing MAP), improving arterial oxygenation, transfusions for a low hemoglobin concentration,[1,5] reducing fever, or treating subclinical seizures. If an underlying cause for the low $PbtO_2$ is not found, or if $PbtO_2$ remains low after optimizing oxygen delivery, obtaining a follow-up computed tomography (CT) scan of the head might be considered to assess whether a delayed hematoma or hemorrhagic contusion has developed. A sustained (>30 min) $PbtO_2$ of 0 mm Hg and no response to oxygen challenge are consistent with brain death,[39] although care related to interpretation in this regard is needed, depending on the location of the probe or potential probe malfunction.[40]

NEAR-INFRARED SPECTROSCOPY

Near-infrared spectroscopy (NIRS) is based on the fact that light in the near-infrared range (700–1000 nm) can pass through skin, bone, and other tissues with relative ease. After the light has penetrated, it will either be scattered or absorbed. Tissues such as bone and skin will scatter the light, whereas oxygenated and deoxygenated hemoglobin, possessing a different absorption spectra, will mostly absorb it and have a lower scattering effect.[41] Changes in the absorbance of near-infrared light as it passes through these compounds can be quantified using a modified Beer-Lambert law, which describes optical attenuation. The main advantage of NIRS is that it is a noninvasive method for estimating regional changes in cerebral oxygenation.[1] Some studies have reported its potential utility in the prehospital management of severe TBI.[42] However, its clinical use is limited by an inability to differentiate between intracranial and extracranial changes in blood flow and oxygenation; lack of standardization between commercial devices; and confounded saturation signals because of the presence of epidural, subdural, or intracranial hematomas.[42] Given the latter limitation, Brogan and colleagues conducted a systematic review and meta-analysis on the use of NIRS as a possible diagnostic tool to detect traumatic intracranial hematomas. The authors found NIRS to have a low cross-study sensitivity and negative predictive value (NPV) for intracranial hematomas, making it inadequate for use as a diagnostic tool.[41] Currently, there are no studies providing evidence that NIRS use alone can influence outcomes in adult neurocritical care.

ELECTROENCEPHALOGRAM

An electroencephalogram (EEG) depicts the spontaneous electrical activity of the cerebral cortex and is generated mainly by the summation of excitatory and inhibitory postsynaptic potentials of cortical neurons. It does not reflect activity in subcortical levels, cranial nerves, or the spinal cord. The electrical signal is amplified, filtered, and then displayed as either 8 or 16 channels (8 channels per hemisphere) to give an accurate representation of electrical activity throughout the cortex. EEG activity is usually interpreted in terms of frequency, amplitude, and location (focal or generalized activity).

EEG is the most frequently used electrophysiologic technique in the ICU. It offers information about brain electrical activity and is essential to detect clinical and subclinical seizures. The presence of seizures, including duration and response to therapy, may predict outcome after coma, with or without known acute brain injury in the ICU setting.[30] After TBI, a cascade of neurometabolic disruptions (i.e., release of excitatory neurotransmitters, neuroinflammation) unfold, adversely affecting cerebral physiology and leading to posttraumatic seizures (PTSs) and secondary brain injury.[5,43] PTSs can occur in up to 40% of TBI patients, with the vast majority of these being nonconvulsive seizures (NCSs) or nonconvulsive status epilepticus (NCSE).[43] Continuous EEG (cEEG) in comatose TBI patients admitted to the ICU has been recommended in order to monitor subclinical seizures, as routine noncontinuous EEG could not capture these events.[44]

A low threshold for obtaining a continuous EEG must be considered in patients with acute brain injury and unexplained alteration of consciousness. It is also urgently needed in patients with convulsive status epilepticus who remain unresponsive after 1 hour of administering adequate antiepileptic treatment.[30,44] cEEG is strongly recommended in patients undergoing therapeutic hypothermia and within 24 hours of rewarming to exclude NCS in all comatose patients after cardiac arrest.[45]

In recent years, a more invasive form of cerebral electrical activity monitoring has been studied in humans: intracranial EEG using either subdural strip electrodes or intracortical depth electrodes.[1,46] This invasive form of EEG has been shown to be superior at identifying certain forms of seizures not detected by standard scalp EEG, in addition to slowing potential changes that move across the cortex, called *cortical spreading depolarizations (CSDs)*.[46,47] CSDs (or just spreading depressions) have been described in animal models by Leão since the 1940s.[48] CSDs have been identified in up to 70% of TBI patients through intracranial EEG and are associated with secondary insults and worsening of clinical outcomes.[1,47,49,50] Currently, observational studies are underway to better elucidate the application and effect of CSD monitoring on TBI patients, such as the "Spreading Depolarizations in Traumatic Brain Injury" trial, a substudy of the TRACK-TBI consortium.

MICRODIALYSIS

Microdialysis is a technique used to sample the extracellular fluid of cerebral tissue. This method is based on the diffusion of water-soluble substances through a semipermeable membrane, which can sample small molecules (<20 kDa) such as glucose, glycerol, glutamate, lactate, and pyruvate and larger ones (>100 kDa) such as cytokines. The degree of permeability of the membrane determines the molecular weight of the substances that can cross it. Although the recovery of larger molecules has been better studied in the past decade, 100-kDa catheters are not yet Food and Drug Administration (FDA) approved as of the time this manuscript was created.[51]

The concentration of substances in the dialysate depends on the flow rate and chemical composition of the perfusate, the length of the dialysis membrane, the type of dialysis membrane, and the diffusion coefficient of the tissue. The recovery of a particular substance is defined as the concentration in the dialysate divided by the concentration in the interstitial fluid. If the membrane is long enough and the flow slow enough, the concentration in the perfusate will be the same as that in the interstitial fluid (i.e., 100%).

The technique of cerebral microdialysis allows continuous and online monitoring of changes in brain tissue chemistry. As with brain tissue oxygenation monitoring, microdialysis also involves inserting a fine catheter (diameter 0.62 mm) into the brain. Catheter location will vary depending on the site and type of injury and the goals of treatment.[51] The dialysate, which is collected in vials that are exchanged every 10–60 minutes, is then analyzed using sensitive assays.

The key substances measured by microdialysis that have proven to be clinically significant because of their representation of brain chemistry are glucose, lactate, pyruvate, glutamate, and glycerol.[1,51] The clinical value of these substances can be described in a tiered fashion (with tier 1 being the most clinically significant) as follows:
Tier 1: Lactate:pyruvate (LP) ratio and glucose
Tier 2: Glutamate
Tier 3: Glycerol

Lactate:Pyruvate Ratio

An elevated LP ratio has been associated with worse outcomes. If the LP ratio is elevated in the presence of low pyruvate, it signifies ischemia. If, however, the LP ratio is elevated in the presence of normal or high pyruvate, it indicates mitochondrial dysfunction.

Glucose

Studies have shown that both low brain glucose (<0.8 mM) and high brain glucose are associated with worse outcomes; however, a definitive normal range has not been established yet.

Glutamate

Glutamate is an excitatory neurotransmitter that is released during seizures and ischemia; it is also associated with worse outcomes after TBI.

Glycerol

Glycerol, a marker of oxidative stress, has limited specificity for brain injury and/or ischemia; it is influenced by systemic concentrations, and no association with outcomes after TBI has been found yet.

Metabolite variations over time can help with clinical management and are not limited to identification of ischemia, but allow monitoring of energy metabolism in the brain as well.

Cerebral microdialysis has a very low complication rate; nonetheless, there are a number of limitations regarding its clinical use, including its focal measurement and the fact that it discloses different metabolite concentrations when inserted into pathologic versus preserved brain areas. Consequently, microdialysis results should be interpreted based on the location of catheter insertion, confirmed by postinsertion CT.[30]

Microdialysis, when used with multimodality monitoring, may enhance the understanding of cerebral physiology and pathophysiology and guide management and individualized therapy.[51,52] Future research studies should focus on assessing the effectiveness of microdialysis-guided management as part of a multimodal monitoring approach in acute brain injury.

KEY POINTS

- Evaluation of neurologic and mental status should be included in the monitoring protocol whenever possible.
- The ventriculostomy catheter remains the preferred device for monitoring ICP and is the standard against which all new monitors are compared.
- The two major complications of ICP monitoring are ventriculitis and ICH.
- The simplest measure of cerebral perfusion is CPP. For equivalent levels of CPP, cerebral perfusion is impaired more by decreases in blood pressure than by increases in ICP.
- TCD ultrasonography is a noninvasive monitor that provides indirect information about CBF in one of the major arteries at the base of the brain. In the absence of vessel stenosis, vasospasm, or changes in arterial blood pressure or blood rheology, pulsatility reflects the distal cerebrovascular resistance.
- The Lindegaard (hemispheric) index is the ratio of flow velocity in the middle cerebral artery and the internal carotid artery. The mean hemispheric index in normal individuals is 1.76 ± 0.1, and pathologic values suggestive of vasospasm are generally above 3.
- Normal values for $PbtO_2$ are 20–40 mm Hg, and critical reductions are below 20 mm Hg.
- The use of EEGs in the ICU to detect early subclinical seizures may help reduce mortality and morbidity in status epilepticus. Invasive EEG has been proven to be the only monitoring modality in detecting spreading depolarizations, which have been associated with worse outcomes after TBI.

Coma

Melissa B. Pergakis and Wan-Tsu W. Chang

COMA

Disorders of altered consciousness present a diagnostic dilemma to the clinician in the critical care setting. They represent a wide of range of pathology that can be systemic in nature or the result of structural or nonstructural intracranial pathology. Immediate evaluation and accurate diagnosis leading to lifesaving interventions are of paramount importance, as some causes of coma are irreversible. However, this can be a difficult task in critically ill patients. As such, the clinician must have an understanding of underlying disorders of consciousness and coma, the anatomy and pathophysiology leading to this disease state, a systemic approach in history taking and examination, and a rapid approach to workup and early therapeutic interventions.

DEFINING DISORDERS OF CONSCIOUSNESS

Consciousness is defined as a state of full awareness of one's self and relationship to the environment and is composed of content and arousal.[1,2] Whereas arousal is akin to one's wakefulness and alertness, content of consciousness includes higher cerebral functional activity and awareness of one's relationship to self and environment. As one might expect, content of consciousness is not possible without a certain level of arousal.[1]

Coma is defined as a state of unresponsiveness. The patient lies in the bed with eyes closed without any purposeful response to external stimuli.[1] Motor responses to deep painful stimuli may include flexor or extensor posturing, but comatose patients will not have any meaningful or purposeful movements, including localization.

Several other pathologic states of consciousness often referred to in the critical care setting demonstrate variable levels of arousal and awareness. These include *lethargy, obtundation, stupor, clouding of consciousness,* and *delirium. Lethargic* patients are severely somnolent, although they can be awoken by minimal stimuli; however, they will drift off to a state of drowsiness when continuous stimuli are not applied. *Obtunded* patients are similar to lethargic patients but have even less interest in their surroundings and slower responses to any sort of stimulation. These patients often exhibit more somnolence than lethargic patients. *Stuporous* patients require vigorous stimulation to be kept awake and if not stimulated will quickly fall into a state of unresponsiveness, and thus represent a state between awareness and coma.[1,3,4]

In contrast to patients requiring minimal or more extreme forms of stimuli for wakefulness, patients can also have *clouding of consciousness, confusional state,* and *delirium. Clouding of consciousness* refers to an altered state of consciousness that is defined by inattention and reduced wakefulness, whereas a *confusional state* tends to be more extreme and includes disorientation and inability to follow commands. *Delirium* and *confusional state* are often used interchangeably; however, *delirium,* by definition of the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edn (DSM-V) is defined as altered consciousness with shifting attention or inability to focus and fluctuating course.[5]

As one can imagine, these terms can be nebulous, oftentimes overlap, and are not always used in the appropriate clinical context to accurately describe a patient's level of consciousness. Consequently, standardized scales have been developed to aid providers in measuring level of consciousness in patients. These scales serve as important tools when communicating with other healthcare providers. The scale most often used is the Glasgow Coma Scale (GCS)[6] (Table 43.1), which was initially used in trauma patients. The GCS measures three different criteria—eye opening, motor response, and verbal response—with lower scores indicating a poor examination. Typically, a score of 8 or below is indicative of coma.[6] It is important to note that it is not possible to assess verbal response in intubated patients. Brainstem reflexes, an essential aspect of the examination in a comatose patient, are also not accounted for in GCS. With these shortcomings in mind, Wijdicks and colleagues developed the Full Outline of UnResponsiveness (FOUR) score (Table 43.2).[7] This scale includes eye response, motor response, brainstem reflexes, and respiratory patterns. The FOUR score provides more specific neurologic subtleties and consequently allows the clinician to differentiate between stages of herniation.[7]

DIFFERENTIAL DIAGNOSIS

Though the etiology of coma encompasses a wide range of causes, the differential diagnosis of coma is, in contrast, quite limited. Differentiating between coma and the following diagnoses requires an eloquent understanding of neuroanatomy in addition to precise and careful neurologic examination, differentiating between disorders of consciousness, and an appropriate time course for the specified disease process.

Locked-in syndrome results from damage to the ventral pons and the corticobulbar, corticospinal, and corticopontine tracts. The clinical presentation includes quadriplegia and anarthria with *retained* level of consciousness. Locked-in syndrome at times mimics as coma if a focused but thorough neurologic examination is not performed. In this case, careful inspection of the eye movements would reveal preservation of vertical eye movements when asking the patient to "look up." However, failure to do so may result in an inaccurate diagnosis of coma. The causes of locked-in syndrome are numerous, including ischemic, hemorrhagic, traumatic, neoplastic, metabolic (central pontine myelinolysis), demyelinating (multiple sclerosis), and infectious; consequently, appropriate and swift diagnosis allows for timely therapeutic intervention if possible.[8]

Persistent vegetative state refers to patients who have had a prolonged disorder of consciousness for longer than 1 month. Over time, patients may appear to have their eyes open, but remain unresponsive and unaware of external stimuli. The term *persistent vegetative state*,

TABLE 43.1 Glasgow Coma Scale[8]

Eye Opening Response	
Spontaneous	4
To verbal stimuli	3
To pain only	2
No response	1
Verbal Response	
Oriented	5
Confused, but able to answer questions	4
Inappropriate words	3
Incomprehensible speech	2
No response	1
Motor Response	
Obeys commands	6
Purposeful movement to noxious stimuli	5
Withdrawal to noxious stimuli	4
Flexion to noxious stimuli	3
Extension to noxious stimuli	2
No response	1
Total Score	**3–15**

TABLE 43.2 Full Outline of Unresponsiveness Score[7]

Eye Response	
Eyes open, tracking, or blinking to command	4
Eyes open but not tracking	3
Eyes closed but open to loud voice	2
Eyes closed but open to pain	1
Eyes remain closed with pain	0
Motor Response (Upper Extremities)	
Thumbs-up, fist, or two fingers	4
Localizing to pain	3
Flexion in response to pain	2
Extension in response to pain	1
No response to pain or generalized myoclonus status	0
Brainstem Reflexes	
Pupil and corneal reflexes present	4
One pupil wide and fixed	3
Pupil or corneal reflexes absent or fixed	2
Pupil and corneal reflexes absent	1
Absent pupil, corneal, and cough reflexes	0
Respiration Pattern	
Not intubated, regular breathing pattern	4
Not intubated, Cheyne-Stokes breathing pattern	3
Not intubated, irregular breathing	2
Breathes above ventilatory rate	1
Breathes at ventilator rate or apnea	0
Total Score	**0–16**

which can be pejorative, has been replaced by *unresponsive wakefulness syndrome*,[9] which more specifically describes the patient's clinical presentation. Typically, these patients have widespread cerebral structural injury and will have significant cerebral atrophy over time.[10]

Akinetic mutism was first described by Cairns and colleagues in the 1940s as a state in which the patient does not move or speak; in the first case report, it was the result of an epidermoid cyst in the third ventricle.[11] Since that time, akinetic mutism has been reported in bifrontal dysfunction or mesencephalic damage. Akinetic mutism is also associated with Creutzfeldt-Jakob disease and is one of the diagnostic criteria.[12] In contrast to coma, patients with akinetic mutism are in fact aware and alert but are apathetic.

Brain death is death because of *irreversible* damage of the brain.[13] Coma is one of the prerequisites for brain death, and neuroimaging must be consistent with irreversible brain injury. Additionally, all other confounding factors must be eliminated, including medication side effects, electrolyte imbalances, acid-base disturbance, endocrine abnormalities, hypothermia, and hypotension.[14] Given that coma and brain death are intimately intertwined, it is essential to know when the comatose patient meets the prerequisites and criteria for brain death. In addition to the aforementioned prerequisites, the patient must have an examination consistent with brain death, including absent brainstem reflexes and absent motor response in all four limbs to noxious stimuli. Apnea testing must also be done. In certain circumstances, ancillary testing may be needed if components of the clinical examination or apnea testing cannot be performed, such as with massive facial trauma or hemodynamic instability. Ancillary testing includes four-vessel cerebral angiography, nuclear brain perfusion scan, electroencephalogram (EEG), and transcranial Doppler.[14]

Psychogenic unresponsiveness or *functional coma* is a diagnosis of exclusion and is described as a state of unresponsiveness with preservation of brainstem reflexes. It can present in patients who have a history of depression, factitious disorders, or conversion disorders. Though a diagnosis of exclusion, the neurologic examination may alert the clinician to the fact that coma may not be organic in nature. Physical signs include resistance to eyelid opening and looking to the ground when turned on one side, termed "eye gaze sign."[15] Patients may not appear to have a normal vestibulo-ocular reflex (VOR), as they are able to fixate on a particular point with head turn. However, caloric stimulation with the instillation of cold water in the ear of a patient with psychogenic coma would cause eye deviation to the ipsilateral ear with contralateral horizontal nystagmus. This examination finding would be in contrast to organic coma, in which the VOR would be abnormal. Typically in psychogenic coma, EEG frequencies are consistent with patients in the awake state.

ANATOMY AND PHYSIOLOGY

Discussion regarding the anatomy of consciousness would be remiss without briefly delving into the pivotal experiments of the 1930s and 1940s that helped synthesize understanding of the anatomic basis of consciousness. Constantin Von Economo studied patients during the epidemic of encephalitis lethargica and suggested that the upper brainstem and posterior hypothalamus controlled arousal.[16] Bremer, while transecting the brains of cats, showed that transection through the midbrain caused a state of persistent sleep and EEG findings consistent with slow wave sleep; conversely, transection at the level of the cervicomedullary junction did not have any effect on arousal or sleep/wake cycles.[17] Moruzzi and Magoun extrapolated on this premise further by showing that stimulating cholinergic neurons in the pontine tegmentum caused a state of arousal that was independent of the sensory pathways, including the medial lemniscus and spinothalamic tract.

Destruction of the lesions in the reticular formation did not disrupt sensory pathways; disruption of sensory pathways did not cause a state of unarousal.[18]

As such, the idea arose that two separate ascending pathways existed: ascending sensory pathways and an ascending reticular activating system (ARAS). Though the ascending sensory pathways and the ARAS terminate in the cerebral cortex (more specifically, in the primary sensory cortex and diffusely throughout the cortex, respectively), these ascending pathways synapse in different thalamic nuclei.[2] The long ascending pathways synapse in the ventral posteromedial and ventral posterolateral nuclei, whereas the ARAS synapses in the intralaminar, midline, and reticular thalamic nuclei, also known as the *nonspecific thalamic nuclei.*[19–21] As evidenced earlier, the ARAS either communicates or is located at multiple levels of the neuroaxis, including the afferent sensory pathways, the reticular formation in the brainstem, the thalamus, and the cerebral cortex. Pathology anywhere along this neuroaxis could contribute to alterations of consciousness.

Though underlying physiology is not entirely understood, neurons in the rostral pons and caudal midbrain have been implicated as major contributors to the pathways of the ARAS. Cholinergic nuclei in the pontine-midbrain junction that project to the thalamocortical neurons also modulate wakefulness. Additionally, norepinephrine in the locus coeruleus and serotonin in the raphe nuclei contribute to increasing levels of arousal.[22,23] These neurotransmitters of wakefulness and arousal are modulated by GABAergic and galaninergic inputs from the ventrolateral preoptic nucleus of the hypothalamus promoting onset of sleep.[24,25]

ETIOLOGY

With a more thorough understanding of the anatomic basis of coma, it is clear that coma arises from dysfunction of the bilateral cerebral hemispheres, the diencephalon, or the brainstem. Taking this into account, there are both nonstructural and structural causes of coma. Swift and accurate diagnosis allows for timely management that in fact may be vastly different. Therapeutic interventions can range from neurosurgical intervention to correction of electrolyte abnormalities in order to reverse the cause of coma or mitigate downstream injury.[26]

Nonstructural

Nonstructural causes of coma comprise about two-thirds of unresponsive patients presenting to the emergency department.[27] Nonstructural causes include systemic disease states causing diffuse neuronal dysfunction, including toxic, metabolic, endocrine, or nutritional etiology. *Toxic* causes include barbiturate, alcohol, or opioid overdose and carbon monoxide poisoning. *Metabolic* causes include hyponatremia and hypocalcemia in addition to renal failure, hepatic failure, hyperammonemia, or acidosis. Case reports of D-lactic acidosis seen after small bowel resection or intestinal bypass can also progress to severe encephalopathy and eventually coma.[28] Hypoglycemia, Addison disease, or myxedema coma constitute endocrine causes of coma.[29] *Nutritional deficiency* such as niacin deficiency[30] or, more specifically, Wernicke encephalopathy, usually presenting with ataxia, ophthalmoplegia, nystagmus, and encephalopathy, can rarely present as coma.[31] Vitamin B_{12} deficiency typically presents with subacute combined degeneration of the spinal cord, and dementia can also present with encephalopathy that can progress to coma.[32] Hypothermia often presents as coma and even mimics brain death at times.[33]

In the case of nonstructural causes of coma, onset is not typically abrupt but may fluctuate and evolve, with depressed level of mentation worsening over time. This is not always the case, especially in toxic ingestion or overdose, where conversely onset may be abrupt. Given that the underlying pathophysiology includes bi-hemispheric cerebral and/or brainstem depression because of toxic or metabolic causes, the neurologic examination should be grossly nonlateralizing. A focal neurologic deficit should alert the clinician to initiate search for an underlying structural cause of coma.

Structural

In contrast to nonstructural causes of coma, structural lesions account for about one-third of patients presenting with altered mental status to the emergency department.[27] The brain sits within an enclosed space in the skull along with cerebrospinal fluid (CSF) and blood, all of which has a fixed volume. Mass effect from abscess, tumor, meningitis, cerebral or cerebellar edema from stroke, obstruction of CSF flow, or disruption of venous drainage from a venous sinus thrombosis can cause compression by displacement of structures, specifically the ARAS, bilateral thalamus, or bilateral cerebral hemispheres, and subsequently cause coma.

Structural lesions are either *supratentorial* or *infratentorial* and associated with herniation syndromes, with accompanying clinical findings (Table 43.3). *Central* or *transtentorial herniation* is a type of supratentorial herniation in which the diencephalon and midbrain herniate through the tentorium. There are four stages of herniation. In the diencephalic state, pupils are small and sluggish. Gaze is conjugate or minimally skewed with impaired upgaze. Motor examination may be within normal limits, though extensor toes, or Babinski sign, may be seen. Cheyne-Stokes respirations are seen, or there may only be sighing or yawning. If central herniation is not reversed at this point, the midbrain–upper pontine stage occurs next. Pupils are midline, dilated or irregular in shape, and fixed. Gaze is typically disconjugate, and the oculocephalic reflex (OCR) is impaired. Motor response is decerebrate, which is extension of all four limbs and the trunk. Cheyne-Stokes respirations or hyperventilation is seen. It will then progress to the lower pontine stage where pupils remain midline, fixed, and dilated with absent OCR and a flaccid motor examination. Tachypnea and shallow breathing mark this stage. At this point, the prognosis is usually irreversible. The final stage is the medullary stage in which pupils are fully dilated and fixed, respirations are ataxic, pulse is irregular, and the patient is hypotensive. This stage is fatal.

The second supratentorial herniation syndrome is *uncal herniation,* which is medial displacement of the uncus and hippocampal gyrus across the edge of the tentorium cerebelli compressing the third cranial nerve and midbrain. Given the anatomic landmark of the medial temporal lobe, an expanding or edematous tumor or stroke within that region should alert the clinician that uncal herniation syndrome may be imminent. As with central herniation, uncal herniation also has four stages as the third cranial nerve (CN III) and brainstem become compressed over time in a rostral–caudal progression. The first stage is the early CN III stage in which the pupil may be dilated or sluggish ipsilateral to the lesion, with or without ptosis. Gaze is variable, either normal or disconjugate. Motor examination may not show any abnormality. Next is the late CN III stage where the ipsilateral pupil is widely dilated and fixed with ptosis. Usually at this stage, OCRs of the ipsilateral eye are impaired. Motor examination shows weakness ipsilateral to the intracranial lesion. This is due to the Kernohan notch phenomenon, where the contralateral cerebral peduncle of the midbrain compresses against the tentorium. In the midbrain–upper pontine stage, both pupils become fixed and dilated with extensor posturing. The final stage is the same as the aforementioned medullary stage in central herniation, which is terminal.

Infratentorial lesions tend to develop rapidly. The stages seen in supratentorial herniation are typically not seen in infratentorial herniation. Infratentorial herniation is typically the result of tonsillar

TABLE 43.3 Herniation Syndromes

Herniation Syndrome	Etiology	Mechanism	Clinical Findings
Supratentorial			
Transtentorial or central herniation	Frontal, parietal, occipital lobe lesions; seen with diffuse brain swelling	Downward displacement of the brainstem from supratentorial structures	
		Diencephalic stage: preservation of red nuclei; loss of sympathetic output from hypothalamus	Pupils are pinpoint, roving eye movements; conjugate or mildly skewed gaze; motor examination may be normal or may have hemiplegia contralateral to the lesion with ipsilateral paratonia; bilateral hyperreflexia or Babinski sign; Cheyne-Stokes breathing pattern, or sighing and yawning
		Midbrain–upper pontine stage: red nucleus becomes affected with preservation of the reticulospinal nucleus of rostral pons	Pupils are midline and dilated, but can be irregularly shaped; gaze is disconjugate; oculocephalic reflex (OCR) is impaired; extensor posturing is seen; Cheyne-Stokes respirations or hyperventilation
		Lower pontine stage	Pupils remain dilated, fixed, and midline; OCRs and oculovestibular reflexes are impaired; motor examination is flaccid; bilateral Babinski sign; tachypnea
		Medullary stage	Pupils fixed and dilated; ataxic respirations, irregular pulse, hypotension; apnea; finally, death
Uncal herniation	Supratentorial lesions, but specifically those of the temporal lobe	Medial displacement of the uncus and hippocampal gyrus across the edge of the tentorium cerebelli causing compression of midbrain and third cranial nerve (CN III)	
		Early CN III stage: medial temporal lobe begins to exert pressure on CN III	Pupil may be dilated or sluggish ipsilateral to the lesion with or without ptosis; gaze is variable but can be disconjugate; motor examination does not show any abnormality
		Late CN III stage: midbrain becomes further compressed with compression of the contralateral cerebral peduncle against the tentorium	Ipsilateral pupil is widely dilated and fixed with ptosis; OCRs may be impaired; weakness ipsilateral to side of lesions because of Kernohan notch phenomenon
		Midbrain–upper pontine stage	Both pupils become fixed and dilated with extensor posturing
		Lower pontine–medullary stage	Pupils fixed and dilated; ataxic respirations, irregular pulse, hypotension; apnea; finally, death
Infratentorial			
Tonsillar herniation	Posterior fossa mass or lesion	Cerebellar tonsils herniate through the foramen magnum	
		Medullary compression; increased pressure and tension from dura around cerebellar pressure cone	Stiff neck/nuchal rigidity
		Compression of bilateral corticospinal tracts	Flaccid quadriplegia
		Compression of medulla	Cardiovascular and respiratory collapse
Cerebellar/upward herniation	Posterior fossa lesions or ventriculostomy	Cerebellum and mesencephalon travel up through the tentorium	
		Posterior fossa becomes displaced across tentorium into the middle cranial fossa; compresses midbrain, thalami, and bilateral superior cerebellar arteries	Rapid decline in mentation and progression to comatose state; apnea
		Third ventricle enlargement with obstruction of cerebral aqueduct	Parinaud syndrome (impaired upgaze, convergence-retraction nystagmus, eyelid retraction, impaired pupillary light reflex with intact accommodation); diabetes insipidus because of damage on pituitary stalk

herniation, cerebellar herniation, or midbrain–pontine reticular formation compression. In *tonsillar herniation*, the cerebellar tonsils herniate through the foramen magnum, marking a fatal descent as the patient suffers from cardiovascular and respiratory failure. *Cerebellar herniation* is an upward herniation syndrome in which the cerebellum and mesencephalon travel up through the tentorium. Coma results from increased intracranial pressure because of venous congestion or noncommunicating hydrocephalus.

The clinical presentation of comatose patients presenting with nonstructural causes of coma because of global cerebral neuronal dysfunction can vary greatly from comatose patients with a structural lesion who often have a lateralizing examination. Parsing out supratentorial from infratentorial lesions may be slightly more nuanced and challenging in the critical care setting, where many patients may have both systemic and structural causes at play, but the earlier framework lends several neuroanatomic clues to aid in diagnosis.

APPROACH TO A PATIENT WITH COMA

History

The history may be the first piece of information that alerts the clinician to the underlying cause of coma. A bystander who witnessed the event is an extremely useful asset. Additionally, friends, family members, emergency service personnel, and first responders to the scene may provide the most substantial information. Once the patient has arrived at the hospital, use of the electronic medical record also provides vital information. If the patient is already admitted to the hospital, the hospital course and complications up to that point provide invaluable information.

A report of sudden onset of loss of consciousness would be expected in a massive intracranial hemorrhage either from a ruptured cerebral aneurysm causing subarachnoid hemorrhage or parenchymal hemorrhage. Ischemic brainstem stroke from basilar artery occlusion would also likely be sudden in onset. Conversely, altered sensorium over a period of hours to days suggests an underlying toxic-metabolic cause of coma. Trauma may be observed by a bystander. Bystanders may be able to give information regarding toxic exposures such as herbicides or intoxication resulting from opioids, inhalants, MDMA (ecstasy), or other dissociative agents.[34]

The patient's past medical history is also important in considering underlying causes of coma. Patients with diabetes mellitus may be hypoglycemic or hyperglycemic and in diabetic ketoacidosis or hyperosmolar hyperglycemic state (HHS). HHS more often causes mental status changes, given that serum osmolality has the most effect on mental status.[35] A history of epilepsy may suggest seizure. A recent diagnosis of brain tumor could suggest hemorrhage secondary to tumor, tumor expansion, or worsening edema, though the time course of these three entities may be quite different. If the patient is on anticoagulation, one should consider coagulopathic intracranial hemorrhage or other bleeding diathesis causing hypotension or shock. If the patient is immunosuppressed, one should consider infectious etiology, either the result of meningitis, encephalitis, or systemic infection as causes of septic shock. Additionally, knowledge of the patient's medication list could assist if there are concerns for neuroleptic malignant syndrome or serotonin syndrome.

When gathering the clinical history, the clinician should take care not to prematurely close the diagnosis. Some disease states may coexist, and as such, the clinician should not become anchored on one diagnosis. For example, in ethanol intoxication, subdural hemorrhage and hypoglycemia can occur together.[36] Reconsidering one's initial hypothesis as to the underlying cause of coma may change over the course of the patient's evaluation as new data become available.

Physical Examination

Physical examination should start with a general systemic examination to assess for clues suggestive of an underlying etiology. Hypertension may indicate hyperadrenergic response from intracranial hemorrhage, whereas hypotension may indicate septic or cardiogenic shock. Hypothermia or hyperthermia suggests underlying infection. Hypothermia could also be seen in an endocrine abnormality such as hypothyroidism or Addison disease. Hyperthermia could additionally suggest neuroleptic malignant or serotonin syndrome. Hypertension and hyperthermia may be seen in a variety of drug intoxications, including cocaine, amphetamines, or phencyclidine. A thorough examination of the skin may show a rash suggestive of meningitis, cutaneous findings of endocarditis, or hematomas suggestive of coagulopathic state. Cutaneous bullae are often seen in barbiturate poisoning. Periorbital ecchymosis, or "raccoon eyes," or postauricular bleeding ("Battle sign") may be seen on inspection of the head, indicating basilar skull fracture. Fundoscopic examination can show papilledema suggesting increased intracranial pressure because of a multitude of causes. Point-of-care ultrasound can be used to assess optic nerve sheath diameter, which has been found to correlate with intracranial pressure.[37] Nuchal rigidity is seen in meningoencephalitis or subarachnoid hemorrhage. Jaundice and ascites suggest underlying liver disease and possible hepatic encephalopathy or, more worrisome, cerebral edema because of liver failure. Finally, the breath may be fruity in ketoacidosis, musty in acute hepatic failure, smell like onion in paraldehyde toxicity, or like garlic in organophosphate toxicity.[38]

The neurologic examination, though limited, serves as an important indicator for localization of intracranial pathology as the underlying cause of coma. The clinician is also able to follow the neurologic examination over time to detect signs of improvement or deterioration. As previously mentioned, the important aspects of the neurologic examination in coma include motor response, pupillary response, eye movements, and respiratory patterns in assisting with localization. Motor response is one of the measured examination findings in both the GCS and FOUR score. Flexor or decorticate posturing localizes to the bilateral cerebral hemispheres or thalamic dysfunction. Extensor or decerebrate posturing localizes to the red nucleus in the midbrain. As mentioned, asymmetric motor examination suggests focal intracranial pathology. Abnormal movements such as asterixis may be seen in toxic-metabolic encephalopathy, whereas a combination of asterixis and myoclonus can be seen in uremic encephalopathy. Severe myoclonus is often seen after cardiac arrest and in lithium intoxication, cephalosporin intoxication, or with pesticides.[38] It is important to distinguish between myoclonus and shivering or rigor, which may lead the clinician to a separate underlying cause entirely. Movements that are rhythmic in nature can indicate seizure and warrant further investigation.

Pupillary response in toxic-metabolic coma may be small and sluggish without any other brainstem reflex abnormalities. Unilateral or bilateral dilated and fixed pupils should alert the physician to a structural cause of coma and compression of the brainstem. The detailed discussion earlier regarding herniation syndromes outlines the pupillary abnormalities found in these syndromes.

Oculomotor findings, though often confusing, can be helpful in localization of coma, as they are located in the brainstem where the centers for arousal are located. When the ocular reflex is present in a comatose patient, it indicates preserved function of the brainstem. Posterior fossa and brainstem lesions cause skew deviation. Forced gaze deviation of the eyes to one side suggests a lesion or seizure in the frontal eye fields or a lesion in the parapontine reticular formation. In the case of a stroke in the frontal eye field, one would expect that the gaze deviation would be toward the stroke and away from the side of hemiparesis. Gaze deviation in seizure is opposite of this, as the frontal eye fields drive gaze away from the area of epileptic activity. Gaze deviation toward the side of hemiplegia is seen in a pontine stroke or lesion. Pontine lesions can also cause ocular bobbing, which is a rapid downward jerk of the eyes.[39] Roving eye movements are typically seen in toxic-metabolic coma or bi-hemispheric coma. Ping-pong gaze and ocular dipping can be seen in bi-hemispheric dysfunction.[38] Ping-pong gaze is conjugate horizontal eye movements that move from one extreme to the other at 2–4 Hz.[40] Ocular dipping constitutes a slow downward phase followed by rapid upward movement.[41]

Respiratory patterns can often be difficult to interpret if not assessed in the context of the entire clinical picture. For example, Cheyne-Stokes breathing can be seen in patients with congestive heart failure, elderly patients, or patients with bi-hemispheric lesions.[27] The Cheyne-Stokes respiratory pattern is defined by periods of apnea with increasing and subsequent decreasing of tidal volumes.[42] Ataxic

respirations may be seen in patients with medullary dysfunction. Tachypnea can be seen in patients with severe acidosis, whereas bradypnea is seen in opioid intoxication. It is important to take caution that many of these breathing patterns can be masked by mechanical ventilation.

DIAGNOSTIC EVALUATION

Laboratory testing likely ensues in the midst of the first few minutes of initial encounter and should include a basic set of tests, including complete blood count, chemistry panel, finger stick blood glucose, coagulation panel, liver function panel, ammonia, thyroid function tests, arterial blood gas, and serum osmolality. In cases of suspected intoxication, a drug screen should be sent along with any specific toxicology testing. If the patient is febrile, an infectious evaluation should be initiated. Calculation of the anion gap in metabolic acidosis would account for methanol, salicylates, ethanol, or paraldehyde ingestion. An increased osmol gap would be seen with atypical alcohols.

In regard to neuroimaging, patients who rapidly improve with treatment of underlying hypoglycemia or other measures are unlikely to need neuroimaging. Any patients with suspected traumatic brain injury (TBI) or a localizing neurologic examination should have a noncontrast computed tomography (CT) of the brain as the initial test. CT of the brain will show intracranial hemorrhage such as epidural, subdural, intraparenchymal, or subarachnoid hemorrhage or gross abnormalities such as infarct or mass. In the case of trauma with suspected vascular injury, CT angiography should also be obtained if it is readily available. Additionally, in patients with a normal noncontrast CT of the brain in whom basilar artery occlusion is suspected, CT angiography should also be obtained. Suspicion of cerebral venous sinus thrombosis as a cause of intracranial hypertension necessitates a venogram. Brain magnetic resonance imaging (MRI) shows greater anatomic detail of the cortical and subcortical structures of the brain. In cases of suspected posterior fossa stroke and impending obstructive hydrocephalus, brain MRI should be obtained to further visualize these structures, given that brain CT is poor at visualizing structures of the posterior fossa. MRI is also a particularly useful tool in assessment of hypoxic-ischemic injury and to aid in prognostication after cardiac arrest.

EEG is a useful diagnostic tool for convulsive or nonconvulsive status epilepticus. However, more often than not in patients with diffuse cerebral dysfunction, diffuse slowing or triphasic waves are seen. It is important to note that even patients with structural injury can have an EEG that appears slow or have triphasics. As such, the clinician should not rely heavily on the EEG, and caution should be taken in these cases.

Lumbar puncture (LP) should be performed to rule out central nervous system (CNS) infections. In a comatose patient, noncontrast brain CT is done before LP. Opening pressure should be measured. Studies sent from the CSF should include cell count, protein, glucose, differential, CSF culture, cryptococcal antigen, and viral polymerase chain reaction (PCR). The clinician should note appearance of the CSF, whether it is clear, cloudy, xanthochromic, or bloody.

MANAGEMENT

The recommendations that follow should be completed within the first hour of a patient presenting with altered consciousness.[38] As with any patient on initial evaluation, the airway should be secured and attention to breathing and circulation addressed at first encounter in order to ensure adequate oxygenation and ventilation. In cases of severe facial trauma, intubation is indicated for airway protection. Intravenous (IV) or central access should be established as indicated for suspected underlying cause. If the patient is hypotensive and not responsive to fluid resuscitation, start vasopressors to avoid cerebral hypoperfusion. In cases of trauma, the cervical spine should be immobilized until it can be cleared.

If the patient is hypertensive, consider beta-blockers and calcium channel blockers such as nicardipine or clevidipine for strict blood pressure control, especially in intracranial hemorrhage or acute ischemic stroke. Avoid sodium nitroprusside and nitroglycerin if there is clinical suspicion for raised intracranial pressure because of the risk of worsening intracranial pressure through cerebral vasodilation. If the patient had a cardiac arrest, therapeutic hypothermia should be initiated, regardless of whether the patient had a shockable or nonshockable rhythm.[43] In cases of hypothermia, warm the patient with a warming blanket, and, conversely, hyperthermic patients should be placed on cooling blankets. Some have suggested the use of a "coma cocktail" consisting of IV thiamine, glucose, naloxone, flumazenil, or physostigmine; however, it is safer to take a more targeted approach in management.[34,44] Use of flumazenil is controversial, as it can precipitate seizures in patients with underlying seizure disorder or who also present with tricyclic antidepressant intoxication.[38] The risk of seizure outweighs its empirical use for suspected benzodiazepine overdose and limits it to a highly select population of patients presenting with coma.[45] Acute hyponatremia should be treated with 3% hypertonic saline. Emergent hemodialysis may be needed for toxin removal, and bicarbonate may be used to alter pH for salicylate or tricyclic antidepressant overdoses. Endocrine emergencies, including myxedema coma, should be treated with thyroid hormone and supportive measures to correct hypothermia and hyponatremia[29]; and diabetic ketoacidosis (DKA) with fluids, electrolyte repletion, and insulin.[46] Finally, if infectious etiology is suspected, broad coverage with antibiotics is recommended. If there is suspicion for meningoencephalitis, empiric treatment should be started at dosing adequate for CNS penetration with concomitant administration of dexamethasone.

In the event of structural brain injury because of intracranial hemorrhage or mass, neurosurgery should be consulted for appropriate interventions, including ventriculostomy or surgery if necessitated. Emergent treatment for intracranial hypertension, if suspected, should be initiated by raising the head of the bed at or above 45 degrees, maintaining the head midline and in a neutral position to facilitate intracranial venous drainage, avoiding hypoxia, and maintaining normotension and normothermia. If needed, 0.5-1 g/kg of 20% mannitol or 2.5-5 mL/kg of 3% hypertonic saline may be given as IV bolus over 15-20 minutes. Hyperventilation for a goal partial pressure of carbon dioxide ($PaCO_2$) of 30–35 mm Hg should only be used as a bridging measure to definitive therapies. If basilar artery occlusion is identified on CT angiogram, stroke and neurointerventional specialists should be consulted immediately for possible IV tissue plasminogen activator and/or mechanical thrombectomy.

PROGNOSIS

Prognosis of coma is dependent on the underlying etiology. Most patients with coma regain consciousness, and very few persist into a prolonged minimally conscious state.[47] In general, several overarching principles portend a poor prognosis. Any injury that causes massive hemispheric swelling, a clinically deteriorating examination with loss of brainstem reflexes, basilar artery occlusion without recanalization of the vessel, TBI with corpus callosum and brainstem injury, and

pontine hemorrhage with thalamic extension are all likely to have a poor prognosis.[47]

Regarding *TBI,* as a general principle most patients who are elderly tend to have a worse prognosis. Young patients who have TBI can have a variable outcome.[47] Otherwise, the structures involved, concomitant association with cerebral edema, and time to treatment have important prognostic influence on outcome. Use of biomarkers as both diagnostic and prognostic tools is on the forefront in the hopes that these biomarkers are used in the development of therapy.[48] Likewise, the prognosis after *stroke* reaches beyond the scope of this chapter and is in part determined by a myriad of factors, including hemorrhagic versus ischemic stroke, the size of the infarct, patient characteristics and comorbidities, intervention performed, time to intervention, and a variety of other factors.

Perhaps the best prognostication studies for coma come from patients suffering from *cardiac arrest*. Before the era of targeted temperature management, Levy and colleagues[49] found that patients with postanoxic encephalopathy had several clinical examination findings portending poor outcome. Poor outcomes were associated with absent pupillary response and absent corneal reflexes. Additionally, no movement or extensor posturing to noxious stimuli predicted poor outcome.[49] With the advent of therapeutic hypothermia, these prognostic predictors have not held up, likely because of different reasons, including prolonged effects of sedating medications and paralytics used during targeted temperature management. More recent data have shown that pupillary reactivity continues to be a robust predictor of outcome, though corneal reflexes and motor response have fallen out of favor.[50] Other promising tools include EEG to assess for patterns of reactivity, somatosensory-evoked potentials, and neuroimaging.[51] Though prospective studies are needed to help guide the prognostic utility of these tools, likely a multimodal approach is best. As a general rule, the clinician should wait at a minimum 72 hours before withdrawal of any life-sustaining measures, except if the patient is brain dead, and in some cases it may take even longer for drug clearance in the age of therapeutic hypothermia.[50]

In cases of *meningitis,* patients who present with a low GCS or FOUR score are likely to have a poor outcome.[47,52] In a study by Lucas and colleagues on patients presenting with bacterial meningitis, approximately 3% presented with a GCS of 3. The GCS could in part be explained by hydrocephalus, seizures, or cerebral edema.[52] Thus poor prognosis in meningitis usually is the result of intracranial and systemic complications of the disease.

CONCLUSION

Coma is often seen in the critical care setting because of a variety of underlying pathologies. Accurate and timely diagnosis allows for rapid medical or surgical decision making regarding therapeutic intervention and management. Ultimately, treatment and prognosis are disease specific.

KEY POINTS

- Coma is a state of unconsciousness in which patients do not respond to any external stimuli. Scales to measure coma include GCS and FOUR score.
- Coma arises from dysfunction of the bilateral cerebral hemispheres, the diencephalon, or the brainstem.
- Nonstructural causes of coma include toxic-metabolic disorders, endocrine disorders, and nutritional deficiencies and comprise about two-thirds of patients presenting with coma to the emergency department. The other one-third of patients are found to have structural lesions, which are classified as supratentorial or infratentorial.
- The neurologic and physical examination helps the clinician differentiate the stages of herniation syndromes and identify any lateralizing deficit.
- The management of nonstructural and structural causes of coma is vastly different, but both require timely recognition and swift treatment.
- The mainstay of initial evaluation includes airway, breathing, and circulation.
- A detailed and thorough history may give the clinician important clues to the underlying cause of coma, and details should be obtained from family, friends, and bystanders.
- Noncontrast CT of the brain is readily available and thus is the initial diagnostic test of choice for suspicion of structural intracranial lesions. Additionally, CT angiogram and CT venogram can be obtained for evaluation of vessel abnormality such as thrombus.
- Prognostication in coma is dependent on the underlying cause of coma, though most patients regain consciousness, with few progressing to a persistent vegetative state.
- In cases of cardiac arrest, withdrawal of any life-sustaining measures should not be done before 72 hours, especially in the age of therapeutic hypothermia.

Use of Brain Injury Biomarkers in Critical Care Settings

Marie-Carmelle Elie-Turenne, Zhihui Yang, J. Adrian Tyndall, and Kevin K.W. Wang

Brain injury represents a constellation of both well- and ill-defined neurologic conditions that are the sequelae of both traumatic and nontraumatic illness, including stroke, anoxic-ischemic events, and sepsis. Traditionally, computed tomography (CT), magnetic resonance imaging (MRI), and electroencephalography (EEG) have been the diagnostic standards for differentiating brain injury from other forms of encephalopathy. In addition, these studies have been used as adjuncts to the clinical assessment in order to monitor progression, response, and resolution of neurologic disease. However, these modalities present both diagnostic and logistical challenges. In cases of clinical instability, transportation of patients to facilitate these diagnostic studies may be delayed by hours or days. Moreover, imaging and EEG may lack sensitivity in mild cases of brain injury that manifest more subtly.

The emergence of biologic fluid–based biomarkers of brain injury has great potential for aiding in diagnostics, monitoring disease, and providing therapeutic applications in neurointensive care. Specifically, brain injury biomarkers such as neuron-specific enolase (NSE) have already demonstrated some prognostic utility in patients after cardiac arrest and have potential uses in a variety of intensive care unit (ICU)–relevant central nervous system (CNS) insults such as traumatic brain injury (TBI) and stroke.[1] In this chapter, we use TBI as a prototype disease to demonstrate how brain injury biomarkers could complement conventional diagnostic and monitoring tools in ICU management.

BIOFLUID-BASED BIOMARKERS FOR DETECTING BRAIN INJURY IN THE ICU

A biomarker is defined as a "biologically based parameter that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention."[2] During brain injury, a variety of cellular changes can occur, including degeneration, protease activation, oxidative stress, and metabolic disturbances. These changes result in the shedding of specific proteins into the cerebrospinal fluid (CSF) or serum that can be identified and studied for their association with disease presence, outcome, and progression. These biofluid-based biomarkers reflect the earliest changes that occur in the cells before the evidence of injury appears on images. Therefore the use of biomarkers could offer a rapid, noninvasive, and cost-effective tool for the diagnosis of brain injury and determination of the subsequent need for additional diagnostic testing, monitoring, or therapeutic intervention.

Most biofluid-based markers of CNS injury to date are proteins or protein fragments. In the context of basic research, several brain injury biomarkers, including NSE, glial protein *S-100B*, glial fibrillary acidic protein (GFAP), and myelin basic protein (MBP), have been shown to have great utility in TBI specifically. Alpha-II spectrin protein and its breakdown products (SBDPs) are potential biomarkers of necrosis and apoptosis after TBI. The cleaved form of the axonally located microtubule binding protein tau (c-tau) has been identified as a new biomarker in mouse and rat TBI models. In addition, inflammation markers such as neurofilament-H are promising axonal injury biomarkers of various forms of acute brain damage in experimental TBI models.

Proteomics is the large-scale study of proteins, particularly their structures and functions. This field includes the study of changes in protein expression patterns as related to diseases and environmental conditions. The search for biomarkers of TBI has been approached by integrating biofluid and tissue information. This new approach takes advantage of functional synergy between certain biofluids and tissues with the potential for clinically significant findings. Using differential neuroproteomic methods, a systematic assessment has successfully identified additional protein biomarkers for TBI, such as ubiquitin C-terminal hydrolase-L1 (UCH-L1) and microtubule-associated protein 2 (MAP2), with relevant animal models.[3]

The application of basic scientific discoveries to the clinical setting remains a challenge. Systems biology (the computational and mathematical modeling of complex biologic systems) is an approach to building a holistic, systematic, and unbiased understanding of the structural and behavioral elements of biologic networks. Translating these findings into the clinical, data-driven development cycle and data-mining steps for discovery, qualification, verification, and clinical validation are needed. Data mining techniques used in this field extend beyond the level of data collection to an integrated scheme of animal modeling, instrumentation, and functional data analysis. In the context of TBI proteomics, systems biology tools can be incorporated in several ways to overcome many of the limitations of simple proteomics.[4]

CURRENT BIOMARKER CANDIDATES AND THEIR PROPERTIES

Although neurobiomarkers are not yet Food and Drug Administration (FDA) approved for clinical use, considerable research into protein biomarkers for TBI has produced several putative diagnostic and prognostic markers. Table 44.1 describes the most studied potential TBI biomarkers and reflects the current state of the art. Other possible markers include neurofilament proteins MAP2 (2A, 2B), fatty acid binding protein-H (H-FABP), brain-derived neurotropic factor (BDNF), and autoantibodies to brain antigens. But more studies are required for further clinical utility verification and biomarker characterization.

TABLE 44.1 Potential TBI Protein Biomarkers That Could Have Critical Care Utility

TBI Protein Biomarker	Full Protein Name	Origin	Human Severe TBI Data	Human Moderate-to-Mild TBI or Concussion Data
GFAP (and BDPs)	Glial fibrillary acidic protein (and its breakdown products)	Astroglial injury	Yes	Yes
UCH-L1	Ubiquitin C-terminal hydrolase-L1	Neural cell body injury	Yes	Yes
Tau (P-tau)	Microtubule-associated tau protein (phosphorylated tau protein)	Axonal injury; neurodegeneration	Yes	Yes
S100B	*S100B* protein	Astroglia/BBB	Yes	Yes
SBDPs (SBDP150, 145, and 120)	αII-spectrin breakdown products of 150, 145, and 120 kDa	Axonal injury; brain cell necrosis-apoptosis	Yes	?
MBP	Myelin basic protein	Demyelination	Yes	—
NSE	Neuron-specific enolase	Neural cell body injury	Yes	—
NF-L, NF-H	Neurofilament protein-light and -heavy	Axonal injury	Yes	—

TBI, Traumatic brain injury.

The first listed biomarker is *GFAP*. It is an astrocyte-specific intermediate filament protein known as a marker of astrocyte activation. Eight different isoforms of this protein are expressed across numerous subsets of astrocytes. Measurements of GFAP and its breakdown products have provided promising data on injury pathways, focal versus diffuse injuries, and prediction of morbidity and mortality. It has also been studied in both CSF and serum of patients with severe TBI.[5–10] Serum GFAP levels in severe and moderate TBI with Glasgow Coma Score (GCS) <12 are associated with unfavorable outcome at 6 months.[11] New enzyme-linked immunosorbent assay (ELISA) for GFAP and its breakdown products detected both mild-to-moderate TBI[12] and the full spectrum of TBI (TRACK-TBI cohort)[13] in two independent studies. Similarly, Metting and colleagues demonstrated that serum GFAP was increased in patients with an abnormal CT after mild TBI.[14] Another follow-up study using the TRACK-TBI cohort demonstrated that the combination of UCH-L1 with GFAP/BDP further improves its diagnostic utility.[15] A recent paper also found that a caspase-6–generated form of GFAP is elevated at 72 hours after cardiac arrest, but did not predict outcome.[16]

UCH-L1 is a deubiquitinating enzyme highly expressed in neuronal cells. It is one of the few markers identified using proteomic methods. In addition, its high brain specificity and abundance in brain tissue make it an attractive candidate marker. CSF and serum UCH-L1 levels were found to be elevated in patients with severe TBI, correlating with the severity and outcome of injury.[17,18] Increased levels of UCH-L1 post-TBI are proposed to be secondary to blood-brain barrier (BBB) dysfunction.[19] Several other studies also report the detectability of UCH-L1 in blood after mild TBI and with UCH-L1 levels correlating with traditional clinical assessments.[12,20] However, the utility of UCH-L1 in mild TBI with respect to its sensitivity and specificity requires further clinical assessment.

In the ALERT-TBI trial (1959 participants), UCH-L1 and GFAP assays in combination were found to discriminate those with CT abnormalities defined clinically with mild to moderate TBI when measured within 4 hours postinjury.[21] These findings in part led to US FDA clearance for testing of this combination among the mild TBI cohort.[22]

Tau is an intracellular MAP with a molecular mass of 48–67 kDa that is highly enriched in axons. TBI was found to cause the cleavage of tau protein, with elevated levels of c-tau in CSF and serum. c-tau possesses many desirable characteristics of a biochemical marker and is associated with both disruption of the BBB and postinjury cleavage of tau protein.[23] Other studies from two groups have demonstrated the significance of tau/c-tau in predicting outcome in severe TBI patients.[24,25] Similarly, several studies report the utility of tau or c-tau in the prediction of outcome in mild TBI.[26,27] However, other studies have reported the poor ability of tau protein to predict outcome and postconcussion syndrome in mild TBI.[28] Recently, two ultrasensitive assay platforms were developed to enable the robust detection of tau (and a phosphorylated form of tau) in serum from acute-phase TBI patients with various levels of TBI severity.[29]

S100B is a glia-specific calcium-binding protein. Elevated *S100B* levels accurately reflect the presence of neuropathologic conditions, including TBI or neurodegenerative diseases linked to astroglial injury. More importantly, *S100B* levels are reported to rise before any detectable changes in intracranial pressure, neuroimaging, or neurologic examination findings. *S100B* is considered a prognostic biomarker of BBB permeability and CNS injury. Several studies have reported that S100B protein might detect brain death after severe TBI.[30,31] Another study showed that serum and urine levels of *S100B* after TBIs have prognostic significance for survival and disability.[32] A similar study on serum S100B measured 24 hours after injury reported that it predicts unfavorable outcome (i.e., Glasgow Outcome Scale [GOS] score <4 or death at 3 months after injury in severe TBI patients).[33] *S100B* elevation has also been found after mild TBI.[34] Although *S100B* remains promising as an adjunctive marker, the main limitation toward its use is the lack of specificity for brain trauma; this is likely, given that *S100B* can be released by cells other than astrocytes.

αII-spectrin is a cytoskeletal protein enriched in neuronal axons and presynaptic terminals. *SBDPs* are produced by the breakdown of αII-spectrin by calpain and caspase, which are activated in the brain after TBI. SBDPs thus reflect axonal damage. SBDP150 and SBDP145 are indicative of calpain activation, often associated with acute necrotic neuronal cell death, and SBDP120 is generated by the action of caspase-3 and is associated with delayed apoptotic neuronal death. αII-spectrin has been studied primarily in the context of severe TBI. Elevation of SBDP150 and/or SBDP145 levels in CSF was reported as a possible outcome predictor in patients with severe TBI versus initial CT diagnosis with Marshall grade. SBDPs, especially CSF SBDP150, may be useful as a differential diagnostic biomarker for its ability to distinguish between focal and diffuse injury in the acute phase of TBI.[35,36] Whereas αII-spectrin is present in various nucleated cells and most tissues, its high abundance and enrichment in brain and the fact that SBDPs are injury generated make SBDPs potentially useful TBI biomarkers, especially in combination with other more brain-specific markers.

MBP is one of the most abundant proteins in white matter, composing 30% of the myelin protein. It is important in the myelination of nerves. As a constituent of the sheath, MBP is essential for normal myelination and axonal signal conduction. Several studies on severe TBI patients have reported that MBP levels could track the occurrence of post-TBI hypoxia, predict the outcome, and prompt adequate treatment.[8,37] Serum MBP is elevated in the majority of children with acute TBI, including well-appearing children with TBI from child abuse in whom the diagnosis might otherwise have been missed.[38] Most recently, a review by Kochanek and colleagues suggests that MBP is a potential biomarker for pediatric TBI.[39] Because MBP lacks clinical sensitivity, the interest in MBP as a biomarker for TBI is lower than that of *S100B*, NSE, and GFAP. One possible explanation for this lack of sensitivity is that MBP undergoes extensive fragmentation/degradation after TBI, thus complicating its robust detection by traditional sandwich ELISA.

NSE is a glycolytic enzyme that is present in central and peripheral neurons and neuroendocrine cells, with serum levels rising after cell injury. NSE is passively released into the extracellular space only under pathologic conditions during cell destruction. Acute post-TBI levels of NSE and MBP were correlated with outcome in children, particularly those under 4 years of age.[40,41] In the setting of diffuse axonal injury in severe TBI, levels of NSE at 72 hours after injury have shown an association with unfavorable outcome.[42] However, in very early studies, serum or CSF NSE was considered of limited utility as a marker of neuronal damage.[43,44] A limitation of NSE is the occurrence of false-positive results that occur because NSE is also present at high levels in red blood cells.

Neurofilament (NF) proteins are the key intermediate filaments in neurons and a major component of the axonal cytoskeleton. The major neuronal filaments in the CNS are those assembled from NF triplet proteins: neurofilament light (NF-L; 61 kDa), medium (NF-M; 90 kDa), and heavy (NF-H; 115 kDa). After TBI, calcium influx into the cell contributes to a cascade of events that activates calcineurin, a calcium-dependent phosphatase that dephosphorylates neurofilament side-arms, presumably contributing to axonal injury. Phosphorylated NF-H (pNF-H) was found to be elevated in the CSF of adult patients with severe TBI compared with controls.[45] Similarly, hyperphosphorylated NF-H has also been shown to significantly correlate with neurologic deficit in severe TBI children.[46] More recently, phosphorylated NF-H was shown to stratify lower grades of injury, with significant rises in pNF-H seen up to 3 days after mild TBI. pNF-H levels in CSF are also elevated in amateur boxers. Although pNF-H is showing promise as both a sensitive and specific marker of axonal injury after TBI, consideration of other NF isoforms is needed to stratify injury severity in TBI patients. For example, amateur boxers also have elevated CSF levels of NF-L.[27]

TBI is a complex injury: primary injury occurs at the moment of trauma, when tissues and blood vessels are stretched, compressed, and torn; secondary injury then follows. Secondary injury events include damage to the BBB, release of factors that cause inflammation, free radical overload, excessive release of the neurotransmitter glutamate (excitotoxicity), influx of calcium and sodium ions into neurons, and dysfunction of mitochondria. We thus anticipate a growing list of putative TBI biomarkers with different cell or subcellular origins and different diagnostic and prognostic properties. Such findings are also very likely for other relevant CNS insults in neurointensive care. Preclinical and clinical studies suggest the potential alteration of the following proteins in some cases of TBI: neurite degeneration markers, MAP2, amyloid β peptide (Aβ1-40, Aβ1-42), neuroinflammatory markers (microglial ionized calcium-binding adapter molecule 1, inflammasome proteins-caspase-1, Nacht leucine-rich-repeat protein-1 (NALP-1), apoptosis-associated speck-like protein containing a caspase recruitment domain (ACS),[47,48] biofluid levels of neurotropic markers (BDNF, nerve and growth factor, and heart-type fatty acid—binding protein).[49–51] Last, autoimmune markers (autoantibodies to brain antigens such as GFAP) have also been reported as potential biomarkers for subacute or chronic phases of TBI.[52] However, future work is required for their clinical utility verification and biomarker characterization.

POTENTIAL USES OF BRAIN BIOMARKERS FOR TBI PATIENT MANAGEMENT

Severe TBI

TBI severity is assessed immediately upon presentation and subsequently monitored serially using clinical examination, GCS, and cranial imaging. CT scans are useful for identifying hemorrhage, swelling, or skull fracture and direct localization information that guides possible surgical intervention. Lesions contributing to increased intracranial pressure (ICP) or intracranial hemorrhage frequently require decompressive craniectomy, ventriculostomy, or treatment to increase cerebral perfusion pressure with the objective of restoring energy and oxygen supply. During the acute phase of severe TBI, protein biomarkers are thought to be released into the CSF and/or into the circulation by passing through the disrupted BBB. These body fluid–based biomarkers represent the extent of damage to neurons or astrocytes and reflect a great diversity in outcomes, ranging from immediate death to full recovery. Thus far, no single protein biomarker can describe the complete profile of TBI pathology, which involves a complex cascade of pathophysiologic events, subsequent degeneration of various brain cell types (neurons, glia, oligodendrocytes), and deterioration of brain micro- and macrostructures and functions. Brain function relies not only on intact neurons and astrocytes but also on intact network connectivity. Thus ideally, we should use a combination of complementary TBI biomarkers that originate from different cell types or subcellular structures that are vulnerable to TBI (see Table 44.1). This approach will likely allow us to assess the extent of cellular and structural damage and, eventually, the recovery process of the brain as a whole at different stages after the initial TBI event (Fig. 44.1). Thus by serial monitoring of biofluid levels (CSF, blood) for a panel of protein biomarkers, we can gain information regarding the severity of the injury, the progression of the injury, possible occurrence of secondary insult, and prognosis of TBI patients, and may even be able to formulate personalized therapeutic strategies (Fig. 44.2).

In conclusion, we have described the importance of biofluid-based protein biomarker detection after severe TBI germane to neurointensive care. We also propose a possible logistic workflow where the use of TBI biomarker assays may be integrated into clinical practice for acute TBI patients in the critical care setting. We described several TBI protein biomarkers with potential utility in the diagnostic and management approach of TBI. A limitation at present is the lack of real-world utility, as these tests are not universally available. Establishing a point-of-care device (POC platform) that can readily provide biomarker results within minutes would serve as a potential adjunct for prompt bedside evaluation in hemodynamically unstable or critical patients. Another challenge is to determine whether we already have the optimal biomarkers for formulating the best possible biomarker panel for TBI or if we need to continue to search for more ideal candidates. The next 5–10 years promise to be an exciting time for witnessing how the implementation of TBI biomarker–based diagnostics will change medical practice regarding critical care TBI patient management and, ultimately, for the full spectrum of patients in the neurointensive care setting.

ACKNOWLEDGMENTS

The authors wish to thank Dr. Dongnan Yu for his scientific and literature input and for his preparations of previous editions of the chapter.

KEY POINTS

- Serum biomarkers of brain injury are being developed for multiple purposes and applications in a wide variety of patients in the neurointensive care setting, including (1) prognostication, (2) injury severity stratification, (3) detection in occult presentations of brain injury in ICU patients, and (4) to monitor treatment effects.
- GFAP is a marker of brain injury derived from astrocytes and is showing promise for clinical translation.
- Two neuronal markers, namely UCH-L1 and NSE, also have potential to identify brain injury. NSE is currently used in some centers for prognostication after cardiac arrest.
- MBP is an emerging marker of white matter damage that is being assessed in clinical studies.
- The MAP tau is an emerging biomarker that is implicated as an initiator of chronic neurodegenerative disease, including chronic traumatic encephalopathy.

References for this chapter can be found at expertconsult.com.

Practice parameter: Prediction of outcome in comatose survivors after cardiopulmonary resuscitation (an evidence-based review): Report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology.* 2006;67(2):203–210.
This is a systematic review of several studies of comatose patients after cardiac arrest Among other clinical and diagnostic study findings, serum neuron-specific enolase higher than 33 μg/L predicted poor outcome.

Yan EB, Satgunaseelan L, Paul E, et al. Hypoxia is associated with prolonged cerebral cytokine production, higher serum biomarker levels, and poor outcome in patients with severe traumatic brain injury. *J Neurotrauma.* 2014;31(7):618–629.
In a study of TBI patients, eight cytokines were measured in the CSF and serum over 6 days and classified as hypoxic and normoxic. Patients were divided into Hx ($n = 22$) and Nx ($n = 20$) groups. Markers of neuroinflammation, including granulocyte macrophage-colony stimulating factor (GM-CSF), interferon (IFN)-γ, and tumor necrosis factor (TNF), were prolonged in the CSF of hypoxic patients 4–5 days post-TBI. In addition, S100B, MBP, and NSE were significantly higher in Hx patients with unfavorable Glasgow Outcome Scale Extended, suggesting these markers could be used in the acute setting to detect the occurrence of post-TBI hypoxia.

Cardiopulmonary Cerebral Resuscitation

Joshua C. Reynolds

Cardiopulmonary arrest occurs as the endpoint or consequence of many diseases. The mechanism is often unknown when treatment is initiated, and an algorithmic approach titrated to real-time monitoring is used. When the cause is known or suspected, individualized therapy can be directed at that cause. In all cases, management has two priorities: (1) rapid restoration of cardiopulmonary function and (2) minimization of ischemic damage to end organs, especially the brain. Restoration of circulation is composed largely of mechanical, pharmacologic, and electrical treatment. In contrast, treatment of brain and other organ injury primarily involves prevention of reperfusion-mediated and secondary cellular and molecular events using specific and detailed intensive care. Meaningful survival is unlikely without detailed attention to the longitudinal scope of this disease.

From the first introduction of closed-chest compressions until 2000, there was little change in long-term survival after cardiac arrest.[1,2] However, subsequent regional efforts to improve resuscitation practices at multiple levels, including emergency response and post–cardiac arrest care, have yielded significant improvements in meaningful survival.[3,4] Specific patterns of physiologic changes after cardiac arrest have been described, and there is accumulating evidence about which aspects of post–cardiac arrest management influence final outcomes.[5–7] Improving outcomes further requires an integrated approach to immediate resuscitation, subsequent intensive care management, and post–intensive care recovery. This chapter reviews the epidemiology of cardiac arrest, the initial approach for reversing cardiopulmonary arrest, modifications of this approach appropriate for specific disease states, and post–cardiac arrest intensive care oriented around minimizing secondary brain injury.

EPIDEMIOLOGY

In industrialized countries, heart disease is the overall leading cause of death, with an incidence of cardiopulmonary arrest outside the hospital ranging from 55 to 120 events per 100,000 people per year.[8–11] Median survival after out-of-hospital cardiac arrest is estimated at 10.6%,[8] but the range varies regionally from less than 2%[12,13] to 16% in certain exemplary systems.[11] The incidence of cardiac arrest in hospitals is about 0.17 events per hospital bed per year.[14] For inpatients experiencing cardiac arrest, median survival to hospital discharge is about 20%.[15] Almost half of in-hospital cardiac arrests occur in an intensive care unit (ICU) setting, where survival is higher than that in an unmonitored unit.[15] Respiratory insufficiency is the most common preexisting condition for in-hospital cardiac arrest,[15] and as many as 17% of episodes of respiratory compromise in hospitals progress to cardiac arrest.[16]

Although out-of-hospital cardiac arrest is more common in men than in women, both outside[10] and inside hospitals,[14] the incidence of cardiac arrest is higher in women (6%) than in men (4.4%) who are admitted to a hospital for acute myocardial infarction (MI).[17] Cardiac arrest outside a hospital affects blacks and Latinos more than Caucasians or Asians,[10,12,18] and rates are higher in neighborhoods composed of minority and lower-socioeconomic-status populations. These groups are also more likely to have a cardiac arrest, less likely to have bystander cardiopulmonary resuscitation (CPR), and less likely to survive.[19,20] Although sudden death can affect patients of all ages, the mean age for sudden cardiac arrest is between 65 and 70 years in most studies.[10,11,14]

Most mortality after cardiac arrest is attributable to cardiopulmonary collapse or brain injury. Only one-third to one-half of patients who collapse outside a hospital and only 44% of patients who collapse in a hospital have restoration of circulation long enough to be admitted to the ICU.[14] Approximately two-thirds of patients who are admitted to a hospital after an out-of-hospital collapse[21] and 60% of patients who are resuscitated from cardiac arrest in a hospital[14] die before discharge from the hospital. Variation around this estimate differs between academic medical centers and tends to be higher in hospitals with higher case volume, higher surgical volume, and greater availability of invasive cardiac services.[8] Postischemic brain injury is the most common reason for in-hospital death after out-of-hospital cardiac arrest,[14,22] whereas multiple organ failure is more common after in-hospital cardiac arrest.[23] Failure to awaken contributes to withdrawal of life-sustaining treatment for about 61% of out-of-hospital cardiac arrest patients.

RESTORING CIRCULATION

Acute treatment of cardiac arrest consists of two concurrent, goal-directed activities: (1) artificial circulation of oxygenated blood to the heart and brain and (2) electric shock to terminate ventricular fibrillation (VF) and other unstable tachydysrhythmias (Fig. 45.1). Continuous, uninterrupted, high-quality chest compressions are the cornerstone of resuscitation,[24] whereas electrical rescue shocks are used only when appropriate.[25] The organization of an electrocardiogram (ECG) and the presence of a pulse will prompt appropriate selection of therapy. The recommended division of time and prioritization of activities to accomplish these goals is depicted in Fig. 45.2. All other treatments, including medications and advanced airway maneuvers, are designed to supplement these two core activities, and their optimization necessitates minimal interruption. Focused bedside ultrasound evaluation can aid in the assessment of critically ill patients and identify reversible causes only if performed without interrupting resuscitation.[26] The American Heart Association and European Resuscitation Council provide consensus scientific statements about the acute management of cardiac arrest, including a detailed review of specific drugs and procedures.[27] The following sections provide an overview of airway management, circulation support, rescue shock for defibrillation, and drug therapy.

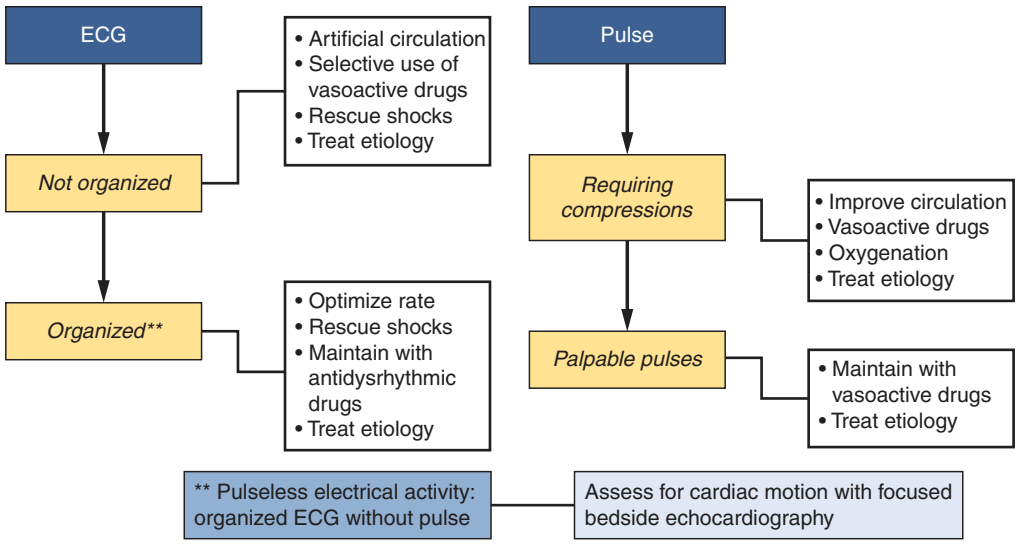

Fig. 45.1 Continuous reassessment of the patient during cardiac resuscitation relies on an electrocardiogram (ECG) and on the presence of cardiac mechanical activity (pulses). If an organized ECG is not present, interventions should be undertaken to restore an organized ECG. If mechanical cardiac activity is not present, interventions should be undertaken to improve mechanical cardiac activity. Achieving both goals results in return of circulation.

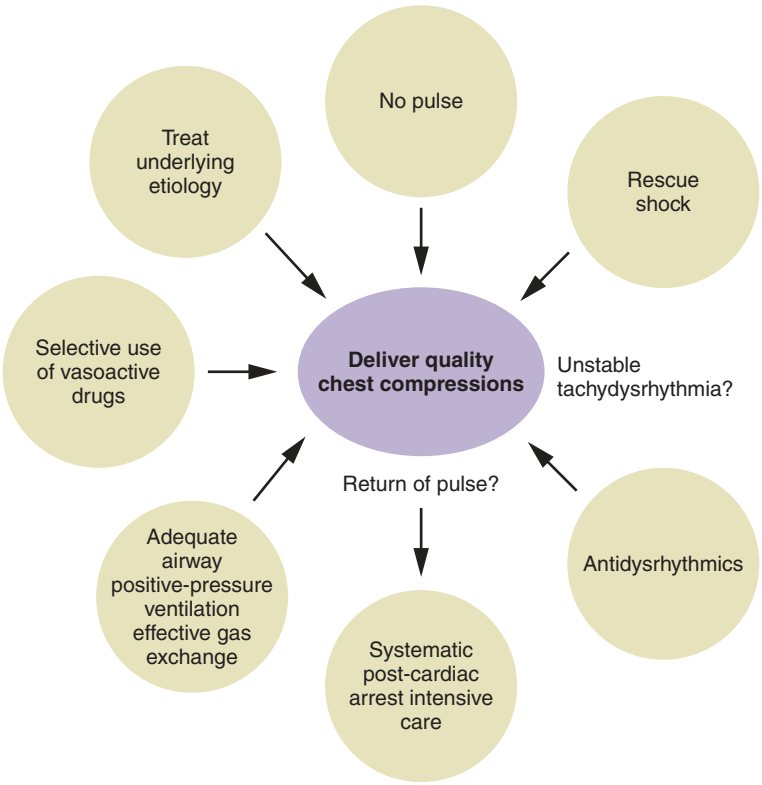

Fig. 45.2 Prioritization of activities must occur during cardiac resuscitation. *Central circle* emphasizes that core activity of chest compression should be interrupted only to provide rescue shocks when appropriate or when restoration of circulation occurs. All drugs, airway devices, and other interventions are designed to augment either artificial circulation or defibrillation. None of these adjuncts should interrupt or detract from providing artificial circulation. *VF,* Ventricular fibrillation.

Airway and Gas Exchange

Obstruction of the airway occurs in patients with impaired consciousness, including cardiac arrest, preventing oxygenation and ventilation.[28] Agonal respiration occurs after acute cardiac arrest for an additional 1–2 minutes,[29] which may confuse lay people and delay the recognition of cardiac arrest. Although associated with survival, it is unclear whether agonal respiration generates sufficient ventilation to support life.[30] Regardless, artificial ventilation is required for patients requiring more than momentary resuscitation efforts.

Simple maneuvers to open the airway include extension of the neck (head tilt) and forward displacement of the mandible (chin lift or jaw thrust). Insertion of an oropharyngeal or nasopharyngeal airway can displace the tongue from the posterior pharynx. Positive-pressure ventilation using mouth-to-mouth or bag-valve-mask (BVM) ventilation with as little as 400 mL in adults (6–7 mL/kg) delivered over 2–3 seconds will cause the chest to rise.[31] Minute ventilations smaller than those required for long-term support probably provide adequate gas exchange during cardiac arrest. Conversely, hyperventilation or hyperexpansion of the chest can impair venous return and decrease circulation during resuscitation.[32]

The need for gas exchange must be balanced against the fact that even brief interruptions in chest compressions reduce coronary perfusion pressure (CPP) (Fig. 45.3).[33] In swine, comparison of different chest compressions to ventilation ratios suggests that two breaths per 50 or more chest compressions are optimal for resuscitation.[34] One innovative practice to reduce interruptions in compressions is to provide chest compressions without any artificial ventilation[35] or with passive insufflation of oxygen.[36] Accounting for anatomic dead space, chest compressions alone probably do not generate significant ventilation in humans.[28,37] As a compromise, some systems deliver uninterrupted chest compressions and asynchronous positive-pressure breaths. A large, randomized trial comparing continuous compressions with positive-pressure ventilation to interrupted compressions at a ratio of 30 compressions per two ventilations found no meaningful difference in survival or short-term favorable neurologic recovery.[38] Regardless of ratio, the duration of any pause to deliver breaths must be minimized.

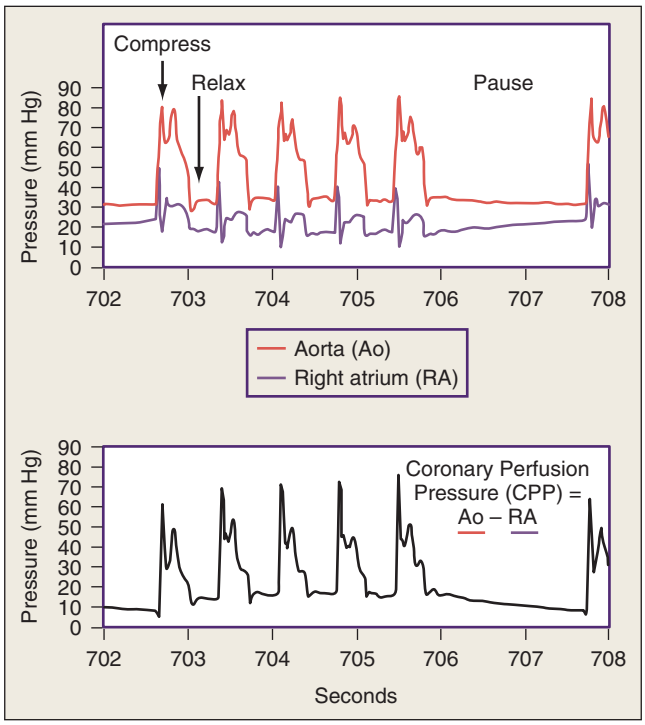

Fig. 45.3 Chest compressions provide coronary perfusion by creating a pressure gradient between the aorta (***Ao***) and the inside of ventricles (approximated by the right atrium [***RA***]). The gradient between sites is the coronary perfusion pressure (*CPP*). During chest compression, pressure increases in both Ao and RA. During relaxation, pressure persists in Ao more than in RA. Thus myocardial blood flow is most related to CPP during the relaxation phase of chest compressions. Note that CPP declines within 1–2 seconds when compressions pause for ventilation. (Unpublished laboratory data.)

Waveform capnography can confirm ventilation and monitor adequacy of circulation. During cardiac arrest, end-tidal CO_2 is related to cardiac output and pulmonary blood flow.[39] Therefore CO_2 levels may be very low (<10 mm Hg) at the onset of resuscitation. Adequate artificial circulation will cause CO_2 levels to increase, and these levels may be used as a feedback to improve or modify chest compressions. An end-tidal CO_2 level greater than 15–16 mm Hg is associated with successful cardiac resuscitation.[40,41] Conversely, end-tidal CO_2 less than 10 mm Hg after 20 minutes of resuscitative efforts can confirm failure of resuscitation.[42] Common resuscitation drugs disrupt the association between capnography readings and pulmonary blood flow: epinephrine infusion reduces CO_2 levels, and sodium bicarbonate infusion produces a transient elevation of CO_2 levels. An abrupt increase in end-tidal CO_2 levels, usually to levels over 35 mm Hg, may be useful in recognizing the return of circulation, without interrupting chest compressions for pulse checks (Fig. 45.4).

Airway Devices

The most common ventilation device used by rescue personnel, paramedics, and other healthcare providers is a self-inflating bag attached to a face mask (BVM), which requires adequate training and practice for ventilation success by a single provider. Two providers achieve more reliable airway management. BVM ventilation also pushes air into the stomach,[43] which can promote emesis and abdominal distention, impair venous return, and reduce lung compliance.[44] Normal esophageal resistance to air entry into the stomach (15–20 cm H_2O)[45] declines with loss of muscle tone during cardiac arrest (5–8 cm H_2O).[46]

Tracheal intubation with a cuffed tracheal tube secures the airway definitively and protects from emesis. However, laryngoscopy typically requires an interruption in chest compressions. Observational studies found extremely long interruptions in chest compressions during "uncomplicated" tracheal intubation.[47] Conversely, supraglottic airway adjuncts such as laryngeal tubes (e.g., King LT) or laryngeal mask airways can temporarily secure the airway during resuscitation.[48,49] These devices have the advantage of blind insertion within seconds without laryngoscopy or associated interruptions in chest compressions.[43]

Three randomized trials of out-of-hospital cardiac arrest subjects conducted in different emergency response systems with ranges of intubation success (52%–98%) compared various advanced airway strategies with BVM.[50–52] Subjects randomized to BVM were subject to variable durations of BVM while preparing for device insertion. One trial explicitly allowed crossover between interventions at the discretion of providers. Even in settings with high tracheal intubation success rates, an advanced airway (supraglottic airway or tracheal intubation) did not improve survival or neurologic outcome compared with BVM. The rationale for transitioning from BVM to advanced airways is contingent on clinical context, patient anatomy, aspiration risk, and oxygenation and ventilation success. If an advanced airway is required, providers should select a device (supraglottic airway or tracheal intubation) based on the clinical context and their individual skill set.

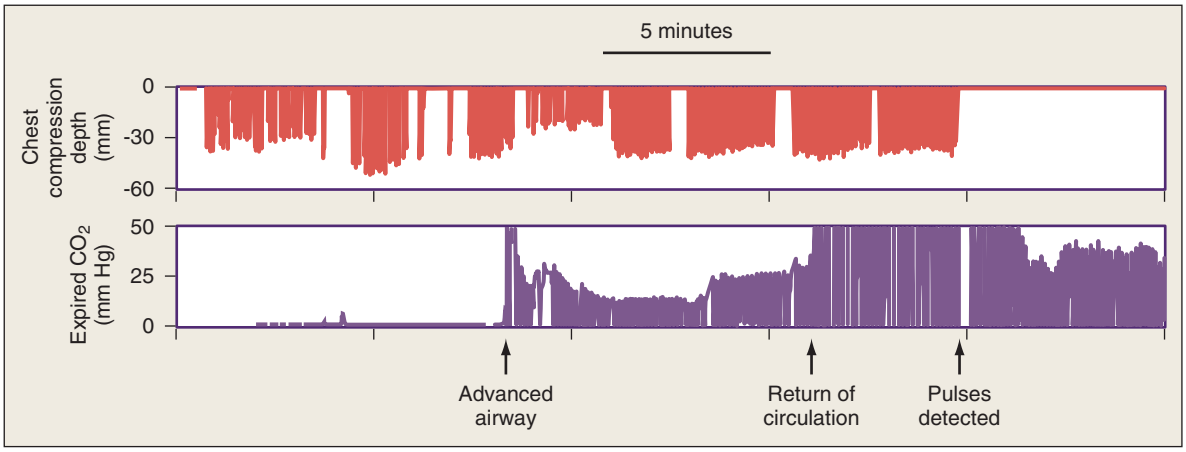

Fig. 45.4 End-tidal CO_2 changes during resuscitation. Tracings from monitor-defibrillator with an accelerometer to measure chest compression depth *(top trace)* and waveform capnography to measure exhaled CO_2 *(bottom trace).* Exhaled CO_2 confirms correct placement of an advanced airway. Note frequent interruptions in chest compressions before placing an advanced airway. More continuous chest compressions are followed by an abrupt rise in exhaled CO_2, corresponding to a return of circulation, including pulmonary circulation. Chest compressions continue for 2–3 minutes until providers detect a palpable pulse.

Ultimately, resuscitated patients with coma or continued respiratory failure will require tracheal intubation.

Artificial Circulation

In patients without a pulse, compression of the heart and chest by repetitive depression and release of the sternum circulates blood. The critical parameter for restoring myocardial energy stores, and thus spontaneous circulation, is the development of adequate CPP. CPP is the pressure gradient between the aorta and the inside of the ventricles at the end of diastole or during the relaxation phase of chest compressions. Most blood flows through the ventricular walls during diastole or during the relaxation phase of chest compressions, when ventricular pressure is the lowest (see Fig. 45.3). CPP is highly correlated with myocardial perfusion and consequently with the likelihood of resuscitation.[53] In humans, return of circulation requires that the developed CPP exceeds 15–20 mm Hg.[53]

Peak arterial pressure or palpable pulses measured during chest compressions do not necessarily represent CPP because ventricular pressures are simultaneously elevated. Consequently, palpation of pulses and systolic pressures developed by chest compressions may be misleading. It is most useful to follow the "diastolic" or relaxation-phase arterial pressure. If unable to follow any of these pressures, the clinician must rely on indirect evidence of myocardial perfusion, such as improved electrical and mechanical activity or increased pulmonary CO_2 excretion.

Even brief interruptions in chest compressions decrease CPP, and interruptions are inversely associated with restoring circulation and survival.[24] When chest compressions are measured during actual resuscitations by paramedics or hospital providers, interruptions and pauses are frequent.[54,55] Some monitor-defibrillators now have features to measure and record chest compressions and to provide real-time feedback about depth and rate to providers.[56] These features have no detectable effect on survival.[57] The chest compression fraction is one metric of compression continuity that is emphasized as a component of high-quality resuscitation[24] (Fig. 45.5), and many clinicians feel that the real-time and automated feedback is a useful safety and quality improvement mechanism to enhance total system performance.

Until the 1960s, thoracotomy was the standard approach for treatment of sudden cardiac arrest, but this procedure has now been supplanted by closed-chest compressions. Direct cardiac compression is more effective than external chest compressions, producing roughly a threefold increase in CPP.[58–60] This approach also allows recognition of cardiac tamponade, treatment by pericardiotomy, direct visualization of mechanical activity and fibrillation, and direct electrical defibrillation or pacing. In the setting of cardiopulmonary collapse resulting from exsanguination, thoracotomy also allows for aortic compression to shunt blood to the heart and brain and to direct control of intrathoracic bleeding. It should be considered in specific clinical circumstances, such as patients with traumatic cardiac arrest or recovering from recent cardiac surgery.

To improve delivery of uninterrupted chest compressions, a variety of mechanical devices have been developed.[24,33,61–63] Some of these devices exploit circumferential compression or active compression/decompression of the chest. A Cochrane review of mechanical versus manual chest compressions for cardiac arrest found no evidence of benefit of mechanical compressions in the return of spontaneous circulation or survival to hospital admission, and a subsequent pragmatic randomized trial found no improvement in 30-day survival.[63,64] Although no current device is superior to well-conducted manual compressions, these devices may play a role in providing chest compressions in settings where manual compressions are difficult or impossible (e.g., during ambulance transport, under the fluoroscopy arm, or when multiple providers are not available) or as a bridge to recovery and/or definitive treatment of the suspected etiology (e.g., extracorporeal circulatory support, percutaneous coronary revascularization, fibrinolysis of massive pulmonary embolism).

Extracorporeal Circulation

Extracorporeal perfusion for restoration of circulation (ECPR) can be used to resuscitate subjects for whom chest compressions have failed.[65–67] However, this approach requires specialized technical skill, system commitment, and increased costs and risks. Logistical issues include limited availability of perfusion equipment, setup time for circuit priming, and delays in establishing adequate venous and arterial access. Portable cardiopulmonary bypass devices that can be

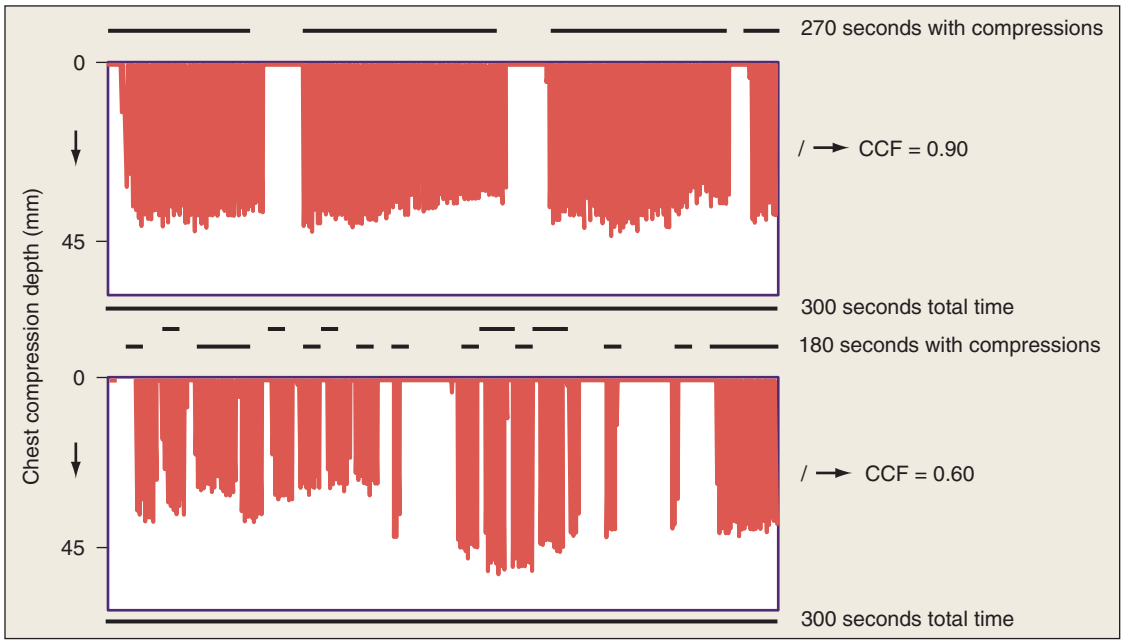

Fig. 45.5 Chest compression fraction (***CCF***) describes the continuity of chest compressions during resuscitation. Tracings of chest compressions detected by the accelerometer of a monitor-defibrillator can be used to calculate the proportion of time when chest compressions are occurring. In the *top tracing*, there are few pauses, and CCF is 0.90. In the *lower tracing*, frequent interruptions for breaths or procedures result in a CCF of 0.60.

primed quickly, along with improved techniques for rapid vascular access, have broadened the use of ECPR.

Multiple observational studies demonstrate the operational feasibility of ECPR and suggest the possibility of improved clinical outcomes, but it remains critical that ECPR be used for appropriately selected patients.[68] The ideal candidate is young with a witnessed cardiac arrest from a shockable rhythm, with a presumed cardiac (or other reversible) etiology, who receives immediate CPR and who has a brief interval until successful cannulation and commencement of extracorporeal resuscitation.[69] Examples of selection criteria from three centers are given in Table 45.1.

The timing of ECPR is equally important because irreversible myocardial and neurologic injury can preclude survival despite mechanically restoring circulation. Conventional resuscitation is clearly

TABLE 45.1 Sample Selection Criteria for Extracorporeal Perfusion for Restoration of Circulation (ECPR)

	Surugadai Nihon University Hospital Tokyo, Japan	Sharp Memorial Hospital San Diego, California	Alfred Hospital Melbourne, Victoria, Australia
Inclusion criteria	Age 18–74	Persistent cardiac arrest	Age 18–65
	Witnessed cardiac arrest	Shock refractory to standard therapies	Suspected cardiac etiology
	Presumed cardiac etiology		Any CPR within 10 minutes of collapse
	EMS arrival ≤15 minutes		Initial rhythm of ventricular fibrillation
	Defibrillation by AED or EMS personnel		30 minutes of persistent cardiac arrest
	Persistent cardiac arrest on arrival to ED		
Exclusion criteria	Presumed noncardiac etiology	Initial rhythm of asystole	Known preexisting significant neurologic disability
	Successful ROSC ≤10 minutes of arrival to ED	Any CPR not initiated ≤10 minutes of cardiac arrest	Known significant end-stage comorbidities
	Core body temperature <30°C on arrival to ED	Estimated EMS transport time >10 minutes	Terminal illness because of malignancy
	Pregnancy	Total arrest time >60 minutes	
		Suspicion of sepsis or hemorrhage	
		Preexisting severe neurologic disease	

Sample selection criteria for extracorporeal life support (ECLS) in out-of-hospital cardiac arrest (OHCA).

preferred when patients have early recognition, early high-quality chest compressions, and early defibrillation. However, increasing the duration of treated cardiac arrest decreases the odds of functionally favorable survival (as low as 1%–15%, depending on case features, initial cardiac rhythm, witnessed collapse, and bystander CPR).[70] Observational data of ECPR candidates treated with traditional resuscitation suggest the therapeutic window for conversion to ECPR occurs after 10–20 minutes of professional resuscitation.[71] Several randomized trials of ECPR are in progress.

Electrocardiogram Monitoring

Continuous three-lead ECG monitoring is essential for guiding resuscitation. A practical approach is to divide rhythms into organized and nonorganized. Organized rhythms include supraventricular rhythms or ventricular tachycardia (VT). Nonorganized rhythms include VF and asystole. Nonorganized rhythms cannot support cardiac output, regardless of volume status, cardiac muscle state, or vascular integrity. Therefore restoring cardiac electrical activity to an organized rhythm is an essential step in resuscitation. Organized rhythms can support cardiac output unless they are too slow (<30–40 complexes/min) or too fast (>170–180 complexes/min). An organized rhythm in the absence of a palpable pulse is termed *pulseless electrical activity* (PEA).

As the incidence of PEA as the initial cardiac rhythm increases, with a relative decrease in the incidence of VF,[10,72–74] PEA is an area of increased study and focus. Point-of-care echocardiography during resuscitation allows for more nuanced assessment of PEA. PEA may be subdivided into an organized rhythm in the absence of palpable pulse with or without echocardiographic motion ("true PEA" vs. "pseudo-PEA"). In cases of pseudo-PEA, pausing compressions and administering vasopressors may aid in restoring circulation.[75] Alternatively, cases of pseudo-PEA with insufficient cardiac output from a tachydysrhythmia and dwindling preload should be corrected by rescue shock.

The absence of perfusion with slow organized electrical activity may result from primary myocardial injury (e.g., massive MI) or from uncoupling of electrical and mechanical activity (e.g., prolonged circulatory arrest). The rate of complexes may be used to monitor resuscitation efforts. With increasing ischemia, energy depletion will occur in the electrical system and the rate of PEA will slow down. If resuscitation improves the energy state of the heart, the rate of PEA will accelerate. Narrow complexes reaching rates of 80–100 beats per minute often herald the return of a pulse. Falling rates reflect unsuccessful resuscitation efforts.

VF and asystole lie along a continuum of not-organized ECG. Arbitrary peak-to-peak amplitude of the ECG is usually used to distinguish asystole (amplitude <0.1–0.2 mV) from VF (amplitude >0.2 mV).[76] However, VF also exhibits temporal structures that may be absent in asystole.[77] VF is a chaotic electrical activity formed by multiple interacting waves of activation within the heart.[78] VF emerges from broken wavefronts that result from areas of ischemia (e.g., MI), areas of prolonged refractoriness (e.g., drug-induced or inherited prolonged QT intervals), or too-rapid succession of activation potentials (e.g., tachycardia or an "R on T" premature beat). As the organization and amplitude of these waves decline because of ischemia or hypoxemia, the amplitude of the ECG also declines. Reperfusion of the heart in asystole may restore VF. Furthermore, the amplitude and organization of the VF increases with reperfusion, providing a marker of adequate artificial perfusion.

Rational Use of Rescue Shocks for Defibrillation

Delivery of immediate transthoracic electric rescue shocks to patients in VF can convert VF into an organized cardiac rhythm. Rescue shocks are highly effective when VF is for a very brief duration (<1–2 minutes). These shocks may work by depolarizing the heart, canceling the original wavefronts, or prolonging the refractory periods.[78] Although rescue shocks can successfully restore an organized rhythm, repeated shocks may directly damage the myocardium.[79] Optimal therapy should provide rescue shocks at the lowest effective energy while minimizing the number of unsuccessful rescue shocks.

In the out-of-hospital setting when the collapse is not witnessed by paramedics, only 9%–12% of rescue shocks restore an organized ECG,[80,81] and most shocks convert VF into asystole.[82] Even after successful defibrillation, VF may recur because of incomplete depolarization by the shock, heterogeneous areas of refractoriness, or persistent foci of chaotic activity.[83] Multiphasic shock waveforms are more effective for depolarization of individual myocytes and require less energy than monophasic waveforms.[78] Consequently, most available defibrillators deliver biphasic waveforms. Increasing pressure of paddles from 0.5 kg to 8 kg on the chest decreases transthoracic impedance by as much as 14% and increases delivery of current to the heart.[84,85] This advantage of paddles must be weighed against the increased safety and convenience afforded by hands-free self-adhesive defibrillation pads, which are now used in most settings. In the past, multiple shocks would be delivered in rapid succession to decrease chest impedance. However, repetitive shocks decrease chest impedance by about 8% or less in actual patients,[84,86,87] which does not justify the interruption of artificial circulation to deliver "stacked" shocks. Reducing the interruption in chest compressions before and after a rescue shock is associated with greater resuscitation success,[88] which led to the coining of the term *perishock pause*. Duration of the perishock pause is inversely associated with survival to hospital discharge.[89] Specific techniques to reduce the perishock pause include continuing chest compressions while the defibrillator is charging, only stopping at the last moment before shock, and eliminating the postshock pulse check. Alternatively, manual compressions may be continued during rescue shocks if the rescuer is using Class 1 electrical insulating gloves complying with International Electrotechnical Commission (IEC) standards and modern self-adhesive defibrillation pads. In this scenario, the risk of shock to rescuers from touching a patient during defibrillation is small.[25]

For VF that has lasted more than 3–4 minutes, preclinical data suggest that delaying rescue shocks until after a few minutes of chest compressions will improve success.[90–93] To date, two clinical studies in out-of-hospital cardiac arrest patients have found that either 90 seconds or 3 minutes of chest compressions before delivery of the initial rescue shock improved resuscitation rates for subjects with VF outside a hospital, particularly when rescuer response intervals were longer than 4 minutes.[2,94] However, a third study found no difference in outcome with 5 minutes of chest compressions before shock,[95] and a fourth study found no difference in outcome with 3 minutes of chest compressions before shock.[96] Finally, a large multicenter trial comparing immediate rescue shock to 3 minutes of chest compressions before rescue shock stopped enrollment, finding no difference between groups.[97] Taken together, the clinical data suggest that the first rescue shock for VF should be delivered as soon as possible within 3–5 minutes as long as chest compressions are started immediately but that there is no reason to intentionally delay the rescue shock.

Quantitative analysis of the VF waveform can distinguish early VF from late VF and may be useful in estimating the likelihood of rescue shock success.[98] Larger amplitude of VF[99] in addition to frequency-based measures and nonlinear dynamic measures of VF organization[100–103] are associated with a higher probability of rescue shock success. Future generations of defibrillators may provide real-time, semiquantitative estimates of the probability that a rescue shock will succeed in restoring an organized rhythm. It is unknown if these quantitative measures will be clinically useful for titrating resuscitation.

Beta-blockade with a short-acting agent such as esmolol represents another therapeutic option for VF. Beta-activation (e.g., systemic epinephrine) increases myocardial oxygen requirements, worsens ischemic injury, lowers the VF threshold, and worsens postresuscitation myocardial function.[104–106] Blocking beta-receptors may terminate the electrical storm responsible for refractory VF.[104–108] Esmolol is a favorable agent given its ultra-short half-life.[109] Low-certainty observational evidence suggests that beta-blockade is associated with improved clinical outcomes, primarily restoration of circulation, and short-term survival.[110]

Drug Therapy

Drug therapy in cardiac arrest can be divided into three categories: pressors, antidysrhythmics, and metabolic drugs. Pressors are used during resuscitation and include epinephrine and vasopressin. Both of these drugs can increase CPP via the alpha-adrenergic (epinephrine) or vasopressin receptors (Fig. 45.6).[111,112] Epinephrine is usually administered in 1-mg (~0.015 mg/kg) increments. In laboratory studies, the pressor effects of epinephrine during cardiac arrest were brief (~5 minutes). Vasopressin is administered as 40-unit boluses (~0.5 units/kg) and produces a longer-lasting increase in CPP (~10 minutes).

Epinephrine consistently improves return of circulation and survival, but its effects on neurologic recovery are less certain. Older clinical trials testing moderate (7 mg vs. 1 mg) and higher (15 mg vs. 1 mg) initial boluses of epinephrine found higher rates of pulse restoration and admission to hospital, but overall survival was not significantly different.[113–115] Accumulated beta-adrenergic toxicity likely increases myocardial oxygen consumption, ectopic ventricular arrhythmias, hypoxemia from pulmonary arteriovenous shunting, and postarrest myocardial dysfunction.[116] However, higher doses of epinephrine may impair cerebral circulation, a detrimental effect that may offset any benefit from increasing rates of restoration of circulation.[117,118] A massive, population-based, matched cohort study found that prehospital epinephrine was associated with restoration of circulation but with lower probability of 1-month survival and favorable functional outcome.[119] Taken together, these data raised the worrisome possibilities that when epinephrine is required to restore cardiac activity, severe brain injury has already occurred or that it contributes to brain injury.[117] Two randomized trials comparing epinephrine with placebo in out-of-hospital cardiac arrest consistently demonstrated superior return of circulation, survival to hospital admission, and survival to hospital discharge.[120,121] One trial noted additional survivors with worse neurologic outcome at hospital discharge in the epinephrine arm, but also improved survival to 3 months without statistical difference in favorable or unfavorable neurologic outcomes.[121] The net increase in survivors constituted those with both favorable and unfavorable neurologic outcomes. Of note, neurologic status of initially comatose cardiac arrest survivors can improve for up to 6 months.[122]

The optimal dosing and timing of epinephrine remain an active area of investigation. Both drugs should ideally be titrated to improvement in clinical indicators (ECG waveform, mechanical activity, changes in end-tidal CO_2 or diastolic arterial pressure as a surrogate for CPP). Rote, repeated administration is unlikely to result in meaningful outcome improvements. Titrated epinephrine infusions may balance the positive and negative physiologic effects, but this approach has not yet been explored clinically. The concept of goal-directed cardiac arrest resuscitation is an emerging paradigm within resuscitation science supported by preclinical and preliminary clinical work.[123,124]

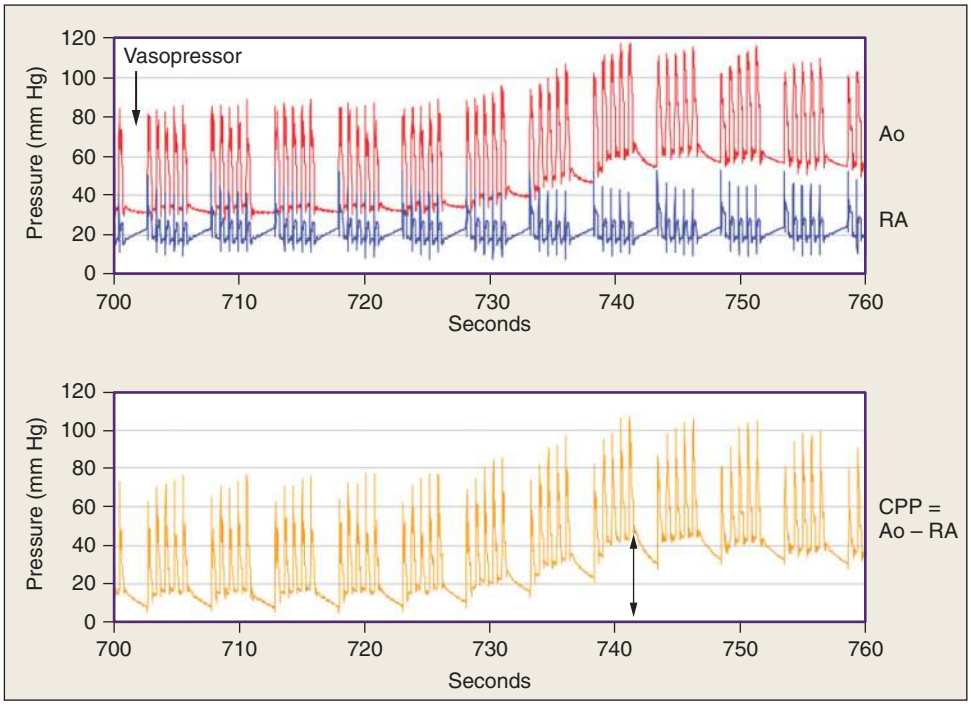

Fig. 45.6 Administration of a vasoactive drug can increase coronary perfusion pressure (*CPP*) produced by chest compressions. Note that CPP generated by chest compressions alone is below the 15–20 mm Hg believed necessary for restoration of circulation. However, aortic pressure (*Ao*) and thus CPP increase above this threshold 40–60 seconds after drug administration *(arrow)*, whereas right atrial (*RA*) pressure remains unchanged. When treating cardiac arrest, it is reasonable to expect the vasoactive drug will act after 60 more seconds of chest compressions. (Unpublished laboratory data.)

Vasopressin can increase CPP without complicating beta-adrenergic effects. Resuscitation rates and survival are identical for patients resuscitated with vasopressin and standard doses of epinephrine after in-hospital[125] or out-of-hospital cardiac arrest.[126] Some post hoc analyses suggest vasopressin may be superior for resuscitation and survival of patients whose first ECG rhythm is asystole and for those subjects requiring multiple doses of vasopressors.[126] Subsequent trials of the combination of epinephrine with vasopressin versus epinephrine alone found no difference in outcome with the different combinations of drugs.[127,128] Given its lack of clear advantage over epinephrine, vasopressin is typically excluded from treatment guidelines and algorithms in the interests of simplification.

The role of antidysrhythmic drugs during cardiac arrest is equivocal.[129,130] Atropine may relieve bradycardia when it is vagally mediated. However, nervous system influences on the heart are largely eliminated after more than 1–2 minutes of circulatory arrest. Therefore there is little expectation that atropine will improve resuscitation from asystole or PEA. Lidocaine, procainamide, and bretylium have a long history of use in the treatment of VF. Once VF is established, lidocaine can increase the electrical energy required to defibrillate by more than 50%.[131] Other classes of antidysrhythmics without sodium channel blockade do not alter defibrillation energy requirements. For example, amiodarone (5 mg/kg) is superior to placebo[132] and to lidocaine[133] in terms of restoring the pulse in out-of-hospital patients with VF that is not terminated by three rescue shocks. A large clinical trial comparing amiodarone, lidocaine, or placebo for shock-refractory VF found no overall difference in survival.[134] However, both lidocaine and amiodarone were superior to placebo in the subgroup of witnessed VF.

Empiric treatments of metabolic disturbances with bicarbonate or other buffers may improve acidemia resulting from ischemia, but do not necessarily translate into improved clinical outcomes.[135,136] Originally proposed as an antagonist of adenosine released during ischemia, two prospective studies of aminophylline in subjects with PEA or asystole found no improvement in resuscitation.[137,138] Use of dextrose-containing fluids versus dextrose-free fluids did not alter outcome for out-of-hospital cardiac arrest patients.[139] Other metabolic therapies, including calcium and magnesium, also lack supporting data.[140,141] However, it is appropriate to consider specific use of these agents to correct known abnormalities that are contributing to cardiac arrest, such as hyperkalemia, calcium channel blocker overdose, torsades, or hypomagnesemia.

Taken together, the data support a simple pharmacologic approach to the treatment of cardiac arrest: epinephrine can augment CPP generated during chest compressions, antidysrhythmic drugs may be useful for maintaining organized rhythms in witnessed shock-refractory VF, and all other drug therapies should be based on the clinical situation and the response of the patient.

ASPECTS OF CARDIAC ARREST IN SPECIFIC SITUATIONS

If the original etiology of cardiac arrest is available, treatment and prognosis can be individualized to the specific patient. Among out-of-hospital patients, as many as 66% have primary cardiac disturbances.[142] For in-hospital patients experiencing cardiac arrest, dysrhythmia and cardiac ischemia account for 59% of events.[14] This section reviews unique features of cardiac arrest resulting from both cardiac and noncardiac causes.

Primary Cardiac Events

Primary dysrhythmia or cardiogenic shock is the most common proximate cause of cardiac arrest.[142,143] Patients undergoing angioplasty have a 1.3% incidence of cardiac arrest, and survival in these patients resembles survival in other populations.[144] Among patients admitted to a hospital with acute MI, cardiac arrest occurs in 4.8%.[17] Dysrhythmias are common during the hours after reperfusion therapy,[144] although reperfusion therapy reduces the overall risk of cardiac arrest.[145] During acute MI, cardiac arrest is most likely to occur in patients with lower serum potassium levels, more than 20 mm of total ST elevation, and a prolonged QTc interval during the first 2 hours of their event.[145] Some 3.3% of subjects surviving acute MI suffered sudden cardiac death.[146] Abnormalities of the heart are present in most cases of cardiac arrest, with coronary artery disease present in at least 65% of autopsies.[147] Taken together, these data suggest that most patients with cardiac arrest will have contributing cardiovascular disease.

When angiography was performed on consecutive patients resuscitated from cardiac arrest, acute coronary artery occlusion was identified in 48%–58% of the patients.[148,149] Similarly, 51% of initially resuscitated outpatients exhibited an elevation in cardiac enzymes or ECG evidence of acute MI.[150] In one series, troponin T was elevated in 40% of out-of-hospital patients undergoing CPR.[151] The direct myocardial injury from defibrillation and CPR may cause spurious elevations of creatine kinase that are unrelated to cardiovascular disease.[152] However, elevation in cardiac troponin levels are believed to reflect acute MI rather than injury from electric shocks.[153] Thus the 40% of subjects undergoing CPR with elevated troponin probably suffered myocardial injury before collapse. Unless a clearly noncardiac etiology for cardiac arrest is evident, acute coronary angiography may reveal an indication for angioplasty, thrombolysis, or other reperfusion therapy. Primary revascularization is safe in comatose patients undergoing hypothermia treatment.[154,155]

Primary ventricular tachydysrhythmias are rapidly reversible and are the initially recorded rhythm in 23%–41% of out-of-hospital cardiac arrest patients[10,11,156] and in 25% of in-hospital cardiac arrest patients.[14] Long-term antidysrhythmia treatment should be considered for patients who survive sudden cardiac arrest. At a minimum, treatment should be considered for patients with depressed left ventricular function or primary dysrhythmia without a reversible etiology.[157] Importantly, subjects surviving a life-threatening ventricular dysrhythmia have a 15%–20% risk of death during a mean of 16 months of follow-up, even when a reversible cause of the dysrhythmia such as electrolyte disturbance or hypoxia is identified.[158] Implantable defibrillators are superior to antidysrhythmic drugs for reducing the risk of subsequent death.[159] This benefit is primarily in subjects with a left ventricular ejection fraction (LVEF) less than 35%.[160] Implantable defibrillators were not better than antidysrhythmic drugs in a European trial that enrolled subjects resuscitated from cardiac arrest secondary to ventricular dysrhythmia without regard to LVEF.[161] Nevertheless, these devices offer significant hope of preventing sudden cardiac death, and identification of patients that they may benefit is an active area of research. At present, implantable defibrillators should be discussed for patients who recover from coma with LVEF less than 0.35 or who survive a ventricular arrhythmia in the absence of clearly reversible causes.

Asphyxia

Asphyxia causes transient tachycardia and hypertension, followed by bradycardia and hypotension, progressing to PEA or asystole. This period of blood flow with severe hypoxemia before cardiac arrest may worsen central venous hypoxemia and subsequent oxygen debt, rendering asphyxiation a more severe injury than VF or other rapid causes of circulatory arrest.[162] Brain edema is more common on computed tomography (CT) scans after resuscitation when cardiac arrest is caused by pulmonary rather than cardiac etiologies.[163] During cardiac arrest, pulmonary edema develops from redistribution of blood into the pulmonary vasculature,[164] worsening oxygenation in the asphyxiated

patient. Attention to the primary cause of asphyxia, in addition to maneuvers that will increase oxygenation, may be necessary.

Pulmonary Embolism

Pulmonary emboli may occur in postsurgical patients and in medical patients with impaired mobility.[165] In two series, pulmonary emboli were present in 10% of both in-hospital deaths[166] and out-of-hospital deaths.[167] Pulmonary emboli can result in rapid cardiopulmonary collapse and should be considered as a possible etiology of cardiac arrest in the proper clinical setting or when collapse is preceded by sudden shortness of breath, hypoxemia, and/or pleuritic chest pain.

Pulmonary emboli cause cardiac arrest from hypoxemia or when a large thrombus obstructs right ventricular outflow into the pulmonary arteries. This situation results in a dilated, distended right ventricle and an empty left ventricle, which can be seen on a transthoracic echocardiogram. Circulation cannot be restored unless this obstruction is relieved. Because the primary disturbance is hypoxemia and decreased cardiac output, cardiac arrest from pulmonary embolism often presents with an initial rhythm of PEA or asystole.

Administration of a bolus of fibrinolytic drugs such as tenecteplase has been used with reported success in nonrandomized trials during resuscitation of undifferentiated patients,[168] but failed to demonstrate benefit in a larger randomized trial of undifferentiated patients in cardiac arrest.[169] Likewise, a randomized trial of tissue plasminogen activator to undifferentiated patients with out-of-hospital cardiac arrest and an initial rhythm of PEA failed to demonstrate any benefit.[170] Observational studies and subgroup analyses from randomized data report varying degrees of association between intra-arrest systemic fibrinolysis and survival. The potential effects on longer-term outcomes are unknown. Low-certainty evidence suggests that this treatment increases overall risk of bleeding (including any intracranial hemorrhage), but not necessarily risk of major bleeding (including symptomatic or major intracranial hemorrhage).[27] Case series report the feasibility of surgical embolectomy and percutaneous mechanical thrombectomy.[171–173] When logistically feasible, ECPR is a reasonable bridge to recovery or definitive therapy in cases of cardiac arrest from known or highly suspected massive pulmonary embolism.

Electrolyte Disturbances

Potassium disturbance is the most likely electrolyte disturbance to result in cardiac arrest. In cardiac patients, hypokalemia has been linked to the incidence of VF after MI.[174,175] Hypokalemia may also account for the increased incidence of sudden death in patients taking large doses of diuretics. VF is rare in patients where serum potassium is maintained over 4.5 mEq/L. Conversely, hyperkalemia can prolong repolarization, increasing the likelihood of VF initiation. Hyperkalemia may also suppress automaticity in the myocardial electrical system, leading to bradycardic PEA or asystole. Interestingly, cardiac arrest occurring during hemodialysis is not associated with high or low potassium levels but is more common after patients are dialyzed against a low (0 or 1 mEq/L) potassium dialysate.[175] These data suggest that rapid changes in potassium rather than the absolute value are important triggers of cardiac arrest in this population. Derangements of calcium and magnesium may produce similar or synergistic changes in cardiac conduction.

The clinical setting of cardiac arrest or widened ventricular complexes with repolarization abnormalities on ECG may suggest a primary electrolyte disturbance. If hyperkalemia is suspected, the usual acute resuscitation maneuvers can be supplemented by a bolus injection of calcium carbonate (1 g), bicarbonate (1 mEq/kg), and perhaps insulin (0.1 units/kg) with glucose (0.5–1 g/kg). These drugs may improve cardiac electrical stability, facilitating restoration of circulation.

Poisoning

Cardiac arrest can result from drug overdose. Therapy does not change except when specific antidotes or countermeasures to the poison are available. For example, calcium channel blocker overdose may be countered by administration of intravenous (IV) calcium.[176] Beta-blocker toxicity may require large doses of inotropic agents[177] or may respond to glucagon.[178] Digoxin overdose may respond to digoxin-binding antibodies.[179] In the case of narcotic-induced respiratory depression, subsequent cardiac arrest is usually a specific case of asphyxia rather than specific cardiotoxic effects. Intravenous lipid emulsion is typically recommended to treated life-threatening local anesthetic toxicity (including cardiac arrest) and has been used for other lipid-soluble poisonings.[180,181] In cases of refractory cardiac arrest, both IV lipid emulsion and ECPR are reasonable therapeutic considerations.[182,183] Poisoned patients are often younger, with few comorbidities, and may recover well once the poison is eliminated. This potential for a better outcome may justify longer and more aggressive efforts at resuscitation. A cohort study of recreational drug overdose-related cardiac arrest found that overdose-related patients who survived to hospital discharge were more likely than other cardiac arrest patients to have a favorable discharge disposition.[184]

Sepsis

Cardiac arrest developing from sepsis may involve direct myocardial depression from humoral factors.[185,186] Vasodilation also results in apparent hypovolemia. Finally, impaired oxygen extraction, shunting, and mitochondrial depression can produce cellular hypoxia. Because pump and vascular failure are the principal physiologic derangements, the most common initial ECG rhythm would be expected to be a rapid PEA that slows to asystole with ischemia. Large doses of inotropes, vasoconstrictors, and volume may be needed to restore circulation. Acute volume resuscitation may require 100 mL/kg of isotonic fluids or more and must be titrated to physiologic endpoints (for example, central venous oxygen saturation, CVP, or urine output). Because the underlying sepsis physiology will still be present when the pulse is restored, these patients may prove exceedingly unstable during the subacute recovery period and have a reduced chance of survival.[30,187–189]

Trauma/Hemorrhage

Hypovolemic cardiac arrest occurs after severe trauma, gastrointestinal hemorrhage, or other blood loss. Absence of venous return results in an empty heart that cannot produce cardiac output despite a normal inotropic state and vascular tone. As with sepsis, this situation would most likely present with a rapid PEA that slows to asystole, but VF can develop in response to global ischemia. Because cardiac function and vascular function are initially normal, inotropes and vasoconstrictors are unlikely to benefit hypovolemic cardiac arrest. Likewise, during hypovolemic cardiac arrest, the empty cardiac ventricles render external chest compressions ineffective. As such, there is no physiologic justification to employ the same resuscitation measures that are used for more traditional cases of cardiac arrest. Instead, attention should be turned toward emergent procedures to control hemorrhage, intravascular volume expansion with crystalloid fluids or blood products,[190] and mobilization toward definite surgical repair. After restoration of circulation, patients with hemorrhagic cardiac arrest are likely to develop multisystem organ failure.[190]

If blood loss is ongoing or if massive volume replacement cannot be rapidly instituted, thoracotomy allows clamping or compression of the aorta, perhaps retaining sufficient blood in the proximal aorta to perfuse the coronary and cerebral arteries. This procedure has reported success in the treatment of penetrating traumatic injuries[191] but

not in blunt trauma.[192] Survival is better if thoracotomy occurs in the operating room after a brief loss of pulse and best if the penetrating injury has created a cardiac tamponade that is directly relieved by pericardiotomy. Clearly, restoration of circulation must be accompanied by repair of the site of hemorrhage.

Hypothermia

Hypothermia represents an important situation where prolonged resuscitative efforts are justified by the greater tolerance of the cold heart and brain to ischemia. Survival with favorable neurologic recovery has been reported after cold water submersion or exposure, with cardiac arrest, and resuscitation efforts lasting several hours.[193,194] Subjects in whom circulatory arrest occurs because of hypothermia appear to be more salvageable than subjects who asphyxiate or have circulatory arrest before becoming cold.[195]

Treatment should be based upon the initial temperature of the patient. For temperatures between 32°C and 37°C, no change in drug or electrical treatment is required, and this level of hypothermia may be beneficial for resuscitation of both brain and heart.[196,197] For temperatures between 29°C and 32°C, cardiac activity may be preserved, and external warming (warm air, heating lights, warm blankets) and warm IV fluids should accompany the usual resuscitation efforts. The likelihood of generating sufficient perfusion to rewarm the body declines as temperatures decrease from 32°C to 29°C, and more invasive warming should be considered if external warming fails to elicit a rapid response. Mechanical and electrical activity of the heart is disrupted at temperatures below 28°C, and patients may exhibit PEA, VF that is refractory to defibrillation attempts, or asystole. Repetitive rescue shocks in such patients are not justified and may be detrimental; instead, rescue shocks should be reserved until the patient has been rewarmed in the setting of ongoing circulatory support. The efficacy of most resuscitation drugs may be impaired.

Active rewarming during resuscitation of victims of severe hypothermia can include arterial and venous access for partial or complete cardiopulmonary bypass. Extracorporeal circulation is particularly useful because it can provide artificial circulation and warming, simultaneously.[195,198,199] Another option is the placement of thoracostomy tubes and lavage of the chest with warm fluids.[200] Thoracostomy is intuitively preferable to peritoneal lavage because the heart is directly warmed. Warm air forced over the body surface provides the least heat exchange.[201] In any case, it is difficult to determine whether circulation can be reestablished in profoundly hypothermic patients until near-physiologic core temperatures (32°C–36°C) are restored.

Other Medical Conditions

Comorbidities have a tremendous influence on the outcome of patients with cardiac arrest.[143,202,203] In some cases, cardiac arrest may be an expected progression of the patient's disease. For example, no survivors were reported among cancer patients with expected cardiac arrest.[203] Therefore it may be appropriate to set limits on resuscitation efforts in certain medical conditions before cardiopulmonary collapse. Ideally, discussion about the expectations for resuscitative efforts should be held with the patient, his or her family, or the patient's representatives before cardiac arrest. If those discussions did not occur before the first cardiac arrest, they should promptly follow any initially successful resuscitation.

POST–CARDIAC ARREST CARE TO MINIMIZE BRAIN INJURY

Post–cardiac arrest syndrome is a defined clinical entity, consisting of brain injury, myocardial dysfunction, systemic ischemia/reperfusion, and the persistent precipitating pathology that caused the cardiac arrest.[7] Management of this syndrome in patients after restoration of circulation directly affects their ultimate outcome. For example, survival varies for comparable patients treated by a single ambulance service who are delivered to different hospitals with institutional differences in in-hospital management.[5,6] The American Heart Association and European Resuscitation Council now incorporate guidelines for the treatment of post–cardiac arrest syndrome into their consensus scientific statement.[27] This section will highlight a bundled post–cardiac arrest care package, designed to mitigate primary injury and prevent secondary brain injury.

Brain injury after ischemia is an active process that develops in successive phases (e.g., ischemic injury, reperfusion injury, and secondary injury) over hours to days after resuscitation.[204] Multiple cellular and molecular mechanisms contribute to this brain injury.[204–210] Protein synthesis is inhibited at the level of translation initiation for several hours.[208] Ischemic injury is characterized by energy failure, anoxic depolarization, loss of ion gradients, dysregulation of calcium and glutamate, and disruption of the blood–brain barrier. Reperfusion injury is characterized by release of excitatory amino acids, generation of free radicals and reactive oxygen species, reactive hyperthermia, no-reflow phenomenon, and cerebral edema.[209] Secondary injury is characterized by failure of autoregulation, cerebral hypoperfusion, ongoing cerebral ischemia, additional oxidative injury, cerebral edema, seizure, and hyperpyrexia. Ultimately, activation of specific proteases between 24 and 72 hours after reperfusion is associated with the appearance of histologic signs of neuronal death.[210] Despite detailed knowledge of the mechanisms involved with brain ischemia, no monotherapy drug to date has demonstrated a clear benefit in human trials. Randomized trials have examined thiopental, the calcium channel blocker lidoflazine, magnesium, and diazepam.[211–213] One explanation for this failure is that multiple mechanisms contribute simultaneously to the process of ischemic neuronal death. Antagonizing one pathway leading to neuronal death may leave other backup mechanisms unaffected. Less specific therapies, such as reducing brain temperature with or without general anesthesia, may prove more effective. For example, multiple prospective randomized clinical trials found that controlling body temperature for 12–24 hours after resuscitation improved survival and neurologic recovery.[196,214,215] Preliminary clinical trials suggest that inhaled xenon combined with induced mild hypothermia mitigates neuronal white matter injury and myocardial injury.[216,217] Confirmatory randomized trials are in progress. Whether temperature reduction itself confers benefit or merely served to prevent deleterious hyperthermia, it is important to note the success of this type of systemic therapy.

Opportunities to mitigate secondary brain injury require attention to other organ systems and physiologic processes. Observational data also support coronary revascularization and meticulous avoidance of hyperthermia, hypotension, hypocarbia, hypoxia, and hyperglycemia.[5,218–220] Taken together, systematic brain-oriented intensive care is more likely to improve outcome rather than a single therapeutic drug or intervention (Table 45.2).

Coronary Revascularization

Given the prevalence of acute coronary occlusions and high-risk coronary artery disease in this population, appropriate treatment of ST elevation MI (STEMI) should be promptly initiated, regardless of initial level of consciousness.[221] Historically, this has been extrapolated to patients without STEMI because acute coronary ischemia is such a common precipitant of cardiac arrest. Repeated observational studies have highlighted immediate coronary angiography with concomitant coronary intervention as an independent predictor of survival and favorable neurologic outcome, irrespective of the presence or absence of STEMI on the initial ECG.[221] But this evidence base was subject to a

TABLE 45.2 Post–Cardiac Arrest Intensive Care

Temperature	Targeted temperature management 33°C–36°C for at least 24 hours
	Rewarm slowly (<0.25°C/h)
	Avoid fever for 72 hours or until awake
Cardiovascular	Mean arterial pressure >80 mm Hg during the first day (inotropic and vasopressor support as needed; invasive monitoring as needed)
	Reperfusion therapy for STEMI, regardless of concurrent coma or treatment with hypothermia
	Reperfusion therapy for acute coronary syndromes without STEMI if hemodynamically or electrically unstable
	Medical management for acute coronary syndromes (antiplatelet drugs, anticoagulation)
Pulmonary	Avoid hyperventilation
	Avoid hypoxia or unnecessary hyperoxia
	Pneumonitis is common
Gastrointestinal	Usual care
	Consider early refeeding (after hypothermia) to reduce translocation
Fluids/ Electrolytes	Monitor CVP and urine output with hypothermia/rewarming
	Monitor potassium/electrolytes during temperature changes
	Keep potassium ≥3.5 mEq/L
	Monitor glucose frequently, normal treatment of hyperglycemia >180 mg/dL
Infection	Pneumonia is common
	Prophylactic antibiotics are of unproven benefit
	Treat infections as they are identified
	Antipyretics are reasonable
Neurologic	CT scan to exclude intracranial lesions
	Sedation and muscle relaxation as needed for targeted temperature management
	Monitor for seizures with continuous EEG
	Suppress malignant EEG patterns with antiepileptic therapy
	Serial clinical examinations for prognosis
	Examinations may change dramatically over first 72 hours (or longer with hypothermia treatment)
	EEG, SSEP, and MRI with DWI can supplement clinical examination for prognosis
	Consider pharmacologic stimulation in patients with intact SSEP but persistent coma

high degree of selection bias that likely favored treating patients with a presumed better prognosis. Factors typically associated with a higher probability of emergency cardiac catheterization include male sex, younger age, shockable initial cardiac rhythms, witnessed collapse, and bystander CPR.[221]

Although emergency cardiac catheterization is still recommended for patients with STEMI, the requisite timing of cardiac catheterization for those with suspected acute coronary syndrome, but without STEMI, is an active area of clinical investigation. The first trial to randomize patients after out-of-hospital cardiac arrest from an initially shockable rhythm without STEMI or ongoing shock to coronary angiography performed immediately or in a delayed fashion after neurologic recovery was neutral for survival and neurologic recovery.[222] This neutral finding may be from the mitigation of selection bias or differing patient populations. Although nearly two-thirds of patients enrolled had coronary artery disease, the vast majority constituted stable lesions, and few patients had unstable lesions or thrombotic occlusions. Of note, half of the patients in the delayed angiography group with acute thrombotic occlusions manifested cardiac deterioration and crossed over to receive urgent intervention. A second trial randomizing out-of-hospital cardiac arrest patients without STEMI to immediate coronary angiography or intensive care with potential for delayed coronary angiography reported preliminary pilot data that did not detect prohibitive concerns with feasibility or safety.[223] A culprit lesion was identified and revascularized in approximately one-third of subjects randomized to immediate coronary angiography, and 15% of subjects randomized to intensive care crossed over to early coronary angiography for subsequent manifestations of ischemia. Multiple additional randomized trials are in progress.

Further complicating the interpretation of available data, the majority of nonsurvivors after resuscitation from cardiac arrest die from neurologic complications or iatrogenic withdrawal of life-sustaining therapies because of perceived poor neurologic prognosis. Even among randomized trials of coronary angiography, death from neurologic injury was three times as frequent as death from a cardiac etiology. Multiple scores and rubrics have been developed to risk stratify patients with respect to death from neurologic injury when selecting patients for coronary angiography, but none has been rigorously tested in a prospective fashion.

Until additional randomized data are available, a reasonable approach is to pursue emergency coronary angiography and revascularization for patients resuscitated from cardiac arrest with STEMI regardless of initial level of consciousness. Patients without STEMI but suspected of acute coronary syndrome fall along a continuum of risk. Those with an initial shockable rhythm or ongoing hemodynamic or electrical instability are at higher risk for acute coronary lesions and are more likely to benefit from definition of coronary artery anatomy, revascularization, or percutaneous mechanical circulatory support, all of which can be facilitated by left heart catheterization. Whereas for patients without these "STEMI-equivalents," it may be reasonable to delay coronary angiography in lieu of optimizing other aspects of critical care and estimating the trajectory of neurologic recovery.

Targeted Temperature Management

Meticulous temperature control is important during the first 24–48 hours after ischemic brain injury. Bacteremia and spontaneous fever are common in resuscitated patients, making active prevention of hyperthermia mandatory.[224,225] Fever prevention is beneficial to the injured brain after traumatic brain injury, stroke, and cardiac arrest.[218,226,227] Mechanistically, temperature probably affects more than the brain metabolic rate (manipulations of temperature that improve neurologic recovery in laboratory studies produce no effect on jugular venous lactate or oxygen uptake).[228] Instead, a variety of signaling pathways and cellular responses are sensitive to relatively small (1°C–2°C) changes in brain temperature.[211,212] Also, lowering brain temperature can reduce intracranial pressure[229] and vulnerability to seizures.[230]

For nearly 20 years, mild induced hypothermia (32°C–34°C) for 12 or 24 hours has been the cornerstone of post–cardiac arrest intensive care. Two randomized trials published in 2002 found a 24%–30% reduction in relative risk for death or poor neurologic outcome[231] and

significant improvement in the odds of survival and good neurologic outcome for subjects resuscitated from VF cardiac arrests.[196,214] A subsequent large, prospective, randomized trial comparing a targeted temperature of 33°C with 36°C found that both groups had similar mortality and neurologic outcome at 180 days.[215] The most notable difference between the 2002 trials compared with the subsequent trial was that the earlier studies did not adequately control temperature in the control arm. Temperatures greater than 37°C commonly occurred in subjects for both control groups, whereas tight control at 36°C was followed in the subsequent trial. Additionally, the subsequent trial used a blinded neurologic assessment along with regimented decisions about prognosis. Finally, patients in the 33°C versus 36°C trial had very high rates of witnessed cardiac arrest, bystander CPR, initial shockable rhythm, and very brief intervals from collapse until start of basic life support.[215] It is possible that subgroups of patients with greater post–cardiac arrest illness severity may benefit from a specific target temperature or from titrated use of temperature.

Current recommendations are to keep all comatose post–cardiac arrest patients at a constant target temperature ranging between 32°C and 36°C. This differs from reactive treatment of fever, which is an active area of investigation in an ongoing randomized trial. It is erroneous to assume that selection of 36°C as a target temperature is synonymous with not managing temperature or fever prevention without active controls. Active measures require thermostatically controlled devices, of which there are many. Importantly, there is no clinical situation where, at minimum, active control of temperature at 36°C is contraindicated.

There is no biologic basis to believe that the neurologic benefit of temperature management is specific to patients with one type of cardiac rhythm. Patients with all rhythms were included in the largest clinical trial.[215] Multiple case series report successful application of induced hypothermia for patients after out-of-hospital and in-hospital cardiac arrest with all initial rhythms.[3,232,233] One randomized trial specifically comparing a targeted temperature of 33°C with 37°C in comatose patients resuscitated from cardiac arrest with nonshockable rhythms found a 5% absolute increase in 90-day favorable neurologic outcome.[234] At the time of resuscitation, most patients are already mildly hypothermic, with core temperatures between 35°C and 35.5°C.[197,214,215] This spontaneous cooling results from mixing of core and peripheral blood compartments during circulatory arrest, but patients typically rewarm within a few hours after restoration of circulation unless specific interventions are instituted.[215,235]

The maximum delay in achieving target temperature has been tested in several randomized trials of prehospital induction of temperature management with both rapid infusion of cold crystalloid fluid after return of spontaneous circulation and transnasal evaporative cooling with perfluorocarbons before return of spontaneous circulation.[236–240] Although subgroups treated with transnasal evaporative cooling suggest potential for efficacy, these trials have been mostly neutral. Of note, more instances of re-arrest and pulmonary edema requiring diuresis were observed after undifferentiated prehospital administration of cold IV fluid boluses.[236–238] This intervention is likely best used in a hospital-based critical care setting with adequate monitoring and resources.

The optimal duration of temperature management is an active area of investigation. Laboratory studies suggest that secondary brain injury occurs for several days after restoration of circulation, manifesting as cerebral energy failure, metabolic stress, edema, and seizures.[241] Although statistically neutral, one trial randomizing patients to a target temperature of 33°C for 24 or 48 hours suggests the potential for improved survival and neurologic recovery with longer durations of lower temperature. A subsequent trial testing assorted durations of targeting 33°C between 6 and 72 hours is in progress.

Laboratory studies suggest that rewarming should be performed slowly (<0.25°C/h). Until additional data are available, a regimen similar to the largest clinical trial (at least 24 hours of temperature management targeting 33°C–36°C, followed by meticulous fever suppression for at least 3 days) is reasonable.[215]

After cardiac arrest, temperature management can be achieved by a variety of techniques, including surface cooling with ice packs, cooling blankets, or endovascular devices.[242–251] Initial studies using surface cooling alone suggested that it is slow and may require 4–6 hours to reach 34°C.[243–246] However, neuromuscular blockade and sedation to prevent shivering greatly accelerate surface cooling.[246] There are few direct comparisons of surface cooling and endovascular cooling; however, endovascular catheters may provide more stable control of temperature over time.[246,247] Local cooling of the head is unlikely to produce brain hypothermia when there is adequate perfusion by warm core blood,[248] although the head can be an effective site for removing heat from the body.[251]

Rapid infusion of 30 mL/kg cold (4°C) crystalloid fluid produces a rapid decrease in core temperature in post–cardiac arrest patients.[249,250] Cold fluid boluses must be administered quickly into the central circulation (via a central line or under pressure infusion via a peripheral line). The volume required may limit this intervention in some patients. Cold IV fluids only produce a transient decrease in core temperature, requiring that a maintenance technique (endovascular or surface cooling device) be in place after the infusion.[242,251]

Induction of cooling can result in peripheral vasoconstriction, with an apparent reduction in vascular volume, rise in CVP, and diuresis.[252,253] Rewarming causes vessels to dilate, CVP to fall, and the patient to appear relatively hypovolemic. Inattention to these fluid shifts was cited as a pitfall in trials of therapeutic hypothermia for traumatic brain injury.[254] Hypokalemia, hypophosphatemia, and hypomagnesemia also occur during cooling, followed by hyperkalemia during rewarming.[255,256] Frequent monitoring and correction of electrolytes are warranted.

Primary angioplasty is safe in patients undergoing hypothermia treatement.[154,155] Mild hypothermia greater than 30°C does not interfere with defibrillation. Cooling from 37°C to 31°C has a positive inotropic effect, increasing stroke volume to a greater extent than it decreases heart rate.[252] Clinical data report a transient 18% decline in cardiac index with cooling to 33°C.[253]

Although mild hypothermia can inhibit platelet function and coagulation,[257] these changes are of a small magnitude, leading to few bleeding complications, even in subjects with concurrent trauma or administration of heparinoids and glycoprotein IIb/IIIa inhibitors.[197,226] Bleeding after hypothermia and cardiac catheterization was reported in 6.2% of post–cardiac arrest patients.[258] However, mild hypothermia may inhibit antiplatelet medications (ticagrelor, prasugrel, and clopidogrel). Early studies of post–cardiac arrest patients treated with mild hypothermia and percutaneous coronary intervention found a high incidence of stent thrombosis (11%–31%), but it was impossible to distinguish between the relative contributions of post–cardiac arrest syndrome and iatrogenic mild hypothermia.[259] Subsequent large observational studies comparing post–cardiac arrest subjects with and without mild hypothermia found no difference in stent thrombosis (~4%).[260] Mild hypothermia seems to disproportionately affect platelet inhibition by clopidogrel compared with other antiplatelet medications, and more stent thrombosis has been observed in patients treated with clopidogrel compared with ticagrelor.[261,262]

Infections may become more common when patients are cooled for 24 hours or longer.[214,263] Elevation in pancreatic enzymes has been reported in cooled patients, but these changes resolve with rewarming.[214]

Creatinine clearance and platelet count may fall during cooling, but both parameters normalize with rewarming.[214]

Hemodynamic Management

Myocardial function declines transiently after cardiac arrest.[264] Oxidative stress or other triggers can lead to myocyte damage after reperfusion.[265] Clinically, some vasoactive and/or inotropic drug support is necessary in most patients resuscitated from cardiac arrest, with expected hemodynamic recovery over the subsequent 24–48 hours.

During the first day after resuscitation from cardiac arrest, patients exhibit increased cerebral vascular resistance[266] and absent or right-shifted cerebral autoregulation, such that brain perfusion declines when mean arterial pressure (MAP) declines below 80–120 mm Hg.[267,268] When blood pressure is maintained, clinical positron emission tomography (PET) studies suggest that regional perfusion remains matched to metabolic activity after cardiac arrest,[269,270] yet microvascular dysfunction can still lead to regions of no-reflow. The brain is particularly sensitive to hypotension and may require a higher MAP than normal during the first hours to days after cardiac arrest. Periods of hypotension after circulation is restored add further secondary ischemic brain injury and are associated with death and poor neurologic recovery.[219,271] Higher MAP is associated with survival and better neurologic recovery.[272,273] Conversely, broad indiscriminate application of higher MAP targets may worsen vasogenic edema or oxidative injury in the subset of patients with intact autoregulation. Invasive monitoring of cerebral oxygenation and blood flow to titrate hemodynamic parameters to patient-specific optimal cerebral perfusion pressure is an active area of investigation.[204]

For most patients, relative hypertension (MAP of 80–100 mm Hg), if tolerated by the heart, should be considered using inotropes and/or pressors to prevent brain hypoperfusion. Hemodynamic management strategies are not well defined in most post–arrest care implementation studies,[274] and no specific choice of pressors has been demonstrated to be superior. Dopamine (5–20 μg/kg/min), norepinephrine (0.01–1 μg/kg/min), and/or epinephrine (0.01–1 μg/min) are all potential agents. Dopamine has the disadvantage of inducing tachydysrhythmias. Epinephrine has more positive inotropy than norepinephrine but can prolong lactic acidosis. Thus norepinephrine is a common first-line agent. Additional inotropic support (dobutamine 2–15 μg/kg/min; milrinone 50 μg/kg/min loading dose followed by 0.375–0.75 μg/kg/min infusion) may be necessary in cases of ongoing shock despite adequate MAP and hemoglobin (as assessed by severe hypokinesis, low venous oxygen saturation [SvO_2], oliguria, and/or failure to clear serum lactate). Ultimately, the choice and doses of these agents must be titrated to individual patients.

Mechanical circulatory support should be strongly considered for patients with persistent shock despite optimization of medical management. Historically, the intraaortic balloon pump was frequently used for hemodynamic support, but multicenter randomized trials have failed to demonstrate a mortality reduction in patients with STEMI and cardiogenic shock.[275] An alternative approach is utilization of a temporary left ventricular assist device that augments left ventricle-to-aorta blood flow via an axial pump.[276] It provides up to 3.5 L/min of blood flow when placed percutaneously and up to 5 L/min of blood flow when placed surgically.[277] Extracorporeal circulatory support with a venous-to-arterial circuit may be preferred in patients with ongoing cardiopulmonary resuscitation, right heart failure, or those without sufficient gas exchange. Ultimately, the means of mechanical support selected depends on the patient's hemodynamics, the expected hemodynamic impact of the device, the ease and rapidity of insertion, underlying comorbidities or contraindications, and the ultimate goals of support.

Oxygenation and Ventilation

Oxygenation must be balanced to avoid both cerebral hypoxemia and additional oxidative stress. Multiple observational studies note that post–cardiac arrest hyperoxia (partial pressure of oxygen [PaO_2] ≥300 mm Hg) is associated with higher inpatient mortality than normoxia.[278,279] These studies speculate that high oxygen concentration increases oxidative free radical damage. One multicenter cohort study found a linear, dose-dependent relationship between levels of oxygen tension and inpatient mortality but could not identify a single threshold for harm.[280] Few randomized data are available, and several large prospective randomized trials testing different oxygen titration strategies are in progress.[281] In the absence of evidence to support a specific FiO_2 goal for patients, it is reasonable to titrate fraction of inspired oxygen (FiO_2) to the lowest values sufficient to maintain a normal arterial oxyhemoglobin saturation (94%–98%).

Although cerebral autoregulation is frequently impaired, carbon dioxide (partial pressure of carbon dioxide [$PaCO_2$]) remains a major regulator of cerebral blood flow.[268] Observational studies note that both hypocapnia ($PaCO_2$ ≤30 mm Hg) and hypercapnia ($PaCO_2$ ≥50 mm Hg) are independently associated with poor neurologic outcome.[282] Few randomized data are available, and large prospective randomized trials are in progress.[281] In the absence of evidence to support a specific $PaCO_2$ goal for patients, extrapolating from traumatic brain injury suggests it is best to ventilate with a goal of normocarbia ($PaCO_2$ 35–45 mm Hg).

Glucose Control

Elevated serum glucose is common after cardiac arrest and is associated with poor outcome,[139,283] but hyperglycemia may simply be a marker of greater illness severity. Both epinephrine and physiologic stress can elevate serum glucose, and mild hypothermia may reduce insulin sensitivity.[284] However, multivariate models that account for resuscitation time and medication usage show an effect of serum glucose on admission and the first 48 hours of intensive care on long-term outcome.[5,285] Monitoring of glucose and treatment of hyperglycemia are reasonable.

Intensive glycemic control with a low target range (72–108 mg/dL, 4–6 mmol/L) has not proven beneficial outside of the surgical population where it was first studied[286] and may be harmful in medical intensive care.[287,288] After cardiac arrest, there was no difference in outcome when a moderate glucose range was targeted (108–144 mg/dL; 6–8 mmol/L) versus a strict lower range (72–108 mg/dL; 4–6 mmol/L).[289] However, the incidence of hypoglycemic events was higher in the strict versus moderate control group (18% vs. 2% of patients). Given the available data, treatment of glucose levels above 180 mg/dL (10 mmol/L) is reasonable.

Hematologic Changes

Cardiac arrest is associated with activation of coagulation that is not balanced by fibrinolysis and is perhaps related to ischemic injury to the endothelium. This hematologic profile is reminiscent of disseminated intravascular coagulation and may contribute to subsequent end-organ dysfunction via the no-reflow phenomenon.[290] Markers of thrombogenesis that have been reported include increased thrombin–antithrombin complexes and fibrinopeptide A.[290,291] These increases are not balanced by fibrinolytic factors for at least 24 hours.

At present, use of anticoagulation is variable, and there are no prospective trials evaluating the effect of empiric anticoagulation after resuscitation. Anticoagulation and even fibrinolytic drugs are safe after CPR.[169,292–294] A retrospective series noted a univariate relationship between anticoagulation and 6-month survival that was not significant in a multivariate model.[285] Given the hematologic evidence of active thrombogenesis, anticoagulation should be considered whenever there is a possibility of a thrombotic etiology.

Infection

Both ischemia-triggered systemic inflammatory responses and infections are common after cardiac arrest.[263] Pneumonia, bloodstream infections, and catheter-related infections are the most common infectious complications.[263,295] Pneumonia, especially, is associated with the duration of mechanical ventilation and length of ICU stay but does not appear to have an impact on mortality or neurologic outcome.[263,295,296] Bacteremia occurs in 39% of patients during the first 12 hours after resuscitation.[224] The accurate diagnosis of post–cardiac arrest infections is hampered by an associated increase in inflammatory markers[297,298] and body temperature control.

Observational studies suggest that antibiotic prophylaxis is not associated with a reduction in the incidence of pneumonia or improved clinical outcomes. Subsequent randomized trials of antibiotic prophylaxis compared with placebo in mechanically ventilated adults resuscitated from cardiac arrest found a lower incidence of early ventilator-associated pneumonia (VAP), but no statistical change in other intermediate outcomes or clinical outcomes.[299] Institutional VAP prevention bundles are appropriate, but the clinical value of prophylactic antibiotics does not appear to outweigh the associated costs and adverse effects.[299] Otherwise, selective treatment of identified infections is reasonable and appropriate.

Predicting Neurologic Recovery

The goal of clinical practice is always to restore the patient to full consciousness and function.[300] Nearly all patients with circulatory arrest of more than 1 or 2 minutes will be comatose at initial presentation, but some of these patients can recover and awaken. Therefore signs of neurologic activity immediately after restoration of circulation are encouraging, but their absence does not preclude eventual recovery. Unfortunately, many cardiac arrest survivors fail to completely awaken and may meet criteria for a persistent vegetative state.[301,302] The status of patients who do not quite meet these criteria but are not awake has been described as a minimally conscious state.[303] Less than 10% of patients who are hospitalized after cardiac arrest progress to formal brain death.[23]

Determining the neurologic prognosis of patients resuscitated from cardiac arrest has been the subject of multiple reviews and guideline statements[304–307] before and after the setting of modern ICU care. Some of the traditional findings associated with poor outcome[308–310] are no longer valid in the setting of modern ICU care and targeted temperature management. In fact, good survival has been reported after some situations previously believed to have universally poor outcomes such as post–cardiac arrest status myoclonus and seizures[311,312] or the absence of cortical responses on evoked potentials.[313] Neurologic recovery continues over a longer period than the 3 days recommended in historical publications.[304,305] Therefore longer periods of support and observation are appropriate for many patients. Furthermore, a multimodal approach that includes physical examination, imaging, and neurophysiologic studies is essential to determine prognosis.[311] No examination finding or test should be used in isolation to finalize neurologic prognosis. In a practical approach, the clinician can make an initial estimate of the probability of recovery based on clinical examination. As more information becomes available from clinical progression, imaging studies, and neurophysiologic studies, this estimate is revised in order to advise families and proxy decision makers. Daily reevaluations are required to decide if ongoing therapy is consistent with the patient's goals in light of the best estimate of the probability of various outcomes.

Baseline Probability of Recovery

In cohorts of patients admitted to a hospital after in-hospital and out-of-hospital cardiac arrest, approximately 31%–33% of patients recovered to a favorable functional status.[22,23] Although clinicians could start with an estimate that all patients have about 30% chance of good recovery, it is obvious that some patients have much greater illness severity than others at admission. The initial expectation of survival should be revised based on this fact. Various prognostic tools or scores can refine the estimated odds of recovery based on initial physiologic status or case features.[314,315] One simple score is the Pittsburgh Cardiac Arrest Category (PCAC) (Box 45.1). This score divides patients into four categories based on initial coma examination and degree of cardiopulmonary failure.[316] Probability of survival, good functional recovery, and risk of multiple organ failure vary by category. This particular score offers the advantages of being fast, easy to communicate, and validated in prospective cohorts.[317]

BOX 45.1 Post–Cardiac Arrest Category

The category of a patient can be assessed quickly on arrival to better stratify the initial probability of survival and risk of different complications. Precise research definitions of the categories use scoring systems assessed within 6 hours of return of pulses,[316] but clinical examination can usually sort patients into categories. Neurologic examination cannot be assessed if drugs or paralytics are confounding.

Category 1—Awake (Follows Commands)
80% chance of survival; 60% chance of good functional recovery
<5% chance of multiple organ failure

Category 2—Coma With Preserved Brainstem Reflexes*
60% chance of survival; 40% chance of good functional recovery
20% chance of multiple organ failure

Category 3—Coma With Preserved Brainstem Reflexes and Severe Cardiopulmonary Failure**
40% chance of survival; 20% chance of good functional recovery
40% chance of multiple organ failure

Category 4—Coma With Loss of Brainstem Reflexes
10% chance of survival; 7% chance of good functional recovery
35% chance of multiple organ failure

* Coma with preserved brainstem reflexes = FOUR score Motor + Brainstem scale ≥4; typically present with pupillary light reflex, corneal reflex, and some movement of extremities (at least posturing)
** Severe cardiopulmonary failure = SOFA score cardiac + respiratory subscales ≥4; typically more than one pressor drug, norepinephrine, or equivalent at rates >0.1 μg/kg/min and/or ventilator settings with PaO_2/FiO_2 ratio <100.

Clinical Examination

Pupillary reflexes, corneal reflexes, and motor activity can change over the first 72 hours after resuscitation and should not be used to definitively prognosticate during these initial 3 days.[310] The false-positive rate ([FPR] percentage where tests predict a poor outcome but patients have a good outcome) for absent pupillary light reflexes is much lower after 72 hours or more (FPR 0%–10%) compared with less than 72 hours (FPR 8%–52%). Likewise, absent corneal reflexes after 72 hours or more (FPR 0%–11%) are more informative compared with less than 72 hours (FPR 11%–75%).[27] Motor response less than flexion at 3 days has an FPR of 8%–14%.[27] The presence of myoclonus is less precise for predicting poor outcome (FPR 3%–12%) and must be distinguished from status myoclonus (persistent, repetitive myoclonus). Status myoclonus within 72 hours is associated with death or vegetative state (FPR 0%–3%).[27] Regardless of the clinical examination

finding in question, subjects with lower body temperature require longer periods of observation to clear potentially confounding factors introduced by sedation.[318]

Physiologic response to targeted temperature management provides another avenue for insight into the potential for neurologic recovery. The presence of shivering,[319] the amount of patient heat generation (derived from the inverse average water temperature of cooling devices),[320] and the presence of bradycardia (<60 beats/min)[321] during the induction and maintenance of temperature management are each associated with favorable neurologic outcome.

Imaging Studies

Imaging of the brain is important to exclude injury incurred at the time of collapse and to exclude intracranial causes of collapse. A noncontrast cranial CT scan to exclude hemorrhage is prudent in comatose patients after cardiac arrest and before anticoagulation or fibrinolytic therapy.[322,323] In general, noncontrast CT scan is insufficiently sensitive to determine prognosis after cardiac arrest unless severe changes are present, such as generalized edema that is often associated with loss of brainstem reflexes and may progress to herniation and brain death (Fig. 45.7). The amount of brain edema can be quantified with a ratio of attenuation (Hounsfield units) in select regions of gray matter and white matter. This "gray-to-white ratio" (GWR) is directly associated with survival and functional outcome.[324,325] Very low GWR values averaged throughout the brain within 6 hours after restoration of circulation are associated with poor outcome (FPR 0%–15%). Whether treatment of cerebral edema is worthwhile or futile has not yet been studied.

Magnetic resonance imaging (MRI) can visualize subtler changes in the brain after cardiac arrest via increased cortical signals on diffusion-weighted images (DWI) or apparent diffusion coefficient (ADC) maps.[326–328] For patients who remain comatose for several days and in whom clinical or electrophysiologic testing is indeterminate, MRI provides additional information about the extent of brain injury. Expectations and enthusiasm for long-term support may be reduced if extensive cortical lesions are present, whereas persistence may be justified if the anatomic extent of injury appears limited. An important caveat with the interpretation of all brain imaging after global ischemia is the differing clinical impact of lesions in different brain regions. The anatomic complexity of the brain precludes any simple quantitative relationship between the number or size of lesions and outcome. Isolated DWI abnormalities or low ADC values in single anatomic locations are not specific for poor neurologic outcome.[329] Furthermore, the existing literature about MRI is limited by indication bias: only a select subgroup of patients who are not improving clinically have this test, potentially inflating the prognostic significance of any findings. Long-term cognitive deficits are associated with global brain volume loss after cardiac arrest.[330] MRI should be used as an adjunct for assessing post–cardiac arrest brain damage in centers with neurologic or neuroradiologic expertise for interpreting these tests.

Neurophysiology

Electroencephalogram (EEG) patterns after resuscitation change over time.[331,332] The primary utility of an EEG is to diagnose seizures and exclude nonconvulsive seizures as an etiology of unresponsiveness. Seizures are diagnosed clinically in 5%–20% of comatose patients after cardiac arrest,[312] and the true incidence of nonconvulsive electrographic seizures may be higher. Termination of seizures, if possible, is essential to allow untainted assessment of the neurologic examination (Fig. 45.8). EEG abnormalities occur over a spectrum of severity (nothing epileptiform, nonperiodic epileptiform discharges, periodic discharges, and polyspike-wave discharges) directly associated with subsequent likelihood of poor outcome.[333] Generalized suppression (<20 μV), burst-suppression pattern associated with generalized epileptic activity, or diffuse periodic complexes on a flat background during the first week after resuscitation are associated with poor neurologic outcome.[308] Likewise, refractoriness of epileptiform patterns to antiepileptic therapy, as estimated by the number of antiepileptic drugs administered, also portends worse outcomes.[333] The presence of malignant EEG patterns provides information that is additive with clinical evaluation.[334] Thus EEG should not be used by itself to determine prognosis, but the information provided by EEG can exclude confounders (seizures) and be integrated into the total clinical picture used to assess prognosis.

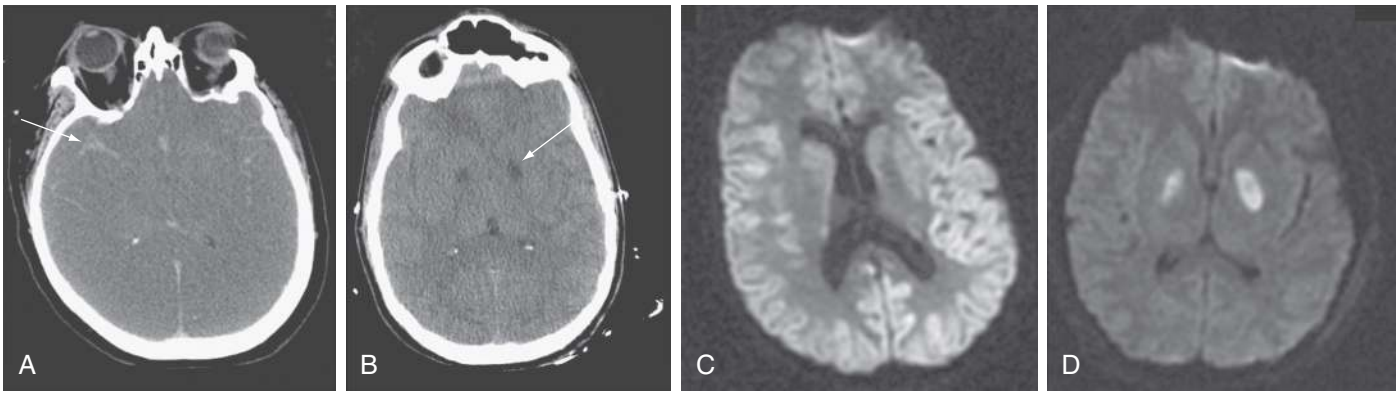

Fig. 45.7 Imaging of the brain after cardiac arrest. **A,** Severe cerebral ischemia appears as sulcal effacement, with loss of contrast between gray matter and white matter. Congestion of blood in meninges (pseudosubarachnoid hemorrhage *[arrow]*) sometimes is evident. This pattern on early computed tomography (CT) scan often progresses to herniation and brain death. **B,** Less severe early changes show edema (hypodensity) restricted to the basal ganglia *(arrow)*, with sparing of the cortex. **C,** Increased magnetic resonance imaging (MRI) signal from extensive areas of cortex on diffusion-weighted images (DWI) of this patient correspond to devastating brain injury with persistent coma. This patient showed no improvement in coma. **D,** DWI for same patient in **B** illustrates high-intensity signal from damaged subcortical areas. In this case, the cortex and other structures are normal. After 5 days of coma, this patient awoke, completed rehabilitation, and recovered completely.

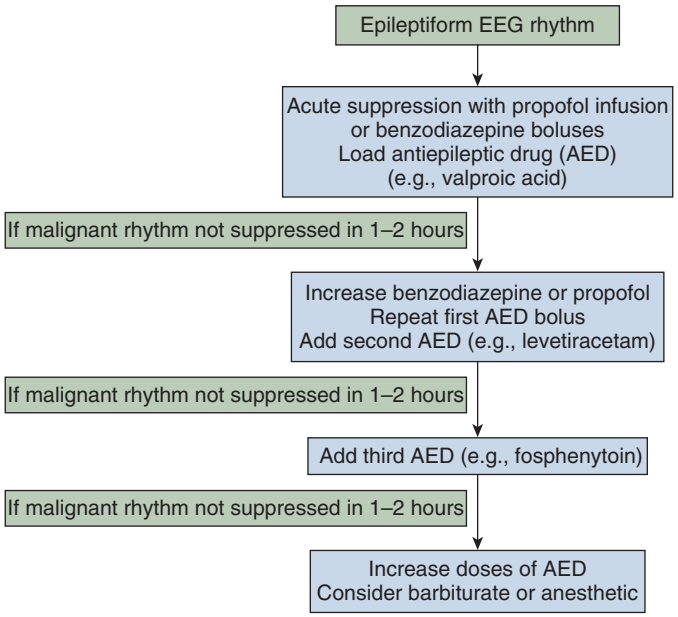

Fig. 45.8 Electroencephalogram (*EEG*) and antiepileptic drug (*AED*) management after resuscitation.

Electrophysiologic response to stimuli can also be used to assess whether cortical regions are intact. Recovery of longer latency event-related potentials are associated with awakening.[335–337] Conversely, absence of short latency (N20) cortical response to somatosensory evoked potentials (SSEPs) is very specific for poor neurologic outcome (FPR 0%; 95% confidence interval [CI], 0%–2%).[305–307] Like EEG, SSEP responses vary with the elapsed time since resuscitation.[331] Recent data suggest that the use of therapeutic hypothermia may increase the time-dependent changes in SSEP. One case series reported two patients treated with hypothermia who had absent N20 responses at 3 days after cardiac arrest but recovered cognition.[312] Therefore it may be reasonable to repeat SSEPs that show absent N20s several days apart in order to avoid false-negative tests.

Blood Markers

Several peptides appear in the blood after brain injury, including neuron-specific enolase (NSE) and the glia-derived protein S-100B. After cardiac arrest, NSE reaches a maximum level in serum at 72 hours. High NSE levels at 48–72 hours or NSE levels that continue to rise over the first 72 hours after resuscitation are associated with poor outcome.[337–339] In contrast to NSE, peak levels of S-100B in serum occur during the first 24 hours after resuscitation, and higher S-100B levels are associated with poor neurologic outcome.[338,340] Hypothermia treatment appears to alter serum NSE levels.[341] Use of NSE or S-100B to determine prognosis is limited by the absence of a clear cutoff value that is unsurvivable and the lack of a universal standard for laboratory assays. NSE can also be released by injury from nonbrain organs.[342] These neuronal markers may be considered a tool for following brain injury longitudinally, analogous to troponin levels for following myocardial injury. Additional biomarkers under investigation include glial fibrillary acidic protein, serum tau protein, and serum neurofilament light chain.

In summary, the determination of neurologic prognosis after cardiac arrest varies from patient to patient. Changes in clinical examination are the cornerstone of prognostication. While the patient is recovering, hypothermia and supportive care may increase the likelihood of recovery. However, electrophysiologic and imaging techniques add further useful information to help guide clinicians and families. The approximate timing for each of these studies is depicted in Fig. 45.9. Prognostication guidelines from the European Resuscitation Council and European Society of Intensive Care Medicine[343] emphasize the bilateral absence of pupillary and corneal reflexes or N20 wave of

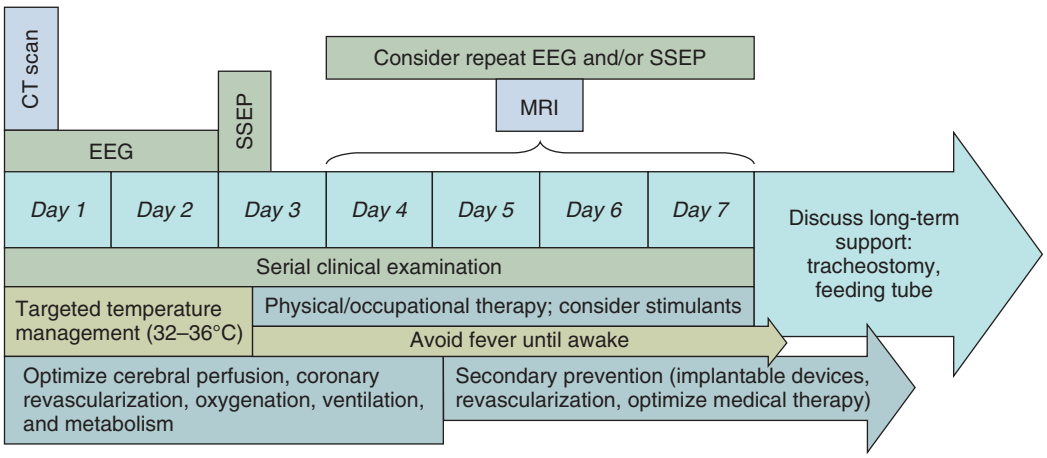

Fig. 45.9 Rational approach to neurologic treatment, monitoring, and testing after cardiac arrest. For patients remaining in a coma, hypothermia treatment followed by therapy and stimulation may improve recovery. Early electroencephalogram (*EEG*) monitoring is recommended to allow detection and treatment of seizures and to supplement estimations of prognosis. Absence of cortical response on somatosensory evoked potential (*SSEP*) or malignant EEG patterns after hypothermia treatment help identify subsets of patients unlikely to ever show improvement. When those tests are indeterminate and there is no sign of clinical improvement, magnetic resonance imaging (*MRI*) of the brain helps quantify the extent and location of injury, which in turn assists in decisions about continuing long-term support in light of patient and surrogate wishes. Most tests are not required when patients exhibit clear clinical improvement. Conversely, patients who progress to brain death should undergo formal brain death testing once sedative confounders, metabolic abnormalities, and shock have been corrected.

SSEPs as the most robust predictors of poor outcome irrespective of body temperature. Early myoclonus, elevated values of NSE at 48–72 hours from cardiac arrest, unreactive malignant EEG patterns after rewarming, and diffuse signs of anoxic injury on CT or MRI are useful but less robust predictors. Prolonged observation should be considered when the results of these initial assessments are inconclusive.

REHABILITATION

The role of rehabilitation or other therapy in recovery from neurologic impairment after cardiac arrest is an active area of investigation. It is clear that both patients and their caregivers have complex needs if neurologic injury is severe.[344] Rehabilitation after global brain ischemia can produce similar improvements to those after traumatic brain injury.[345,346] Early utilization of basic rehabilitative services, including physical therapy and occupational therapy, may help promote recovery, just as in acute stroke.[347] When arousal or level of consciousness is impaired after traumatic brain injury, stimulants such as methylphenidate or amantadine have been employed with reduction in total ICU stay or improved final status.[348,349] Although these data are few and indirect, addition of stimulants for post–cardiac arrest patients who linger in intermediate coma might be considered, if medically tolerated.[350] Functional and cognitive recovery in survivors who were initially comatose occurs over at least 6 months.[122] Global measures of outcome such as cerebral performance category (CPC) and modified Rankin scale (mRS) do not fully characterize the nuanced patterns of disability, which tend to center around memory, attention, executive function, mood, fatigue, and participation.[351,352]

WITHDRAWAL OF LIFE-SUSTAINING TREATMENT

For adults who are neurologically devastated after cardiac arrest in North America, it is more common to die in a hospital than to receive long-term care. An estimated 44% of patients who are initially resuscitated from cardiac arrest in a hospital have withdrawal of care later in their hospitalization.[14] For patients resuscitated from out-of-hospital cardiac arrest, 61% die after withdrawal of life-sustaining treatments because of predicted neurologic prognosis.[23] Because these decisions are often based on the neurologic prognosis of the patient, withdrawal of life-sustaining treatment limits the number of neurologically impaired individuals who are discharged from the hospital. Consequently, quality of life for those patients who do leave the hospital is generally high.[21,353,354] Popular reports of awakening after long coma may cause inappropriate optimism for families of patients or surrogate decision makers. Partial awakening of patients into a persistent vegetative state or minimally conscious state can further confuse their expectations. Decision makers should receive information about these syndromes, realistic expectations of recovery, and any specific considerations for the individual patient. Religious, cultural, and personal beliefs will contribute to decisions, and appropriate social service and pastoral support should be provided. Finally, for patients who survive cardiac arrest but who later progress to death or brain death, it is reasonable to evaluate their candidacy to become organ donors: outcomes for transplanted organs from this population are comparable to all other donors.[355]

SUMMARY

Improvement in outcome after cardiac arrest will require attention both to the reversal of cardiopulmonary arrest and to restoration of consciousness. Isolated attention to only the heart or only the brain is unlikely to improve outcomes for many patients. Appropriate prioritization of the various tools for cardiac resuscitation, along with emphasis on the basic mechanics of artificial circulation, may increase the number of individuals reaching the ICU. Induction of mild hypothermia, correction of hemodynamic and metabolic perturbations, along with proper treatment of the root cause of the cardiac arrest may increase the number of initially comatose patients who awaken. Constant reassessment of the likelihood of meaningful recovery, based on clinical examination and ancillary testing, can guarantee that continued care and interventions are appropriate.

KEY POINTS

- Improvement in outcome after cardiac arrest requires attention both to immediate reversal of cardiopulmonary arrest and promoting recovery of brain function through subsequent ICU interventions. Isolated attention to only the heart or only the brain is unlikely to improve outcomes for many patients (see Fig. 45.8).
- Increased emphasis on the basic mechanics of artificial circulation, specifically uninterrupted vigorous chest compressions, may increase the number of individuals reaching the ICU.
- It is necessary to prioritize the various adjunct tools for cardiac resuscitation. For example, time devoted to tracheal intubation may delay drug therapy and interrupt chest compressions without altering overall hemodynamics.
- The cornerstone of drug therapy during resuscitation attempts is the selective administration of vasoactive drugs that will increase CPP developed by chest compressions. Rote, repeated administration is unlikely to result in favorable neurologic outcome.
- Induction of targeted temperature management, correction of hemodynamic and metabolic perturbations, and proper treatment of the root cause of the cardiac arrest may increase the number of initially comatose patients who awaken.
- Neurologic prognosis is determined using serial clinical examinations supplemented by neurophysiologic or imaging tests. Clinical examination continues to change for many days after cardiac arrest, and even longer periods of observation are required for patients with lower body temperature. Constant reassessment of the likelihood of meaningful recovery can guarantee that continued care and interventions are appropriate.

Christenson J, Andrusiek D, Everson-Stewart S, et al., Resuscitation Outcomes Consortium Investigators. Chest compression fraction determines survival in patients with out-of-hospital ventricular fibrillation. *Circulation*. 2009;120:1241–1247.
This study monitored the performance of chest compressions in out-of-hospital VF. There is a strong association between survival and the proportion of time when chest compressions are performed (chest-compression fraction).

Granfeldt A, Avis SR, Nicholson TC, et al. Advanced airway management during adult cardiac arrest: a systematic review. *Resuscitation*. 2019;139:133–143.
This systematic article synthesizes the randomized and observational data on advanced airway management during adult cardiac arrest. Notably, three randomized trials conducted in different EMS systems with a range of intubation success have compared advanced airway strategies (tracheal intubation or supraglottic airway) with each other and to bag-mask ventilation. In settings with lower tracheal intubation success rates, supraglottic airway insertion improved short-term survival and neurologic outcomes. In settings with higher tracheal intubation success rates, advanced airway management did not improve survival or neurologic outcomes compared with bag-mask ventilation. The rationale for transitioning from a basic to advanced airway strategy is highly dependent on the clinical context, including patient anatomy, aspiration risk, and oxygenation and ventilation success. If an advanced airway strategy is used, clinicians should choose an advanced airway strategy based on their particular skill set.

Lemkes JS, Janssens GN, van der Hoeven NW, et al. Coronary angiography after cardiac arrest without ST-segment elevation. *N Engl J Med.* 2019;380:1397–1407.
This trial randomized 552 patients without STEMI resuscitated after out-of-hospital cardiac arrest from a shockable rhythm to a strategy of immediate or delayed invasive coronary angiography. Patients with ongoing shock were excluded. Most patients had stable coronary artery disease and comparatively few had unstable lesions or acute thrombotic occlusion. Some patients randomized to delayed coronary angiography crossed over after subsequently manifesting cardiac deterioration. The trial was statistically neutral for survival or neurologic recovery at 90 days, suggesting that hemodynamically and electrically stable patients without STEMI may tolerate a delay in coronary angiography to optimize critical care and estimate neurologic recovery.

Nielsen N, Wetterslev J, Cronberg T, et al. Targeted temperature management at 33°C versus 36°C after cardiac arrest. *N Engl J Med.* 2013;369:2197–2206.
This trial in patients with out-of-hospital cardiac arrest detected no difference in short- or long-term outcomes between two temperature management regimens: 33°C versus 36°C for 24 hours. The outcomes for both groups were similar to the intervention groups in prior trials and much better than the outcomes in prior control groups that had no temperature management, supporting the use of active temperature management, even at a higher temperature of 36°C.

Perkins GD, Ji C, Deakin CD, et al. A randomized trial of epinephrine in out-of-hospital cardiac arrest. *N Engl J Med.* 2018;379:711–721.
This trial randomized 8103 patients with out-of-hospital cardiac arrest to receive 1 mg epinephrine or placebo every 3–5 minutes. Epinephrine improved the rate of restoration of circulation, survival to hospital admission, survival to hospital discharge, and 3-month survival. The net increase in survivors constituted additional patients with both favorable and unfavorable neurologic outcomes without clear evidence of long-term benefit or harm.

Sandroni C, Cariou A, Cavallaro F, et al. Prognostication in comatose survivors of cardiac arrest: an advisory statement from the European Resuscitation Council and the European Society of Intensive Care Medicine. *Resuscitation.* 2014;85:1779–1789.
This detailed review of data on prognostic testing to predict favorable recovery after cardiac arrest is synthesized into recommendations for specific testing to evaluate patients.

Sunde K, Pytte M, Jacobsen D, et al. Implementation of a standardised treatment protocol for postresuscitation care after out-of-hospital cardiac arrest. *Resuscitation.* 2007;73:29–39.
This report described the implementation of multiple changes in a system of care, from ambulance destination to implementation of specific goals in the ICU. This system-wide change resulted in significant improvements in long-term survival.

Management of Acute Ischemic Stroke

Ashutosh P. Jadhav and Lawrence R. Wechsler

Stroke is currently recognized as the fifth most common cause of death and the leading cause of permanent disability in the United States, affecting nearly 795,000 people annually.[1] Acute ischemic stroke is a true medical emergency and must be treated with a swift yet pragmatic approach. The rationale for acute ischemic stroke treatment is based on the concept of the *ischemic penumbra*. When arterial occlusion occurs, an area of irreversibly infarcted brain (i.e., core infarct) is surrounded by a region that has reduced blood flow that impairs function (i.e., ischemic penumbra), although not of sufficient severity to result in irreversible infarction. If adequate blood flow can be restored within a critical time frame, this area of at-risk tissue may be salvageable and return to normal function. The relationship between blood flow levels and duration for human stroke is still being elucidated, but based on laboratory studies, the more quickly restoration of blood flow occurs, the greater the probability that the salvageable tissue will be spared from permanent damage.[2,3]

In 1995 the National Institute of Neurological Disorders and Stroke (NINDS) rt-PA Stroke Study Group showed for the first time an improvement in ischemic stroke outcome with acute treatment.[4] At present, intravenous tissue plasminogen activator (tPA) is the only treatment that has been approved by the Food and Drug Administration (FDA) for acute ischemic stroke patients presenting within 3 hours of symptom onset. Intraarterial therapy with stent retriever thrombectomy should be considered in patients presenting with acute ischemic stroke within 24 hours of symptom onset.[5,6] Other treatments for acute ischemic stroke, such as neuroprotective agents and cell replacement therapy, continue to be investigated.

EMERGENT STROKE EVALUATION

For patients in the field who develop symptoms concerning for acute ischemic stroke, once emergency medical services (EMS) are activated, a rapid neurologic assessment is performed using one of several prehospital stroke scales. These quick screening tools allow uniformity in assessing stroke deficits that clarify communication of the patient's status to the receiving emergency department. It is helpful if prehospital personnel are able to firmly establish with family or bystanders who witnessed the patient's symptom onset the precise time at which the patient last appeared normal. Upon arrival, or more ideally, before arrival at the emergency department, a "brain attack code" or "stroke code" is disseminated to members of the stroke team.

A stroke team typically consists of individuals from multiple disciplines with specialized knowledge and interest in acute stroke care and often includes a vascular neurologist, nursing coordinator, and where available, a neurointerventionalist. A neurologist performs a National Institutes of Health Stroke Scale (NIHSS) (Table 46.1) assessment as an additional rapid neurologic assessment tool to better localize and ascertain the degree of clinical deficit, as the score may affect which therapies are available to the patient. For patients developing focal neurologic symptoms while already hospitalized in an intensive care unit (ICU) or other hospital floor, the algorithm should be identical.

Ischemic strokes generally are classified as large artery atherosclerosis, small vessel occlusion, cardioembolism, stroke of other determined etiology, or stroke of undetermined etiology.[7] In the first few minutes to hours after ischemic stroke, identification of stroke mechanisms may be difficult or impossible. Emergent diagnosis is greatly enhanced by imaging modalities and should include both parenchymal and vessel imaging, such as computed tomography (CT) and magnetic resonance imaging (MRI)[8] with angiography.

IMAGING OF ACUTE STROKE

Differentiating ischemic from hemorrhagic stroke is necessary before deciding on thrombolytic administration, and imaging obviously plays a key role in this regard. However, imaging may provide much more information. At most stroke centers, time from symptom onset (i.e., time when patient was last confirmed to be seen at normal baseline) is a major determining factor in whether a patient is a candidate for intravenous thrombolysis (up to 3 hours) or intraarterial therapy (up to 24 hours). An emerging concept is that physiology rather than time should be used to decide on treatment eligibility.[9] For example, some patients within the 3-hour time window may already have established infarction that would not reverse with thrombolysis and may result in hemorrhage owing to reperfusion of infarcted brain. Conversely, some patients may have salvageable brain tissue despite presentation well after the 3-hour time window.[10,11] A physiologic estimate of tissue viability would be preferable to a fixed time interval if a study were found that reliably predicted viability of brain after stroke. CT and MRI have the potential to provide this measurement.[12]

Computed Tomography

A noncontrast head CT is the initial imaging modality of choice for patients with suspected stroke. The foremost reason is that CT scans can be readily and quickly obtained because of the widespread availability of CT scanners; the second reason is the ability of CT to exclude intracranial hemorrhage. In addition to differentiating ischemic stroke from hemorrhage, CT may demonstrate subtle parenchymal abnormalities indicative of early edema or infarction. Previously, it was believed that these changes did not occur on CT for at least 6 hours after ischemic stroke. More recent studies indicate, however, that early changes of ischemia frequently occur within a few hours of stroke onset and have been seen as soon as 1 hour after stroke.[13] These changes include reduced attenuation in the basal ganglia[2]; loss of gray-white differentiation, particularly in the insular region[14]; low density in the cortex and subcortical white matter; and loss of sulcal markings, suggesting early mass effect and edema (Fig. 46.1A and B).[15]

TABLE 46.1 National Institutes of Health Stroke Scale

1A. Level of Consciousness (LOC)	1B. LOC Questions	1C. LOC Commands
0 = Alert 1 = Not alert, but arousable 2 = Not alert, obtunded 3 = Coma	Ask the month and his or her age. 0 = Answers both correctly 1 = Answers one correctly 2 = Answers neither correctly	Open and close the eyes. Fig. 46.1 A, Normal computed tomography (CT) scan of brain 2 hours after onset of aphasia and left hemiparesis. **B,** Repeat CT scan at 5 hours after stroke onset shows early CT changes, including basal ganglia hypodensity, loss of the insular ribbon, and slight effacement of the sulci on the left. **C,** CT angiogram at 5 hours after stroke onset shows complete occlusion of the left middle cerebral artery (MCA). **D,** Rapid reconstruction of the CT angiogram again shows occlusion of the left MCA.

A hyperdense middle cerebral artery (MCA) occurs in 20%–37% of cases,[16] indicating acute thrombus within the artery. This condition rarely occurs without at least one other early CT abnormality. Hyperdensity in the basilar artery associated with thrombosis also has been reported.[17] In 100 patients studied within 14 hours (mean 6.4 hours) of stroke onset, multiple early CT abnormalities correlated with the size of the subsequent infarct and poor outcome.[16] In the ECASS I trial of tPA for acute stroke, early CT changes correlated with larger subsequent infarct volume and a greater likelihood of hemorrhagic conversion after tPA.[18] Quantitative assessment of CT changes using the

Alberta Stroke Program Early CT Score (ASPECTS) scale in patients treated with intravenous tPA also showed a relationship between early CT hypodensity (ASPECTS <8) and hemorrhage.[19,20] Thus some experts recommend withholding thrombolytic therapy in patients with extensive early CT changes, particularly in those later in the thrombolytic time window,[21] although this practice is controversial. For example, subsequent analysis of the NINDS rt-PA trial data revealed that early ischemic changes did not predict symptomatic hemorrhage or response to treatment,[22] and more recent evidence reports no association between early ischemic CT changes and outcome.[23]

Computed Tomography Angiography

CT angiography (CTA) can be performed using spiral CT, allowing for imaging of the intracranial and extracranial circulation. Optimally, CTA of the neck should also include visualization of the aortic arch. The typical single bolus of iodine contrast material is about 70 cc. This injection limits the use of CTA in patients with renal failure or contrast hypersensitivity. In acute stroke, CTA of the head and neck is highly reliable for diagnosis of intracranial occlusions and correlates with other imaging modalities.[24,25] Three-dimensional reconstruction images can also be created, providing additional views and information about the carotid bifurcation and carotid lesions, revealing eccentric lesions and ulceration (see Fig. 46.1C and D).

Computed Tomography Perfusion

In addition to imaging the brain parenchyma with a noncontrast head CT and the cerebral vasculature with CTA, CT perfusion (CTP) adds assessment of cerebral blood volume (CBV) and cerebral blood flow (CBF) (Fig. 46.2). In patients with acute stroke, CTP has been correlated with final infarct size and outcome, particularly after recanalization.[26] CTP maps combining CBV and CBF identify brain tissue that progresses to infarction if not reperfused, consistent with ischemic penumbra.[27] Recent evidence suggests that the inclusion of CTP in a stroke imaging protocol increases diagnostic performance.[26,28,29]

Whereas CTP serves as a qualitative measure of CBF, there have been investigations into using xenon CT to measure CBF quantitatively.[30] Stable xenon is an inert gas inhaled as a mixture of 27% xenon and 73% oxygen. During inhalation over a few minutes, rapid scanning is performed, and pixel-by-pixel blood flow values are calculated at different brain levels (Fig. 46.3). In a series of patients with MCA occlusion studied with xenon CT, areas of penumbra were present in all patients, and the percentage of MCA territory in the penumbral range (CBF 8–20 mL/100 g/min) remained relatively constant across the group. In contrast, the percentage of MCA territory with CBF values representing infarcted tissue (CBF <8 mL/100 g/min) varied greatly. Outcome correlated highly with the area of infarcted MCA territory, not the amount of ischemic penumbra. Thus after the first few hours, the size of the core infarcted tissue, not the amount of penumbral tissue, may be the most important imaging parameter to determine suitability for acute stroke therapy.[31]

Magnetic Resonance Imaging

Compared with CT modalities, MRI is advantageous because it is more sensitive to cerebral infarction, especially in the brainstem and deep white matter. Typical sequences included in an MRI stroke protocol include diffusion-weighted imaging (DWI) and apparent diffusion coefficient (ADC) to evaluate for potential acute ischemia, multiplanar gradient-recalled (MPGR) or gradient-recalled echo (GRE) to evaluate for hemorrhage, and fluid-attenuated inversion recovery (FLAIR) to evaluate for important signs in both hyperacute and acute stages of stroke (i.e., assessment for absence of flow void in major cerebral arteries, suggesting occlusion or slow flow in that artery). Perfusion-weighted imaging (PWI) is often used to determine abnormal tissue perfusion based on transit times for contrast material through brain parenchyma (Fig. 46.4).

DWI shows parenchymal abnormalities earlier than conventional T2-weighted images in patients with acute stroke.[32] It detects the diffusion of water in the brain and shows hyperintensity in areas of reduced diffusion (see Fig. 46.4). As water moves from the extracellular to the intracellular space, there is less movement of water and loss of signal, resulting in hyperintensity.[33] Early detection of lesions by DWI helps differentiate cerebral ischemia from other conditions that mimic stroke, such as seizures or toxic-metabolic states. Additionally, combining DWI with PWI may identify reversibly ischemic tissue. If there is a large area of PWI abnormality indicating reduced CBF but limited established infarction, as evidenced by DWI abnormality, penumbral tissue is likely present, indicating areas at risk of undergoing infarction.

In stroke patients, the size of the DWI lesion and the growth of these abnormal DWI regions are strong predictors of outcome. In acute stroke, a marker of tissue viability is needed, and some investigators have suggested that the extent of mismatch between lesions on DWI and PWI could serve as this marker. The concept of DWI/PWI

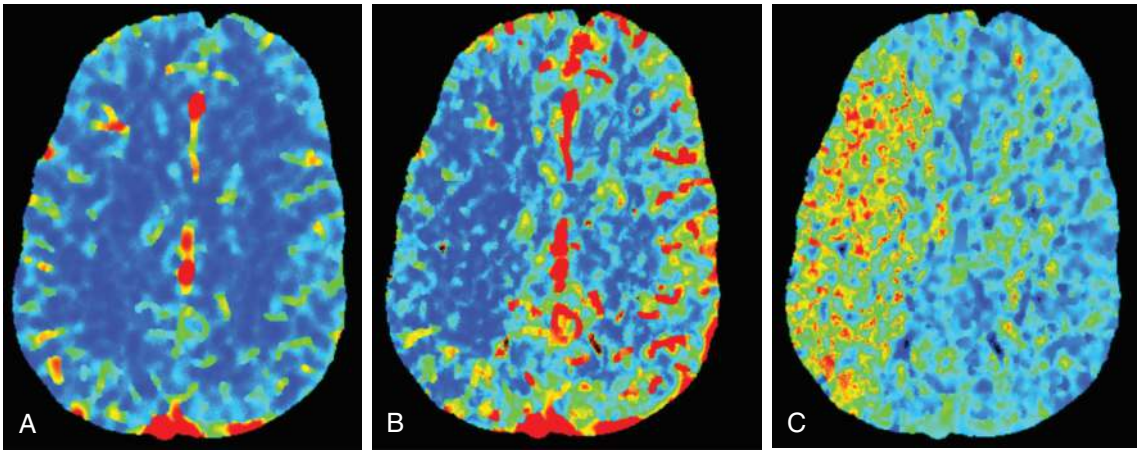

Fig. 46.2 Computed Tomography Brain Perfusion Scan with Sequencing Maps. **A,** Cerebral blood volume (CBV) showing no clear evidence of core infarct. **B,** Cerebral blood flow (CBF) showing a decrease in the right middle cerebral artery (MCA) territory. **C,** Mean transit time (MTT) showing delayed perfusion in the right MCA territory. These sequences together indicate a large ischemic penumbra in the right MCA territory.

These sequences together suggest a large ischemic penumbra in the right middle cerebral artery (MCA) territory.

mismatch has been used as an inclusion criterion in several studies (DIAS, DIAS-2, among others) assessing thrombolytic agents and is being employed more frequently to select patients who may benefit from reperfusion therapy.[34–41] Patients[11] with mismatch might be more likely to respond to reperfusion therapy.[42] Patients with large areas of DWI abnormality or large severe PWI abnormalities may be at greater risk for hemorrhage if reperfusion therapy is pursued.[10,43]

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) of the head and neck offers a noninvasive method of imaging the intracranial and extracranial vasculature. MRA typically uses gadolinium contrast in appropriate patients, but important information can be obtained based on time-of-flight techniques not using contrast.[44,45] Detection of dissection or occlusion in the circle of Willis and the extracranial vertebral and carotid arteries can be examined with MRA, but occlusions of small peripheral branch arteries may not be detected. Artifacts may also obscure proper identification of arterial pathology. Signal dropout may occur at the site of arterial stenosis owing to the effects of turbulent flow. If an artery is tortuous, it may extend out of the imaging section and appear occluded. MRI tends to overestimate the severity of stenosis, and evidence of severe stenosis should be confirmed with another modality. MRA is better for localizing the site of stenotic lesions than determining severity of stenosis. Similarly, differentiation between severe stenosis and occlusion is unreliable with MRI, and apparent occlusions by MRA should also be confirmed with angiography.

Digital Subtraction Angiography

Catheter-based digital subtraction angiography (DSA) remains the gold standard for determining the degree of vessel stenosis and understanding

the collateral circulation. The high quality of anatomic delineation allows for precise determination of carotid stenosis as with CTA, whereas MRA and carotid Dopplers can misclassify stenosis. Historically, the procedure has been associated with a high risk of complications, although more modern experience estimates a much lower risk of stroke (0.3%) at experienced centers.[46,47] The technique requires specialized personnel and equipment and may not be readily available at all centers.

TREATMENT OF ACUTE STROKE

Intravenous Thrombolysis

Acute stroke trials using intravenous thrombolytic agents date back to the early 1960s, with the use of streptokinase,[48] fibrinolysin,[49] and urokinase[50] showing either no benefit or a higher mortality in patients treated with thrombolysis. These studies preceded CT imaging, and thus patients with hemorrhage were not excluded. The discouraging results hindered the development of more acute stroke trials until the 1980s, when several case reports showed favorable outcomes with intraarterial thrombolytic therapy within a few hours of stroke onset.[51,52] These reports resulted in small randomized trials and feasibility studies of intravenous thrombolytics[53,54] that ultimately gave rise to the pivotal NINDS rt-PA trial that showed a beneficial effect of thrombolytic therapy for acute stroke treatment when administered within 3 hours of symptom onset.[4]

Tissue Plasminogen Activator Within 3 Hours

The NINDS trial included more than 600 patients with acute ischemic stroke. All patients were treated within 3 hours, and half of the patients were treated within 90 minutes. Patients were randomly assigned to receive either intravenous tPA at a dose of 0.9 mg/kg to a maximum of 90 mg or intravenous placebo. Primary outcome measures were favorable outcomes at 90 days measured by the NIHSS, Barthel Index, Glasgow Outcome Scale, and modified Rankin Scale (mRS). By all four measures, significantly more patients had a favorable outcome at 90 days in the tPA group compared with placebo. Treatment with tPA resulted in an 11%–13% absolute increase in good outcomes and a minor, nonsignificant decrease in mortality at 3 months. The benefit was sustained at 12 months.[55] Intracerebral hemorrhage with clinical deterioration occurred in 6.4% of patients treated with tPA versus only 0.6% of placebo patients. Despite the increased hemorrhage rate, there was no significant increase in mortality or severe disability in the tPA group versus placebo. All subtypes of strokes had more favorable outcomes with tPA. There were no clear factors that predicted response to tPA.[56] Patients with large strokes as measured by NIHSS score >20 and evidence of early low density or edema on CT had a higher rate of hemorrhage after tPA.[57]

Based on these results, the FDA approved intravenous tPA for treatment of stroke within 3 hours of onset in June 1996. This result was supported by the results of an analysis of patients treated within 3 hours of onset in the ATLANTIS trial.[58] A subsequent pooled analysis of NINDS rt-PA, ECASS, and ATLANTIS data showed that clinical benefit with tPA is greatest when given early, especially if started within 90 minutes (Table 46.2).[59] Not all patients recanalize with intravenous tPA. In a dose escalation trial of intravenous tPA, angiography was performed before thrombolysis in all patients documenting the site of arterial occlusion and was repeated 2 hours later. Proximal occlusions in the MCA opened less frequently than distal branch occlusions, and only 8% of carotid occlusions recanalized.[60]

Given the importance of early drug administration, much attention has been placed on improving systems of care to deliver the drug early and often. The use of telemedicine has played a great and expanding role in allowing patients presenting to stroke-ready hospitals without in-house vascular neurology expertise to receive remote clinical examination and imaging review via video streaming. Within our stroke network at the University of Pittsburgh, the implementation of telemedicine at 12 neighboring hospitals increased the use of intravenous thrombolysis from 2.8% to 6.8%, with a lower incidence of symptomatic hemorrhage.[61] Similar experiences have been reported across the country. Emphasis has also been placed on minimizing additional tests (i.e., coagulation profile or platelet count) in selected patients and prioritizing imaging and early stroke team activation. Campaigns to improve times have driven door-to-needle times down to 22 minutes at some centers.

TABLE 46.2 Odds Ratios for Modified Rankin Score 0–1 in the Combined tPA Analysis

Time	N	Odds Ratio	95% CI
0–90	311	2.83	1.77, 4.53
91–180	618	1.53	1.11, 2.11
181–270	801	1.40	1.06, 1.85

Tissue Plasminogen Activator Beyond 3 Hours

Several subsequent tPA trials attempted to extend the window for treatment beyond 3 hours. The ECASS I and II trials and the ATLANTIS trial treated patients with intravenous tPA up to 6 hours after stroke onset but failed to show benefit versus placebo.[62–64] Pooled analysis of NINDS rt-PA, ECASS, and ATLANTIS data suggested a potential benefit beyond 3 hours. The ECASS III trial recently revealed that intravenous alteplase administered between 3 and 4.5 hours after symptom onset significantly improved clinical outcomes in patients with acute ischemic stroke, thereby potentially extending the therapeutic window in which patients may receive intravenous tPA. In addition to standard intravenous tPA exclusion criteria (Table 46.3), ECASS III exclusion criteria include the combination of previous stroke and diabetes, an NIHSS score >25, oral anticoagulant treatment, or age >80 years.[65] Whether patients in this time window with these exclusions also benefit from intravenous tPA is unknown.

IST-3 is a clinical trial that randomized 3035 patients with ischemic stroke within 6 hours of symptom onset to intravenous alteplase (0.9 mg/kg; $n = 1515$) plus standard care or standard care alone (control; $n = 1520$). Although the primary endpoint of good outcome was no different between groups, the study did show improved outcomes in patients presenting within early time windows and enrolled a high percentage of elderly patients (age >80), thus establishing the efficacy of intravenous tissue plasminogen activator (IV tPA) in this population. Several ongoing trials are investigating a role for IV tPA in patients presenting at late time windows with favorable imaging profiles (i.e., small core and large penumbra or DWI/FLAIR mismatch).

Mild and Rapidly Improving Symptoms

Whereas the original NINDS study considered mild or rapidly improving symptoms as a relative contraindication for IV thrombolysis, subsequent retrospective analysis of this population has revealed poor

TABLE 46.3 ASPECTS Measurement Tool for Early Changes on Computed Tomography

outcomes, with up to 30%–40% of patients requiring inpatient rehabilitation at discharge and a subset suffering further neurologic decline. Although the natural history in this population may not be as benign as previously perceived, the benefit of intravenous thrombolysis remains to be proven. A review of patients within the SPOTRIAS database revealed practice variation across centers with a range of 2.7%–18% of mild stroke patients receiving IV tPA. Furthermore, the proportion of patients with mild NIHSS increased from 4.8% in 2005 to 10.7% in 2009 ($P = .001$). The PRISMS trial did not demonstrate any additional of alteplase versus aspirin in patients with acute onset of nondisabling mild symptoms.

Tenecteplase

Tenecteplase is a modified form of human tPA designed to achieve more effective thrombolysis. The half-life of tenecteplase is longer, allowing administration as a single bolus. Tenecteplase has greater fibrin specificity and less fibrinogen depletion than tPA.[66] A phase IIb study randomly assigned 75 patients to receive alteplase (0.9 mg per kilogram of body weight) or tenecteplase (0.1 mg per kilogram or 0.25 mg per kilogram) less than 6 hours after the onset of ischemic stroke. The two tenecteplase groups had greater reperfusion ($P = .004$) and clinical improvement ($P < .001$) at 24 hours than the alteplase group, with no differences in intracranial bleeding or serious adverse events. The higher dose of tenecteplase (0.25 mg per kilogram) was superior to the lower dose and to alteplase for all efficacy outcomes, including absence of serious disability at 90 days. The NOR-TEST phase III trial compared intravenous tenecteplase to intravenous alteplase in patients presenting within 4.5 hours of symptom onset who met intravenous r-tPA criteria. The primary endpoint of mRS 0–1 was comparable in both groups with similar safety profiles. The EXTEND-TNK trial compared intravenous tenecteplase with intravenous alteplase in patients presenting within 4.5 hours of symptoms onset in the setting of a large vessel occlusion. The primary outcome of reperfusion of greater than 50% of the target lesion territory was met in 22% of the tenecteplase cohort compared with 10% of the alteplase cohort. Several trials are now underway to test the efficacy of tenecteplase versus alteplase in the early time window in addition to tenecteplase in the late time window.

Intravenous tPA Beyond 4.5 Hours

A pooled analysis of IV tPA trials indicated a declining benefit of treatment with increasing time from stroke onset reaching unity at approximately 4.5 hours. However, there is growing recognition that in some patients, particularly those with good collateral, reversibility might extend well beyond the perceived time limits. Imaging software now enables identification of patients with large territories at risk and small established infarcts likely to benefit from reperfusion therapy. In addition, those who awaken with deficits or with undetermined time of onset who have similar favorable physiology can now be identified with imaging tools. Two recent trials demonstrated benefit of IV tPA treatment beyond the 4.5-hour time window in patients selected using imaging.

In the WAKE-UP trial[10] 503 patients with unknown time of onset but greater than 4.5 hours underwent MRI. If a diffusion abnormality was present without a corresponding hyperintensity on FLAIR imaging, they were randomized to standard-dose IV tPA or placebo. The mismatch between DWI and FLAIR imaging suggests the true time from stroke onset was within 3 hours. Favorable outcomes at 90 days were 11.5% greater in the tPA group (53.3% vs. 41.8%, odds ratio [OR] 1.61 $P = .02$). The study did not reach planned completion because of lack of funding, and the difference in favorable outcome did not correspond to a difference in final infarct volume.

The EXTEND trial[11] tested the hypothesis that advanced imaging could identify patients beyond 4.5 hours likely to benefit from IV tPA. The study enrolled 225 patients but was terminated early because of publication of the WAKE-UP trial results. Patients were randomized to IV tPA or placebo if they were 4.5–9 hours since last seen well and if there was a mismatch between the ratio of perfusion abnormality and core infarct volume of at least 1.2 using CT or MR perfusion using RAPID automated software. Favorable outcome (mRS 0–1) occurred in 35.4% of the tPA group and 29.5% of the placebo group ($P = .05$) at 90 days. In both trials there was an increase in hemorrhages in the tPA group.

These studies suggest treatment with IV tPA is reasonable to consider in patients waking up with stroke deficits or with unknown time from onset and last-known well time between 4.5 and at least 9 hours using imaging to select those with favorable physiology.

Intraarterial Therapy

Intraarterial Thrombolysis

An alternative approach to intravenous thrombolysis is direct delivery of thrombolytic agents by a microcatheter embedded in the clot (Fig. 46.5). The advantage of the intraarterial approach is direct visualization of the occluded artery and knowledge of the recanalization status as thrombolysis proceeds. Theoretically, delivery of the thrombolytic agent to the site of the clot should be more effective than intravenous infusion. The disadvantage is the additional time needed to bring the patient to the angiography suite, prepare the groin, catheterize the femoral artery, and guide the catheter from the femoral artery to the intracranial circulation before the thrombolytic agent can be administered.

Urokinase was used in early studies of intraarterial thrombolysis but is no longer available.[67] Recombinant prourokinase was evaluated formally in clinical trials,[68–70] and the PROACT II study was the first acute stroke trial to show a significant improvement in outcome when administered within 6 hours of stroke symptom onset. The median time to treatment was 5.5 hours, and most patients were treated after

Fig. 46.5 **A,** Right carotid angiogram from a patient with embolic occlusion of the right middle cerebral artery (MCA) 4 hours after onset of symptoms. **B,** Angiogram from the same patient after placement of a microcatheter into the MCA clot and infusion of 120,000 U of urokinase. There is no recanalization. **C,** Angiogram after infusion of 1 million U of urokinase directly into the clot, showing complete recanalization of the MCA.

5 hours.[69] The clinical benefit was apparent despite this late time to treatment; a greater benefit may have been found had patients been treated earlier or mechanical manipulation also been allowed. Symptomatic hemorrhage occurred in 10% of patients treated with recombinant prourokinase and in 2% of controls. Although the hemorrhage rate was higher than previous intravenous thrombolytic studies, the median NIHSS score of 17 indicates that the patients in the PROACT II study had more severe strokes treated at a later time interval. A higher hemorrhage rate would be expected in these scenarios. There was also no differential effect of recombinant prourokinase across risk strata, indicating that all patients, regardless of risk, benefit equally from recombinant prourokinase.[70] Nevertheless, prourokinase has not been FDA approved to date, and tPA tends to be more often used in cases of intraarterial thrombolysis. The exact dose, efficacy, and safety profile of intraarterial tPA is limited, but recent studies have suggested doses up to 40 mg are reasonably safe for use.[71]

First-Generation Mechanical Devices

Although most thrombolytic studies concentrate on time to treatment, the most important factor for clinical outcome is probably time to recanalization of an occluded vessel. When infusion of thrombolytic agents often requires 1–2 hours for complete thrombus dissolution, time to recanalization can be quite long. Mechanical devices offer the possibility of considerably shortening time to recanalization. Devices may be able to clear thrombi from large arteries within a few minutes. The use of thrombolytic agents may not be necessary, possibly reducing the rate of intracranial hemorrhage.

The revolutionary Merci Retriever clot retrieval device (Concentric Medical, Inc., Mountain View, CA) received FDA approval for the removal of blood clots from the brain in patients experiencing ischemic stroke after it was shown to be effective in restoring vascular patency in patients within 8 hours of symptom onset and could serve as an alternative therapy for patients who are otherwise ineligible for thrombolytic drug administration.[72] The Merci device is a flexible nickel titanium (i.e., nitinol) wire that assumes a helical shape once it is passed through the tip of the guidance catheter. In practice, the catheter/wire is passed distal to the thrombus, the catheter is removed, and a helical configuration is assumed by the wire. The clot is then trapped in the helix and withdrawn from the vasculature. Second-generation Merci devices (e.g., L5 Retriever) have been developed and their use shown to be associated with higher rates of recanalization, although these differences did not achieve statistical significance. They also produced lower mortality and a higher proportion of good clinical outcomes.[73] Mechanical embolectomy using an aspiration platform was the basis for the creation of the Penumbra System (Penumbra, Inc., Alameda, CA), which uses a microcatheter and separator-based debulking approach that allows for continuous aspiration of thrombus. A recent trial found that the Penumbra System resulted in safe and effective revascularization in patients who present with large vessel occlusive disease within 8 hours of stroke onset, as 81.6% of patients achieved a Thrombolysis In Myocardial Infarction (TIMI) grade of 2 or 3.[74]

First-Generation Randomized Trials of Intraarterial Therapy

Three clinical trials investigated the role of intraarterial therapy as an alternative or adjunctive treatment to standard medical therapy. The SYNTHESIS trial compared intravenous thrombolysis alone with intraarterial therapy alone and showed comparable outcomes in both cohorts despite an hour delay in initiating intraarterial therapy.[75] Although the trial did not observe improved outcomes in the intraarterial therapy group, it did not require documentation of a large vessel occlusion before initiation of treatment; 92 patients were treated with intraarterial therapy outside the context of the trial, further diluting the study population of patients likely to benefit from intraarterial therapy. The MR RESCUE trial implemented a penumbral imaging-based paradigm in which patients were randomized to medical or intraarterial therapy.[76] There was no difference between groups. Finally, IMS 3 compared the additional benefit of mechanical thrombectomy in patients receiving IV tPA.[77] Once again, intraarterial therapy proved to be safe but no more efficacious than medical therapy. However, it is likely that a high percentage of patients had little or no chance of benefit.[78] Time to treatment was prolonged, as the mean IV tPA start to groin puncture time was 81 ± 27 minutes and the mean groin to IA start time was 41 ± 21 minutes, with a greater than 2-hour delay between CT head and groin puncture.[79]

Stent Retrievers and Recent Trials

These three first-generation trials highlighted an important concept in revascularization—namely, that treatment likely favors patients with a

large clinical deficit in the setting of a small core on presentation who undergo early and effective recanalization. In 2012 the FDA approved two new devices for the indication of thrombus removal in acute stroke: SOLITAIRE and TREVO. Both devices are in the stent retriever class of mechanism and consist of intracranial stents that can be delivered across the thrombus with the dual benefit of achieving a temporary endovascular bypass and trapping the clot within the struts of the stent. The stent retriever is subsequently recovered along with the thrombus. In comparison to the Merci device, stent retrievers yield higher rates of high-quality recanalization (86%–89% vs. 60%–66%).[80,81] Several randomized clinical trials have now tested the hypothesis that intraarterial therapy may be superior to medical management if revascularization is achieved implementing this new technology.[82–86] The first trial to be completed was MR CLEAN, which demonstrated an adjusted common OR of 1.67 in favor of intervention and an absolute difference of 13.5% in the rate of functional independence. These results prompted several ongoing trials to review their outcomes, and a similar benefit was seen across studies (Tables 46.4–46.6).

Most of these trials focused on patients presenting within early time windows and predominantly used CT imaging to determine patient selection. The role of intraarterial therapy beyond 6 hours was studied in the DAWN[87,88] and DEFUSE-3 trials. Both trials used advanced imaging to identify patients with large vessel occlusion (M1 or ICA location) in the setting of a small core that was disproportionate to the clinical deficit (clinical-core mismatch in the DAWN trial) or perfusion deficit (perfusion-core mismatch in the DEFUSE-3 trial). In both trials, endovascular therapy was associated with significantly higher rates of functional independence (see Tables 46.4–46.6).

Intraarterial therapy trials predominantly focused on patients with anterior circulation occlusions in the setting of small core and high NIHSS. The subject on future and ongoing trials includes patients with large core (TENSION, TESLA, and IN EXTREMIS-LASTE) and low NIHSS (ENDO-LOW, IN EXTREMIS-MOSTE). Many practitioners favor revascularization for patients with basilar artery occlusive disease, given the high rate of mortality in this stroke subtype.[89] The recently completed BEST trial randomized patients presenting with basilar artery occlusions within 8 hours of symptom onset to endovascular therapy versus medical therapy[90]. There was no difference in favorable outcomes between the two groups; however, there were high rates of crossovers because of lack of equipoise. Secondary prespecified analyses of the primary outcome showed higher rates of mRS 0–3 at 90 days in patients who actually received the intervention compared with those who received standard medical therapy alone. The ongoing BAOCHE

trial is comparing the benefit of endovascular therapy versus medical therapy in patients presenting with basilar artery occlusion between 8 and 24 hours of symptoms.

Surgical Options

Cerebral edema and herniation are frequent causes of death from stroke in the first few days after massive infarction. Edema gradually increases and peaks 2–3 days after stroke onset. Steroids do not effectively reduce edema caused by stroke, and antiedema measures such as mannitol or hyperventilation are of limited benefit. Control of intracranial pressure (ICP) is associated with improved outcome, but whether ICP monitoring is helpful to guide therapy remains unclear. Surgical decompression of large hemispheric infarcts causing edema and increased ICP is logical because the edema is usually self-limited. If herniation can be avoided, recovery may occur similar to stroke without severe edema. Several different approaches to decompression have been proposed.

Hemicraniectomy is the first and most commonly performed procedure. It involves removal of a generous bone flap ipsilateral to the side of the infarction. Often, a durotomy is performed to allow outward herniation of the brain to decrease ICP and prevent downward herniation. For large MCA infarctions, timing of surgery, side of lesion, presence of signs of herniation before surgery, and involvement of other vascular territories do not significantly affect outcome.[91] This analysis was obtained from uncontrolled, retrospective data; thus no meta-analysis could be completed.

The optimal timing of hemicraniectomy in patients with malignant MCA infarction is unclear. If herniation is in progress, irreversible brainstem damage may occur, thereby limiting the benefit of the operation. More recent evidence suggests that surgical intervention should occur early regardless of whether signs of herniation are present. Three concurrent European trials (i.e., DECIMAL, DESTINY, HAMLET) including patients undergoing hemicraniectomy for malignant MCA infarction were combined in a pooled analysis.[92–94] In this analysis, thresholds were established for 45 hours to randomization and 48 hours to surgery from stroke onset. The combined results showed that decompressive surgery undertaken within 48 hours of stroke onset decreased mortality and increased the number of patients with a favorable functional outcome.[95]

Surgical decompression for hemispheric infarction should be considered for younger patients with a greater potential for recovery from massive stroke. The role of surgical decompression of extensive MCA stroke in patients greater than 60 years of age remains controversial. A comparison of medical management versus early decompression in patients greater than 60 years of age in the DESTINY 2 trial did show improved survival in the surgical group, although a majority of the survivors required assistance for most daily activities. Cerebellar infarction is a special case that requires urgent surgical intervention.[96] Compression of the brainstem and fourth ventricle leading to hydrocephalus or severe pontomedullary compromise can be reversed by rapid surgical decompression of the infarcted cerebellum.

Other Medical Therapies

Anticoagulation

The use of anticoagulants in acute stroke is controversial, although several randomized clinical trials provide information regarding its efficacy. Retrospective data previously suggested a significant incidence of early recurrences after ischemic stroke, with reported rates of 20%. These studies also suggested that anticoagulation with heparin reduced recurrences. Hemorrhagic complications were acceptably low, particularly when patients with large strokes and uncontrolled hypertension were excluded from treatment. The results of recent randomized clinical trials have challenged these findings and call into question the value of anticoagulation for treatment of acute stroke.[97] However, more recent studies indicate that for cardioembolic stroke, warfarin can be safely started shortly after stroke without bridging therapy with heparin or enoxaparin.[98]

The studies do not support a reduced recurrence rate or improved outcome with anticoagulation when given within 24–48 hours of stroke onset. Hemorrhage rates ranged from 1% to 2.5%. The results suggest that there is little value in anticoagulation for all patients with acute stroke, but it remains possible that some subgroups benefit. The TOAST study suggested that patients with large vessel disease may achieve better functional outcome with anticoagulation.[99] The relatively high hemorrhage rate in some studies also may have obscured some benefit. In the International Stroke Trial (IST), a significant reduction in recurrent strokes from 3.8% in the control group to 2.9% in patients treated with subcutaneous heparin ($P < .01$) was offset by an increase in hemorrhagic stroke from 0.4% in controls to 1.2% in patients receiving heparin ($P < .0001$).[100] Even in patients with atrial fibrillation, the value of early anticoagulation is uncertain, with some studies showing benefit and others showing lack of benefit in reducing recurrent stroke.[97] If anticoagulation is started, it should only be given more than 24 hours after intravenous thrombolysis and after imaging confirmation that no hemorrhagic transformation has occurred. The roles of newer anticoagulant drugs such as rivaroxaban, apixaban, and dabigatran in the acute stroke setting remain unclear, although similar to warfarin, acute administration of these medications is likely safe if

the stroke burden is small. These medications have the added benefit of not requiring bridging therapy, as therapeutic dosage is reached early after administration.

Antiplatelet Therapy

There is less uncertainty about the benefit of aspirin in acute stroke. Two large randomized controlled trials, CAST[101] and IST,[100] showed a small but significant improvement in outcome in patients treated with aspirin. In IST, patients received 300 mg of aspirin daily for 14 days. There was a significant reduction in stroke recurrence within 14 days in the aspirin group (2.8%) versus nonaspirin groups (3.9%) and a significant decrease in the risk of death or nonfatal recurrent stroke in the aspirin group (11.3%) versus nonaspirin group (12.4%). In CAST, 160 mg of aspirin was given per day for 4 weeks or until hospital discharge. In the aspirin group, there was a significant reduction in death within 4 weeks (3.3%) versus placebo (3.9%) and a significant reduction in death or nonfatal stroke during hospitalization. There also was a significant reduction in recurrent ischemic strokes in the aspirin group (1.6%) versus placebo (2.1%), which was offset only by a trend of excess hemorrhagic strokes (aspirin 1.1% versus placebo 0.9%).

CAST and IST were designed to be considered together and included more than 40,000 patients. Combining the results of both studies shows a significant reduction in recurrent stroke of 7 per 1000 ($P < .000001$) and reduction of death or dependency of 12 per 1000 ($P = .01$).[102] The risk of aspirin in the absence of thrombolytics is minimal, and the small but significant benefit argues in favor of routine treatment, but only after 24 hours if intravenous thrombolysis has been used and absence of hemorrhagic transformation is confirmed.

The initiation of dual antiplatelets (aspirin and clopidogrel) was shown to reduce recurrent ischemic events in patients with transient ischemic attack (TIA) or mild strokes in the CHANCE trial. The generalizability of this study across populations is unclear, as the trial was conducted in China, where there is a higher incidence of intracranial atherosclerotic disease compared with the US population, and so the treatment effect may reflect a particular benefit of dual antiplatelets in this stroke subtype. Furthermore, the metabolism of the prodrug clopidogrel into the active form is dependent on several P-450 enzymes, with highly variable degrees of active drug across individuals depending on particular genetic variants of the enzyme.

The POINT trial was conducted in North America, Europe, Australia, and New Zealand and randomized a TIA and mild stroke population in double-blind fashion to receive aspirin alone versus dual antiplatelets for 90 days. Dual therapy was associated with lower risk of major ischemic events, but there was a higher risk of hemorrhage at 90 days compared with the aspirin monotherapy group. A pooled individual patient-level data analysis of the POINT and CHANCE trials revealed that the clopidogrel-aspirin group had reduced risk of major ischemic events at 90 days when treatment was confined to the first 21 days.

Statin Therapy

Statins reduce the incidence of strokes among patients who are at increased risk for cardiovascular disease. However, whether statins reduce the risk of stroke after a recent stroke or TIA was established by the SPARCL trial. In SPARCL, patients who had a stroke or TIA within 1–6 months before randomization, had a low-density cholesterol (LDL) of 100–190, and had no known coronary artery disease were randomized to receive 80 mg of atorvastatin or placebo. The primary endpoint was a first nonfatal or fatal stroke. In the cohort receiving high-dose atorvastatin, the overall incidence of strokes and cardiovascular events was reduced. High-dose atorvastatin should thus be administered in the setting of acute ischemic stroke, although there may be a higher risk of hemorrhagic stroke.[103]

Special ICU Management Considerations

General Assessment

In patients with acute stroke, initial concerns include assessment of respiratory function, cardiovascular stability, and level of consciousness. An adequate airway must be established to ensure proper ventilation, particularly in obtunded or comatose patients. Aspiration is a serious concern that often results in pneumonia and serves as a major cause of morbidity and mortality during hospitalization. Supplemental oxygen is often administered, but the benefit is uncertain when oxygenation is already adequate. Hypoxemia should be corrected immediately, however, and its source aggressively investigated. Arrhythmias are common in acute stroke, as bradycardia may signal underlying increased ICP or cardiac ischemia. Atrial fibrillation associated with rapid ventricular response often impairs cardiac output requiring immediate treatment and may also be an embolic source of stroke. Ventricular tachycardia or fibrillation rarely occurs with stroke; when present, it usually is the result of coexistent myocardial infarction. Hypotension should be corrected with intravenous fluids. Seizures should be controlled with anticonvulsants. Fever should be treated aggressively with antipyretics.

Blood Pressure

Hypertension often accompanies ischemic stroke, and in most cases abrupt lowering of blood pressure is not advised because of the risk of further impairing perfusion in the ischemic region.[104] In the presence of a systemic or cardiac reason for reducing blood pressure, such as aortic dissection or acute myocardial infarction, the relative importance of the systemic and neurologic issues must be considered. Hypertensive encephalopathy is a syndrome of extreme hypertension, papilledema, altered mental status, microangiopathic hemolytic anemia, and renal insufficiency that responds to the lowering of blood pressure. In the absence of papilledema or systemic features, it is unlikely that acute neurologic deficits are caused by hypertensive encephalopathy, and acute lowering of blood pressure will more likely worsen than improve deficits.

When thrombolytic therapy is considered, reducing blood pressure within the prescribed limits is necessary. Before thrombolytic therapy is given, systolic blood pressure should be less than 185 mm Hg and diastolic less than 110 mm Hg.[21] Labetalol typically is administered in increasing doses every 5–10 minutes to control blood pressure. Enalapril is a reasonable alternative. Sublingual nifedipine should be avoided because of its potential to lower blood pressure precipitously. If these agents do not provide adequate control, a nicardipine drip could be considered, although such patients may not be good candidates for thrombolysis. After thrombolysis, blood pressure should be aggressively controlled, keeping systolic blood pressure below 185 mm Hg and diastolic pressure below 110 mm Hg for the first 24 hours.

Fluids

Most patients with acute stroke are volume-depleted, and intravenous fluids should be replete with either normal saline or lactated Ringer's solution. In patients with large strokes in danger of developing brain edema, fluid administration should be titrated carefully, and free water should be limited. Mild hyponatremia need not be treated acutely, but more severe hyponatremia should be corrected slowly and usually reverses with infusion of normal saline.

The role of hypertonic saline (3%–23%) in the treatment of acute ischemic stroke and its ability to minimize cerebral edema remains

controversial. Those who oppose its use cite that it can lead to rebound parenchymal swelling once it is weaned off. Proponents will usually use a goal serum sodium range of 145–150 mEq/L and a serum osmolality goal of 315–320 mOsm/L. Sodium and serum osmolality levels are usually checked every 6 hours.[105,106]

Glucose

Evidence from animal models of stroke suggests that hyperglycemia increases the severity of ischemic injury.[107] Increased glucose concentration in the area of ischemia causes higher lactate concentrations and local acidosis, which increases free radical formation and thus damages neurons. Hyperglycemia also may increase ischemic edema, release excitatory amino acid neurotransmitters, and weaken blood vessels in the ischemic area. Studies of stroke in humans show an inconsistent association between outcome and initial blood glucose; however, admission glucose concentration correlates with initial stroke severity. Initial hyperglycemia also has been associated with higher mortality rates after stroke.[108] Some suggest that hyperglycemia in acute stroke is a stress reaction, but the relationship between initial blood glucose concentration and outcome is independent of initial stroke severity, arguing against a stress phenomenon.

The GIST-UK trial investigated whether treatment with a glucose-potassium-insulin (GKI) infusion to maintain euglycemia immediately after the acute stroke event had an impact on mortality at 90 days. This trial was stopped because of slow enrollment but concluded that whereas GKI infusions reduced plasma glucose concentrations and blood pressure, treatment was not associated with clinical benefit. The study was underpowered, and alternative results should not be dismissed.[109] The GRASP pilot trial found that insulin infusion for patients with acute ischemic stroke is feasible and safe. Three treatment arms were used, employing controls that were tight (70–110 mg/dL), loose (70–200 mg/dL), and usual (70–300 mg/dL).[110] More recently, the SHINE trial randomized acute ischemic strokes to intensive (80–130 mg/dL) versus standard (80–179 mg/dL) glucose control for up to 72 hours after presentation. Intensive insulin treatment compared with standard treatment did not lead to better functional outcomes. An important limitation of the SHINE trial was that recanalization data were not captured.

SUMMARY

The availability of effective treatments to alter outcome within the first few hours after stroke onset is rapidly evolving. Patients with symptoms suggesting cerebral ischemia must be treated emergently, and imaging must be performed rapidly and in a high-quality manner. Therapy for acute stroke includes much more than thrombolysis, and understanding the benefits and hazards of thrombolysis continues to evolve with greater experience and additional clinical trials. Newer generations of mechanical devices are being developed, and neuroprotection and neurorestoration hold great promise as synergistic complements to stroke reperfusion therapies. Appropriate management of blood pressure, glucose, and intravenous fluids all contribute to the overall outcome from acute stroke. At present, only a small fraction of patients with stroke (less than 5%) arrive at an emergency department in time for acute stroke therapy. Development of new acute stroke therapies and expected improvements in outcome with lower hemorrhage rates should encourage the medical system to further support the framework for a seamless and integrated stroke system of care. Such efforts should ensure that all stroke patients receive the optimal available therapy in the shortest time possible.

KEY POINTS

- When an arterial occlusion occurs, an area of irreversibly infarcted brain (core infarct) is surrounded by a region of reduced blood flow impairing function (ischemic penumbra) that is not yet severe enough to result in irreversible infarction. If adequate blood flow can be restored within a critical time frame, this area of at-risk tissue may be salvageable and return to normal function.
- Acute ischemic stroke imaging ideally involves some combination of a noncontrast head CT, CA of the head and neck, CT brain perfusion, MRI brain, MRA of the head and neck, or MR brain perfusion.
- The only FDA-approved therapy for acute ischemic stroke presenting within 3 hours of symptom onset is IV tPA.
- Evidence from the ECASS III trial indicates that the therapeutic window for IV tPA may be extended to 4.5 hours in select patients.
- Several studies (MR CLEAN, EXTEND-IA, ESCAPE, SWIFT PRIME, and REVASCAT) have demonstrated improved outcomes in select patients undergoing intraarterial therapy with a stent retriever device within 6–12 hours of symptom onset.
- Intraarterial therapy for acute ischemic stroke presenting beyond 6 hours is superior to medical management in appropriately selected patients (DAWN and DEFUSE-3 trials).
- Surgical decompression for large infarctions is recommended to be completed within 48 hours from symptom onset in appropriately selected patients.
- In patients receiving intravenous thrombolysis, no anticoagulation or antiplatelet agents should be administered in the first 24 hours until hemorrhagic transformation can be excluded. After that time, anticoagulation can be started in appropriate patients. If anticoagulation is not used, antiplatelet agents should always be started.
- High-dose statin therapy can be administered acutely after ischemic stroke in patients with previous stroke or TIA and without history of coronary artery disease.
- Patients presenting with TIA or mild stroke may be at high risk for recurrent events. A short course of dual antiplatelets (21 days) reduces the likelihood of recurrent ischemic events in patients. Longer periods of dual antiplatelets may lead to higher risk of hemorrhage.
- Although hyperglycemia has been associated with higher mortality in acute ischemic stroke patients there are no current data to suggest improved outcomes with intensive glucose control.

High-dose atorvastatin after stroke or transient ischemic attack. *N Engl J Med.* 2006;355(6):549–559. *This trial evaluated whether statins reduced the risk of stroke in patients who experienced a recent stroke or TIA and were not known to have coronary artery disease. Over 4700 patients were randomized to receive 80 mg atorvastatin per day or placebo. High-dose statin therapy reduced the overall incidence of strokes and of cardiovascular events despite a small increase in the hemorrhage rate.*

The ATLANTIS, ECASS and NINDS rt-PA Study Group Investigators. Association of outcome with early stroke treatment: pooled analysis of ATLANTIS, ECASS and NINDS rt-PA stroke trials. *Lancet.* 2004;363:768–774. *This article represents a combined analysis of five clinical studies in 2775 patients randomly allocated to rt-PA or placebo. The study addresses the use of intravenous rt-PA and provides specific insight into its use beyond 3 hours of*

the onset of stroke. The authors concluded that the sooner that rt-PA is given to stroke patients, the greater the benefit, especially if started within 90 minutes. Their findings also suggested a potential benefit from this therapy applied beyond 3 hours, but this potential might come with some risks.

Broderick JP, Palesch YY, Demchuk AM, et al. Endovascular therapy after intravenous t-PA versus t-PA alone for stroke. *N Engl J Med*. 2013;368(10):893–903.
This landmark study was the first randomized controlled trial to compare the efficacy of first-generation intraarterial therapy as an adjunctive therapy to intravenous thrombolysis compared with intravenous thrombolysis alone. Although the results were neutral in the two study groups, analysis of this trial identified a potential benefit with adjunctive intraarterial therapy in patients with small infarct on presentation with documented proximal large vessel occlusion undergoing fast and high-quality recanalization.

Chen ZM, Sandercock P, Pan HC, et al. Indications for early aspirin use in acute ischemic stroke: a combined analysis of 40,000 randomized patients from the Chinese Acute Stroke Trial and the International Stroke Trial. On behalf of the CAST and IST collaborative groups. *Stroke.* 2000;31:1240–1249.
This article represents a combined analysis of two clinical trials, each with 20,000 patients, showing a reduction in recurrent stroke and death rates with aspirin treatment. There was a highly significant reduction of 7 per 1000 in recurrent ischemic stroke in patients treated with aspirin versus control and a significant reduction in death rate of 4 per 1000 with aspirin treatment. Thus early aspirin treatment is of benefit for a wide range of patients, and its prompt use should be widely considered for all patients with suspected acute ischemic stroke to reduce the risk of early occurrence.

Campbell BC, Mitchell PJ, Kleinig TJ, et al. Endovascular therapy for ischemic stroke with perfusion-imaging selection. *N Engl J Med*. 2015;372(11):1009–1018.
These five seminal studies collectively demonstrate the benefit of stent retriever mechanical thrombectomy in patients presenting with early time windows with anterior circulation occlusions. A majority of the patients received intravenous rt-PA, were treated within 6 hours of symptom onset, and predominantly underwent intraarterial therapy with the Solitaire stent retriever device.

Hacke W, Kaste M, Bluhmki E, et al. Thrombolysis with alteplase 3 to 4.5 hours after acute ischemic stroke. *N Engl J Med*. 2008;359(13):1317–1329.
This is the first randomized controlled trial confirming the efficacy and safety of alteplase given between 3 and 4.5 hours after the onset of a stroke. There are some exclusion criteria in addition to the normal contraindications for administration of intravenous tPA for this extended therapeutic window. Intravenous alteplase administered between 3 and 4.5 hours significantly improved clinical outcomes in patients with acute ischemic stroke, but it was also more frequently associated with symptomatic intracranial hemorrhage versus placebo.

The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group. Tissue plasminogen activator for acute ischemic stroke. *N Engl J Med.* 1995;333:1581–1587.
A key clinical report in the field of stroke that showed for the first time in a randomized controlled trial a reduction in stroke morbidity with acute treatment. In June 1996 the FDA approved intravenous tPA for the treatment of stroke within 3 hours of onset.

Smith WS, Sung G, Starkman S, et al. Safety and efficacy of mechanical embolectomy in acute ischemic stroke: results of the MERCI trial. *Stroke*. 2005;36(7):1432–1438.
This trial evaluated the alternative strategy of mechanical embolectomy for opening intracranial vessels during stroke. Patients who were ineligible for intravenous tPA and found to have occluded intracranial large vessels within 8 hours of stroke symptom onset received this therapy. The strategy was deemed both safe and efficacious and was the primary support for the FDA approval of the Merci retriever device.

Vahedi K, Hofmeijer J, Juettler E, et al. Early decompressive surgery in malignant infarction of the middle cerebral artery: a pooled analysis of three randomised controlled trials. *Lancet Neurol*. 2007;6(3):215–222.
Pooled analysis of three concurrent European randomized controlled trials (i.e., DECIMAL, DESTINY, HAMLET) evaluating decompressive surgery for patients with large MCA hemispheric infarctions in terms of mortality and functional outcome. The analysis included 93 patients between the ages of 18 and 60 years who were either treated within 48 hours after stroke onset or randomized to a control group. Early decompressive surgery was found to reduce mortality and increase the likelihood of a favorable outcome.

Nontraumatic Intracerebral and Subarachnoid Hemorrhage

Subhan Mohammed and Christopher P. Robinson

HEMORRHAGE

Epidemiology

Intracerebral hemorrhage (ICH) is the second most common type of stroke, following only ischemic stroke in frequency. Spontaneous, nontraumatic ICH accounts for approximately 9%–27% of all strokes globally.[1,2] The incidence doubles every decade after age 35.[3,4] Outcomes are typically poor, with a mortality of 50% at 30 days.[5] A systematic review in 2013 found that the burden of death and disability is greatest with ICH, although the incidence of ischemic stroke is far greater.[6]

Causes and Risk Factors

The major risk factor for ICH, accounting for over 50% of cases, is hypertension.[7] Old age, anticoagulant use, and cerebral amyloid angiopathy (CAA) are other important risk factors. The impact of smoking,[8] alcohol abuse,[9,10] and diabetes mellitus[11,12] on the risk of ICH is disputed.

Hypertension

The most common etiology of ICH is hypertension. Hypertension more than doubles the risk of ICH.[13–16] Hypertensive ICH predominantly occurs deep in the cerebral hemispheres, most often in the putamen,[17] thalamus, lobar white matter, cerebellum, and pons (Fig. 47.1). The link between these sites is the supply of small penetrating arteries[18]—that is, perpendicular branches directly off major arteries that are subject to high shear stress and have no collaterals.

Intracranial Aneurysms and Vascular Malformations

Although aneurysmal rupture is most commonly associated with hemorrhage in the subarachnoid space, blood may also be directed into the parenchyma of the brain. Aneurysms located at the middle cerebral artery bifurcation can produce hemorrhages into the basal ganglia similar to hypertensive hemorrhage, and anterior communicating artery aneurysms can produce flame-shaped hemorrhages at the base of the frontal lobes. About half of adults with intracranial arteriovenous malformations (AVMs) present with ICH.[19] In 60% of cases, the hemorrhage is parenchymal, involving virtually any location of the brain.[20] Hemorrhage resulting from AVM occurs more frequently in a younger population than that resulting from aneurysms or hypertension.

Cerebral Amyloid Angiopathy

CAA is an important cause of primarily lobar, often recurrent, ICH in the elderly. The prevalence of amyloid deposition in cerebral vessels increases dramatically with age[21,22] and may contribute to the exponential rise in the risk of ICH with age. Although CAA is asymptomatic, it is an important cause of ICH. Apolipoprotein E ϵ2 and ϵ4 genotypes are associated with an earlier age at onset of first hemorrhage and a higher risk of early recurrence.[23,24] The presence of multiple or recurrent lobar ICH in individuals 55 years or older without other known causes of hemorrhage strongly suggests this etiology.[25]

Antithrombotic Therapy

Antithrombotics include anticoagulants, antiplatelets, and thrombolytic agents, which increase the risk of spontaneous ICH. The incidence of oral anticoagulant–associated ICH has been increasing in parallel with the rising use of the anticoagulants. Warfarin increases the risk of ICH by twofold. Although the risk of ICH is greater with a supratherapeutic international normalized ratio (INR), a significant number of hemorrhages occur when the INR is therapeutic.[26] Hematoma expansion among warfarin users may be more common and occur over a longer time frame, contributing to a higher mortality rate versus spontaneous ICH.[27] The novel anticoagulants (NOACs), which act by inhibition of thrombin or factor Xa, may have a lower risk of ICH than warfarin.[28–31]

Most studies suggest that antiplatelet use at ICH onset is not associated with larger hematoma size, hematoma growth, or poor clinical outcome.[32] Platelet dysfunction is associated with hematoma expansion and worse outcome,[33] but to date, platelet transfusion has not provided a mortality benefit or improved functional outcome.[34]

Alteplase administered intravenously for the treatment of acute ischemic stroke (presenting within the time window) increases the risk of spontaneous ICH 5%–7%.[35,36]

Other Causes

Hemorrhage from an underlying neoplasm is rare but occasionally occurs with malignant primary central nervous system (CNS) tumors such as glioblastoma multiforme and lymphoma and with metastatic tumors.[37]

ICH may also occur in association with infection,[38,39] vasculitis,[40] venous sinus occlusion,[41] after head trauma,[42] after reperfusion,[43] and with the use of various drugs, particularly sympathomimetics.[44] Some degree of hemorrhagic transformation of acute cerebral infarcts is common,[45] although symptomatic ICH in this setting is rare in the absence of anticoagulation or thrombolytic therapy.

Systemic diseases (e.g., thrombocytopenia, leukemia, and hepatic and renal failure) and congenital or acquired clotting factor deficiencies also increase the risk for spontaneous ICH.

Pathophysiology

Several mechanisms account for brain injury in ICH. Primary brain injury occurs secondary to local tissue destruction from initial vessel

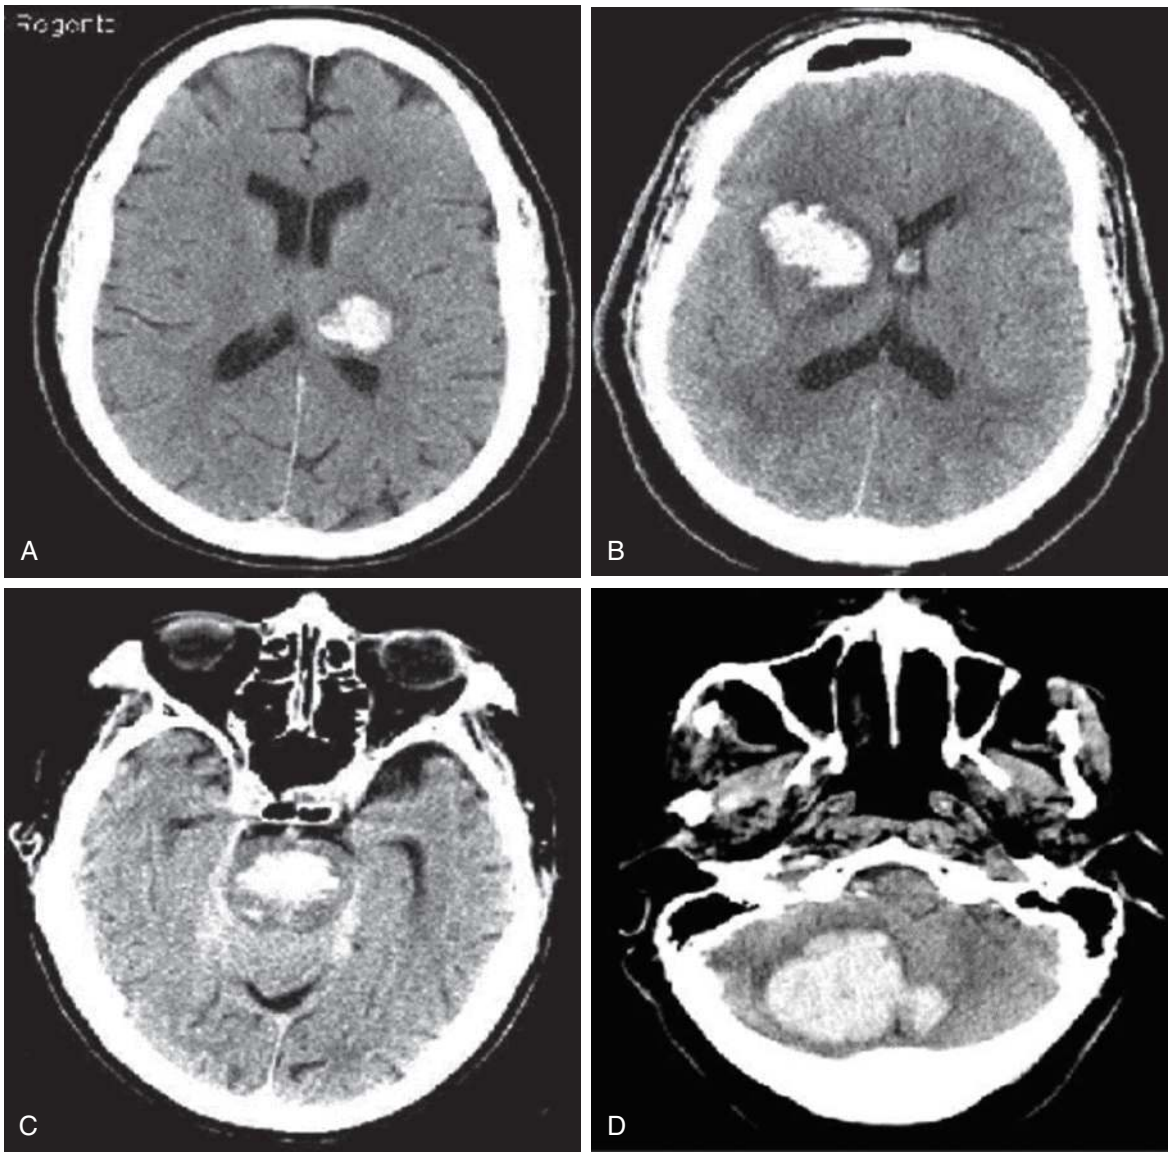

Fig. 47.1. CT Scans Showing Common Locations of Spontaneous Hypertensive Intracranial Hemorrhage. **A,** Thalamus, **B,** caudate/putamen, **C,** pons, and **D,** cerebellum.

rupture. Further bleeding into the hematoma cavity results in hematoma enlargement,[46] producing further tissue distortion and mass effect.

Secondary brain injury is believed to occur after the bleeding stops. Proposed mechanisms include ischemia, perilesional edema, and toxic effects of parenchymal blood. Although each of these can be detected in animal models, their clinical importance remains unsettled. Contrast enhancement seen in the peri-hematomal area on computed tomography (CT) or magnetic resonance imaging (MRI) represents blood–brain barrier disruption.[47,48]

Despite experimental models of ICH[49,50] and studies in human patients[51–53] consistently demonstrating reduced blood flow around the hematoma, this does not appear to represent ischemia.[54,55] Positron emission tomography (PET) and MRI studies in humans indicate that the peri-hematomal cerebral metabolism is reduced to a greater degree than local cerebral blood flow (CBF).[56] These findings suggest that hypoperfusion reflects reduced metabolic demand of the tissue surrounding the hematoma rather than ischemia.[55,57]

Cerebral edema occurs within hours of ICH and may result from the toxic effects of blood-derived enzymes, increased osmotic pressure exerted by clot-derived serum proteins, or ischemia.[58] The cause, time course, and importance of edema formation in humans are debated, and the best predictor of edema volume is the size of the hematoma. Early edema does not appear to contribute to increases in mass effect,[59] worsened functional outcome, or increased mortality.[60]

Clinical Features

The clinical presentation of ICH is often indistinguishable from that of ischemic stroke; however, ICH more commonly presents with an altered level of consciousness, headache, and vomiting.[17] Signs and symptoms usually correspond to the location of ICH. Blood pressure is elevated in the majority of patients. Seizures may occur at onset or in the first few days in approximately 15% of patients,[61–63] particularly in those with lobar hemorrhages or underlying vascular or neoplastic lesions.[64] Symptoms may be maximal at onset or evolve over minutes

to hours. Neurologic deterioration within 48 hours after hospital admission has been reported to occur in 20% of patients.[65] A majority are related to hematoma expansion, but, for some, the cause is not always evident. Some patients may be obtunded or comatose on presentation.

Diagnostic Studies

Noncontrast CT scan is the gold standard for the diagnosis of acute ICH. The typical CT appearance of an acute hematoma consists of a well-defined, hyperdense area surrounded by a rim of hypodensity. Over time, the borders of both the high- and low-attenuation regions become increasingly indistinct such that the hematoma is isodense with adjacent brain parenchyma by 2–6 weeks.[66] Termed the *swirl sign,* these hypodense or isodense foci represent fresh, unclotted blood of lower attenuation signifying acute extravasation of blood into a hyperdense hematoma.[67,68] Although MRI also has high sensitivity and specificity for the diagnosis of acute ICH,[69–71] it is less accessible and more time consuming.[72] The benefits of MRI over CT are accuracy in determining the approximate age of a hematoma[73] and its ability to detect evidence of previous asymptomatic hemorrhages.[74]

CT angiography (CTA) is a noninvasive imaging modality useful in evaluating the cause of ICH if an underlying aneurysm or vascular malformation is suspected. It has a sensitivity of 96% and a specificity of 99%–100%.[75,76] The yield is higher in younger patients, those without hypertension or impaired coagulation, and those with lobar or infratentorial ICH.[75] CTA can identify active contrast extravasation into the hematoma, an indicator of active hemorrhage. The *spot sign* is a foci of intralesional contrast enhancement seen in up to one-third of patients with acute ICH.[77] *Swirl sign* on a CT is analogous to *spot sign* on a CTA. They are independent predictors of hematoma expansion, in-hospital mortality, and poor outcome in survivors.[67,78–80]

Diagnostic cerebral angiography is an invasive diagnostic study useful in evaluating the cause of ICH if the suspicion for underlying aneurysm or vascular malformation remains high despite a negative CTA. Conventional angiography is able to identify aneurysms smaller than 3 mm in size that can be missed on CTA.[81] The yield is extremely low when patients have hypertension and the ICH is in a typical site associated with hypertensive hemorrhage.[82]

Treatment

Initial Stabilization

Acute ICH is a medical emergency requiring careful attention to airway, blood pressure, and correction of underlying coagulopathy. Multidisciplinary teams with expertise in emergency medicine, neurology, and neurosurgery should evaluate and manage ICH patients in a dedicated neurocritical care unit. Acute-phase care may require mechanical ventilation, blood pressure control, reversal of coagulopathy, ventriculostomy, treatment of intracranial hypertension and seizures, and surgical evacuation. Blood pressure is often elevated at presentation, sometimes markedly so, and early control is an important component of initial stabilization.

Airway and Respiratory Management

As many as half of all patients with ICH require mechanical ventilation.[83] With decreased level of consciousness, the pharyngeal and tongue musculature relax and cough and gag reflexes are inhibited, leading to airway compromise. Additionally, if the hemorrhage is in the brainstem or cerebellum, there may be complete loss of pharyngeal tone and early airway obstruction.

Initial airway management includes proper positioning,[84] frequent suctioning, and placement of an oral or nasal airway to maintain patency. If snoring respiration, inability to clear oral secretions, or decreased oxygen saturation does not improve, intubation is warranted. A rapid-sequence intubation is necessary for patients showing signs of herniation, apneic breathing, Glasgow Coma Scale (GCS) score <8, or soiled airway. In the absence of these findings, a semi-elective protective intubation is recommended to avoid the harmful consequences of hypotension, exaggerated sympathetic reflex from stimulation during laryngoscopy, and worsening of intracranial hypertension.[85] Perform a complete neurologic examination if time permits.

Premedication should be administered to produce adequate sedation and jaw relaxation and to prevent elevation of intracranial pressure (ICP). Short-acting intravenous (IV) anesthetic agents (e.g., etomidate or thiopental) block this response[86] and additionally suppress brain metabolic rate.[87] Etomidate is generally preferred over thiopental because it is less likely to lower blood pressure. IV lidocaine (1–1.5 mg/kg) has been recommended to block this response,[88] although data supporting its use are lacking.[89] Paralytic agents are usually unnecessary, but if needed, short-acting agents should be used.

Hemodynamics

Arterial blood pressure is often elevated on admission in the majority of patients with ICH, even in the absence of a history of hypertension.[17,90] Although this acute increase in blood pressure is often implicated as the cause of the hemorrhage, it more likely reflects the brain's attempt to maintain cerebral perfusion pressure (CPP) in response to the sudden increase in ICP, pain, anxiety, and sympathetic activation. Even without treatment, blood pressure tends to decline to premorbid levels within a week of ICH.[91]

There has been substantial controversy over if and when to lower elevated blood pressure after acute ICH.[92] Proponents of rapid treatment of acute hypertension argue that high blood pressure may make the hematoma prone to enlargement and exacerbate vasogenic edema. Another compelling reason to lower blood pressure in ICH patients with moderate to severe hypertension is the potential for end-organ damage, including myocardial ischemia, congestive heart failure, and acute renal failure.

The major argument against the treatment of elevated blood pressure is reduction of CBF and exacerbation of ischemia surrounding the hematoma.[93] Because chronic hypertension shifts the cerebral autoregulatory curve to the right, a higher CPP may be required to maintain adequate CBF.[94,95] Lowering the blood pressure to "normal" levels might thus lead to ischemic damage. Similarly, lowering blood pressure may critically reduce CPP in patients in whom ICP is elevated.

Several studies have addressed this issue in patients with mean arterial pressure (MAP) more than 130–140 mm Hg.[96–98] These studies demonstrate that regional and global CBF are preserved when MAP is lowered to 110 mm Hg or 80% of the admission MAP.

These observations set the stage for the INTERACT trial,[99] a prospective trial of blood pressure management beginning within 6 hours of symptom onset. Patients were randomized to either an early, intensive blood pressure–lowering group (systolic blood pressure [SBP] <140 mm Hg) or a control group (SBP <180 mm Hg). After adjusting for initial hematoma volume and time from onset to CT, median hematoma growth at 24 hours differed by 1.7 mL. Intensive blood pressure lowering did not increase the risk of adverse events or improve 90-day clinical outcome. This was followed by the much larger INTERACT2, which used the identical protocol and enrolled almost 3000 patients.[100] Again there was a very small, if any, impact on hematoma expansion, although the hematoma sizes of those enrolled were fairly small. Although the study did not reach its primary endpoint, an ordinal analysis of modified Rankin scores (mRS) indicated improved functional outcomes with intensive lowering of blood pressure. Based on this study, many clinicians are now more aggressive in treating early hypertension in these patients. For patients presenting with SBP

between 150 and 220 mm Hg, lowering of SBP to 140 mm Hg is generally safe. In patients presenting with SBP >220 mm Hg, the optimal target is unknown, and targeting SBP between 140 and 160 mm Hg is reasonable.[61] In the ATTACH-2 trial, the group with intense lowering of SBP to <140 mm Hg (110–139 mm Hg) was found to have more adverse renal events compared with less intense SBP lowering from 140 to 179 mm Hg.[101]

In the setting of ICH, the ideal antihypertensive agent would be easily titrated, have minimal cerebral hemodynamic effects, and not be prone to sudden, large reductions in blood pressure. Vasodilators, especially venodilators, can raise ICP by increasing cerebral blood volume and should be avoided. Sodium nitroprusside[102] and nitroglycerin[103] increase ICP and lower CBF in patients with reduced intracranial compliance and should not be used. Calcium channel blockers, beta-blockers, and angiotensin-converting enzyme inhibitors have minimal effect on CBF within the autoregulatory range of MAP and do not alter ICP. Therefore popular treatment options in the setting of acute ICH include intermittent boluses of labetalol,[84,104] enalapril,[84] and/or hydralazine[84] or continuous infusion of nicardipine[104] or clevidipine.

Prevention of Hemorrhage Extension and Reversal of Anticoagulation

Abrupt discontinuation of all antithrombotic therapy is imperative. Hemorrhage expansion occurs within the first few hours after symptom onset in about one-third of patients; therefore it is reasonable to correct any existing coagulopathy as rapidly as possible. Patients taking warfarin should receive IV vitamin K and replacement clotting factors. Until recently, fresh frozen plasma (FFP) was used for this purpose, but it can precipitate congestive heart failure, transfusion-related acute lung injury, and transfusion-associated circulatory overload. Four-factor prothrombin complex concentrate (PCC) is an effective alternative that can be administered much more quickly without these risks and is now primarily recommended for reversal.[105]

Management of hemorrhage in patients taking thrombin and factor Xa inhibitors is more difficult. Recently, the Food and Drug Administration (FDA) has approved the antidotes idarucizumab[106] and andexanet alfa[107] for agent-specific reversal.

Symptomatic ICH occurs after thrombolytic treatment of acute ischemic stroke in about 6% of patients.[108] No reliable data are available to guide correction of the thrombolytic effect of tissue plasminogen activator (tPA). Current practice is highly variable and may include administration of FFP, PCC, cryoprecipitate, platelets, and antifibrinolytic agents.

Even in those patients without coagulopathy, promoting early hemostasis might limit ongoing bleeding and decrease hematoma volume. Factor VIIa is a coagulation factor that interacts with tissue factor to initiate platelet aggregation and accelerate formation of a fibrin clot. Although earlier studies suggested a decrease in the hematoma expansion with its use, there was no significant difference in clinical outcomes.[109] Therefore routine use of factor VIIa is not recommended.[110]

Intraventricular Hemorrhage and Hydrocephalus

Intraventricular hemorrhage (IVH) (Fig. 47.2) complicates about 40%–60% cases of ICH.[111,112] It is independently associated with death and poor outcome, especially when it occurs late in the course.[113–115] IVH may present with an abrupt headache, nausea, vomiting, and worsening of neurologic status that may partly be attributed to a sudden rise in ICP. Hydrocephalus may develop because of obstruction of the cerebrospinal fluid (CSF) flow in the ventricles in association with IVH or because of direct mass effect on a ventricle. CT scan is the imaging modality of choice to diagnose IVH. External ventricular drainage (EVD) is often used to treat hydrocephalus and IVH. Ventriculostomy in the setting of IVH is difficult to manage because of catheter obstruction from thrombus, interrupting drainage and raising ICP. Flushing the system helps remove thrombus but increases the risk of ventriculitis. A multicenter randomized study of Clot Lysis Evaluation of Accelerated Resolution (CLEAR-III) of IVH compared the use of ventriculostomy with intraventricular alteplase to ventriculostomy with saline. At 180 days, the treatment group had lower case fatality versus placebo but functional outcomes were no different. Ventriculitis was less in the treatment group, whereas the rate of symptomatic bleeding was similar in both groups.[116]

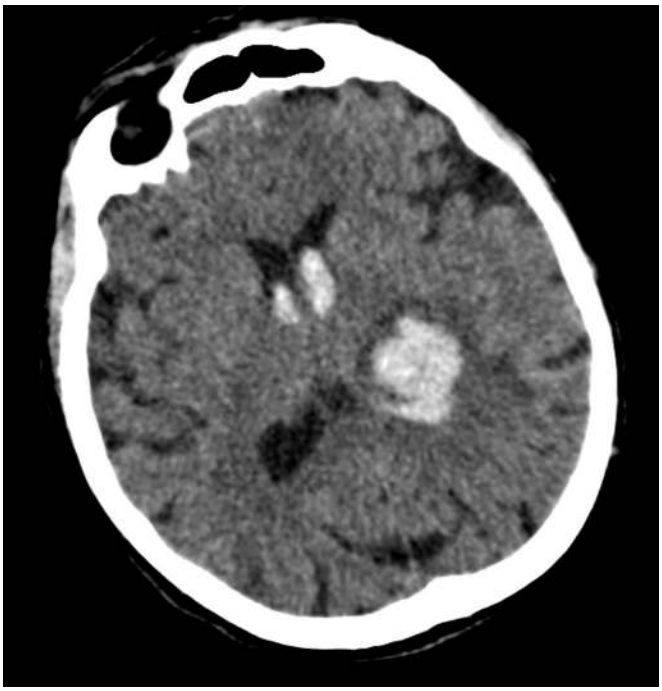

Fig. 47.2. CT Scan Showing Associated Intraventricular Hemorrhage in the Setting of Acute Thalamic Intracranial Hemorrhage.

Intracranial Hypertension

Factors contributing to intracranial hypertension in ICH include hematoma size, minimal degree of underlying cerebral atrophy, hydrocephalus, and cytotoxic edema. The true incidence of intracranial hypertension is unclear, as routine ICP monitoring is not performed. Because the hematoma is localized, increases in volume can be compensated for to some degree by reduction in the size of the ventricles and subarachnoid space—a global increase in ICP may not be seen unless the hemorrhage is large or associated with marked hydrocephalus. However, mass effect from the hematoma and local tissue shifts can compress the brainstem and result in herniation in the absence of a global increase in ICP.[117,118] Thus the utility of ICP monitoring is not clear. In some cases, EVD placement is considered to manage hydrocephalus or IVH.

Acutely elevated ICP, edema, and tissue shifts are often treated with osmotic agents. There are only a few small clinical trials of osmotic agents in ICH, which do not provide sufficient data to support their routine use.[119] Furthermore, corticosteroids in ICH or IVH do not provide benefit. Their use is not routinely recommended, as they increase comorbidities.[120]

Management of Seizures

Risk of seizures in patients with acute spontaneous ICH is approximately 15%.[61–63] They are more common in patients with lobar hemorrhage

compared with cerebellar or deep ICH. Seizures may be convulsive or nonconvulsive; thus the true frequency depends at least partly on the extent of monitoring. Although seizures may theoretically exacerbate ICH, they have not been shown to alter outcome. The 2015 American Heart Association/American Society of Anesthesiologists (AHA/ASA) guidelines recommended against antiseizure prophylaxis.[61] A 2019 systematic review and meta-analysis evaluating antiseizure prophylaxis found no reduction in incident seizures, disability, or mortality in patients with spontaneous ICH.[121] Any seizure should be treated to prevent recurrent seizures. Treatment of clinical seizures typically begins with an IV benzodiazepine followed by an IV antiepileptic depending on individual circumstances and contraindications. The use of phenytoin is discouraged based on the poor outcomes associated in observational studies.[61]

Surgical Evacuation

The role of surgery in hematoma evacuation is controversial and lacks well-defined indications. The rationale for surgical evacuation is reducing mass effect and removing neurotoxic clot constituents to minimize injury to adjacent brain tissue, decrease the risk for herniation, improve ICP, and hence improve outcome. Early randomized controlled trials of surgery for supratentorial ICH, however, failed to show a benefit.[122–125] A meta-analysis of three of these trials reported that patients undergoing surgical evacuation via open craniotomy had a higher rate of death or dependency at 6 months compared with those managed medically.[126] Criticisms of these trials are that outdated surgical techniques were used, patient selection was inadequate, and surgery was delayed. Because open craniotomy is complicated by tissue damage sustained during the approach to the hematoma, a variety of new techniques for clot removal have been proposed, including an ultrasonic aspiration and endoscopic approach. However, the recurrence of bleeding because of the loss of tamponade effect on adjacent tissue remains a concern. In addition, because the newer techniques involve limited surgical exposure, concern exists that rebleeding will be more difficult to control than with open craniotomy.

A lack of benefit of surgery in ICH was also shown in the STICH trial, a multicenter study in which 1033 patients were randomized within 72 hours of ICH onset to surgical hematoma evacuation or initial conservative management. Outcome did not differ between groups. Subgroup analysis, however, suggested a possible benefit of surgery in patients with superficial hematomas.[127] Subsequently, the STICH II trial enrolled conscious patients with superficial lobar ICH of 10–100 mL and no intraventricular hemorrhage within 48 hours of ictus. There was a trend toward better survival in the surgical group.[128] In the Minimally Invasive Surgery with Thrombolysis in Intracerebral hemorrhage Evacuation (MISTIE) phase III trial, 516 patients with supratentorial ICH ≥30 mL were randomized to stereotaxic placement of a catheter in the hematoma and instillation of tPA for up to 72 hours or medical management. The number of patients with a good functional outcome, defined by a mRS of 0–3, was similar for both groups at 365 days, although mortality was lower in the surgical group.[129]

Because of the high risk of brainstem compression and hydrocephalus, cerebellar hemorrhages were excluded from the randomized trials of surgery. Case series report good outcomes for surgically treated patients with cerebellar hemorrhages that are large, associated with brainstem compression, or obstruct the fourth ventricle. Recommended criteria for evacuation of a cerebellar hematoma have thus included diminished level of consciousness, large size of the hematoma (>3 cm in diameter), midline location, compression of basal cisterns and/or brainstem, and presence of hydrocephalus.[130–132] Patient selection is important, as many patients with smaller hemorrhages do well with medical management.[133] A recent 2019 individual participant data meta-analysis of four observational ICH studies concluded that surgical hematoma evacuation in cerebellar hemorrhages compared with conservative medical management did not improve functional outcome.[134]

Supportive Care

Patients with ICH are prone to the same medical complications seen in patients with ischemic stroke, including fever, deep venous thrombosis (DVT), pulmonary embolism, myocardial infarction, dysphagia, gastrointestinal bleeding, and pneumonia.[135,136] Given the association between fever and worsened outcome in experimental models of brain injury, it is reasonable for antipyretic medications to be administered in febrile patients with ICH. A meta-analysis found that fever was significantly associated with higher rates of mortality, disability, dependency, worse functional outcome, higher severity, and longer intensive care unit (ICU) stays.[137] The randomized trials Clots in Legs Or sTockings after Stroke (CLOTS) 1, 2, and 3 assessed different treatment modalities for the prevention of DVT.[138–141] In the CLOTS 1 trial, the use of thigh-high compression stockings did not reduce DVT, pulmonary embolism (PE), or death.[139] In the CLOTS 2 trial, the incidence of DVT was higher in patients who had below-knee graduated compression stockings compared with thigh-high graduated compression stockings.[138] In the CLOTS 3 trial, intermittent pneumatic compression reduced the occurrence of proximal DVT, with the effect being particularly prominent in patients with hemorrhagic stroke.[140] Subcutaneous heparin at a dose of 5000 units three times daily when initiated on day 2 after hemorrhage has been shown to significantly reduce the frequency of DVT relative to treatment begun on day 4 or 10, with no concomitant increase in hematoma expansion.[142] In another study, subcutaneous enoxaparin (40 mg daily) initiated at 48 hours after ICH was also safe.[143] A meta-analysis of thromboprophylaxis assessing the early use of subcutaneous enoxaparin or heparin (from 1 to 6 days after admission) observed a significant reduction in PE, a nonsignificant mortality reduction, and no difference in DVT or hematoma enlargement.[144]

Similar to patients with ischemic stroke, ICH patients should not be fed orally until swallowing is evaluated. Dysphagia is a common complication after ICH and a cause for aspiration pneumonia.[145] Patients should consistently be monitored for signs of aspiration pneumonia. Early mobilization and rehabilitation are generally recommended for clinically stable patients with ICH.

Prognostic Factors and Causes of Mortality

Thirty-day mortality after ICH is high (35%–52%),[146–152] with over half of the deaths occurring in the first 48 hours.[149,153,154] Overall mortality from ICH has been decreasing because of advances in treatment, whereas a majority of ICH survivors have significant residual disability.[5,155–157] Predictors of poor outcome are impaired level of consciousness, hematoma size, hematoma expansion, associated IVH, age, antecedent antithrombotic use, uncontrolled hypertension, history of diabetes, male gender, and elevated troponin level. Predictive radiographic features of poor prognosis include deep or infratentorial hematoma location, IVH, midline shift, hydrocephalus, hematoma growth, and the presence of the spot or swirl sign on CTA.[77–80,113–115] A number of prognostic models have been developed to allow risk stratification upon presentation with ICH. The ICH score (Table 47.1), which is based on point assignments for GCS, ICH volume, presence of IVH, infratentorial location, and patient age, has been validated to accurately predict 30-day mortality.[158]

Concern has been raised, however, that withdrawal of life-sustaining interventions, including early use of do not resuscitate (DNR) orders in ICH patients, is likely to have a poor outcome bias on predictive models and invalidates the predictive value of other variables.[159–164] Thus the most frequent cause of death after ICH is withdrawal of care,

TABLE 47.1 ICH Score

Component		Score
GCS	13–15	0
	5–12	1
	3–4	2

	Yes	1
TOTAL ICH SCORE		0–6

GCS, Glasgow Coma Scale; *ICH,* intracerebral hemorrhage; *IVH,* intraventricular hemorrhage.

followed by early (within 48 hours) transtentorial herniation with progression to brain death. Medical complications of immobility account for most of the subsequent deaths.[156]

SUBARACHNOID HEMORRHAGE

Epidemiology

Subarachnoid hemorrhage (SAH) is a sudden, dramatic event that has multisystem consequences. Hemorrhagic strokes account for approximately 20% of strokes, of which SAH accounts for 10%. In the United States, SAH accounts for approximately 3% of all strokes.[165] Approximately 80% of nontraumatic SAHs are caused by ruptured intracranial aneurysms. In 2019, a systematic review and meta-analysis concluded that the overall global incidence of aneurysmal was 7.9 per 100,000 person-years.[166] The incidence of aneurysmal SAH varies by geographic location.[166] In 2010, the incidence in North America was 6.9 per 100,000 person-years, whereas it was 28 in Japan and 5.1 for Central and South America regions.[166] Approximately 15%–20% of patients with SAH do not have a vascular lesion on initial cerebral angiography, referred to as *nonaneurysmal SAH.*[167] One-quarter of patients presenting with SAH die before reaching medical attention,[168] and because of secondary insults (rebleeding, hydrocephalus, and delayed ischemia), more than half of those who reach medical attention either die or are left with significant neurologic deficits.

Causes and Risk Factors

Rupture of saccular aneurysms is the most common cause of spontaneous SAH. Cigarette smoking and hypertension are the most common modifiable risk factors associated with aneurysmal formation.[169,170] Genetic conditions susceptible to developing aneurysms include polycystic kidney disease and connective tissue disorders. In some patient populations, genetic factors play a role in aneurysm formation without other associated conditions.[171] Some environmental factors have been implicated in increasing the susceptibility in the familial form.[172,173] Other types of aneurysms that less commonly cause SAH include atherosclerotic, mycotic, and traumatic aneurysms. Trauma is the most common cause of nonaneurysmal SAH. AVMs, stimulant abuse, neoplasia, and vasculitis account for the bulk of the remainder of cases. SAH may accompany ICH, particularly in the setting of CAA. In 10%–15% of cases of SAH, no source of bleeding is identified.

Pathophysiology

In SAH, the primary site of bleeding is the subarachnoid space, but it may also involve hemorrhage into the brain parenchyma, ventricular system, or subdural space.[174,175] Aneurysm rupture causes local tissue damage because of the jet of blood under arterial pressure, in addition to a transient increase in ICP to match arterial pressure. Saccular, or berry, aneurysms are small, rounded protrusions of the arterial wall occurring predominantly at bifurcations of the large arteries of the circle of Willis at the base of the brain. About 20% of patients have multiple aneurysms.

Most aneurysms rupture at the dome, where the wall may be as thin as 0.3 mm. Tension on the aneurysm wall is determined by the radius of the aneurysm and the pressure gradient across the wall. The probability of rupture is related to location and size. The most common sites of ruptured aneurysms are the distal internal carotid artery and its posterior communicating artery junction (41%), anterior communicating artery/anterior cerebral artery (34%), middle cerebral artery (20%), and vertebrobasilar arteries (4%).[176] Aneurysms less than 5 millimeters in diameter have a very low rate of rupture, and the aneurysm–to–vessel size ratio may help predict the risk of rupture.[177]

Clinical Features

Presentation

The most common initial symptom of SAH, occurring in over 90% of patients, is a sudden and severe thunderclap headache.[178] Less severe warning or sentinel headaches may precede the presenting event in as many as half of patients and are thought to represent minor aneurysmal leaks.[179] In about half of patients, loss of consciousness accompanies the headache because of either the sudden surge in ICP at the moment of hemorrhage or cardiac arrhythmias.[180,181] Vomiting can be a prominent symptom. Seizures may be reported,[182] but it is unclear whether this represents true epileptic seizures or reflex posturing. Focal deficits at the onset of hemorrhage occur in less than 10% of cases. Meningismus, characterized by a stiff neck, can develop after a few hours, reflecting meningeal inflammation induced by the presence of blood in the subarachnoid space.[183]

Complications

Neurologic and medical complications are common after SAH and contribute significantly to morbidity and mortality.[184] A worsening of neurologic status often indicates one of the four major complications of SAH: rebleeding, hydrocephalus, vasospasm, or delayed cerebral ischemia (DCI). An understanding of the timing and nature of the deterioration facilitates rapid diagnosis and treatment. It must be emphasized that systemic perturbations such as infection, hyponatremia, fever, hypoxia, and hypotension may produce similar symptoms and should be sought out and corrected as part of the evaluation process.

Rebleeding. Rebleeding is heralded by a sudden worsening of headache, vomiting, blood pressure elevation, development of a new neurologic deficit, or arrhythmia. It occurs in up to one-third of patients and has a mortality rate of up to 70%. The risk of rebleeding is greatest during the first 24 hours (4%–14%),[185] declining rapidly over the next 2 weeks. Rates of rebleeding are highest in patients with seizure or loss of consciousness at onset, previous sentinel headaches, large aneurysm size, those who are a poor clinical grade, those who have hypertension, and longer time to aneurysm treatment.[185,186] Rerupture is associated with a significantly high mortality.[187]

Hydrocephalus. Hydrocephalus occurs in approximately 20%–30% individuals after SAH because of disturbances of CSF flow or reabsorption. Acute hydrocephalus can develop within the first few minutes to hours of SAH,[188] often in the absence of intraventricular blood. It usually manifests as a gradual decline in the level of consciousness

and can easily be treated by placement of an EVD. In many, but not all, patients, ocular signs of elevated ICP (miosis, downward-eye deviation, or restricted upgaze) occur. Delayed hydrocephalus may also develop gradually days to weeks later. If acute hydrocephalus is untreated, about one-third of patients progress, one-third spontaneously improve, and one-third remain static.[189]

Vasospasm and delayed cerebral ischemia. The term *vasospasm* refers to complex changes in intracerebral vessels, with segmental or diffuse narrowing of the lumen secondary to spasmogenic substances generated from lysed blood clots. If the reduction in flow is severe enough, ischemia and infarction typically follow. The term *DCI* describes the clinical scenario where vasospasm, impaired autoregulation, hypovolemia, spreading cortical depression, and microthrombosis combine to produce ischemia.[190] Arterial narrowing can be detected angiographically in up to 70% of patients,[191] of whom almost half will have symptoms. The onset of vasospasm is delayed, most commonly developing 5–10 days after initial hemorrhage, and may persist for up to 3 weeks. The strongest predictors of vasospasm are clinical condition on presentation and the amount of subarachnoid blood on the initial CT scan.[192–194] The highest risk is in those who have thick subarachnoid clots and intraventricular blood (graded using a modified Fisher Scale; Table 47.2).[192,193] Focal neurologic deficits resulting from vasospasm may appear abruptly or gradually and may fluctuate, exacerbated by hypovolemia, hypotension, or fever. If untreated, cerebral infarction may occur.

Hypertension. Blood pressure is often elevated after SAH and is associated with a greater risk of rebleeding, vasospasm, and mortality. Multiple factors may underlie the rise in blood pressure, including increased sympathetic outflow, agitation, and pain. Early on, blood pressure management focuses on treating hypertension to help prevent re-rupture of the aneurysm. After repair of the aneurysm, the risk of rebleeding is decreased, and spontaneous elevations in blood pressure should be allowed to occur without intervention, because the risk of vasospasm becomes the primary concern in management.

Hyponatremia and hypernatremia. Disturbances in sodium and water balance occur in about one-third of patients, and hyponatremia and volume depletion after SAH are correlated with an increased risk of symptomatic vasospasm and poor outcome.[195–197] Although hyponatremia was previously attributed to syndrome of inappropriate antidiuretic hormone (SIADH), later evidence suggests that both sodium and water are lost because of cerebral salt wasting (CSW).[198] SIADH is a state of euvolemia or hypervolemia, whereas CSW is a hypovolemic state.[198] In fact, when administered normal, maintenance volumes of fluid (2–3 L/day), as many as half of patients develop intravascular volume contraction.[199]

TABLE 47.2 Fisher Grade of Subarachnoid Hemorrhage on Initial CT Scan

1. No blood detected
2. Diffuse or vertical layers <1 mm thick
3. Localized subarachnoid clot and/or vertical layers ≥1 mm thick
4. Intraparenchymal or intraventricular clot with diffuse or no SAH

Modified Fisher CT Rating Scale

1. Minimal or diffuse thin SAH without IVH
2. Minimal or thin SAH with IVH
3. Thick cisternal clot without IVH
4. Thick cisternal clot with IVH

CT, Computed tomography; *IVH,* intraventricular hemorrhage; *SAH,* subarachnoid hemorrhage.

Cardiopulmonary. Cardiac abnormalities are common in the first 48 hours after SAH. Electrocardiographic (ECG) changes, including peaked T waves (cerebral T waves), diffuse T-wave inversion, ST-segment depression, and prolonged QT segments,[200,201] occur frequently and are linked to elevated levels of circulating catecholamines. These changes usually do not represent myocardial ischemia, as the myocardial lesions reported are pathologically distinct from ischemia. Cardiac enzymes may be mildly elevated.[202] Cardiac rhythm disturbances occur in about 30%–40% of patients, especially on the day of hemorrhage or in the postoperative period.[203,204] In rare cases, a stunned myocardium, referred to as *Takotsubo cardiomyopathy,* may occur, with impairment of myocardial contractility leading to a fall in cardiac output, hypotension, and pulmonary edema.[205] Apical ballooning is a common echocardiographic finding. This can be dramatic but is transient, usually lasting 2–3 days, after which cardiac function recovers.[206] Management is the same as with other causes of cardiogenic shock.[207] During hemodynamic treatment for vasospasm, pulmonary edema may occur in up to one-quarter of patients,[208] although its incidence is now lower with careful monitoring.[209]

Diagnostic Studies

CT is the imaging modality of choice in screening for SAH.[210] Blood appears as high attenuation within the basal cisterns, Sylvian fissure, and sulci (Fig. 47.3). CT may fail to demonstrate SAH if the volume of blood is very small, if the hemorrhage occurred several days before the CT scan, or if the hematocrit is extremely low.[211] Lumbar puncture for CSF analysis is indicated if the CT is negative and clinical suspicion is high. Red blood cells in the CSF are indicative of SAH but can also be seen with traumatic puncture. The common technique of comparing cell counts in the first and last tubes collected is not reliable; however, the presence of yellow pigment (xanthochromia), resulting from red cell breakdown, can help distinguish between the two.[212] Xanthochromia develops 6 hours after hemorrhage and persists for 1–4 weeks.[213]

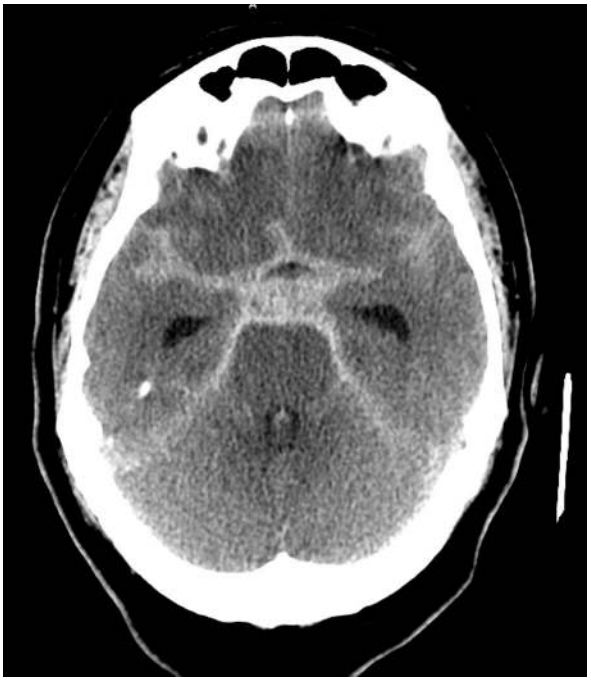

Fig. 47.3. Characteristic CT Scan Showing Acute Aneurysmal Subarachnoid Hemorrhage with Blood in the Perimesencephalic Cisterns and Sylvian Fissures.

Once the diagnosis of SAH is established, the etiology must be determined. With its wide availability, ease of use, and safety profile, CTA is increasingly being used as the initial diagnostic tool. Overall sensitivity is more than 90% compared with conventional angiography but is notably lower for aneurysms smaller than 5 mm[214]; thus a negative CTA should be followed by conventional catheter angiography.[215] Magnetic resonance angiography (MRA) has good sensitivity for detecting medium and large aneurysms, but sensitivity falls to less than 40% for small aneurysms. MRA and CTA may also be of assistance in planning surgical or endovascular approaches to treatment.

Angiography fails to identify a source of bleeding in 10%–15% of patients with nontraumatic SAH. Repeat angiography in about 1 week is thus recommended.[216] There are a subset of patients in whom the blood on CT is localized to the perimesencephalic cisterns. In these cases, angiography is usually negative, and the bleeding is thought to be venous in origin; the prognosis is typically excellent, and repeat angiography is almost always negative.[215]

Treatment

In 2011, the Neurocritical Care Society (NCS) held an international consensus conference on the critical care management of patients with SAH, and evidence-based recommendations were developed.[217]

Initial Stabilization

The initial steps in the evaluation of a patient with suspected SAH should include assessment of airway, hemodynamic status, and the level of neurologic function. The Hunt and Hess Scale[218] and the World Federation of Neurological Surgeons Scale[219] provide standardized measures of the patient's clinical condition (Tables 47.3 and 47.4). These scales should be scored after the patient is stabilized, including treatment of seizures and hydrocephalus if indicated. If the patient is lethargic or agitated, elective intubation should be considered before angiography, as sedation is often necessary. Indications for endotracheal intubation include a GCS ≤8, elevated ICP, poor oxygenation or hypoventilation, hemodynamic instability, and requirement of heavy sedation or paralysis.

TABLE 47.3 Hunt and Hess Clinical Classification of Subarachnoid Hemorrhage

Grade	Neurologic Status
I	Asymptomatic or mild headache and neck stiffness
II	Moderate to severe headache and neck stiffness ± cranial nerve palsy
III	Mild focal deficit, lethargy, or confusion
IV	Stupor, moderate to severe hemiparesis
V	Deep coma, extensor posturing

TABLE 47.4 World Federation of Neurological Surgeons Clinical Classification of Subarachnoid Hemorrhage

Grade	Glasgow Coma Scale	Motor Deficits
I	15	Absent
II	13–14	Absent
III	13–14	Present
IV	7–12	Present or absent
V	3–6	Present or absent

Admit or Transfer to an Expert Center

Early, aggressive, and expert care can dramatically affect outcomes in SAH. Dedicated neurocritical care units and expert staff, including neurocritical care intensivists, neurosurgeons, and neurovascular surgeons, play a critical role in providing appropriate care of SAH patients.[220–224]

Routine Care and Monitoring

The routine monitoring of all patients with acute SAH should include serial neurologic examinations; continuous ECG monitoring; and frequent determinations of blood pressure, electrolytes, body weight, and fluid balance.

Antithrombotic Reversal

Initial management should include discontinuation of all antithrombotic therapy. The 2015 NCS and Society of Critical Care Medicine (SCCM) guidelines recommend reversal of antithrombotics until the aneurysm is secured. For patients on antiplatelet therapy deemed to be candidates for neurosurgical procedures, a single IV dose of desmopressin and platelet transfusion are reasonable after platelet function testing demonstrates decreased function.[225]

Seizure Prophylaxis

Use of prophylactic anticonvulsants is controversial but may be reasonable in the immediate posthemorrhagic period in patients with unsecured aneurysm, poor neurologic grade, and associated ICH; however, the duration of administration should be limited to several days.[185,226] Recent retrospective studies have suggested that routine use of anticonvulsants for a longer duration is associated with worse neurologic outcome.[227,228]

Fluid Management

A stable intravascular volume should be maintained by hydration with crystalloids or colloids.[185] The goal of IV fluids is to achieve and maintain euvolemia, a counterbalance to vasospasm.[229] Combining multiple clinical indicators of volume status such as daily monitoring of fluid balance, body weight, hematocrit, central venous pressure, and replacing urine output is needed.[185,230]

Sodium Homeostasis

Hyponatremia in SAH can be either from SIADH or CSW.[198] SIADH is often managed with restriction of free water, which is not desirable in SAH patients. Thus hypertonic fluids should be used to treat hyponatremia associated with SIADH. There may be a role for antidiuretic hormone (ADH) antagonists such as conivaptan, but because they increase urine volume, extreme caution must be exercised to avoid hypovolemia.[231] In CSW, excessive secretion of natriuretic peptides leads to hypovolemia and hyponatremia. Aggressive fluid resuscitation with isotonic or hypertonic fluids is required to prevent intravascular volume contraction.[232,233] Fludrocortisone may be helpful in treating salt wasting and hypovolemia[198,199,234,235]

Hypertension

Optimal management of blood pressure is not well defined in SAH patients. SBP <140 mm Hg or MAP <100 mm Hg is a reasonable goal in patients with unsecured aneurysm.[185,217] Initial attempts to treat hypertension should include analgesics and nimodipine; other antihypertensive agents should follow if needed. Useful medications include intermittent doses of beta-blockers and vasodilators. If a continuous infusion is needed, nicardipine or clevidipine are effective.[185] When

significant hydrocephalus is present, hypertension should not be treated until after the hydrocephalus is addressed, as the hypertension may be acting to maintain adequate cerebral perfusion in the face of elevated ICP.

DVT Prophylaxis

Intermittent pneumatic compression devices should be started on admission even before the definitive treatment of aneurysm,[176] with subcutaneous heparin started after securing the aneurysm.

Magnesium Sulfate

Magnesium antagonizes calcium and thus can potentially reduce vasospasm, but recent meta-analysis and systematic review found no support for its use.[236,237]

Statins

Statins are not routinely recommended in the treatment of SAH patients.[238] A multicenter phase III trial of simvastatin 40 mg or placebo found no short- or long-term benefit of the drug.[239]

Aneurysm Treatment

Surgical and endovascular methods are available to secure the ruptured aneurysm. Surgical management involves placing a clip across the neck of the aneurysm. Advancement of microsurgical techniques has made clipping a safe and effective method. Endovascular techniques such as electrolytically detachable platinum coils, stent-assisted coiling, and balloon-assisted coiling are routinely used to repair ruptured aneurysms.[185]

Management of Secondary Complications

Rebleeding.

Multiple clinical trials have demonstrated that antifibrinolytic agents such as aminocaproic acid and tranexamic acid (TXA) reduce the risk of rebleeding, but this benefit is offset by an increased incidence of vasospasm and hydrocephalus.[240,241] With the advent of early intervention, the use of these agents has declined dramatically. More recently, there has been interest in a shorter course of antifibrinolytic therapy while awaiting surgery or endovascular treatment in the absence of medical contraindications.[185] TXA begun immediately upon SAH diagnosis and continued until the aneurysm was secured (within 72 hours) reduced the risk of rebleeding from 10.8% to 2.4% and did not increase the risk of DCI.[242]

Other measures directed at prevention of rebleeding include avoiding situations that produce sudden changes in the transmural pressure across the wall of the aneurysm. Patients are placed on bed rest and stimulation minimized. Agitated patients should be carefully sedated and long-acting agents avoided. Measures should be taken to minimize cough and Valsalva maneuvers. Stool softeners are administered to avoid straining. The definitive way to prevent rebleeding is to repair the aneurysm[243] by surgical or endovascular means as early as possible, preferably within 24 hours.

Hydrocephalus

The decision to treat hydrocephalus is usually based on the CT appearance of enlarging ventricles in a patient whose level of consciousness is deteriorating. During placement of an EVD, the CSF pressure must be reduced slowly to lessen the risk of aneurysmal re-rupture. CSF drainage may be needed for many days to clear intraventricular blood before it can be determined if a permanent shunt is required. Approximately 14%–40% of patients with acute hydrocephalus develop shunt-dependent chronic hydrocephalus. The need for a shunt is evaluated in the subacute period with weaning of the EVD and subsequent clamping trial.[228,244–246]

Delayed Cerebral Ischemia

Approximately 30% of cases of SAH are complicated by DCI, which typically occurs between 3 and 14 days after symptom onset.[247,248] It contributes significantly to morbidity and mortality.[185] Vasospasm is presumed to be the most common cause of DCI.[249] Monitoring for DCI involves serial neurologic examinations, serial transcranial Doppler (TCD),[250,251] and catheter angiography. Neurologic signs may be vague, such as a global decline in responsiveness, or may include focal deficits. Symptoms may wax and wane, being exacerbated by hypovolemia or hypotension. Daily TCD recordings provide a window of opportunity for vasospasm treatment before neurologic decline. Vasospasm can be identified on TCD by an increase in linear blood flow velocity, defined as mild (>120 cm/sec), moderate (>160 cm/sec), or severe (>200 cm/sec).[252] Alternatively, the rate of rise in the Lindegaard Ratio, calculated as mean velocity in the middle cerebral artery (MCA) / mean velocity in ipsilateral extracranial internal carotid artery, is used to define the onset of vasospasm. The sensitivity of TCD in detecting vasospasm is about 80% when compared with angiography, at least partly because TCD samples only a small segment of the vasculature.[253] Noninvasive techniques such as CTA and CT perfusion (CTP) can be used to confirm DCI on TCD.[185] Digital subtraction angiography (DSA) is recommended in patients with symptomatic vasospasm who might benefit from intervention.

When making a clinical diagnosis of DCI, alternative causes of neurologic changes such as sedatives, rebleeding, hydrocephalus, cerebral edema, seizures, metabolic derangements, and infections should be promptly excluded. Detection of clinical signs of DCI is particularly difficult in poor-grade patients because of the limited examination that is possible.

Prevention. Routine measures taken to reduce the risk of DCI include mechanical removal of subarachnoid blood at the time of aneurysm surgery or by CSF drainage, administration of the centrally acting calcium channel antagonist nimodipine, and avoidance of intravascular volume contraction or hypotension. Nimodipine for 3 weeks after SAH is the standard of care and improves functional outcomes.[254–256] Its beneficial effect may be the result of action on the cerebral vessels or by preventing calcium influx into ischemic neurons. Any hypotension developing with nimodipine can usually be managed with fluids or by adjusting the dosage schedule. If the impact of nimodipine on blood pressure cannot be overcome in patients with DCI, it may have to be discontinued and reevaluated when hemodynamically stable.

Although there is general agreement that hypovolemia must be avoided, the use of prophylactic hypervolemia is more controversial.[185,257–259] In a prospective controlled study, prophylactic volume expansion with albumin failed to reduce the incidence of clinical or TCD-defined vasospasm and had no effect on outcome.[260] Costs and complications may be higher with the use of prophylactic hypervolemia.

Prophylactic use of transluminal balloon angioplasty was evaluated in a prospective, randomized controlled trial.[261] Although it reduced the need for therapeutic angioplasty and reduced ischemic deficits, these benefits were offset by procedure-related vessel complications.

Treatment of DCI

The trigger for instituting more aggressive interventions varies widely. Some centers actively intervene in the setting of rising TCD velocities[262] or angiographic vasospasm in asymptomatic patients,[263] whereas others institute aggressive measures in the setting of clinical deterioration. Aggressive measures include both hemodynamic and endovascular manipulations.[264–266] The goal is to improve CBF in ischemic regions. Hemodilution, hypervolemia, and induced hypertension *(triple H therapy)* was previously employed to achieve an increase in CBF, but accumulating evidence has shown that maintaining euvolemia and only inducing hypertension during vasospasm are beneficial.[229,267,268]

Induced Hypertension

Blood pressure augmentation is considered the first-line therapy for DCI in euvolemic patients and can be achieved with vasopressor agents, although the optimal target is not well defined.[229] Goals for blood pressure should be defined as a percent change from baseline (beginning with an approximately 15% change) rather than prespecified levels.

The presence of other small, untreated aneurysms does not exclude use of this therapy. The degree of blood pressure augmentation should be titrated continuously to the patient's neurologic status; thus if a goal is reached but there is no neurologic improvement, the goal should be modified. Once the optimal goals have been reached, they are usually maintained for 2–3 days and then gradually weaned. Risks associated with this therapy include volume overload, pulmonary edema, heart failure, and cerebral edema.

Anemia is common after SAH and may contribute to DCI by compromising brain oxygen delivery.[185,269] Although transfusion can have beneficial effects on brain physiology, it may be associated with medical complications, infection, vasospasm, and poor outcome after SAH. Still, given the high risk of ongoing cerebral ischemia, the results of the Transfusion Requirements in Critical Care Trial and subsequent observational studies on red blood cell transfusion in general critical care should not be applied to SAH patients.[270,271] Practice surveys indicate that transfusion thresholds of 8–10 g/dL are commonly used, with the higher range reserved for patients with DCI. Current recommendations are to maintain hemoglobin closer to 10 g/dL in patients at risk of ischemia rather than use the standard transfusion threshold of 7 g/dL.[272]

Endovascular Treatments

The endovascular approach to vasospasm involves treatment of constricted vessels with either balloon angioplasty or intraarterial infusion of vasodilating agents.[230,273] Angioplasty on the proximal segments of vasospastic cerebral vessels yields impressive sustained angiographic changes.[274,275] Vasoconstriction in more distal vessels usually cannot be reached by angioplasty catheters and can be treated with intraarterial infusion of vasodilators. Intraarterial papaverine rapidly dilates the entire cerebral vasculature, but reversal of clinical deficits is inconsistent.[276–278] Its use has largely been abandoned because of its short-lived effect and complications, including increased ICP, apnea, worsening of vasospasm, neurologic deterioration, and seizures.[279] It has been replaced by nicardipine, verapamil, nimodipine, and milrinone.[280–282]

The timing of when to initiate endovascular therapy is debated. It is generally used if, after a few hours, the response to hemodynamic augmentation is inadequate, but it may be the initial therapy in patients with poor cardiac function who are at high risk of complications of hemodynamic manipulation.[283]

Endothelin-1 Antagonists

Endothelin-1 (ET-1) is a 21–amino acid peptide that mediates vasoconstriction. In early studies, an endothelin antagonist, clazosentan, reduced angiographic vasospasm[284,285] and tended to reduce vasospasm-related morbidity/mortality. Subsequently, two very large randomized controlled trials confirmed the reduction in angiographic vasospasm, but clazosentan did not change clinical outcome.[286]

Fever

After SAH, fever develops in well over half of patients and is associated with increased length of stay, worse outcome, and higher mortality.[287–290] Early in the disease course, most fevers are central in origin. Antipyretics are effective in a minority of patients, although IV forms may be more effective. Surface and intravascular cooling devices are much more effective, but benefits from cooling may be offset by negative consequences from shivering.[291]

Prognostic Factors and Causes of Mortality

Untreated aneurysmal SAH carries a poor prognosis, with an estimated mortality rate of about 50%.[292,293] Of those who make it to medical attention, mortality is 20%–40%. Causes of death are about equally distributed among direct effects of the initial hemorrhage, rebleeding, vasospasm, and medical complications. Overall, less than one-third of patients achieve good neurologic recovery. Predictors of poor prognosis include loss of consciousness or poor neurologic condition on admission, older age, hypertension, preexisting medical illness, ≥1 mm thickness of subarachnoid blood on CT, seizures, cerebral edema, aneurysm location in the basilar artery, and symptomatic vasospasm.[294–298] Scales quantifying the degree of physiologic illness are also predictive of outcome in patients with SAH.[299] Long-term survivors of the initial hemorrhage continue to suffer a 3% annual risk of re-hemorrhage unless the aneurysm is repaired. Advancements in diagnostic and therapeutic options in neurocritical care are plausible explanations for improved prognosis in patients with SAH.[300]

KEY POINTS

- Major risk factors for primary ICH include hypertension and CAA, which account for nearly 80% of all cases.
- Initial management and stabilization of ICH should include aggressive blood pressure reduction with IV medications to a target blood pressure less than 160 mm Hg and, with caution, to less than 140 mm Hg.
- Prognostic factors in ICH associated with poor outcomes include low CGS on admission, IVH, advanced age, large hematoma size, and infratentorial location of the hemorrhage.
- Abrupt discontinuation and reversal of anticoagulation with ICH are imperative to decrease the risk of hematoma expansion and rebleeding.
- Patients presenting to a tertiary care center with either intracerebral or subarachnoid hemorrhage should be urgently triaged to a neurocritical care intensive care unit based upon evidence of improved outcomes.
- SAH is classified as either nonaneurysmal or aneurysmal, with the latter accounting for 80% of all hemorrhages.
- Early complications such as rebleeding and late complications such as vasospasm and DCI occur in aneurysmal SAH.
- The use of nimodipine in SAH has been shown to improve neurologic outcomes, but not reduce the prevalence of vasospasm.

Seizures in the Critically Ill

Sebastian Pollandt, Adriana C. Bermeo-Ovalle, and Thomas P. Bleck

INTRODUCTION

The routine use of continuous electroencephalographic (cEEG) recordings in intensive care demonstrates that clinical seizures in critically ill patients, both with neurologic and nonneurologic conditions, are the tip of the iceberg regarding seizure frequency in this vulnerable population. Nonconvulsive seizures are detected in 10%–30% of critically ill patients with altered mental status and in up to 60% of critically ill patients who have been witnessed to have prolonged clinical seizures earlier during their hospital stay.[1] The presence of seizures in this population is associated with worse functional outcome at discharge,[2] multiple markers of disease severity,[3] and long-term neurologic injury.[4] The routine use of cEEG monitoring and quantitative EEG (qEEG) analysis leads to the diagnosis of electrographic seizures and timely modification of treatment,[5] which may affect early and long-term disability and mortality. The use of cEEG has become standard care in the intensive care unit (ICU). Its use is strongly recommended in cases of recent status epilepticus, unexplained coma, altered mental status, and behavioral changes and also in most patients with intracranial hemorrhage, as these cases are more likely to be associated with subclinical seizures.[1]

Among patients without primarily neurologic conditions, the presence of a seizure may be the first indication of a central nervous system (CNS) complication; delay in recognition and treatment of seizures is associated with an increased risk of mortality.[6] Thus rapid diagnosis, treatment, and follow-up of epileptic activity and seizures are crucial. In addition, because epilepsy affects around 2% of the population, patients with a predisposition to seizures may enter the ICU for treatment of other systemic problems. These patients are at high risk for developing seizures and status epilepticus in the context of acute or severe illness.[7] Patients developing status epilepticus often require critical care management as treatment escalates to include multiple antiseizure medications and sedatives that require airway protection, hemodynamic support, and close monitoring.

Status epilepticus refers to prolonged seizure activity beyond the usual duration of a self-limited, isolated seizure; it may be the primary indication for admission to the ICU, or it may occur in ICU patients. Seizures that persist longer than 5 minutes or recurrent seizures without recovery to the patient's neurologic baseline between seizures should be considered and treated as status epilepticus.[8] Status epilepticus can also be subclinical, with little or no overt signs of seizures. Of patients monitored with EEG as part of a coma evaluation, 8%–10% were reported to be in nonconvulsive status epilepticus (NCSE).[9] Recognizing the risk factors, clinical presentation, diagnosis, and management of clinical and subclinical seizures in the ICU is a frequent task for the intensivist. Recent technologic advances enormously facilitate the diagnosis and follow-up of these patients in real time. Communication between the ICU team and the neurology/neurophysiology team is crucial to offer the patient timely therapy that significantly affects outcome.[6]

EPIDEMIOLOGY

Limited data are available on the epidemiology of seizures in the ICU. A 10-year retrospective study of all ICU patients with seizures revealed that 7 patients had seizures per 1000 ICU admissions.[10] A 2-year prospective study of medical ICU patients identified 35 with seizures per 1000 admissions.[11] In a retrospective analysis of 570 patients undergoing cEEG monitoring, seizures were detected in 110 patients (19%). Of those patients with seizures, the majority were in ICUs at the time of the EEG ($n = 101$; 89%). In this series, 92% of the recorded seizures were nonconvulsive, requiring EEG for the diagnosis.[12] Up to 34% of hospital inpatients experiencing a seizure die during their hospitalization.[11] In a study of medical ICU patients, having even one seizure while in the ICU for a nonneurologic reason doubled in-hospital mortality.[11] Incidence estimates for status epilepticus in the United States and Europe vary from 10.3 to 41/100,000.[3,13–15] The incidence has a bimodal distribution, peaking in young children and in the elderly.[13,16]

Mortality estimates vary widely, but data suggest that prolonged seizure duration is a negative prognostic factor. For patients whose generalized convulsive status epilepticus (GCSE) resolves within 30–59 minutes, the reported mortality is 2.7%, whereas patients seizing for more than 60 minutes have a mortality of 32%.[17] If GCSE develops de novo in hospitalized patients, the mortality is 61%.[18] For patients in NCSE, the mortality has been reported as high as 57%[6] and correlates with the underlying cause, severe impairment of mental status, and development of complications, especially respiratory failure and infection.[19] Determining the contribution of status epilepticus to mortality is challenging because of the large impact of the underlying etiology on outcomes.

Table 48.1 summarizes the most common causes of status epilepticus in adults in the community. Almost 50% of the cases were attributed to cerebral vascular disease.[20] Antiseizure medication nonadherence is the main cause of status epilepticus in patients with a previous history of epilepsy; CNS infection, stroke, and metabolic disturbances predominate in patients without previous seizures.[7]

Limited data are available concerning the functional abilities of GCSE survivors, and no data reliably permit distinction between the effects of status epilepticus and the effects of its causes. GCSE has the worst prognosis for neurologic recovery. Causes associated with increased mortality include anoxia, intracranial hemorrhages, tumors, infections, and trauma. In addition, intellectual ability declines as a consequence of status epilepticus.[21] Survivors of status epilepticus often have memory and behavioral disorders out of proportion to the structural damage produced by the cause of their seizures. Case reports

of severe memory deficits after prolonged focal status epilepticus with impairment of consciousness have been published.[22] Conversely, one prospective study of 180 children with febrile status epilepticus reported no deaths or new cognitive or motor disability.[23] Experimental animal[24] and human[25] epidemiologic studies suggest that status epilepticus may be a risk factor in the development of future seizures. Whether treatment of prolonged seizures reduces the risk of subsequently developing epilepsy remains uncertain.

CLASSIFICATION

Seizures are the clinical manifestation of the underlying predisposition for abnormal excessive and synchronous brain activity that defines epilepsy. Seizures can affect all measurable brain functions and follow a predictable clinical presentation largely related to the site of origin of the epileptic activity and the pattern of propagation.

The most recent revision of the terminology and classification of seizures and epilepsy from the International League Against Epilepsy (ILAE) was published in 2017 (Table 48.2).[26–29] Seizures are initially divided into focal- versus generalized-onset or unknown-onset seizures. Focal seizures are then further subdivided into focal-aware or focal-impaired awareness seizures. Additional classifiers for motor onset and nonmotor onset may be added. The motor classifiers include automatisms, atonic, clonic, epileptic spasms, hyperkinetic, myoclonic, and tonic, whereas nonmotor classifiers are autonomic, behavior arrest, cognitive, emotional, and sensory. Similarly, generalized-onset seizures are classified based on motor (e.g., tonic-clonic, myoclonic, atonic, and others) or nonmotor (i.e., typical absence, atypical absence, myoclonic) features.[26,27,29]

The ILAE terminology classifies epilepsy types based on varying levels of diagnosis: seizure type, epilepsy type, and epilepsy syndrome. Based on the three seizure types (focal, generalized, or unknown), the epilepsy type is determined as either focal, generalized, combined generalized and focal, or unknown. Potential etiologies should be considered, which include structural, genetic, infectious, metabolic, immune, or unknown etiologies. Epilepsy syndromes such as juvenile myoclonic epilepsy or childhood absence epilepsy refer to a cluster of features (seizure type, EEG, and imaging findings) that typically occur together.[28] Determining the epilepsy type may aid in the selection of treatment options and prognosis. Careful

description of the phenomenology of seizures, etiology, and localization continues to be an important part of the patient's care. The identification of clinical features of seizures can be challenging in the ICU, except for observation of motor manifestations. ICU patients often have altered awareness caused by medications, hypotension, sepsis, or intracranial lesions; thus the presentation of focal seizures may be difficult to establish by observation alone, and EEG monitoring is often the only way to determine if a patient is seizing.

An ICU patient who has continuous, regular repetitive contractions in a stable muscle group in the right arm while awake and responsive can be classified as having focal right arm clonic status epilepticus without impairment of consciousness or awareness. *Epilepsia partialis continua,* a special form of focal status epilepticus in which repetitive movements of epileptic origin affect a small area of the body, can sometimes continue relentlessly for months or years and is notoriously refractory to treatment. The ILAE continues to work toward revising

and updating the current classification system. For the most recent information, refer to www.ilae.org.[30]

PATHOGENESIS AND PATHOPHYSIOLOGY

The causes and effects of status epilepticus at the cellular, brain, and systemic levels are interrelated, but their individual analysis is useful for understanding them and their therapeutic implications. The ionic events of a seizure follow the opening of ion channels coupled to excitatory amino acid receptors. From the standpoint of the intensivist, three channels are important, as their activation may raise intracellular free calcium to toxic levels: alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor (AMPAR), *N*-methyl-D-aspartate receptor (NMDAR), and metabotropic channels. These excitatory amino acid systems are crucial for learning and memory. Counterregulatory ionic events are triggered by the epileptiform discharge as well, such as the activation of inhibitory interneurons suppressing excitatory neurons via ionotropic gamma-aminobutyric acid ($GABA_A$) synapses.

The cellular effects of excessive excitatory amino acid channel activity include the following: (1) generation of toxic levels of intracellular free calcium; (2) activation of autolytic enzyme systems; (3) production of oxygen free radicals; (4) generation of nitric oxide, which both enhances subsequent excitation and serves as a toxin; (5) phosphorylation of enzyme and receptor systems, making seizures more likely; and (6) an increase in intracellular osmolality, producing neuronal swelling. If adenosine triphosphate production fails, membrane ion exchange ceases, and neurons swell further. These events produce the neuronal damage associated with status epilepticus. Longer status epilepticus duration produces profound alterations and an increasing likelihood of becoming refractory to treatment.[31] Many other biophysical and biochemical alterations occur during and after status epilepticus. The mechanisms by which status epilepticus damages the nervous system have been reviewed.[32,33] Absence status epilepticus is an exception; it consists of rhythmically increased inhibition and does not appear to produce clinical or pathologic abnormalities.[34]

The electrical phenomena of status epilepticus seen in the scalp EEG reflects the seizure type (e.g., absence status epilepticus begins with a 3-Hz spike-and-wave pattern). The sustained depolarizations that characterize status epilepticus alter the extracellular milieu, raising extracellular potassium, which subsequently exceeds the buffering ability of astrocytes.

The increased cellular activity of status epilepticus increases oxygen and glucose demands, and cerebral blood flow initially increases. After about 20 minutes, however, energy supplies are exhausted, causing local catabolism to support ion pumps, which is thought to be a major cause of epileptic brain damage. GCSE also produces life-threatening systemic effects.[35] Excess secretion of epinephrine and cortisol causes systemic and pulmonary arterial pressures to rise dramatically at seizure onset and produce hyperglycemia. Muscular work accelerates heat production, increases core body temperature, and raises blood lactate levels. Airway obstruction and abnormal diaphragmatic contractions impair respiration. Carbon dioxide production increases markedly while excretion falls. The combined respiratory and metabolic acidosis frequently reduces the arterial blood pH to 6.9 or lower. The associated hyperkalemia has deleterious effects on cardiac electrophysiology and may propagate seizure activity. Coupled with hypoxemia and the elevation of circulating catecholamine levels, these conditions can produce cardiac arrest. Neurogenic pulmonary edema is the likely cause of death in many cases. Rapid termination of seizure activity is the most appropriate treatment; the restitution of ventilation and the metabolism of lactate quickly restore a normal pH.

After about 30 minutes of continuous convulsions, motor activity may diminish while electrographic seizures persist. Hypotension and hyperthermia ensue, and gluconeogenesis can fail, resulting in hypoglycemia. GCSE patients often aspirate oral or gastric contents, producing chemical pneumonitis or bacterial pneumonia. Rhabdomyolysis is common and may lead to renal failure. Compression fractures, joint dislocations, and tendon avulsions are other serious sequelae.

The mechanisms that terminate seizure activity are poorly understood. Leading candidates are inhibitory mechanisms, primarily GABAergic interneurons and inhibitory thalamic neurons.

CLINICAL MANIFESTATIONS

The ICU environment poses a challenge to early seizure recognition because of multiple factors: (1) the occurrence of nonconvulsive seizures in patients with impaired awareness, (2) the occurrence of seizures in patients receiving neuromuscular blockade and/or sedation, and (3) misinterpretation of nonepileptic abnormal movements and behaviors as seizures. The most common symptom of nonconvulsive status epilepticus is altered mental status. Although other symptoms such as speech disturbances, myoclonias, bizarre behaviors, and others do occur, they are far less frequent.[36] ICU patients often have depressed consciousness in the absence of seizures owing to their disease, its complications (such as hepatic[37] or septic[38] encephalopathy), or drug administration. A further decline in alertness may reflect a seizure, but unless actions are taken to make this diagnosis, seizures and even status epilepticus may go unrecognized.

Patients receiving neuromuscular blocking agents do not manifest motor signs of seizures. Patients with increased intracranial pressure (ICP) from primary brain injury, hepatic encephalopathy, or other critical illnesses may be both paralyzed and sedated, making identification of seizures challenging in the absence of EEG monitoring. Tachycardia, tachypnea, and hypertension are signs of seizures that can be misinterpreted as evidence of inadequate sedation or primary cardiorespiratory conditions.

Seizures are the second most frequent neurologic complication after encephalopathy in critically ill patients with primarily nonneurologic conditions,[11] making it imperative for ICU providers to be able to identify and suspect the presence of seizures in all patients with altered awareness in the ICU setting.

Generalized motor seizures and convulsive status epilepticus are more common in patients with a prior history of epilepsy in relation to acute illness or medication nonadherence. However, even among patients without a history of epilepsy, subtle clinical seizures and NCSE are increasingly recognized in the context of systemic illness or acute brain injury. Nonconvulsive seizures and NCSE occur in 10%–30% of patients with altered mental status in the ICU. Risk factors include the presence of CNS infection (meningitis or encephalitis) and focal lesions such as a brain tumor or an area of encephalomalacia. Seizures in the ICU are often subtle and may be related to the anatomic location of the brain lesion. Minor twitching of the face or extremities, fluctuating levels of awareness or level of interaction, nystagmus or eye deviation, abnormal orofacial movements, and repetitive blinking are more commonly seen than generalized tonic-clonic events. cEEG monitoring is warranted in this population if seizures are suspected, because a delay in the diagnosis and treatment of NCSE likely leads to worse functional prognosis at discharge and increased mortality.[39]

Patients with metabolic disturbances, anoxia, and other types of CNS injuries may demonstrate abnormal movements that can be mistaken for a seizure. Asterixis is a brief asynchronous loss of tone at the wrist or hip joints that can appear in the setting of metabolic encephalopathy. Stimulus-sensitive massive myoclonus after anoxia can be

dramatic but usually self-abates in a few days. Controversy exists as to the epileptic origin of this disorder, and post–anoxic myoclonus has been reported in the presence of almost total cortical suppression.[40] Brain-injured patients may manifest paroxysmal sympathetic hyperactivity and associated rigidity or extensor posturing.[41] Patients with tetanus are awake during their spasms and flex rather than extend their arms as seizure patients do. Psychiatric disturbances in the ICU occasionally manifest as psychogenic nonepileptic events. As these events tend to cluster and manifest as dramatic convulsive episodes, they are often treated in the emergency department as refractory status epilepticus, which may prompt ICU admission. The clinical manifestations of seizures and status epilepticus depend on the type and the cortical area of abnormality. Table 48.2 presents the classification of epileptic seizures recognized by the ILAE; all of these may be seen in the ICU.

Convulsive seizures or status epilepticus are described when the main characteristics of the seizures are generalized tonic-clonic movements. During the tonic phase, there is a sustained muscle contraction of a group of muscles in a regional or generalized distribution. During the clonic phase, there are regular, predictable, rhythmic, and repetitive contractions of a muscle group. Myoclonic seizures are brief, involuntary muscle contractions; they are unpredictable and irregular. Motor seizures can manifest in any combination of the described motor phenomena and in any order; they can involve the axial muscles and extremities from the beginning of the seizure without warning, or they can start regionally in one body part and progress into a generalized motor seizure.

When a patient with GCSE is treated with antiseizure medications in inadequate doses, visible convulsive activity can stop, but the electrographic seizure may continue. A prospective evaluation of 164 patients showed that nearly half manifested persistent electrographic seizures in the 24 hours after clinical control of convulsive status epilepticus.[42] Thus EEG monitoring after control of convulsive status epilepticus is essential in directing therapy.[43]

Patients typically begin to awaken within 15–20 minutes after the successful termination of status epilepticus; many regain consciousness much faster. Patients who do not start to awaken after 20 minutes should be assumed to have entered NCSE. Careful observation may disclose slight motor activity as described earlier. However, patients may present in NCSE without an inciting episode of GCSE. Failure to recognize NCSE is common in patients presenting with nonspecific neurobehavioral abnormalities such as delirium, lethargy, bizarre behaviors, cataplexy, or mutism.[44] A high suspicion of this disorder should be maintained in ICU patients with unexplained alteration of consciousness or cognition.

DIAGNOSTIC APPROACH

Observation is very important when a patient has a single clinical seizure, as this is the time to collect evidence of a focal onset suggestive of a structural brain lesion. The postictal examination is similarly valuable; language, motor, sensory, or reflex abnormalities after an apparently generalized seizure may uncover evidence of focal pathology.

Seizures in ICU patients have several potential causes that must be investigated. Drugs are a major cause of ICU seizures, especially in the setting of diminished renal or hepatic function or when the blood-brain barrier is breached. Imipenem-cilastatin[45] and fluoroquinolones[46] can lower the seizure threshold, especially in patients with renal dysfunction. However, they should be avoided in patients at risk for seizures. Other antibiotics, especially beta-lactams, are also implicated.[47] Sevoflurane, a volatile anesthetic agent, is dose-dependently epileptogenic in patients with no predisposition to seizures.[48]

Recreational drugs are overlooked offenders in patients presenting to the ICU. Acute cocaine or methamphetamine intoxication is characterized by a state of hypersympathetic activity followed by seizures.[49] Although ethanol withdrawal is a common cause of seizures, discontinuing any hypnosedative agent may prompt convulsions 1–3 days later. Narcotic withdrawal may produce seizures in the critically ill.[11] In the absence of a structural etiology for the seizure, complete toxicologic, infectious, and metabolic screening should be performed.

Serum glucose, electrolyte concentrations, and serum osmolality should be measured. Nonketotic hyperglycemia[50,51] and hyponatremia can precipitate both focal and generalized seizures. Seizure activity may infrequently be the first presenting sign of diabetes mellitus. Hypocalcemia rarely causes seizures beyond the neonatal period, and its identification on analysis must not signal the end of the diagnostic work-up. Hypomagnesemia has an equally unwarranted reputation as the cause of seizures in malnourished alcoholic patients.

The physical examination should emphasize assessment for both global and focal abnormalities of the CNS. Evidence of cardiovascular disease or systemic infection should be sought, and the skin and fundi examined closely. The need for imaging studies should be addressed as soon as the clinical seizure is controlled. The management of epileptic seizures and convulsive status epilepticus should not be delayed by the need to obtain images or neurophysiologic data. If possible, treatment and diagnostic strategies should be instituted simultaneously. A prospective study in medical ICU patients determined that 38 of 61 patients (62%) had a vascular, infectious, or neoplastic explanation for their seizures.[11] Magnetic resonance imaging (MRI) should be performed on all ICU patients with new-onset seizures. Many ICP monitors are compatible with MRI. Patients who need cerebrospinal fluid analysis always require imaging of the brain first. When CNS infection is suspected, empiric antibiotic treatment should be started while these studies are being performed.

EEG is a vital diagnostic tool for evaluating patients with diagnosed or suspected seizures. Focal seizures usually show EEG abnormalities that begin in the region of cortex that produces seizures. Primary generalized seizures show bilateral hemispheric involvement from the onset. Postictal slowing or an asymmetric EEG amplitude provides clues as to the focal cause of the seizures, and epileptiform activity helps classify the type and origin of epileptic activity and may guide treatment. An emergency EEG is necessary to exclude NCSE soon after clinical seizures have apparently been controlled (Fig. 48.1).

cEEG can help establish the diagnosis, frequency, localization, and duration of seizures. It also aids in the evaluation of the response to treatment and degree of encephalopathy. It offers continuous and often long-term data and real-time feedback that can be lifesaving in the ICU, with few added risks or costs to the patient.[52] Given the high prevalence of NCSE in this patient population and the low relative risks associated with cEEG, a low level of suspicion should trigger such evaluation. The advent of modern techniques of EEG analysis and trend analysis, as in qEEG, are invaluable in the ICU, as they allow the reviewer to identify trends of electrographic activity over longer periods, identify subtle asymmetries, and aid in the identification and quantification of EEG seizures. The use of this technology has gained recent attention and interest from the EEG and the ICU community. Indications for cEEG include patients with altered mental status and history of epilepsy, fluctuating level of consciousness, acute brain injury, after convulsive status epilepticus, and abnormal stereotypical movements or behaviors. Other indications include assessing the level of sedation, vasospasm monitoring, and monitoring the response to antiseizure medications or sedative weaning.[53,54] In the context of hypothermia after cardiac arrest, cEEG may provide prognostic information[55] and should

be used throughout the cooling protocol and until rewarming has been completed. The value of cEEG in the long-term evaluation of severe anoxic encephalopathy with or without myoclonus remains to be determined.

The interpretation of EEG findings seen in the ICU is challenging for neurophysiologists and clinicians alike. Many EEG patterns, in particular rhythmic and periodic patterns, are of uncertain clinical significance. In an effort to standardize terminology and to aid in future research of EEG patterns encountered in critically ill patients, a subcommittee of the American Clinical Neurophysiology Society (ACNS) proposed a classification system in 2005.[56] The classification system has been revised several times, most recently in 2021.[57] All terms consist of two main terms with numerous modifiers that can be added to the descriptions. The use of this system has been validated with good interrater reliability. Details of the terminology for these rhythmic and periodic patterns are outlined in Table 48.3.

A routine EEG may miss the chance to diagnose seizures in critically ill patients, and cEEG recording is generally recommended in this setting. The presence of NCSE, lateralized periodic discharges, generalized periodic discharges, and an abnormal EEG background are associated with worse outcomes.[2] More than half of the seizures diagnosed in ICU patients with EEG monitoring are detected within the first 30 minutes of recording; a third of these patients are found to have interictal epileptiform discharges within the same period. The risk of seizures diminishes if no epileptiform abnormalities are seen within 2 hours.[58] A quick but accurate seizure risk assessment tool is the 2HELPS2B score, which assigns points to six clinical and EEG variables: 2 points for brief (ictal) rhythmic discharges; 1 point for the presence of lateralized periodic discharges, lateralized rhythmic delta activity, or bilateral independent periodic discharges; 1 point for a prior seizure; 1 point for sporadic epileptiform discharges; 1 point for periodic/rhythmic patterns at >2.0 Hz; and 1 point for the presence of "plus" features according to ACNS terminology. A score of 0 portends a seizure risk of only 5%, whereas a score of 6 or 7 indicates a seizure risk >95%.[59]

The diagnosis of NCSE can be challenging. A unified terminology and classification system for NCSE was proposed at the Fourth London-Innsbruck Colloquium on status epilepticus in Salzburg, which has become known as the *Salzburg criteria.* Clinical signs and symptoms have to be present for at least 10 minutes, and concordant clinical data are essential in establishing the diagnosis of NCSE. EEG findings compatible with NCSE include epileptiform discharges at 2.5 Hz or faster, or at less than 2.5 Hz, if secondary criteria are fulfilled. These include typical spatiotemporal evolution, subtle clinical phenomena associated with the discharges, or EEG and clinical improvement with the administration of an antiseizure drug. Similarly, continuous rhythmic or quasi-rhythmic delta-theta activity faster than 0.5 Hz may also indicate NCSE, if secondary criteria are fulfilled. These criteria have been validated with high diagnostic accuracy and excellent interrater agreement and are deemed suitable for clinical practice.[60–62]

MANAGEMENT APPROACH

Treating Isolated Seizures

Administering antiseizure medications to an ICU patient experiencing one or a few seizures in the absence of structural CNS lesions requires consideration of a provisional cause, estimation of the likelihood of recurrence, and recognition of the utility and limitations of antiseizure medications. For example, the occurrence of seizures during ethanol withdrawal does not necessarily indicate the need for chronic treatment. The patient may need prophylaxis against delirium tremens, but the few seizures themselves seldom require treatment. Patients with convulsions during barbiturate or benzodiazepine withdrawal, in contrast, should receive short-term treatment with a benzodiazepine to prevent status epilepticus. Prolonged or frequent seizures caused by metabolic disturbances can be treated temporarily with benzodiazepines while the abnormality is being corrected. For example, treatment of patients with focal seizures related to nonketotic hyperglycemia should be directed at correction of the hyperglycemia and hypovolemia rather than antiseizure medications.[51] On the other hand, ICU patients with CNS disease who have even one seizure should be given chronic antiseizure medication. Initiating this treatment after the first *unprovoked* seizure may help prevent subsequent epilepsy,[63] although there is considerable difference of opinion regarding this concept.[64] If a critically ill patient's clinical condition would be seriously complicated by a convulsion, antiseizure medication even after the first seizure may be vitally important.

In general, intravenous (IV) formulations are preferred for critically ill patients to avoid variability in drug absorption and metabolism. In the United States, IV formulations of levetiracetam, brivaracetam, lacosamide, phenytoin/fosphenytoin, valproate, and phenobarbital are available.

Levetiracetam is a newer antiseizure medication that is being used increasingly in ICUs for seizure treatment and prophylaxis.[65] The

TABLE 48.3 ACNS Terminology for Rhythmic or Periodic EEG Patterns[57]

Main Term #1 Localization	Main Term #2 Type of Activity	Main Modifiers	Minor Modifiers
Generalized	Periodic discharges	Prevalence	Sudden onset versus gradual onset
Lateralized	Rhythmic delta activity	Duration	
Bilateral Independent	Spike-and-wave or sharp-and-wave	Frequency	Triphasic morphology
Unilateral Independent		Number of phases	Anterior-posterior or posterior-anterior lag
Multifocal		Sharpness	
		Voltage	Polarity
		Stimulus-induced or stimulus-terminated	
		Evolution

recommended initial dose is 500–1000 mg per day every 12 hours. Monitoring of serum concentrations is not indicated. Levetiracetam is efficacious against a wide variety of seizure types, is generally well tolerated, has minimal drug-drug interactions, and is not metabolized by the liver. Renal failure requires dose adjustments, and supplementary doses should be given after hemodialysis.

Lacosamide was approved as adjunctive therapy for focal-onset seizures in adults in 2008 and is commonly used in ICUs given its efficacy and favorable side-effect profile. It has a novel mechanism of action and has been studied for use in status epilepticus. The initial dose is 100 mg twice a day, to be increased based on response and tolerability to a recommended dose of 150–200 mg twice a day. No target serum concentration has been established. It has no known drug-drug interactions, but dose adjustments for renal and hepatic impairment are recommended. It has not been studied in severe hepatic failure. The most common side effects include PR prolongation and hypotension.

Despite growing evidence of deleterious adverse effects on cognition, fever, and increased risk of poor outcome,[66,67] phenytoin is still frequently selected for prophylaxis or treatment of seizures. It is indicated for all seizure types at a dose of 100 mg two to four times per day, with target serum levels of 10–20 μg/mL. Hypotension and arrhythmias may complicate IV administration. Because of the rare occurrence of third-degree atrioventricular block, an external cardiac pacemaker should be available when patients with known conduction abnormalities receive IV phenytoin. Phenytoin requires propylene glycol as a solvent, is highly protein bound, and free serum levels can vary widely depending on nutritional status. The phenytoin prodrug fosphenytoin is water soluble; local adverse effects are less common with fosphenytoin than with IV administration of phenytoin, although cardiovascular complications are just as frequent.[68,69] Fosphenytoin is dosed by phenytoin-equivalent units, and no dosage adjustments are needed when converting patients from phenytoin to fosphenytoin. It is rapidly converted to phenytoin in vivo, and free phenytoin levels after fosphenytoin administration do not differ markedly from those of phenytoin. If seizures recur despite a serum phenytoin level of 10–20 μg/mL (corresponding to an unbound concentration of about 1–2 μ/mL if the albumin is normal), a second agent is typically required. Both renal and hepatic dysfunction interfere with metabolism and excretion of phenytoin; serum levels should be monitored closely. Adverse reactions to phenytoin and other antiseizure medications have been reviewed elsewhere.[70] Because of its efficacy for generalized seizures, valproate may be the agent of choice for patients with a history of primary generalized epilepsy presenting with seizures. Caution is advised in patients with traumatic brain injury, as a trend toward higher mortality rates was seen in a trial of valproate versus phenytoin for the prevention of posttraumatic seizures.[71] The recommended starting dose is 10–15 mg/kg/day, targeting total serum concentrations of 50–100 μg/mL. Valproate is 80%–90% protein bound and does not require dose adjustment in renal impairment. Lower doses should be used in hepatic impairment, and it is contraindicated in severe hepatic impairment. Side effects of chronic valproate therapy are numerous, including hyperammonemia, thrombocytopenia, hepatotoxicity, and pancreatitis, in addition to many drug-drug interactions.

Phenobarbital remains a useful antiseizure medication for patients who continue to have seizures or are intolerant of other antiseizure medications. Initial dose recommendations are 1–3 mg/kg/day in one to two doses, with a target serum concentration of 20–40 μg/mL. Hepatic and renal dysfunction alter phenobarbital metabolism and require close monitoring of serum levels. Sedation is the major adverse effect; allergy to the drug occurs rarely.

TREATING STATUS EPILEPTICUS

The definition of status epilepticus has evolved over time. Historically, seizures lasting less than 5 minutes are considered brief, seizures lasting 5–30 minutes are prolonged, and seizures lasting more than 30 minutes are considered status epilepticus. However, there is evidence that permanent neuronal injury may occur before this cutoff, and seizures lasting more than 5 minutes often do not stop spontaneously. Therefore treatment algorithms typically start earlier in the course of status epilepticus, with the aim to prevent seizures from reaching 30 minutes.[72] The Neurocritical Care Society Guidelines from 2012 defined status epilepticus as continuous electroclinical or electrographic seizures lasting for 5 minutes or more, or recurrent seizures without recovery to the patient's neurologic baseline between seizures.[1] The 2021 version of the ACNS's Standardized Critical Care EEG Terminology defines electroclinical status epilepticus as an electroclinical seizure lasting continuously for 10 minutes or more, or for a total duration of 20% or more of any 60-minute period of recording. Of note, ongoing seizures with bilateral tonic-clonic motor activity only require 5 minutes of continuous seizure activity to qualify as status epilepticus. The definition of electrographic status epilepticus includes the same time cutoffs of an electrographic seizure lasting 10 minutes or more, or 20% or more of any 60-minute period.[57]

Both GCSE and NCSE have been associated with increased morbidity and mortality and should be approached as neurologic emergencies. Fig. 48.2 shows a management algorithm for status epilepticus, and Table 48.4 summarizes the management approach, including details on drug administration.[1] The treatment approach is generally subdivided into stages. Traditionally, these have been termed first-, second-, third-, and fourth-line treatments, but this may not necessarily reflect the emergent need for control of status epilepticus. The NCS guidelines use the terms *emergent initial therapy, urgent control therapy,* and *treatment of refractory status epilepticus.*[1] The American Epilepsy Society's guidelines for convulsive status epilepticus refer to these stages as *stabilization phase, initial therapy phase, second,* and *third therapy phase.*[72] Immediate considerations to stabilize the patient include airway protection, rapid correction of metabolic abnormalities (in particular, hypoglycemia), obtaining IV access, and ensuring hemodynamic stability. Antiseizure medications should be initiated as soon as the diagnosis of status epilepticus has been established. The goal is termination of clinical and electrographic seizure activity as soon as possible.

Emergent initial therapy or initial therapy phase refers to the administration of first-line agents for termination of seizure activity. There is consensus that benzodiazepines are the agents of choice for initial therapy. A large multicenter clinical trial compared multiple first-line regimens and found that the highest success rate was achieved with lorazepam.[74] Preferred administration routes include IV and intramuscular (IM) injection, but buccal, nasal, or rectal routes are possible. Lorazepam is the agent of choice if IV access is available; midazolam is preferred for the IM route.[75] Diazepam is commonly used for rectal administration. A randomized controlled trial showed that patients treated with lorazepam had lower rates of respiratory or circulatory complications compared with placebo, alleviating concerns of potential respiratory depression with benzodiazepines.[76] The initial dosing for lorazepam is 0.1 mg/kg IV, up to 4 mg per dose, which may be repeated after 5 to 10 minutes. Midazolam is given at a dose of 0.2 mg/kg IM up to a maximum of 10 mg. Some advocate even higher doses for either of these benzodiazepines. In Europe, an IV formulation of clonazepam is available and has been used as emergent initial therapy. From a pharmacokinetic perspective, benzodiazepines are rapidly redistributed, resulting in a short duration of action. Hence,

TABLE 48.4 Treatment Approach to Status Epilepticus[1,72]

Appropriate critical care treatment should be provided as soon as possible and simultaneously with emergent initial therapy for seizures. Treatment should be escalated quickly until seizures are controlled.

1a. Critical care treatment (dictated by clinical circumstances):
- a. Intubation for airway protection and mechanical ventilation
- b. Vital sign monitoring
- c. Peripheral IV access
- d. Treatment of hypotension with vasopressors
- e. Finger stick blood glucose
- f. Nutrient resuscitation (thiamine before dextrose)
- g. Hypertension may be related to ongoing seizure activity, and termination of status epilepticus often substantially corrects it. Additionally, many agents used to terminate status epilepticus can produce hypotension.

1b. Emergent initial therapy with benzodiazepines:
- a. Lorazepam 0.1 mg/kg IV, up to 4 mg per dose, may repeat once after 5–10 min
- b. Midazolam 10 mg IM if body weight >40 kg, 5 mg if body weight 13–40 kg
- c. Diazepam 0.15–0.2 mg/kg, up to 10 mg per dose, may repeat once after 5 min

2. Urgent control therapy—antiseizure medications available in IV formulations
- a. Fosphenytoin/phenytoin 20 mg PE/kg IV, up to 1500 mg PE/dose
- b. Valproic acid 40 mg/kg IV, up to 3000 mg/dose
- c. Levetiracetam 60 mg/kg, up to 4500 mg/dose
- d. Phenobarbital 15 mg/kg IV
- e. Lacosamide 200–400 mg IV
- f. Midazolam 0.2 mg/kg IV bolus, followed by 0.05–2 mg/kg/h continuous infusion

3. Refractory therapy—continuous infusion of antiseizure medications, titrated to either seizure cessation, suppression-burst, or complete suppression on cEEG
- a. Midazolam 0.2 mg/kg IV bolus, followed by 0.05–2 mg/kg/h continuous infusion
- b. Propofol 1–2 mg/kg IV bolus, followed by 20 μg/kg/min continuous infusion, titrate up to 30–200 μg/kg/min
- c. Pentobarbital 5–15 mg/kg IV bolus, may repeat 5–10 mg/kg IV bolus, followed by 0.5–5 mg/kg/h continuous infusion

4. Treat complications

Complications of status epilepticus are numerous and can involve multiple organ systems. In particular, convulsive status epilepticus is associated with cardiac complications such as hypertension and tachycardia, as well as rhabdomyolysis and hyperthermia. Respiratory complications, including respiratory failure, hypoxia, and neurogenic pulmonary edema, may be seen. Status epilepticus is associated with neuronal damage and cerebral edema with increased intracranial pressure, which may require intracranial pressure monitoring and aggressive treatment with hypertonic agents.

cEEG, Continuous electroencephalogram; *IM,* intramuscular; *IV,* intravenous; *PE,* phenytoin-equivalent units.

emergent initial therapy should be seamlessly followed by urgent control therapy (or second therapy phase) that targets rapid attainment of therapeutic levels of conventional antiseizure medications. If benzodiazepines fail to control seizures, the goal of urgent control therapy is seizure termination. If seizures are controlled by benzodiazepines, urgent control therapy targets prevention of seizure recurrence.

As with the treatment of isolated seizures in the ICU, the IV formulation is preferred, especially because therapeutic drug levels can be achieved significantly faster. Phenytoin/fosphenytoin, valproate, levetiracetam, phenobarbital, and continuous infusion of midazolam have all been studied for urgent treatment, and there is no evidence-based preferred agent of choice. A pivotal trial of three antiseizure medications for benzodiazepine-refractory convulsive status epilepticus found that levetiracetam, fosphenytoin, and valproate were each effective and led to seizure cessation and improved alertness in about half of patients with a similar rate of adverse events.[77] Additionally, lacosamide has emerged as an option to treat status epilepticus but has mostly been investigated in refractory status epilepticus.[78,79] Dosing of these drugs in status epilepticus is outlined in Table 48.4.

Refractory status epilepticus refers to status epilepticus that does not respond to a standard treatment regimen. There is controversy regarding this definition, but most experts agree that treatment has failed if seizures persist or recur after adequate doses of an initial benzodiazepine followed by one conventional antiseizure medication.[1] cEEG monitoring is typically required to exclude ongoing electrographic seizure activity. It may be reasonable to attempt management of recurrent seizures with additional intermittent boluses of an alternative antiseizure medication, provided the patient is clinically stable and has not required intubation for airway protection. Once it has been determined that intermittent bolus therapy has failed, treatment should be quickly escalated to a continuous infusion to induce a therapeutic coma. Patients who require any of these treatments will typically require intubation, mechanical ventilation, and close cardiovascular monitoring. The most commonly used drugs for this purpose are midazolam, propofol, pentobarbital, and thiopental. Dosing recommendations are listed in Table 48.4. There is insufficient evidence to recommend any agents over another. Midazolam is the preferred agent at our institution because of its high efficacy in adults and children,[80,81] its water solubility, and the lower incidence of cardiovascular adverse effects compared with pentobarbital or propofol. However, terminal half-lives of three to eight times normal have been reported with extended administration.[82] Propofol is reported to be effective in refractory status epilepticus, but comparisons with other agents have shown mixed results.[83,84] Especially in younger patients, the risk of propofol-related infusion syndrome needs to be considered, particularly if high doses are required for a prolonged period to control seizures. Severe hypotension is the most frequent side effect of pentobarbital therapy and is associated with increased mortality.[85] Increases in nosocomial respiratory tract infection have been reported in patients treated with pentobarbital infusion.[86]

The optimal duration of therapeutic coma remains to be determined. Customarily, 24–48 hours of seizure control has been used,[1] but shorter durations with a deeper therapeutic coma have been suggested.[87] Once clinical or nonconvulsive seizures have been controlled for a certain period, a gradual withdrawal of the continuous infusion should be initiated. If seizures recur upon withdrawal, a diagnosis of super-refractory status epilepticus is made and the continuous infusion should be resumed until seizures are controlled. The addition of other antiseizure medications or other therapies such as hypothermia, immunomodulation, or neurosurgical resection of the seizure focus may be considered at that point. Ketamine can be efficacious for super-refractory status epilepticus and is associated with lower vasopressor requirement. There is literature noting a concern that ketamine increases ICP, leading many practitioners to avoid this drug in patients with intracranial lesions at risk for elevated ICP. However, there is evidence that ketamine does not affect ICP in patients with super-refractory status epilepticus,[88] and it may be considered in patients who fail to respond to other refractory status epilepticus treatment options.[1]

KEY POINTS

- Seizures and status epilepticus are common in ICU patients and are associated with high morbidity and mortality.
- Observation is crucial when a patient has a single seizure. Postictal language, motor, sensory, or reflex abnormalities after a generalized seizure indicate focal pathology.
- Seizures persisting longer than 5 minutes or two or more discrete seizures without neurologic recovery in between should be treated as status epilepticus. Patients who do not regain consciousness within 20 minutes after clinical seizure cessation should be considered to have entered NCSE, and cEEG monitoring is essential in directing the course of treatment.
- The ICU patient with CNS disease who has even one seizure should be given chronic antiseizure medication. This therapy should be reviewed before discharge.
- Emergent initial therapy for treatment of status epilepticus is benzodiazepines (lorazepam, midazolam, diazepam) followed by urgent control therapy with IV formulations of levetiracetam, valproate, phenytoin/fosphenytoin, phenobarbital, or lacosamide. Status epilepticus refractory to an initial benzodiazepine and an appropriately chosen and dosed conventional antiseizure medication should be treated with continuous infusion of midazolam, barbiturates, or propofol.

Neuromuscular Disorders in the Critically Ill

Thomas P. Bleck

Abnormal neuromuscular function may precipitate a patient's admission to an intensive care unit (ICU) or it may develop because of another critical illness and its treatment. This chapter focuses primarily on respiratory failure caused by neuromuscular disease but also addresses autonomic dysfunction that occurs in this setting. A brief review of the motor unit and its physiology is provided to facilitate understanding of the concepts involved, along with consideration of the specific muscles critical to ventilation.

THE MOTOR UNIT AND ITS PHYSIOLOGY

Central nervous system (CNS) activity for motor output is ultimately conducted by the lower motor neurons, also known as *alpha motor neurons*. A motor unit is composed of a lower motor neuron and its distal ramifications, its neuromuscular junctions, and the muscle fibers it innervates. The cell bodies of the lower motor neurons are located in the brainstem for cranial musculature and the anterior horn of the spinal cord for somatic muscles. Motor axons project through the subarachnoid space and penetrate the dura mater as nerve roots. They may join with other motor axons and with sensory and autonomic fibers in a plexus and then travel via the peripheral nerves to the muscles they innervate. Alpha motor neurons are myelinated, a feature that accelerates nerve impulse propagation. The multiple terminal ramifications of the motor neuron synapse on individual muscle fibers.

The motor axon communicates with muscle via a specialized area termed the *neuromuscular junction*. On the presynaptic side of the neuromuscular junction, the neurotransmitter acetylcholine is synthesized, packaged in vesicles, and stored for release. Depolarization of the axon opens the presynaptic voltage-gated calcium channels, which activate the molecular machinery responsible for drawing the vesicles to the presynaptic membrane. The vesicles then fuse with the membrane and release acetylcholine into the synaptic cleft. Acetylcholine molecules bind to receptors on the postsynaptic membrane and cause an influx of sodium, which in turn increases the muscle endplate potential. When the endplate potential exceeds the threshold level, the muscle membrane becomes depolarized. This depolarization releases calcium ions from the sarcoplasmic reticulum, and muscle contraction occurs through a process known as excitation-contraction coupling. After activating the acetylcholine receptor complex, the acetylcholine molecule is degraded by cholinesterase, and the presynaptic neuron then recycles the choline released by this reaction.

MUSCLES OF RESPIRATION

Three muscle groups may be defined based on their importance for respiration (Fig. 49.1)[1]:

1. *Upper airway muscles:* palatal, pharyngeal, laryngeal, and lingual
2. *Inspiratory muscles:* sternomastoid, diaphragm, scalenes, and parasternal intercostals
3. *Expiratory muscles:* internal intercostal muscles (except for parasternals) and abdominal muscles

The upper airway muscles receive their innervation from the lower cranial nerves. Sternomastoid innervation arrives predominantly from cranial nerve XI, with a small contribution from C2. The phrenic nerve originates from cell bodies located between C3 and C5, with a maximum contribution from C4, and innervates the diaphragm. Innervation to the scalenes arises from C4 to C8, whereas that of the parasternal intercostals is from T1 to T7. The other intercostal muscles receive innervation from T1 to T12, and the abdominal musculature receives it from T7 to L1.

Clinical Presentation of Neuromuscular Respiratory Failure

Patients experiencing respiratory dysfunction as a result of neuromuscular disease typically present with a combination of upper airway dysfunction and diminished tidal volume (V_T). Upper airway muscle weakness typically presents with difficulty swallowing liquids, including respiratory secretions, along with a hoarse or nasal voice. In addition to the risk of aspiration, these patients have difficulty with negative-pressure ventilation because the weakened muscles cannot keep the airway open as the pressure falls.

Loss of V_T occurs secondary to weakness of the inspiratory muscles. In addition to diaphragmatic weakness, which may present with paradoxical abdominal movement, parasternal intercostal muscle weakness also causes diminished V_T by preventing the chest wall from expanding against negative intrapleural pressure. Thus lower cervical spinal cord injuries may induce respiratory failure despite preserved phrenic nerve function. The patient often attempts to maintain V_T by contraction of accessory muscles such as the sternomastoids. As parasternal intercostal muscles develop spasticity over weeks, respiratory function of this type typically improves and may permit weaning from mechanical ventilatory support, at least during the daytime.

Patients with progressive generalized weakness (e.g., Guillain-Barré syndrome) commonly begin to lose V_T before developing upper airway weakness. To maintain minute ventilation and carbon dioxide excretion, a patient's respiratory rate increases. Respiratory rate is thus one of the most important clinical parameters to monitor. As the vital capacity falls from the norm of about 65 mL/kg to 30 mL/kg, a patient's cough weakens, and clearing secretions becomes difficult. A further decrease in the vital capacity to 20 mL/kg to 25 mL/kg results in an impaired ability to sigh, resulting in progressive atelectasis. At this point, hypoxemia may be present because of ventilation-perfusion mismatching, and an increasing percentage of V_T is used to ventilate dead space. Respiratory failure is imminent, and ICU admission is recommended for all patients with a vital capacity $<$20 mL/kg. The precise point at which mechanical ventilation is necessary varies with the patient, the underlying condition, and especially the likelihood of a rapid response to treatment.

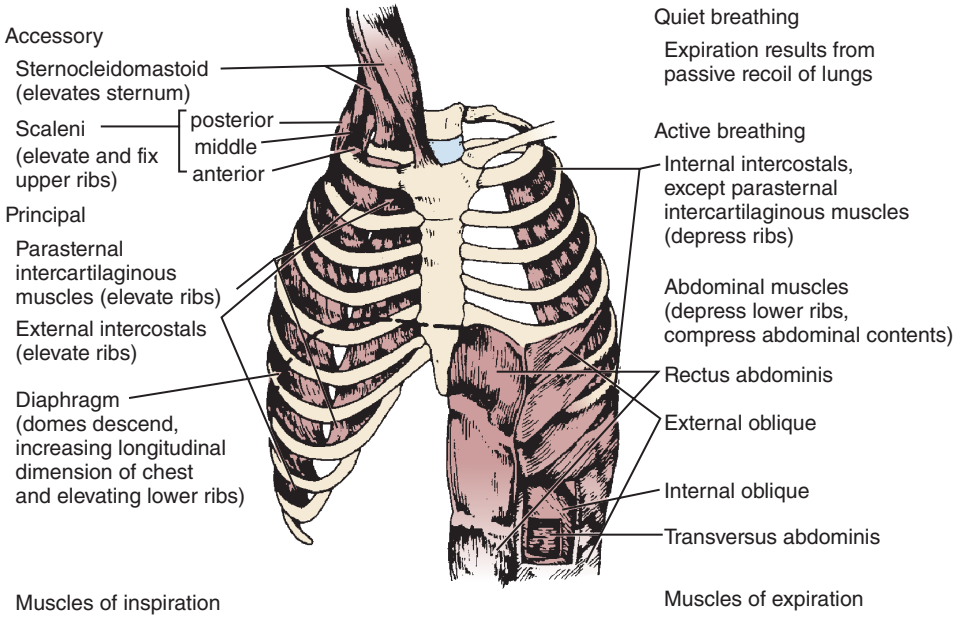

Fig. 49.1 Major respiratory muscles. Inspiratory muscles are indicated on the left, and expiratory muscles are indicated on the right. (From Garrity ER. Respiratory failure due to disorders of the chest wall and respiratory muscles. In: KF McDonnell, PJ Fahey, MS Segal, eds. *Respiratory Intensive Care.* Boston, MA: Little, Brown; 1987:313.)

Regardless of the vital capacity, indications for intubation and mechanical ventilation include evidence of fatigue, hypoxemia despite supplemental oxygen administration, difficulty with secretions, and a rising arterial partial pressure of carbon dioxide ($PaCO_2$). In the absence of hypercapnia, occasional patients (e.g., those with myasthenia gravis) can be managed with very close observation in an ICU with less invasive techniques (e.g., bilevel positive airway pressure [BiPAP]).[2]

In addition to vital capacity, trended measurements of the maximum inspiratory pressure (PImax, also called *negative inspiratory force* [NIF]), are useful indicators of ventilatory capacity. The inability to maintain a PImax greater than 20–25 cm H_2O usually indicates a need for mechanical ventilation. Although the maximum expiratory pressure (PEmax) is a more sensitive indicator of weakness, it has not proven to be as useful as an indicator of the need for mechanical ventilation.

Because a patient with neuromuscular respiratory failure has an intact ventilatory drive,[3] the fall in V_T is initially matched by an increase in respiratory rate, keeping the $PaCO_2$ normal or low until the vital capacity becomes dangerously reduced. Many patients initially maintain their $PaCO_2$ in the range of 35 mm Hg because of either (1) a subjective sense of dyspnea at low V_T or (2) hypoxia from atelectasis and increasing dead space. When the $PaCO_2$ begins to rise in these circumstances, abrupt respiratory failure may be imminent, as CO_2 displaces more oxygen from the alveolar gas. The modest degree of hypoxia in most of these patients therefore worsens when the $PaCO_2$ begins to rise. Moreover, aspiration pneumonia and pulmonary embolism are also frequent causes of hypoxemia in these patients. To determine the relative contributions of these conditions to a patient's hypoxemia, one can use a simplified version of the alveolar gas equation:

$$P_AO_2 = PiO_2 - (PaCO_2/R)$$

where P_AO_2 is the alveolar partial pressure of oxygen, PiO_2 is the partial pressure of the inspired oxygen (in room air, 150 mm Hg), and R is the respiratory quotient (on most diets, about 0.8). This allows for the estimation of the alveolar-arterial oxygen difference ($P_AO_2 - PaO_2$). Under ideal circumstances in young people breathing room air, this value is about 10 mm Hg, but it rises to about 100 mm Hg when the fraction of inspired oxygen (FiO_2) is 1.0. The alveolar air equation allows one to assess the contribution of hypercarbia to the decrease in arterial partial pressure of oxygen (PaO_2); it determines whether there is a cause of significant hypoxemia in addition to the displacement of oxygen by carbon dioxide.

Physicians must observe patients for rapid, shallow breathing[9]; recruitment of accessory muscles; and paradoxical movement of the abdomen during the respiratory cycle. Direct observation is particularly important, as patients may have orbicularis oris weakness, causing an artificially low vital capacity and NIF measurements because they cannot form a tight seal around the spirometer mouthpiece. In addition to physical examination findings, fluoroscopy of the diaphragm is occasionally valuable for the diagnosis of diaphragmatic dysfunction.

Autonomic dysfunction commonly accompanies some of the neuromuscular disorders requiring critical care, such as Guillain-Barré syndrome, botulism, and porphyria (Table 49.1). In Guillain-Barré syndrome (vide infra), dysautonomia is common and may arise in parallel with weakness or may follow the onset of the motor disorder after one or more weeks.

NEUROMUSCULAR DISORDERS

Many chronic neuromuscular disorders and other CNS conditions affecting the suprasegmental innervation and control of respiratory muscles eventually compromise ventilation. In this chapter, we emphasize the more common acute and subacute neuromuscular disorders that precipitate or prolong critical illness caused by ventilatory failure and autonomic dysfunction. A complete listing of neuromuscular diseases appears in Table 49.1; reviews of this subject[6] and Table 49.1 detail the rarer disorders. Some of the diseases listed (e.g., Lambert-Eaton myasthenic syndrome) rarely cause respiratory failure in isolation but may be contributing causes in the presence of other conditions,[7] such as a neuromuscular junction blockade intended only for the duration of a surgical procedure.

TABLE 49.1 Neuromuscular Causes of Acute Respiratory Failure

Location	Disorder	Associated Autonomic Dysfunction?
Spinal cord	Tetanus[4]	Frequent
Anterior horn cell	Amyotrophic lateral sclerosis	No
	Poliomyelitis	No
	Rabies	Frequent
	West Nile virus flaccid paralysis	No
Peripheral nerve	Guillain-Barré syndrome	Frequent
	Critical illness polyneuropathy	No
	Diphtheria	No, but cardiomyopathy and arrhythmias may occur
	Porphyria	Occasional
	Ciguatoxin (ciguatera poisoning)	Occasional
	Saxitoxin (paralytic shellfish poisoning)	No
	Tetrodotoxin (pufferfish poisoning)	No
	Thallium intoxication	No
	Arsenic intoxication	No
	Lead intoxication	No
	Buckthorn neuropathy	No
Neuromuscular junction	Myasthenia gravis	No
	Botulism[5]	Frequent
	Lambert-Eaton myasthenic syndrome	Yes, frequent dry mouth and postural hypotension
	Hypermagnesemia	No
	Organophosphate poisoning	No
	Tick paralysis	No
	Snake bite	No
Muscle	Polymyositis/dermatomyositis	No
	Acute quadriplegic myopathy	No
	Eosinophilia-myalgia syndrome	No
	Muscular dystrophies	No, but cardiac rhythm disturbances may occur
	Carnitine palmitoyl transferase deficiency	No
	Nemaline myopathy	No
	Acid maltase deficiency	No
	Mitochondrial myopathy	No
	Acute hypokalemic paralysis	No
	Stonefish myotoxin poisoning	No
	Rhabdomyolysis	No
	Hypophosphatemia	No

Neuromuscular Diseases Precipitating Critical Illness

Guillain-Barré Syndrome

Guillain-Barré syndrome, or acute inflammatory demyelinating polyradiculoneuropathy, is typically a motor greater than peripheral sensory neuropathy with subacute onset, monophasic course, and nadir within 4 weeks. Although the precise etiology is unknown, it is immune mediated and related to antibodies directed against peripheral nerve components. About 1.7 cases occur per 100,000 population annually. Most patients suffer from a demyelinating neuropathy, but in about 5% of cases, the condition is a primary axonopathy. Numerous antecedents have been implicated, the most common of which are listed in Box 49.1. The association with antecedent infections suggests that certain agents may provoke the production of antibodies that cross-react with peripheral nerve gangliosides. Ganglioside antibodies have been found in Guillain-Barré syndrome after *Campylobacter jejuni* infections, such as GM_1 antibodies in axonal forms and GQ_{1b} antibodies in the Miller-Fisher variant.[8] Immune checkpoint inhibitors have rarely been associated with the development of Guillain-Barré syndrome, although no autoantibody association has been established to date.[9] The association of vaccine administration with the syndrome remains uncertain, with the possible exception of the 1976 influenza vaccine. Patients who have recovered from Guillain-Barré syndrome should not be denied the protective effect of vaccines.[10]

The initial findings of patients with Guillain-Barré syndrome are a subacute and progressive weakness, usually most marked in the legs, associated with sensory complaints but without objective signs of sensory dysfunction. Deep tendon reflexes are often reduced or absent at presentation, though this finding may take several days to develop. The

Box 49.1 Major Antecedents of Guillain-Barré Syndrome

Frequent
Upper respiratory tract infections
Campylobacter jejuni enteritis
Cytomegalovirus (CMV) infection
Epstein-Barr virus (EBV) infection
Hepatitis A infection
Hepatitis B infection
Hepatitis C infection
Human immunodeficiency virus (HIV) infection

Infrequent
Mycoplasma pneumoniae infection
Haemophilus influenzae infection
Leptospira icterohaemorrhagiae infection
Salmonellosis
Rabies vaccine
Tetanus toxoid
Bacille Calmette-Guérin immunization
Sarcoidosis
Systemic lupus erythematosus
Lymphoma
Trauma
Surgery

Questionable
Hepatitis B vaccine
Influenza vaccine
Hyperthermia
Epidural anesthesia

cerebrospinal fluid (CSF) typically reveals an albumin-cytologic dissociation (elevated protein concentration without pleocytosis); however, this may not develop until the second week of illness. The major reason to examine the CSF is to preclude other diagnoses. Although mild CSF lymphocytic pleocytosis (10–20 cells/mm^3) may suggest the possibility of associated human immunodeficiency virus (HIV) infection, in most patients, the nucleated cell count is <10 cells/mm^3.[11] Although they may be normal initially, results of electrodiagnostic studies (motor and sensory nerve conduction studies and needle electromyography) often reflect segmental nerve demyelination with multifocal conduction blocks, temporally dispersed compound muscle action potentials, slowed conduction velocity, and prolonged or absent F waves. Diagnostic considerations for patients with suspected Guillain-Barré syndrome are primarily those listed in the Peripheral Nerve section of Table 49.1.

The components of treatment for patients with Guillain-Barré syndrome are as follows:

- Management of ventilatory failure
- Management of autonomic dysfunction
- Meticulous nursing care
- Psychological support
- Physical and occupational therapy
- Prevention of deep venous thrombosis
- Nutritional support
- Early planning for rehabilitation
- Immunotherapy for the underlying autoimmune condition

Patients with Guillain-Barré syndrome with evolving respiratory failure should be intubated when the vital capacity falls to about 15 mL/kg or when difficulty with secretions begins because the response to treatment is slow. If a patient has been immobile for several days before intubation and a neuromuscular junction blockade is needed, a nondepolarizing agent should be used to avoid transient hyperkalemia. Oral intubation is preferable to the nasal route because the tracheal tube is frequently required for a week or longer, raising the risk of sinusitis.

Many patients are too weak to trigger the ventilator, and in such cases, the assist/control or intermittent mandatory ventilation mode is initiated. Weaning patients with Guillain-Barré syndrome from mechanical ventilation must wait for an adequate improvement in strength reflected by a vital capacity of greater than 15 mL/kg and NIF greater than 25 cm H_2O. However, a formula using a combination of ventilatory and gas exchange variables may allow for a more accurate determination of a patient's ability to be weaned. Although pressure support ventilation is often used for weaning, evidence of its superiority over intermittent mandatory ventilation or synchronized intermittent mandatory ventilation modes is anecdotal. Most patients require mechanical ventilation for more than 4 weeks; however, as many as one-fifth need at least 2 months of support before they can breathe without assistance. Autonomic dysfunction typically presents as a hypersympathetic state and is often heralded by unexplained sinus tachycardia. The blood pressure may fluctuate wildly. Patients can also experience bradycardic episodes, which may require temporary pacing. Autonomic surges during tracheal suctioning or because of a distended viscus may be very dramatic and should be minimized. Autonomic failure and pulmonary embolism are now the major causes of mortality in Guillain-Barré syndrome.

Nursing care for patients with Guillain-Barré syndrome is similar to that for other paralyzed and mechanically ventilated patients, but special care must be taken to remember that patients are completely lucid. In addition to explaining any procedures carefully, arranging for distractions during the daytime (e.g., television, movies, conversation, or visitors) and adequate sleep at night are very important. For the most severely affected patients, sedation should be considered. In concert with physical and occupational therapists, passive exercise should frequently be performed throughout the day.

Deep venous thrombosis is a significant danger. An episodic arterial desaturation is a common event, presumably owing to transient mucus plugging; therefore submassive pulmonary emboli may be overlooked. Adjusted-dose heparin (to slightly prolong the partial thromboplastin time) should be given, and sequential compression devices should be used on the legs. Moreover, therapeutic anticoagulation may be considered. The risk of fatal pulmonary embolism extends through the initial period of improvement until the patients are ambulatory.

Nutritional support should begin as soon as a patient is admitted, with appropriate concern for the risk of aspiration. Most mechanically ventilated patients with Guillain-Barré syndrome can be fed via soft, small-caliber feeding tubes; autonomic dysfunction affecting the gut occasionally requires total parenteral nutrition.

Immunotherapy for Guillain-Barré syndrome includes the removal of autoantibodies with plasma exchange or immune modulation with a high dose of intravenous immunoglobulin (IVIg). The efficacy of the plasma exchange has been evaluated in a Cochrane systematic review of six class II trials comparing plasma exchange alone with supportive care.[12] Most of the trials employed up to five plasma exchanges of 50 mL/kg over 2 weeks. In a large North American trial, the time needed to improve one clinical grade (i.e., being weaned from the ventilator or being able to walk) was reduced by 50% in the plasma exchange group compared with the control group. There was no significant benefit when the plasma exchange commenced later than 2 weeks after the onset of symptoms. A meta-analysis revealed more rapid recovery in

ventilated patients treated with a plasma exchange within 4 weeks of onset. The optimal number of plasma exchanges has been assessed in patients with mild (unable to run), moderate (unable to stand without assistance), and severe (requiring mechanical ventilation) Guillain-Barré syndrome by the French Cooperative Group.[13] On the basis of this trial, two exchanges are better than none in mild Guillain-Barré syndrome, four are better than two in moderate Guillain-Barré syndrome, and six are no better than four in severe Guillain-Barré syndrome. Albumin is the preferred replacement solution.[14] Treatment with IVIg for Guillain-Barré syndrome has also been examined in a Cochrane systematic review. Five randomized controlled trials in adults showed that IVIg (0.4–0.5 g/kg over 4–5 days) is as effective as plasma exchange in Guillain-Barré syndrome patients with impaired walking.[15] IVIg is also more likely to be completed than plasma exchange, although the adverse events were not different. A large international multicenter randomized trial compared plasma exchange (50 mL/kg × 5 exchanges over 8–13 days), IVIg (0.4 g/kg × 5 days), and plasma exchange followed by IVIg.[16] No significant outcome differences between these therapies were found with respect to functional improvement at 4 or 48 weeks. The lack of benefit of a second course of IVIg in a group of patients expected to have a poor prognosis was recently demonstrated in a double-blind, randomized trial.[17] In this trial, serious adverse events were significantly more common in the group receiving the second course.

Evidence-based guidelines for Guillain-Barré syndrome immunotherapy have been published by the Quality Standards Subcommittee of the American Academy of Neurology.[18] Plasma exchange is recommended for adult patients who cannot walk within 4 weeks of symptom onset. IVIg is recommended in these patients within 2 or possibly 4 weeks of symptom onset. Both treatments are deemed equivalent in efficacy, and combining treatment with plasma exchange and IVIg confers no additional benefit. In light of their therapeutic equivalence, the decision whether to employ plasma exchange or IVIg in treating acute Guillain-Barré syndrome may be determined by resource availability and by avoiding potential side effects related to a patient's medical comorbidities. Patients with heart disease, renal insufficiency or failure, hyperviscosity, or IgA deficiency may be more susceptible to complications of treatment with IVIg, whereas plasma exchange may be complicated in patients with labile blood pressure, septicemia, and significant venous access problems.

Despite the autoimmune pathophysiology of Guillain-Barré syndrome and the efficacy of corticosteroids in more chronic forms of inflammatory neuropathy, corticosteroids have not shown effectiveness in Guillain-Barré syndrome and are therefore not recommended.[18] A large multicenter trial failed to demonstrate efficacy of high-dose intravenous methylprednisolone, and another large multicenter trial reported no added clinical benefit with the combined treatment of IVIg and methylprednisolone.[19]

West Nile Virus Acute Flaccid Paralysis Syndrome

The large outbreak of West Nile virus encephalitis in the summer of 1999 in New York City marked the emergence of a relatively new cause of neuromuscular weakness with the potential for neuromuscular respiratory compromise. West Nile virus is a flavivirus transmitted by birds and mosquitoes. Humans may acquire West Nile virus from the bite of an infected *Culex* species mosquito, and a corresponding peak in human disease occurs in the late summer and fall. West Nile virus may also be transmitted to humans by organ transplantation,[20] blood and blood product transfusion,[21] transplacental exposure,[22] breastfeeding,[23] and percutaneous laboratory injuries.[24] About 20% of humans experience a mild flulike illness lasting 3–6 days, and about 1 in 150 develops CNS disease, which usually presents as meningoencephalitis.[25]

In the initial North American outbreak of West Nile virus, about 10% of infected patients experienced flaccid weakness with clinical features resembling Guillain-Barré syndrome.[26] Although patients with West Nile virus infection exhibit a spectrum of clinical weakness,[27,28] the most prominent and distinctive syndrome documented in several subsequent reports is an acute "poliomyelitis-like" or acute flaccid paralysis syndrome with pathology localized to the ventral horns of the spinal cord and/or ventral roots.[29–35] These relatively younger patients developed acute, asymmetric, flaccid weakness in the absence of sensory abnormalities, diffuse areflexia, or bowel/bladder dysfunction.[36] Some of the patients experienced concurrent meningoencephalitis, and a few required mechanical ventilation.[28,30]

Electrodiagnostic studies in patients with West Nile virus acute flaccid paralysis syndrome exhibit normal sensory potentials, and the absence of findings suggests segmental demyelination (e.g., motor conduction block, reduced conduction velocities, prolonged distal, and F-wave latencies), low-amplitude compound muscle action potentials in the affected regions, and marked denervation changes in the affected limbs and in corresponding paraspinal muscles on needle electromyography. Corresponding magnetic resonance imaging (MRI) findings are sometimes observed and include an abnormal signal in the spinal cord on T2-weighted images[34,35] and abnormal enhancement of the nerve roots and cauda equina.[32,33] CSF analysis usually reveals mild pleocytosis with lymphocytic predominance and a mild to moderate protein elevation and normal glucose.[37] Prognosis for the recovery of strength in these patients appears to be poor.[38]

West Nile virus infection may be diagnosed by demonstrating West Nile virus RNA in the serum, CSF, or other tissues by reverse-transcriptase polymerase chain reaction, although this test is not highly sensitive.[39] More commonly, a diagnosis is made by the demonstration of West Nile virus immunoglobulin M (IgM) in CSF or serum by antibody-capture enzyme-linked immunosorbent assay (ELISA). When serum West Nile virus IgM is present, diagnosis is confirmed by a fourfold increase in West Nile virus immunoglobulin G (IgG) titers between acute and convalescent sera obtained 4 weeks apart. Positive IgM and IgG antibody titers should be confirmed by a plaque-reduction viral neutralization assay to exclude false-positive results related to other flaviviral infections, such as St. Louis encephalitis. Serology may not become positive until 8 days after symptom onset.[25]

Particularly in the absence of a more typical encephalitic presentation of West Nile virus infection, a high index of clinical suspicion is needed to make a diagnosis and to distinguish such cases from Guillain-Barré syndrome in patients presenting with acute weakness in the late summer or fall. Electrodiagnostic studies may help localize the pathology to the ventral horns of the spinal cord or ventral roots in West Nile virus cases and to exclude findings of segmental demyelination suggesting Guillain-Barré syndrome. CSF evaluation can help discriminate between the albumin-cytologic dissociation of Guillain-Barré syndrome and the lymphocytic pleocytosis in a West Nile virus infection.

There is no specific treatment for West Nile virus. A multicenter study to evaluate the efficacy of Israeli IVIg (containing high levels of West Nile virus antibodies) in patients with West Nile virus meningoencephalitis or weakness was terminated early because of lower-than-expected enrollment, expiration of the study product, and insufficient quantities of control IVIg.[40] Two candidate vaccines against West Nile virus are currently being evaluated.[41,42]

Myasthenia Gravis

Myasthenia gravis is a consequence of the autoimmune attack on the acetylcholine receptor complex at the postsynaptic membrane of the neuromuscular junction. This process results in clinical weakness with

a fluctuating pattern that is most marked after prolonged muscle exertion. Myasthenia gravis occurs at a higher rate in early adulthood in women, but in later life, the incidence rates for men and women become nearly equal. The reported prevalence is 14.2 cases per 100,000 population. Myasthenia gravis typically involves ocular muscle weakness producing ptosis and diplopia, in addition to bulbar muscle weakness resulting in dysphagia and dysarthria. A clinical diagnosis of myasthenia gravis may be supported by electrophysiologic studies, including repetitive nerve stimulation studies and single-fiber electromyography, and by acetylcholine receptor and muscle-specific receptor tyrosine kinase (MuSK) antibody testing.[43]

Approximately 20% of patients with myasthenia gravis develop myasthenic crisis with respiratory failure requiring mechanical ventilation. The most common precipitating factors include bronchopulmonary infections (29%) and aspiration (10%).[44] Other precipitating factors include sepsis, surgical procedures, rapid tapering of immune modulation, beginning treatment with corticosteroids, pregnancy, and exposure to drugs that may increase myasthenic weakness (Box 49.2).[44] Patients with myasthenia gravis are exceptionally sensitive to nondepolarizing neuromuscular blocking agents but are resistant to depolarizing agents. Thymomas are associated with more fulminant disease and identified in about one-third of patients in a myasthenic crisis.

Upper airway muscle weakness is a common mechanism leading to the myasthenic crisis.[45] Oropharyngeal and laryngeal muscle weakness may result in upper airway collapse with obstruction. Dysphagia further contributes to the obstruction and aspiration of secretions. Because a direct assessment of oropharyngeal muscle strength is impractical, a focused history and examination to assess surrogate muscles in the head and neck region are important. Findings of bulbar myasthenia associated with upper airway compromise include flaccid dysarthria with hypernasal, staccato, or hoarse speech; dysphagia (sometimes associated with nasal regurgitation); and chewing fatigue. Patients may exhibit facial weakness with difficulty holding air within the cheeks. Jaw closure is often weak and cannot be maintained against resistance. Patients with myasthenic tongue weakness may be unable to protrude the tongue into either cheek. Although neck flexors are often weaker, a dropped head syndrome because of neck extensor weakness may occur. Vocal cord abductor paralysis may produce laryngeal obstruction with associated stridor.[46]

Patients with features of impending myasthenic crisis, including severe bulbar weakness, marginal vital capacity (less than 20–25 mL/kg), weak cough with difficulty clearing secretions from the airway, or paradoxical breathing while supine should be admitted to an ICU and made nothing by mouth (NPO) to prevent aspiration. Serial vital capacity and NIF measurements may be used to monitor ventilatory function in an impending myasthenic crisis. However, with significant bulbar weakness, these measurements are often inaccurate if the patient has difficulty sealing the lips around the spirometer mouthpiece or is unable to seal the nasopharynx. Vital capacity measurements may not reliably predict respiratory failure in myasthenia gravis, owing to the fluctuating nature of the myasthenic weakness.[47] The criteria for intubation and mechanical ventilation are similar to those for Guillain-Barré syndrome. If the upper airway is competent and there is no difficulty handling secretions or gross hypercapnia ($PaCO_2$ >50 mm Hg), intermittent nasal BiPAP may be a useful temporizing measure.[2] Most patients who develop hypercapnia in myasthenic crisis require intubation, as do those who are becoming fatigued.

Plasma exchange is an effective short-term immunomodulating treatment for myasthenic crisis and surgical preparation in symptomatic myasthenic patients. Significant strength improvement in myasthenic crisis is well documented in several series, although there have been no controlled trials. We perform a series of five to six exchanges of 2–3 L every other day. The onset of improved strength is variable but occurs after two to three exchanges.

IVIg may represent an alternative short-term treatment for myasthenic exacerbations or crises in patients who are poor candidates for plasma exchange because of difficult vascular access or septicemia. Comparable efficacy for plasma exchange and IVIg was demonstrated in myasthenic exacerbations and crises in a relatively small randomized controlled trial of IVIg at 1.2 and 2 g/kg over 2–5 days.[48] However, in a retrospective multicenter study of myasthenic crisis, plasma exchange proved more effective than IVIg in the ability to extubate at 2 weeks and in the 1-month functional outcome. Treatment failures to IVIg subsequently responding to plasma exchange have also been reported.[49] Experience with preoperative IVIg for thymectomy in myasthenia gravis suggests that the time course of the maximal response may be considerably delayed in some patients.

Corticosteroids (e.g., prednisone 1 mg/kg/day) are occasionally used in prolonged myasthenic crises that fail to respond to plasma exchange or IVIg. If begun early in the course of the myasthenic crisis, the transient increase in myasthenic weakness associated with initiating corticosteroids may prolong mechanical ventilation. When preceded by an unequivocal improvement in strength after plasma exchange or IVIg treatment, long-term treatment with corticosteroids may begin, with a reduced risk for corticosteroid-related exacerbations. Treatments with monoclonal antibodies appear promising in clinical trials.

In the context of myasthenic crisis, excessive dosing of cholinesterase inhibitors may superimpose a cholinergic crisis caused by depolarization blockade and result in increased weakness. Other symptoms of cholinergic crisis include muscle fasciculations and prominent muscarinic symptoms, including miosis, excessive lacrimation and salivation, abdominal cramping, nausea, vomiting, diarrhea, thick bronchial secretions, diaphoresis, and bradycardia. Cholinergic crisis is rare in contemporary series of myasthenic crisis, and it is now common practice to avoid repeated dose escalations of cholinesterase inhibitors in an impending myasthenic crisis and to discontinue the use of cholinesterase inhibitors after intubation to reduce muscarinic complications. When there is a question of cholinergic excess contributing to respiratory insufficiency, it is prudent to discontinue all cholinesterase inhibitors, protect the airway, and support respiration as necessary.

Thymectomy may result in the long-term improvement of patients with a suspected thymoma or with a life expectancy of more than 10 years.

Box 49.2 Drugs That May Increase Weakness in Myasthenia Gravis

- Neuromuscular blocking agents
- Selected antibiotics
  - Aminoglycosides, particularly gentamicin
  - Macrolides, particularly erythromycin and azithromycin
- Selected cardiovascular agents
  - Beta-blockers
  - Calcium channel blockers
  - Procainamide
- Quinidine
- Quinine
- Corticosteroids
- Magnesium salts
  - Antacids, laxatives, intravenous tocolytics
- Iodinated contrast agents
- d-Penicillamine

However, a patient in acute respiratory failure is considered a poor operative risk, and thymectomy is delayed until the patient's condition has improved.[50] Post-thymectomy pain control and ventilatory function may be improved by the postoperative administration of epidural morphine.

Neuromuscular Diseases Secondary to Critical Illness and Its Treatment

Critical Illness Polyneuropathy and Myopathy

Critical illness polyneuropathy is a widespread axonal peripheral neuropathy that develops in the context of multiple organ failure and sepsis. In a prospective series of 43 patients with sepsis and multiorgan failure, 70% developed electrophysiologic evidence of a sensorimotor axonal neuropathy, and 15 patients developed difficulty weaning from mechanical ventilation as a consequence of the neuropathy.[51] Critical illness polyneuropathy is possibly the most common neuromuscular cause of prolonged ventilator dependency in patients without prior known neuromuscular disease. Given the limitations to the detailed clinical motor and sensory examinations in the setting of critical illness, the clinical features of critical illness polyneuropathy (extremity muscle weakness and wasting, distal sensory loss, and paresthesias) may not be recognized. Deep tendon reflexes are reduced or absent in the setting of superimposed CNS insult with pyramidal tract dysfunction; however, deep tendon reflexes may be normal or increased.

Electrodiagnostic studies are important in establishing a diagnosis of critical illness polyneuropathy because the clinical findings may be unobtainable or indeterminate in this setting. Nerve conduction findings include normal or near-normal conduction velocity and latency values and significantly reduced compound muscle action potential and sensory nerve action potential amplitudes. Needle electrode examination reveals denervation changes that are the most marked in the distal muscles, including fibrillation potentials, positive sharp waves, and reduced recruitment of motor unit potentials. With recovery over time, the denervation potentials abate, and the motor unit potentials become polyphasic and enlarged. Peripheral nerve histopathology has revealed widespread primary axonal degeneration in distal motor and sensory fibers, and skeletal muscle has exhibited fiber-type grouping.

Although the clinical history is usually adequate to distinguish between critical illness polyneuropathy and Guillain-Barré syndrome, the latter can develop in the context of recent surgery complicated by infection. However, Guillain-Barré syndrome is commonly associated with facial and oropharyngeal weakness, which is rarely seen in critical illness polyneuropathy. Furthermore, dysautonomia and occasionally external ophthalmoplegia is also observed in Guillain-Barré syndrome but has virtually never been attributed to critical illness polyneuropathy.

Electrophysiologic findings are also helpful in distinguishing between these two disorders. Features of segmental demyelination may be observed in Guillain-Barré syndrome on nerve conduction studies (e.g., reduced conduction velocity, prolonged distal and F-wave latencies, conduction block, and temporal dispersion of compound muscle action potentials); these findings are not observed in critical illness polyneuropathy. Needle electromyographic findings may differ in that relatively less spontaneous activity is observed in clinically weak muscles within the first few days in patients with Guillain-Barré syndrome. Although electrophysiologic studies are quite helpful in demonstrating the classic demyelinating form of Guillain-Barré syndrome, an electrophysiologic distinction between the axonal forms of Guillain-Barré syndrome and critical illness polyneuropathy may not be reliable. The mean CSF protein level in Guillain-Barré syndrome is significantly higher than in critical illness polyneuropathy, although there is overlap between these populations. Peripheral nerve histopathology may also distinguish between these two groups because segmental demyelination and inflammatory changes may be observed in Guillain-Barré syndrome and are not observed in critical illness polyneuropathy.

Although the overall prognosis in critical illness polyneuropathy is dependent on recovery from the underlying critical illness, most patients who survive experience a functional recovery from the neuropathy within several months. Critical illness polyneuropathy may prolong ventilator dependence, but it does not worsen the long-term prognosis. Proper positioning and padding are important to prevent compression neuropathies because the prognosis from superimposed compression neuropathies in the context of critical illness polyneuropathy is less favorable.

The pathophysiology of critical illness polyneuropathy is unknown. No clear metabolic, drug, nutritional, or toxic factors have been identified, although the severity of critical illness polyneuropathy has been correlated with the amount of time in the ICU, the number of invasive procedures, increased glucose concentrations, a reduced albumin concentration, and the severity of multiple organ failure. Given the common antecedents of multiple organ failure and sepsis in which release of cytokines occurs, increased microvascular permeability has been postulated to produce axonal hypoxia and degeneration as a consequence of endoneurial edema.[52]

Critical illness neuromyopathy, with evidence of myonecrosis, is the co-occurrence of neuropathy and myopathy; the latter is discussed later under Acute Quadriplegic Myopathy. The diagnosis requires electrophysiologic studies and may be confirmed with muscle biopsy, although the latter is rarely performed.[53]

Prolonged Effects of Neuromuscular Blocking Agents

A prolonged neuromuscular blockade may occur with most depolarizing and nondepolarizing agents, particularly when the hepatic or renal function is impaired.[54] In one study, the administration of vecuronium for 2 or more consecutive days resulted in prolonged neuromuscular blockade and paralysis lasting from 6 hours to 7 days.[55] Although vecuronium is hepatically metabolized, patients with renal failure were susceptible to prolonged effects because of delayed excretion of the active 3-desacetyl metabolite. Acidosis and elevated serum magnesium levels were also associated with prolonged paralytic effects of vecuronium. A peripheral nerve stimulator may be used to monitor muscle twitch responses to a train-of-four stimulus during the use of neuromuscular blocking agents. Drug dosage should be titrated to preserve one or two twitches to avoid overdosing. Two- to three-Hz repetitive nerve stimulation studies may also be used to confirm neuromuscular blockade when it is suspected. Because atracurium and cisatracurium do not require organ metabolism for clearance, they are rarely associated with this problem.

Acute Quadriplegic Myopathy

The syndrome, known as *acute quadriplegic myopathy* or *acute myopathy of intensive care*, was originally described in 1977 by a young woman who developed severe myopathy after treatment of status asthmaticus with high doses of corticosteroids and pancuronium.[56] Subsequently, there have been many citations of an acute myopathy developing in critically ill patients without preexisting neuromuscular disease. Acute quadriplegic myopathy has developed most frequently in the setting of severe pulmonary disorders in which neuromuscular blockade is used to facilitate mechanical ventilation, and high doses of corticosteroids are concurrently administered. In most reported cases, myopathy developed when nondepolarizing neuromuscular blocking agents were used for more than 2 days.[56] The development of acute necrotizing myopathy with myosin loss also occurs in patients receiving high doses of corticosteroids and hypnotic doses of propofol and benzodiazepines to induce paralysis.[57] This observation highlights the

significance of high-dose corticosteroid exposure in the development of this syndrome and suggests that the paralyzed muscles may be susceptible to the toxic effects of corticosteroids. The mechanism of this myosin abnormality appears to lie at the level of transcriptional regulation of protein synthesis. The occurrence of acute quadriplegic myopathy after organ transplantation may be caused by the use of high doses of corticosteroids to prevent graft rejection, along with perioperative exposure to neuromuscular blocking agents.[58] Although most cases of acute quadriplegic myopathy have been associated with critical illness and high doses of corticosteroids and paralytic agents, acute quadriplegic myopathy has developed after isolated corticosteroid exposure,[59] isolated nondepolarizing neuromuscular blocking agent use, or neither. Factors that may impair neuromuscular transmission (e.g., hypermagnesemia and aminoglycoside exposure), factors that may slow the elimination of nondepolarizing neuromuscular blocking agents (e.g., hepatic or renal failure), and factors associated with critical illness (e.g., sepsis and acidosis) are also associated with acute quadriplegic myopathy.

In typical cases, a diffuse flaccid quadriparesis with the involvement of respiratory muscles and muscle wasting evolves after several days of induced paralysis. External ophthalmoparesis has rarely been noted. Sensation remains intact, but deep tendon reflexes are reduced or absent. The creatine kinase level is commonly elevated, but this may not be observed if creatine kinase is measured well after the myopathy has developed. Although the paralysis may be quite severe and necessitate or prolong mechanical ventilation, the prognosis for the myopathy is good, with functional recovery over several weeks to months. Electromyographic findings include reduced amplitude of compound motor action potentials with normal sensory nerve action potentials and normal nerve conduction velocities. M-wave amplitude improvement accompanies clinical recovery. Repetitive nerve stimulation studies may yield decremental responses, while the residual effects of nondepolarizing neuromuscular blocking agents or their active metabolites persist. Needle electromyography often reveals small, low-amplitude, polyphasic motor unit potentials exhibiting early recruitment, along with positive sharp waves and fibrillation potentials. A spectrum of muscle histologic changes may be observed, ranging from type II fiber atrophy and the loss of adenosine triphosphatase (ATPase) reactivity in atrophic fibers to fiber necrosis in severe cases. However, the distinctive findings in most cases is an extensive loss of thick filaments corresponding to myosin loss.[59] This finding may be demonstrated by immunohistochemical staining or electron microscopy. The increased expression of steroid receptors in denervated and immobilized muscle may render these muscles susceptible to toxic catabolic effects of steroids. Given the growing recognition of acute quadriplegic myopathy, the use of high doses of corticosteroids should be avoided if possible when neuromuscular blockade or induced paralysis is required. One should exclude nutritional causes of muscle breakdown, along with drug toxicity (e.g., because of statins).

However, in a Cochrane review of interventions for preventing critical illness polyneuropathy and critical illness myopathy,[60] a randomized controlled trial of 180 patients with acute respiratory distress syndrome comparing corticosteroids with placebo that found no effect of treatment on critical illness polyneuropathy/myopathy[61] was cited as moderate-quality evidence. Additional results from the review found moderate-quality evidence for intensive insulin therapy in reducing polyneuropathy/myopathy at the expense of increased hypoglycemia[62,63] and for a potential benefit for early rehabilitation.[64] Larger randomized controlled trials of early rehabilitation and electrical muscle stimulation are needed to explore the value of these therapies.

ACKNOWLEDGMENT

Diana Goodman, MD, contributed substantially to the previous version of this chapter.

KEY POINTS

- Respiratory dysfunction resulting from neuromuscular disease typically presents with a combination of upper airway dysfunction and diminished tidal volume (V_T).
- Along with vital capacity, trended measurement of the maximum inspiratory pressure (PImax or NIF) is a useful index of ventilatory capacity. Inability to maintain a PImax greater than 20–25 cm H_2O usually indicates a need for mechanical ventilatory assistance.
- Autonomic failure and pulmonary embolism are now the major causes of mortality in Guillain-Barré syndrome.
- Evidence-based guidelines for Guillain-Barré syndrome immunotherapy have been published by the Quality Standards Subcommittee of the American Academy of Neurology. Plasma exchange is recommended for adult patients who cannot walk within 4 weeks of symptom onset. IVIg is recommended in these patients within 2 or possibly 4 weeks of symptom onset. Plasma exchange and IVIg are considered equivalent in efficacy, and no additional benefit is conferred by combining these treatments. In light of the therapeutic equivalence, the decision whether to employ plasma exchange or IVIg in treating acute Guillain-Barré syndrome may be determined by resource availability and by avoiding potential side effects related to a patient's medical comorbidities.
- In the initial North American outbreak of West Nile virus, about 10% of infected patients experienced flaccid weakness with clinical features resembling Guillain-Barré syndrome.
- Approximately 20% of patients with myasthenia gravis develop myasthenic crisis with respiratory failure requiring mechanical ventilation.
- Critical illness polyneuropathy is a widespread, axonal peripheral neuropathy that develops in the context of multiple-organ failure and sepsis. Critical illness polyneuropathy is possibly the most common neuromuscular cause of prolonged ventilator dependency in patients without prior known neuromuscular disease.
- Acute quadriplegic myopathy has developed most frequently in the setting of severe pulmonary disorders in which neuromuscular blockade is used to facilitate mechanical ventilation, and high-dose corticosteroids are concurrently administered.

Traumatic Brain Injury

Thaddeus J. Puzio and Sasha D. Adams

INTRODUCTION

Traumatic brain injury (TBI) is a medical and social problem worldwide, with an estimated 10 million cases leading to hospitalization or death each year.[1] Most TBIs are mild, and the incidence of TBI varies widely by ages and between countries.[2] In the United States, trauma is the leading cause of death in individuals aged 1–45 years old, and TBI accounts for the majority of these, with over 50,000 deaths per year.[3]

Traditionally, TBI has been classified based on mechanism (closed vs. penetrating), clinical severity (by Glasgow Coma Scale), and assessment of structural damage (by neuroimaging). TBI is a constellation of cellular responses that result from a primary and secondary injury. Primary brain injury results from external forces to the brain via various mechanisms. This can occur as a consequence of direct impact, rapid acceleration or deceleration, penetrating objects (e.g., gunshot), or blast waves from an explosion.[4] Secondary brain injury occurs from physiologic derangements that occur after the initial insult.[5]

PREHOSPITAL CARE

Care of the patient with TBI begins immediately in the prehospital setting. Proper field triage is critical, as the acutely injured brain is immediately vulnerable to secondary injury from physiologic derangements such as hypotension, hypercarbia, and hypoxemia. Care of the TBI victim always should begin with evaluating and securing a patent airway and restoring normal breathing and circulation, as such treatment has been shown to reduce mortality after severe TBI.[6] The airway can be quickly and safely secured by orotracheal intubation, but in patients with concomitant maxillofacial trauma, a surgical airway (cricothyroidotomy) should be performed if other attempts to secure an airway have failed. Rapid-sequence intubation is recommended to prevent transient hypertension, tachycardia, increased intracranial pressure (ICP), and agitation that can interfere with the procedure. Avoid inadvertent hyperventilation. Ventilatory rates of 10–12 breaths per minute for adults, 20 breaths per minute for children, and 25 breaths per minute for infants should supply adequate oxygenation. Therapeutic hyperventilation is inadvisable unless neurologic deterioration is clearly evident during evaluation and transport. Aggressive hyperventilation can cause cerebral vasoconstriction, reducing already low cerebral blood flow (CBF) and potentially causing or exacerbating cerebral ischemia.[7]

Another critical component of prehospital care for TBI patients is avoidance of hypotension. Rapid resuscitation and restoration of a normal blood pressure are critical, as hypotension has been associated with doubling of the mortality rate after severe TBI. In multisystem trauma, the most likely cause of hypotension is hemorrhage, usually in the abdomen or chest. Hypovolemia should be assumed to be hemorrhagic, and therefore these patients are ideally treated with blood transfusion. If blood products are unavailable, isotonic crystalloid should be infused, targeting normotension.

In all cases of suspected TBI, patients should be treated as if they have a spinal fracture until an adequate examination of the spine proves otherwise. Among those who survive long enough to reach the emergency department, the likelihood of a cervical spine fracture is 2%–7%. More troubling, however, is that an estimated 10%–25% of all posttraumatic cervical spinal cord injuries are iatrogenic because of improper cervical spine manipulation occurring during transport to the hospital in the setting of cervical spine fracture.[8] Spinal immobilization should occur immediately by placing the patient in a neutral position on a flat, hard surface. A rigid cervical spine collar should be placed, followed by immobilization on a long spine board.

It is important for prehospital providers to monitor patients for the "Cushing reflex." This phenomenon often signals impending brainstem herniation and is identified by hypertension, bradycardia, and abnormal breathing rhythm.[9] These patients need immediate neurosurgical evaluation with neuroimaging and may benefit from temporary hyperventilation.

PATHOPHYSIOLOGY

Under normal conditions, the total volume within the skull remains constant and is determined by the sum of the cerebrospinal fluid (CSF), blood, and brain tissue compartments.[4] This relationship is known as the *Monro–Kellie hypothesis.* CBF remains constant under normal conditions over a range of blood pressures via cerebral autoregulation. When one compartment is increased, such as in the setting of hematoma, there must be a compensatory decrease in another compartment in order to prevent intracranial hypertension.[3] A large proportion of TBI management is spent attempting to maintain homeostasis by controlling ICP, mean arterial pressure (MAP), and cerebral perfusion, and preventing cerebral edema.

FORMS OF PRIMARY BRAIN INJURY

Epidural Hematoma

Epidural hematomas (EDHs) develop between the inner table of the skull and the dura and are seen on computed tomography (CT) as a lens-shaped hyperdensity (Fig. 50.1). They are most commonly caused by disruption of the middle meningeal artery or one of its branches by a skull fracture. Classically, patients have a brief loss of consciousness followed by a "lucid interval" of normal mentation and then suffer an abrupt loss of consciousness. EDHs occur in 8%–10% of those rendered comatose by TBI.[10]

The majority of epidural hematomas are located in the temporal or parietal regions, but they can also occur over the frontal or occipital lobes and (rarely) in the posterior fossa. Their spread is limited by the

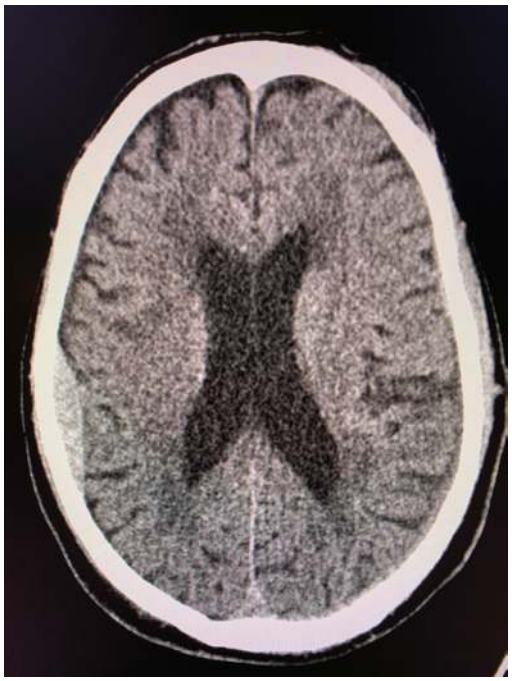

Fig. 50.1 Epidural hematomas have a lens shape and smooth inner border because they strip the dura from the inner table of the skull as they enlarge (axial computed tomography scan).

Fig. 50.2 Acute subdural hematomas (SDHs) typically spread over the entire surface of the hemisphere. Occasionally, mixed-density SDH is seen, indicative of injuries occurring at different times.

Fig. 50.3 Subarachnoid hemorrhage (SAH) is bleeding in the subarachnoid space, which lies between the arachnoid and pia mater.

suture lines of the skull, where the dura is very adherent. EDHs are uncommon in infants and toddlers, presumably because their skulls are more deformable and less likely to fracture, and in TBI victims older than 60 years of age, because the dura is extremely adherent to the skull.

Subdural Hematoma

Subdural hematomas (SDHs) develop between the surface of the brain and the inner surface of the dura and are seen on CT as a crescent-shaped hyperdensity (Fig. 50.2). They are believed to result from the tearing of bridging veins over the cortical surface or from disruption of major venous sinuses or their tributaries. The hematoma is limited to a single hemisphere by the falx cerebri and therefore does not cross hemispheres. SDHs are seen in 20%–25% of all comatose victims of TBI.[10]

SDHs are classified as acute, subacute, or chronic, each having a characteristic appearance on noncontrasted CT. Acute hematomas are bright white, subacute lesions; they are isodense with brain tissue and are therefore often overlooked. Chronic hematomas are hypodense relative to the brain.[11] Patients with SDH have a worse prognosis than patients with EDH because of the concomitant damage to neural tissue more commonly seen with traumatic SDH. Underlying cerebral contusions were found in 67% of patients with SDHs in one series.[12]

Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) is bleeding in the subarachnoid space, which lies between the arachnoid and pia mater (Fig. 50.3). This injury results from disruption of the parenchyma and subarachnoid vasculature. Trauma is the most common cause of SAH, but 80% of nontraumatic SAHs are the result of aneurysmal rupture.[13]

Traumatic SAH can sometimes be differentiated from nontraumatic SAH with noncontrasted CT, as traumatic SAH are typically located in a peripheral distribution and nontraumatic SAH are more likely to be central. CT angiogram (CTA) is the most sensitive and can identify nontraumatic SAH from a ruptured aneurysm. Traumatic SAH seen in the setting of moderate and severe TBI is a poor prognostic indicator and is associated with increased morbidity and up to twofold increase in mortality.[10,14] These patients may present with headache, meningeal signs, and photophobia.[13]

Diffuse Axonal Injury

Diffuse axonal injury (DAI) refers to lacerations or punctate contusions at the interface between the gray and white matter. Such punctate contusions are thought to result from the disparate densities of the gray and white matter and the consequent difference in centripetal force associated with a rotational vector of injury.[15] DAI was once thought to result solely from mechanical disruption at the time of

impact; however, more recent research has identified cases in which the histologic footprints of DAI, such as fragmentation of axons and axonal swelling, do not appear until 24–48 hours after the incident, suggesting that some cases are a secondary manifestation of trauma.[15] The gold standard for radiographic diagnosis of DAI is magnetic resonance imaging (MRI) of the brain. DAI is present in almost half of all patients with severe TBI and in a third of those who die, and it is a common cause of persistent vegetative or minimally conscious state.[16]

Cerebral Contusion

Contusions are heterogeneous lesions comprising punctate hemorrhage, edema, and necrosis and are often associated with other intracranial lesions (Fig. 50.4). One or more contusions occur in 20%–25% of patients with severe TBI. Because they evolve over time, contusions may not be evident on the initial CT scan or may appear as small areas of punctate hyperdensities (hemorrhages) with surrounding hypodensity (edema). Local neuronal damage and hemorrhage lead to edema that may expand over the next 24–48 hours. With time, contusions may coalesce and look more like intracerebral hematomas. Depending on their size and location, they may cause significant mass effect, resulting in midline shift, subfalcine herniation, or transtentorial herniation. Contusions are most common in the inferior frontal cortex and the anterior temporal lobes,[17] where the surface of the inner table of the skull is very irregular. Direct blunt-force trauma to the head can produce a contusion in the tissue underlying the point of impact (coup contusion). If the head was in motion upon collision with a rigid surface, a contusion may occur in the brain contralateral to the point of impact (contrecoup contusion).

Skull Fracture

Skull fracture results from a contact force to the head that is usually severe enough to cause at least a brief loss of consciousness. Linear fractures are the most common type of skull fracture and typically occur over the lateral convexities of the skull. A depressed skull fracture, in which skull fragments are pushed into the cranial vault, usually results from blunt force by an object with a relatively small surface area, such as a hammer. Basilar skull fractures are most common in the anterior skull base and often involve the cribriform plate, disrupting the olfactory nerves and resulting in olfactory deficits (Fig. 50.5). Posterior basilar skull fractures may extend through the petrous bone and internal auditory canal, thereby damaging the acoustic and facial nerves.

Fig. 50.4 Contusions are most common in the inferior temporal and frontal lobes. In the first few hours after injury, they appear only as areas of hemorrhage mixed with edematous brain. Within 24–48 hours after injury, further hemorrhage may occur, causing significant enlargement of the contusion and hematoma (axial computed tomography scan).

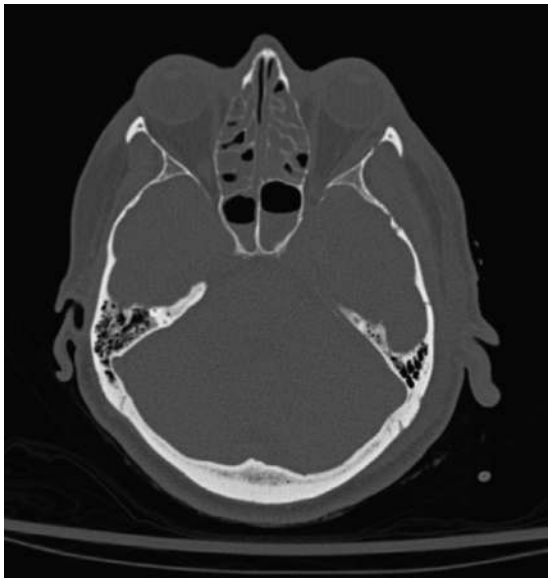

Fig. 50.5 Basilar skull fractures through the anterior skull base typically cause rhinorrhea and tears in adjacent dura. Computed tomography (CT) scans through the base of the skull may not show the fracture itself, but often show fluid in the sphenoid sinus or other paranasal sinuses (axial CT scan, bone window).

Skull fractures are markers of significant force to the head and are normally associated with underlying injuries. Skull fractures that involve the squamous portion of the temporal bone are frequently accompanied by a tear of the middle meningeal artery, causing an epidural hematoma. They can also cause facial nerve injury, exhibited as facial asymmetry that can present immediately or in a delayed fashion. Depressed skull fractures are often associated with contusions of the underlying brain tissue, and a scalp laceration overlying a depressed skull fragment can contaminate the fragment with bacteria from the scalp and hair. With a basilar skull fracture, the dura underlying the fracture is often disrupted, resulting in a CSF fistula and leakage of CSF from the nose or ear. Such fistulas may allow bacteria to enter the intracranial space from the normally colonized nose, paranasal sinuses, or external auditory canal.

CHARACTERIZATION AND MANAGEMENT

Glasgow Coma Scale

Patients with TBI are assessed with the Glasgow Coma Scale (GCS). This scoring system was originally developed in the United Kingdom in 1974 for patients with altered levels of consciousness.[18] It is now the cornerstone for assessing and comparing patients with TBI (Table 50.1). The GCS provides a common language to describe these patients, which then drives treatment decisions, allows for classification, and improves the quality of research on these patients.[19] Patients with TBI should be assessed for GCS in a prehospital setting, reassessed at hospital arrival, and continually reassessed throughout the course of their stay to monitor for changes.

TABLE 50.1 Glasgow Coma Scale

Response	Points
Speech	
Alert, oriented, and conversant	5
Confused, disoriented, but conversant	4
Intelligible words, not conversant	3
Unintelligible sounds	2
No verbalization, even with painful stimulus	1
Eye Opening	
Spontaneous	4
To verbal stimuli	3
To painful stimuli	2
None, even with painful stimuli	1
Motor	
Follows commands	6
Localizes painful stimulus	5
Withdraws from painful stimulus	4
Flexor posturing with central pain	3
Extensor posturing with central pain	2
No response to painful stimulus	1

Data from Teasdale G, Jennett B. Assessment of coma and impaired consciousness: a practical scale. *Lancet.* 1974;2:81–84.

The GCS is a sum of three component scores assigned for eye, verbal, and motor response. The score ranges from 3 to 15, and it is important to report the individual scores in addition to the total score. Up to 4 points are scored for the best eye-opening response, up to 5 points for the best verbal response, and up to 6 points for the best motor response.[18] The motor score provides the most points and has the most relevance to long-term prognosis. It is important to point out that in addition to brain injury, scores can be influenced by multiple other factors such as alcohol, drugs, and shock.[19]

Finally, the GCS score allows us to define severity for head injuries, which provides useful prognostic information. A GCS score 13–15 reflects a mild TBI, GCS 9–12 a moderate TBI, and GCS less than 9 a severe TBI.[20]

Goal-Directed TBI Management

In the acute phase after injury, a patient with TBI is best treated with goal-directed therapy in an attempt to minimize the physiologic derangements that create secondary brain injury (Table 50.2). These parameters encompass multiple body systems with potential for multiple interactions.

Neurologic Goal-Directed Therapy

The guiding principle for maintaining homeostasis is the desire to maintain cerebral perfusion pressure (CPP). Goal CPP is ≥60 mm Hg. This is thesd within the brain and is not directly measured, but calculated by the following equation:

$$\text{Cerebral perfusion pressure} = (\text{Mean arterial pressure}) - (\text{Intracranial pressure})$$

CPP is worsened (lowered) by systemic hypotension and/or by increasing ICP. Intracranial hypertension is defined as sustained ICP

TABLE 50.2 Goal-Directed Parameters for Head Injury

Pulse oximetry ≥95%	ICP 20–25 mm Hg	Serum sodium 135–145 mEq/L
PaO_2 ≥100 mm Hg	$PbtO_2$ ≥15 mm Hg	INR ≤1.4
$PaCO_2$ 35–45 mm Hg	CPP ≥60 mm Hg*	Platelets ≥75 × 10^3/mm^3
SBP ≥100 mm Hg	Temperature 36°–38°C	Hemoglobin ≥7 g/dL
pH 7.35–7.45	Glucose 80–180 mg/dL	

CPP, Cerebral perfusion pressure; *ICP,* intracranial pressure; *INR,* international normalized ratio; *$PaCO_2$,* partial pressure of carbon dioxide; *PaO_2,* partial pressure of oxygen; *$PbtO_2$,* brain tissue oxygen tension; *SBP,* systolic blood pressure.
*Depending on status of cerebral autoregulation.

greater than 20 mm Hg. Several clinical studies have found that morbidity and mortality increase significantly when the ICP persistently remains above this threshold.[21] Based on this association and the widely accepted premise that elevated ICP can compromise cerebral perfusion and cause ischemia, the aggressive treatment of intracranial hypertension is almost uniformly endorsed. Seizures, fever, jugular venous outflow obstruction (e.g., poorly fitting cervical collars), and agitation can cause or exacerbate intracranial hypertension.

Seizures have been shown to be detrimental to the injured brain. For this reason, patients with moderate and severe TBI should be maintained on an antiepileptic medication for 7 days postinjury. Additionally, fevers can lower the seizure threshold and should be prevented with scheduled antipyretics and aggressive treatment of infections.

Paroxysmal sympathetic hyperactivity, also known as *sympathetic storming,* may become evident when sedation weaning begins in up to 30% of patients. Hallmarks of storming include periodic episodes of seemingly unprovoked hypertension, tachycardia, tachypnea, diaphoresis, and hyperthermia.[22] Spontaneous posturing or dystonia may also be present during these episodes. Recognition of these symptom complexes as being neurologic in origin is key to avoiding treatment delays and unnecessary diagnostic testing. Treatment protocols are individualized, with most patients requiring various combinations of pain management, sedation, and reduced stimulation.

Respiratory Goal-Directed Therapy

Patients with GCS less than 8 should undergo intubation. This is in part because of a desire to avoid hypercapnia and hypoxia, which worsen long-term outcomes. These patients should be maintained at normocapnia (partial pressure of carbon dioxide [$PaCO_2$] 35–45 mm Hg). Hyperventilation is to be avoided, as it can cause cerebral vasoconstriction and should only briefly be performed in the setting of pending herniation (Cushing triad). Additionally, these patients should be monitored with pulse oximetry, and hypoxia is to be avoided, as it can lead to a worse prognosis. Goal PaO_2 should be greater than 100 mm Hg and pulse oximetry ≥95%.

Patients suffering severe TBI will require mechanical ventilation in an intensive care unit (ICU). If their level of consciousness remains persistently depressed, these patients should undergo tracheostomy, which should be performed within 8 days of injury.[20] Benefits of performing tracheostomy for patients undergoing prolonged mechanical ventilation include improved patient comfort because of reduced oropharyngeal irritation and improved pulmonary toilet. Early tracheostomy (fewer than 8 days) is associated with shorter mechanical ventilation duration and shorter ICU and hospital stays. Additionally, it is associated with lower risks of pneumonia, deep venous thrombosis, and decubitus ulcers.[23]

Hemodynamic Goal-Directed Therapy

Hypotension has been associated with a dramatic increase in mortality rate after severe TBI.[24] Thus it is critically important to avoid hypotension with a goal systolic blood pressure (SBP) ≥100 mm Hg. Trauma patients should be transfused blood in the setting of hypotension, but vasopressors can be used once resuscitated to euvolemia. These patients should be monitored closely with arterial line pressure monitoring and consideration given to trending central venous pressure. Additionally, vasopressors should be used to increase MAP in an attempt to target goal CPP ≥60 mm Hg.

Electrolyte Goal-Directed Therapy

Sodium regulation disturbances are common in TBI, and goal serum sodium is 135–145 mEq/L.[20] Hypertonic saline is used as a therapy for elevated ICP, as discussed in the next section, and in these patients target serum sodium levels are higher. Hyponatremia, defined as serum sodium ≤135 mEq/L, is the most common electrolyte abnormality encountered in patients with TBI and is an independent predictor of poor neurologic outcome.[25] In the setting of TBI, hyponatremia is believed to worsen brain edema, increase ICP, and result in secondary brain injury. The most common causes for hyponatremia include cerebral salt wasting (CSW), syndrome of inappropriate antidiuretic hormone (SIADH), hypopituitarism, and inadequate salt intake.[26]

Another disorder of sodium disturbance seen in TBI is diabetes insipidus (DI). This disorder arises from damage to the hypothalamic antidiuretic (ADH)-producing neurons in the posterior pituitary, which leads to a lack of ADH production.[6] This form of DI is termed "central," which delineates a neurologic etiology, in contrast to "peripheral" DI, which is a renal disorder. Central DI results in high-volume, dilute urine. This disorder is common and can be seen in up to ≈26% of patients with TBI. It is most commonly transient, but permanent DI can develop.[27] Patients with TBI should be closely monitored for polyuria and urine evaluated for low osmolarity, and they are treated with DDAVP or vasopressin.[28]

ELEVATED INTRACRANIAL PRESSURE MONITORING

ICP monitoring is indicated in patients with GCS ≤8 and should be considered in patients with a GCS >8 who have structural brain damage with high risk for progression.[20] The preferred method for ICP monitoring is an external ventricular drain (EVD) because it can diagnostically measure ICP and therapeutically drain off CSF, but it can be difficult to place, particularly if there is already edema and/or distortion of the brain parenchyma, and has risks of causing bleeding during placement. Intraparenchymal ICP monitoring is also a reliable method but does not allow for therapeutic CSF drainage. Finally, newer devices are available to measure brain tissue oxygenation (PbO_2), but their effect on outcomes remains unclear.[29]

ELEVATED INTRACRANIAL PRESSURE MANAGEMENT

A stepwise tiered approach for ICP treatment is usually followed, with the least toxic therapies used first and more toxic therapies added only if the initial tier of treatment is unsuccessful.

First-Tier Treatment for Elevated ICP: Positioning and Sedation/Analgesia Medications

A simple noninvasive method to decrease ICP is to elevate the head of the bed (or reverse Trendelenburg if on spinal precautions) to improve cerebral venous outflow. Next, sedation and neuromuscular blockade are often an effective treatment, particularly if the patient is agitated or posturing.[30] Narcotics (e.g., morphine, fentanyl), short-acting benzodiazepines (e.g., midazolam), or hypnotic agents such as propofol can be used for sedation. Narcotic-induced hypotension can be averted by using relatively low doses and ensuring the patient is normovolemic before treatment. If an EVD is present, an additional method to decrease ICP is to intermittently drain CSF via an EVD. If ICP remains >20 mm Hg despite these measures, one should move to second-tier strategies.

Second-Tier Treatment for Elevated ICP: Osmotic Agents and Brief Hyperventilation

Hyperosmolar therapy should be administered via intermittent boluses. A bolus administration of mannitol (0.25-2g/kg every 3–4 hours as needed) or hypertonic saline is recommended.[8,31] Mannitol exerts its effect through osmotic diuresis, lowering the ICP and increasing the CPP by expanding the blood volume, reducing the blood viscosity, and increasing CBF and oxygen delivery to the tissues within a few minutes of infusion. Its duration of effect averages 3–5 hours, but it should be avoided in the setting of hypotension or hemorrhagic shock and is therefore often avoided in multitrauma patients with concomitant injuries. Hypertonic saline appears to create osmotic mobilization of water across the blood-brain barrier without significant diuresis and is more appropriate in the setting of hypotension. Concentrations ranging from 3% to 23.4% have been used to decrease ICP.[32] The serum osmolarity and sodium level should be monitored frequently during the use of osmotherapy. The drugs should be discontinued if the serum sodium level exceeds 160 mg/dL or the serum osmolarity exceeds 320 mOsm in order to minimize the risk of acute kidney injury.[33]

An additional measure to lower ICP includes adjusting the ventilatory rate to reduce the arterial PCO_2 to 30 mm Hg.[7] Hyperventilation should be used cautiously during the first 24–48 hours after injury, because it will cause cerebral vasoconstriction at a time when CBF is already critically reduced. Evidence also suggests that even brief periods of hyperventilation can lead to secondary brain injury by causing an increase in extracellular lactate and glutamate levels. Its clinical use is therefore limited to pending herniation or as a bridge to third-tier treatment. Finally, if the previous measures still fail to reduce ICP, third-tier measures should be employed.

Third-Tier Treatment for Elevated ICP: Barbiturates, Cooling, and Surgical Intervention

If intracranial hypertension persists despite all these treatments, particularly if the ICP rises rapidly or if the patient's initial CT scan showed a small contusion or hematoma, another CT scan should be obtained immediately to determine whether a new mass lesion is present or a preexisting lesion has enlarged. Even if the lesion has enlarged only slightly, an emergent craniotomy and evacuation of the contusion or hematoma may be the best way to reduce the ICP quickly and effectively.

In the absence of new or expanding mass lesions, deepening sedation with high-dose barbiturates can be considered in patients with salvageable neurologic examinations. Pentobarbital is the most commonly used drug for this purpose and is administered as an intravenous (IV) loading dose of 10–15 mg/kg over 1–2 hours, followed by a maintenance infusion of 1–2 mg/kg per hour. Continuous electroencephalographic monitoring is recommended while increasing the dose until a burst suppression pattern is observed. Hypotension is the most common adverse effect of barbiturates and can usually be averted by ensuring a normal intravascular volume before administering the drug. In addition to deepening sedation, a paralytic agent should be considered.

Therapeutic moderate hypothermia has been used in several clinical trials over the past decade. Although some clinical trials have not found that this treatment improves neurologic outcome compared with normothermia, they have consistently shown that hypothermia significantly reduces ICP.[34] The body temperature is lowered to 32°C–33°C as soon as possible after injury and kept at that temperature for 24–48 hours using surface cooling techniques.

The use of decompressive craniectomies, such as large lateral or bifrontal bone flaps, with or without a generous temporal or frontal lobectomy, can be considered for a small subset of patients. Two studies report good outcomes in 56%–58% of patients whose refractory intracranial hypertension was treated with decompressive craniectomy as a last resort,[35] and another study suggested that decompressive temporal lobectomy, when performed soon after injury, improves the outcome for young patients.[36] However, others found that decompressive craniectomy does not improve ICP, CPP, or mortality rates.[37] Because age has such a profound impact on the likelihood of a meaningful recovery, these third-tier therapies are recommended only for patients who are younger than 40 years old.

SPECIAL CONSIDERATIONS

Penetrating Injuries

The most common cause of penetrating TBI is gunshot wounds to the head, which usually cause massive destruction of brain tissue, severe brain swelling, and, if the trajectory is transcranial, death. The wounding potential of a bullet depends primarily on its velocity at impact and its mass, although the shape of the bullet and its lateral movements also play a role. The impact velocity is by far the most important determinant of a bullet's wounding potential. Consequently, high-velocity rifle wounds to the head are invariably fatal, whereas low-velocity open-chambered handgun wounds often are not. When a bullet enters the skull, it creates a variety of pressure waves within the brain, some of which can cause tissue pressures of nearly 100 atmospheres, resulting in further tissue injury. Bullets often fragment after they strike the skull, fracturing the bone into multiple fragments. Both the bullet and the bone fragments then become numerous secondary missiles that can cause additional tissue damage.

Low-velocity missile wounds, such as those from knives, ice picks, or arrows, do not cause the massive brain injuries seen with bullets. Usually only the tissue in the immediate path of the missile is damaged, and patients often have a complete neurologic recovery after the missile is surgically extracted. Nonetheless, vascular injuries are always possible with high- or low-velocity missile injuries to the head, especially those in or near the skull base or the sylvian fissures.

The initial assessment and resuscitation of patients with penetrating head injuries are the same as for those with closed head injuries. Knives or other missiles protruding from the head should never be removed in the field or emergency department, as they may be creating a tamponade effect and removal could lead to massive intracranial hemorrhage. When a patient has a gunshot wound to the head, the rest of the body should be inspected carefully for other gunshot wounds, because wounds to the heart or great vessels in the chest or abdomen may be even more life threatening. A CT scan of the head defines the intracranial path of the missile and related skull and tissue damage. More importantly, it identifies any large intracranial hematomas or contusions that may significantly affect outcome. If the missile trajectory is in or near the skull base or sylvian fissures and the patient is deemed salvageable, cerebral angiography should be performed because this injury pattern is often associated with the development of pseudoaneurysms.[21]

Most patients who are expected to survive a penetrating head injury require limited operative treatment. Large intracranial hematomas should be evacuated promptly, and a craniotomy is required for low-velocity missile wounds in which the object is still protruding from the head. After removing a segment of skull containing the missile and a large enough area to allow for intracerebral exploration, the surgeon can seek and immediately repair or occlude any vascular injuries caused by the missile. For gunshot wounds to the head, the surgeon should perform a limited debridement of the scalp and skull wound, removing scalp, bone, and bullet fragments penetrating the brain only if they lie near the surface. Easily accessible necrotic brain should be debrided and meticulous hemostasis achieved. Subsequent medical management of penetrating injuries is as described previously for closed head injuries. Because a penetrating TBI by definition disrupts and contuses brain tissue, all patients with these injuries should also receive anticonvulsants for at least 7 days.[32]

Management Considerations for TBI in the Elderly

Elderly patients represent a special population that is at a higher risk of TBI than the general population and has a worse prognosis than younger injury-matched controls. Factors that contribute to this higher risk include anticoagulation for comorbidities, baseline neurocognitive disorders, and higher risk of falls seen in this group.[38] Neurologic evaluation of the elderly patient with TBI can often be complicated by preexisting dementia, cognitive decline, or hearing/vision deficits. Family and caregivers can be invaluable sources of information when trying to determine a neurologic "baseline." Elderly patients with mild TBI are at higher risk for intracerebral bleeding than younger patients, and therefore any patient age ≥65 years who presents with a mild head injury should undergo CT scanning.[39] Additionally, a multicenter study established that older patients after isolated TBI have poorer functional status at discharge and make less improvement at 1 year compared with all other patients despite a higher initial GCS.[40]

Prognosis After TBI

Predicting outcome soon after a TBI can help guide acute and chronic care and help prepare family members for the typically protracted recovery process. Equally important is that further treatment may be deemed futile, and expensive critical care or surgery can be reserved for those who are likely to benefit. Of course, early prognostication must be reliable, especially when withdrawal of life support is a consideration.

Several clinical and radiographic characteristics have proven useful for outcome prediction, but they must be used in concert.[41] Moreover, these criteria are more reliable for predicting death or vegetative survival than for accurately predicting mild or no dysfunction and a complete return to normalcy. The most powerful outcome predictors are age, initial GCS score (particularly the motor component), pupil size and reaction to light, ICP, and the nature and extent of intracranial injuries.

Marshall and colleagues devised a CT-based classification scheme that proved prognostically useful when applied to the patients in the Traumatic Coma Data Bank study (Tables 50.3 and 50.4).[42] The classification emphasizes the mass effect of posttraumatic intracranial lesions. Not surprisingly, these investigators found the worst outcomes among patients with large intracranial mass lesions and uncal herniation.

The patient's salvageability and prognosis after a penetrating injury are far clearer than for those with closed head injuries. Most victims of high-velocity gunshot wounds to the head die before or shortly after hospital arrival. A meta-analysis of recent clinical studies examining civilian gunshot wounds to the head and initial GCS of 3–5 found that

TABLE 50.3 Computed Tomographic Classification of Traumatic Brain Injury

Category	Definition
Diffuse injury I	No visible intracranial pathology
Diffuse injury II	Cisterns present, with midline shift 0–5 mm; no high-density lesion >25 mL
Diffuse injury III (swelling)	Cisterns compressed or absent, with midline shift 0–5 mm; no high-density lesion >25 mL
Diffuse injury IV (shift)	Midline shift >5 mm; no high-density lesion >25 mL
Evacuated mass lesion	Any lesion surgically evacuated
Non-evacuated mass lesion	High-density lesion >25 mL; not surgically evacuated

Data from Marshall LF, Marshall SB, Klauber MR, et al. A new classification of head injury based on computerized tomography. *J Neurosurg.* 1991;75 (Suppl.):S14–S20.

TABLE 50.4 Relationship of Computed Tomographic Classification to Outcome at Discharge

Category	No. of Patients	Unfavorable Outcome* (%)	Favorable Outcome† (%)
Diffuse injury I	52	38	62
Diffuse injury II	177	65	35
Diffuse injury III	153	84	16
Diffuse injury IV	32	94	6
Evacuated mass	276	77	23
Non-evacuated mass	36	89	11

Data from Marshall LF, Marshall SB, Klauber MR, et al. A new classification of head injury based on computerized tomography. *J Neurosurg.* 1991;75(Suppl.):S14–S20.
*Death, persistent vegetative state, or severe disability.
†Moderate disability or good recovery.

favorable outcomes occurred in only 5 of 490 patients.[43] Mortality rates ranged from 51% to 87% for patients with scores of 8 or less. In contrast, those whose initial GCS scores were 13–15 all survived and had favorable outcomes. Other clinical signs associated with death or a poor outcome are fixed and dilated pupils, intracranial hypertension, and hypotension.

The CT-defined extent of intracranial injury caused by the missile also has prognostic significance. Hyperdense lesions with a volume greater than 15 mL, midline shift of more than 3 mm, compressed or absent basal cisterns, SAH, and intraventricular hemorrhage are all associated with mortality rates of 80%–90%, as is a bullet trajectory that traverses both hemispheres, the basal ganglia, or the posterior fossa.[44]

ACKNOWLEDGMENT

The authors would like to thank Drs. Kimberly S. Meyer and Donald W. Marion, who wrote this chapter in previous editions and whose work informs much of the present discussion.

KEY POINTS

- Severe TBIs are the leading cause of morbidity and mortality for Americans between the ages of 1 and 45 years.
- Outcome after TBI is determined not only by the primary injury, such as skull fracture and subdural hematoma, but also by secondary injuries caused by physiologic derangements.
- Under normal conditions, the total volume within the skull remains constant and is determined by the sum of the CSF, blood, and brain tissue compartments.
- Proper field triage is critical for patients with suspected TBI, as the acutely injured brain is immediately vulnerable to secondary injury from physiologic derangements such as hypotension, hypercarbia, and hypoxemia.
- In the acute phase after injury, a patient with TBI is best treated with goal-directed therapy in an attempt to minimize the physiologic derangements that create secondary brain injury.
- A stepwise tiered approach for ICP treatment is usually followed, with the least toxic therapies used first and more toxic therapies added only if the initial tier of treatment is unsuccessful.

Spinal Cord Injury

Christian Cain and Jose J. Diaz, Jr.

INTRODUCTION

Despite many advances made in its diagnosis and treatment, spinal cord injury (SCI) continues to present challenging critical care issues to be treated, both acutely and chronically. The injury undoubtedly results in substantial psychological and financial impact not only on patients and their families but also to the general society. To date, the basis of care for patients with SCI has primarily focused on providing supportive care and preventing secondary injury. However, current investigations will certainly expand treatment options and improve the quality of care provided.

EPIDEMIOLOGY

The latest tabulations and projections provided by the National Spinal Cord Injury Statistical Center report an estimated incidence of 54 cases of patients with SCI per 1 million people living in the United States. More than 17,000 new patients will experience a SCI this year (this number does not include those with multiple traumatic injuries who die at the scene). The prevalence of injury is roughly 291,000, related mostly to improvements in critical care, and this number has increased steadily. The average patient is 43 years old, likely male, and may come from various socioeconomic and racial backgrounds.

The estimated lifetime cost of caring for one patient injured at the age of 25 with a cervical SCI is estimated to be more than $5 million. Acute care of patients with SCI only represents one phase of the rest of their lives. Seventeen percent of patients are employed 1 year postinjury, and this increases over time to around 30%. The combination of costly medical expenses, increasing overall survival, and high unemployment rates position SCI as a significant public health burden estimated to cost the United States at least $9.7 billion annually.[1]

ETIOLOGY

The causes of SCI vary widely. As of 2019, the leading cause of injury is still vehicular crashes, followed by falls, violence, and sports-related causes. Although these are among the most represented, it is essential to consider other nontraumatic etiologies, found in Table 51.1, as well. Early assessment starts with determining whether the injury is complete versus incomplete. This assessment is most important for predicting neurologic prognosis. The American Spinal Injury Association (ASIA) provides a classification system that characterizes the severity of cord injury. An initial incomplete injury (ASIA B–D) predicts a "potentially greater improvement in functional status" compared with a complete injury (ASIA A).[2]

PATHOPHYSIOLOGY

Acute SCI is the result of blunt or penetrating injury (traumatic etiologies) or numerous nontraumatic etiologies that result in the disruption of normal motor, sensory, or autonomic function. Two distinct phases characterize SCI. The primary phase consists of the physical compression of the spinal cord because of acute fractures or dislocation, leading to microhemorrhage, axonal damage, and cellular membrane damage.[3] The secondary injury is the result of cell membrane permeability changes, leading to loss of membrane stability, apoptosis, and tissue loss.[3] The degree and extent of the primary and secondary injuries determine the neurologic deficit.

INITIAL MANAGEMENT

If the patient might have a SCI, it is crucial to maintain a high index of suspicion and use spinal immobilization. These maneuvers include the use of in-line immobilization, maintenance of neutral position, cervical immobilization with a rigid collar, and use of backboards. From the field, a rigid collar immobilizes the cervical spine, and spinal precautions are taken to transport the patient. Upon arrival at the emergency department, precautions continue until physical examination and imaging confirm or refute a diagnosis. Rigid backboards are removed to avoid pressure ulceration. A thorough history and physical examination will determine whether the injury is complete or incomplete (i.e., is there any function below the level of injury?). Note any risk factors the patient may have for SCI. The level of injury is determined and baseline sensory, motor, and reflex abilities are described. For suspected high cervical injuries, baseline respiratory mechanic data, such as negative inspiratory force (NIF), force vital capacity (FVC), and tidal volume (TV), are useful for clinical assessment. The use of these data points as trends may highlight impending respiratory failure.

Resuscitation of the hypotensive patient with an SCI proceeds as with all trauma patients. Although upper spinal cord injuries can be associated with neurogenic shock, hypotension in the traumatically injured patient should be presumed hemorrhage until proven otherwise and may require isotonic fluid replacement or blood transfusion. An additional consideration is due in the case of the concomitant head injury, where the goal of hemodynamic support coexists with avoiding cerebral edema.

Once the ABCs of advanced trauma life support (ATLS) are addressed, the diagnostic algorithm proceeds to obtain imaging, as indicated. The National Emergency X-Radiography Utilization Study (NEXUS)[4] and the Canadian C-Spine Rule (CCR)[5] offer clinical guidance to help decide which patients do not require cross-sectional imaging to rule out cervical spine injury. Table 51.2 summarizes the guidelines. When considering imaging, it is essential to remember the

TABLE 51.1 Common Etiologies of Spinal Cord Injury

Category	Definition
Trauma	Blunt trauma
	Penetrating trauma
	Central cord syndrome
Nontraumatic	Ankylosing spondylitis
	Spina bifida
	Polio
	Osteoporosis
	Multiple sclerosis
	Spinal stenosis
	Metastatic fractures
	Acute blood loss/cord ischemia
	Anterior cord syndrome

TABLE 51.2 Decision Rules Guiding the Radiologic Assessment of Cervical Spine Injury

National Emergency X-Radiography Utilization Study (NEXUS)[4]	Imaging not necessary if age <60 + all five of the following: • Absence of posterior midline cervical tenderness • Normal level of consciousness • No evidence of intoxication • No abnormal neurologic findings • No painful distracting injuries
Canadian C-Spine Rule (CCR)[5]	Condition one (perform imaging): • Age >65 • Dangerous mechanism • Extremity paresthesia Condition two (low-risk factor allowing for range-of-motion assessment): • Simple rear-end motor vehicle collision • Arriving to emergency department in sitting position • Ambulatory at any time • Delayed onset of neck pain • Absence of midline cervical spine tenderness Condition three (active rotation of the neck 45 degrees to the left and right): • Imaging not necessary in patients able to rotate their neck, regardless of pain

Note: These rules are not applicable to patients with direct blows to the neck, penetrating trauma, or adults >60 years (NEXUS).

limitations of each of the modalities and choose the type that is best suited to answer the clinical question. Computed tomography (CT) is the most often used modality of imaging for several reasons. First, imaging can be obtained rapidly and can provide swift clinical answers. Second, it is available in most centers. Lastly, it can provide a complete assessment of other body zones that may be traumatized. Conversely, magnetic resonance imaging (MRI) is the preferred modality for ruling out ligamentous injury, hematoma, or disc herniation. Also, it provides the ability to assess the degree of cord compression.

In the case of the obtunded patient, practice guidelines from the Eastern Association for the Surgery of Trauma Practice Management Guidelines Committee describe three options for management. These are leaving the cervical collar in place until a clinical examination can be performed, removing the collar based on a negative CT alone, or obtaining an MRI of the cervical spine.[6] The literature lacks support for one method versus another. There is no guideline recommendation and should be at the discretion of each institution.

Finally, disposition of the patient is at the discretion of the clinician, but an intensive care unit admission, especially in the case of cervical injuries, for respiratory monitoring is recommended.

PROGNOSTIC FACTORS FOR RECOVERY

To properly advise the patient and family on the expected outcome and projected clinical course, a thorough history and physical examination, in addition to imaging, is necessary. In general, the patient's age, the involved level of injury, and the neurologic grade of injury (i.e., incomplete vs. complete) predict overall survival.[4] Patients with SCI often suffer multiple traumatic injuries in addition to any medical comorbidities they may have. Thus these factors will augment projected morbidity and mortality.[7] Initially, the ASIA score, mentioned earlier, aids not only in characterizing each injury type but also provides outcome data for each subtype.[8] A complete injury is the lack of motor or sensory function below the level of injury. Patients with a complete cervical SCI who remain neurologically deficient in the first 24 hours of admission are unlikely to regain significant ambulatory function.[9,10] Most patients who have an incomplete injury, however, will attain some degree of neurologic recovery within the first year postinjury. Cervical injury, when compared with thoracic or thoracolumbar injuries, have a higher potential for recovery.

Although much in this chapter corresponds to the acute management of a patient with SCI, it is worth noting that some patients may require the assistance of palliative care and hospice. It is of particular importance in the care of a patient with a remote history of SCI who is no longer responding to medical management of chronic complications of SCI; with progressive worsening of symptoms; those who have increased emergency department, inpatient, or outpatient visits related to complications; or those with a life-threatening complication. Further resources to aid in discussions of prognosis and functional outcome are located at https://pva.org/research-resources/publications/clinical-practice-guidelines/.

PEDIATRIC SPINAL CORD INJURY

Pediatric spine trauma is relatively uncommon, representing approximately 5% of all SCIs.[11] For a specific discussion of pediatric SCI, see published guidelines on this topic.[4]

THERAPEUTIC HYPOTHERMIA

With prevention being the key to decreasing the incidence of primary injury, there are few options to decrease secondary injury mechanisms. Because the treatment of SCI has consisted mainly of high-quality critical care and avoidance of secondary injury, other treatment options have been sought to add to the clinical armamentarium. One such intervention is therapeutic hypothermia. The use of therapeutic hypothermia began in the 1950s with cardiac surgery, and its use expanded to neurosurgery and SCI in the 1970s and 1980s with regional hypothermia.[12,13] The degree of cooling is divided by target temperature as "profound" (below 30°C), "moderate" (30°–32°C), and "modest" (32°–34°C).[14] The use of modest cooling is neuroprotective and reduces many of the known unwanted effects of cooling: acidosis, myocardial contractility abnormalities, coagulopathy, decreased renal

and hepatic function, electrolyte disturbances, prolonged drug clearance, and impaired insulin resistance.[13] Several animal models using modest cooling support the concept that hypothermia mitigates many of the secondary injury mechanisms.[12] The use of therapeutic hypothermia was introduced in 2007 to the United States publicly after the high-profile SCI of a National Football League player who sustained a C3–C4 injury with complete motor and sensory deficits. As part of his treatment, he received doses of methylprednisolone per the treating institution's protocol, prompt surgical decompression and fusion, and was cooled to 33.5°C 16 hours postoperatively. Within 2 hours, he experienced remarkable neurologic improvement that continued weeks into his recovery. The cause of the dramatic clinical improvement is likely the resolution of spinal shock and prompt repair of an incomplete SCI.[12] This outcome has prompted further questions regarding the potential use of hypothermia with SCI.

The American Association of Neurological Surgeons/Congress of Neurological Surgeons (AANS/CNS) position regarding therapeutic hypothermia recognizes the lack of data and evidence for or against its use and finds that "modest hypothermia might be applied safely to the population," but data from a multicenter, randomized controlled trial is needed.[15,16] The Miami Project for Paralysis and the University of Miami are among the leading centers investigating this question with their Acute Rapid Cooling Therapy for Injuries of the Spinal Cord (ARTIC) trial that has completed phase I and is undergoing phase II/III to evaluate the safety of different durations of hypothermia initiated 6 hours postinjury.[13] Without question, the findings of this study are necessary and highly anticipated.

MANAGEMENT IN THE INTENSIVE CARE UNIT

When admitted to the intensive care unit, patients with SCI are best approached with consideration of particular system issues. Knowledge of these critical concerns is imperative for caring for the patient and potentially avoiding complications that have a significant impact on morbidity and mortality. What follows is a systematic review of these critical topics.

Respiratory System

Respiratory complications are the most common cause of morbidity and mortality of patients with SCI. An estimated 80% of deaths in hospitalized patients with SCI are attributable to pulmonary causes, with pneumonia responsible for half of these cases.[17] Multiple hypotheses exist regarding the vulnerability of patients with SCI to infections. These include prolonged exposure to hospital pathogens, prolonged intubation, reduced ciliary clearance, nutritional deficiencies, and elemental exposure secondary to surgical procedures.[18] Additionally, the term *acute SCI immunodeficiency* has been coined to describe the impaired immunity that may occur secondary to the impaired gut microbiome.[18]

Besides the alteration of the patient's immunity, neurologic deficits affect the risk of pulmonary complications and lead to respiratory failure. In general, functional impairment worsens as the level of injury is more cephalad. A complete SCI, defined as the absence of motor or sensory function below the injury (ASIA score A), yields greater impairment than incomplete injuries (ASIA scores B–D).[18,19]

In neurologically intact patients, the diaphragm is the essential inspiratory muscle. It derives its innervation from the phrenic nerve supplied by cervical nerves three through five. Contraction of the diaphragm, along with the intercostal and scalene muscles, increases negative intrathoracic pressure and improves the efficiency of inspiration by caudally displacing the abdominal contents.[19] Most cervical spine injuries below C4 maintain diaphragm innervation. Diaphragm dysfunction occurs in patients with more cranially located lesions. Expiration, which is generally considered a passive process, requires the use of abdominal musculature to aid in thoracic emptying. Because the abdominal musculature receives innervation from thoracic and lumbar nerves, abdominal muscle function is absent in patients with complete injuries or injuries arising from upper thoracic levels. As a result, the combined clinical effect is a reduction in TV (most notably in the upright position versus supine), FVC, inspiratory capacity, and forced expiratory volume in 1 second (FEV_1).[19] In general, patients tend to exhibit respiratory decline between 24 and 72 hours postinjury. Thus early recognition of dysfunction requires a high index of suspicion.

The most common respiratory complications are atelectasis, pneumonia, and acute respiratory distress syndrome (usually related to multitrauma etiology). Although the incidence is low, pulmonary embolism is also of concern. The pathophysiology of most of the respiratory complications is related directly to the neurologic deficit and the inability for deep breathing, coughing, and clearing tracheobronchial secretions. Accumulation of secretions and mucous plugs may result in respiratory failure. Plugging can be prevented with regular pulmonary toilet chest physiotherapy, the use of intrapulmonary ventilation machines, bronchodilators, and mechanical ventilation.

Pulmonary infections are relatively common in patients with SCI for many of the reasons highlighted previously. The cause of pneumonia, when recognized, should be assumed normal respiratory flora if present on admission. Nosocomial organisms are likely causative agents the longer the patient resides in the hospital.

When patients with SCI are mechanically ventilated, their weaning should follow medical stabilization and take into consideration the location of the neurologic insult and any contribution the injury may have for further respiratory failure (i.e., higher cervical spine injuries). Weaning follows the typical course as with other critically ill patients. Special consideration for early tracheostomy should be made for patients with injury patterns that portend a poor respiratory outcome, preexisting pulmonary disease, and advanced age. Studies support the use of early tracheostomy in patients with these risk factors and may help shorten the time for liberation from mechanical ventilation.[20,21] Additionally, there is support from the literature that early tracheostomy, even after anterior spinal fusion, is safe and does not increase infectious risk.[21]

An estimated 40%–85% of patients with SCI will have a need for long-term ventilation. This need increases the higher the level of injury because of the loss of neural input to the diaphragm. Diaphragmatic pacing systems (DPSs) are used to stimulate diaphragm contraction and aid in ventilator liberation. Published retrospective data from one institution's experience with DPS resulted in fewer days to ventilator liberation and shorter hospital length of stay in patients with DPS compared with those without.[22] More investigation is needed to elucidate the complete benefits DPS may offer patients with SCI, but should be considered among the strategies for ventilator liberation.

Cardiovascular System

Spinal cord injuries above T6 disrupting sympathetic input may lead to neurogenic shock. Heralded by the presence of bradycardia and hypotension, neurogenic shock is the manifestation of unopposed vagal tone secondary to the disruption of sympathetic input, slowing the heart rate, decreasing systemic vascular resistance, and ultimately requiring vasopressor support. Although this clinical entity exists in patients with SCI, hypotension in any acutely traumatized patient should be considered the result of hypovolemic/hemorrhagic shock until proven otherwise—a condition corrected only with blood replacement and/or surgical hemostasis.

This clinical entity differs from the commonly confused misnomer of "spinal shock," which refers to temporary disruption of sensory and motor abilities below the level of SCI secondary to contusion with the gradual recovery of reflexes. Spinal shock occurs mainly with complete injury and is seen clinically as a period of areflexia and flaccidity replaced with hypertonia and spasticity.

The hemodynamic goal for the patient with SCI is the restoration of normal hemodynamics. Correction of hypotension should proceed with periodic intravenous (IV) fluid boluses to restore intravascular volume and may ultimately require the use of vasopressors. In cases of decreased systemic vascular resistance, a peripherally acting vasoconstrictor, such as norepinephrine, will counter the tendency for venous pooling and increase cardiac venous return.

Hypotension should be avoided, as decreased perfusion may accentuate the blossoming secondary injury of the spinal cord. Early aggressive volume resuscitation and increasing a patient's mean arterial pressure ("MAP push") is associated with enhanced neurologic outcome in SCI, should be considered an additional management tool,[23] and has become an essential component of our clinical practice in patients with SCI. Catapano and colleagues found a positive correlation between MAP ≥85 mm Hg and neurologic recovery in ASIA A, B, and C subtypes and concluded that those with initially complete injuries might benefit the most from "MAP push."[24] Current management guidelines call for early surgical decompression and maintenance of MAP ≥85 mm Hg for 5 consecutive days.[25]

Gastrointestinal System

Most of the gastrointestinal complications in patients with SCI are a result of unopposed vagal stimulation. The goals for patients are to tolerate oral intake and have regular elimination of waste without diarrhea or constipation. Some well-recognized bowel symptoms with SCI are constipation and fecal incontinence. Additional symptoms of concern are generalized abdominal pain and distension. Gastric distention may predominate upon initial management, and nasogastric tube placement is indicated.[26]

Patients with SCI are at particular risk for developing stress gastric or duodenal ulcers and require acid suppression prophylaxis. This risk increases in the case of patients receiving corticosteroids, as the risk of gastrointestinal bleeding in patients receiving corticosteroids (methylprednisolone) in the NASCIS II trial was 1.5 times that of the control group.[27,28]

Gastric emptying may also be impaired and complicate the full resumption of oral intake. Feeding access may then be required to provide adequate caloric intake. Professional swallow evaluation may be deemed necessary, particularly in patients with complete SCI, as impaired abdominal muscular innervation is associated with this injury type and may lead to gastrointestinal motility abnormalities.

Urinary System

Several patterns of SCI result in genitourinary system complications. In traumatic suprasacral injury, there is a period of spinal shock, as described earlier in the "Cardiovascular System" section, with resultant detrusor atony and areflexia.[29] The bladder experiences no contractions during this time, and the return of function follows the recovery of skeletal muscle reflexes (typically 6–8 weeks postinjury). The bladder atony manifests clinically as urinary incontinence and may lead to autonomic dysreflexia (also discussed in the "Cardiovascular System" section). Patients may experience "detrusor-external sphincter dyssynergia," where the bladder contracts but the external sphincter may not completely relax, leading to inefficient voiding. The result is high voiding pressures required for bladder emptying, hydronephrosis, and renal dysfunction if not recognized in routine outpatient care of the patient. In SCI with sacral lesions, areflexic bladder predominates, where the bladder does not contract, causing an overdistended bladder.[29]

A Foley catheter is placed initially for bladder decompression and may be switched to intermittent catheterizations, every 4–6 hours, 4 days postinjury to maintain bladder volumes less than 500 mL. The combination of bladder dysfunction, stasis, and instrumentation increases the risk of urinary tract infection, and diagnosis follows the routine algorithm. More comprehensive urinary system management recommendations can be found at https://pva.org/research-resources/publications/clinical-practice-guidelines/.

Hematologic System

Patients with SCI are at risk for venous thromboembolism (VTE) despite an overall decreasing incidence of occurrence in recent years. These thrombi in the deep veins of the upper or lower extremity may propagate, leading to pulmonary emboli. The majority of these events occur early in the clinical course of treatment. A high index of suspicion should be maintained, especially in patients of advanced age, those who are obese, those with complete injuries, and those with a history of previous thromboembolic events.[30,31] Current recommendations for prevention are the combined use of mechanical, pneumatic compression stockings and chemical prophylaxis with low-molecular-weight heparins (LMWHs), as the duration of its half-life is longer. Additionally, a lower risk of hemorrhagic complications is associated with the use of LMWH versus other heparins, and they have a more predictable dose-related effect.[32]

Evaluation for suspected venous thromboemboli requires the use of Doppler ultrasound. Cross-sectional imaging with IV contrast is used for high-resolution imaging if pulmonary embolism is suspected. Heparin is used to treat identified thromboemboli, and an inferior vena cava (IVC) filter should be considered in cases where a contraindication to anticoagulation exists. Prophylactic placement of vena cava filters in patients with SCI is not recommended.[32–34] This recommendation rests on two important findings. First, the trend of using IVC filters in trauma has decreased despite level three recommendation from the Eastern Association for the Surgery of Trauma in 2002 suggesting IVC filters be placed prophylactically in "very high-risk trauma patients" who either cannot be anticoagulated or have an anticipated prolonged immobilization course. This decrease correlates with the findings that in some trauma patients, the use of IVC filters correlates with increased deep venous thrombosis (DVT) risk.[34] Second, despite the decrease in IVC filter use, the incidence of pulmonary embolism has remained roughly the same. The conclusion suggests that there is limited utility in the use of IVC filters in trauma patients.[33]

Integumentary System

Pressure ulcers are the most common skin complication affecting patients with SCI. Ulcers result from contact of the skin with support surfaces and result in ischemic insult to microvasculature, pain, necrosis, and skin sloughing.[35] A thorough history and physical examination identifies patients with skin at risk for pressure ulcers. Strategies for prevention include pressure offloading, daily integumentary checks, frequent repositioning, and proper wound care.[35] Treatment of the wound may be nonsurgical, surgical, or a combination of both. More extensive information is at https://pva.org/researchresources/publications/clinical-practice-guidelines/.

PHARMACOTHERAPY

The role of corticosteroids and gangliosides in the treatment of acute SCI is highly debated. The proposed benefit of the use of methylprednisolone

sodium succinate is attributed to its antiinflammatory properties. The properties prevent "the loss of spinal cord neurofilament proteins, facilitate neuronal excitability and impulse conduction, improve blood flow, enhance N^+/K^+-ATPase activity, and preserve the cord structure by decreasing lipid peroxidation and preventing ischemia-induced tissue damage."[3] To date, three trials have evaluated the outcomes of the use of corticosteroids in patients with SCI. Summarized in Table 51.3, the NASCIS trials (I–III)[27,36,37] explore questions regarding the role of glucocorticoids in the treatment of SCI. The lack of level one, evidence-based evidence makes the routine use of steroids highly controversial.

The use of GM-1 gangliosides has been proposed as a potential treatment for SCI. These compounds are found within the cell membrane of mammalian central nervous tissue and work to promote anti-excitotoxic activity and neuritic sprouting, potentiate the effect of nerve growth factor, and prevent apoptosis.[28] There are two studies published by Geisler and colleagues describing the use of the GM-1 ganglioside Sygen in acute SCI patients.[38,39] These outcome data did not demonstrate a significant difference in neurologic recovery between those receiving the drug versus placebo. Because of the limited supporting data, the most recent AANS/CNS guideline contains level one recommendations against the use of corticosteroids and GM-1 ganglioside for the treatment of acute SCI.[28]

CHRONIC COMPLICATIONS

Because neurologic deficits experienced by patients with SCI span multiple organ systems, chronic complications are frequent. A listing of these complications is included in Table 51.4.

TABLE 51.4 Common System-Based Problems in Patients With Spinal Cord Injury (Acute and Chronic)

	Acute	Chronic
Respiratory system	Atelectasis Pneumonia Diaphragmatic paralysis Need for tracheostomy	Atelectasis Pneumonia
Cardiovascular system	Neurogenic shock Symptomatic bradycardia Coronary artery disease (chronic)	Autonomic dysreflexia Orthostatic hypotension
Gastrointestinal system	Stress ulceration Delayed gastric emptying	Chronic diarrhea or constipation SMA syndrome Neurogenic bowel
Genitourinary system	Urinary tract infection Sexual dysfunction	Urinary calculi
Hematologic system	Venous thromboembolism	Venous thromboembolism
Integumentary/ musculoskeletal systems	Decubitus ulcers	Contractures Spasticity and pain syndromes Osteoporosis and bone fractures

SMA, Superior mesenteric artery.

FUTURE INTERVENTIONS

The current treatment of SCI focuses on spinal cord stabilization and prevention of secondary injury. However, more potential targets for therapy will be identified as more is understood regarding the pathogenesis of injury. As of this writing, there are no Food and Drug Administration (FDA)–approved treatments available for SCI and a limited number of evidence-based support therapies for symptom and complication management.[40] The combined effort of the National Institutes of Health (NIH), societies such as the AANS/CNS, and major academic institutions have led to the development of new clinical trials that may address the dearth of information and data. A few privately funded institutions are also dedicated to the development of therapeutics and expanding the available knowledge.

In general, the treatment arms of research can be divided broadly into two main categories: those that limit secondary injury and those that promote regeneration. Future areas of investigation will include pharmacologic treatments for SCI, cell-based therapies to aid in the modulation of the inflammatory response in secondary injury, biomaterials to aid in structural repair of the spinal cord, and interventions aimed to improve functional and rehabilitative outcomes.[41]

CONCLUSION

Although there have been several advancements in the acute identification and treatment of SCIs in recent years, many questions remain unanswered that could guide clinical decision making acutely and aid in the management of chronic complications. Many of those questions are currently under investigation with high-quality randomized controlled trials. For the time being, the most prudent strategy would be the provision of evidence-based strategies for high-quality critical care delivery and maintaining an open mind to the strategies that may be proposed.

TABLE 51.3 Summary of Key Studies of Methylprednisolone Use in Spinal Cord Injury

Study Name	Study Summary	Conclusions
NASCIS I[36]	Low- vs. high-dose methylprednisolone (MP) for 10 days' duration with acute spinal cord injury (SCI)	Patients receiving high-dose steroids had more incidence of infections.
NASCIS II[27]	MP vs. naloxone vs. placebo in thoracic SCI patients	No difference in resulting neurologic function; post ad hoc findings showed a moderate motor improvement in patients receiving MP versus placebo. Wound infections more commonly noted in MP group.
NASCIS III[37]	MP ×48 hours vs. MP ×24 hours vs. tirilazad mesylate ×48 hours	No difference in outcomes in patients receiving medications within 3 hours of injury; MP given between 3 and 8 hours of injury associated with greater motor but not functional recovery. Increased incidence of sepsis and pneumonia in MP group.

KEY POINTS

- SCI continues to be a relevant healthcare issue.
- Most SCIs result from high-speed motor vehicle collisions.
- Outcomes of SCI are influenced by primary (occurring at the time of impact) and secondary (causing the progressive changes associated with SCI) injury.
- The sequelae of SCI span various organ systems.
- There are not many novel interventions for treatment; current treatment depends on the delivery of high-quality critical care.

Neuroimaging

Orrin L. Dayton IV

This chapter reviews available neuroimaging methods and their application in the evaluation and management of the critically ill and injured.

IMAGING MODALITIES

Radiography

Plain radiography plays a minor role in evaluating the neurologically ill or injured patient. Radiography is not sensitive for the detection of intracranial pathology and is not part of the standard imaging approach for the evaluation of patients with such pathology.[1] Conventional radiography plays a role in the evaluation of suspected spinal pathology, particularly in the setting of traumatic spine injury and assessment of spinal stability and postoperative complications.[2] Plain radiography is also used as a screening tool to assess for metallic foreign bodies, particularly in the orbits and intracranial compartment, in patients requiring magnetic resonance imaging (MRI), as the presence of such foreign bodies may result in injury to adjacent structures secondary to heating and motion from the strong magnetic field.[3]

Computed Tomography

Computed tomography (CT) uses ionizing radiation to create anatomic images on the basis of differential attenuation of photons between various tissue types. This results in an image composed of grayscale pixels on a spectrum ranging from dark, or hypodense, from tissues with low photon attenuation (air, water, fat) to bright, or hyperdense, from tissues with high photon attenuation (bone, metal). Soft tissues, such as brain parenchyma and muscle, are intermediate attenuators of photons and therefore exhibit grayscale values between low and high attenuators.[4]

CT is widely available, and there are no absolute contraindications to CT imaging in the acute setting. Its use of ionizing radiation does confer minimal risk to the patient related to radiation exposure. However, in the acute setting, the risk–benefit ratio almost always points towards imaging to aid in timely diagnosis. Advances in CT technology, particularly multidetector row CT (MDCT) and volumetric acquisition, allow for rapid imaging with high temporal and spatial resolution.[5] MDCT also allows for thin-slice image acquisition with the ability to manipulate CT data in multiple planes and perform postprocessing, such as volume rendering.

Iodinated contrast may be administered intravenously to increase sensitivity for detection of blood–brain barrier disruption and mass lesions and to evaluate the cerebral vasculature with CT angiography (CTA) techniques. CT perfusion imaging of the brain allows for assessment and quantification of brain perfusion parameters, including cerebral blood flow, cerebral blood volume, mean transit time, and time to peak enhancement. CT perfusion imaging is primarily used in the setting of cerebral ischemia.

Magnetic Resonance Imaging

MRI uses a strong external magnetic field and a series of radiofrequency pulses (nonionizing radiation) to confer energy to protons in tissues. Images are constructed based on the differential responses of these energized protons in different tissues (protons in water versus protons in fat). Imaging parameters are adjusted to allow for variable tissue weighting, thus highlighting specific tissues and pathologic processes.[6]

MRI is more sensitive than CT for detection of brain and spine pathology in almost all circumstances. However, longer imaging time precludes particularly unstable patients, given the required time away from the intensive care unit. Patients with certain medical devices and known or suspected retained ferromagnetic foreign bodies may not be eligible for MRI.

MRI uses nonionizing radiation. Therefore no radiation risk is conferred to patients. Gadolinium-based contrast media can be administered intravenously to detect blood–brain barrier disruption, masses, and vascular lesions. Contrasted imaging may also be used to assess the cerebral vasculature and brain perfusion parameters, similar to that described with CTA and CT perfusion. Noncontrast MR angiography (MRA) and perfusion techniques are also available for patients who cannot receive gadolinium-based contrast. Gadolinium is now known to be retained in the brain and in other organ systems. There are no known clinical sequelae to date; however, many investigators are studying the potential long-term effects of gadolinium retention.[7]

Several advanced MRI techniques are used in the evaluation of critically ill patients. Diffusion-weighted imaging (DWI) is based on the principle of water molecules being freely mobile and able to diffuse freely in all directions. Some pathologic processes, such as ischemia, cytotoxic edema, and abscess, restrict this free diffusion of water, which can be represented visually with DWI techniques. Diffusion restriction is also seen in pathologic processes associated with high cellularity, such as high-grade neoplasms. Diffusion-tensor imaging (DTI) is based on the same principles as DWI and allows for anatomic mapping of white matter tracts in the brain. This can be used to assess for alterations in brain connectivity in the setting of traumatic brain injury and to assess the anatomic relationship of white matter tracts to focal brain lesions.[8]

Nuclear Medicine

Several nuclear medicine studies are encountered in the neurocritical care setting. Planar brain scans using Tc-99m–labeled radiotracers

assess brain perfusion and are used in the determination of brain death.[9] Nuclear medicine cisternography is used to confirm and localize the site of a suspected cerebrospinal fluid (CSF) leak. Positron emission tomography (PET) and single-photon emission tomography (SPECT) play a role in the evaluation of epilepsy and seizure focus localization. Nuclear medicine scans using gallium-68 and radiolabeled white blood cells are used to localize occult infection and are useful in monitoring response to therapy, particularly in the skull base and spine.

BRAIN

Patterns of Disease

Cerebral Edema

Cerebral edema is a common response to brain pathology and is classified as either cytotoxic, vasogenic, or interstitial. Cytotoxic edema results from failure of adenosine triphosphate (ATP)–dependent transmembrane ion channels, leading to intracellular accumulation of fluid. The major causes of cytotoxic edema are ischemia and excitotoxicity. Vasogenic edema is the result of blood–brain barrier disruption, resulting in extravascular extravasation of serum proteins and fluid into the extracellular space. Common pathologic processes that cause vasogenic edema include neoplasms, infection, hemorrhage, and acute hypertensive syndromes. Interstitial edema occurs in the setting of increased ventricular pressure, which results in CSF flow through the minor CSF drainage pathways in the periventricular white matter. Interstitial edema is seen in the setting of acute hydrocephalus.[10] Regardless of subtype, edema appears as areas of hypodensity on CT and increased intensity on T2-weighted and fluid-attenuated inversion recovery (FLAIR) MRI sequences.

Cytotoxic edema presents on CT as areas of hypodensity involving the cerebral cortex to a greater extent than the underlying white matter, resulting in loss of normal gray matter–white matter differentiation. Gyri become swollen, and sulci are effaced (Fig. 52.1A). MRI will show increased signal, or hyperintensity, on T2-weighted and FLAIR sequences, which are sensitive to water. T1-weighted sequences will show corresponding regions of decreased signal, or hypointensity. DWI sequences will show hyperintensity, implying the presence of restricted diffusivity of water molecules within swollen neurons and glial cells. In contrast to cytotoxic edema, vasogenic edema preferentially involves white matter with relative sparing of gray matter. CT and fluid-sensitive MRI sequences show hypodensity and hyperintensity, respectively, throughout the involved white matter extending up to adjacent cortex and deep gray structures (see Fig. 52.1B). Interstitial edema presents in the setting of acute hydrocephalus and will show hypoattenuation on CT and increased signal on T2/FLAIR MRI sequences in the periventricular white matter, especially near the frontal and occipital horns of the lateral ventricles (Fig. 52.2).[11]

Intracranial Hemorrhage

The CT appearance of intracranial hemorrhage varies with chronicity. Immediate hyperacute hemorrhage may appear isodense to brain parenchyma or heterogeneous with admixed areas of isodensity and hyperdensity. Acute hematoma (0–3 days) develops when blood begins to form clots and retract, resulting in increased density over the ensuing hours and days. Focal areas of low density within an acute hematoma, particularly in a swirling pattern, may represent active bleeding. Acute hemorrhage reaches peak density at 3 days.

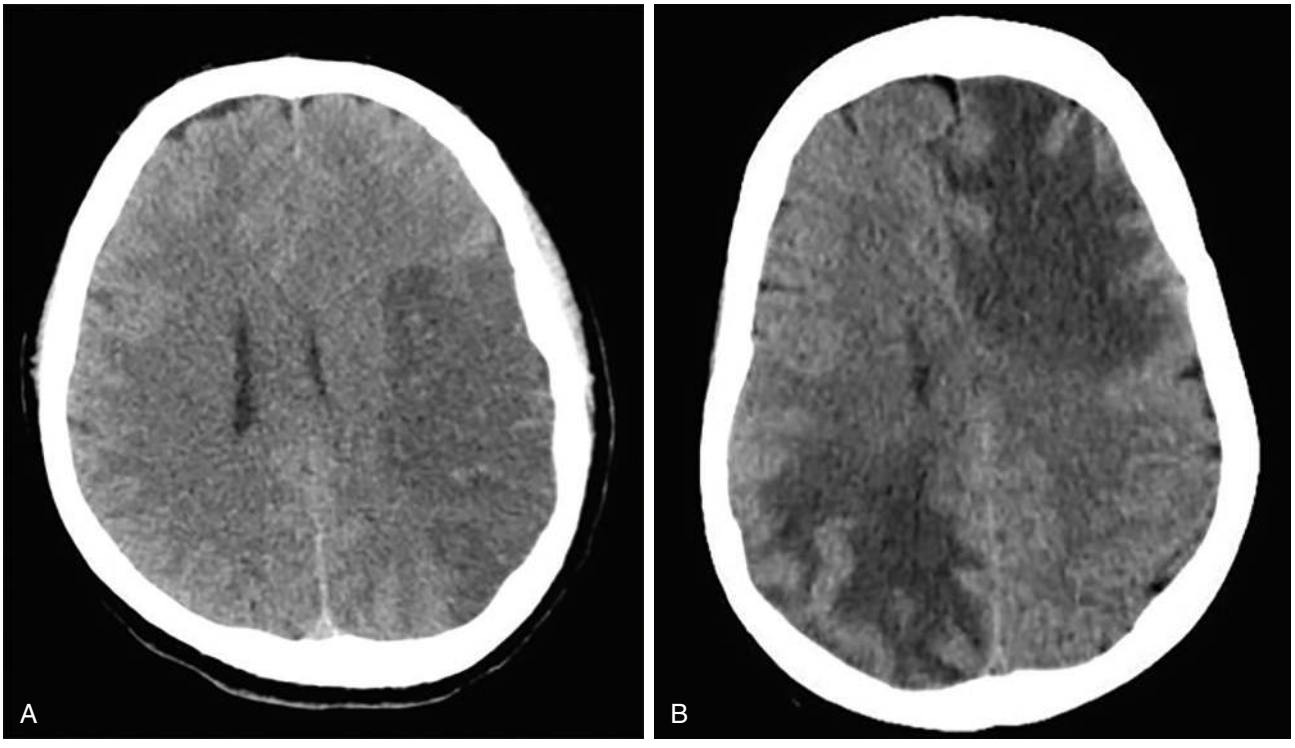

Fig. 52.1 Cytotoxic versus vasogenic edema. A, Noncontrast CT in this patient with left middle cerebral artery territory infarction shows cytotoxic edema as a region of hypoattenuation involving the cortex and adjacent white matter with effacement of the sulci. **B,** Vasogenic edema in a patient with metastatic disease presents as white matter–predominant hypoattenuation with relative sparing of the overlying cortex.

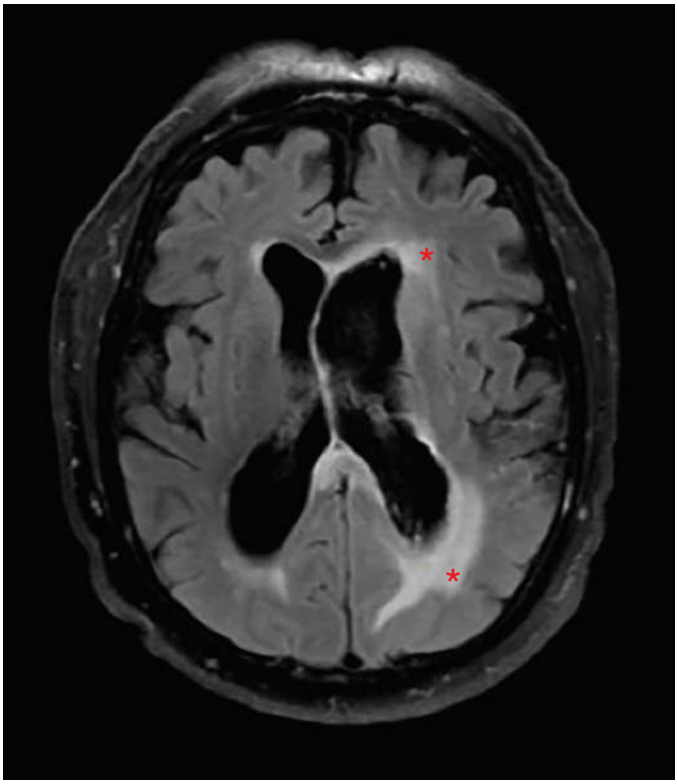

Fig. 52.2 Interstitial edema. FLAIR MRI shows hyperintense fluid signal in the periventricular white matter adjacent to the frontal and occipital horns of the left lateral ventricle *(red asterisks)* in this patient with intraventricular hemorrhage and acute obstructive hydrocephalus.

Progressive attenuation loss occurs after day 3 during the subacute phase of intracranial hemorrhage, with blood products usually becoming isodense to brain parenchyma 1–4 weeks after the initial hemorrhage. Chronic hemorrhage appears hypodense to parenchyma and similar to that of CSF, sometimes causing a diagnostic dilemma when trying to differentiate chronic subdural hematoma from subdural hygroma (Fig. 52.3).

Evolution of intracranial blood products on MRI is more complicated than on CT and is dependent on the stage of hemoglobin metabolism. Acute hemorrhage is composed predominantly of red blood cells (RBCs) containing deoxyhemoglobin, which presents as isointensity on T1-weighted images and hypointensity on T2-weighted images. Deoxyhemoglobin is oxidized to methemoglobin within RBCs during the early subacute stage, resulting in T1 hyperintensity and T2 hypointensity (Fig. 52.4A and B). The late subacute stage is characterized by RBC lysis, resulting in the release of methemoglobin into the extracellular space, which exhibits T1 hyperintensity and T2 hyperintensity (see Fig. 52.4C and D). Methemoglobin is consumed by macrophages and converted to ferritin and hemosiderin, resulting in areas of T1 and T2 hypointensity at the site of prior hemorrhage, representing chronic blood products (Fig. 52.5).

Mass Effect and Herniation

The dural partitions within the skull—the falx cerebri and the tentorium cerebelli—create compartments across which the brain may herniate.[12] The cranial vault is rigid, and therefore increased intracranial volume, in the form of blood, edema, or mass lesion, causes mechanical displacement of the brain parenchyma across dural reflections.[13]

Subfalcine herniation describes the herniation of the inferior portion of the medial frontal and parietal lobes—the cingulate gyrus—under the inferior margin of the falx cerebri. The ipsilateral ventricle

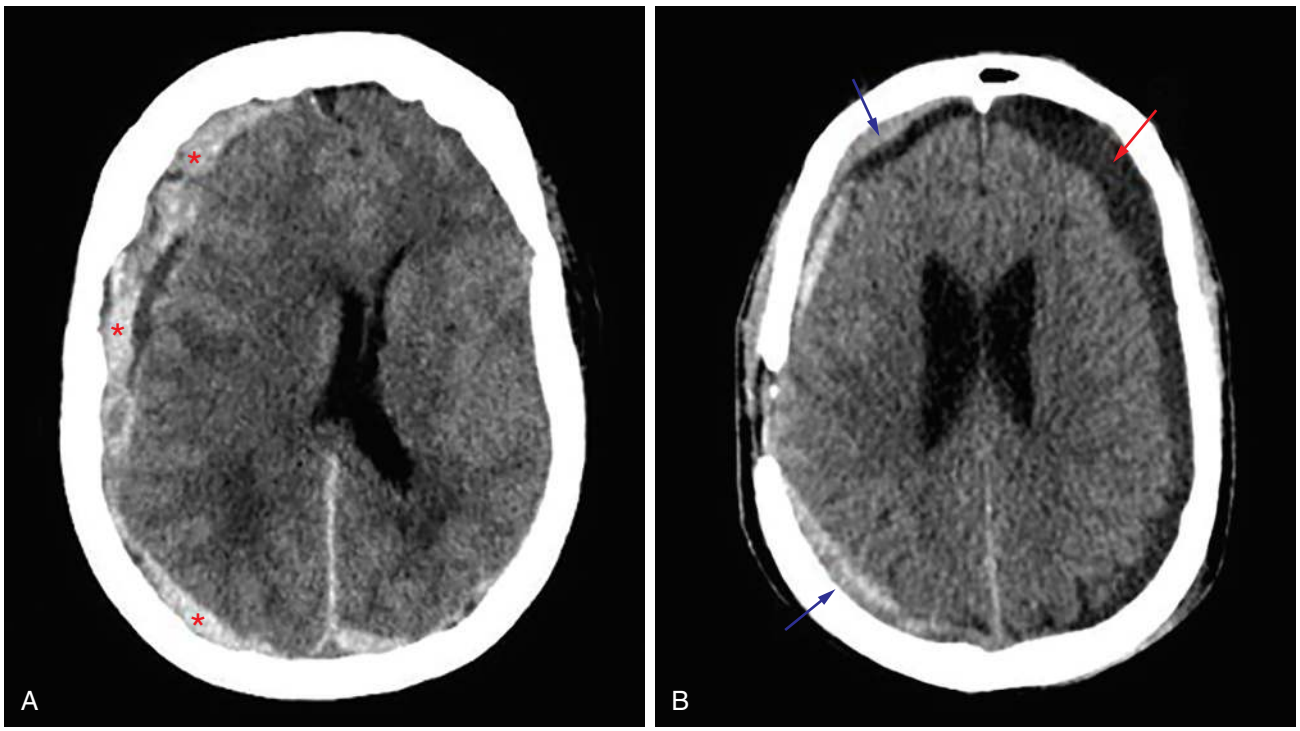

Fig. 52.3 Evolution of intracranial hemorrhage on CT. A, Acute subdural hematoma appears as a crescentic extraaxial collection hyperdense to adjacent brain parenchyma *(red asterisks)*. **B,** Subacute blood appears isodense to brain *(blue arrows)* and chronic blood appears hypodense to brain *(red arrow)* in this patient with mixed-age subdural hematomas.

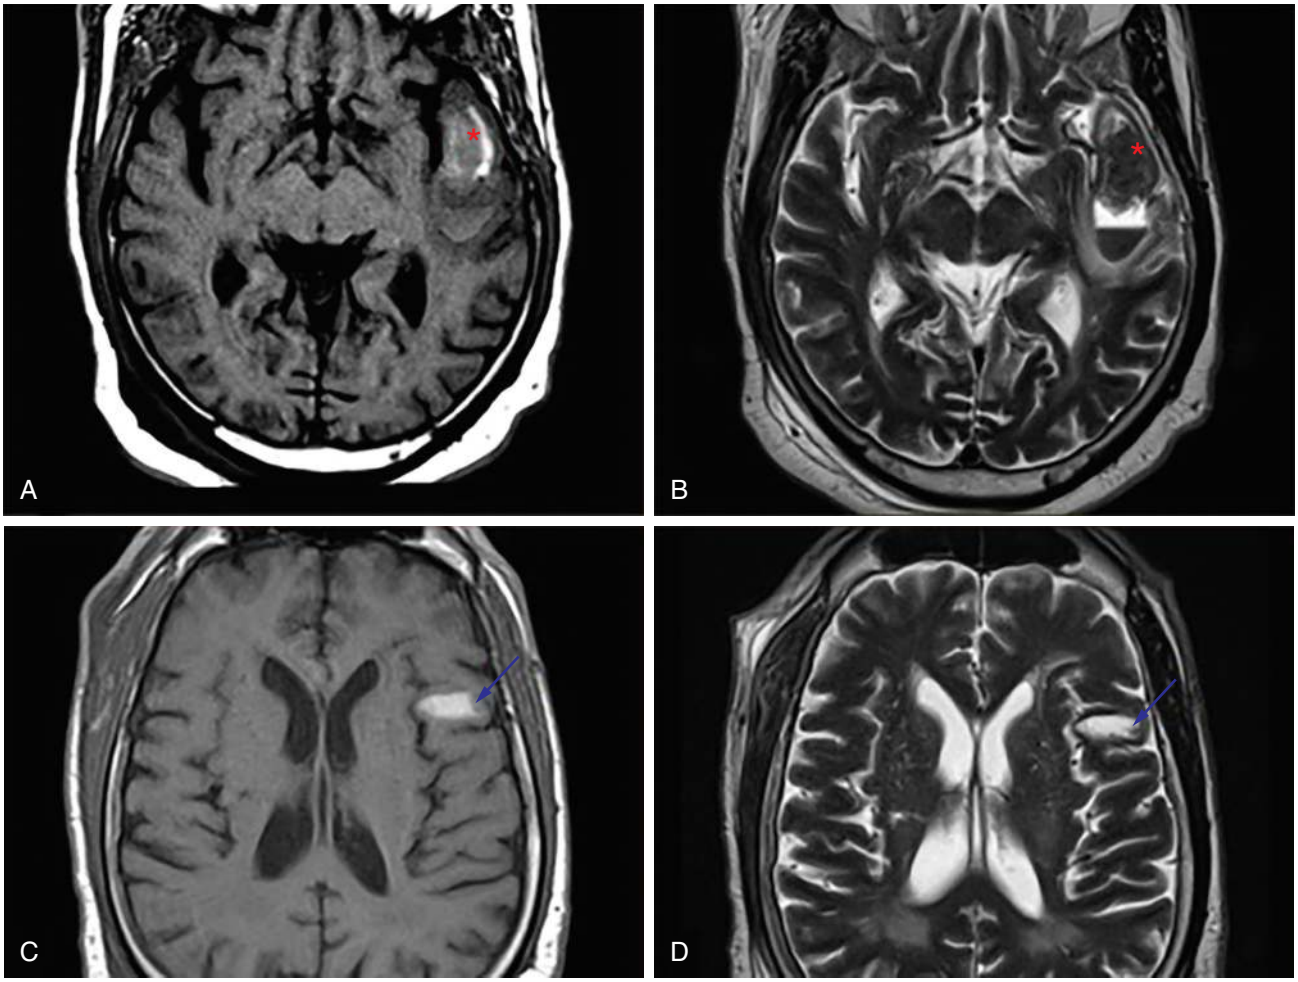

Fig. 52.4 Evolution of intracranial hemorrhage on MRI. **A and B,** Early subacute blood appears hyperintense on T1-weighted images **(A)** and hypointense on T2-weighted images **(B)** *(red asterisks).* **C and D,** Late subacute blood appears hyperintense on both T1- and T2-weighted images *(blue arrows).*

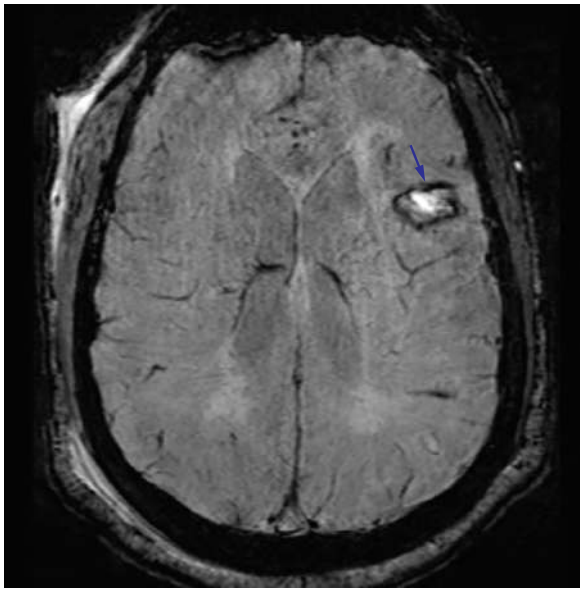

Fig. 52.5 Chronic blood products on susceptibility-weighted imaging (SWI). SWI sequence shows peripheral hypointensity surrounding an evolving intraparenchymal hemorrhage, representing deposition of chronic blood products in the form of hemosiderin *(blue arrow).*

will appear distorted and displaced across the midline, and the midline structures, including the third ventricle, will be shifted to the contralateral side. Severe subfalcine herniation may compress the contralateral foramen of Monro, resulting in entrapment of the contralateral lateral ventricle. The anterior cerebral arteries (ACAs) may become compressed under the falx cerebri, resulting in ACA territory ischemia and infarction (Fig. 52.6A).[14]

Descending transtentorial herniation occurs when the medial temporal lobe is displaced medially and inferiorly over the free edge of the tentorium cerebelli. The herniating brain effaces the suprasellar cistern and compresses the midbrain. The contralateral cerebral peduncle may be compressed against the contralateral tentorium, a phenomenon eponymously termed *Kernohan notch.* The ipsilateral posterior cerebral artery (PCA) may become compressed along the tentorial edge, resulting in occipital lobe ischemia and infarction (see Fig. 52.6B).[15] Ascending transtentorial herniation occurs in the setting of cerebellar pathology and is seen when the superior cerebellum herniates up through the tentorial incisura. The quadrigeminal cistern is effaced and the tectal plate of the midbrain is compressed, resulting in obstruction of the cerebral aqueduct and obstructive hydrocephalus.[16]

Tonsillar herniation describes the inferior displacement of the cerebellar tonsils through the foramen magnum into the upper cervical canal and occurs in the setting of posterior fossa pathology. The

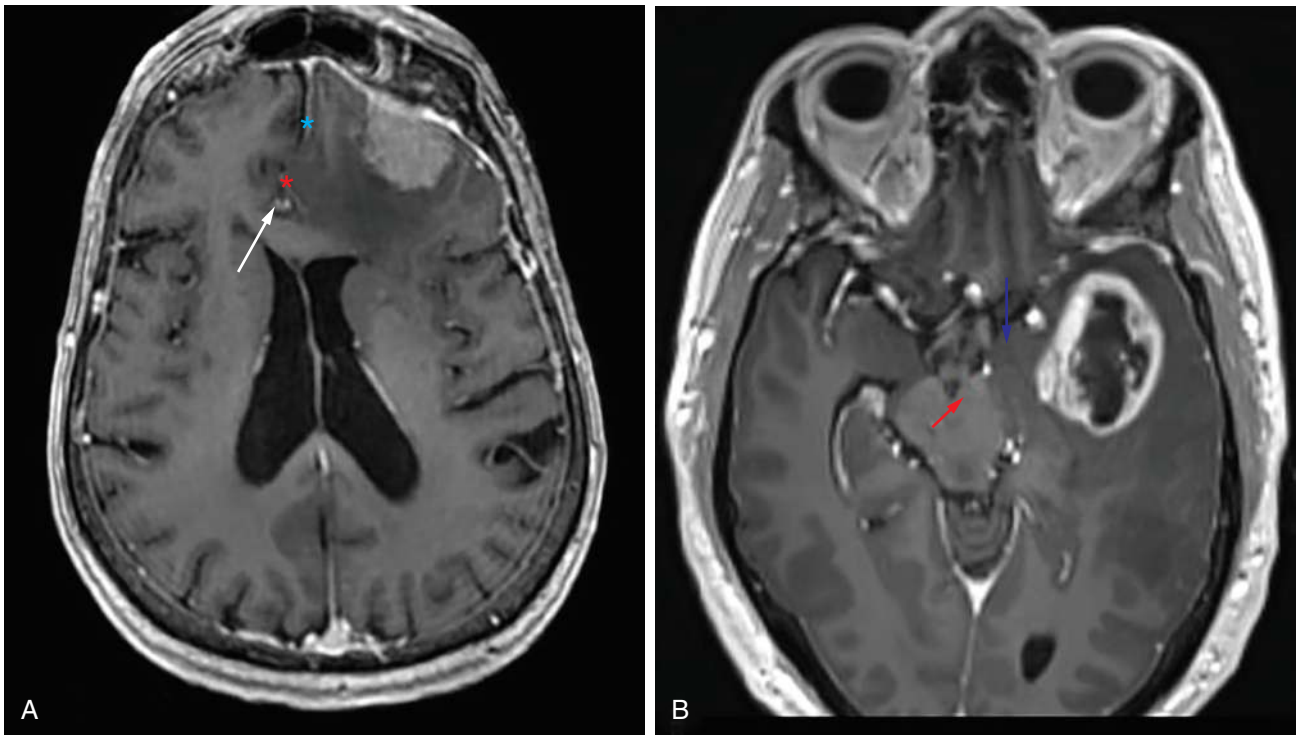

Fig. 52.6 Subfalcine and downward transtentorial herniation. **A,** T1-weighted image with contrast shows herniation of the left cingulate gyrus *(red asterisk)* under the inferior margin of the falx cerebri *(blue asterisk)* in this patient with a left frontal meningioma. Note deviation of the anterior cerebral arteries to the right *(white arrow)*, placing them at risk for injury. **B,** T1-weighted image with contrast shows downward herniation of the left uncus over the tentorium *(blue arrow)* in this patient with high-grade glioma, causing compression of the ipsilateral cerebral peduncle *(red arrow)*.

cerebellar tonsils may compress the medulla and upper cervical spinal cord, resulting in severe neurologic dysfunction and cardiorespiratory arrest.[17]

Transalar herniation describes the herniation of the brain and middle cerebral artery (MCA) vessels across the greater wing of the sphenoid and may be ascending (temporal lobe and MCA vessels) or descending (inferior frontal lobe). The major complication is MCA territory ischemia and infarction.

Pathologic Conditions

Traumatic Brain Injury

Traumatic brain injury (TBI) can be divided into primary injury and secondary injury. Primary injuries occur at the time of initial trauma and include skull fractures, contusion, intracranial hemorrhage, and axonal shear injury. Secondary injuries occur in a delayed manner and include cerebral edema and the herniation syndromes. Secondary injuries exacerbate the damage done at the time of primary injury.[18] The role of neuroimaging in TBI is to identify treatable primary injuries and to monitor for the development of secondary injuries. CT is the primary modality used for initial evaluation of TBI because of its wide availability, short image acquisition time, high sensitivity for intracranial hemorrhage, and lack of absolute contraindications. MRI is used to answer specific clinical questions and to provide more detailed information about the extent of injury.[19]

Cerebral contusions involve direct injury to the cortex and subjacent white matter as a result of direct impact of the brain against the calvarium or skull base. Typical locations include the inferior frontal and temporal lobes because of their close proximity to the undulating cortex of the anterior and middle cranial fossae, respectively. Contusions present as areas of hypodensity involving the cortex and white matter representing edema, which causes local mass effect and sulcal effacement. Areas of admixed hyperdensity represent petechial hemorrhage. Edema and hemorrhage often progress, or "bloom," in the first 24–48 hours resulting in increased mass effect and risk for secondary injury from brain compression and herniation (Fig. 52.7).[20]

Intracranial hemorrhage is a common sequela of TBI and may involve all intracranial compartments. Epidural hematoma appears as a lentiform extraaxial hematoma that does not cross calvarial suture lines. The outer layer of dura is adherent to the suture and is not stripped away by the expanding hematoma. Injury to a meningeal artery from a skull fracture is the most common etiology, and, as such, rapid hematoma expansion is possible (Fig. 52.8).[21] Subdural hematomas are caused by torn bridging veins, which traverse the subdural space as they drain the cerebral cortex to the overlying dura. They appear as a crescent-shaped extraaxial hematoma that crosses calvarial suture lines but not dural reflections (see Fig. 52.3).[22] Subarachnoid hemorrhage (SAH) and intraventricular hemorrhage (IVH) arise from injured cortical vessels and subependymal vessels, respectively. Traumatic SAH will present as curvilinear areas of high density within cerebral sulci commonly layering dependently in the posterior aspect of the sylvian fissure and the interpeduncular fossa of the midbrain. Traumatic IVH will present as high-density layering dependently in the occipital horns of the lateral ventricles.

Diffuse axonal injury (DAI) represents a pattern of injury involving axonal stretching and, in severe cases, shearing. It results from differential acceleration/deceleration forces on gray and white matter

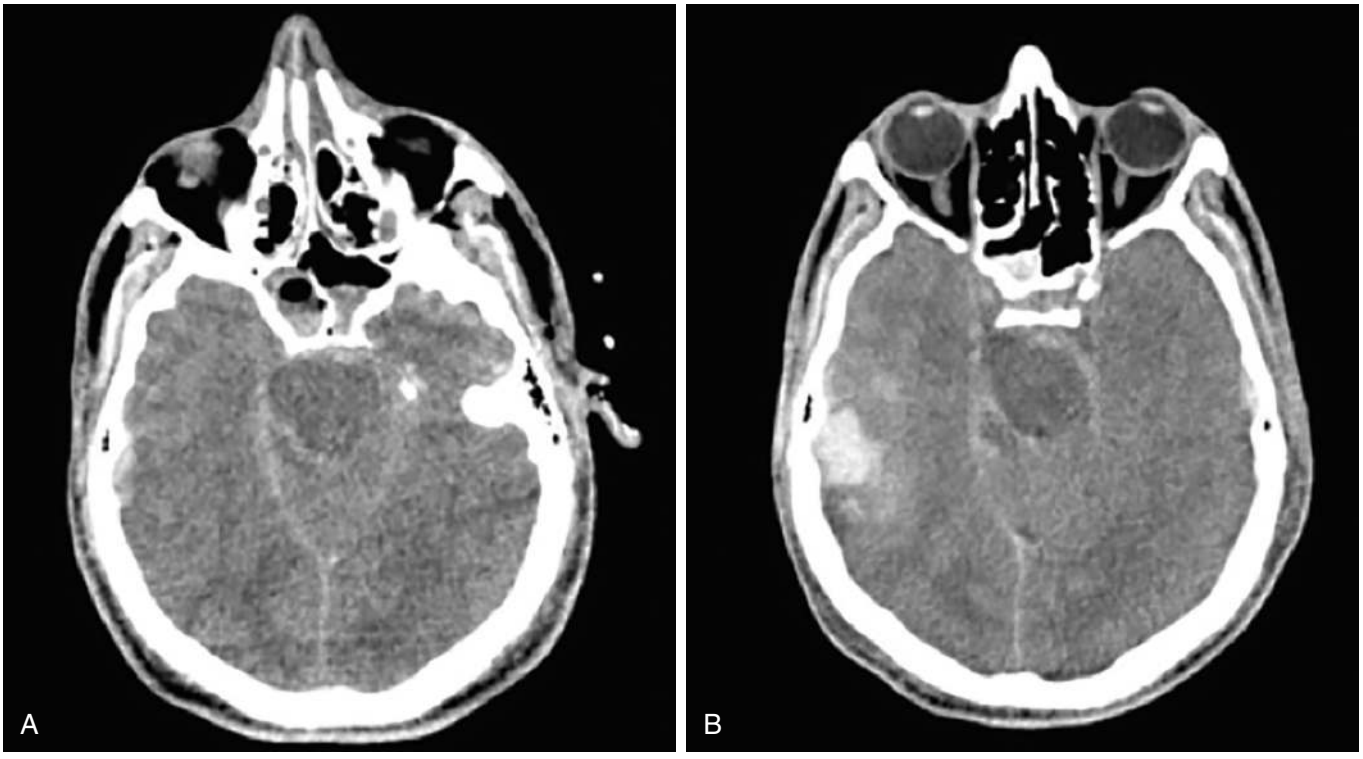

Fig. 52.7 Cerebral contusion. A, Noncontrast CT shows a subtle area of cortical hypodensity and interspersed hyperdensity along the inferolateral right temporal lobe in this patient with closed head injury representing a cerebral contusion. **B,** CT performed 24 hours later shows marked progression of the hemorrhagic right temporal lobe contusion.

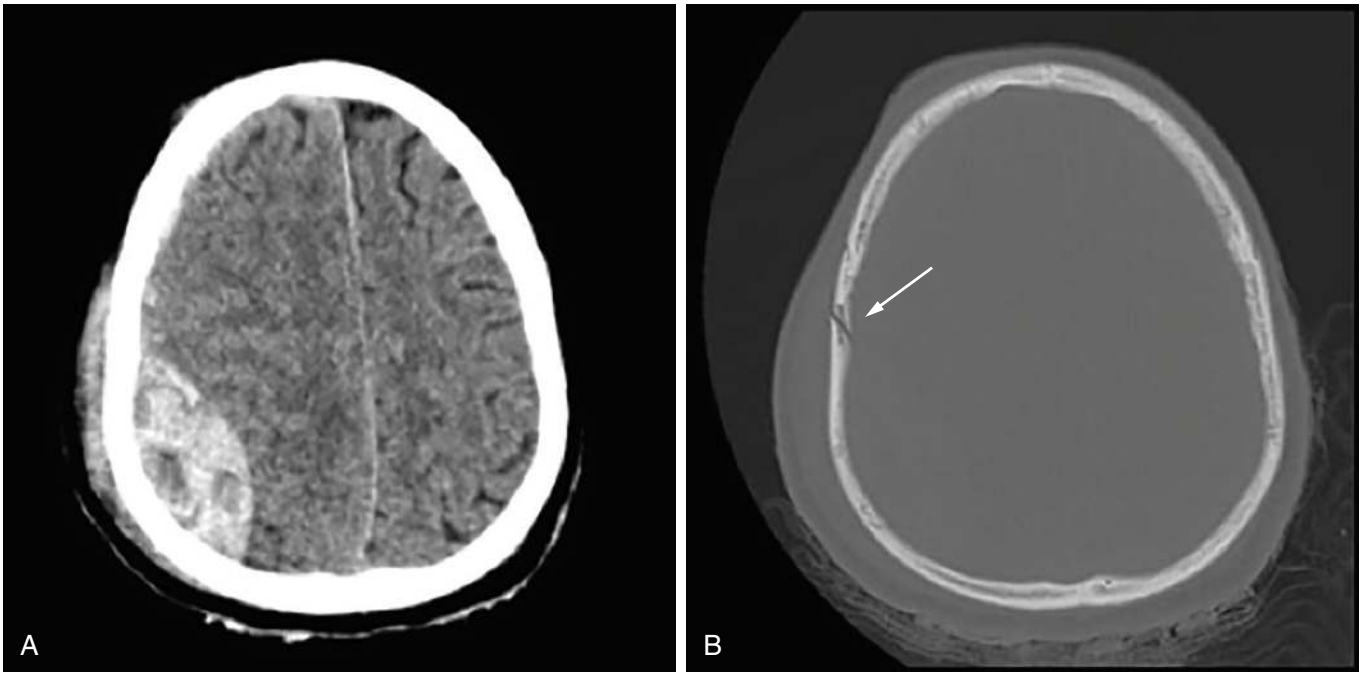

Fig. 52.8, Epidural hematoma. A, Noncontrast CT shows a hyperdense, lens-shaped extraaxial collection representing an acute epidural hematoma in this patient with closed head injury. **B,** Same CT viewed in bone windows shows a nondisplaced calvarial fracture *(white arrow)* associated with the epidural hematoma.

structures and occurs at predictable locations, including the gray matter–white matter junction (particularly in the frontal and temporal lobes), splenium of the corpus callosum, and dorsolateral brainstem. CT is normal in more than half of cases but may show small, round areas of hypodensity in nonhemorrhagic DAI and small, round foci of hyperdensity in hemorrhagic DAI. MRI is more sensitive for detection of DAI and is the modality of choice to delineate the extent of injury. Susceptibility-weighted imaging (SWI) sequences will show foci of hypointensity corresponding to small foci of hemorrhage, and DWI will show round or ovoid areas of restricted diffusion (Fig. 52.9). Several advanced MRI techniques, including DWI and DTI, are used to quantitatively assess the integrity of white matter tracts and provide a more detailed assessment of axonal damage. These techniques are also routinely being used to monitor changes in brain connectivity in the months and years after TBI.[23]

Vascular Pathology

Ischemia and infarction. Ischemic stroke accounts for approximately 85% of strokes and can be classified chronologically as acute, subacute, and chronic. CT is the initial imaging modality used to evaluate a patient with an acute neurologic deficit and primarily serves to identify an alternative cause for the patient's symptoms, such as intracranial hemorrhage or tumor. Acute stroke (0–48 hours) may present on CT as subtle loss of gray–white differentiation and parenchymal hypodensity representing cytotoxic edema. Thrombus within the affected vessels may appear hyperdense. Gyral swelling and sulcal effacement develops in 24–48 hours, representing progressive cytotoxic edema (see Fig. 52.1A). Subacute stroke (2–14 days) will show a wedge-shaped region of hypodensity with edema and mass effect peaking at 7–10 days. Contrast-enhanced CT will reveal a gyriform pattern of cortical enhancement beginning at 2 days, peaking at 2 weeks, and resolving at 2 months. Chronic infarct will appear as an area of hypodense, fluid-attenuation encephalomalacia and retracted parenchyma with volume loss resulting in ex vacuo enlargement of adjacent ventricles and sulci (Fig. 52.10).[24]

MRI is more sensitive than CT for detecting acute ischemia, especially in the first 24 hours. Acute infarct will present on DWI as an area of hyperintensity with a matching region of hypointensity on the apparent diffusion coefficient (ADC) map. It is important to interpret the DWI images in context with the ADC map to exclude T2 shine-through as the etiology for increased DWI signal (Fig. 52.11B and C). FLAIR shows increased signal in the affected cortex within 6 hours of ictus, representing developing cytotoxic edema (see Fig 52.11A). Slow or absent flow in leptomeningeal arteries may show increased signal on FLAIR images. SWI may show foci of hypointensity on the cortical surface corresponding to a clot within the vessel and correlating to the hyperdense vessel seen on CT (see Fig 52.11D). Subacute stroke is seen as parenchymal hyperintensity on T2 and FLAIR images involving the cortex and white matter, with mass effect and cytotoxic edema peaking at 7–10 days. Hemorrhagic transformation is best assessed on SWI, which is sensitive to even small regions of petechial hemorrhage. DWI will remain hyperintense, and ADC will normalize with the adjacent brain parenchyma and ultimately become hyperintense as gliosis and encephalomalacia predominate. Chronic infarct appears as areas of fluid-intensity encephalomalacia and hyperintense gliotic, contracted brain tissue. SWI may show foci of hypointensity corresponding to areas of hemosiderin deposition from chronic blood products.[25]

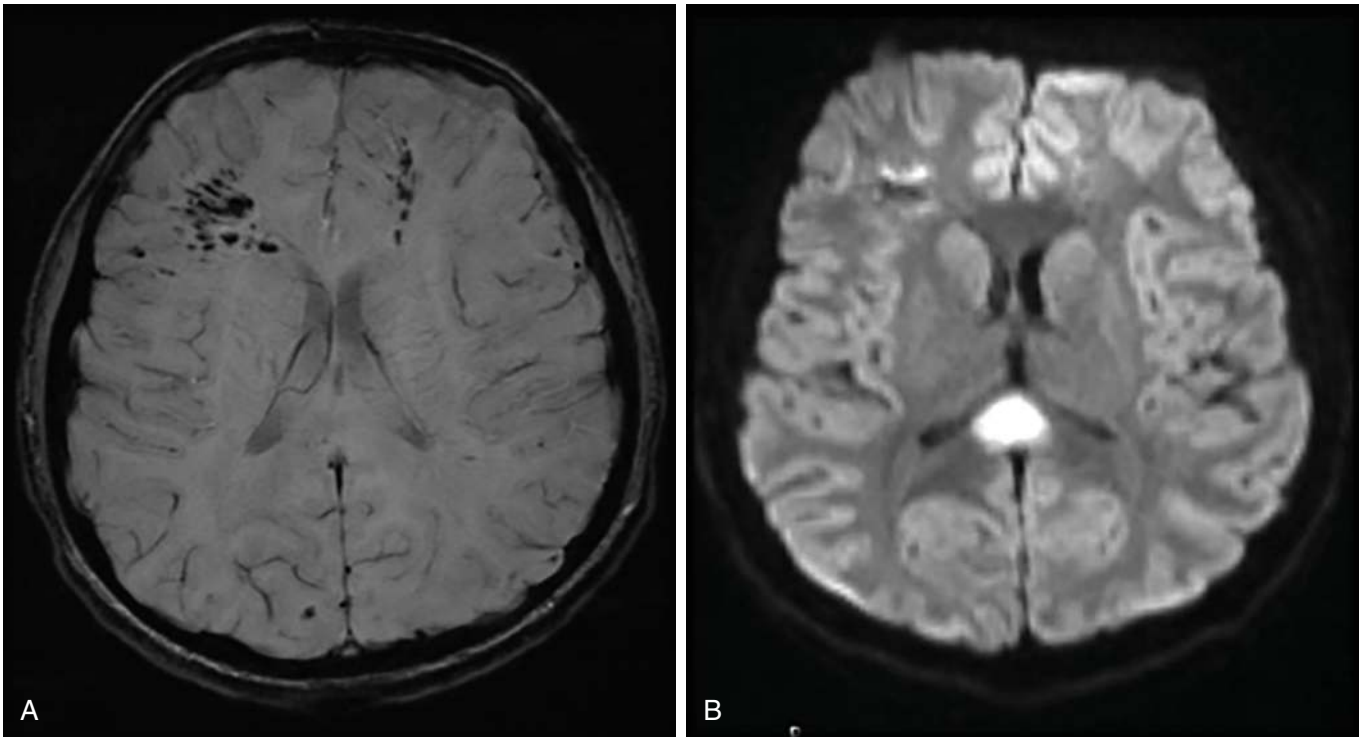

Fig. 52.9 Diffuse axonal injury. A, Susceptibility-weighted imaging demonstrates multiple foci of hypointensity centered at the gray matter–white matter junctions of both frontal lobes, representing hemorrhagic foci of diffuse axonal injury in a teenager with a closed head injury. **B,** Diffusion-weighted imaging in the same patient shows a large focus of restricted diffusion, representing nonhemorrhagic diffuse axonal injury centered in the splenium of the corpus callosum.

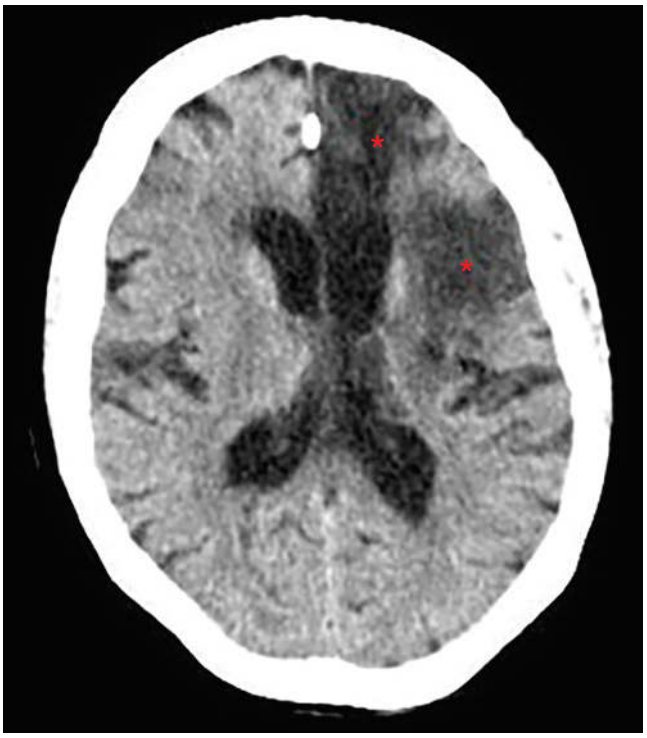

Fig. 52.10 Chronic infarction. Noncontrast CT shows fluid-density encephalomalacia and volume loss in the left anterior and middle cerebral artery territories *(asterisks)* in this patient with chronic left hemisphere infarctions.

CT and MR perfusion imaging techniques allow for qualitative and quantitative assessment of cerebral perfusion parameters. These techniques allow for early detection of reversible and potentially treatable areas of ischemic penumbra and differentiation of these lesions from areas of irreversible ischemia (Fig. 52.12).[25]

Aneurysmal subarachnoid hemorrhage. Cerebral aneurysms account for 85% of spontaneous SAH. CT is the initial imaging modality used to assess for the presence of SAH. Lumbar puncture is often pursued in patients with a compelling clinical presentation and negative CT to assess CSF for hemoglobin breakdown products. If CT for lumbar puncture is positive for SAH, then imaging with CTA or MRA is performed to identify the culprit aneurysm. CTA and MRA have reported sensitivities of 90%–95% for the detection of cerebral aneurysms (Fig. 52.13).[26]

Cerebral vasospasm is a complication of SAH and contributes to the high morbidity and mortality associated with aneurysmal hemorrhage. Vasospasm presents clinically 3–21 days after the ictus and can be detected with CTA. CT perfusion adds information regarding the physiologic significance of the vasospasm and guides management decisions. Symptomatic cerebral vasospasm can be treated endovascularly with pharmacologic agents and balloon angioplasty.[27]

Vascular malformations. Arteriovenous malformations (AVM) are the most common cerebral vascular malformations and are composed of a compact tangle of malformed vessels (the nidus) with feeding arteries and a single or multiple drainage veins. AVMs commonly present with intracerebral hemorrhage or seizures. An unruptured AVM may be apparent on CT as tubular structures that enhance with contrast. Conventional MRI may show the abnormal vessels as tubular hypointensities related to flow void from rapid blood flow. CTA and MRA are used to delineate important features of the AVM, including location, size, origin of feeding arteries, course of draining veins, and presence or absence of associated aneurysms (Fig. 52.14). AVMs may be treated endovascularly either completely or partially as a prelude to open surgical resection.[28]

Developmental venous anomalies (DVAs) are composed of a large draining vein surrounded by small feeding veins. The veins are typically inapparent on noncontrast-enhanced CT but enhance with contrast and can be seen on conventional MRI as flow voids. DVAs are rarely symptomatic other than when associated with a cavernous malformation, and dedicated cerebrovascular imaging is recommended

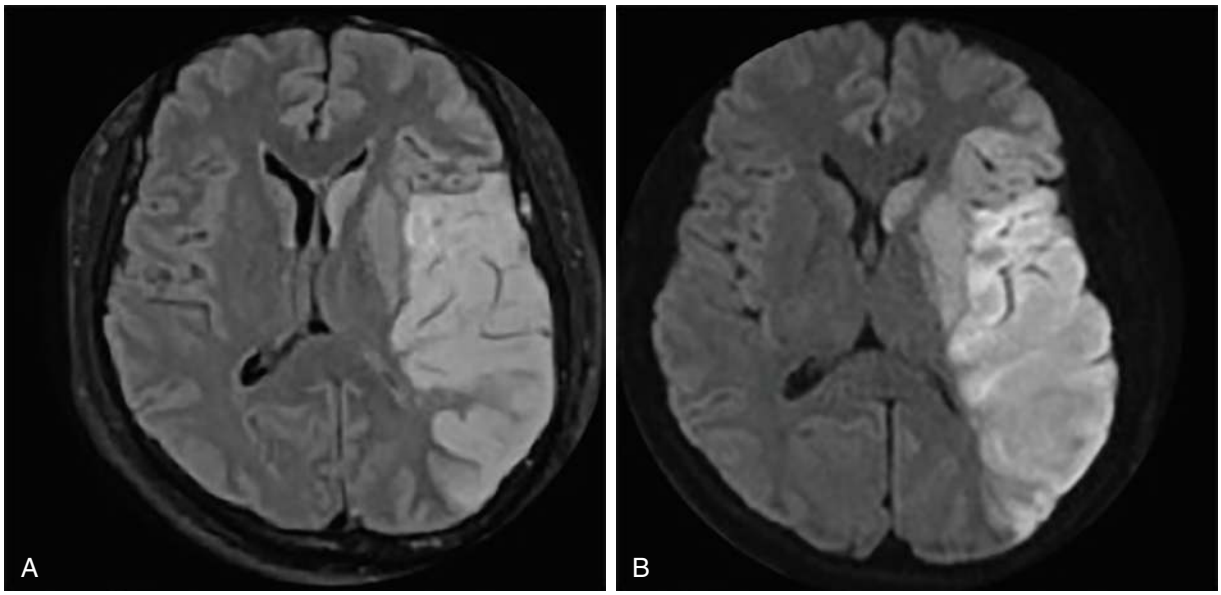

Fig. 52.11 MRI appearance of acute left middle cerebral artery territory infarct. A, FLAIR shows hyperintense cytotoxic edema involving the cortex and subjacent white matter in the left MCA territory with sparing of the left anterior and posterior cerebral artery territories. **B,** DWI shows increased signal intensity corresponding to the area of cytotoxic edema seen on FLAIR.

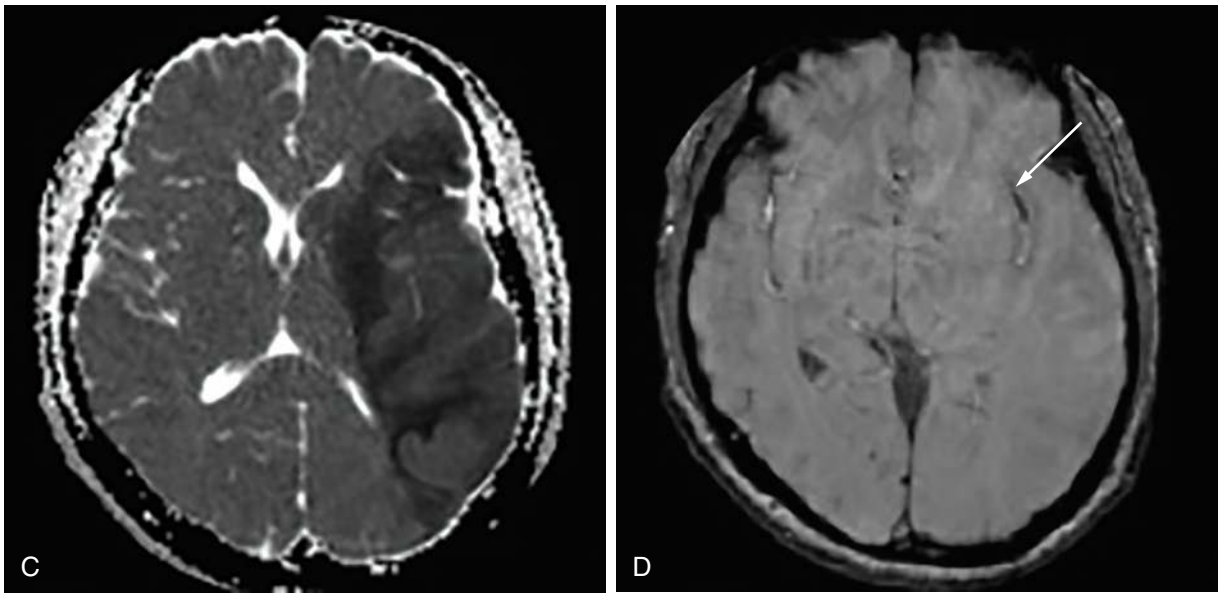

Fig. 52.11, cont'd **C,** ADC map shows correlative hypointensity in the same region, confirming the presence of true restricted diffusion, and thus confirming acute ischemia. **D,** SWI shows a linear focus of hypointensity in the left sylvian fissure *(white arrow),* representing thrombus in the left middle cerebral artery.

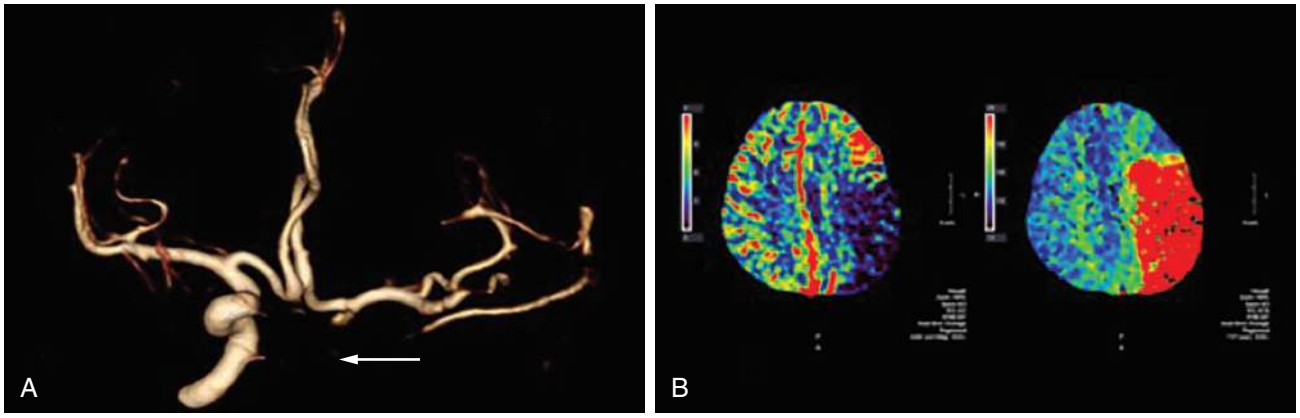

Fig. 52.12 **CT angiography and perfusion imaging in acute infarction. A,** Volume-rendered reconstruction of a CT angiogram shows absence of the cavernous and supraclinoid segments of the left internal carotid artery *(white arrow)* secondary to thrombotic occlusion. The left ACA and MCA partially fill via collateral flow through the anterior communicating artery. **B,** CT perfusion maps show increased time-to-peak enhancement *(right)* and decreased cerebral blood volume *(left)* in the left MCA territory consistent with core infarction and irreversible ischemia.

only when an apparently simple DVA is associated with unexplained hemorrhage or edema.

Neoplasia

The imaging appearance of brain tumors is variable and depends on tumor location (extraaxial versus intraaxial), histologic subtype, and grade. Vasogenic edema is a common finding in brain tumors, particularly high-grade gliomas and metastatic tumors, and results from disruption of the blood–brain barrier and neoangiogenesis. CT and MRI demonstrate vasogenic edema surrounding the lesion, which, if severe, results in mass effect and herniation. High-grade gliomas and metastases classically demonstrate peripheral ringlike enhancement after administration of intravenous contrast, with the central nonenhancing component representing areas of necrosis or cystic degeneration (Fig. 52.15). DWI may show restricted diffusion corresponding to the solid, enhancing component of the tumor, indicating high cellularity.[29]

Magnetic resonance spectroscopy (MRS) is a technique used to detect the presence and concentration of various metabolites in a region of interest and is helpful in differentiating neoplasia from other pathologies, such as demyelinating disease and infection. DTI and functional MRI allow for mapping of important white matter tracts and eloquent brain regions, respectively, with the aim of reducing the risk of neurologic impairment at the time of surgical resection (Fig. 52.16).[30]

Infection and Inflammation

Infectious and inflammatory processes can involve the meninges and brain parenchyma. Meningitis is diagnosed based on clinical and

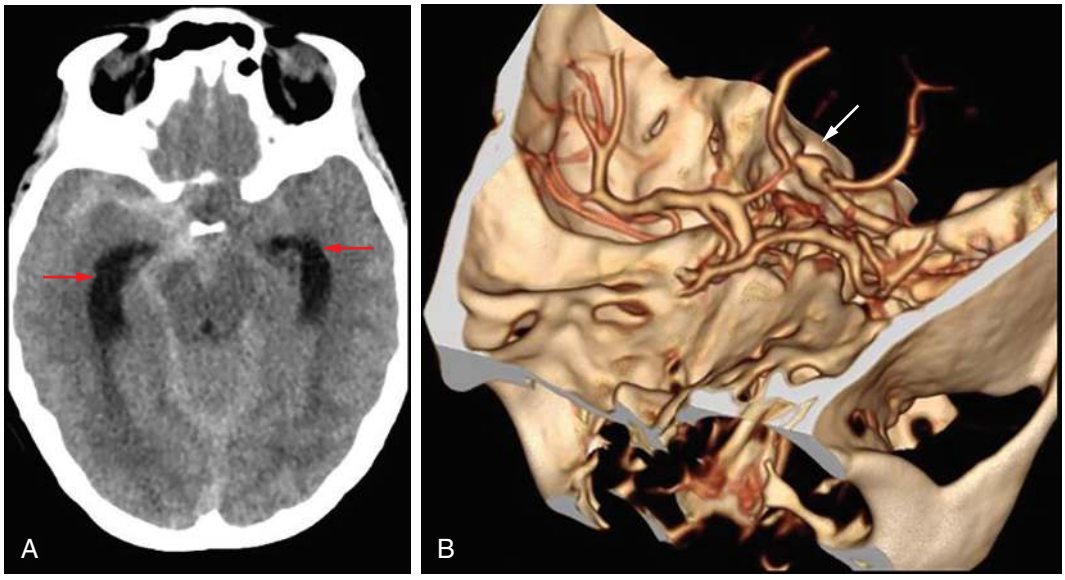

Fig. 52.13 Aneurysmal subarachnoid hemorrhage. A, Noncontrast CT shows acute hyperdense subarachnoid hemorrhage filling the perimesencephalic cisterns and extending laterally into the right sylvian fissure. The temporal horns of the lateral ventricles are dilated *(red arrows)*, representing acute hydrocephalus, which is a common complication of aneurysmal SAH. **B,** CTA in the same patient viewed using a volume-rendered reconstruction shows a complex saccular aneurysm arising from the tip of the basilar artery.

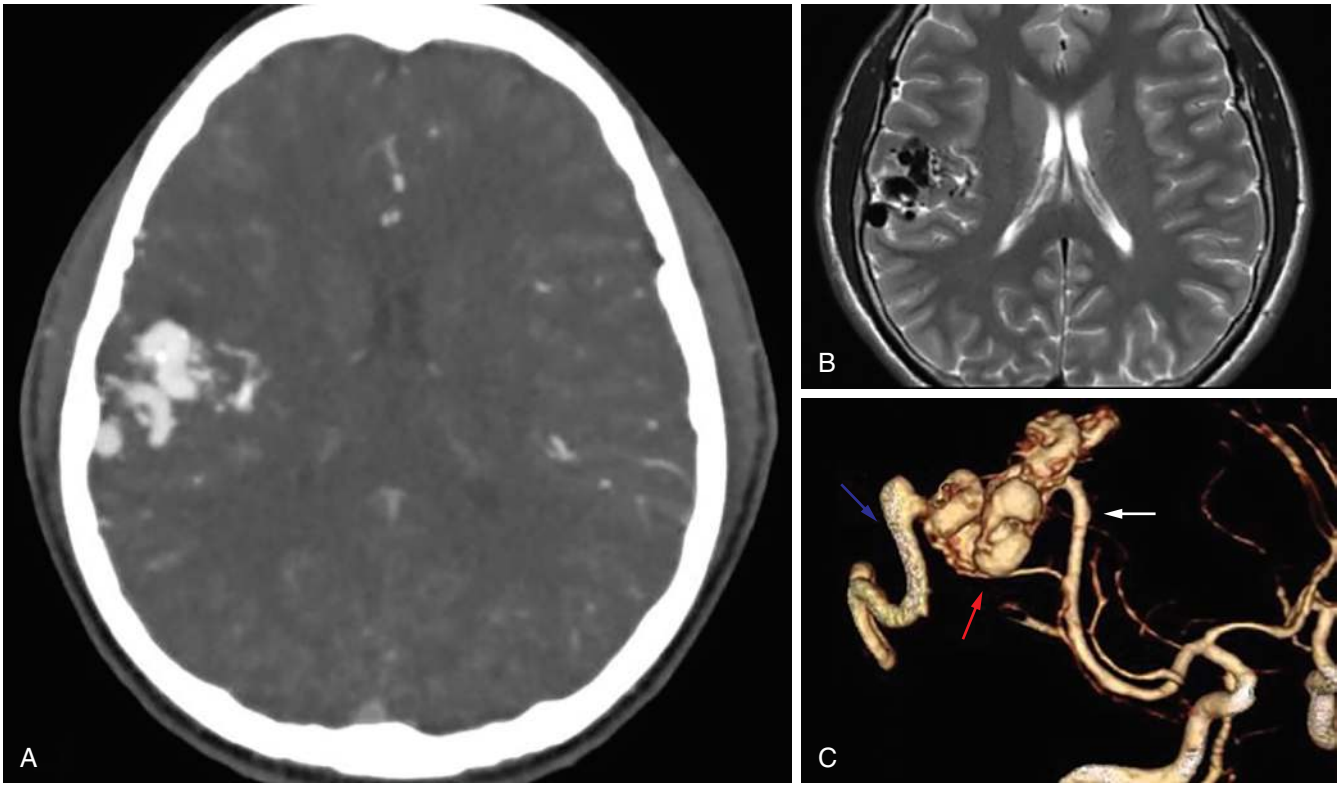

Fig. 52.14 Arteriovenous malformation. A, CT with contrast shows hyperdense tubular structures in the right frontal lobe representing the enlarged enhancing vessels of an arteriovenous malformation. **B,** T2-weighted MRI shows the vessels to be hypointense and devoid of signal. This lack of MRI signal is the result of rapid flow of blood. **C,** CTA of the head viewed as a volume-rendered reconstruction demonstrates the arterial feeders *(white arrow)*, nidus *(red arrow)*, and draining vein *(blue arrow)* of the arteriovenous malformation. Identification of these components is important for treatment planning and surgical approach.

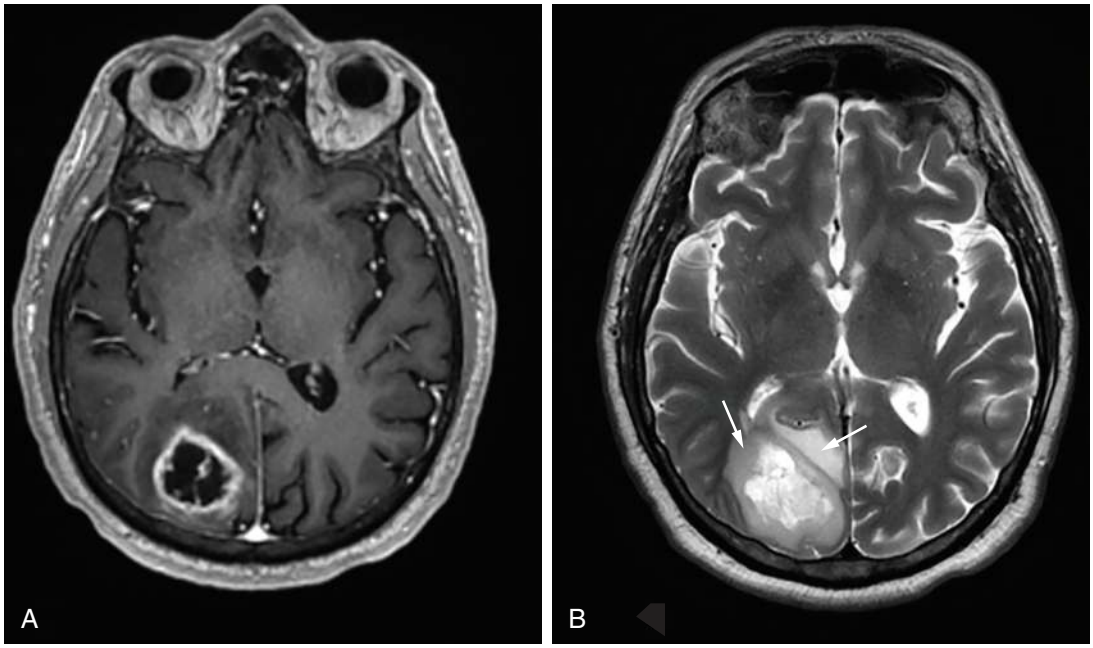

Fig. 52.15 MRI appearance of high-grade glioma. A, T1-weighted MRI with contrast shows a peripherally enhancing intraaxial mass in the medial right occipital lobe. This mass was resected, and pathology returned glioblastoma (WHO grade IV). **B,** T2-weighted MRI shows extensive surrounding vasogenic edema. Vasogenic edema is commonly seen surrounding intraaxial brain tumors and results from disruption of the blood–brain barrier by the neoplastic process.

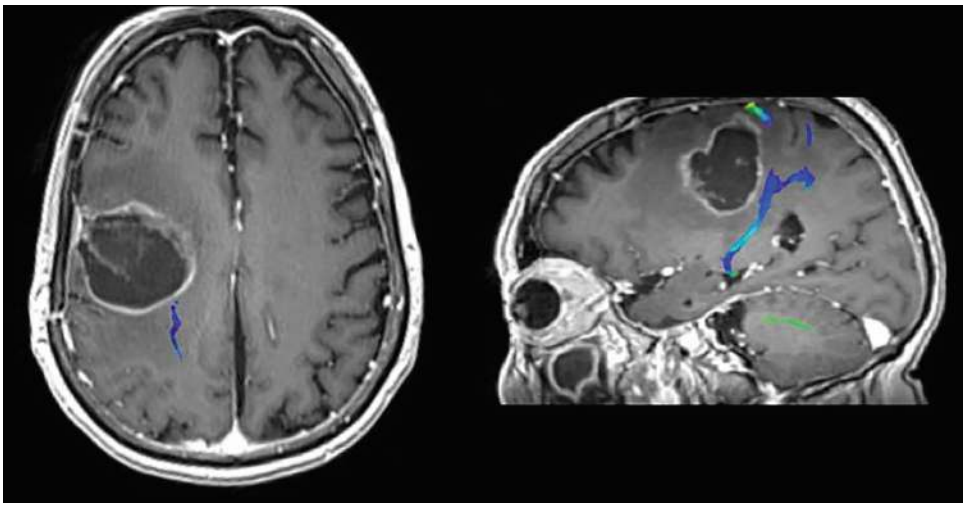

Fig. 52.16 MR tractography using DTI technique. DTI imaging was performed to localize the right corticospinal tract in this patient with a right frontal lobe glioblastoma. This tractography data was fused to the T1-weighted contrast-enhanced MRI to demonstrate the precise anatomic relationship of the corticospinal tract to the tumor.

laboratory evaluation and may be classified as infectious or noninfectious. Although CT and MRI may show evidence of meningeal inflammation, the role of imaging in cases of known or suspected meningitis is to evaluate for complications, such as hydrocephalus, abscess, and ischemia. The inflammatory exudate of meningitis may present as increased density of the involved CSF spaces on CT. Leptomeningeal inflammation produces a cellular and proteinaceous exudate that is seen as hyperintense signal within sulci and the basal cisterns on FLAIR sequences where normal CSF signal should be suppressed. Contrast administration will show abnormal enhancement of the leptomeninges on CT and MRI.[31]

Pyogenic infection of the brain parenchyma presents on a spectrum from cerebritis to abscess. Abscess presents on CT and MRI as a peripherally enhancing lesion with extensive surrounding vasogenic edema. Several findings on MRI may help distinguish abscess from other peripherally enhancing brain lesions such as high-grade glioma and metastases. Abscesses commonly show hypertense signal centrally on T2-weighted images and a hypointense rim, which represents the

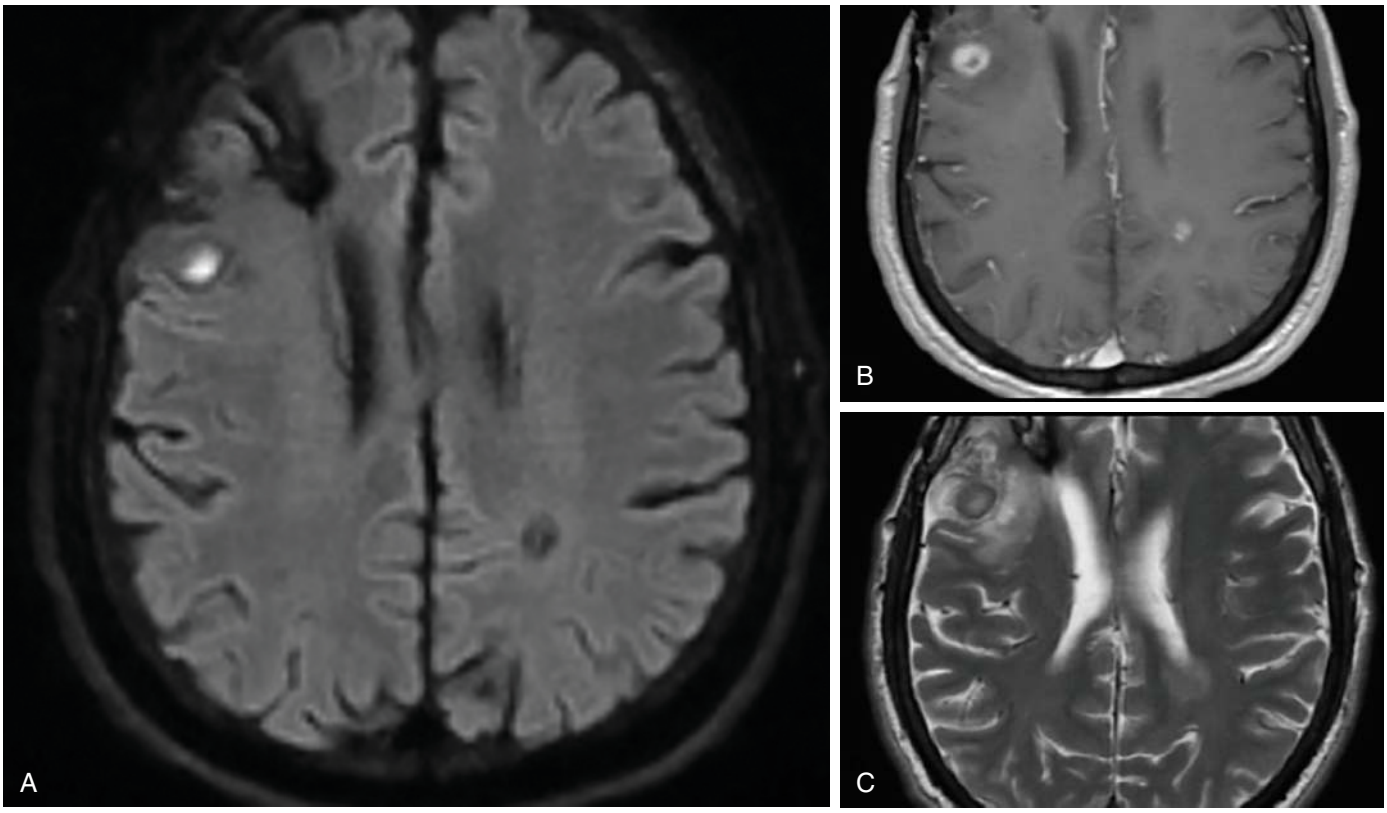

Fig. 52.17 Cerebral abscess. A, Diffusion-weighted image shows a round lesion in the right frontal lobe with central hyperintensity representing restricted diffusion. Central diffusion restriction is a classic finding in cerebral abscess. **B,** T1-weighted MRI with contrast shows the abscess to demonstrate a pattern of peripheral contrast enhancement. **C,** T2-weighted MRI shows the characteristic hypointense rim of a cerebral abscess representing a fibrotic-like reaction. There is surrounding vasogenic edema related to blood–brain barrier disruption from the local inflammatory process.

fibrotic-like reaction surrounding the abscess (Fig. 52.17B and C). DWI classically shows restricted diffusion (hyperintensity) within the central portion of the abscess cavity (see Fig 52.17A).[32]

Encephalitis refers to an inflammatory parenchymal process that may be infectious or noninfectious. Herpes encephalitis results from infection of brain parenchyma with herpes simplex virus-1 (HSV-1), typically as a result of reactivation of a latent infection. HSV has a predilection for the limbic system (mesial temporal lobes, insula, subfrontal region, and cingulum) and causes a hemorrhagic necrotizing infection. CT and MRI may be normal early in the course of the disease. Eventually, cortical and subcortical edema will become apparent in the involved parenchyma, commonly in the medial temporal lobes. SWI sequences will show foci of hypointensity representing areas of hemorrhage. Postcontrast images and DWI may show patchy areas of enhancement and restricted diffusion, respectively.[33]

Miscellaneous White Matter and Metabolic Diseases

Numerous disease processes present with abnormalities in the cerebral white matter. Posterior reversible encephalopathy syndrome (PRES) is a disorder of cerebrovascular autoregulation and has many proposed etiologies, all with hypertension as a common component. Common associations include acute systemic hypertension, preeclampsia/eclampsia, drug toxicity, uremia, and systemic infection.[34] PRES presents with vasogenic edema centered in the white matter predominantly involving brain parenchyma perfused by the posterior circulation. Parietal and occipital lobe involvement is common, as is involvement of the cerebellum. The brainstem, particularly the pons, and basal ganglia may also be involved. The edema is vasogenic, not cytotoxic, and therefore DWI rarely shows regions of restricted diffusion. Contrast-enhanced imaging may show patchy areas of contrast enhancement secondary to blood–brain barrier disruption.[35]

Disorders of metabolism often present with abnormal brain imaging. Wernicke encephalopathy results from thiamin deficiency and is commonly seen in alcoholics. MRI shows T1 hypointensity and T2/FLAIR hyperintensity in the medial thalami, mammillary bodies, and periaqueductal gray matter (Fig. 52.18). These regions also demonstrate restricted diffusion and contrast enhancement.[36]

SPINE

Trauma

CT is the initial imaging modality used to assess suspected spine injury. CT demonstrates exquisite detail of the osseous structures and is therefore the modality of choice to evaluate for spine fractures. Displacement of fracture fragments and their protentional encroachment on the spinal canal and neural foramina are best delineated on CT. Alterations in vertebral alignment are also well demonstrated on CT and can be used to infer injury to ligamentous structures (Fig. 52.19A and B).

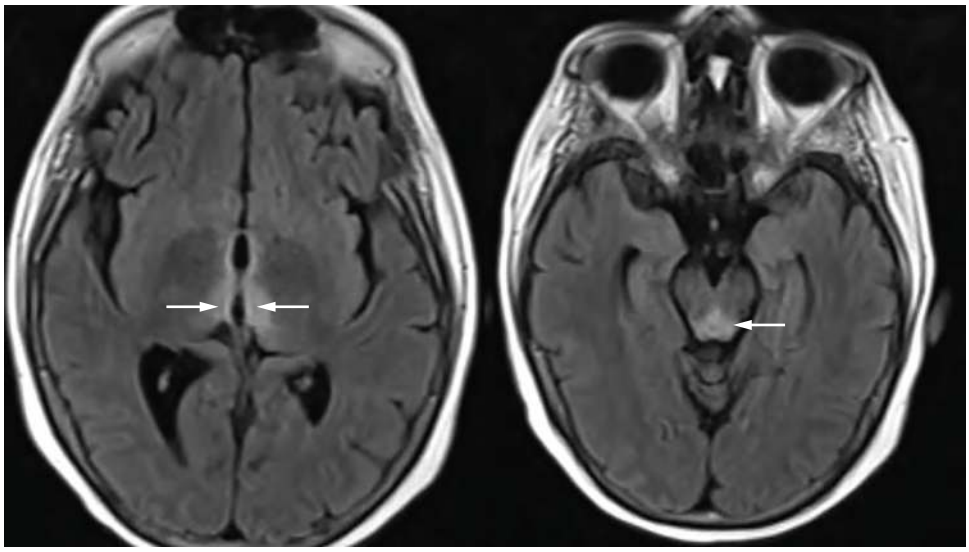

Fig. 52.18 Wernicke encephalopathy. FLAIR MR images show hyperintensity in the medial thalami and periaqueductal gray matter *(white arrows)* in this patient presenting with altered mental status and oculomotor dysfunction.

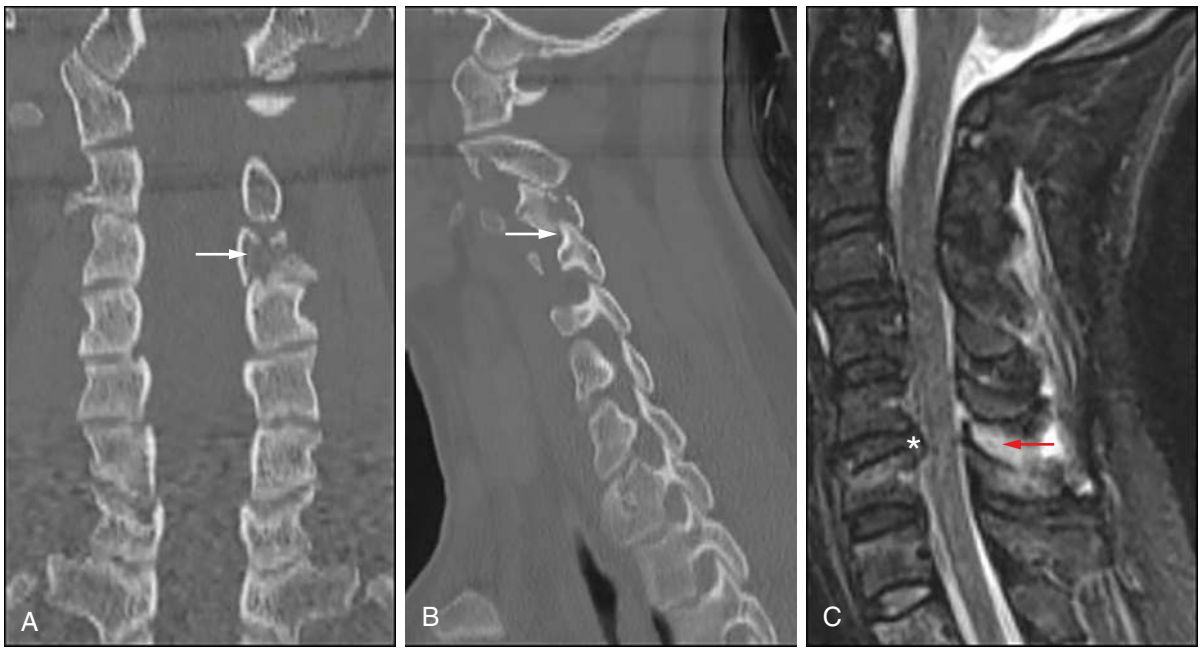

Fig. 52.19 Cervical spine trauma. A and B, CT of the cervical spine viewed in coronal and sagittal reconstructions shows an acute comminuted fracture of the C3 left articular pillar with subluxation, or perching, of this pillar on the C4 articular pillar *(white arrows)*. **C,** Short-tau inversion recovery (STIR) MR image in the same patient shows a traumatic C5–C6 intervertebral disc herniation *(white asterisk)* and injury to the C5–C6 interspinous ligament, as evidenced by hyperintense signal *(red arrow)*. These soft tissue injuries were not suspected based on the findings of CT and demonstrate the utility of MRI for detecting additional soft tissue injuries.

MRI provides improved visualization of the soft tissue structures, including ligaments, intervertebral discs, nerve roots, and the spinal cord. MRI is pursued to evaluate for etiology of a neurologic deficit or to assess for evidence of ligamentous injury that may predispose to spinal instability. Findings on MRI often direct care toward surgical or nonsurgical pathways (see Fig. 52.19C). Acute traumatic injury to the spinal cord may be inferred by the presence of increased T2 signal, with the substance of the cord representing edema. Chronic cord injury shows volume loss and T2 representing axonal loss and gliosis. Gradient echo sequences, which are sensitive to blood products, may show foci of hypointensity within a region of cord injury representing hematomyelia.[37] This portends a poor neurologic prognosis.

Infection

Spondylodiscitis is characterized by infection of the intervertebral disc space and adjacent vertebral bodies. Infection destroys the

intervertebral disc and may extend into the epidural space, placing the spinal cord and nerve roots at risk for injury. MRI is more sensitive than radiography and CT for spondylodiscitis, particularly early in the disease course.[38] MRI shows T2 hyperintense fluid signal in the disc space with associated contrast enhancement in addition to marrow edema and enhancement in the adjacent vertebral bodies. There is disc space height loss, and the vertebral body endplates are irregular from erosions. Extension of infection into the epidural space may result in epidural abscess formation, which presents as a peripherally enhancing collection (Fig. 52.20).[39]

Neoplasia

Tumors of the spine can be broadly categorized anatomically as extradural, intradural extramedullary, and intradural intramedullary. Extradural tumors are the most common and include lesions of the osseous vertebral column, which is the third most common site for metastatic disease.

MRI is the most sensitive imaging modality for detection of vertebral metastases and other spinal lesions. Normal vertebral bone marrow should appear brighter than the adjacent intervertebral discs on T1- and T2-weighted sequences. Infiltration of the vertebral marrow by tumor will show replacement of the normal hyperintense marrow signal by hypointense soft tissue on T1-weighted images. Metastases will often demonstrate contrast enhancement. DWI is more commonly being incorporated into spine imaging and has proved to be of significant benefit in evaluating vertebral metastatic disease and multiple myeloma.[40]

KEY POINTS

- CT is fast, safe, and sensitive and serves as the imaging modality of choice for initial evaluation of the brain and spine in cases of suspected or known neurologic illness or injury. MRI is more sensitive than CT for detection and characterization of most neurologic pathology and is used to answer specific clinical questions.
- Cerebral edema is a common response to brain pathology. Accurate characterization of the edema pattern as cytotoxic, vasogenic, or interstitial is useful in generating a differential diagnosis.
- Intracranial hemorrhage and cerebral ischemia evolve in a predictable manner on CT and MRI. Understanding this pattern of evolution can help in determining the chronicity of the underlying pathologic process.
- The role of neuroimaging in TBI is to identify treatable primary injuries and to monitor for the development of secondary injury.
- MRI is useful in characterizing tumors as low-grade or high-grade tumors and for differentiating neoplastic from infectious pathology.
- Advanced MRI techniques are more commonly being used to image neurologic function and interconnectivity, which are inapparent on standard morphologic imaging.
- CT is useful in characterizing abnormalities of bone and alignment in suspected spine pathology. MRI is the modality of choice to assess the soft tissue structures of the vertebral column and the neural elements within the spinal canal and neural foramina.

Core Principles of Respiratory Physiology and Pathophysiology in Critical Illness

John J. Marini and Luciano Gattinoni

INTRODUCTION

Understanding physiology underpins the logical decisions of critical care practice. Although facts and knowledge of literature findings and recommendations for specific problems clearly help inform good management, bedrock principles of physiology and pathophysiology translate across patients; awareness of them is a salient trait of the expert clinician. Providing respiratory support is among the defining features of intensive care, and to execute this effectively, an understanding of the rationale and consequences of related interventions is required. It follows that the fundamentals of respiratory mechanics and gas exchange must be mastered. Rather than detail specific respiratory conditions or ventilatory approaches, this chapter aims at surveying the indispensable physiologic elements that are vital to making appropriate decisions at the bedside. Our discussion of respiratory physiology rests on its two pillars: mechanics and gas exchange.

RESPIRATORY MECHANICS

What are Respiratory Mechanics and How are They Measured?

Because the lung is a flexible but passive structure, gas flows to and from the alveoli driven by differences between airway and alveolar pressures—no matter how they are generated. The total pressure gradient expanding the respiratory system is accounted for in two primary ways: (1) driving gas between the airway opening and the alveolus and (2) expanding tissue against the recoil forces of the lung and chest wall. The pressure required for inspiratory flow dissipates against friction, whereas the elastic pressure that expands the respiratory system is stored temporarily in its tissues until dissipated in driving expiratory flow.

The mechanical properties of the respiratory system are those characteristics that influence the energy cost of breathing. Because pressure provides the forces driving gas flow and counterbalancing elastic recoil, assessing respiratory mechanics involves the measurement of flows, volumes (flow integrated over time), and pressures. In simplified form, the expression of these relationships, the equation of motion of the respiratory system, can be written: $P = RV' + V/C + Pex$. In this equation P is the pressure applied across the entire respiratory system, R is inspiratory resistance to flow, C is inspiratory compliance, V' and V are flow rate and the volume inspired in excess of the end-expiratory value, and Pex is end-expiratory alveolar pressure—applied positive end-expiratory pressure (PEEP) and any supplemental end-expiratory pressure generated as a result of the ventilatory pattern itself (auto-PEEP, discussed later). Although regional mechanics are of unquestioned importance in determining ventilation, gas exchange, and tissue strain, the technology available at most bedsides currently limits measurements and monitoring to the global properties of the integrated respiratory system, composed of the lungs encased by the surrounding chest wall. Pressure changes relevant only to the lungs must be assessed as the difference between the airway pressure (Paw) and the pleural pressure (Ppl) that surrounds them (defined as the transpulmonary pressure, Ptp). The esophagus provides a convenient site from which to measure the changes of intrapleural pressure that occur during tidal ventilation with a balloon-tipped catheter.[1] It may also measure with reasonable accuracy the absolute pleural pressure across the same horizontal gravitational plane.[2] With the airway occluded and flow stopped, pressure measured at the airway opening estimates gas pressure at the alveolar level.

Transpulmonary Pressure

For any expandable compartment, such as the chest, the absolute volume and volume change depend on its flexibility (compliance) and the pressure difference inside and outside the structure (Fig. 53.1). For the lung, this transmural pressure is $Ptp = Paw - Ppl$. Under passive conditions the corresponding transmural pressure for the integrated respiratory system is the airway pressure minus atmospheric pressure, or Paw. For the passive chest wall alone, transmural pressure is simply the average pleural pressure. Pleural pressure is not helpful in assessing chest wall compliance during spontaneous breathing, however, as its embedded musculature generates the negative pleural pressure deflections that drive tidal movement. During muscular effort, the transmural pressure acting across the lung remains the airway pressure minus intrapleural pressure difference; therefore the actual transstructural pressure to which the lung is exposed is less than the measured Paw under passive conditions and greater than the measured Paw during spontaneous or patient-assisted breathing (Fig. 53.2). Because the lungs are inherently passive, their mechanical properties can be assessed during any form of spontaneous, patient-triggered but machine-assisted, or controlled, ventilation. The mechanical properties of the chest wall, in contrast, can only be directly evaluated during controlled ventilation

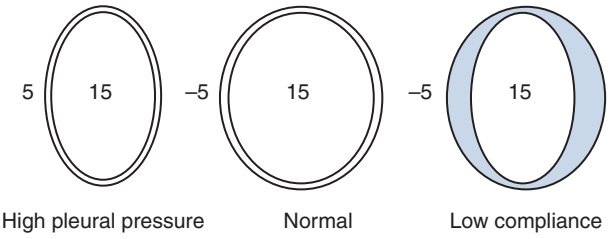

Fig. 53.1 Importance of transpulmonary pressure and compliance to volume of a nonrigid, expandable structure such as a lung unit or alveolus.

when the actual pleural pressure acting to distend that structure can be estimated by a balloon-tipped esophageal catheter.

Key Differences Between Active and Passive Breathing

It is sometimes taught that regarding the lung itself, there are few perceptible differences in mechanical behaviors between passive and active inflation.[3] Although that statement holds approximately true for global transmural pressures and volume measurements made in healthy excised lungs, it is not precisely accurate in vivo—especially not for acutely injured lungs. Active contraction of the diaphragm decreases the local transmural pressures of nearby alveoli somewhat more than average, whereas the nondependent zones within a passive chest may be surrounded by lower pleural pressures and therefore experience greater resting transpulmonary pressures and lesser swings of transpulmonary pressure during tidal inflation.[4] Such regional differences are accentuated by conditions that increase lung weight and produce heterogeneous mechanics, such as acute respiratory distress syndrome (ARDS) (Fig. 53.3). Not only does regional expansion and distribution of volumes differ in accordance with modifications of *effective* local compliance by spontaneous breathing efforts, but the filling and distention of the pulmonary blood vessels are significantly different as well[5] (Fig. 53.4). Negative pleural pressure swings and lower mean pleural pressures promote venous return and pulmonary vascular filling, whereas positive pleural swings and higher

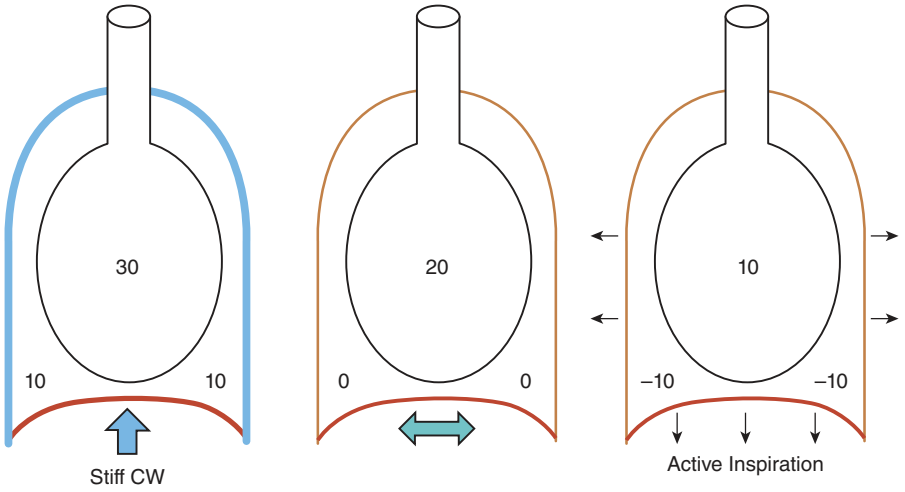

Fig. 53.2 Equal lung unit volumes are produced by the same transpulmonary pressures. The airway (alveolar) pressures that are externally recorded differ remarkably, depending on the elastance of the chest wall (*CW*) and the intrapleural pressures.

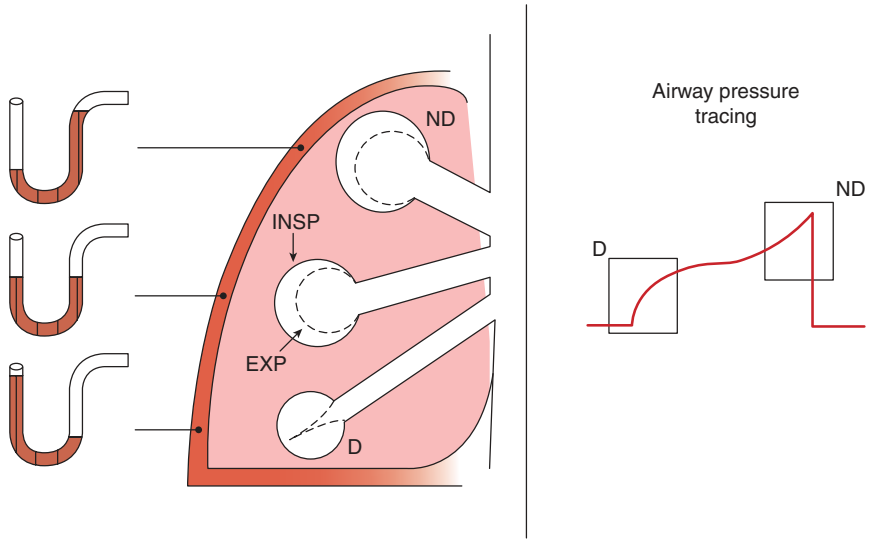

Fig. 53.3 Regional transpulmonary pressures vary with the local pleural pressures. Dependent lung units (*D*) have reduced transpulmonary pressures compared with nondependent ones (*ND*) and may be subject to reopening and collapse. Recruitment and overdistention of regional units contribute to the changing contours of the airway pressure-volume curve recorded in the external ventilator circuit.

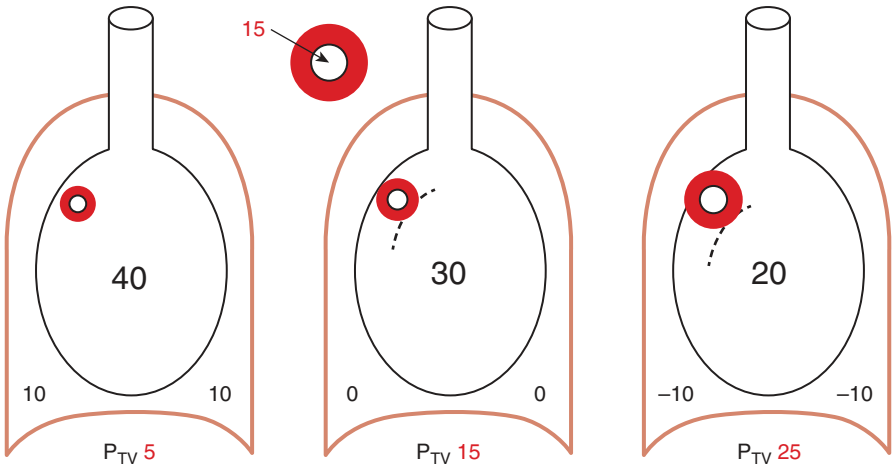

Fig. 53.4 Given the same intraluminal blood pressure (15 cm H_2O in this hypothetical example), the transmicrovascular pressures (P_{TV}) that influence edema formation vary with the surrounding interstitial pressure that surrounds them. Intrapleural pressure is often used as a measurable surrogate for the unmeasured interstitial pressure.

mean pressures impede venous return and pulmonary vascular filling. Greater vascular filling tends to reduce the compliance of the lung parenchyma.

Pulmonary Elastance and Compliance

In the clinical setting, the global mechanical properties of the chest are assessed during passive mechanical ventilation by the pressures and volume changes measured at the airway opening. One routinely used value that characterizes the capacity and stiffness of the respiratory system is termed *compliance,* the ratio of a volume change to the static pressure difference that caused it. Compliance, C, is the inverse of elastance, E, defined as the ratio of pressure change required to produce a volume change.[6] Because the lungs are enclosed by the chest wall, they share equivalent volumes. Consequently, under passive conditions the total positive alveolar pressure partitions itself into two components that expand the lungs and chest wall. The corresponding elastance components add in series: Ers = El + Ew[7] (Fig. 53.5). In contrast, compliances of the lungs and chest wall add in parallel: 1/Crs = 1/Cl +1/Cw. Therefore even though Crs is often used clinically to assess the elastic properties and capacity of the lung, the relationship of Crs to Cl is not entirely straightforward: Crs = (Cl × Cw) / (Cl + Cw). It should be noted here that the surface tension of the alveolar lining liquid film, increased by inflammation and attenuated by functional surfactant, may dramatically affect the lung's flexibility.[8]

The Crs and Cl can be reduced by depleting the *number* of open lung units available to ventilate and by altering their individual mechanical properties. This dual interpretation of compliance assessed at the airway opening is reflected in the sigmoidal shape of the inflation pressure-volume curve, which becomes more pronounced in the setting of acute parenchymal disorders, such as acute respiratory distress syndrome (ARDS) (Fig. 53.6). Under such conditions, increases of airway pressure made from low values near relaxation tend to impressively recruit previously collapsed alveoli, improving the Crs measured at the airway opening. As pressure builds to higher levels, however, this recruiting tendency progressively diminishes.[9] At the same time, greater transpulmonary pressures applied to units already open may

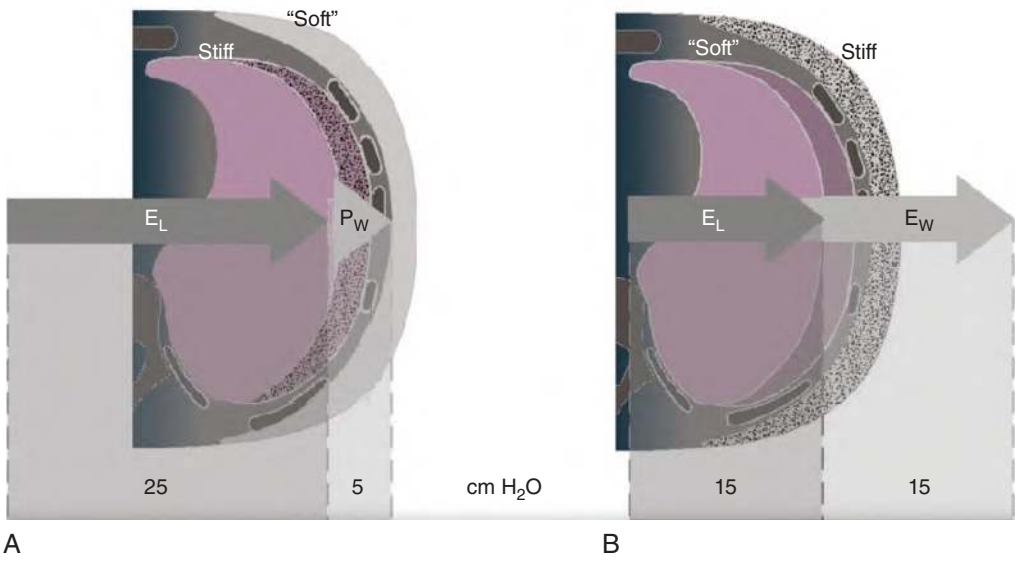

Fig. 53.5 Partitioning of an alveolar pressure of 30 cm H_2O across the lung and chest wall as a function of their elastance values (E_L and E_W). The lung and chest wall share an identical volume.

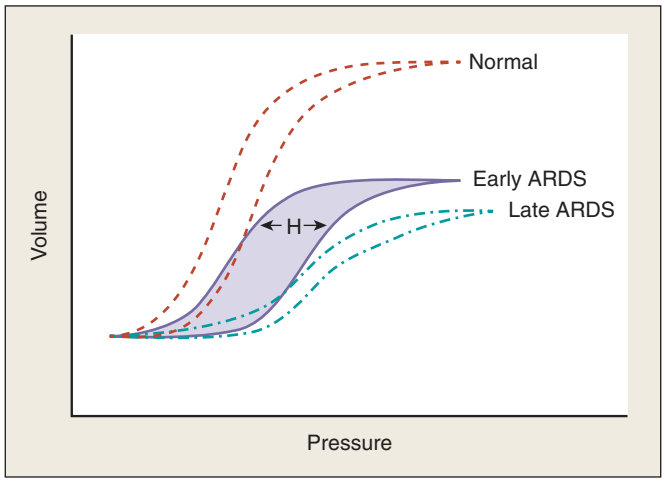

Fig. 53.6 Static pressure-volume loops for the respiratory system under normal conditions and under two severities of acute lung injury (early and late acute respiratory distress syndrome [*ARDS*]). Hysteresis (*H*) is reflected in the pressure difference that separates the inflation and deflation recoil characteristics.

stretch them into a less compliant range. This trade-off between recruitment in some zones (which often occurs disproportionately in the gravitationally dependent regions with higher surrounding pleural pressures) and stretching of open units eventually favors the latter at high volumes, bending the pressure-volume curve of the respiratory system toward the airway pressure axis.

Massive obesity is a prevalent condition in well-developed, adequately resourced countries. The increased body weight of such patients gives rise to a less compliant chest wall.[10] Apart from the load imposed by the mass of soft tissue that overlies the chest, one important reason for this apparent noncompliance is raised intraabdominal pressure. Because the flexible diaphragm forms the caudal boundary of the chest cavity, approximately half of each increment of abdominal pressure that exceeds ~6 cm H_2O is reflected the pleural space[11] (Fig. 53.7). It deserves emphasis that the *overall* effect of massive obesity resembles that of a static load or weight, rather than a true increase of elastance that raises pressure in direct proportion to increments of lung volume.

Energetics of Inflation

When a pressure difference is applied to the passive respiratory system, that total pressure (Paw) must be accounted for by its dynamic component that overcomes flow resistance (Pr) and its "elastic" components that expand the chest. At end inflation, the latter is composed of the elastic pressure that corresponds to the tidal volume, known as the *driving pressure* (DP = Vt/C), and the pressure above the ambient baseline, known as *positive end-expiratory pressure (PEEP)*. Expressed as an equation, end-inspiratory pressure is:

$$\text{Paw} = \text{Pr} + \text{DP} + \text{PEEP} \qquad \textbf{(Eq. 1)}$$

The mechanical energy (or work, W) delivered to cause a volume change of the passive respiratory system is the product of total airway pressure and volume—on a two-dimensional surface, a pressure × volume area.[12] This equivalence between energy and P × V area is made more intuitive by recalling that energy is a force-length product, where length is the distance moved by an unbalanced force. Pressure is force per unit area, and volume is the product of area and length. Consequently, the P × V product has the dimensions of force × length. Assuming constant inspiratory flow, the individual expenditures of

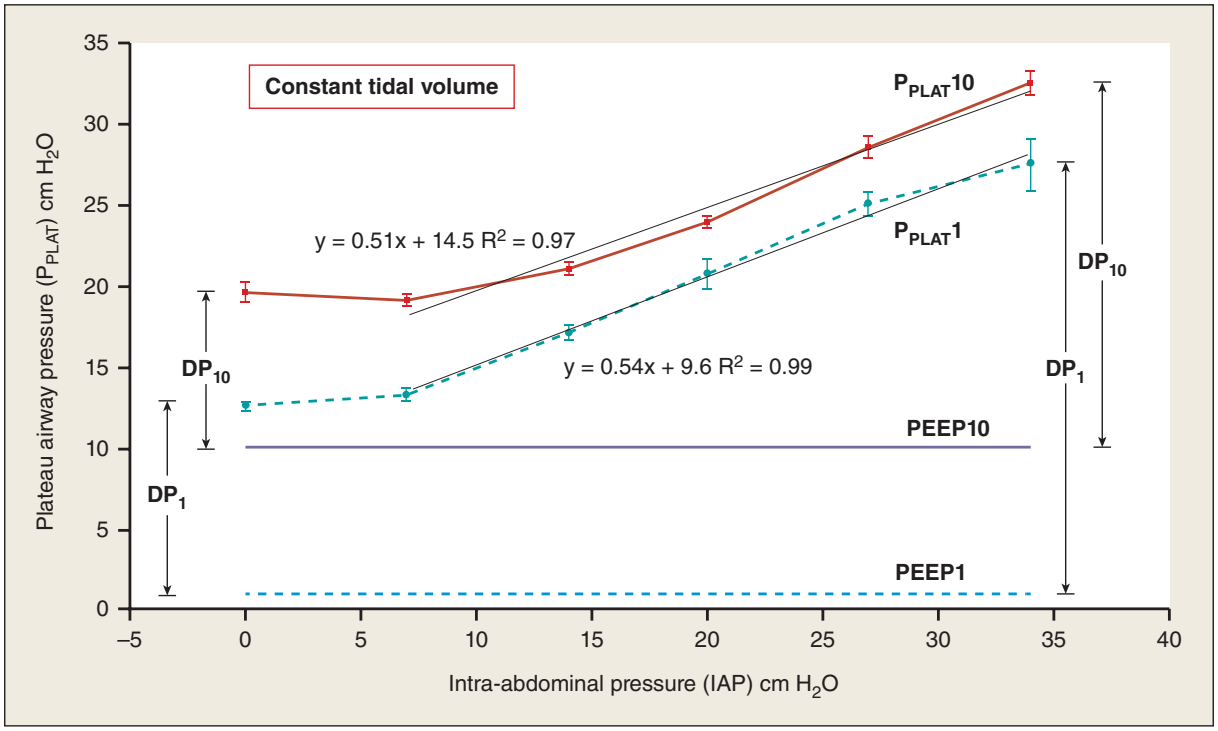

Fig. 53.7 Influence of increasing intraabdominal pressure (*IAP*) on the externally measured end-inspiratory static airway pressure (P_{PLAT}) and the corresponding driving pressures (*DP*) at two levels of positive end-expiratory pressure (*PEEP*, 1 and 10 cm H_2O). Tidal volume is unchanged. (Adapted from Cortes-Puentes GA, Gard KE, Adams AB, et al. Value and limitations of transpulmonary pressure calculations during intra-abdominal hypertension. *Crit Care Med.* 2013;41[8]:1870–1877.)

energy against the components that make up total inflation pressure are therefore approximated:

$$W = Vt(Pr) + Vt(Dp/2) + Vt(PEEP)$$

A transmural pressure × volume plot inscribes a tracing whose area quantifies the work and energy of tidal inflation (Fig. 53.8). For the entire passive respiratory system, this is Paw vs. V, and under conditions of constant inspiratory flow, time is a linear analog of inflation volume. Inflation work can be further partitioned into the P × V areas that correspond to the energy required to overcome flow resistance, to deliver volume increments, and to offset PEEP[13] (Fig. 53.9). Because the same total mechanical energy is required under passive and patient-assisted conditions for flow controlled, volume-cycled breaths, the area deficit between passive and active conditions reflects the energy contribution from the patient[14] (Fig. 53.10). Similar principles of energy expenditure apply selectively to the lung when transpulmonary pressure (Paw − Ppl, rather than Paw) is substituted.

Mechanical Power

Power, a measure of the rate of energy expenditure, is defined as the amount of energy per unit of time of any duration. Instantaneous power (Pi) may vary within the span of an individual inflation half-cycle by altering the flow profile (Fig. 53.11). Thus the intracycle power (ICP) being applied to the passive respiratory system at volume V above the unpressurized resting value is expressed as the product of airway pressure and flow: Pi = Paw × V′, or Pi = V′(V′R) + V′ ([V/VT] × DP) + V′ (PEEP).[15] On a longer time scale, mechanical power, as the term is currently understood in the clinical setting, is the product of the total inflation energy per cycle (Paw × V) area and the cycling frequency.[16] Defined in this way, power is a cumulative measure of repetitive energy pulse applications per minute. Experiments indicate that if the tidal strains of each inflation cycle exceed a certain threshold, the amplitude and duration of such power exposures may be a fundamental determinant of the extent of damage that results from that ventilation pattern (ventilation-induced lung injury [VILI]).[3]

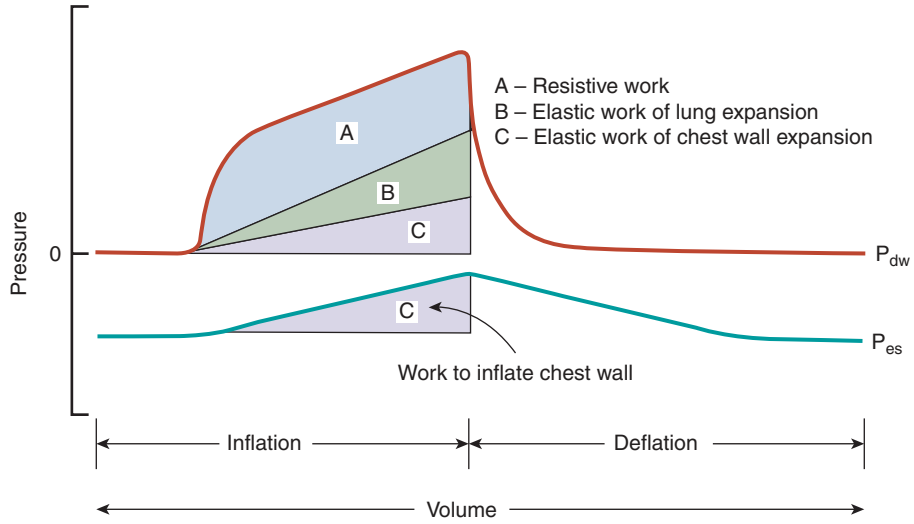

Fig. 53.8 Partitioning of the work (energy cost) of passively inflating the structures of the respiratory system without positive end-expiratory pressure (*PEEP*) applied. The pressure-volume areas quantify the work components. *Paw,* Airway pressure; *Pes,* esophageal (pleural) pressure.

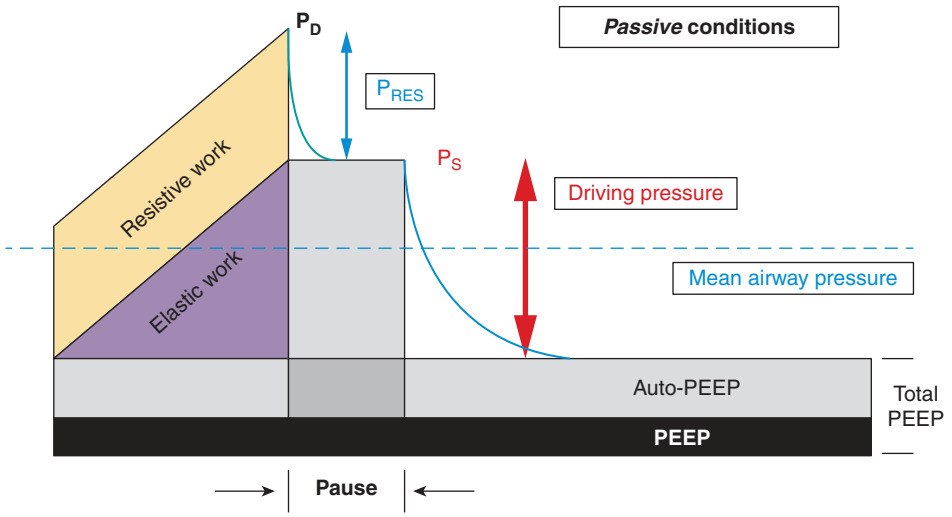

Fig. 53.9 Partitioning of inflation work under passive conditions of constant inspiratory flow. The horizontal axis is time. During constant flow, time is an analog of volume. Total positive end-expiratory pressure (*PEEP*) the sum of applied and auto-PEEP, has an associated energy cost during inflation.

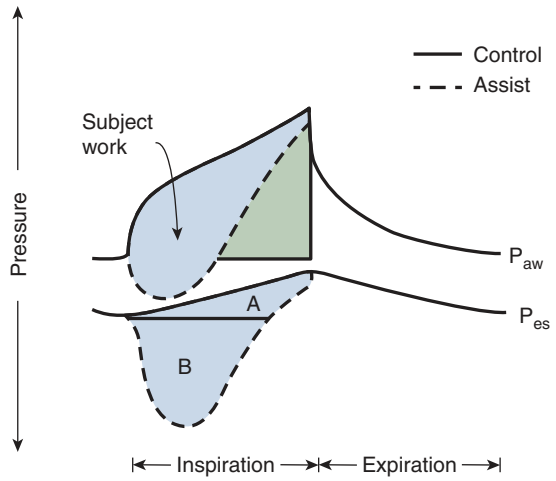

Fig. 53.10 Subject work of breathing under conditions of constant inspiratory flow provided under full control and patient-assisted breathing. Because the total mechanical task of inflation is the same, the pressure-volume area difference in machine work indicates the subject's contribution. Pressures can be inscribed either at the airway pressure (*Paw*) or esophageal pressure (*Pes*) sites. A, Chest wall work; B, lung inflation work.

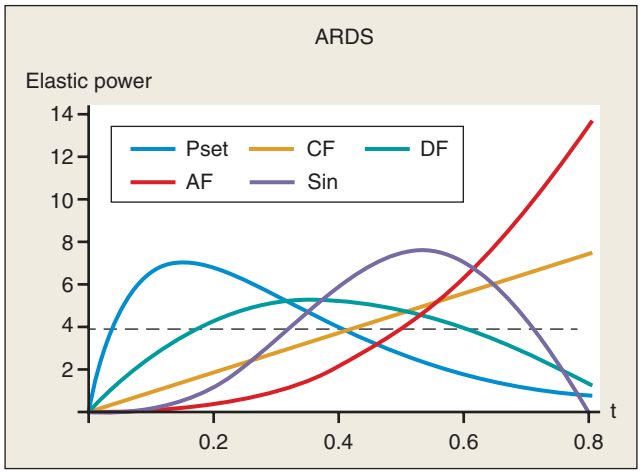

Fig. 53.11 Intracycle elastic power applied to the lung as a function of time for five flow patterns of ventilation. *AF,* Accelerating flow; *CF,* constant flow; *DF,* linearly decelerating flow; *Pset,* pressure control; *Sin,* sinusoidal pattern of unassisted breathing.

Influence of Body Position on Lung Volume

Modification of body position is too often neglected as a therapeutic tool. Gravitational forces exert an important influence on lung volume, on ventilation distribution, and on respiratory system compliance. Under most circumstances, more upright positioning substantially increases functional residual capacity (FRC). In normal subjects, reclining decreases FRC, primarily because of the upward pressure of the abdominal contents on the diaphragm and dorsal lung compression by the heart.[17] Normally, the FRC declines by approximately 30% (or approximately 600–900 mL for healthy persons) in shifting from the sitting to the horizontal supine position and by less in shifting from the sitting to lateral decubitus position[18] (Fig. 53.12). The magnitude of these reductions is somewhat less in older than in younger patients. Raising end-expiratory pressure with PEEP or continuous positive airway pressure (CPAP) elevates FRC. A simple calculation based on

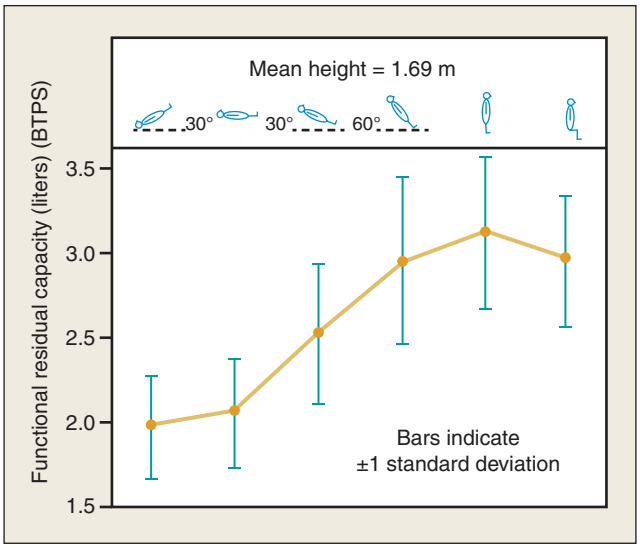

Fig. 53.12 Resting lung volume (functional residual capacity [FRC]) as a function of body positioning. *BTPS,* body temperature pressure saturated with water vapor.

these positional losses of volume and assuming normal supine respiratory system compliance (~80 mL/cm H_2O) suggests that 5–8 cm H_2O of PEEP may be necessary in healthy persons simply to offset the sitting-to-supine reduction of FRC. Patients of similar age with severe airflow obstruction generally lose much less volume than do normal healthy subjects when assuming supine recumbency. In massive obesity, the expiratory reserve volume (the FRC minus residual, "empty gas tank" volume) may nearly disappear even when fully upright. Sitting-to-supine changes of end-expiratory lung volume may be minimal not only for this reason but also because of positional airway closure and gas trapping.[19]

Recumbency redistributes lung volume because it alters the geometry of the thorax. When supine, the heart directly compresses the left lower lobe bronchi, and its weight is partially supported bilaterally by the lung tissues beneath. This anatomy helps account for the tendency for atelectasis to develop commonly in the left lower lobe in postoperative and bedridden patients—especially in those with cardiomegaly.[20] The pleural pressures in gravitationally dependent zones are less negative than at the apex. The vertical gradient of transpulmonary pressure (alveolar minus pleural pressure) is approximately 0.25 cm H_2O per centimeter of vertical height for normal subjects in the erect position and approximately 0.17 cm H_2O per centimeter for normal subjects in recumbency; consequently, local alveolar volumes are greatest in the nondependent regions.[17] For semi-recumbent patients with edematous lungs, an intensified gravitational gradient of pleural pressure accentuates the tendency for dorsal and peri-diaphragmatic atelectasis and consolidation.

The gradient of pleural pressure is less in the prone than in the supine position, in part because of reshaping of the thoracic cavity and shifting of the weight of the heart and mediastinal contents.[17] The supporting surface compresses the anterior chest and abdomen when prone, causing chest wall compliance to decline. Although conversion from the supine to the prone position is usually accompanied by marginal net changes of resting lung volume (<15%), there is usually a major shift of aerated lung volume toward dorsal regions (Fig. 53.13).

The lateral decubitus position causes the upper lung to assume a resting volume nearly as large as it has in the sitting position, whereas the lower lung is compressed to a size similar to or less than in the supine position. *Total* resting lung volume is somewhat greater in the lateral decubitus than in the supine horizontal orientation.[18]

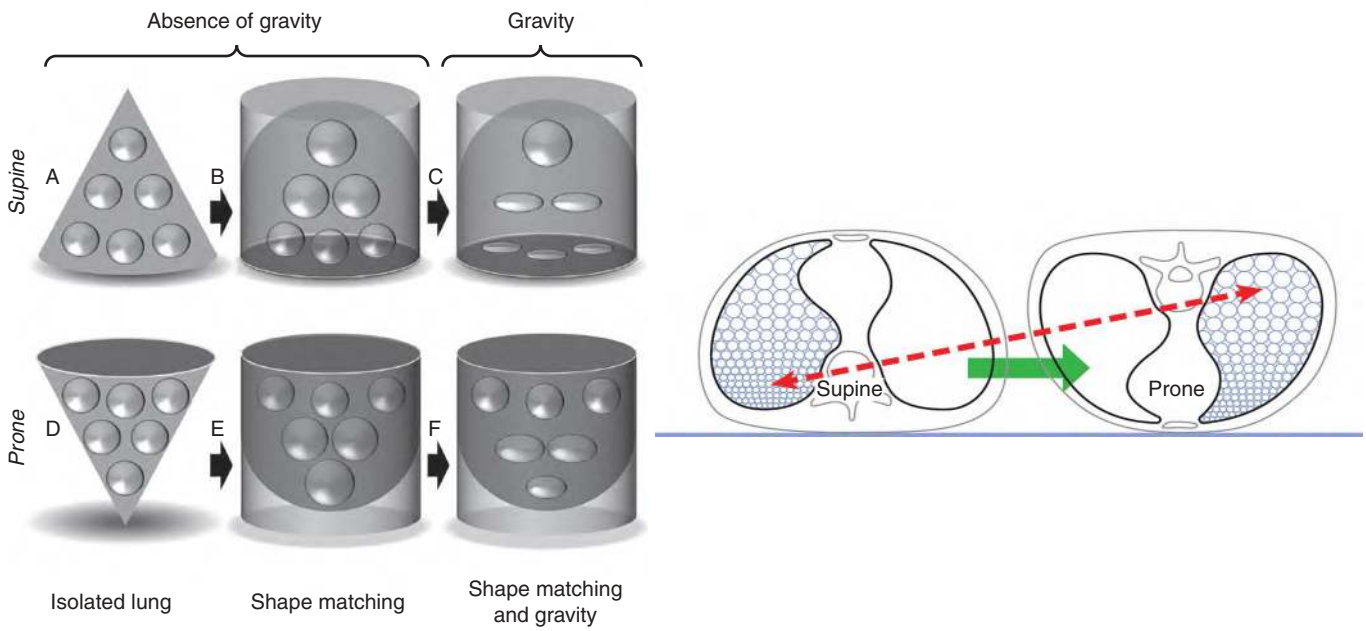

Fig. 53.13 Combined effects of gravity and shape matching on regional alveolar dimensions in the supine and prone positions.

Distribution of Ventilation. During spontaneous breathing, ventilation distributes preferentially to the dependent lung zones in the supine, prone, and lateral positions.[21,22] To avert atelectasis, the healthy subject typically breathes with low tidal lung volumes at rest, takes "sigh" breaths two to four times deeper than the average tidal volume multiple times per hour, and postural changes are unconsciously made frequently. Microatelectasis and arterial O_2 desaturation tend to develop if breathing remains shallow and uninterrupted by these periodic sighs or variations of position.[22–24]

Mechanics in Disease States

Management details regarding specific diseases are provided elsewhere in this volume. Yet certain basic features of mechanics for two common classes of breathing disorders are of such fundamental importance as to deserve emphasis here.

Acute Lung Injury

Acute lung injury ranks among the most challenging problems confronted in intensive care practice. ARDS may arise from diverse causes, most of which generate inflammation and high-permeability edema from pneumonia or sepsis. Mechanical ventilation provides indispensable life support but simultaneously holds the potential to injure lung tissue by applying excessive forces and tidal energy. Adverse consequences stem primarily from lung tissue's vulnerability to excessive stretching and mechano-signaling of inflammation, amplified by topographically heterogeneous mechanical properties and forces that act within the injured lungs.[25]

Despite the regional nonuniformity of transpulmonary pressures, only one airway pressure and/or one flow rate and flow profile can be selected and monitored at the airway opening. The low measured compliance that helps define ARDS was originally visualized as resulting from diffuse stiffening of all lung units, but now it is understood that compliance relates inversely to the number of units having relatively normal inflation properties. In other words, during the early phase of the process, *specific* compliance of each ventilated unit may be relatively normal and therefore susceptible to overstretching by high transalveolar pressure. This low-capacity condition has become known as the "baby lung"[26] (see Fig. 53.13). The degree to which that normality and vulnerability persists into the later stages of the ARDS process is not entirely clear. The gravitational gradient of transpulmonary pressure in ARDS is heightened by the increased weight of the lung, and the tendency for collapse of gravitationally dependent lung units is accentuated by the instability of surfactant-depleted air-liquid interfaces. As a consequence, sufficient PEEP is needed to generate a transpulmonary pressure at end expiration adequate to prevent their collapse. Not only does preserving alveolar patency help with gas exchange but also it prevents repeated tidal opening and closure of small airways—a process that accentuates potentially damaging stresses. Even when unit patency is preserved, focused stresses and high shearing forces arise at the interfaces between open and nonaerated tissues.[27] In this "amped up" environment, the repetitive application of relatively high tidal transpulmonary pressures may inflict damaging strain. These injurious transpulmonary forces may result from vigorous spontaneous efforts alone (patient self-induced lung injury [P-SILI]), from high airway pressures alone, or from any combination of both.[28] Even when it does not dramatically improve dorsal recruitment, prone positioning is currently thought to reduce VILI risk primarily by evening the distribution of transpulmonary pressures, thereby damping maximal tissue stresses and strains.

Acute Airflow Obstruction

Alveolar pressure at the end of passive tidal expiration may exceed set PEEP when the expiratory phase cannot be completed to the fully relaxed position of the respiratory system before the next inspiration begins (Fig. 53.14). The resulting pressure *gradient* driving end-expiratory flow (auto-PEEP, from the Greek word *autos* for "self") persists until interrupted by inspiratory forces generated by the patient or ventilator.[29] Total end-expiratory alveolar pressure (total PEEP) is the sum of the applied PEEP and auto-PEEP (AP). Unlike applied PEEP, AP local values (and therefore total PEEP) among lung units with diverse mechanical properties may not be the same throughout the diseased lung, and regional gas trapping may occur at higher pressures

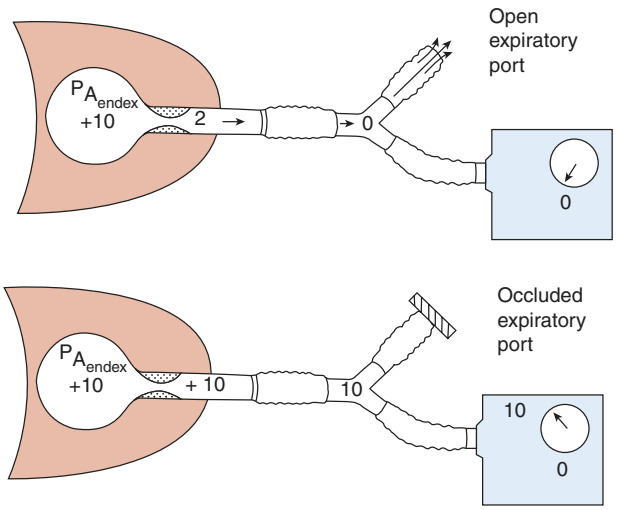

Fig. 53.14 The auto-PEEP effect and its measurement. Note that the true alveolar pressure (total PEEP) can only be estimated by the ventilator circuit when end-expiratory flow is stopped . In this case, no applied PEEP was present, and auto-PEEP was 10 cm H_2O. *PEEP,* Positive end-expiratory pressure. (From Pepe PE, Marini JJ. Occult positive end-expiratory pressure in mechanically ventilated patients with airflow obstruction (the auto-PEEP effect). *Am Rev Respir Dis.* 1982;126:166–170.)

than measured at the airway opening[30] (Fig. 53.15A). For this reason, the end-inspiratory static (plateau) airway pressure is generally a better indicator of hyperinflation than is the end-expiratory measurement of AP itself. Under passive conditions the detectable presence of AP and end-expiratory flow is invariably linked to increased end-expiratory distention, usually termed *dynamic hyperinflation (DH).* However, regional compliance determines the degree of lung unit expansion that corresponds to AP.

Determinants of Dynamic Hyperinflation and Auto-PEEP

Under passive conditions, the addressable variables that tend to increase DH and auto-PEEP are increased airway resistance, long inspiratory duty cycles (Ti/Ttot), and high minute ventilation (VE). Among these targets for therapy, perhaps the most effective strategy is to reduce ventilation requirement.[31] Lessening VE and accepting associated hypercapnia was adopted as a lifesaving approach for the treatment of intubated asthmatics well before permissive hypercapnia was implemented for ARDS.[32] Manipulation of the ventilatory *pattern* (frequency and VT combination) also influences DH, but reducing Ti/Ttot is generally of limited effectiveness when VE remains unchanged. Many who require ventilatory assistance for airflow obstruction have biphasic flow curves during tidal exhalation, with the second flow-limited phase much slower than the first.[33,34] Such

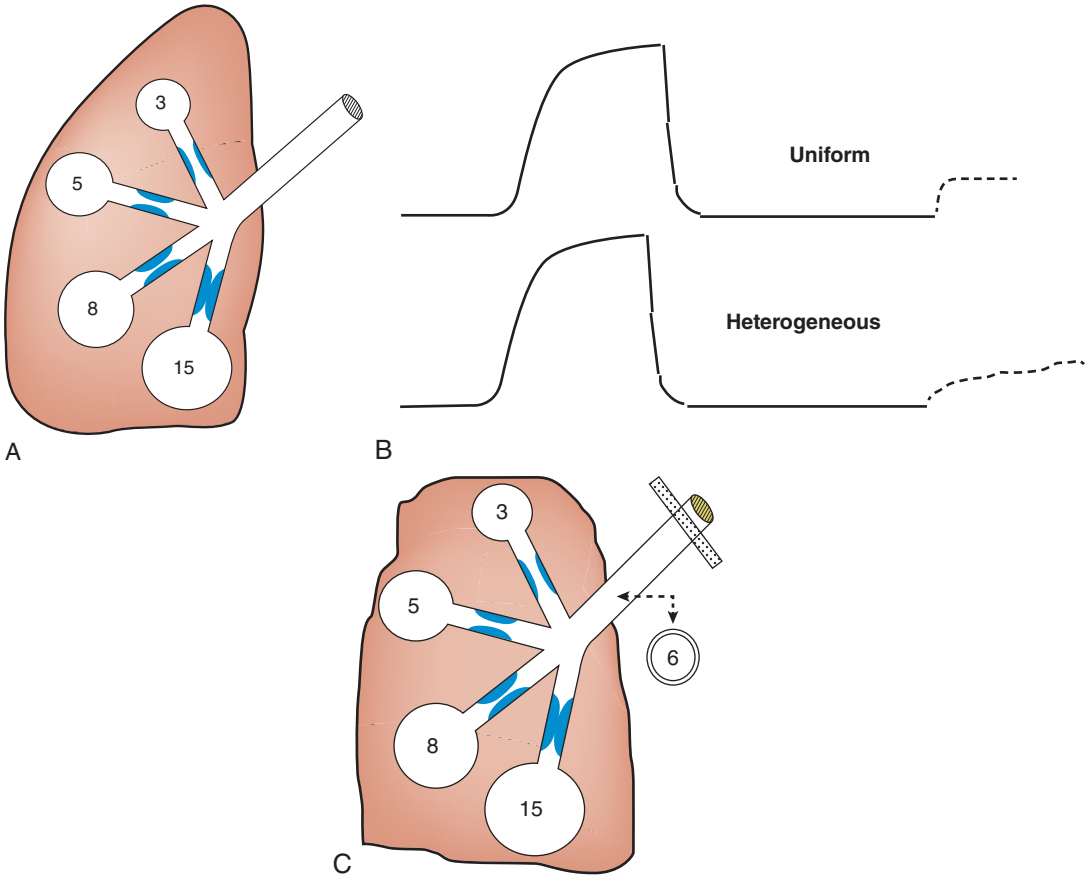

Fig. 53.15 A, Diverse regional values of auto-PEEP in a nonhomogeneous lung. Note that some lung units seal before the end of the deflation interval. **B,** Comparison of airway pressure profiles for a mechanically uniform and a mechanically nonuniform (*heterogeneous*) lung. At the point of end-expiratory flow stoppage *(arrow),* the slowly rising pressure profile at the airway opening reveals the mechanically heterogeneous lung as the varied alveolar pressures redistribute and equilibrate. **C,** Underestimation of maximal hyperinflating pressures by the auto-PEEP measured during end-expiratory port occlusion. Some of the most obstructed units seal before the end of expiration. The end-inspiratory (plateau) pressure provides a more reliable quantitative indicator of tidal hyperinflation. *PEEP,* Positive end-expiratory pressure.

biphasic deflation patterns are more often observed in chronic obstructive pulmonary disease (COPD) than in acute asthma, but do occur in both conditions.

Dynamic Hyperinflation

End-expiratory flow reliably implicates auto-PEEP during passive ventilation; however, the magnitude of flow bears little relation to the level of auto-PEEP that drives it through an undetermined upstream resistance.[30,31] At present, measuring static airway pressure after airway occlusion timed at end exhalation remains the method most commonly used to quantify *total* PEEP and to index global DH during *passive* ventilation. Under passive conditions, total PEEP can be measured by delaying the next breath as precisely timed airway occlusion terminates flow at the very end of the usual expiratory period. The contour of the resulting occlusion pressure helps reflect the uniformity or nonuniformity of auto-PEEP distribution (see Fig. 53.15B). Unfortunately, this maneuver cannot be performed reliably when the patient controls the breathing rhythm because of variations in the expiratory cycle length and/or muscular effort. This occlusion estimate is neither the highest nor lowest regional end-expiratory alveolar pressure during tidal breathing, but rather the *measurable* volume-averaged value (see Fig. 53.15C).

Consequences of Dynamic Hyperinflation and Auto-PEEP

Auto-PEEP associated with DH may affect hemodynamics, predispose to barotrauma, increase work of breathing, cause dyspnea, disrupt patient-ventilator synchrony, confuse monitoring of hemodynamics and respiratory system mechanics, and interfere with the effectiveness of pressure-regulated ventilation.[31] Barotrauma risk and the hemodynamic and energetic costs of auto-PEEP largely relate to any accompanying expansion of lung and chest wall volumes (DH)—not to alveolar pressure per se. Therefore as with the end-inspiratory plateau pressure, AP that occurs in association with stiff lungs or chest wall is less likely to be consequential than the same value measured in a setting of better respiratory system compliance.

Practical Bedside Indicators of Respiratory Mechanics

Compliance and resistance of the respiratory system can be easily estimated at the bedside under passive conditions during constant inspiratory flow. An end-inspiratory pause is applied to hold the inspired tidal volume trapped before exhalation is begun. Tidal compliance is the quotient of tidal volume and the difference between static plateau pressure (Ps) and PEEPtot, the so-called *driving pressure* (Δ) (see Fig. 53.8).[35] This contribution to stored elastic pressure, which is built up during inflation, drives expiratory flow. Importantly, calculations of Ps and Δ are valid for any inspiratory flow profile. Unless an automated estimate is provided by the ventilator, constant flow conditions flow conditions are required to estimate resistance, the difference between peak dynamic pressure (PD) and plateau pressures, divided by the rate of constant flow (see Fig. 53.8). The difference between PD and the pressure at which flow first becomes zero after the pause is applied (P_{ZF}) reflects the least resistance pressure because it excludes most stress relaxation, ventilation redistribution (pendelluft), and viscoelastic pressure adjustments that naturally occur during the pause. Finally, the slope of the airway pressure tracing at the end of inspiration obtained under constant flow conditions reflects elastance of the respiratory system ($1/C_{RS}$).

Mean Airway Pressure

Mean airway pressure is an easily observed and underused clinical tool. Under passive conditions, mean alveolar pressure and its only measurable analog, mean airway pressure (mPaw), relate intimately to the average forces that drive ventilation and hold the lung distended. When the nonelastic pressures dissipated in inspiration and expiration are identical, the airway pressure averaged over the entire ventilatory cycle should be the same everywhere, including the alveoli (mPalv) (Fig. 53.16). This mean pressure obtained in the absence of breathing effort is the pressure averaged over both phases of the tidal cycle. It distends the alveolus and passive chest wall and therefore correlates with alveolar size and with mean intrapleural pressure.[4] It follows that changes in mean airway (mean alveolar) pressure, when measured without patient effort, influence lung size and arterial oxygenation in the setting of pulmonary edema and lung injury. As a key determinant of mean intrapleural pressure, it also correlates under passive conditions with the "backpressure" to venous return. Mean airway pressure can be raised by increasing VE, by raising end-expiratory pressure, or by extending the inspiratory time fraction. To avoid serious and unanticipated problems in the passive patient, mean airway pressure is a key variable to monitor when the clinician changes minute ventilation or alters the mode of ventilation, breathing pattern, or PEEP setting. Although the relationship between mPalv and mP_{AW} is a close one, these pressures are not identical.[4] Any such pressure difference that generally

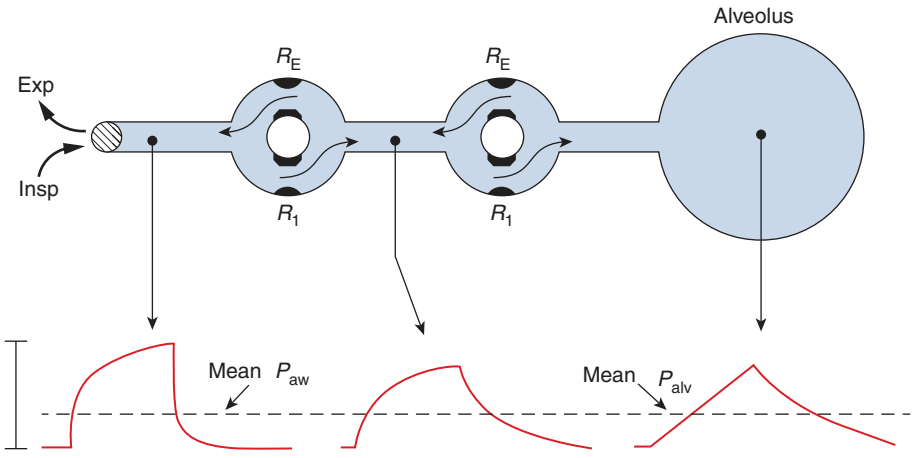

Fig. 53.16 Mean pressures along the path from airway opening to alveolus. When averaged over the entire tidal cycle, the mean airway pressures are theoretically very similar wherever they are measured; therefore mean alveolar pressure may be approximated by mean airway pressure in the external circuit. Note that when expiratory flow resistive losses exceed inspiratory flow resistive pressure losses (not illustrated), mean alveolar pressure may significantly exceed mean airway pressure.

favors a more positive Palv, may be striking in the setting of severe airflow obstruction that generates high levels of auto-PEEP.

Stress Index

Noticeable curvature of the inspiratory pressure tracing during passive inflation with constant flow suggests that disproportionate recruitment (concave to the time axis) or disproportionate overdistention (convex to the time axis) is taking place during the tidal cycle (Fig. 53.17). From the standpoint of lung protection, both are undesirable. During constant flow, the relationship between pressure and time can be expressed: $P_{AW} \alpha (t^s + [RV' + PEEP_{TOT}])$.[36] In this expression P_{AW} is airway pressure, t is inspiratory time since inflation onset (a correlate of volume), R is inspiratory resistance, and s is the "shaping" coefficient, or stress index (see Fig. 53.17). When s = 1.0, the Paw contour is linear. When it is significantly less than 1 or greater than 1, the stress index suggests undesirable degrees of tidal recruitment or overdistention, respectively (see Fig. 53.13). Adjustments to PEEP and/or VT are advisable, accordingly. Although the stress index is conceptually useful and often helpful, it is important to note that in practice its potential utility as an indicator of lung mechanics may be influenced strongly by the presence of a pleural effusion, abnormal chest wall properties, variations of auto-PEEP, and body position.[37] Any inspiratory muscular effort essentially invalidates its inferences.

Assessing Mechanics During Patient Effort

Although esophageal pressure measurement is seldom undertaken in clinical practice and therefore cannot be considered a basic skill, it deserves brief mention here because it provides the only direct and relatively noninvasive means for tracking lung mechanics during nonpassive breaths and for separating the forces applied to the lung and chest wall.[5] By noninvasively measuring the pressure in the pleural space that surrounds the lungs, the esophageal balloon catheter enables estimation of the transpulmonary pressure acting on the lung during all patient-initiated breaths (spontaneous or machine-assisted) and allows partitioning of transthoracic pressure into its lung and chest wall components during passive inflation (Fig. 53.18). The Pes

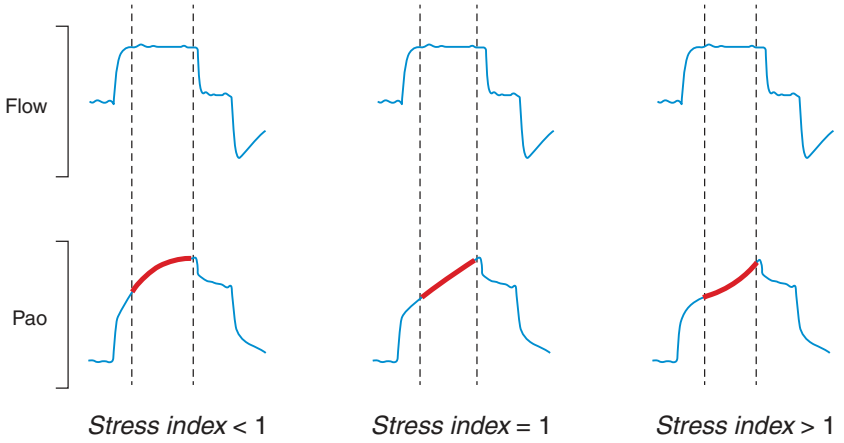

Fig. 53.17 Concept of the stress index. During constant inspiratory flow, the profile of the airway opening pressure (*Pao*) versus time indicates whether net tidal recruitment (<1) or net tidal overdistension (>1) are occurring with that combination of tidal volume and total PEEP. Significant departures from the ideal linear stress index of 1.0 are concerning.

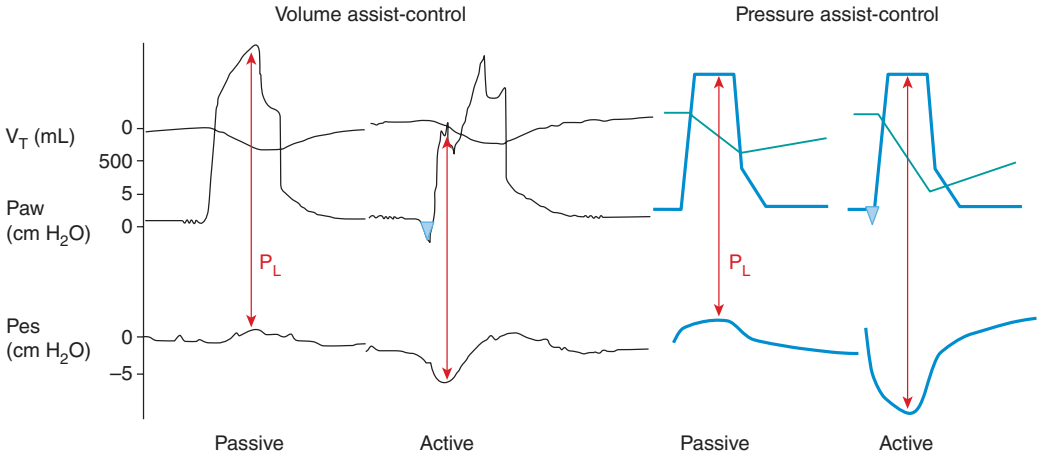

Fig. 53.18 Importance of the patient's contribution to the transpulmonary pressure under conditions of flow-regulated, volume-controlled ventilation *(left panels)* versus pressure regulated inflation *(right panels).* Note the potential for unregulated and greater transpulmonary pressure (P_L) during active breathing under the pressure assist-control condition. *Paw,* Airway pressure; *Pes,* esophageal (pleural) pressure. (From Akoumianaki E, Maggiore SM, Valenza F, et al., for the PLUG Working Group [Acute Respiratory Failure Section of the European Society of Intensive Care Medicine] The application of esophageal pressure measurement in patients with respiratory failure. *Am J Respir Crit Care Med.* 2014;189[5]:520–531, Fig. 2.)

provides a valuable indicator for detecting excessive effort, patient-ventilator asynchrony, lung stress, and weaning tolerance.[6,7,38] Having an intrapleural pressure permits direct calculation of lung compliance and airway resistance during spontaneous breathing, and Pes also can be used to compute the work of breathing. Finally, knowing the transpulmonary lung stress applied by a given plateau pressure may help to prevent VILI by guiding PEEP selection and by estimating lung-relevant transpulmonary stresses and driving pressures. Such information may prove influential during management of the massively obese[8] and during vigorous breathing.

GAS EXCHANGE

Oxygenation:

Directly Measured Variables

Partial oxygen pressure. The partial pressure of oxygen (PO_2) is the pressure exerted by the free oxygen molecules present in a gas or a fluid (in the form of unbound oxygen). The equilibrium between gas and fluid is the condition in which an equal number of oxygen molecules flow from the fluid to the gas and from the gas to the fluid. This equilibrium between oxygen in the alveoli and the free and unbound blood oxygen is defined by the solubility coefficient, which is equal to 0.0031 mL/mm Hg of oxygen/dL of blood.

Hemoglobin oxygen saturation. The hemoglobin oxygen saturation represents the fraction of hemoglobin to which the oxygen is bound. One molecule of hemoglobin, in which four binding oxygen sites are present, may only have a saturation fraction of 0%, 25%, 50%, 75%, or 100%. Therefore the clinically measured hemoglobin saturation is the weighted mean of the saturation of the single molecules (for example, if we assume that in a given patient 10% of the hemoglobin molecules are saturated at 50%, 20% at 75%, and 70% at 100%, the measured saturation will be 95%).

Indirectly Computed Variables

Alveolar PO_2. The alveolar PO_2 (PAO_2) is a key variable in the oxygenation process, as all blood perfusing an alveolus with a given PAO_2 will leave the lungs with the same oxygen tension (i.e., alveolar PO_2 = pulmonary capillary PO_2 [$PccO_2$]). Establishing the value of PAO_2 is a challenging task because of the cyclic nature of breathing and, furthermore, the values of PAO_2 differ significantly in distinct regions of the lung. This variation precludes accurate direct measurement of PAO_2 and has led to the development of indirect techniques for PAO_2 assessment, or in general, the assessment of all alveolar gases, by introducing the concept of the "ideal gases."[9]

The ideal PAO_2 may then be considered the average PO_2, which fully justifies the observed gas exchange, that is, which satisfies the following equation for a given respiratory quotient (RQ):

$$VO_2 = (FiO_2 - FAO_2) * VA = (CcO_2 - CvO_2) * Qc \qquad \textbf{(Eq. 2)}$$

$$\text{note: } VA = VE * \left(1 - \frac{Vd}{Vt}\right) \text{ and } Qc = Qt * \left(1 - \frac{Qs}{Qt}\right)$$

where VO_2 is the oxygen consumption per minute, FiO_2 the inspired fraction of oxygen, FAO_2 the alveolar fraction of oxygen, VA the alveolar ventilation, CcO_2 and CvO_2 the capillary and venous contents of oxygen, and Qc is the nonshunted perfusion of the lung. VE is the minute ventilation, Vd and Vt the dead space and the tidal volume, Qt is the total cardiac output, Qs is the shunted blood flow, and Qs/Qt the shunt fraction.

Equation (2) is consistent with a simple three-compartment model of pulmonary gas exchange: one ventilated and not perfused (Vd/Vt), one perfused but not ventilated (Qs/Qt), and one both perfused and ventilated. As illustrated by the equation, all oxygen *exchange* (VO_2) occurs in the ideal compartment having both Va and Q. (The same can be shown for CO_2 exchange.)

Although the "ideal" PAO_2 may be computed in different ways, one of the ones most used in the daily practice of mechanical ventilation is the following:

$$PAO_2 = FiO_2 * (P_B - P_{H_2O}) - \frac{PACO_2}{RQ} \qquad \textbf{(Eq. 3)}$$

where P_B is barometric pressure, P_{H_2O} is water vapor pressure at 37°C, $PACO_2$ is the alveolar PCO_2, and RQ is the respiratory quotient.

Although Eq. 3 accounts for the RQ—that is, the difference between oxygen consumption (VO_2) and CO_2 production (VCO_2)—it ignores the discrepancy between inspired and expired tidal volumes. This is evident after rearrangement of Eq. 3 into Eq. 4:

$$RQ = \frac{VCO_2}{VO_2} = \frac{FACO_2 * VA}{(FiO_2 - FAO_2) * VA} = \frac{FACO_2}{(FiO_2 - FAO_2)} \qquad \textbf{(Eq. 4)}$$

The earlier alveolar-gas equation (Eq. 3) is then derived by solving Eq. 4 for FAO_2 and expressing it as a partial pressure, according to the following general relationship:

$$P_p = F_g * (P_B - P_{H_2O}) \qquad \textbf{(Eq. 5)}$$

where P_p is the partial pressure of the gas and F_g is the fraction of the gas in the total gas volume.

As shown, the alveolar PAO_2 depends on the barometric pressure (P_B, which changes with altitude), on the $PACO_2$ (which depends on VCO_2 production and ventilation), and on the RQ (in the critical care setting it is usually approximated as 0.8).

A word of caution, however, is mandatory when assessing the alveolar PAO_2 in the setting of extracorporeal respiratory support; as an example, when using the extracorporeal CO_2 removal technique, the RQ disproportionately eliminates CO_2, causing RQ to be extraordinarily low, with remarkable effects on the computed PAO_2 and gas equilibrium.

Oxygen content. Essential information in the acutely critical patient is the blood content of oxygen, CnO_2, whose defining equation can be applied to arterial blood, central venous blood, or mixed venous blood:

$$CnO_2 = Hb * 1.39 * SatO_2 + 0.0031 * PO_2 \qquad \textbf{(Eq. 6)}$$

We may wonder why different coefficients are used in the literature: 1.35, 1.36, or 1.39 mL of oxygen per gram of fully saturated hemoglobin. The classical molecular weight of hemoglobin is 64,500 Da (or g/mol, if expressed as molar mass); therefore because 1 mole of fully saturated hemoglobin binds 4 moles of oxygen (at 760 mm Hg and 0°C) and the volume to mass relationship of ideal gases is 22.414 L/mol, fully saturated hemoglobin binds 4 * 22.414 = 89.656 L/mol. The ratio between 89,656 mL/mol and 64,500 g/mol equals 1.39 mL/g of Hb. The correction for the body temperature would give a higher coefficient (1.54 mL/g of Hb), whereas the coefficients used in literature are usually lower than 1.39 mL/g.

This adjustment is a result of the different molecular weights associated with the different strains of hemoglobin present within the erythrocytes.

Oxygen consumption. The oxygen consumption may be computed through the Fick method as the product between the cardiac output and the arterial-venous content difference:

$$VO_2 = (CaO_2 - CvO_2) * Qt * 10 \quad \textbf{(Eq. 7)}$$

Under normal conditions, the fraction of the oxygen transported from the arterial blood to the periphery is computed as follows:

$$DO_2 = Qt * CaO_2 \quad \textbf{(Eq. 8)}$$

As a consequence, the amount of oxygen returning to the right heart (vDO_2) amounts to:

$$vDO_2 = Qt * CvO_2 \quad \textbf{(Eq. 9)}$$

In normal conditions, the oxygen transported to the periphery is approximately 20 mL/dL of blood (for 5 L/min of cardiac output, it would amount to 1000 mL O_2 per minute). If the oxygen subtracted in the periphery (i.e., the oxygen consumption) is equal to 250 mL/min, the blood returning to the central venous compartment will be 750 mL/min. The ratio between returned and delivered oxygen in this example is 0.75, the approximate saturation. This underlines the importance of the mixed venous oxygen saturation, SvO_2, or its surrogate, the central venous saturation, as a key assessment tool in intensive care practice. Indeed, proceeding from the concept described earlier:

$$SvO_2 = SaO_2 - \frac{VO_2}{Qt * 1.39 * Hb} \quad \textbf{(Eq. 10)}$$

As shown, SvO_2 depends on arterial saturation, oxygen consumption, cardiac output, and hemoglobin concentration. Hence, any change in SvO_2 from baseline should immediately alert the intensive care physician that something potentially important is happening, either in the respiratory system (SaO_2), in the metabolic status (VO_2), in hemodynamics (Qt), or in the oxygen transporter (hemoglobin). Although SvO_2 is an unspecific tool, a sudden change of its value should immediately prompt the physician to evaluate all components that determine it.

Oxygenation assessment. Hypoxemia is defined by an oxygen partial pressure below the normal values. In subjects breathing in room air at normal atmospheric pressure, the PaO_2 is a function of age and may be approximated as:

$$PaO_2 = 100 - age * 0.3 \quad \textbf{(Eq. 11)}$$

where age is expressed in years.

As the partial pressure of a gas is equal to the total gas pressure times the fraction of the gas, and assuming that the oxygen exchange is in equilibrium between blood and alveoli, it follows that the arterial oxygen concentration is strongly related to (but not entirely determined by) the inspired oxygen fraction (FiO_2) and the barometric pressure. This must be taken into account under conditions of high altitude, as the P_B varies accordingly. The general equation to assess the inhaled PO_2 (PiO_{2new}) according to the external pressure is the following:

$$PiO_{2new} = FiO_2 * P_{Bnew} \quad \textbf{(Eq. 12)}$$

where P_{Bnew} is the barometric pressure at the new altitude.

In this setting, the alveolar oxygen pressure will be the following:

$$PAO_2 = (PiO_{2new} - 47) - \frac{PACO_2}{RQ} \quad \textbf{(Eq. 13)}$$

where 47 mm Hg represents the normal value of water vapor pressure at 37°C times the FAO_2.

PaO_2 and PaO_2/FiO_2 ratio. The simplest means by which to assess the efficacy of patient oxygenation is the direct measurement of arterial PO_2. However, because this value does not account for the fraction of inhaled oxygen, it cannot be used to assess the lung's oxygen exchanging status. The ratio between PaO_2 and FiO_2 was proposed decades ago as a tool for the assessment of the oxygenation status and the severity of hypoxemia; generally, mild hypoxemia is defined as a PaO_2/FiO_2 ratio of 200–300 mm Hg, mild to moderate hypoxemia as a PaO_2/FiO_2 ratio between 150 and 200 mm Hg, moderate to severe hypoxemia as 100–150 mm Hg, and severe hypoxemia below 100 mm Hg. The limitations of the PaO_2/FiO_2 ratio are twofold. First the relationship between FiO_2 and PaO_2 is not linear, and this nonlinearity implies that for a given degree of true oxygenation impairment, the PaO_2/FiO_2 ratio may vary depending on the FiO_2 at which it is determined. Second, a given FiO_2 results in a different alveolar partial pressure of oxygen, depending on the barometric pressure and, more importantly, on the RQ. This is especially relevant in patients under extracorporeal support, in which the RQ may be far different from the usual values. To overcome the first limitation of the PaO_2/FiO_2 ratio, it would be appropriate to compute the PaO_2/PAO_2 ratio, which takes into account the values of $PaCO_2$ and usually assumes an R equal to 0.8. The second limitation relating to distortions of RQ could only be overcome by measuring the actual VO_2/VCO_2 occurring in the natural lung.

Right-to-left shunt. This variable was introduced by Riley and colleagues in 1949 as a surrogate for directly measuring the ventilation-perfusion ratio (Va/Q).[9] As noted earlier, Riley and colleagues proposed a three-compartment model: one (ideal) ventilated and perfused, one (dead space) ventilated but not perfused, and one (right-to-left shunt, or more correctly, venous admixture) not ventilated but perfused.

The blood and gas leaving the ideal compartment have the same PaO_2, $PaCO_2$, and RQ as the body as a whole. In other words, the gas exchange (i.e., the oxygen transferred from the lung to the blood and the carbon dioxide removed by the lungs) occurs in this ideal compartment. In contrast, the blood leaving the right-to-left shunt compartment has the same PaO_2 and $PaCO_2$ of the mixed venous blood. The gas leaving the dead-space compartment has the same composition of the gas that enters it (CO_2 close to zero) and no blood comes out. In Fig. 53.19 we reproduce the original scheme of Riley and colleagues.

To understand the computations relating to the shunt compartment, it is convenient to consider gas content instead of pressure. Indeed, the oxygen content flowing per minute in the arterial blood [Qt * CaO_2] is the sum of that coming from the ideal compartment [(Qt − Qs) × CcO_2] and the blood [Qs] coming from the right-to-left shunt compartment:

$$Qt * CaO_2 = (Qt - Qs) * CcO_2 + Qs * CvO_2 \quad \textbf{(Eq. 14)}$$

where Qt is the cardiac output and Qs is the shunt flow. Rearranging the equation by dividing the two sides of the equation by Qt leads to the following equation:

$$CaO_2 = \left(1 - \frac{Qs}{Qt}\right) * CaO_2 + \frac{Qs}{Qt} * CvO_2 \quad \textbf{(Eq. 15)}$$

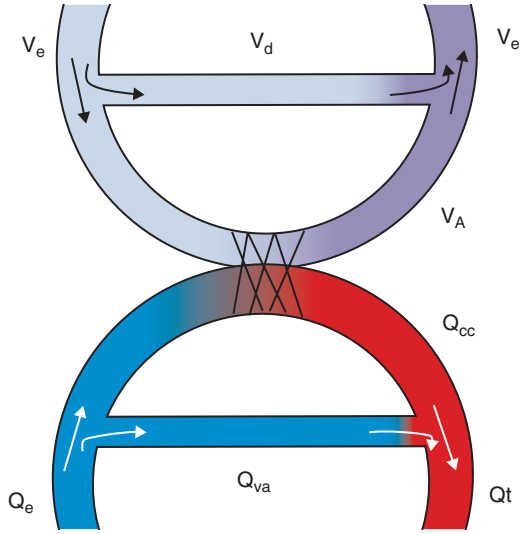

Fig. 53.19 Schematic representation of ventilation and perfusion exchange. *Upper part of the figure:* The gas entering the lungs (minute ventilation) splits in two compartments: dead space ventilation and alveolar ventilation. After the gas-exchange process within the pulmonary capillary, the CO_2-enriched alveolar gas is in part diluted, after leaving the perfused alveoli, by the dead space gas. *Lower part of the figure:* The blood entering the lungs (cardiac output, venous, in *blue color*) splits in two compartments: venous admixture flow (Q_{va}) and capillary blood flow (Q_{cc}). After the gas exchange the O_2-enriched capillary flow is in part diluted, after leaving the ventilated alveolar units, by the venous admixture. *Qt,* Cardiac output; *VA,* alveolar ventilation; *Vd,* dead space; *VE,* minute ventilation. (Adapted from Riley RL, Cournand A. Ideal alveolar air and the analysis of ventilation-perfusion relationships in the lungs. *J Appl Physiol.* 11949;1[12]:825–847.)

The variable of interest, the right-to-left shunt (Qs/Qt), can be then computed as follows:

$$\frac{Qs}{Qt} = \frac{CcO_2 - CaO_2}{CcO_2 - CvO_2} \qquad \textbf{(Eq. 16)}$$

It is noteworthy that Va/Q equal to zero is formally defined as a "true" right-to-left shunt. Using Riley and colleagues' model, however, all blood flowing in lung regions with Va/Q values intermediate between ideal and zero is assigned in proportion to the ideal or to the dead-space compartments. When perfused but low Va/Q units contribute to the Qs/Qt calculation, as they virtually always do to some extent, the appropriate terminology is "venous admixture" instead of right-to-left "shunt."

Oxygenation index and ROX index. The Oxygenation Index (OI) was introduced several decades ago by Bartlett and colleagues[10] as a composite measure for assessing the need of extracorporeal support in a pediatric population. It is calculated as follows:

$$OI = FiO_2 * \frac{MAP}{PaO_2} \qquad \textbf{(Eq. 17)}$$

where MAP is the mean airway pressure The MAP under passive conditions correlates with average aerated lung size and with lung unit recruitment. (MAP is discussed in the section on mechanics in this chapter.) Actually, rather than the adequacy of oxygenation, the OI assesses the costs of compensating for impaired oxygenation. Indeed, a high FiO_2 or MAP (which includes PEEP) are well-known potential boosters for VILI development and/or impaired venous return.

The ROX index has been recently introduced into daily clinical practice as an easy-to-apply tool for assessing patient oxygenation efficiency.[11] It is calculated as follows:

$$ROXi = \frac{SpO_2}{FiO_2} * \frac{1}{RR} \qquad \textbf{(Eq. 18)}$$

where SpO_2 is expressed as a percentage (0%–100%), FiO_2 is expressed as a fraction (0–1), and RR is the respiratory rate.

The ROXi normalizes the SpO_2 (using pulse oximetry as a surrogate of PaO_2) to the inspired FiO_2 and introduces the respiratory rate as an indicator of severity. Its advantages are ease of application, low cost, and potential for continuous monitoring. However, it is well-known how variations of temperature, pH and erythrocyte 2.3-diphosphoglycerate, and so on, shift the oxygen-hemoglobin dissociation curve, potentially leading to values of SpO_2 of 100% with values of PaO_2 ranging from 100 to 500 mm Hg. Consequently, the ROX index may be associated with unnecessarily high PaO_2 and, by contrast, cannot detect PaO_2 worsening until oxygen saturation decreases.

Clinical Applications

The arterial oxygen saturation of hemoglobin is the most widely used method of monitoring oxygenation, as it mirrors changes in arterial PaO_2 values below 90–100 mm Hg. Because values of PaO_2 higher than 100 mm Hg will be associated with a hemoglobin oxygen saturation of 100%, it is convenient to adjust FiO_2 in order to obtain a baseline oxygen saturation less than 100%. In doing so, any change in arterial oxygenation is immediately reflected by a modification in hemoglobin saturation. It is prudent to remember that a saturation of 50% is usually associated with a PaO_2 of approximately 25 mm Hg, whereas 90% usually corresponds to a PaO_2 of around 60 mm Hg. Within the range of 50% and 90%, oxygen saturation and PaO_2 are almost linearly related (i.e., any point change of saturation corresponds to ~1 mm Hg of PaO_2). Although these guidelines are obviously imprecise, they do help estimate blood oxygenation status.

Although the PaO_2/FiO_2 ratio is the most widely used indicator for classifying oxygenation impairment, its limits include the lack of linearity between PaO_2 and FiO_2. This implies that the PaO_2/FiO_2 ratio may change for a given shunt fraction, depending on the FiO_2 at which it is determined. The same occurs if the hemoglobin arterial oxygen saturation/FiO_2 ratio is used, as shown in Fig. 53.20.

In our opinion, the venous admixture and the dead space are the best assessment tools to assess any impairment of gas exchange (dead space will be discussed in detail later in this chapter). It must be noted, however, that venous admixture relates strongly to the cardiac output: an increased cardiac output promotes right-to-left shunt, whereas a decrease of cardiac output may raise PaO_2. This phenomenon becomes especially relevant when the airway pressures are high; indeed, an increased PaO_2 in a setting of high airway pressure may be the result of a decrease in cardiac output rather than increased recruitment.[39]

Finally, whereas hemoglobin saturation, PaO_2/FiO_2 ratio, and venous admixture account for the severity of oxygenation impairment, the OI and the ROX index include variables that reflect the conditions required to obtain a specific gas-exchange level. The OI includes the MAP and the FiO_2, and the ROX index incorporates the respiratory rate. Consequently, these indices are primarily indicated to help decide the level of intervention: extracorporeal support in the case of OI and tracheal intubation in the case of ROX index.

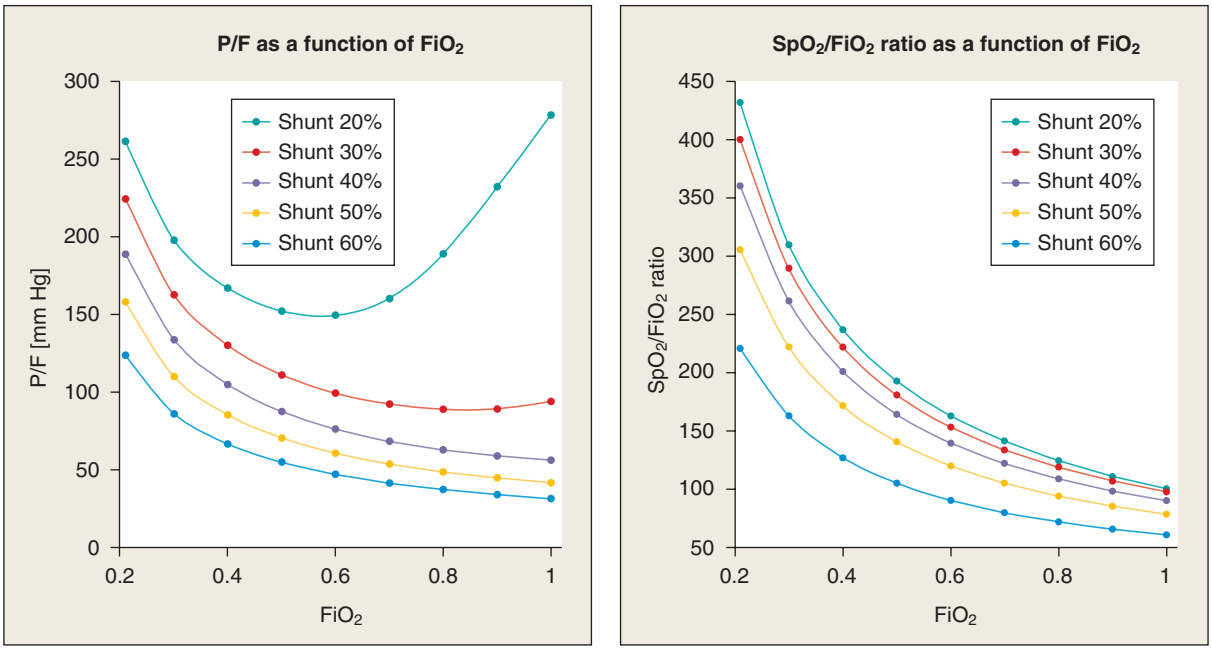

Fig. 53.20 *Left panel,* partial pressure of oxygen/fraction of inspired oxygen (PaO_2/FiO_2) ratio as a function of FiO_2 at different levels of shunt fraction. As shown, the same shunt may result in sharply different PaO_2/FiO_2 ratios, depending on FiO_2 at which the measurement has been performed. *Right panel:* SpO_2/FiO_2 as a function of FiO_2. As shown, the SpO_2/FiO_2 ratio is even less effective in reflecting the shunt fraction than the PaO_2/FiO_2 ratio. As an example, a shunt fraction of 40% may result in an SpO_2/FiO_2 ratio of 250 vs. <150, depending on the FiO_2 applied when making the measurement.

Carbon Dioxide Removal

Directly Measured Variables

Partial pressure of PCO_2. The partial pressure of carbon dioxide (PCO_2) is the pressure exerted by the free CO_2 molecules present in the gas or in a fluid. Carbon dioxide is characterized by a solubility coefficient of 0.0306 mmol/L*mm Hg. Note that the carbon dioxide solubility coefficient is measured as mmol/mm Hg per liter, whereas the oxygen coefficient refers to mL/mm Hg per deciliter. As 1 mmol of gas corresponds to 22.4 mL, it follows that the solubility of CO_2 compared with the oxygen is significantly higher when expressed with the same unit of measure: 0.0306 vs. 0.0074.

pH. The pH scale is used to assess acidity or alkalinity (basicity) of an aqueous solution by measuring the concentration of free H^+ protons in the solution, according to the following relationship:

$$pH = -\log[H^+] \qquad \textbf{(Eq. 19)}$$

where $[H^+]$ is the concentration of protons, in mmol/L.

In blood, at pH 7.4, the concentration of H^+ is 39.8×10^{-9} mol/L, or 39.8 nanomoles per liter. Remarkably, the magnitude of hydrogen ion concentration is on the order of nanomoles (10^{-9}), compared with the mmol (10^{-3}) of the other ions. An equilibrium constant (Kw) characterizes the process of water dissociation ($2H_2O \rightarrow H_3O^+ + OH^-$):

$$Kw = [H_3O^+] * [OH^-] \qquad \textbf{(Eq. 20)}$$

Accordingly, any increase or decrease of H^+ corresponds to an equal and opposite change of OH^-. For a better understanding of the relationship between CO_2 and pH, the concept of "electrical-charge equilibrium" needs to be introduced: the number of positive and negative charges in plasma must be equal. Directly Measured and Indirectly Computed are subcategories under Oxygenation. Electric charges originate from the dissociation of different substances. A strong ion is a substance that is always completely dissolved in a solution: that is, it always has an electric charge (e.g., sodium, chlorine, potassium, and lactate). Under normal conditions, the number of positively charged strong ions is higher than of the negatively charged anions; this difference is called the *strong ions difference (SID),* and it amounts to approximately 40 mmol. As a consequence, to maintain the electrical neutrality, 40 mmol of negative charges must be present in the system.

The weak acids, or buffers, are the substances that provide such missing negative charges, and they are present in two forms: dissociated (electrically charged) or undissociated (electrically neutral). Buffers can be conceptually divided into two groups, one represented by the total CO_2, which may be present as HCO_3^- (dissociated) or CO_2 (undissociated), and the other enclosing all the remnant weak acids, collectively called A_{tot}, primarily represented by albumin and phosphates. Again, A_{tot} may be either dissociated (A^-) or undissociated (AH) (Fig. 53.21).

To maintain the electrical-charge equilibrium, CO_2 and A_{tot} must dissociate in a way such that the sum of their dissociated forms is equal to the SID (i.e., $SID = HCO_3^- + A^-$). If a negative strong ion is added to the system, the SID decreases and, as a consequence, the sum of HCO_3^- and A^- should decrease by the same amount. Part of the HCO_3^- will convert to carbonic acid and eventually to CO_2 plus H_2O, and part of the A^- will become AH. Therefore in a condition of metabolic acidosis, the decrease of SID will lead to a decrease of HCO_3^- and A^-. Noteworthy, other than the decrease of HCO_3^- and A^-, the OH^- will decrease too, and because the product of OH^- and H^+ is constant, any decrease in OH^- will result in an increase of free H^+ (i.e., acidosis).

In respiratory acidosis the increase of pCO_2 leads to a higher HCO_3^-. Because the sum of HCO_3^- and A^- maintains the SID

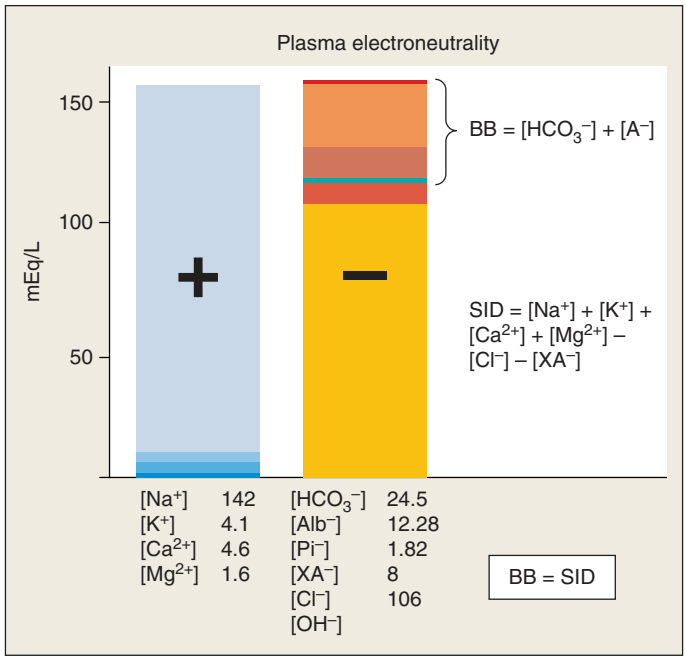

Fig. 53.21 Principle of plasma electroneutrality. As shown, electroneutrality (the height of the two columns) is reached when the 150 mEq/L of always-positive charges (strong ions always present with a positive charge) are neutralized by the 150 mEq/L of ions with negative charges. Of this 150 mEq/L, 108 mEq/L are always present with negative charges (strong ions), whereas 42 mEq/L may lose their negative charges if other negative ions are added to the system. In this case, part of $H_2CO_3^-$ will become $H_2O + CO_2$ and part of these anions (A^-) will become AH. Note that these "weak" ions are known as the buffer base (*BB*) and quantitatively equal the difference between strong positive and strong negative ions. *SIS,* Strong ions difference.

constant, any increase of HCO_3^- is matched by a decrease of A^-, which is then converted to AH. Again, a fraction of OH^- decreases, producing H^+ and therefore promoting respiratory acidosis.

Indirectly Measured Variables

Bicarbonates. Bicarbonate (HCO_3^-) is the dissociated part of carbon dioxide and the main form of transporting CO_2 in the blood; its equilibrium with the free CO_2 is classically represented by the Henderson-Hasselbalch equation:

$$pH = pk + \log \frac{HCO_3^-}{0.0306 * PCO_2} \qquad \textbf{(Eq. 21)}$$

Isolating bicarbonate on the left side of the equation results in the following expression:

$$HCO_3^- = 10^{pH-pk} * PCO_2 * 0.0306 \qquad \textbf{(Eq. 22)}$$

It is evident how any change of PCO_2 is followed by a change of HCO_3^- in the same direction. Furthermore, the proportionality constant () dictates the magnitude of this change. It should be noted that the algorithms used to compute bicarbonates are slightly different. Consequently, especially at pH values far from 7.4, the same $PaCO_2$/pH couple may result in bicarbonate differences as high as approximately 2 mmol.

Alveolar PCO_2. Alveolar PCO_2 ($PACO_2$) is the partial pressure of CO_2 in the alveolar space. Because of the complexity of alveolar gas assessment, it is again convenient to refer to the "ideal compartment" model we discussed earlier.

In a perfect gas exchanger, the alveolar PCO_2 equals the PCO_2 measured in the pulmonary venules and arterial blood ($PcCO_2$ and $PaCO_2$). If shunt is present, the blood coming from the ideal compartment is mixed with the blood coming from the shunted compartment, relatively rich with PCO_2. As a result, the $PaCO_2$ is higher than the $PACO_2$. On the other hand, in the perfect gas exchanger, the alveolar PCO_2 is equal to the end-tidal PCO_2 ($PetCO_2$), which is the pressure exerted by CO_2 within the exhaled gases. If dead space is present, the end-tidal PCO_2 will reflect the admixture of CO_2-free gas that never contacted blood and therefore will be lower than arterial PCO_2. In the perfect gas exchanger the ratio between end-tidal PCO_2 and $PaCO_2$ equals 1, whereas it varies in the presence of shunt or alveolar dead space.

For the sake of simplicity, however, in the clinical setting the alveolar PCO_2 is usually considered equal to the arterial $PaCO_2$. This difference is limited to no more than 2 mm Hg in the presence of shunt fraction lower than 20% and becomes more relevant at higher levels of shunt.

CO_2 content. The CO_2 content in the plasma is the sum of the dissolved PCO_2, bicarbonate, carbonate, and carbon dioxide bound to plasma proteins. However, the total plasma CO_2 content measured by blood gas-analysis machines only takes into account the sum of dissolved PCO_2 and bicarbonate:

$$PCO_2 + bicarbonate\ plasma\ CCO_2 = PCO_2 * 0.0306 * (1 + 10^{pH.rbc - pK}) \qquad \textbf{(Eq. 23)}$$

where $plasmaCCO_2$ is the total plasma content of CO_2.

It is important to realize that the CO_2 content of whole blood is markedly different from the total CO_2 content of plasma, as the pH of the red cells is lower than the pH of plasma, and pH influences CO_2 content. Therefore the total CO_2 in blood is:

$$bloodCCO_2 = plasmaCCO_2 * (1 - Ht) + Ht * 0.0254 * PCO_2 (1 + 10^{pH.rbc - pK}) \qquad \textbf{(Eq. 24)}$$

where Ht is the hematocrit, 0.0254 is the solubility of CO_2 within red blood cells (rbc), and pH.rbc is the intra-erythrocyte pH value.

Several formulas[40,41] have been proposed to compute the total CO_2 amount in the blood. However, for practical purposes, no one of these is really satisfactory because even a small error in the measurement of PCO_2, pH, or hematocrit may significantly change the computation. What is important to underline is the relationship between PCO_2, CO_2 content, and pH. Indeed, as shown in Fig. 53.22, for a given CO_2 content, any addition of strong ions leads to a decrease of base excess and pH and is eventually associated with an important rise of PCO_2.

At equilibrium, a given amount of carbon dioxide is produced and a given amount of oxygen is consumed, their relationship being equal to the RQ:

$$RQ = \frac{VCO_2}{VO_2} = \frac{Qt * (CvCO_2 - CaCO_2)}{Qt * (CaO_2 - CvO_2)} \qquad \textbf{(Eq. 25)}$$

where VCO_2 is the production of CO_2 per minute, VO_2 is the minute oxygen consumption, Q is the cardiac output, and Cv and Ca are the venous and arterial contents of CO_2 and O_2.

In critically ill patients this ratio is usually assumed to be 0.8. If a strong ion (lactate or chloride) is added to the venous blood, the pH suddenly decreases and the CO_2 content remains equal but the PCO_2 increases markedly, as shown in Fig. 53.23. This is the "Coca-Cola"

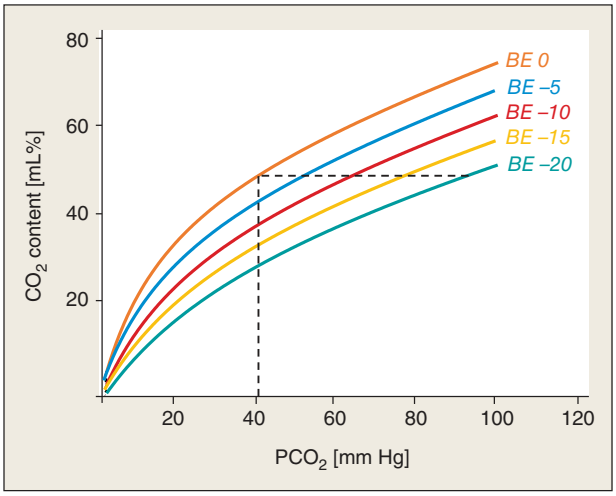

Fig. 53.22 CO_2 content as a function of partial pressure of carbon dioxide (PCO_2), according to different levels of base excess. For the same content of CO_2, the decrease of base excess may cause a sharp increase in PCO_2. In this case, in a closed system that contains 50 mL of CO_2 in 1 liter, adding, as an example, 20 mmol of lactates (strong negative ions) will cause PCO_2 to rise from 40 mm Hg to almost 100 mm Hg.

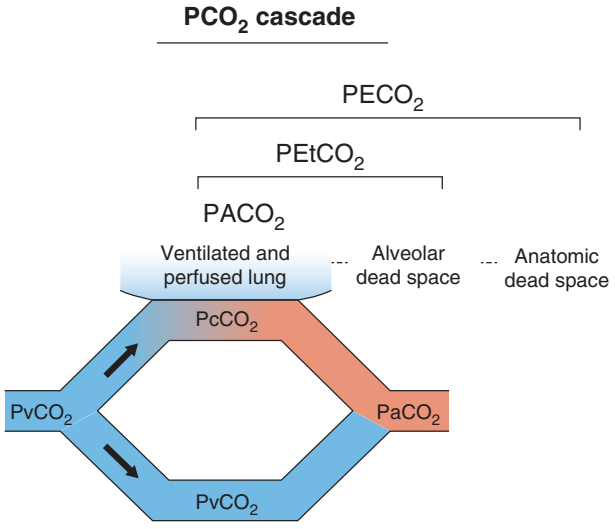

Fig. 53.23 Schematic representation of the cascade of CO_2. As shown, part of the free unbound CO_2 molecules ($PvCO_2$) leaves the blood phase and enters the alveoli. After CO_2 is removed by ventilation, the alveolar PCO_2 ($PACO_2$) and the PCO_2 in the pulmonary capillary leaving the alveoli are the same. The capillary PCO_2, however, mixes with the shunt flow (with higher PCO_2, the $PvCO_2$) after the venous admixture, thus generating the arterial PCO_2. If the shunt fraction is zero, $PaCO_2$, $PcCO_2$, and $PACO_2$ are equivalent. The $PACO_2$, present in the alveolar gases, is first diluted by the alveolar dead space, generating the $PEtCO_2$, and subsequently, by the anatomic dead space (airways plus circuit dead space), generating the $PECO_2$. If the alveolar dead space is equal to zero, the $PEtCO_2$ and $PECO_2$ are the same. It follows that $PEtCO_2/PECO_2$ are equal if both dead space and shunt fraction are zero.

effect, where an increased bubbling appears after squeezing a lemon (citric acid) into a soda. Of course, the bubbles are composed of free molecules of CO_2. The delta pCO_2 compared with the delta arteriovenous difference is therefore a suitable indicator for a strong negative ion addition.

CO_2 production. Although several methods have been described to measure the production of CO_2, the most reliable is based on the analysis of the exhaled gases. The carbon dioxide production (VCO_2) equation is as follows:

$$VCO_2 = VE * FECO_2 \quad \textbf{(Eq. 26)}$$

where VE is the minute ventilation and $FECO_2$ is the fraction of expired CO_2.

If CO_2 pressure is measured, it can be converted in fractions (FCO_2) according to the following formula:

$$FCO_2 = \frac{PCO_2}{P_B - 47} \quad \textbf{(Eq. 27)}$$

where PCO_2 is the partial pressure of CO_2, P_B is the barometric pressure, and 47 mm Hg is the pressure exerted by the water vapor at 37°C.

Several ventilators provide the capnographic curve, so they automatically measure the VCO_2 value. In this setting, VCO_2 is computed as the integral of the area below the capnographic curve. Despite being an extremely informative variable, VCO_2 is rarely assessed in the intensive care setting. It is worth noting that the level of mechanical ventilation required relates strictly to the amount of CO_2 to be cleared. Because a high intensity of mechanical ventilation is associated with a higher degree of VILI, a high VCO_2 is a main trigger for lung damage associated with mechanical ventilation.

CO_2 stores. Differently from oxygen, for which the body resources are limited to the oxygen dissolved in plasma and oxygen bound to the hemoglobin, carbon dioxide is present in large amounts in different body compartments. Indeed, CO_2 is stored in the blood, as discussed earlier, in the interstitium, where it is dissolved in the same form of blood, and in tissues, primarily in the bones. Here, it is accumulated in different chemical forms, on the whole bicarbonates and carbonates.[42]

The blood reserves are about 2.5%, interstitium accounts for an 8.5%, and the remaining CO_2 in the peripheral tissues amounts to 89%.[12] Traditionally, the extracellular compartment is considered "fast," as its CO_2 content may rapidly reduce by increasing the minute ventilation. Conversely, the CO_2 stored in tissues constitutes the "slow" compartment.

When measuring CO_2 production, or better, CO_2 clearance, the presence of mobilizable stores of CO_2 must be always taken into account. Indeed, the clearance of CO_2 may (1) be equal to the metabolic production, in which case the CO_2 store remains unmodified; (2) be increased, for example, during hyperventilation, leading to a decrease of the store of CO_2; or (3) be decreased, for example, in hypoventilation, associated with an increase of CO_2 stores. It must be remembered that despite the fact that arterial PCO_2 almost reaches the steady state in 5 minutes during hyperventilation and in 30 minutes during hypoventilation, the equilibrium, in terms of CO_2 depletion, is not reached even after 48 hours.

CO_2 assessment. The direct measurement of arterial PCO_2 allows one to classify any patient into normocapnic (35–45 mm Hg), hypocapnic (<35 mm Hg), or hypercapnic (>45 mm Hg). The determinants of arterial PCO_2 are the following:

$$PaCO_2 = \frac{VCO_2 * 863}{VA} \quad \textbf{(Eq. 28)}$$

where VCO_2 and VA (alveolar ventilation) are measured in L/min; 863 is a coefficient that converts the volume of a gas from a standard

temperature and pressure and dry (STPD) condition (0°C and 760 mm Hg, dry) to the body temperature pressure saturated with water vapor (BTPS) condition. In other words, a gas volume at 0°C (standard temperature, Ts) and 760 mm Hg (standard pressure, Ps) must be converted to body temperature (Tb = 37°C) and body pressure (Pb = 713 mm Hg).

The gas volume in BPTS conditions is equal to:

$$V\,btps = \frac{Ps * Tb}{Pb * Ts} * V\ stpd \qquad \textbf{(Eq. 29)}$$
$$\frac{760\ mmHg}{713\ mmHg} * \frac{310\ K}{273\ K} = 1.21$$

where body and standard temperatures are expressed in Kelvin degrees.

To convert the gas volume from STPD to BTPS, it must be multiplied by 1.21. Finally, to convert BTPS volume into a pressure, one must multiply the volume times the difference between barometric pressure (usually 760 mm Hg) and water vapor pressure (usually 46 mm Hg). Briefly: 760 minus 47 equals 713; multiplying by 1.21, the final result is 863.

According to Eq. 28, arterial PCO_2 increases either when VCO_2 increases or, more frequently, it increases when alveolar ventilation decreases. Alveolar ventilation is equal to:

$$VA = VE * \left(1 - \frac{Vd}{Vt}\right) \qquad \textbf{(Eq. 30)}$$

where VE is the minute ventilation, and Vd/Vt is the fraction of dead space over tidal volume. As a consequence, any increase of dead space or decrease in minute ventilation leads to an increase of PCO_2.

Therefore to fully understand PCO_2 behavior, its three determinants must be considered: carbon dioxide production, minute ventilation, and the BTPS converting factor.

Dead space and $PEtCO_2/PaCO_2$ ratio. The dead space is defined as the proportion of each breath that fails to take part in gas exchange, either because it remains in the conducting airways (anatomic) or because it ventilates regions of the lung that are not perfused adequately (alveolar). The physiologic dead space is the sum of the anatomic and the alveolar dead spaces.

To estimate the physiologic dead space, one should understand the relationship between alveolar and minute ventilation and arterial and exhaled pressure of carbon dioxide:

$$VCO_2 = \frac{VA * PACO_2}{863} = \frac{VA * PECO_2}{863} \qquad \textbf{(Eq. 31)}$$

Rearranging Eq. 31, we obtain:

$$\frac{VA}{VE} = \frac{PECO_2}{PACO_2} \qquad \textbf{(Eq. 32)}$$

where VA/VE is the fraction of the inspired air reaching the perfused alveoli. Noteworthy, the complement of this fraction is the dead space. Consequently:

$$DS = 1 - \frac{VA}{VE} = 1 - \frac{PECO_2}{PACO_2} = \frac{PACO_2 - PECO_2}{PACO_2} \qquad \textbf{(Eq. 33)}$$

where DS is the physiologic dead space.

For sake of simplicity, alveolar PCO_2 is usually substituted by the arterial PCO_2; however, in the presence of right-to-left shunt, the alveolar and the arterial PCO_2 values are different.

The alveolar dead space is calculated as follows:

$$VCO_2 = PACO_2 * VA_{perf} = PEtCO_2 * (VA_{perf} + VA_{unperf}) \qquad \textbf{(Eq. 34)}$$

As shown, the alveolar ventilation was divided into the alveolar ventilation of the perfused and the nonperfused regions of the lungs. $PEtCO_2$ is the pressure exerted by the carbon dioxide in the exhaled air:

$$\frac{VA_{perf}}{VA_{perf} + VA_{unperf}} = \frac{PEtCO_2}{PACO_2} \qquad \textbf{(Eq. 35)}$$

The ratio $PEtCO_2/PACO_2$ represents the fraction of the alveolar ventilation that actually performs the gas exchange. Conversely, the fraction of alveolar dead space (DSalv) is the following:

$$DSalv = 1 - \frac{VAperfused}{VAperfused + VAunperfuesd} = 1 - \frac{PEtCO_2}{PACO_2}$$
$$= \frac{PACO_2 - PEtCO_2}{PACO_2} \qquad \textbf{(Eq. 36)}$$

Remarkably, if alveolar PCO_2 is substituted with arterial PCO_2, the alveolar dead space also includes the shunt effect, and the $PEtCO_2/PaCO_2$ ratio becomes a measure of the adequacy of the gas exchange: any increase of alveolar dead space or true shunt will decrease the ratio. Fig. 53.24 shows the PCO_2 cascade.

Most of these variables are provided by some ventilator machines: the anatomic dead space is derived from the analysis of the capnographic curve, as described by Fowler, whereas the physiologic and alveolar dead spaces require the addition of the $PaCO_2$ value.

Ventilatory ratio. The ventilatory ratio (VR) was developed as a surrogate for dead space.[13] Ideally, it should provide the same information as dead space without the need to measure gas PCO_2. It is calculated as follows:

$$VR = \frac{VE * PaCO_2}{100 * BW * 37.5} \qquad \textbf{(Eq. 37)}$$

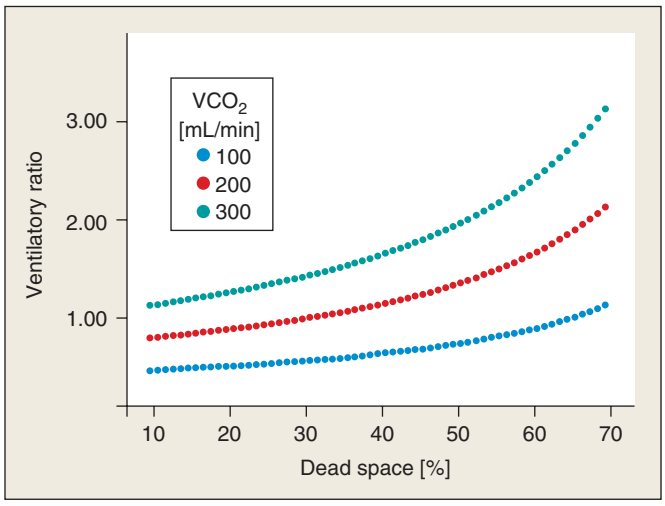

Fig. 53.24 Ventilatory ratio as a function of the dead space, at different levels of VCO_2. As shown, the same dead space may be associated with markedly different values of ventilatory ratio, depending on the VCO_2, whereas for the same VCO_2, the ventilatory ratio shows a near-exponential trend, according to the value of dead space. *VCO_2*, Production of CO_2 (mL/min).

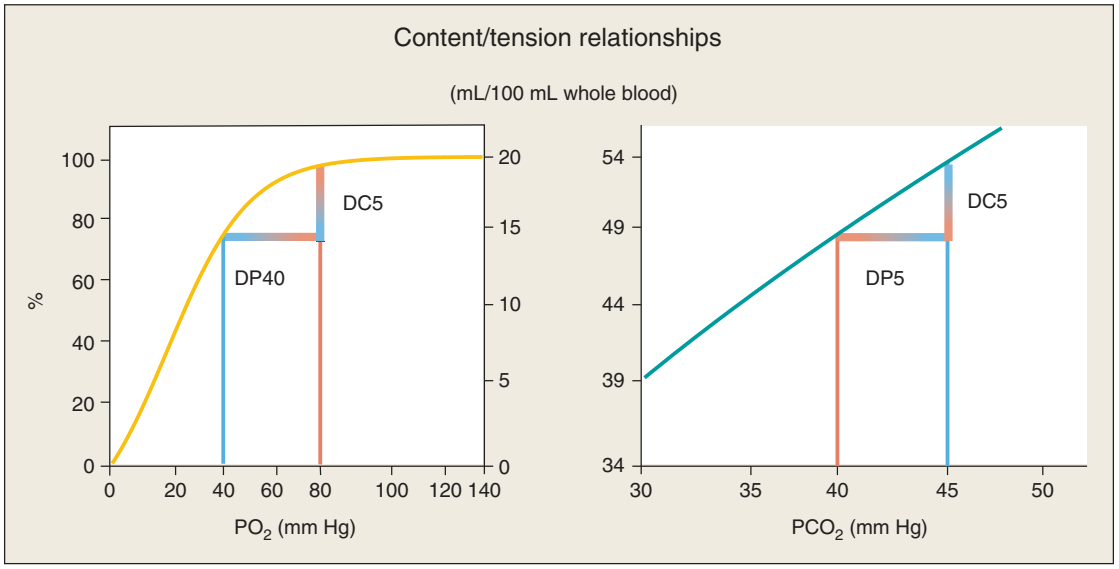

Fig. 53.25 Dissociation curve of oxygen and CO_2. Because of the different solubilities and different shapes of oxygen and CO_2 dissociation curves, the same gas transfer per liter is associated with a markedly different gas tension of partial pressure of oxygen (PO_2) and partial pressure of carbon dioxide (PCO_2). In the figure, 5 mL/100 mL of gas volume transferred from venous to arterial sides is associated with 55 and 5 mm Hg for PO_2 and PCO_2, respectively. That is, any change of 1 mm Hg of PCO_2 corresponds to the same gas-content change of approximately 10 mm Hg of oxygen.

where BW is the body weight, 100 mL is the "standard" value of ventilation for each kilogram of weight, and 37.5 mm Hg is the "standard" ideal value of arterial PCO_2. The value of 37.5 is often substituted with 40 mm Hg.

To fully understand the strengths and limitations of the VR, it is convenient to rearrange the defining VR equation (Eq. 37). The arterial PCO_2 in the numerator is substituted by its determinants (Eq. 28), and the alveolar ventilation contained in Eq. 28 is again substituted by its determinants (Eq. 30). The resulting equation is the following:

$$VR = \frac{VCO_2 * 863}{1 - \frac{Vd}{Vt}} * \frac{1}{k * BW} \qquad \textbf{(Eq. 38)}$$

where k is equal to 4 when ventilation is expressed in liters. Consequently, the VR is directly related to the CO_2 production and to the dead space. This is shown in Fig. 53.24, where the VR is expressed as a function of the dead space for a given VCO_2. As shown, the VR is markedly different for the same dead space if the VCO_2 is different.

Clinical Applications

The immediate assessment of the CO_2 clearance is best obtained by the direct measurement of the arterial PCO_2. However, in most instances, the central venous PCO_2 may be used as a surrogate, being usually 3–5 mm Hg greater than the arterial PCO_2. The presence of hemodynamic impairment or sepsis, in which the metabolic acidosis may lead to a rise of central venous PCO_2 with venous-arterial difference exceeding their normal range. The assessment of $PaCO_2$ alone, however, although allowing the definition of normocapnia, hypocapnia, or hypercapnia, is of limited value if not considered together with its determinants (VCO_2 and VE) and the CO_2 stores (primarily the bicarbonate levels).

When the CO_2 clearance equals the metabolic CO_2 production, the system is at steady state, and this may occur either with hypercapnia or hypocapnia, if the product of alveolar ventilation and the $PACO_2/713$ remains constant. It is important to realize if a given CO_2 gas-exchange pattern represents a steady state or if it reflects an actual disequilibrium, where the cleared CO_2 is lower or higher than the metabolic production. The first condition would be associated with a progressive rise of PCO_2 and CO_2 reserves (primarily bicarbonate), associated with a decrease of pH, whereas the second will be characterized by a decrease of CO_2 reserves and increased pH. The process will continue until the VA and $PACO_2$ product again equals the metabolic VCO_2 production. The VCO_2 changes resulting from changes of metabolism must be taken into account, although the primary CO_2 alterations are caused by changes of alveolar ventilation, either the result of impairment or overdrive of the respiratory centers or disruption of lung parenchyma with ventilation-perfusion mismatch, in acute or chronic conditions. In this case, measuring and monitoring the dead space, particularly in critical patients under mechanical ventilation, is of paramount importance.

The $PEtCO_2/PaCO_2$ ratio and ventilatory ratio are also useful tools for the assessment of dead space. However, they are both affected by a significant number of variables, including VCO_2, which in turn is influenced by many pulmonary and extrapulmonary conditions. Furthermore, all scores or tools that are calculated as ratios are prone to mathematical pitfalls with the potential to distort them.

In the routine clinical practice, in our opinion, the knowledge of $PACO_2$ and total ventilation is already a strong indicator of the lung condition if the basic principles of physiology are known. Finally, it should be reminded that in terms of gas exchange, 1 mm Hg change of $PaCO_2$ is equivalent to approximately 10 mm Hg change of PaO_2. This may appear surprising, but we must remember that in normal gas-exchange conditions, 200 mL/min of oxygen consumption are associated with a PaO_2 change from 40 to 100 mm Hg (normal arterial-venous PO_2 difference), whereas the same amount of CO_2 clearance is associated with an arterial-venous PCO_2 difference of approximately 5 mm Hg (from 45 to 40 mm Hg). This underlines the importance of monitoring the PCO_2 levels, whose modest changes as 1/2 mm Hg being the total ventilation unmodified are strong indicators of lung structural damage.[14,43]

CONCLUSION

Personalized mechanical ventilation is rooted in a mastery of basic physiologic principles.[44] As the COVID-19 pandemic has reminded us, this approach, rather than reliance on population- based evidence, guidelines, and tables, makes a lifesaving difference. Although new knowledge may reshape our understanding, the elements of physiology will always be the unshakable foundation of rational and effective ICU management.

KEY POINTS

- For any expandable compartment, such as the lung, volumes depend on flexibility (compliance) and the pressure difference inside and outside the compartment—the transstructural pressure. Regional properties may vary considerably site to site within the chest, both for the lung and the chest wall.
- Because the lungs are inherently passive, their mechanical properties can be assessed during any form of spontaneous, patient-triggered but machine-assisted, or controlled, ventilation by the transpulmonary pressure. The mechanical properties of the chest wall, in contrast, can only be directly evaluated during controlled ventilation when the actual pleural pressure acting to distend that structure can be estimated.
- The compliances of the lung and respiratory system can be reduced by depleting the *number* of open lung units available to ventilate and by altering their individual mechanical properties. This dual interpretation of compliance assessed at the airway opening is reflected in the sigmoidal shape of the inflation pressure-volume curve, which becomes more pronounced in the setting of acute parenchymal disorders, such as ARDS.
- When a pressure difference is applied to the passive respiratory system, that total airway pressure (Paw) must be accounted for by its dynamic component that overcomes flow resistance and its "elastic" components that expand the chest. At end inflation the latter comprises the elastic pressure that corresponds to the tidal volume, known as the driving pressure, and the pressure above the ambient baseline (PEEP).
- Modification of body position is too often neglected as a therapeutic tool. Gravitational forces exert an important influence on lung volume, on ventilation distribution, and on respiratory system compliance. The gradient of pleural and transpulmonary pressures is lower in the prone than in the supine position, in part because of reshaping of the thoracic contents by stiffening of the ventral chest wall surface and by the shifting weight of the heart and mediastinal contents. Even when it does not dramatically improve dorsal recruitment, prone positioning is currently thought to reduce VILI risk primarily by evening the distribution of transpulmonary pressures, thereby damping maximal tissue stresses and strains.
- Unlike PEEP that is intentionally applied, auto-PEEP (and therefore total PEEP) among lung units with diverse mechanical properties may not be the same throughout the diseased lung. The end-inspiratory static (plateau) airway pressure is generally a better indicator of hyperinflation risk than is the end-expiratory measurement of total PEEP itself.
- Essential information in the acutely critical patient is the blood *content* of oxygen, which is affected by hemoglobin concentration and oxygen saturation percentage. The defining equation for oxygen content can be applied to arterial blood, central venous blood, or mixed venous blood.
- The simplest means by which to assess the efficacy of patient oxygenation is the direct measurement of arterial PO_2. However, because this value does not account for the fraction of inhaled oxygen, it cannot be used to assess the lung's oxygen-exchanging status. The ratio between PaO_2 and FiO_2, although flawed, is preferable for that purpose.
- The often-neglected mixed venous oxygen saturation, SvO_2, or its surrogate, the central venous saturation, is a key assessment tool for intensive care practice.
- The ROX index normalizes the SpO_2 (using pulse oximetry as a surrogate of PaO_2) to the inspired FiO_2 and introduces the respiratory rate as an indicator of severity. Although imprecise, its advantages include ease of application, low cost, and potential for continuous monitoring.
- Venous admixture and dead space are valuable tools to assess impairment of pulmonary gas exchange. It must be noted, however, that venous admixture relates strongly to the cardiac output: an increased cardiac output promotes right-to-left shunt, whereas a decrease of cardiac output may raise PaO_2. The ratio of end-tidal PCO_2 of exhaled gas to $PaCO_2$ (the $PEtCO_2/PaCO_2$ ratio) and the ventilatory ratio are readily available and useful correlates of dead space.

Patient–Ventilator Interaction

Tommaso Tonetti, Raffaele Merola, Cesare Gregoretti, and V. Marco Ranieri

Clinical management of patients with acute respiratory failure is based on the concept that significant changes in respiratory mechanics, respiratory muscle performance, and control of breathing are the underlying mechanisms responsible for acute respiratory failure.[1] The effects of mechanical ventilation on gas exchange, respiratory muscle load, and dyspnea depend on the matching between the ventilator settings and the patient's respiratory physiology. However, mechanical ventilation is rarely optimized, which would require ventilator settings based on accurate and reproducible measurements of lung and chest wall mechanics, respiratory muscle function, and respiratory drive.[2–5]

RESPIRATORY PHYSIOLOGY

The goal of the intrinsic ventilatory control system is to integrate the timing and intensity of the phrenic nerve signal, inputs from chemoreceptors and pulmonary stretch receptors, and variations in metabolic demands. Contraction of the respiratory muscles leads to the generation of flow and volume to provide adequate alveolar ventilation with tolerable work of breathing.[6] During spontaneous breathing,[7] the respiratory muscles generate pressure (P_{mus}) to produce flow against the resistive properties (R_{RS}), deliver volume against the elastic properties (E_{RS}) of the respiratory system, and overcome any intrinsic positive end-expiratory pressure (PEEPi, known better clinically as *auto-PEEP*). Under these circumstances, the act of spontaneous breathing can be described at any instant as follows:

$$Pmus = Pres + Pel + PEEPi \qquad \textbf{(Equation 1)}$$

where *Pres* represents the resistive pressure and is a function of flow (Pres = Flow × R_{RS}) and *Pel* represents the elastic recoil pressure generated by lung expansion and is a function of volume (Pel = Volume × E_{RS}). Assuming that R_{RS} and E_{RS} are linear, the equation becomes:

$$Pmus = (Flow \times R_{RS}) + (Volume \times E_{RS}) + PEEPi \qquad \textbf{(Equation 2)}$$

In patients with acute respiratory failure requiring ventilatory support, pressure generated by the ventilator (Pappl) is added to the pressure generated by the contraction of the respiratory muscles according to the following equation:

$$Pmus + Pappl = (Flow \times R_{RS}) + (Volume \times E_{RS}) + PEEPi \qquad \textbf{(Equation 3)}$$

The complex interaction among all the variables in Equation 3 can be summarized by the concept of neuroventilatory coupling (Fig. 54.1).[8] Under normal conditions, as well as at the onset of acute respiratory failure before mechanical assistance is delivered, the spontaneous contraction of the respiratory muscles suddenly generates flow and volume; the slope of the relationship between effort and ventilatory output is conditioned by the contractile properties of the respiratory muscles and the impedance of the respiratory system. When positive pressure is applied to assist the action of breathing using most modes of mechanical ventilation, the coupling between effort and output may be compromised.

During volume-targeted assist-control ventilation (ACV), flow and tidal volume remain unaffected by muscle contraction. During pressure-targeted flow-cycled (pressure support ventilation [PSV]) or time-cycled (assist-control pressure-targeted ventilation [AC/PCV]) ventilation, despite better coupling between inspiratory effort and the ventilator's output, any increase in respiratory impedance decreases the amount of delivered flow and volume.[8] During noninvasive ventilation (NIV), air leaks may further compromise the coupling between patient effort and ventilatory output.[9]

PATIENT AND VENTILATOR VARIABLES

Patient Variables

The patient interacts with the ventilator based on three physiologic variables[2,10,11]:

1. Respiratory drive[12]
2. Ventilatory requirements[5]
3. Timing of the breathing pattern[10]

Ventilator Variables

The ventilator interfaces with the patient's physiology based on three technologic variables:

1. Delivery mechanism (control variable); that is, the algorithm used by the ventilator to assist ventilation through the delivery of flow, volume, or pressure[13–18]
2. Inspiratory trigger (phase trigger variable), or the determinant of when the ventilator starts to deliver flow, volume, and pressure[19,20]
3. Cycle-off criterion (phase cycling variable), or the determinant of when the ventilator stops assisting inspiratory effort and opens the circuit to allow tidal deflation[16,17]

Features of ventilators, such as blowers and inspiratory, expiratory, and positive end-expiratory pressure valves, influence the interaction between patient and ventilator.[21–24]

To unload the respiratory muscles, restore adequate gas exchange, and relieve the patient from dyspnea, the clinician has two options: (1) total ventilator-controlled mechanical support or (2) partially patient-controlled support.

Total Ventilator-Controlled Mechanical Support

In this mode, flow, volume, and pressure are imposed by the ventilator, which thus totally replaces the patient's breathing pattern. Any pressure

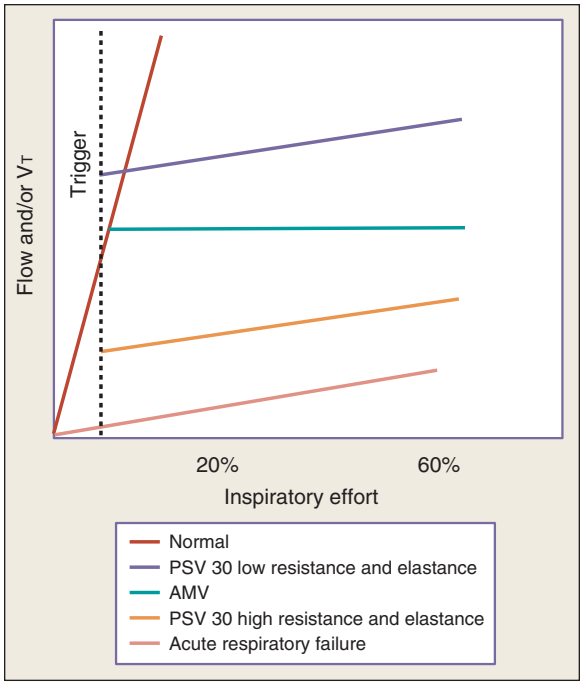

Fig. 54.1 Neuroventilatory Coupling. Under normal conditions, in addition to at the onset of acute respiratory failure, spontaneous contraction of respiratory muscles suddenly generates flow and volume. The slope of the relationship between effort and ventilatory output is conditioned by the contractile properties of the respiratory muscles and impedance of the respiratory system. When positive pressure is applied to assist the action of breathing in the most common modes of mechanical ventilation, the coupling between effort and output is compromised. During volume-targeted assist-control ventilation (ACV), flow and volume remain constant despite changes in muscle contraction. During pressure support ventilation (*PSV*), despite a sort of coupling between inspiratory effort and ventilatory output, any increase in respiratory impedance decreases the amount of delivered flow and volume. V_T, Tidal volume.

generated by the respiratory muscles is silenced or ineffectual. Although this passive condition can be achieved in some conscious patients (i.e., patients with neuromuscular diseases), it usually requires sedation and/or paralysis. The risk of patient-ventilator asynchrony is abolished, but there are potential risks associated with sedation and paralysis,[25] including respiratory muscle atrophy,[26] lung damage caused by overdistention,[27] patient discomfort,[28] retention of airway secretions, and difficulty weaning after prolonged controlled mechanical ventilation.[1]

Partial Patient-Controlled Mechanical Support

In this other type of assistance, spontaneous breathing activity is partially preserved,[29] with a decreased need for sedation and paralysis.[30] The ability to restore gas exchange, unload respiratory muscles, and relieve dyspnea with partial patient-controlled mechanical support depends strongly on the absence of patient-ventilator asynchrony.[31]

Although often unrecognized, underestimated, and inappropriately treated, patient-ventilator asynchrony is a common phenomenon associated with unfavorable outcomes.[3–5,18,31–39] Patient-ventilator asynchrony appears whenever a mismatch between the three physiologic variables characterizing spontaneous breathing (ventilatory drive, ventilatory requirements, and the duration and ratio of inspiratory time to total breath cycle duration) and the three technologic variables characterizing ventilator function (trigger function, the gas delivery algorithm [controlled variable], and cycling criterion) occurs.

RESPIRATORY DRIVE–VENTILATOR TRIGGER ASYNCHRONY

During partial ventilatory assistance, the inspiratory synchronization system (inspiratory trigger) detects the patient's inspiratory effort and activates a mechanical response. Therefore inspiratory effort is tracked to couple the patient's effort with the delivery of pressure, flow, or volume. The goal of an effective inspiratory trigger is to reduce the duration and intensity of the muscular effort as much as possible before the initiation of a mechanically supported breath.[40] It has been suggested that a trigger (independent of the algorithm) must have a response time of less than 100 ms. However, even then the inspiratory effort necessary to trigger a breath may remain a significant part of the total inspiratory effort, representing 17% and 12% of the total inspiratory effort during pressure and flow triggering, respectively.[13–21,32,33] Aslanian and coworkers found that although the time required for triggering was 43% shorter and the effort during the time of triggering was 62% less with flow triggering than with pressure triggering, effort for the posttriggering phase was equivalent for both these modalities.[41] Therefore the clinical benefit of flow triggering appears to be much less relevant than commonly stated.[3]

Inspiratory phase asynchrony may be correlated with respiratory drive. Phase lag quantifies the delay between the start of inspiratory muscle activity and the beginning of mechanical inflation (Fig. 54.2).[3,10,11] The presence of a threshold load, such as auto-PEEP (intrinsic PEEP), may further complicate the patient-ventilator interaction during the triggering phase.[19] Giuliani and colleagues suggest that effort during triggering determines patient effort during the remaining portion of inspiration.[42] Leung and coworkers demonstrated that the higher the level of ventilator-applied pressure, the lower the respiratory drive but the longer the time required to trigger the ventilator. As a result, respiratory muscles generate smaller inspiratory swings in intrathoracic pressure but over a longer inspiratory time.[2] Another problem is related to the fact that pressure is usually detected inside the ventilator, not

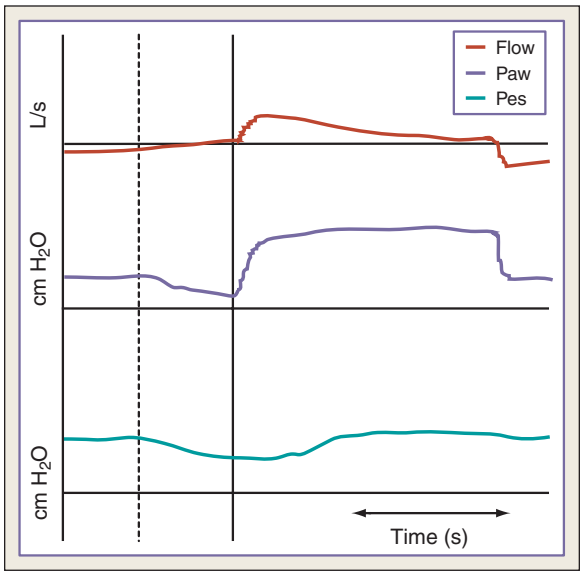

Fig. 54.2 Representative Tracings Show the Interaction Between Patient Effort and Triggering of the Ventilator. The delay between the beginning of inspiratory muscle activity *(dotted line)* and the beginning of mechanical inflation *(solid line)* can cause an inspiratory phase asynchrony. *Flow,* Flow generated at airway opening; *Paw,* the pressure applied at airway opening; *Pes,* esophageal pressure.

inside the patient. Therefore any resistive load (e.g., endotracheal tube or upper airways during NIV) reduces the ventilator trigger sensitivity in response to patient effort.[18]

Auto-triggering can be defined as a mandatory breath delivered in the absence of a patient's inspiratory effort.[22] The number of breaths monitored by the ventilator are higher than those initiated by the patient. Auto-triggering can be generated by too sensitive inspiratory triggers, air leaks, or an external signal, such as heart rate or water in the respiratory circuit.

Ineffective triggering is defined as an inspiratory effort that is not followed by ventilator activation, caused by the inability of the latter to detect the patient's "request" despite substantial inspiratory effort (Fig. 54.3). This asynchrony usually occurs with high levels of ventilator assistance and short expiratory times. Mechanical characteristics that may induce ineffective triggering include low elastance, high resistance, and PEEPi. Ineffective triggering is not correlated to an increase in the patient's inspiratory effort.[2] The application of external PEEP below the level of auto-PEEP can reduce the inspiratory effort required to trigger the ventilator.[43]

Double triggering, defined as the presence of two inspiratory cycles separated by a very short expiratory time, may result in breath stacking. Double triggering can be elicited by high patient ventilatory demand that causes two breaths to be triggered with a limited expiratory phase caused by too short of a ventilator inspiratory time (Ti) compared with the patient's neural time. This problem can be addressed by increasing Ti in time-cycled mode, by adjusting the expiratory threshold time in the flow-cycled mode, or by optimizing the pressure rise time (i.e., the *time taken to reach the targeted pressure set for the ventilator*).[44]

Reverse triggering is a recently discovered form of neuromechanical coupling that occurs in heavily sedated patients.[45,46] In this case, contrary to the usual triggering sequence (patient's effort switching on the ventilator-driven breath), mechanical insufflation triggers diaphragmatic muscle contraction. It has been conjectured that reverse triggering may be associated with an injurious inflation pattern, but this has never been confirmed. During reverse triggering, diaphragm contraction generates a deflection in pleural pressure confined to the dependent lung and draws gas from elsewhere in the lung (*pendelluft* effect) or from the trachea and ventilator toward the dependent lung. This phenomenon was observed in a swine model to cause regional overstretching of the dependent lung.[46]

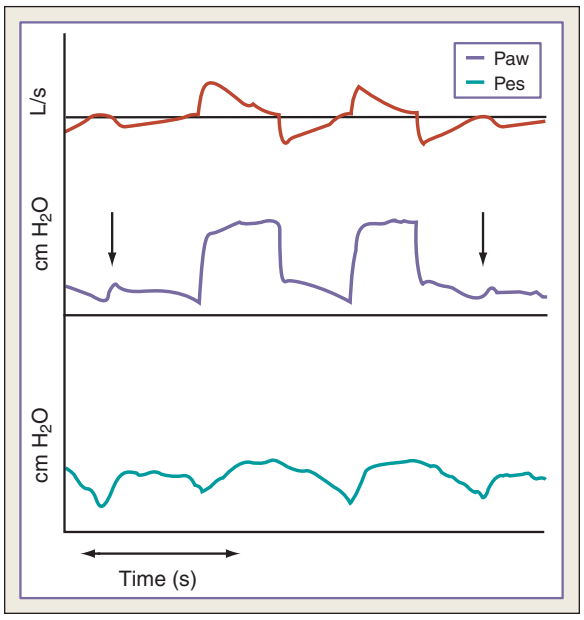

Fig. 54.3 Representative Tracings Show Ineffective Triggering Caused by the Ventilator's Inability to Detect the Patient's "Request" for an Assisted Breath. A substantial inspiratory effort *(arrows)* generates only a bump in the flow and pressure tracings instead of a mandatory assisted breath. *Flow,* Flow generated at airway opening; *Paw,* the pressure applied at airway opening; *Pes,* esophageal pressure.

New triggering algorithms aim to improve the patient-ventilator interaction during sudden changes in flow or respiratory rate and in the presence of air leaks during NIV. Volume triggers, triggers linked to flow waveform algorithms, combining pressure and flow signals in the same trigger algorithm, or using both pressure and flow triggers have been developed. However, all inspiratory trigger drawbacks may be overcome by using a neural trigger obtained using a dedicated nasogastric tube with multiple arrays of electrodes placed in the distal esophageal portion.[8,47,48]

VENTILATORY REQUIREMENT–GAS DELIVERY ASYNCHRONY

Gas delivery asynchrony occurs when ventilator-delivered flow, volume, and pressure are insufficient to meet the patient's ventilatory demand. Ward and coworkers confirmed the observations of Marini and colleagues[29] demonstrating that increasing the flow rate could reduce the patient's respiratory drive and active respiratory muscle work,[13] although this may exert an excitatory effect on the respiratory rate and the rate of rising of inspiratory muscle activity.[3,16,17,49–54] Laghi and coworkers demonstrated that the inspiratory time imposed during mechanical ventilation determined respiratory frequency, independent of inspiratory flow and tidal volume.[16] Pressure-targeted breaths may more effectively match the patient's ventilatory requirements because flow is the dependent (resultant) variable during constant pressure delivery. In addition, rapid pressurization of the airways is coupled with high inspiratory flow only at the beginning of inspiration, thus reproducing the physiologic flow profile.[55] However, during a pressure-targeted breath, the setting for the time of pressure increase may influence the patient-ventilator interaction because its modification determines the dependent flow output.[56,57]

INSPIRATORY TIMING–VENTILATOR CYCLING ASYNCHRONY

A breath can be pressure-, time-, volume-, or flow-cycled.[57] Although volume and pressure cycling are no longer used, a breath is defined as time-cycled when it is terminated after a given preset inspiratory time is reached (e.g., pressure- or volume-controlled time-cycled breaths). The breath is flow-cycled when the generated inspiratory flow decays from its peak by a fixed percentage (e.g., PSV mode).

Ventilator-patient asynchrony occurs when the patient is trying to exhale, but the ventilator is still delivering gas.[35,58,59] Parthasarathy and coworkers demonstrated that prolonging mechanical inflation into neural expiration reduces the time available for unopposed exhalation, resulting in the need for a greater inspiratory effort to trigger the ventilator.[58] Younes and colleagues showed that the delayed opening of the exhalation valve in ventilator-dependent patients exacerbates dynamic hyperinflation.[60]

In patients ventilated with time-cycled breaths, expiratory phase asynchrony occurs when the patient's neural inspiratory time is shorter or longer than the ventilator inflation time. For proper cycling of the ventilator and optimal patient-ventilator synchrony, the patient's inspiratory flow and ratio of inspiratory time–to–total breath cycle duration must be tracked.

During flow-cycled breaths, as in pressure-support mode, inspiratory time is determined exclusively by the time taken for the exponentially declining flow to reach the flow threshold value (the "off trigger" point for cycling between inspiration and expiration).[32,61] The inspiratory flow threshold value, also called the *expiratory trigger,* thus controls the inspiration-to-expiration switch in these modalities under the postulate that the very end of patient inspiration is tracked by inspiratory flow decay.[56,62]

The goal of these ventilatory modes is to optimize the synchronization between spontaneous patient inspiratory time and ventilator inspiratory time. However, for proper cycling-off and optimal patient-ventilator synchrony, the ventilator must always track the patient's inspiratory flow.[58,63,64]

PATIENT-VENTILATOR ASYNCHRONY DURING PRESSURE SUPPORT VENTILATION

Three phases may influence patient-ventilator interaction during PSV: (1) the threshold value of inspiratory flow decay (expiratory trigger), (2) the pressure ramp (pressure slope), and (3) the level of PSV.

(1) The expiratory trigger sensitivity can be fixed (default at 25% of peak flow) or can vary from 1% to 90% or from 5 to 25 L/min in some old ventilator software (Fig. 54.4).[65] It can also be linked to algorithms where there is a ranking logic of expiratory cycling criteria that links cycling to expiration. Setting the expiratory trigger at a higher percentage of peak inspiratory flow (i.e., 40%–70% of decay of the peak inspiratory flow) in patients with obstructive pulmonary disease improves patient-ventilator synchrony and reduces inspiratory muscle effort.[66] In addition, the modification of the cycling-off criteria may have a beneficial effect on reducing the dynamic hyperinflation and inspiratory effort in chronic obstructive pulmonary disease (COPD) patients, especially at low levels of pressure support.[67]

The proper adjustment of the expiratory trigger threshold may be important in improving patient-ventilator synchrony and in decreasing the work of breathing during acute lung injury. Unlike in obstructive pulmonary disease, setting the threshold at 5% of the peak inspiratory flow might be the optimal value for patients with acute respiratory distress syndrome or acute lung injury.[68] Indeed, Chiumello and colleagues found that in patients recovering from acute lung injury during PSV at 15 cm H_2O, the lowest cycling-off criteria reduced the respiratory rate and increased the tidal volume without modifying the work of breathing.[69]

The expiratory sensitivity setting is crucial when ventilators are used to deliver NIV, because air leaks may cause an abnormal prolongation of the mechanical inspiratory time at the expense of a patient's expiration requirements (inspiratory hang-up) (Fig. 54.5).[70–75]

(2) The setting of the pressure rise time (pressure slope) can affect the expiratory threshold by modifying the dependent inspiratory flow.[69,76–79] Although there is some evidence that rapid pressure rise times might reduce a patient's work of breathing,[77] a fast pressure increase may lead to particularly high peak inspiratory flow, which may then cause premature termination of inspiration when the fixed percentage criterion for expiratory cycling is reached (Fig. 54.6).[18,67,79]

Prinianakis and collagues assessed the effects of varying the rate of pressure change during noninvasive PSV on the breathing pattern of patients with COPD, in addition to inspiratory effort, arterial blood gases, tolerance to ventilation, and the amount of air leakage. No significant changes were observed in breathing pattern and arterial blood gases between the differing pressure slopes, but the pressure-time product of the diaphragm—an estimate of its metabolic consumption—significantly decreased with increasing the rate of pressurization. Interestingly, air leaks increased and the patients' tolerance of ventilation was significantly poorer with the fastest rate of pressure change.[80]

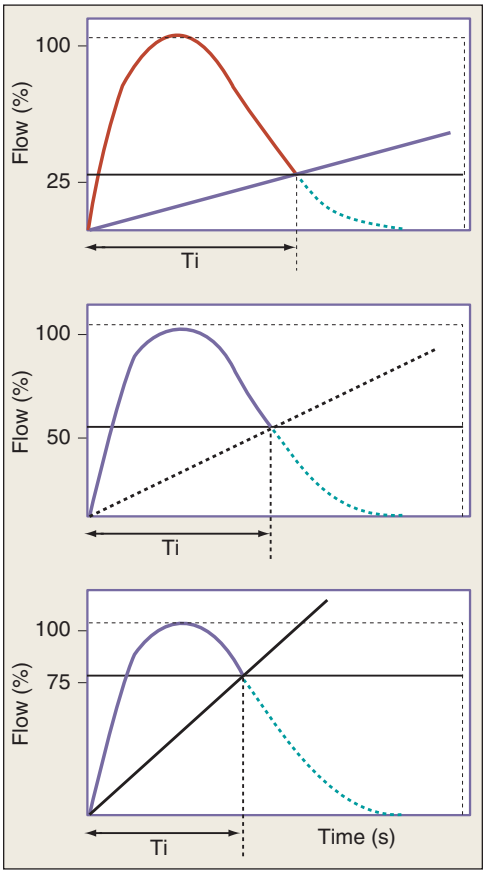

Fig. 54.4 Representative Tracings Show Different Settings for Expiratory Trigger Sensitivity on a Flow-Time Plot. *Top to bottom,* Expiratory trigger set at 25%, 50%, and 75% of peak flow. Ventilator inspiratory time is influenced by preset flow expiratory trigger sensitivity, at which point the ventilator switches to expiration.

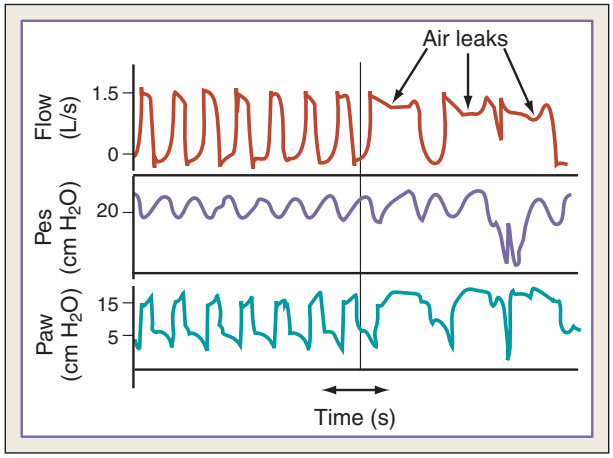

FIG. 54.5 Representative Record of Air Leaks During Noninvasive Face Mask Pressure Support Ventilation. The presence of air leaks causes prolonged ventilator inspiratory time *(arrows). Flow,* Flow generated at airway opening; *Paw,* the pressure applied at airway opening; *Pes,* esophageal pressure.

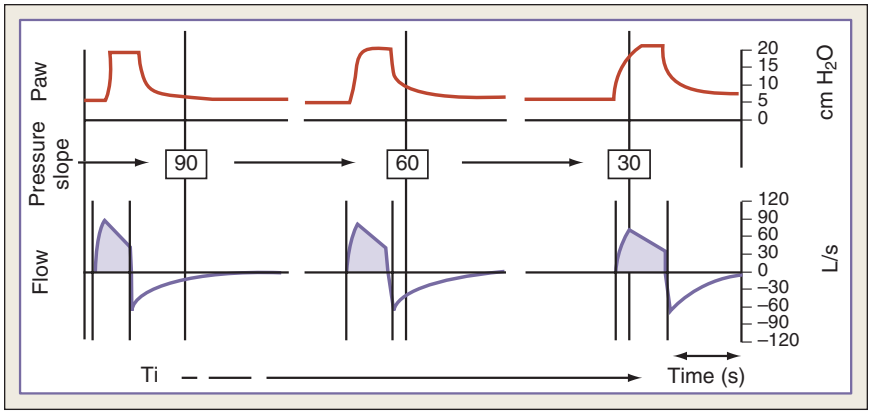

Fig. 54.6 Representative Tracings Show Different Pressure Rise Time Sensitivities on a Flow-Time Plot. *Left to right,* Pressure rise time set at 90%, 60%, and 30% of maximal pressurization time. Ventilator inspiratory time *(shaded area)* is influenced by preset pressure-slope sensitivity that generates a different peak inspiratory flow. *Flow*, Flow generated at airway opening; *Paw*, the pressure applied at airway opening.

(3) During NIV, the pressure support level affects patient-ventilator interactions, mainly through effects on the generation of air leaks.[9,71] Because air leaks may determine modifications in the inspiratory flow profile (see earlier), their reduction by lowering to a PSV level of 1 or 2 cm H_2O has been demonstrated to improve patient-ventilator asynchrony.[9]

In conclusion, dyssynchrony at the termination of a PSV breath can be corrected by varying the cycling-off criteria (e.g., the expiratory trigger threshold) or modulating the inspiratory flow (e.g., modifying the pressure slope or varying the set pressure level).[9] Automated modes designed to achieve an optimal expiratory cycling during PSV are available, but their added value deserves further investigation.[81,82]

TOTAL PATIENT-CONTROLLED MECHANICAL SUPPORT

Optimization of patient-ventilator interactions can be attained only by continuously matching the triggering, flow delivery, and cycling functions of the ventilator with the patient's ventilatory drive, spontaneous inspiratory flow demand, and ratio of inspiratory time to the total breath cycle. This implies a continuous measurement of physiologic variables and continuous adaptation of the ventilator to spontaneous variations in these variables. Future development in ventilator technology should be oriented toward systems with the capability to automatically interface between physiologic parameters and ventilator output. Such technology will be based on closed-loop algorithms able to achieve total patient-controlled mechanical support.[4]

The design features of an automatic control system in a mechanical ventilator include (1) what activates the system (the input), (2) what the system produces (the output), and (3) the protocol used to link input and output (the controlling algorithm). In a closed-loop system, the output will activate and condition the input. When changes in output are opposite to changes in input, the closed loop is said to be negative. The closed loop is positive when variations in output mirror variations in input. The most common example of a negative closed-loop control system in a clinical setting is the ventilator humidifier. In this case, the input is the temperature inside the chamber, and the output is the temperature of the gas being delivered to the patient. The controlling algorithm is designed to keep the latter constantly above a value set by the operator. If the output (i.e., the temperature of gas delivered to the patient) is lower than the preset level, the algorithm will increase the input (i.e., the temperature in the chamber). If the output is higher than the preset level, the algorithm will decrease the input. Closed-loop systems are hence able to stabilize and limit the performance of a mechanical system.

In the case of acute respiratory failure, the patient is unable to provide sufficient output (i.e., minute ventilation). Therefore the ventilator should be able to detect the input from the patient and continuously adapt the output. If the input is increasing (i.e., ventilatory requirements are increasing), the ventilator will increase the output (i.e., apply more positive pressure). If the input is decreasing (i.e., ventilatory requirements are decreasing), the ventilator will decrease the output (i.e., apply less positive pressure). The controlling closed loop eventually applied by the ventilator must be positive. Positive closed-loop control systems are inherently unstable in the sense that they tend to "run away" with ventilatory assistance. If the pressure generated by the ventilator is higher than the pressure required to offset the passive properties of the respiratory system, the ventilator will continue to deliver flow and volume even while the patient stops his or her inspiratory effort and tries to initiate expiration and "extinguish" ventilatory assistance. If the patient does not produce any inspiratory effort, the ventilator will not produce any ventilatory support.

Based on closed-loop algorithms, new modes of mechanical ventilation have been proposed. Such approaches represent modifications of PSV and are characterized by the patient's ability to control the amount of assistance provided by the ventilator. They are differentiated by the patient-related variables used to close the loop.

PROPORTIONAL ASSISTED VENTILATION, PROPORTIONAL PRESSURE SUPPORT, AND PROPORTIONAL ASSISTED VENTILATION PLUS

During proportional assisted ventilation (PAV) and proportional pressure support (PPS), the ventilator generates pressure in proportion to the patient-generated flow and volume[83,84]; the ventilator amplifies patient effort without imposing any ventilatory or pressure targets; and ventilator-generated pressure rises as long as inspiratory muscle effort is produced by the patient. During these modes of mechanical support, the clinician adjusts the percentage of flow-assisted or volume-assisted ventilation after determining the patient's resistance and elastance, with the goal of reducing the load imposed by the patient's inspiratory workload.[85–87] Despite the exciting potential of these techniques[87-90] applied either invasively or noninvasively,[81–99] no large-scale studies have demonstrated an improvement in patient outcome with

PAV or PPS compared with other modes of ventilation. Several studies performed during invasive ventilation showed that PAV improves patient-ventilator synchrony at the start of inspiration[32,92,94] but not necessarily at the end.[84–92]

Compared with PAV, proportional assisted ventilation plus (PAV+) provides a continuous measurement of the patient's elastance and resistance according to the method described by Younes and coworkers.[85–87,95–99] This option requires that the physician set only a given percentage of the overall pressure requirement. During invasive ventilation, PAV+ appears to reduce the incidence of patient-ventilator asynchronies considerably compared with conventional PAV[100] (Fig. 54.7). When compared with PSV, PAV+ decreases the setting time and responds automatically to changes in sedative doses.[101]

NEURALLY-ADJUSTED VENTILATORY ASSISTANCE

With neurally-adjusted ventilatory assistance (NAVA), the electrical activity of the diaphragm is measured using an electrode array inserted into a nasogastric tube placed in the lower esophagus; this information is then used to control the ventilator to generate flow, volume, and pressure by applying pressure in proportion to diaphragm electrical activity.[8,44,45,102,103] A representative tracing of NAVA is shown in Fig. 54.8. With NAVA, therefore, the patient retains full control of the breathing pattern.[104] Unlike the proportional assist mode just described, estimates of respiratory mechanics are not needed. With NAVA, the patient's respiratory center controls the assisted positive breaths in all phases of the ventilation cycle, from triggering to cycling-off of inspiration. Any change in patient ventilatory output

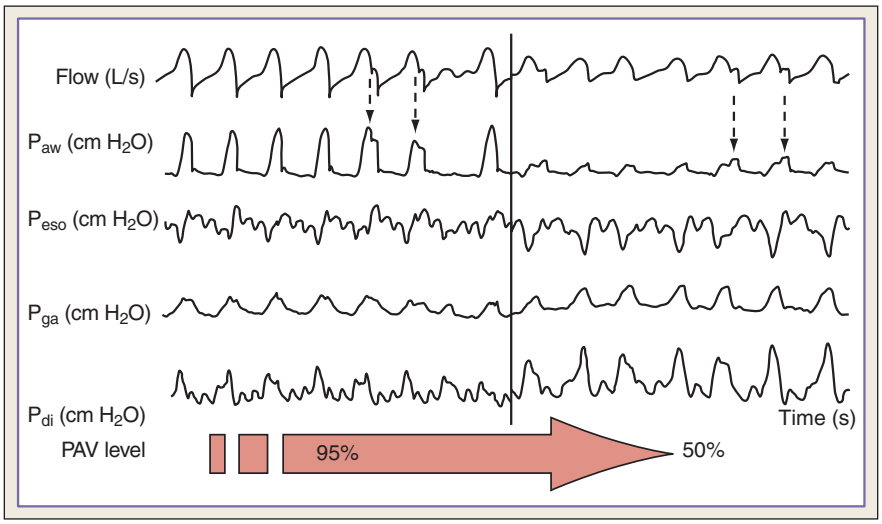

Fig. 54.7 Representative tracing of flow (*Flow L/s*), airway pressure (P_{aw} *cm* H_2O), esophageal pressure (P_{eso} *cm* H_2O), gastric pressure (P_{ga} *cm* H_2O), and transdiaphragmatic pressure (P_{di} *cm* H_2O) during proportional assisted ventilation plus (PAV+) ventilation. *Directional arrow (bottom)* going from left to right shows that the gain is reduced from 95% to 50% with a subsequently increased inspiratory effort. *Dotted arrows (top)* indicate the measurement of respiratory mechanics automatically computed by the ventilator.

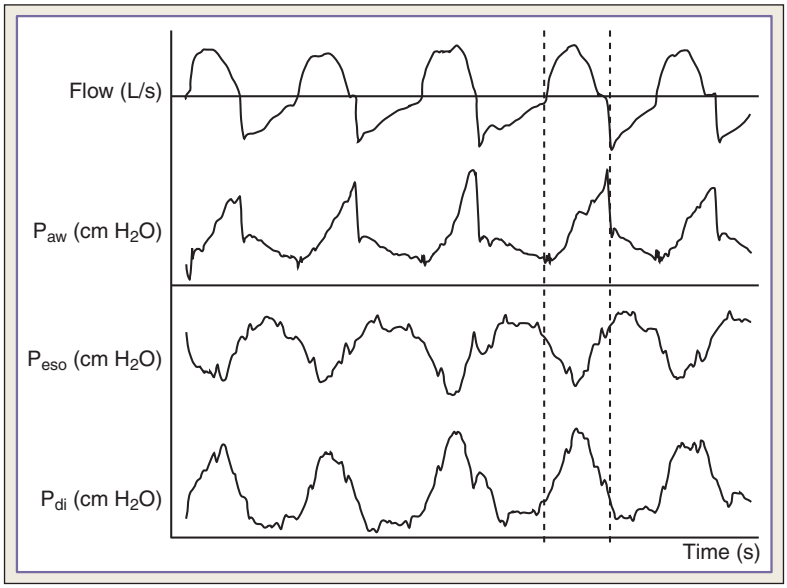

Fig. 54.8 Representative tracing of flow (*Flow L/s*), airway pressure (P_{aw} *cm* H_2O), esophageal pressure (P_{eso} *cm* H_2O), and transdiaphragmatic pressure (P_{di} *cm* H_2O) during NAVA ventilation. *The two dotted lines* define the beginning and end of the patient's inspiratory effort.

is matched within the breath by the ventilator, even in the presence of variations in respiratory mechanics.

NAVA has been shown to decrease ineffective efforts (trigger asynchrony) and premature and delayed cycling (cycle asynchrony) compared with pressure-controlled, flow-cycled ventilation (i.e., PSV).[105–107] Furthermore Vignaux and colleagues showed that compared with pressure support via NIV, NAVA improves patient-ventilator synchrony even in infants and children. It does so by reducing both triggering delay and the number of asynchrony events.[108] NAVA also appears to improve patient-ventilator synchrony during helmet ventilation.[109] NAVA has one major advantage compared with PAV, as air leaks do not interfere with its correct functioning.[110]

Recently, it has been reported that NAVA reduced micro-asynchronies (inspiratory trigger delay, premature and late cycling) in tracheostomized patients, despite no reduction in macro-asynchronies (ineffective, double, and auto-triggering) when compared with PSV.[111]

In conclusion, recent meta-analyses reported that NAVA improves patient-ventilator synchrony; however, its beneficial effect on clinical outcomes is still uncertain, and more studies are needed.[112,113]

ADAPTIVE SUPPORT VENTILATION

Compared with PAV and NAVA, adaptive support ventilation is a time-limited, pressure-targeted mode of ventilation (pressure-controlled ventilation) that relies on a negative closed-loop system of regulating ventilator settings across multiple breaths in response to changes in respiratory impedance (elastance and resistance), spontaneous efforts, and end-tidal PCO_2.[114] The basic principle relies on the work of Otis and colleagues[115] and Mead and coworkers[6] demonstrating that for a given level of minute alveolar ventilation, there is a respiratory rate that is least costly regarding respiratory work. With adaptive support ventilation, the operator enters the patient's body weight and sets the desired minute ventilation. The expiratory time constant is determined by analysis of the tidal expiratory flow-volume curve.[116] Adaptive support ventilation adjusts for inspiratory pressure, inspiratory-expiratory time ratio, and the mandatory respiratory rate to maintain the target minute ventilation and respiratory rate within a framework designed to avoid rapid, shallow breathing; excessive inflation volumes; and dynamic hyperinflation. Spontaneous breathing triggers either a pressure-controlled or a spontaneous breath with inspiratory pressure support, the level of which is adjusted to meet the target respiratory rate–tidal volume combination.

ACKNOWLEDGMENTS

The authors would like to acknowledge Dr. Vincenzo Squadrone and Dr. Lorenzo Appendini for their invaluable contribution as authors of the previous edition of this chapter. The authors would also like to acknowledge Dr. Irene Cavalli for her precious comments and contributions to this edition.

KEY POINTS

- Patient-ventilator asynchrony occurs commonly during mechanical ventilatory support. It is often unrecognized, underestimated, and inappropriately treated in a clinical setting.
- Patient-ventilator asynchrony occurs when the three physiologic variables of the patient's breathing pattern, ventilatory drive, driving, and timing components of the breathing cycle do not match ventilator trigger, ventilator-delivered flow, and ventilator cycling criteria, respectively.

KEY POINTS—cont'd

- Clinical optimization of patient-ventilator interactions can be obtained only by continuously matching the triggering, flow delivering, and cycling functions of the ventilator with the patient's physiologic variables.
- Optimization of patient-ventilator interactions during invasive or noninvasive ventilation implies a continuous measurement of physiologic variables and continuous adaptation of the ventilator to the spontaneous variations in these physiologic variables.
- Future developments in ventilator technology should be oriented toward a system with the capability to interface automatically and seamlessly between physiologic parameters and ventilator outputs. Such technology will be based on closed-loop algorithms able to achieve total patient-controlled mechanical support.

These authors reported that during the assist-control mode, ventilator inspiratory time can determine respiratory frequency independently of inspiratory flow and tidal volume.

Leung P, Jubran A, Tobin MJ. Comparison of assisted ventilator modes on triggering, patients' effort, and dyspnea. *Am J Respir Crit Care Med.* 1997;155(6):1940–1948.
This study found that when receiving assist-control ventilation or high levels of pressure support, one-quarter to one-third of a patient's inspiratory efforts may fail to open the inspiratory valve triggering the machine. The number of ineffective triggering attempts increases in proportion to the level of ventilatory assistance and is not correlated with the magnitude of inspiratory effort at a given level of assistance.

Parthasarathy S, Jubran A, Tobin MJ. Cycling of inspiratory and expiratory muscle groups with the ventilator in airflow limitation. *Am J Respir Crit Care Med.* 1998;158(5):1471–1478.

The continuation of a mandatory mechanical breath into neural expiration was associated with a waste of inspiratory effort, defined as failure of the subsequent inspiratory attempt to trigger the ventilator.

Parthasarathy S, Tobin JM. Effect of ventilator mode on sleep quality in critically ill patients. *Am J Respir Crit Care Med.* 2002;166(11):1423–1429.
Inspiratory assistance during pressure support causes hypocapnia, which combined with a lack of a backup rate and wakefulness drive, can lead to central apneas and sleep fragmentation, especially in patients with heart failure. A backup rate, as during assist-control volume-targeted ventilation, prevents the development of apneas and perhaps decreases arousals.

Sinderby C, Navalesi P, Beck J, et al. Neural control of mechanical ventilation in respiratory failure. *Nat Med.* 1999;5(12):1433–1436.
This article describes a completely new mode of breathing assistance regulated by detecting inspiratory effort, based on the measurement of electrical activity of the diaphragm using an electrode array inserted into a nasogastric tube and placed in the lower esophagus. The output generated from the electrodes, filtered for sources of electrical interference, is used to control the ventilator that finally generates the respiratory output.

Tobert DG, Simon PM, Stroetz RW, et al. The determinants of respiratory rate during mechanical ventilation. *Am J Respir Crit Care Med.* 1997;155(2):485–492.
The authors examined the rate response of eight normal volunteers during both quiet wakefulness and non–rapid eye movement (non-REM) sleep in the setting of mechanical ventilation through a nasal mask in an assist-control mode with a machine backup rate of two breaths per minute. They found that both tidal volume and inspiratory flow settings affect the respiratory rate and can affect carbon dioxide homeostasis. During non-REM sleep, hypocapnia resulted in wasted ventilator trigger efforts. Thus ventilator settings appropriate for wakefulness may cause ventilatory instability during sleep.

Younes M, Webster K, Kun J, et al. A method for measuring passive elastance during proportional assist ventilation. *Am J Respir Crit Care Med.* 2001;164(1):50–60.
A noninvasive method to continuously measure elastance of the respiratory system during proportional assisted ventilation is described.

Noninvasive Positive-Pressure Ventilation

Anas A. Ahmed and Nicholas S. Hill

Noninvasive ventilation is defined as the provision of ventilatory assistance to the lungs without an invasive artificial airway. Noninvasive ventilators consist of a variety of devices, including negative- and positive-pressure units. Until the early 1960s, negative-pressure ventilation in the form of tank ventilators was the most common type of mechanical ventilation used outside the anesthesia suite.[1] However, during the Copenhagen polio epidemic of 1952, it was observed that the survival rate improved when patients with respiratory paralysis were treated with invasive positive-pressure anesthesia devices. Subsequently, invasive positive-pressure mechanical ventilation gradually became the preferred means of treating acute respiratory failure.[2] Negative-pressure and other so-called body ventilators remained the mainstay of ventilatory support for patients with chronic respiratory failure until the mid-1980s.[1]

With improving mask and ventilator technology and recognizing the many advantages of positive- over negative-pressure ventilation,[1] noninvasive positive-pressure ventilation (NIV) displaced negative-pressure ventilation as the treatment of choice for chronic respiratory failure in patients with neuromuscular and chest wall deformities.[3] Over the past 30 years, NIV has spread from the outpatient to the inpatient setting, where it is now used to treat certain forms of acute respiratory failure (ARF). Studies involving large clinical databases show that NIV use for patients with ARF resulting from chronic obstructive pulmonary disease (COPD) and non-COPD diagnoses increased several-fold during the first decade of the millennium.[4] A survey in Massachusetts found that NIV is used very frequently in the acute care setting, constituting up to 40% of initial ventilator starts.[5] This chapter discusses the rationale for the increased use of NIV in critical care, in addition to appropriate indications, practical applications, and monitoring.

RATIONALE

The most important advantage of NIV is the avoidance of complications associated with airway intubation and invasive mechanical ventilation. These hazards include upper airway trauma, the bypass of the upper airway defense mechanisms, increased risk of nosocomial pneumonia, and interference with upper airway functions, including the ability to eat and communicate normally.[6] By avoiding airway intubation, NIV leaves the upper airway intact, preserves airway defenses, and, during breaks, allows patients to eat and vocalize normally and to expectorate airway secretions. Compared with invasive mechanical ventilation, NIV reduces infectious complications, including pneumonia, sinusitis, and sepsis.[7–9] Strengthening the rationale for its use is evidence that NIV lowers the morbidity and mortality rates of well-selected patients with ARF and may shorten hospital length of stay or avoid hospitalization altogether,[10] thus reducing costs.

The main indication for mechanical ventilatory assistance is to treat respiratory failure, either type 1 (hypoxemic), type 2 (hypercapnic), or both. Fig. 55.1 shows that airspace collapse, surfactant abnormalities, and airway narrowing and closure contribute to ventilation-perfusion abnormalities and shunt, which cause hypoxemia. By opening the collapsed air spaces and narrowed airways, sustained positive airway pressure reduces shunt and improves ventilation-perfusion relationships, ameliorating hypoxemia. In addition, positive airway pressure can reduce the work of breathing by improving lung compliance as a consequence of opening collapsed air spaces. Another potential benefit of positive airway pressure is enhanced cardiovascular function via the afterload-reducing effect of increased intrathoracic pressure. Conversely, deleterious cardiovascular effects may occur if the preload-reducing effect outweighs the afterload-reducing effect, as may be observed in patients with reduced intravascular fluid volume.

MECHANISMS OF ACTION

Fig. 55.2 shows the pathophysiologic mechanisms that contribute to ventilatory failure. Increased airway resistance, reduced respiratory system compliance, and intrinsic positive end-expiratory pressure (PEEP) contribute to the increased work of breathing, predisposing patients to respiratory muscle fatigue. In patients with COPD, the increased radius of the diaphragmatic curvature, which increases muscle tension and thereby increases impedance to blood flow, exacerbates the situation. By counterbalancing intrinsic PEEP with extrinsic PEEP and by augmenting tidal volume with intermittent positive-pressure ventilation (IPPV), NIV reduces the work of breathing and avoids the vicious cycle leading to respiratory failure. Work of breathing measurements, including transdiaphragmatic pressure, diaphragmatic pressure-time product, and diaphragmatic electromyographic amplitude, are all decreased when NIV is delivered to patients with exacerbations of COPD. In such patients, continuous positive airway pressure (CPAP) and pressure-support ventilation (PSV) both reduce the work of breathing, but the combination of the two (PSV + PEEP) is more effective than either alone.[11]

INDICATIONS

A number of causes of ARF are now considered appropriate for NIV therapy and are listed in Box 55.1. Evidence supporting these indications is rated and briefly discussed here; guidelines for patient selection are discussed later. The European Respiratory Society/American Thoracic Society (ERS/ATS) Task Force for NIV offered recommendations and suggestions on clinical applications of NIV in 2017,[12] which are incorporated into the discussion that follows. At the outset, it is imperative to emphasize that the interface used to apply NIV may be crucial to its efficacy in any individual patient.

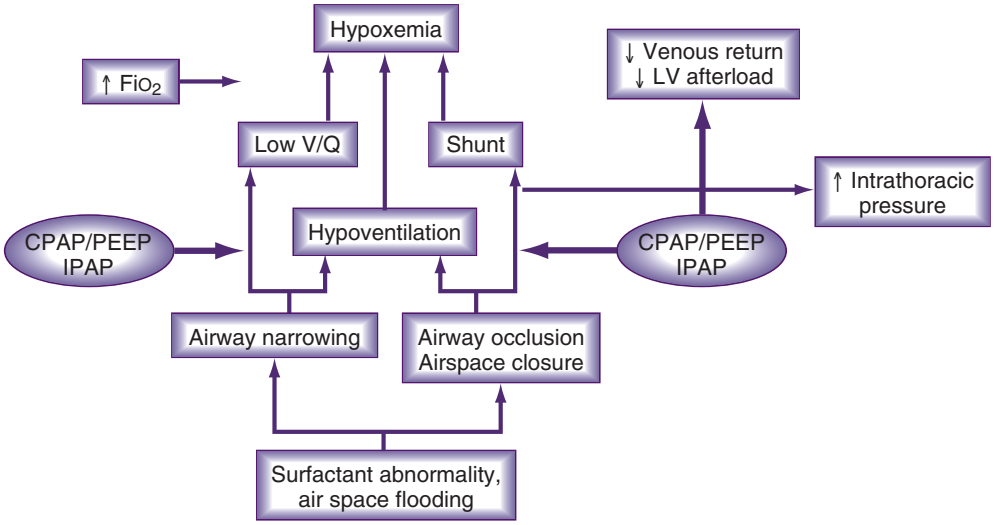

Fig. 55.1 Pathophysiology of acute hypercapnia and points where continuous positive airway pressure (*CPAP*), positive end-expiratory pressure (*PEEP*), and pressure support (PS) interrupt the process *(large arrows).* Hypercapnia (increased partial pressure of carbon dioxide in arterial blood [$PaCO_2$]) occurs when respiratory muscles fail to ventilate alveoli adequately to maintain homeostasis with carbon dioxide production. Respiratory muscle failure occurs when the work of breathing is normal (e.g., acute or chronic neuromuscular disease) or increased (e.g., patients with chronic obstructive pulmonary disease, asthma, or obesity hypoventilation syndrome), presumably because of inadequate oxygen delivery to the respiratory muscles (e.g., approximately one-third of patients presenting with cardiogenic pulmonary edema). Strategies to counter these pathophysiologic mechanisms include applying CPAP or PEEP to counterbalance intrinsic PEEP (PEEPi), increasing alveolar ventilation by augmenting tidal volume (V_t), using intermittent positive-pressure ventilation (IPPV), and reducing CO_2 production by decreasing the work of breathing. *FiO_2*, Fraction of inspired oxygen; *IPAP*, inspiratory positive airway pressure; *LV*, left ventricular.

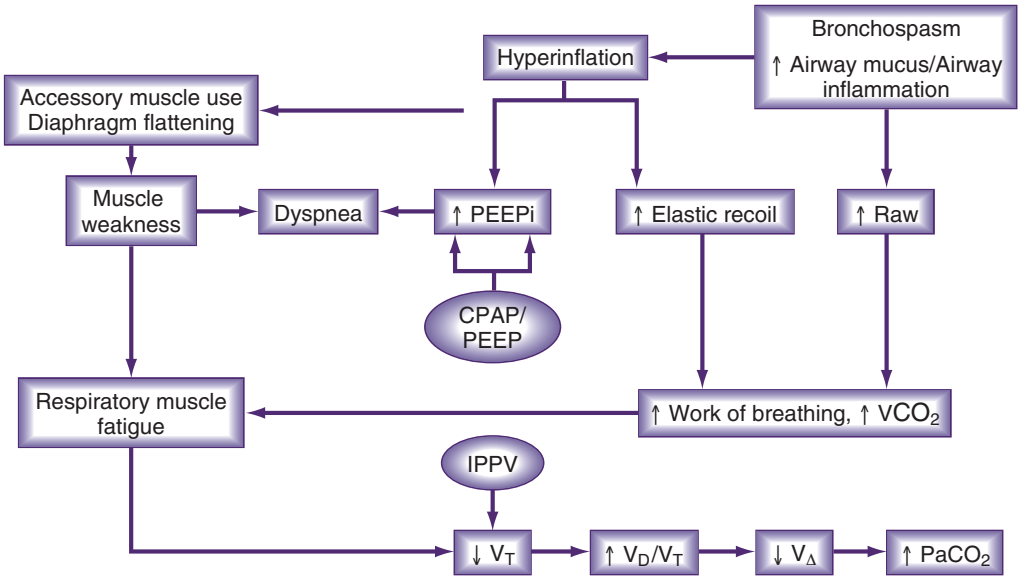

Fig. 55.2 Pathophysiology of acute hypoxemic respiratory failure and points where positive-pressure and oxygen supplementation interrupt the process. Low ventilation-perfusion ratios, shunt, and alveolar hypoventilation cause hypoxemia. Hypoxemia is treated by increasing the fraction of inspired oxygen (FiO_2) (limited benefit with shunt) and applying positive pressure (continuous positive airway pressure [*CPAP*] or positive end-expiratory pressure [*PEEP*]) to increase the residual functional capacity, open collapsed alveoli and narrowed airways, and enhance compliance. An additional beneficial effect of CPAP may occur in patients with cardiogenic pulmonary edema because it reduces both venous return and left ventricular afterload, which may enhance cardiovascular performance in patients with dilated, hypocontractile left ventricles. *IPPV,* Intermittent positive-pressure ventilation; *$PaCO_2$*, arterial partial pressure of carbon dioxide; *PPPi*, intrinsic PEEP; *VCO_2*, production of carbon dioxide.

BOX 55.1 Indications for Use of Noninvasive Ventilation in the Acute Care Setting

Airway Obstruction
COPD (A)*
Asthma (B)
Cystic fibrosis (C)
Obstructive sleep apnea or obesity hypoventilation (B)
Upper airway obstruction (C)
Facilitation of weaning in COPD (A)
Extubation failure in COPD (B)

Hypoxemic Respiratory Failure
ARDS (C)
Pneumonia (C)
Trauma or burns (B)
Acute pulmonary edema (use of CPAP) (A)
Immunocompromised patients (A)
Restrictive thoracic disorders (C)
Postoperative patients (B)
Do-not-intubate patients (C)
During bronchoscopy (C)

ARDS, Acute respiratory distress syndrome; *COPD,* chronic obstructive pulmonary disease; *CPAP,* continuous positive airway pressure.
*Letters in parentheses indicate the level of evidence supporting the use of noninvasive ventilation: *A,* multiple randomized controlled trials: recommended; *B,* at least one randomized controlled trial: weaker recommendation; *C,* case series or reports: can be attempted, but with close monitoring.

Airway Obstruction

Chronic Obstructive Pulmonary Disease

Randomized controlled trials[13,14] and meta-analyses[15] have consistently shown that compared with conventional therapy, NIV improves vital signs, gas exchange, and dyspnea scores; reduces the rates of intubation, morbidity, and mortality; and shortens hospital length of stay in patients with moderate to severe exacerbations of COPD. Thus NIV is considered the ventilatory mode of choice in selected patients with acute exacerbations of COPD. Some studies suggest that the addition of heliox to NIV further improves the work of breathing and gas exchange during COPD exacerbations,[16] but a subsequent multicenter trial found no improvement in other outcomes compared with NIV alone.[17] The ERS/ATS Task Force gave a strong recommendation for use of NIV as the ventilatory modality of first choice for patients with hypercapnic respiratory failure caused by COPD exacerbations.[12] More recent clinical practice guidelines suggest the use of nocturnal NIV in the home in addition to usual care for patients with chronic stable hypercapnic COPD (arterial partial pressure of carbon dioxide [$PaCO_2$] ≥52 mm Hg) given several desirable effects of NIV, including possible reductions in mortality and hospital admissions, improved quality of life (QOL), reduced dyspnea, and produced improvements in functional capacity, awake blood gases, and exertion tolerance.[18,19]

Asthma

Uncontrolled studies have reported improvements in gas exchange and low rates of intubation after the initiation of NIV in patients with severe asthma attacks. Two controlled trials have demonstrated a more rapid improvement in expiratory flow rates with NIV,[20,21] and one showed a decreased hospitalization rate in acute asthma patients treated with NIV compared with a sham mask.[21] Neither study was powered adequately to assess intubation or mortality rates. Nonetheless, these data support a trial of NIV in asthmatics responding poorly to initial bronchodilator therapy. NIV can be combined with continuous nebulization and heliox, although the added value of these latter therapies has not been established in controlled trials. In a more recent study using a large medical record dataset, 13,588 admissions for acute asthma were identified in 58 hospitals.[22] Use of NIV for acute asthma was widely variable between hospitals, with 36% not using it at all, and one hospital using it in 16.3% of such patients. Overall, NIV was used in 4.0% of patients with acute asthma and invasive mechanical ventilation (IMV) in another 5.7%. NIV failure rate was only 4.9%, and the case-fatality rate of patients using NIV was only 2.3%. Despite these low rates, use of NIV was not associated statistically with lower mortality rate than IMV after risk standardization, but hospital length of stay was slightly shorter. Based on the tentativeness of the evidence, the ERS/ATS Task Force made no recommendation regarding the use of NIV for acute asthma.[12]

Cystic Fibrosis

Uncontrolled studies indicate that NIV is useful to stabilize gas exchange in the treatment of acute episodes of respiratory failure in end-stage cystic fibrosis patients and can serve as a bridge to transplantation.[23]

Obesity Hypoventilation Syndrome

Acute hypercapnic respiratory failure related to obesity hypoventilation (OHS) is becoming more prevalent given the high and increasing obesity rates in the general population. A single-center prospective observational study was conducted to examine the use of NIV in these patients. Using COPD patients with acute hypercapnic respiratory failure for comparison, the authors found no change in the rate of NIV failure between the two groups and found lower rates of late NIV failure, readmission to the intensive care unit (ICU), and ICU and hospital mortality in the OHS group. Their conclusion was that NIV can be used safely and efficaciously in acute hypercapnic respiratory failure related to OHS in the ICU.[24] Furthermore, a recent systematic review found that hospital discharge with positive airway pressure devices reduces mortality risk in OHS patients admitted with acute-on-chronic hypercapnic respiratory failure compared with those not discharged on such devices.[25]

Upper Airway Obstruction

Anecdotally, NIV can be used effectively to treat patients with reversible upper airway obstruction, such as that caused by glottic edema after extubation. In this situation, NIV can be combined with aerosolized medications or heliox, but no controlled trials have demonstrated the efficacy of this approach. If therapy with NIV is considered, patients should be selected with great caution and monitored closely, because upper airway obstruction can lead to precipitous deterioration. The use of NIV in patients with tight, fixed upper airway obstruction is inappropriate because it delays the institution of definitive therapy.

Hypoxemic Respiratory Failure

Hypoxemic respiratory failure is defined as severe hypoxemia (arterial oxygen partial pressure to fraction of inspired oxygen [PaO_2/FiO_2] ratio less than 200) combined with an unassisted respiratory rate >30 breaths per minute and a non-COPD diagnosis, including acute pneumonia, acute lung injury (ALI), acute respiratory distress syndrome (ARDS), pulmonary edema, or trauma. Controlled trials of NIV to treat patients with acute hypoxemic respiratory failure have

shown statistically significant reductions in the rate of intubation, length of hospital stay, incidence of infectious complications,[8,26] and in one study, ICU mortality.[26] However, because of the heterogeneity of causes, these studies fail to demonstrate that all patient subgroups with hypoxemic respiratory failure benefit equally from NIV. Furthermore, when patients are stratified according to the acuity of illness, those with a Simplified Acute Physiologic Score (SAPS II) less than 35 fare considerably better with NIV than do those with higher scores.[27] Thus the selection of patients with less severe disease is likely to enhance the success of NIV in treating hypoxemic respiratory failure, and studies that examine individual subgroups within the larger category are likely to be more useful clinically.

Acute Cardiogenic Pulmonary Edema

Use of NIV to treat acute cardiogenic pulmonary edema (CPE) is the second main indication for NIV among causes of ARF, and the ERS/ATS Task Force recommended its use.[12] Meta-analyses of randomized controlled trials demonstrated that compared with oxygen therapy, CPAP (though not a true mode of ventilatory support) is highly effective at relieving respiratory distress, improving gas exchange, and averting intubation when used to treat patients with acute cardiogenic edema.[28,29] Inspiratory assistance combined with expiratory pressure can reduce the work of breathing and alleviate respiratory distress more effectively than CPAP alone. However, several uncontrolled trials and two controlled trials found that NIV and CPAP were equally effective in improving vital signs and avoiding intubation. The current recommendation is to use CPAP alone or NIV as an initial therapy; if CPAP is used initially, inspiratory pressure support should be added if the patient has persistent hypercapnia or dyspnea.[29]

Pneumonia/Acute Respiratory Distress Syndrome

One controlled trial showed that NIV in patients with severe community-acquired pneumonia lowers the rate of endotracheal intubation and shortens the length of ICU stay compared with conventional therapy; however, a subgroup analysis revealed that the benefits occurred only in patients with underlying COPD.[30] No benefit was apparent in the non-COPD patients with severe pneumonia. A subsequent uncontrolled trial in non-COPD patients with severe pneumonia found that two-thirds of such patients treated with NIV eventually required intubation.[31] Although the latter authors deemed a trial of NIV in non-COPD patients with severe pneumonia to be a reasonable approach, controlled data to support such a recommendation are currently lacking. According to the Berlin definition,[32] patients with ARDS have oxygenation defects, bilateral radiographic infiltrates, and no heart failure to explain the infiltrates. Thus many patients hospitalized with severe pneumonia are diagnosed with ARDS as well. Earlier studies on the use of NIV for pneumonia/ARDS patients yielded conflicting findings, and meta-analyses were inconclusive.[33] A prospective cohort study,[34] using NIV as a "first-line" intervention for ARDS, found that ventilator-associated pneumonia and mortality were greatly reduced when patients succeeded rather than failed NIV, and a SAPS score of 34 or less and PaO_2/FiO_2 ratio above 175 within the first hour predicted the success of NIV. However, only 15% of the ARDS patients entered into this study actually succeeded with NIV. More recently, the LUNG SAFE ARDS database found that among 506 ARDS patients in their observational cohort treated with initial NIV,[35] those with a $PaO_2/FiO_2 \leq 150$ had a mortality of 36% compared with 25% in those treated with initial IMV, suggesting that NIV might increase the risk of poor outcomes in patients with more severe oxygenation defects. Based on the weakness of the data, the (ERS/ATS) Task Force made no recommendation on the use of NIV to treat pneumonia/ARDS ("de novo acute respiratory failure") but did allow that a trial of NIV might be considered in selected patients as long as they were closely monitored to avoid any delay in needed intubation.[12]

Coronavirus Disease-19 Pneumonia

The COVID-19 pandemic has created waves of patients entering hospitals with pneumonia and acute hypoxemic respiratory failure around the world and generated debate about the efficacy and safety of NIV as an initial therapy. Given concerns about spreading disease via aerosolization of virus, there was hesitancy about using NIV in this setting, and many centers favored early intubation to limit dispersion of aerosol.[36,37] However, this created shortages of ICU beds, and initially reported outcomes of invasively managed patients were poor.[38] Consequently, many centers gave trials of NIV or high-flow nasal cannula (HFNC) to patients not needing immediate intubation to see if some of these patients could be managed noninvasively outside of the ICU.[39] Guidelines on how to manage patients with COVID-19 pneumonia varied widely,[40] but most discouraged use of NIV except for patients with COVID-19 pneumonia complicated by COPD exacerbations or CPE (i.e., the usual indications). The pandemic encouraged the use of the helmet interface, a clear plastic hood that fits over the head, because of the theoretically superior containment of aerosol if the neck seal is tight. This became the predominant interface at some centers in Italy,[39] but was used infrequently, if at all, at other centers in Europe and the United States.[41] Another innovation of the pandemic was the use of NIV (and HFNC) in combination with awake prone positioning to improve oxygenation and avoid the need for intubation,[42] although the efficacy of this approach has been questioned.[43] Despite an increasing number of reports on the use of noninvasive approaches for treating patients with COVID-19 pneumonia,[39,41,44] NIV failure rates have remained high (usually >50%), and at present, the quality of the evidence base remains low. It therefore remains unclear how efficacious or safe NIV is compared with the more aggressive approach favoring earlier intubation. Notably, the ERS/ATS Task Force made no recommendation for use of NIV during a viral pandemic based on data accrued during the earlier H1N1 and SARS-CoV-1 pandemics in which efficacy of NIV was unclear and concerns were raised about viral spread.[12]

Immunocompromised States

The dismal prognosis of invasively ventilated immunocompromised patients makes NIV an appealing alternative ventilatory mode, with its demonstrated ability to decrease the rate of nosocomial infection.[7] In earlier studies of both solid organ transplantation[45] and neutropenic patients (most of whom had hematologic malignancies)[46] who developed acute hypoxemic respiratory failure, NIV reduced the rates of intubation, nosocomial infection, and ICU mortality compared with conventional therapy. However, more recent studies suggest that the benefit of NIV is difficult to demonstrate, and randomized controlled studies comparing NIV with conventional oxygen therapy, with IMV added if needed, showed no reduction in intubation, mortality rate, or length of hospital stay.[47,48] In immunocompromised patients with *Pneumocystis carinii* pneumonia resulting from acquired immunodeficiency syndrome (AIDS), NIV appears to yield benefit when compared with IMV in physiologically and demographically matched patients.[49] Thus the current suggestion is to reserve NIV for milder cases of acute respiratory failure in immunocompromised patients but resort to intubation without undue delay if progressive deterioration occurs.[50,51] The ERS/ATS Task Force gave a conditional recommendation for use of NIV in immunocompromised patients with hypoxemic respiratory failure,[12] but acknowledged that accruing evidence suggests that HFNC may have efficacy advantages over NIV in this population of patients.[52]

Postoperative Respiratory Failure

NIV and CPAP alone have been studied in postoperative patients who develop respiratory failure after various kinds of surgeries. In particular, they reduce extravascular lung water and improve lung mechanics and gas exchange after coronary artery bypass surgery.[53] Controlled trials show that CPAP or NIV averts postoperative complications compared with oxygen supplementation after high-risk procedures like thoracoabdominal aortic procedures[54] or abdominal surgery.[55,56] NIV improves oxygenation, reduces the need for reintubation, lowers the mortality rate after lung resectional surgery,[57] and enhances pulmonary function after gastroplasty.[58] Thus NIV should be considered in selected postoperative patients at a high risk of pulmonary complications or with frank respiratory failure, especially in the setting of underlying COPD or pulmonary edema.

Trauma and Burns

Trauma patients develop respiratory failure for a multitude of reasons, but some have chest wall injuries, such as flail chest or mild ALIs that might respond favorably to NIV. In a retrospective survey of 46 trauma patients with respiratory insufficiency who had been treated with NIV, Beltrame and coworkers found rapid improvements in gas exchange and a 72% success rate; however, patients with burns responded poorly.[59] More recently, a randomized trial of NIV versus high-flow oxygen in thoracic trauma patients with PaO_2/FiO_2 <200 was stopped early after the enrollment of 50 patients because of significant reductions in the intubation rate (12% vs. 40%) and hospital length of stay (14 vs. 21 days) in the NIV group.[60] The (ERS/ATS) Task Force "suggested" the use of NIV in patients with chest trauma, especially flail chest.[12]

Restrictive Lung Disease

The use of NIV in patients with underlying restrictive disease and acute deterioration of respiratory status has not been studied extensively because they constitute only a small portion of patients admitted to acute care hospitals. Patients with restriction related to an underlying neuromuscular disease and superimposed ARF may benefit from a trial of NIV. Small case series have reported that using NIV in patients with myasthenic crises may avoid intubation.[61,62]

Patients with restriction caused by end-stage pulmonary fibrosis in respiratory extremis have been reported to respond poorly to mechanical ventilation.[63] However, in selected patients with interstitial lung diseases, NIV may play a role in preventing intubation and improving survival. A prospective observational study revealed that patients with APACHE II scores <20 and mixed interstitial lung disease requiring noncontinuous NIV had a higher survival rate than those requiring continuous NIV or invasive ventilation.[64] Similarly, a small retrospective observational study in patients with ARF secondary to idiopathic pulmonary fibrosis (IPF) showed a poor overall prognosis, but for those who survived, NIV helped to shorten the ICU stay and improve the 90-day survival rate.[65] Interestingly, this study also found that patients with IPF and a higher NT-proBNP at baseline appeared to have a greater chance of NIV failure.

Do-Not-Intubate Patients

Although controversial, NIV may be a useful tool in patients with ARF who do not wish to be intubated. There are several reports of good outcomes (>50% survival to discharge) with NIV in this subset of patients, especially those with COPD, congestive heart failure,[66] and end-stage malignancy. NIV may also be used as a palliative technique to reduce dyspnea, preserve patient autonomy, and provide time for the finalization of affairs for some terminal patients.[67,68] However, there is concern that this may merely prolong the dying process, and patients and their families must be informed that NIV is being used as a form of life support in this setting and should be given the option to refuse it. By virtue of its comfort and tolerance advantages, HFNC may be a better choice than NIV for some patients with respiratory failure requiring palliation.

Facilitation of Weaning and Extubation

Patients who require IMV initially and fail to wean promptly are potential candidates for NIV to facilitate extubation, thus reducing the complications related to prolonged intubation. Several randomized controlled trials and subsequent meta-analyses have demonstrated that transitioning to NIV may significantly shorten the duration of IMV, reduce the length of ICU stay, and improve survival when compared with patients weaned in the routine fashion.[69–71] The benefit of NIV in ventilator weaning seems to be highest in patients intubated for acute exacerbations of COPD.[72,73]

Another potential application of NIV in the weaning process is to avoid reintubation in patients with extubation failure, a complication of IMV associated with a high mortality rate. Data for this use of NIV are variable and inconclusive. Earlier studies investigating the role of NIV in this situation showed promise, but one randomized trial found that NIV may delay required intubation in this setting, resulting in an increased ICU mortality rate.[74] More recent studies have demonstrated that patients at high risk of extubation failure,[75] especially those with hypercapnia,[76] have a reduced need for reintubation and mortality if treated with NIV as opposed to oxygen supplementation alone. Subsequent meta-analyses have demonstrated that NIV used prophylactically after planned extubation has decreased reintubation rates.[77,78] However, its effect on ICU and hospital mortality remains unclear. Thus although the use of NIV to facilitate weaning and extubation appears to benefit hypercapnic patients with COPD or congestive heart failure, its overzealous application could lead to delayed reintubation and other adverse consequences.

Bronchoscopy

Both CPAP and NIV can be used to support oxygenation and ventilation during bronchoscopy in patients "at risk" for being stressed by the procedure, such as those with severe COPD. A specially designed open CPAP system has been used during bronchoscopy in patients with marginal oxygenation to maintain adequate gas exchange and avoidance of respiratory failure.[79] Also, a controlled trial demonstrated equivalent oxygenation and complication rates in patients undergoing bronchoscopy and supported with either noninvasive or invasive mechanical ventilation.[80] Thus NIV often provides an effective means of providing ventilation and oxygenation support to patients undergoing bronchoscopy.[80]

ROLES OF HFNC VS. NIV

The increasing use of HFNC over the past decade throughout the world has raised questions about when to use HFNC vs. NIV. HFNC refers to the delivery of heated, humidified (to body conditions), and oxygenated gas via loose-fitting nasal prongs at high flow rates usually ≥20 L/min up to 40–80 L/min, depending on the manufacturer. The interface permits unimpeded speaking and eating, and the heat and humidity make the high flows tolerable. Patients sense HFNC as more comfortable than standard mask oxygen or NIV. The heat and humidity also hydrate mucus in the airways and preserve mucocilliary function better than standard oxygen. Oxygenation is also better with HFNC than with standard oxygen delivery techniques because the higher flow rates reduce the entrainment of room air and promote the delivery of a higher FiO_2 to the lungs. In addition, the higher flow rates flush the upper airways, lowering dead space and improving efficiency

of ventilation. There is also a small and unregulated positive airway pressure applied by HFNC, but this is less than with NIV at the usual settings. Consequently, on average, oxygenation with NIV is better than with HFNC.

The influential FLORALI study[52] randomized patients with acute hypoxemic respiratory failure, mainly caused by pneumonia or ARDS, to NIV, standard oxygen, or HFNC. In patients with $PaO_2/FiO_2 \leq 200$, intubations were fewer in the HFNC group compared with the other groups, and in the overall population, ICU and 90-day mortality rates were less with HFNC. A subsequent systematic review that included the FLORALI results found that HFNC, compared with standard oxygen, slightly reduced escalation of care and intubations but could not substantiate its mortality benefit.[81]

These results and the ease of application and high tolerance of HFNC compared with the other modalities have made it the preferred initial noninvasive modality over NIV to treat hypoxemic respiratory failure at many centers, but as yet, the evidence base isn't adequate to recommend this practice. Furthermore, with regard to the established indications for NIV (i.e., ARF associated with COPD exacerbations and CPE), NIV should still be considered the modality of first choice unless the respiratory failure is mild or the patient is intolerant of NIV. HFNC may be preferred for palliation of do not intubate/do not resuscitate (DNI/DNR) patients because of its superior tolerability, and the two—NIV and HFNC—may be used in tandem, with HFNC performing better than standard oxygen during breaks from NIV.[82]

PRACTICAL APPLICATION

Patient Selection

NIV should be viewed as a "crutch" that assists patients through a period of ARF while reversible factors are being treated, helping them avoid IMV and its attendant complications. To optimize the chance of success, NIV should be used early, when patients first develop signs of incipient respiratory failure. In addition, predictors of success are useful in identifying patients most likely to benefit (Box 55.2). The selection process might be viewed as taking advantage of a "window of opportunity": the window opens when the patient first requires ventilatory assistance and closes when the patient becomes too unstable.

Based on the predictors of success and criteria used in prior controlled trials, we recommend the following three-step selection process: (1) ensure that the patient has an etiology of respiratory failure likely to respond favorably to NIV and (2) identify patients in need of ventilatory assistance by using clinical and blood gas criteria. Patients with mild respiratory distress and only mild gas exchange abnormalities are likely to do well without ventilatory assistance. Good candidates are those with moderate to severe dyspnea, tachypnea, and impending respiratory muscle fatigue, as indicated by the use of accessory muscles of breathing or abdominal paradox. The level of tachypnea used as a criterion depends on the underlying diagnosis. With COPD, candidates for NIV usually have respiratory rates exceeding 24 breaths per minute, but with hypoxemic respiratory failure, respiratory rates are usually higher, in the range of 30–35 breaths per minute. The third step excludes patients for whom NIV would be unsafe. If respiratory arrest is imminent, the patient should be promptly intubated because the successful initiation of NIV requires some time for adaptation. Patients who are medically unstable with hypotensive shock, uncontrolled upper gastrointestinal bleeding, unstable arrhythmias, or life-threatening ischemia are better managed with IMV. Additionally, NIV should not be used for patients who are uncooperative, are unable to adequately protect their airways or clear secretions, or are intolerant of masks. The use of NIV merits caution after recent upper gastrointestinal or airway surgery.

BOX 55.2 Predictors of Noninvasive Ventilation Success in Patients With Acute Respiratory Failure

- Lower acuity of illness (Acute Physiology and Chronic Health Evaluation [APACHE] score)
- Ability to cooperate; better neurologic score
- Ability to coordinate breathing with ventilator
- Less air leakage; intact dentition
- Hypercarbia, but not too severe ($PaCO_2$ between 45 and 92 mm Hg)
- Acidemia but not too severe (pH between 7.1 and 7.35)
- Improvements in gas exchange and heart and respiratory rates within the first 2 hours

$PaCO_2$, Arterial partial pressure of carbon dioxide.

Initiation of Noninvasive Ventilation

After identification of an appropriate candidate for NIV, a ventilator and interface must be chosen, initial settings must be selected, and the patient must be monitored closely in an appropriate location until stabilized. The roles of physicians, respiratory therapists, and nurses are of paramount importance in explaining the process and gaining the confidence of the patient. NIV can be initiated wherever patients present with acute respiratory distress, but they should be transferred to a location with sufficient monitoring (usually an ICU or step-down unit) until stabilized. During transfers, ventilatory assistance and monitoring should be continued.

Ventilator Selection

Selection of a ventilator is based largely on availability, practitioner experience, and patient comfort. Critical care ventilators with NIV modes and devices designed specifically for administration of NIV are acceptable, and the latter often have internal batteries and can be used for transport. Pressure-limited modes, including pressure support and pressure control, are available on most critical care ventilators. Pressure control ventilation (PCV) delivers time-cycled, preset inspiratory and expiratory pressures with adjustable inspiratory/expiratory ratios at a controlled rate. This mode also permits patient triggering and the selection of a backup rate. PSV delivers preset inspiratory and expiratory pressures to assist spontaneous breathing efforts without a backup rate. Nomenclature and the specific characteristics of these modes may differ between ventilators, and this must be taken into account to avoid errors. For example, with some ventilators, pressure support is the amount of inspiratory assistance added to the preset expiratory pressure. Others require the independent selection of inspiratory and expiratory positive airway pressures, with the difference between the two determining the level of pressure support.

PSV is a flow-triggered and flow-cycled procedure, and patient effort determines tidal volume and duration of inspiration. Pressure-support modes have the potential to match breathing pattern quite closely and have been rated by patients as more comfortable for NIV than volume-limited ventilation.[83] However, leaks during NIV can interfere with the detection of reduced inspiratory flow at the termination of inspiration, causing expiratory asynchrony.

Traditional bilevel positive airway pressure (BiPAP) devices designed for home use have limited pressure-generating capability ($\leq$30 cm H_2O) and lack oxygen blenders or sophisticated alarm or battery backup systems and are not suitable for use in patients who require high oxygen concentrations or inspiratory pressures. Bilevel devices designed specifically for the acute setting are equipped with

sophisticated alarm and monitoring capabilities, graphic displays, and oxygen blenders. These devices are capable of enhancing synchrony by offering ways to limit the inspiratory duration and an adjustable "rise time"—the time to reach the targeted inspiratory pressure. Most critical care ventilators include an "NIV" mode that enhances leak compensation capabilities and silences "nuisance" alarms.[84] If desired, volume-limited ventilation can be delivered using critical care ventilators, but a higher tidal volume than that commonly used for IMV is recommended to compensate for air leakage.

Initial ventilator pressure settings are usually set in low ranges to facilitate patient acceptance, but can be set higher if necessary to alleviate respiratory distress. Typical pressures are an inspiratory positive airway pressure in the range of 12 cm H_2O and a PEEP (or expiratory positive airway pressure) of 5–6 cm H_2O.[85] L'Her and colleagues[86] demonstrated that increases in inspiratory pressure are helpful to alleviate dyspnea, whereas increases in expiratory pressure are preferable to improve oxygenation. For volume ventilation, initial tidal volumes range from 6 to 7 mL/kg. The ventilator is set in a spontaneously triggered mode, with or without a backup rate. Pressures commonly used to deliver CPAP in patients with acute respiratory distress range from 5 to 12.5 cm H_2O. CPAP can be applied using compressed air with a regulator system, blower-based CPAP device, bilevel device, or critical care ventilator.

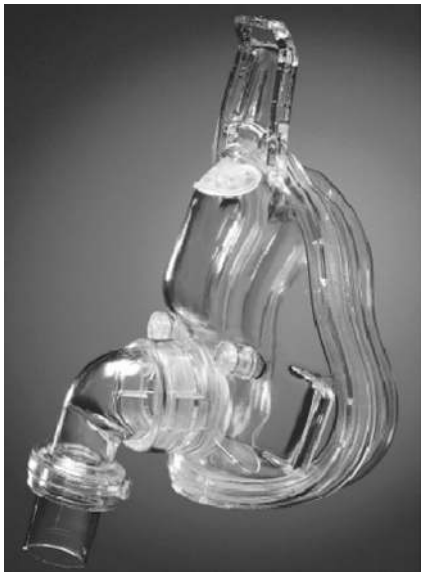

Fig. 55.3 Full-face mask with soft silicon seal to minimize pressure on the nasal bridge. A disposable version of this mask is widely used in the acute care setting.

Interfaces

The major difference between invasive and noninvasive ventilation is that with the latter, pressurized gas is delivered to the airway via a mask rather than via an invasive artificial airway. The open breathing circuit of NIV permits air leaks around the mask or through the mouth, rendering the success of NIV dependent on ventilators designed to deal effectively with air leaks and to optimize patient comfort and acceptance. Interfaces—the devices that connect the ventilator tubing to the nose, mouth, or both—enable pressurized gas to enter the upper airway during NIV. Commonly used interfaces in the acute setting include nasal and full-face (or oronasal) masks.

Nasal masks are widely used for the administration of CPAP or NIV, particularly for chronic applications. Nasal masks are usually better tolerated than full-face masks for long-term applications because they cause less claustrophobia; enhance comfort; and allow eating, conversation, and expectoration. The standard nasal mask is a triangular or cone-shaped clear plastic device that fits over the nose and uses a soft cuff that forms an air seal over the skin. The mask exerts pressure over the nasal bridge, often causing skin irritation and redness, and occasionally ulceration. Pharyngeal gas pressures may decline during mouth opening.

Full-face masks cover both the nose and the mouth (Fig. 55.3) and are preferable to nasal masks in the acute setting. The efficacy of both nasal and oronasal masks in lowering $PaCO_2$ and avoiding intubation is similar in the acute setting, but a randomized controlled trial[87] observed better patient tolerance with full-face masks because of reduced air leakage through the mouth. More recently, "total" face masks have become available; they seal around the perimeter of the face and resemble a hockey goalie's mask or a snorkel mask. Made of optical-grade plastic, they are easy to apply and cause no more claustrophobia than standard face masks.[5] Mouthpieces are seldom used to administer NIV in the acute setting but are occasionally used during initiation when the patient holds the mouthpiece in place to adapt to the sensation of positive-pressure ventilation.

Helmets are clear plastic, inverted, bucket-shaped devices that fit over the entire head and seal over the shoulders and neck.[88] These have achieved popularity in some European countries and were the most commonly used interface for patients with hypoxemic respiratory failure caused by COVID-19 pneumonia at certain Italian centers during the recent pandemic,[39] but not in most other countries where availability and experience are less. A randomized controlled trial performed before the COVID-19 pandemic at a single center in Chicago found a much lower need for intubation and lower mortality rate when patients with ARDS used the helmet as opposed to the standard full-face mask, but this study awaits replication.[89]

Selection of a comfortable interface that fits properly is key to the success of NIV. With the full-face mask, which is the first choice at many centers, the patient should be allowed to hold the mask in place initially if possible. The mask straps are tightened with the least amount of tension necessary to avoid excessive air leakage. Excessive tightening causes discomfort and skin trauma and may lead to NIV failure. Some air leakage is acceptable, and even obligatory with bilevel ventilators, because of the need to flush carbon dioxide from the single-channel ventilator circuit. However, excessive air leakage through the interface can lead to NIV failure with any ventilator.

Oxygenation and Humidification

Oxygen is titrated to achieve the desired oxygen saturation, usually greater than 90%–92%, either by using the oxygen blenders used for critical care applications and for most bilevel ventilators or by adjusting the liter flow (up to 15 L/min) delivered via oxygen tubing connected directly to the mask or ventilator circuit. Bilevel ventilators designed for home use have limited oxygenation capabilities (maximal inspired oxygen fraction, 0.45–0.5) and are not suitable for use in patients with hypoxemic respiratory failure. A heated humidifier should be used to prevent drying of the nasal passage and oropharynx when the duration of application is anticipated to be more than a few hours.

Monitoring

Once NIV is initiated, patients should be closely monitored in a critical care or step-down unit until they are sufficiently stable to be moved to a regular medical floor. The aim of monitoring is to determine whether the main goals are being achieved, including the relief of symptoms, reduced work of breathing, improved or stable gas exchange, good

BOX 55.3 Monitoring of Patients Receiving Noninvasive Ventilation in Acute Care Settings

Location
Critical care or step-down unit
Medical or surgical ward if able to breathe unassisted for >20–30 min

"Eyeball" Test
Dyspnea
Comfort (mask, air pressure)
Anxiety
Asynchrony
Leaks

Vital Signs
Respiratory and heart rates
Blood pressure
Continuous electrocardiography

Gas Exchange
Continuous oximetry
Arterial blood gases (baseline, after 1–2 h, and as clinically indicated)

patient-ventilator synchrony, and patient comfort (Box 55.3). A drop in the respiratory rate with improved oxygen saturation or improving pH with a lower $PaCO_2$ within the first 1–2 hours indicates a successful outcome.[90] Abdominal paradox, if present initially, subsides, and the heart rate usually falls. The absence of these propitious signs indicates a poor response to NIV and the need to make further adjustments. Excessive leaks should be sought and corrected, and patient-ventilator synchrony should be optimized. Pressures may need to be adjusted upward to relieve respiratory distress and achieve a reduction in $PaCO_2$. If these adjustments fail to improve the response within a few hours, NIV should be considered a failure, and the patient should be promptly intubated if it is still clinically indicated. Excessive delay in intubation may precipitate a respiratory crisis and add to the morbidity and mortality.

ADVERSE EFFECTS AND COMPLICATIONS

When applied by experienced caregivers to appropriately selected patients, NIV is usually well tolerated and associated with minimal complications. The most frequent adverse effects and complications are related to the mask, ventilator airflow or pressure, patient-ventilator interaction, or airway secretions. A potentially serious concern raised in recent years is that of excessive tidal volumes generated by some patients, mainly with hypoxemic respiratory failure, who are breathing at excessive tidal volumes (>9.5 mL/kg) that have been associated with poorer outcomes.[91] This is thought to predispose to patient self-induced lung injury (PSILI). Some advocate lowering NIV pressures or earlier intubation in such patients, but neither the need to do so nor the efficacy of these interventions has been tested.

Common adverse effects of NIV depend on the type of mask and include discomfort and erythema or skin ulcers on sealing surfaces, usually on the nasal bridge, related to pressure from the mask seal. Proper fitting and attachment, consistent use of artificial skin over the nose, and newer masks with softer silicone seals help minimize these problems. Adverse effects related to airflow or pressure include conjunctival irritation caused by air leakage under the mask into the eyes and sinus or ear pain related to excessive pressure. Refitting the mask or lowering the inspiratory pressure may ameliorate these problems. Nasal or oral dryness caused by high airflow is usually indicative of air leaking through the mouth. Measures to minimize leakage may be useful, but nasal saline or emollients and heated humidifiers are often necessary to relieve these complaints. Gastric insufflation occurs commonly, may respond to simethicone, and is usually tolerated.

Patient-ventilator asynchrony is a common occurrence during NIV. Failure to adequately synchronize compromises the ventilator's ability to reduce the work of breathing and may contribute to NIV failure. The asynchrony may be related to patient agitation, which can be treated with the judicious use of sedatives. Failure to synchronize can also result from inadequate ventilator triggering or the inability to sense the onset of patient expiration because of air leakage. This can be corrected by minimizing air leaks and using ventilator modes that permit a limitation of maximal inspiratory duration. Even with the best efforts to optimize settings and comfort, a minority of patients still fail. This may be partly because of the progression of the underlying disease process or the patient's inability to tolerate NIV, but every effort should be made to ascertain that it is not the result of technologic problems that could be corrected by mask or ventilator adjustments. Therefore intubation should not be delayed if improvement is not apparent within a few hours.

KEY POINTS

- The use of NIV is established in patients with certain forms of ARF, including as a result of COPD exacerbations and acute CPE.
- For these entities, NIV delivered by nasal or oronasal masks reduces the need for endotracheal intubation, decreases the length of stay in the ICU and hospital, and reduces mortality.
- The efficacy of NIV has also been demonstrated for mild to moderate respiratory failure in immunocompromised patients and to facilitate extubation in COPD patients.
- Patients who develop respiratory failure and who refuse intubation are potentially good candidates for NIV, but all patients must be selected carefully.
- Several factors are vital to the success of NIV: careful patient selection; properly timed initiation; comfortable, well-fitting interface; coaching and encouragement; and careful monitoring.
- NIV should be used to avert endotracheal intubation rather than as an alternative to it. One should not persist in the use of NIV if it leads to a delay in necessary intubation.
- A trial of NIV should be instituted in properly selected patients with ARF before a respiratory arrest is imminent to provide ventilatory assistance while the factors responsible for the respiratory failure are aggressively treated.
- NIV is an important option to assist patients with ARF and, if properly applied in selected patients, improves patient outcomes in the critical care setting compared with conventional oxygen therapy with IMV if necessary.
- Although HFNC is often better tolerated than NIV and is favored as initial therapy for hypoxemic respiratory failure at many centers, NIV is still the favored initial choice to treat ARF caused by COPD exacerbations or cardiogenic pulmonary edema

ANNOTATED REFERENCES

Antonelli M, Conti G, Esquinas A, et al. A multiple-center survey on the use in clinical practice of noninvasive ventilation as a first-line intervention for acute respiratory distress syndrome. *Crit Care Med.* 2007;35:18–25.
A multicenter survey of over 400 ARDS patients, two-thirds of whom were already intubated before they were admitted to the ICU. The remaining patients were treated with noninvasive ventilation when they reached the ICU, and outcomes were assessed. Intubation was avoided in 54% of these patients (one-sixth of the total), and outcomes of these successes were much better than in the failures.

Ferrer M, Sellares J, Valencia M, et al. Non-invasive ventilation after extubation in hypercapnic patients with chronic respiratory disorders: Randomized controlled trial. *Lancet*. 2009;374:1082–1088.
This randomized trial on patients with postextubation respiratory failure identified hypercapnic patients as those likely to benefit from noninvasive ventilation.

Grieco DL, Menga LS, Cesarano M, et al. Effect of helmet noninvasive ventilation vs high-flow nasal oxygen on days free of respiratory support in patients with COVID-19 and moderate to severe hypoxemic respiratory failure: The HENIVOT randomized clinical trial. *JAMA.* 2021;325(17):1731–1743.
One hundred and ten patients with COVID-19 pneumonia and moderate to severe hypoxemic respiratory failure were randomized to receive continuous helmet NIV for 48 hours followed by HFNC vs. HFNC alone. Days free of respiratory support within 28 days (the major outcome variable) were 20 in the helmet group and 18 in the HFNC group (P = NS). Intubation rate was 30% in the helmet group and 51% in the HFNC group (P = .03). In-hospital mortality was 24% in the helmet group and 25% in the HFNC group (P = NS). Although the intubation rate was lower in the helmet group, the major outcome variable and mortality were similar between the groups.

Jaber S, Lescot T, Futier E, et al. Effect of noninvasive ventilation on tracheal reintubation among patients with hypoxemic respiratory failure following abdominal surgery: A randomized clinical trial. *JAMA.* 2016;315(13):1345–1353.
Two hundred and ninety-three patients with hypoxemic respiratory failure after abdominal surgery were randomized to NIV or standard oxygen therapy. Intubation within 7 days (the major outcome variable) was 33.3% in the NIV group and 45.1% in the standard oxygen group (P = .03). There were 2.2 more ventilator-free days and fewer nosocomial infections in the NIV group. Mortality did not differ significantly between the groups. The authors concluded that their results support the use of NIV "in this setting," although the findings would have been more compelling had they found a mortality benefit.

Lindenauer PK, Stefan MS, Shieh MS, et al. Outcomes associated with invasive and noninvasive ventilation among patients hospitalized with exacerbations of chronic obstructive pulmonary disease. *JAMA Intern Med.* 2014;174(12):1982–1993.
Retrospective cohort study on 17,978 patients from 420 hospitals in the Premier database who were treated with initial NIV for their COPD exacerbation. In a propensity-matched analysis, those treated with initial NIV had lower risk of mortality than IMV (odds ratio [OR], 0.54) and hospital-acquired pneumonia (OR, 0.53), lower costs (OR, 0.68), and shorter hospital length of stay (OR, 0.81). These results provide real-life data to substantiate what has been found in randomized controlled trials (RCTs) and meta-analyses.

Ozsancak Ugurlu A, Sidhom SS, Khodabandeh A, et al. Use and outcomes of noninvasive positive pressure ventilation in acute care hospitals in Massachusetts. *Chest*. 2014;145(5):964–971.
This observational cohort study on the use of NIV in eight Massachusetts hospitals registered a large increase between 2002 and 2007, especially in COPD and CPE patients, amounting to nearly 40% of initial ventilator starts..

Patel BK, Wolfe KS, Pohlman AS, et al. Effect of noninvasive ventilation delivered by helmet vs face mask on the rate of endotracheal intubation in patients with acute respiratory distress syndrome: A randomized clinical trial. *JAMA.* 2016;315(22):2435–2441.
Eighty-three patients with ARDS were randomized to helmet versus face mask NIV. Intubation rate, the major outcome variable, was 61.5% for the face mask group and 18.2% for the helmet group (P <.001), ventilator-free days were significantly higher in the helmet group (28 vs. 12.5, P <.001), and at 90 days, mortality was 34.1% in the helmet group compared with 56.4% in the face mask group. The study was stopped early for efficacy. The results suggest that the interface is important in NIV success, but it was a small, single-center study that could not be blinded and needs to be replicated.

Weng CL, Zhao YT, Liu QH, et al. Meta-analysis: Noninvasive ventilation in acute cardiogenic pulmonary edema. *Ann Intern Med.* 2010;152:590–600.
One of a number of meta-analyses showing benefits of CPAP and noninvasive ventilation in patients with cardiogenic pulmonary edema. Intubation, mortality, and myocardial infarction rates were improved by both modalities but did not differ between them.

Advanced Techniques in Mechanical Ventilation

Richard D. Branson

INTRODUCTION

Physiologic closed-loop controlled (PCLC) systems run the gamut from simple negative feedback controllers to fully automated control of airway pressure, tidal volume (V_T), minute ventilation (V_E), fraction of inspired oxygen (FiO_2), and positive end-expiratory pressure (PEEP).[1] Proposed advantages of PCLC systems include maintenance of evidence-based treatment, rapid response to changes in patient condition, reduced necessity for clinician-machine interaction, and less undesirable variation in clinical practice. Disadvantages include reduced of caregivers to clinical changes, loss of situational awareness, and complacency.

Definitions

Wysocki and others have classified closed-loop systems based on the level of sophistication into simple, physiologic signal based, and explicit computerized protocols.[2] Table 56.1 provides examples of closed-loop systems as described by Chatburn and colleagues.[3] This classification method describes operation during traditional and closed-loop control using seven terms describing the targeting schemes for ventilator modes. These are set point, dual, servo, adaptive, bio-variable, optimal, and intelligent.[3] Aside from the added complexity, the use of engineering terms, although consistent with the literature, may seem to infer a value judgment. For instance, "intelligent" implies a system that is perhaps superior to "optimal." In some ways, however, this too is a classification system based on increasing sophistication. Evidence is required to conclude that "intelligent" is superior to "set-point" targeting. As an example, volume control, continuous mandatory ventilation (VC-CMV), a set-point targeting scheme, is the only method to date that has been demonstrated unequivocally to affect clinical outcome in terms of control of V_T during ventilatory support for acute respiratory distress syndrome (ARDS).[4]

ADVANCED MODES

Development of new modes of ventilation can be traced to the current limitations of conventional ventilation and a desire for a competitive edge between manufacturers. Despite marked changes in the understanding of mechanical ventilation in the last 20 years, improvements are still needed. These typically include provision of lung-protective ventilation by limiting driving pressure, power, airway pressures, and volume; encouraging safe spontaneous breathing; improving patient-ventilator synchrony; balancing lung recruitment (avoiding collapse and overdistention); and limiting the hemodynamic interference.

Adaptive Pressure Ventilation: Adaptive Control

Adaptive pressure ventilation (APV) was one of the first closed-loop systems introduced in mechanical ventilation. Also called by various manufacturers by the terms *pressure-regulated volume control, autoflow, volume support,* and *volume control* +, this mode provides a pressure-limited, time-cycled breath while constrained by a tidal volume (V_T) target.[5] APV is classified as an adaptive targeting scheme.

Proposed advantages of APV typically include a more consistent V_T, lower peak airway pressure, and fewer alarms compared with volume control ventilation (VCV).[6] These findings are easily explained by the nature of pressure-limited ventilation. The most frequent ventilator alarm during VCV is high pressure, which is eliminated by pressure-regulating the breath. And although V_T is the target, APV guarantees a minimum V_T, but allows the patient to receive a larger V_T than set during an aggressive inspiratory effort.[7]

Importantly, Jaber and colleagues have shown that aggressive effort during APV can result in an offloading of respiratory work from the ventilator to the patient.[8] Despite automated control of V_T, an increase in patient effort (greater Pmus) results in a reduction in set pressure, as the patient effort contributes to volume delivery. This has been confirmed by other investigators.[9–11]

Comparisons of APV and VCV or pressure control ventilation (PCV) have demonstrated some changes in physiologic parameters (oxygenation, lung mechanics), which may be partially explained by the characteristics of the control group, but these have failed to produce meaningful outcome differences, regardless of disease state.[7,12–19] APV is commonly used in many intensive care units (ICUs), as it does pragmatically reduce ventilator alarms and obviates the need to choose and modify the inspiratory flow setting during VCV. However, this likely results in unrecognized offloading of work to the patient, asynchrony, and imprecise control of V_T and may compromise the objectives of a lung-protective strategy. Use of APV should accompanied by close monitoring of V_T and patient response.

Servo Control Modes: NAVA and PAV+

Two modes of ventilation are considered "servo control" modes. Each allows the patient to control V_T, delivers pressure in proportion to the patient's effort, and requires intact respiratory drive. Both systems can be considered to have closed-loop characteristics, with the changes in output occurring within the breath. Neurally adjusted ventilatory assist (NAVA) delivers inspiratory pressure in proportion to the electrical activity of the diaphragm (EAdi) as a surrogate for neural respiratory drive. EAdi is measured via a nasogastric tube constructed with an embedded array of electrodes.[20] Proportional assist ventilation with load-adjustable gain factors (PAV+) delivers pressure in proportion to the instantaneous flow and volume generated by the patient's inspiratory demand, or Pmus. PAV+ performs programmed, random measurements of respiratory mechanics (elastance and resistance), solving the equation of motion of the respiratory system to determine the level

TABLE 56.1 Targeting Schemes for Mechanical Ventilation as Described by Chatburn et al.[3]

Name (abbreviation)	Description	Advantage	Disadvantage	Example Mode Name
Set point	The operator sets all parameters of the pressure waveform (pressure control modes) or volume and flow waveforms (volume control modes).	Simplicity	Changing patient conditions may make settings inappropriate	Volume control CMV
Dual	The ventilator can automatically switch between volume control and pressure control during a single inspiration.	Can adjust to changing patient conditions and ensure either a preset V_T or peak inspiratory pressure, whichever is deemed more important.	It may be complicated to set correctly and may need constant readjustment if not automatically controlled by the ventilator.	Volume control
Servo	The output of the ventilator automatically follows a varying input.	Ventilator support is proportional to inspiratory effort.	Requires estimates of artificial airway and/or respiratory system mechanical properties.	PAV+, NAVA
Adaptive	The ventilator automatically sets target(s) between breaths in response to varying patient conditions.	Maintains stability of V_T delivery with pressure control for changing lung mechanics or patient inspiratory effort.	Automatic adjustment may be inappropriate if algorithm assumptions are violated or if they do not match physiology.	Adaptive pressure ventilation, PRVC
Bio-variable	The ventilator automatically adjusts the inspiratory pressure or V_T randomly.	Stimulates the variability observed during normal breathing and may improve oxygenation or mechanics.	Manually set range of variability may be inappropriate to achieve goals.	Variable pressure support
Optimal	The ventilator automatically adjusts the targets of the ventilatory pattern to either minimize or maximize some overall performance characteristic (e.g., work rate of breathing).	Adjusts to changing lung mechanics or patient inspiratory effort.	Automatic adjustment may be inappropriate if algorithm assumptions are violated or if they do not match physiology.	ASV, AVM
Intelligent	This is a targeting scheme that uses artificial intelligence programs such as fuzzy logic, rule-based expert systems, and artificial neural networks.	Adjusts to changing lung mechanics or patient inspiratory effort.	Automatic adjustment may be inappropriate if algorithm assumptions are violated or if they do not match physiology.	SmartCare Intellivent ASV

ASV, adaptive support ventilation; *AVM*, adaptive ventilation mode; *CMV*, continuous mandatory ventilation; *NAVA*, neurally adjusted ventilatory assist; *PAV+*, proportional assist ventilation with load-adjustable gain factors; *PRVC*, pressure-regulated volume control; V_T, tidal volume.
Modified from Chatburn RL, El-Khatib M, Mireles-Cabodevila E. A taxonomy for mechanical ventilation: 10 fundamental maxims. *Respir Care*. 2014;59(11):1747–1763.

of assistance.[21,22] Both techniques deliver a variable pressure, and all breaths are patient triggered. Both are intended to speed the transition to spontaneous breathing and avoid the overassistance commonly encountered with pressure support ventilation (PSV). Importantly, neither mode regulates respiratory rate or tidal volume and as such is indicated only when spontaneous breathing is restored or in transition from controlled ventilation.[23,24]

There are some important distinctions between NAVA and PAV+. NAVA uses the EAdi signal to trigger, control, and cycle the ventilator breath. Inspiratory airway pressure is determined by the proportionality gain (NAVA level, in cm H_2O/microvolt) set by the clinician using the equation:

$$\text{Paw} = (\text{NAVA level} \times \text{EAdi}) + \text{PEEP}$$

The NAVA breath is cycled when the EAdi amplitude falls to 70% of the peak value. NAVA triggering is independent of traditional measures of pressure and flow, therefore reducing the impact of intrinsic PEEP or the presence of leaks. Triggering during NAVA may also be accomplished by pressure or flow on a "first come first served" basis if EAdi thresholds are not met.[20]

PAV+ is triggered using a traditional flow or pressure trigger; intrabreath pressure is provided based on solving for the equation of motion, and cycling is based on flow.

$$\text{Paw} = \text{Pmus} \times \%\text{assist} / (100 - \%\text{assist})$$

The machine-delivered pressure during PAV+ is a percentage of the total pressure, based on the gain. If the gain is set to 80%, the ventilator provides 80% of the pressure required to solve the equation of motion, with the remainder provided by patient effort (Pmus).

The primary basis of the advantage for proportional modes is the variable intracycle pressure delivery, compared with a constant fixed pressure, as in PSV. The delivered V_T during PSV is primarily a function of pressure setting and pulmonary compliance.[25,26] During PSV, overassistance occurs commonly, often resulting in excessive V_T, reduced diaphragm activity, hyperinflation, missed triggers, and central apnea events during sleep.[26–31] Fig. 56.1 describes the differences

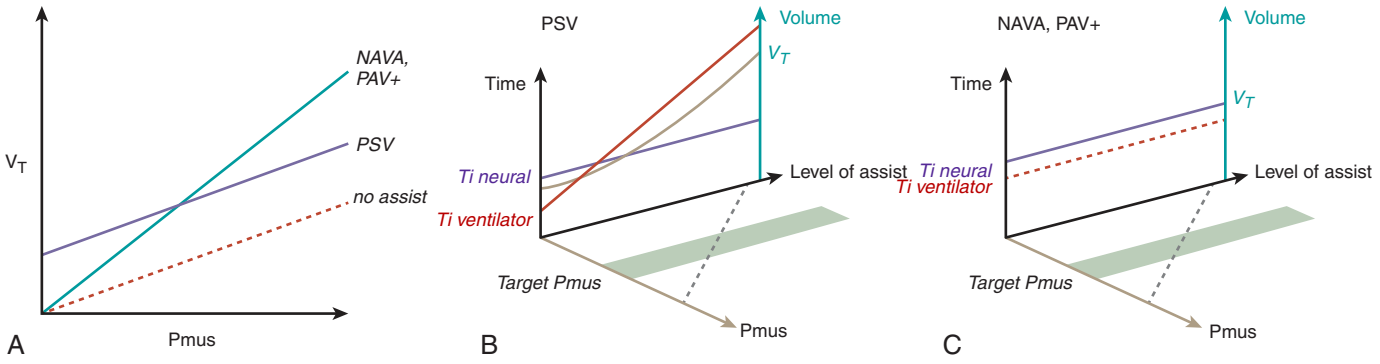

Fig. 56.1 A, The relationship between patient effort (respiratory muscle pressure, *Pmus*) and tidal volume (V_T) in unassisted spontaneous breathing *(dashed line),* during pressure support ventilation (*PSV*) and proportional modes such as proportional assist ventilation with load-adjustable gain factors (*PAV+*) and neurally adjusted ventilatory assist (*NAVA*). **B,** Patient-ventilator interaction during PSV. Increasing the pressure support level increases V_T *(tan line)* and ventilator inspiratory time (Ti, *red line*), whereas patient effort (Pmus, *gray dotted line*) is *downregulated.* In addition, neural Ti *(purple line)* remains unaltered with increasing levels of assist, which results in late cycling. **C,** Patient-ventilator interaction during NAVA and PAV+. Ventilator assist is delivered proportional to the patient's demand over the full inspiratory cycle (neural Ti = ventilator Ti, note that *dashed red and purple lines* overlap). Increasing the inspiratory assist level (NAVA level or PAV+ gain), downregulates Pmus *(gray dotted line).* Because the patient's brain stipulates the desired V_T, changing the level of assist often has only minimal effects on the V_T, as shown by the *horizontal purple line* on the volume vs. level of assist curve. (From Jonkman AH, Rauseo M, Carteaux G, et al. Proportional modes of ventilation: Technology to assist physiology. *Intensive Care Med.* 46[12]:2301–2313.)

that occur in spontaneous breathing, PSV, NAVA, and PAV+ with respect to changes in support level and demonstrates their impact on V_T, level of assistance, and timing.[23]

Proportional modes of ventilation are overwhelmingly associated with improved patient-ventilator interaction and reduced asynchronies compared with PSV.[32–36] NAVA supports respiratory muscle unloading while preventing neuromuscular decoupling.[29] Asynchronies are reduced primarily by a reduction in missed triggers, but NAVA and PAV+ both reduce late cycling by better matching ventilator inspiratory time with neural inspiratory time.[31,33,37] Published studies suggest that preservation of diaphragmatic activity may improve distribution of volume to basilar lung regions, thereby improving gas exchange.[38,39]

Overassistance commonly observed during PSV may be linked to diaphragmatic injury.[40] Proportional modes require maintenance of diaphragmatic contraction throughout inspiration, helping to reduce the risk of this complication. Several studies have shown that proportional modes reduce the risk of overdistention.[29] Leiter and Manning describe the impact of the Hering-Breuer reflex inflation inhibition on downregulation of respiratory drive to avoid hyperinflation.[41] In this instance, Pmus and EAdi are reduced, suggesting an advantage for proportional modes. At increased end-expiratory lung volumes, the diaphragm shortens, and its disadvantaged position results in weaker effort. Patients receiving PAV+ at appropriate gain levels spent >95% of time at a driving pressure <15 cm H_2O and V_T <11 mL/kg. Higher driving pressures are often associated with severely reduced compliance.[42,43] Auto-triggering is also reduced with proportional modes, and in the presence of auto-triggering, delivered pressures and volumes are less when compared with PSV set at customary levels.[44]

The principle of operation of proportional modes reduces the risk of overinflation and ventilator-induced lung injury (VILI) while preventing both disuse atrophy of the diaphragm and excess work that favors fatigue. Jonkman and colleagues suggest caution when using proportional modes in patients with excessive levels of respiratory drive over concern that lung-protective reflexes might be overwhelmed in this scenario.[23] The major advantages of proportional modes are shown in Box 56.1.

Compared with PSV, proportional modes have been reported to reduce weaning duration and increase the chance of the patient continuing to require a patient-triggered mode.[36,45] Faster liberation from mechanical ventilation with proportional modes might be facilitated by reduced asynchronies, improved patient comfort, and fewer sleep interruptions.[36,46–49] Demoule and colleagues demonstrated no differences in weaning duration or other outcomes comparing NAVA with PSV.[50] However, Kacmarek and colleagues reported a randomized controlled trial of patients requiring mechanical ventilation for >72 hours, comparing NAVA with standard lung-protective ventilation. They found that ventilator free-days were increased by 4 days in the NAVA group (22 vs. 18 days), although no differences in mortality or other safety outcomes were identified.[51]

The shortcomings of proportional modes appear to relate to clinician understanding.[35] The interplay of gain and NAVA level on patient effort, Pmus, respiratory rate, and tidal volume is moderately complex are not always understood by bedside clinicians. Appropriate selection of both NAVA level and of gain during PAV+ likely changes with the

BOX 56.1 Potential Advantages of Proportional Modes Compared With PSV

- Avoiding overassistance
- Avoiding excessive V_T and overdistention
- Reducing asynchrony
- Preserving breath-to-breath variability
- Preserving diaphragmatic function—diaphragmatic-protective ventilation
- Facilitate weaning

progression of illness and therefore requires titration. This probably has reduced the adoption of these modes, despite clear advantages regarding synchrony. Additionally, proportional modes require an intact respiratory drive, and poor selection of patient candidates may result in dissatisfaction by clinicians. Monitoring of EAdi, separate of NAVA, may prove useful in titrating other modes of ventilation, a concept that requires further study.

CONTROL OF VENTILATION

A number of modes have been developed to maintain a desired level of minute ventilation and to automatically select ventilation parameters. These include mandatory minute volume, auto-mode, adaptive support ventilation (ASV), and adaptive ventilation mode (AVM).[52–54]

Adaptive Support Ventilation

Adaptive support ventilation is a closed-loop mode of mechanical ventilation designed to titrate ventilator output on a breath-by-breath basis, with the level of ventilatory support determined by respiratory mechanics and breathing effort. The goal of ASV is to provide a preset level of minute ventilation (V_E) while minimizing the work of breathing during ventilator support. Under normal conditions, the minute volume setting is 100% of a "normal" minute volume that is based on predicted body weight of 0.1 L/kg/min. Thus a 70-kg patient would receive a V_E of 7.0 L/min; at a setting of 150%, V_E would be 10.5 L/min.

ASV adjusts inspiratory pressure to achieve a respiratory pattern (V_T and frequency) that minimizes the work of breathing based on the Otis equation.[55] Importantly, however, the range of available V_T is controlled by the maximum pressure (Pmax) setting selected by a clinician. Breaths alternate between pressure-controlled and pressure-supported breaths, based on the presence or absence of spontaneous breathing efforts. Conceptually, ASV can provide synchronized intermittent mandatory ventilation (SIMV) + PSV, but in my experience, breaths are most commonly either all mandatory or all spontaneous. During mandatory breaths, ASV controls the inspiratory time and I:E based on measurement of the expiratory time constant (the product of resistance and compliance). Lower compliance results in a short I:E, whereas high resistance results in a longer I:E to avoid air trapping. ASV requires the clinician to set levels for FiO_2 and PEEP.

Clinical Studies of ASV

ASV can be used during the initiation, maintenance, and weaning of mechanical ventilation. It has been used in a number of studies evaluating time to discontinuation of ventilatory support after coronary artery bypass surgery.[56–63] Studying this large, relatively homogeneous, readily available population is attractive; however, this population requires ventilation primarily as a "casualty of anesthesia" and under normal circumstances has limited pulmonary dysfunction. Studies report faster weaning in half of the trials and no change in the other half. Of note, these studies find that ASV required fewer clinician/ventilator interventions, fewer arterial blood gases, and fewer ventilator alarms and reduced the incidence of postoperative atelectasis on radiograph.[63]

Choosing the appropriate minute volume target to promote weaning in this scenario has not been extensively studied and requires clinician input.[64–67] The selected V_T during ASV can exceed lung-protective limits, and the potential for VILI after surgery is a concern.[67]

Several recent trials have evaluated ASV for weaning patients with acute respiratory failure off machine support. Chen and colleagues reported their experience with ASV in a 16-bed ICU in China staffed daily by a single respiratory therapist with no coverage at night.[68] They compared management of patients with ASV with a matched historical control using SIMV + PSV. Under these rather unique circumstances the authors demonstrated that patients in the ASV group achieved extubation readiness within 1 day of enrollment more often and achieved weaning within 21 days. However, there were no differences in ICU duration or hospital stay. These findings must be considered in light of the staffing model. However, one potential advantage of closed-loop ventilation is the ability to continue appropriate care in the absence of caregivers, and this study seems to support this thesis. Recent findings during the COVID-19 pandemic suggest that in a situation where large numbers of patients with ARDS are managed by too few caregivers, the use of ASV might improve safety and efficacy of ventilatory support, especially during a surge.[69]

Kirakli and colleagues compared ASV with PSV for weaning chronic obstructive pulmonary disease (COPD) patients from ventilation.[70] They found that patients ventilated with ASV had shorter weaning times and equivalent weaning success. However, the total duration of ventilatory support did not change. The use of ASV has been reported for weaning after recovery from acute respiratory failure and after liver transplantation.[71]

ASV has been successfully used as a primary mode of ventilator support during acute respiratory failure. The algorithm, which was based on the expiratory time constant, was shown to select I:E and respiratory frequency appropriately for both obstructive and restrictive disease. Certain reports have found a reduction in manual ventilator adjustments with similar gas exchange and perhaps improved CO_2 elimination for a given combination of V_T and respiratory frequency.[72–74] Patients with obstructive disease, however, have received V_T levels outside the suggested range of current "lung-protective" guidelines.

One criticism of ASV has been the finding that V_T may approach 9–10 mL/kg in some patients.[65,75] This limitation can be overcome by appropriately setting the Pmax and V_T limits. ASV has been commercially available for over 20 years, and widespread adoption has not occurred. Although ASV may facilitate weaning when the % minute volume value is appropriately set, it appears to have no clear advantage over manual techniques. Closed-loop techniques can reduce practice variation through appropriate selection of "hard rules," such as a Pmax chosen by the operator. I have previously argued that techniques like ASV may provide the most benefit in resource-limited environments, and the work by Chen and colleagues and Wendel-Garcia and colleagues appears to support this opinion.[68,69]

Adaptive Ventilation Mode

Adaptive ventilation mode is a modification of ASV on a new ventilator platform. It includes the traditional determination of % minute volume, but also includes automated titration of rise time and flow termination of pressure support breaths. A modified version, AVM 2, differs from ASV in that rather than determining the optimal frequency and V_T based on values observed in spontaneously breathing patients, AVM 2 determines the optimal variables based on assisted ventilation. In a bench and model study, AVM 2 was associated with lower driving pressure and power.[76] Clinical trials are not currently available.

iASV

Intellivent ASV (iASV) is the logical extension of ASV to include the automated selection of FiO_2 and PEEP. The PEEP/FiO_2 controller uses the PEEP tables from the ARDS Network's Ventilation with Lower Tidal Volumes as Compared with Traditional Tidal Volumes for Acute Lung Injury and the Acute Respiratory Distress Syndrome (ARMA) and Assessment of Low tidal Volume and elevated End-expiratory volume to Obviate Lung Injury (ALVEOLI) trials. The ARMA trial

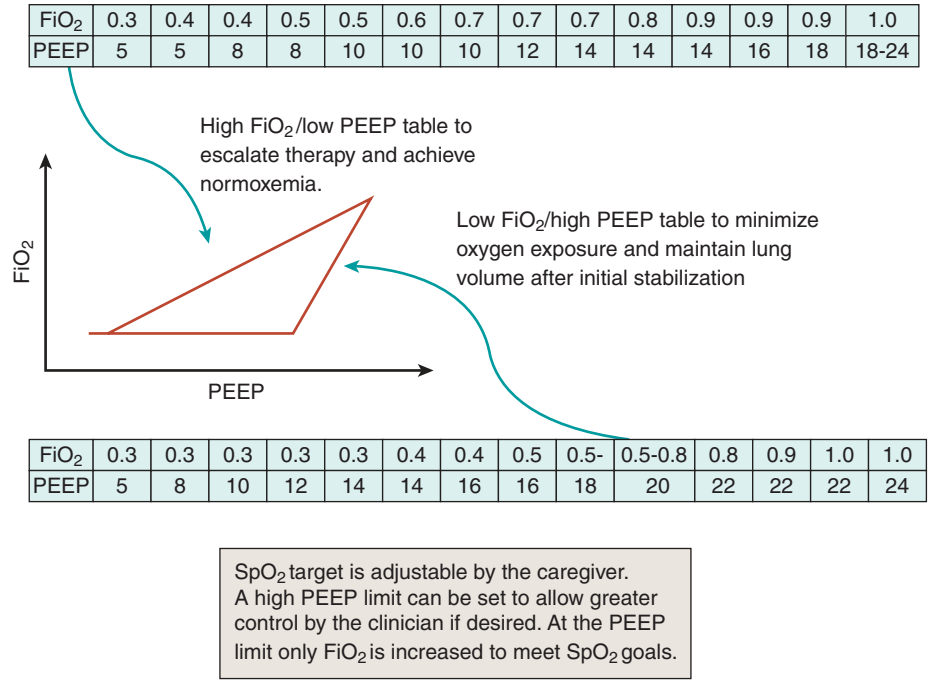

Fig. 56.2 Combination of the PEEP-FiO_2 tables from the ARDSnet ARMA and ARDSnet ALVEOLI trials used for increasing and decreasing oxygenation support during iASV. *iASV,* Intellivent adaptive support ventilation; *FiO_2,* fraction of inspired oxygen; *PEEP,* positive end-expiratory pressure; *SpO_2,* blood oxygen saturation. (From Branson RD. Modes to facilitate ventilator weaning. *Respir Care.* 2012;57[10]:1635–1648.)

used an aggressive FiO_2 strategy, whereas the ALVEOLI trial was PEEP-intensive. An integral pulse oximeter provides the input signal to the ventilator, into which the clinician can set the desired blood oxygen saturation (SpO_2). Pulse volume variability from the oximeter can also provide information regarding patient hemodynamic status, limiting the use of PEEP in favor of FiO_2 during hemodynamic compromise. As of 2021, Intellivent is not commercially available in the United States.

The minimum PEEP is 5 cm H_2O, and at initiation the controller uses the ARMA PEEP/FIO_2 table to reach the desired SpO_2. After stabilization, the FiO_2 and PEEP are weaned using the ALVEOLI table. Fig. 56.2 provides a pictograph of the PEEP/FiO_2 tables used with Intellivent.

Clinical Studies of iASV

In a preliminary trial of sedated patients with acute respiratory failure, Arnal and colleagues demonstrated that during a 2-hour crossover trial, iASV provided ventilation at lower airway pressures, tidal volumes, and FiO_2 while producing the same oxygenation results as ASV.[77] Tidal volumes were slightly lower with iASV and $PaCO_2$ was higher. In a follow-up crossover trial, iASV applied for 24 hours compared with PSV demonstrated improved oxygenation. In this study, PEEP was higher and more variable during iASV, as one might expect.[78] The authors suggested that the bio-variability of PEEP might explain the improved oxygenation. De Bie and colleagues demonstrated fewer hypoxemic events in subjects after coronary bypass and quicker return to spontaneous breathing with iASV.[79]

Clavieras and colleagues applied iASV in a wide range of patient populations ventilated for <24 hours and found that ventilator settings were selected appropriately based on the lung condition, particularly in passive patients. However, like traditional ASV, spontaneously breathing subjects (breathing with adaptive pressure support) have less variability in volume and pattern.[80] A randomized trial of iASV compared safety and efficacy with modes chosen by the attending physician as the time spent within previously defined ranges of nonoptimal and optimal ventilation. Interestingly, iASV was more likely to be in the suboptimal range for Pmax. As in previous trials, iASV made more manipulations but required fewer clinician interactions, and the variability of volumes and airway pressures were greater.[81] Fot and colleagues evaluated iASV compared with protocolized weaning and SIMV + PSV after coronary bypass grafting. They found that iASV and protocolized weaning had similar outcomes and shortened weaning compared with traditional methods. The authors noted the reduction in clinician interaction with the ventilator, but no other advantages.[82] Arnal and others compared iASV with either PSV or VC-CMV in 60 subjects with respiratory failure. They concluded that iASV reduces the number of manual ventilator setting changes with no difference in the number of arterial blood gas analyses or sedation use. Using a Likert scale, caregivers rated iASV as easier to use compared with conventional ventilation modes.[83] More recently, Arnal and colleagues demonstrated that across a wide variety of patients, iASV provided a lower driving pressure and lower mechanical power than traditional ventilation.[84] Work by Buiteman-Kruizinga and colleagues confirmed this finding.[85,86]

Smartcare PS

SmartCare PS describes control of PSV where the pressure support level is based on the patient's V_T, respiratory frequency, end-tidal carbon dioxide ($ETCO_2$), and a series of presets based on the patient condition (e.g., presence of COPD or neurologic injury). SmartCare PS adjusts pressure support to maintain the patient in a "normal" range of ventilation, which is typically defined as a V_T 300 mL, a respiratory frequency between 12 breaths/min and 30 breaths/min, and $ETCO_2$ <55 mm Hg (this can be adapted for subjects with COPD or neurologic injury). Outside of the normal range, SmartCare PS defines other conditions and manipulates the pressure support based on the

current value, the clinician input parameters, and the patient's historical breathing pattern. SmartCare PS is intended for weaning and therefore not used clinically for the supported phase of acute respiratory failure.[11]

Clinical Studies of Smartcare PS

Introduced in 1996, SmartCare PS has been evaluated in a number of weaning trials.[87–92] The original trial simply compared the duration of ventilation in the specified ranges of comfort with clinician-selected PSV. This study found that SmartCare PS maintained patients in the clinician-desired ranges far more frequently.[89] In 2006 Lellouche and coauthors published the first and largest randomized trial compared with traditional weaning in five European centers. This report found significantly shorter weaning times with SmartCare PS compared with traditional weaning. However, in at least two centers, spontaneous breathing trials were not used in the control arm.[87] This may be viewed as a limitation of the study, but does represent a pragmatic trial. Across the world, the use of protocolized weaning clinical practice guidelines are espoused but not routinely implemented.

Subsequent trials of SmartCare PS have found both advantage and no advantage compared with traditional weaning based on patient condition (sepsis vs. COPD vs. cardiac surgery), the type and staffing of ICU, and patient age (adults vs. pediatrics).[93,94] Cochrane reviews of automated weaning routinely find that automated weaning demonstrates approximately a 30% reduction in weaning time compared with traditional weaning. However, the lack of standards in the control arms of trials, trial heterogeneity, and small numbers limit the strength of these conclusions.[91,95] Large multicenter trials are still needed to determine the value of SmartCare PS in routine practice.

Automated Control of Inspired Oxygen

Despite being initially described in neonates nearly 50 years ago, closed-loop control of inspired oxygen is not Food and Drug Administration (FDA) approved.[96] iASV includes closed-loop control of FiO_2 with and without PEEP control. Claure and others introduced a closed-loop FiO_2 system for neonates over two decades ago.[97] The system is a negative feedback controller that adjusts the FiO_2 in an effort to maintain the set SpO_2 target. Numerous studies have demonstrated reduced numbers and durations of desaturation events, less frequent hyperoxemia, and reduced staff burdens in the neonatal intensive care unit (NICU).[98–106] In the NICU, where the consequences of both hyperoxemia and hypoxemia have been known for decades, the introduction of closed-loop control of FiO_2 is overdue.

In adults, automated FiO_2 control has also been shown to reduce hyperoxemia, reduce the duration of hypoxemia, reduce clinician interventions, and conserve oxygen resources.[107]

Concerns with Automated Control of Ventilation

Automation of mechanical ventilation offers a number of advantages, as previously described. The potential disadvantages are less frequently discussed but require additional research. As an example, if the ventilation system increases PEEP and/or FiO_2 rapidly in response to hypoxemia and prevents the typical desaturation events that routinely alert caregivers to worsening lung function, this must be communicated to the staff. Increases in PEEP and airway pressures that may result in hemodynamic compromise also require additional safety measures. As clinicians, we consider heart rate, blood pressure, filling pressures, vasopressor therapy, and fluid status during manipulation of mean airway pressures. At present, no ventilation system has the ability to include these additional inputs into the ventilator decision process. It may be that limiting PEEP is needed and that increases beyond a certain value (e.g., to <12 cm H_2O) must be approved by a clinician with knowledge of hemodynamic performance and current therapy.

As seen with several of these techniques, certain situations can result in excessive V_T and pressure delivery, perhaps leading inadvertently to VILI. Alarm settings and alert settings require additional enhancements.

CONCLUSION

Simple closed-loop control of mechanical ventilation is widely deployed and operates behind the ventilator interface. More complex systems, described as intelligent control, are commercially available but have yet to gain widespread acceptance.[108] New trials demonstrating cost/benefit advantages that accrue to automated ventilation are required. Simply reducing the number of caregiver interactions is not an advantage for the patient or the staff. In fact, automated systems causing lack of situational awareness of the ICU are a concern. Along with these autonomous systems, monitoring and displays that easily inform the staff of the patient's current condition and response to therapy are required. Alert notifications for sudden escalation of therapy are required to assure patient safety.

The use of automated ventilation clearly has utility in remote settings that lack the timely input of experts. There are over 1000 critical access hospitals in the United States, most with fewer than 50 beds, that are the entry point to the healthcare system in rural America. These hospitals typically lack ICUs, trained onsite critical care providers, and respiratory care expertise. Remote care in disaster and military medicine is another area where local expertise may not match the severity of patient illness. These environments represent a natural fit for automated ventilation. Experiences from the COVID-19 pandemic will further expand the use of automated systems. Whether automated ventilation will be accepted in large academic medical centers remains to be seen.

KEY POINTS

- Closed-loop control modes of mechanical ventilation modify ventilator output based on respiratory mechanics and gas exchange variables.
- Automated control of ventilation and oxygenation can provide safe and effective ventilatory support while maintaining evidence-based lung protection.
- Disadvantages of automated modes include loss of situational awareness and reduced attention by caregivers.
- Automated modes of ventilatory support have been shown to reduce the interaction of caregivers and ventilator, perhaps decreasing workload, but this has not been demonstrated as a patient benefit.
- In the absence of expert oversight, automated ventilatory support may improve safety.
- Automated control of inspired oxygen has been demonstrated to reduce the incidence of hypoxemia and hyperoxemia in infants and adults.
- Closed-loop control of PEEP poses challenges related to ongoing assessment of hemodynamics.
- Closed-loop systems, including NAVA and PAV have been demonstrated to reduce asynchrony.

The timeliness of this paper matching COVID-19, patient surges, and ventilator shortages is perfect. In a scenario where patients are too many and experienced staff are too few, the advantages of auomated systems are highlighted. These findings hold true for similar environments, including transport, military medicine, and prehospital care.

Chatburn RL, El-Khatib M, Mireles-Cabodevila E. A taxonomy for mechanical ventilation: 10 fundamental maxims. *Respir Care*. 2014;59(11):1747–1763.
This paper provides a cogent scheme for classifying modes of mechanical ventilation with particular attention to automated systems. It is clear that one of the largest impediments to the introduction of new techniques is lack of understanding by bedside clinicians. Automated systems, by virtue of frequent automated titration, can further distance the staff from the settings. The paper suggests a change in paradigm, focusing on the current response of the patient versus the settings on the ventilator.

Weaning from Mechanical Ventilation

Ferran Roche-Campo, Hernán Aguirre-Bermeo, and Jordi Mancebo

THE CONCEPT OF LIBERATION AND EXTUBATION

Weaning from mechanical ventilation refers to the transition period from total ventilatory support to spontaneous breathing. Approximately 70% of intubated mechanically ventilated patients are extubated after the first spontaneous breathing trial (SBT), either by ventilator disconnection or after breathing at low levels of pressure support for short periods ranging from 30 to 120 minutes.[1,2] The remaining patients (about 30%) require progressive withdrawal from artificial ventilatory support. In half of these patients, mechanical ventilation can be withdrawn in less than 1 week; however, the other half of patients require more than 1 week of mechanical ventilation. Importantly, in this latter group, the prognosis is markedly worse.[3,4]

Early liberation from mechanical ventilation and removal of the endotracheal tube is clinically important. Unnecessary prolongation of mechanical ventilation increases the risk of complications, including infections (particularly of bronchopulmonary origin), barotrauma, cardiovascular compromise, tracheal injuries, and muscle deconditioning. To maximize patient outcomes, clinicians should attempt to hasten the process that ultimately leads to removal of the endotracheal tube.[5] Every additional day that passes after the first weaning attempt increases the risk of death.[3]

Liberation and extubation are different concepts.[6] Liberation refers to weaning from mechanical ventilation, meaning that the patient no longer requires ventilatory support. When liberation has been achieved, the clinician must consider a different question: "Is the patient able to breathe spontaneously and protect the airway without the endotracheal tube?" Removal of the endotracheal tube is referred to as *extubation.* The extubation failure rate is variable, ranging from 5% to 20% of extubated patients.[1,7–9]

MECHANISMS THAT EXPLAIN LIBERATION FAILURE

Respiratory Pump Failure

The most common reason for weaning failure is respiratory pump insufficiency, which is caused by an imbalance between the patient's endurance capabilities and respiratory demands.[10–13] Jubran and Tobin[14] investigated the progression of respiratory mechanics during SBT in patients with chronic obstructive pulmonary disease (COPD). At the very beginning of the trials, patients who subsequently failed had a slightly higher airway resistance, respiratory system elastance, and intrinsic positive end-expiratory pressure (PEEP) compared with those who succeeded. However, during the trials, respiratory mechanics progressively worsened in patients who failed to achieve ventilator liberation. Subjects who failed quickly developed rapid, shallow breathing, and most also developed (but more slowly) an increase in partial pressure of carbon dioxide ($PaCO_2$). Together, these abnormalities of mechanics and chemical drive resulted in increased inspiratory muscle effort. Breathing exertion was likely close to the threshold of muscle fatigue in some patients.

Laghi and Tobin[15] studied 19 intubated patients during weaning from mechanical ventilation; of these, 11 patients failed and 8 succeeded. Several physiologic indices were measured before and 30 minutes after SBT. Before the SBT, the transdiaphragmatic twitch pressure, elicited by magnetic bilateral phrenic stimulation, did not differ between the patients who failed or succeeded at ventilator liberation, and this variable did not decrease after the trial in either group. Patients failing the SBT were reconnected to the ventilator because of clinical signs of intolerance. It was concluded that weaning failure was not accompanied by low-frequency diaphragmatic fatigue. Weaning failure patients did, however, exhibit severe diaphragmatic weakness, because twitch pressures were always low.

Common Disorders That Alter the Balance of Capacity and Load in Critical Illness

Reduced Neuromuscular Capacity and Reserve

Traditionally, peripheral muscular dysfunction—known as *critical illness polyneuropathy*—was associated with difficult weaning.[16] However, in recent years, respiratory muscle dysfunction (mainly the diaphragm)—known as *critical illness–associated diaphragm weakness*[17]—is a condition whose existence has become recognized and its properties better characterized. We now know that respiratory muscle dysfunction is independent of peripheral polyneuropathy and twice as prevalent (present in up to 60% of ventilated patients), exerting a greater impact on weaning.[18] Diaphragm weakness is mainly associated with muscle disuse or a low level of effort associated with controlled ventilation modalities,[19] but it has also been associated with a high breathing effort because of insufficient respiratory assistance.[20] The optimal balance between diaphragm overuse and underuse is difficult to determine. However, it stands to reason that the appropriate level of assisted ventilation could prevent diaphragm atrophy.[21]

Increased Muscle Loads

The increased work of breathing results from increased mechanical loads (elastic and/or resistive). Increased elastic workloads occur when lung and chest wall compliance are reduced (e.g., pulmonary edema, extreme hyperinflation during an acute asthmatic attack, pulmonary fibrosis, abdominal distention, severe obesity, trauma, or thoracic deformities).[15] The presence of intrinsic PEEP is another example of increased elastic workload, and this phenomenon is relatively common, especially in patients with COPD.[22,23] Resistive work of breathing during critical illness may increase as a result of bronchospasm, excessive secretions, endotracheal tube resistance (which increases with kinking and deposition of secretions), and ventilator valves/circuits and

humidifiers, especially when conditioning of inspired gases is provided with heat and moisture exchangers. The latter also increase the dead space posed by the external apparatus.

CARDIOVASCULAR DYSFUNCTION

The presence of cardiovascular dysfunction can contribute to weaning failure by augmenting the loads on the respiratory system and reducing neuromuscular capacity.[24,25] Cardiovascular dysfunction can result from physiologic changes that occur during the resumption of unassisted spontaneous breathing.[26] When spontaneous breathing resumes, the intrathoracic pressure during inspiration is negative, leading to increased left ventricular preload and afterload. Increased heart loads augment myocardial oxygen demand and may precipitate myocardial ischemia in patients with coronary artery disease.[27] Pulmonary vascular congestion may also increase.

Jubran and colleagues[28] examined hemodynamics and mixed venous saturation in patients during weaning trials. Successfully weaned patients demonstrated increases in the cardiac index and oxygen transport compared with values observed during mechanical ventilation. Patients who failed weaning did not increase oxygen delivery to the tissues because, in part, of elevated right and left ventricular afterloads. Consequently, these abnormalities have the potential to jeopardize respiratory muscle function.

In intensive care unit (ICU) patients, congestive heart failure in predisposed patients may occur as a consequence of an increase in venous return, volume overload, or catecholamine release induced by physiologic stresses, such as weaning. Impairment of cardiovascular function can be magnified in cases with a positive fluid balance.[29]

Studies have shown that using a T-tube (instead of pressure support and PEEP) to perform an SBT in difficult-to-wean patients may elicit an adverse cardiovascular response; when support is added (in the form of pressure support and PEEP), respiratory and cardiovascular function both improve.[30]

In the ICU setting, noninvasive tools are available (e.g., echocardiography and measurement of plasma B-type natriuretic peptide [BNP]) to help diagnose cardiovascular dysfunction. Up to 50% of patients who fail a weaning test exhibit cardiogenic pulmonary edema (based on BNP measurements and/or echocardiography), which is more common in patients with COPD and in patients with underlying cardiac dysfunction.[31]

Mekontso-Dessap and colleagues showed that BNP-guided administration of diuretics can reduce weaning time, particularly in patients with left ventricular systolic dysfunction.[32] That same group of authors has also shown that isolated diastolic dysfunction may be associated with a longer weaning time and increased filling pressures, with impaired left ventricular relaxation potentially being a key mechanism for failure of the weaning trial.[33]

PREDICTION OF WEANING AND EXTUBATION OUTCOMES

Yang and Tobin[34] studied the predictive power of several weaning indices, finding that the rapid shallow breathing index (f/VT) had the best predictive value. In their study, 95% of patients with an f/VT ratio >105 failed an SBT. The rapid shallow breathing index appears to be the most useful bedside method of screening for liberation readiness. If the f/VT value is less than 105, then an SBT of 30–120 minutes should be used to confirm the patient's capacity to breathe spontaneously without assistance. However, because the f/VT has a low specificity (the test is positive in a relatively large proportion of weaning failure subjects), the f/VT alone is insufficient to predict weaning failure. From a practical point of view, the information conveyed by weaning indices and clinical judgment should be considered together in making clinically important decisions regarding extubation.

Patients incapable of protecting their airway and clearing secretions with an effective cough are at an increased risk of extubation failure. Traditional assessment has consisted of demonstrating a cough reflex when the airways are stimulated with a suction catheter and by the absence of excessive secretions. Smina and colleagues[35] found that patients with a peak expiratory flow equal to or below 60 L/min were five times more likely to have an unsuccessful extubation than patients with expiratory flows greater than 60 L/min.

EXTUBATION FAILURE

Extubation failure can be defined as the need to reintubate and reinstitute ventilatory assistance within the first 24–48 hours and up to 7 days afterwards. The reintubation rate ranges from 10% to 20%.[3,7]

Mechanisms explaining extubation failure include the presence of abnormalities not diagnosed at the time extubation was performed (e.g., pneumonia, unaddressed cardiac dysfunction, or new arrhythmia precipitated by the physiologic stress that accompanies spontaneous breathing effort) and the inability to maintain the tracheobronchial tree free of copious secretions.[9,36,37]

Extubation failure results in a marked increase in the duration of mechanical ventilation, ICU and hospital stay, need for tracheostomy, and hospital mortality.[3,7,9,38–40] Further studies are needed to understand and detail the pathophysiologic mechanisms of extubation failure.

PROGRESSIVE WITHDRAWAL OF MECHANICAL VENTILATION

When patients fail SBTs, pressure support ventilation (PSV) is the modality most often used for the progressive withdrawal of mechanical ventilation.[4,41] Two prospective multicenter randomized clinical trials have shown that the implementation of synchronized intermittent mandatory ventilation (SIMV) is generally less efficacious than other techniques.[1,2]

Sedation and analgesia are important components of care for mechanically ventilated patients. An important study found that daily interruption of sedation significantly reduced the duration of mechanical ventilation.[42] Because sedation and weaning from mechanical ventilation cannot be separated from one another, the results are more effective when these two strategies are combined (i.e., daily interruption of sedation plus systematic use of SBTs) to hasten liberation from the ventilator than when used separately.[43]

PRESSURE SUPPORT VENTILATION

Clinical experience[1,2] and data from clinical trials[44,45] suggest that the "optimal" initial levels for PSV are those that provide respiratory rates between 25 and 30 breaths/min. In this setting, it is particularly important to rule out the existence of asynchronous breathing or ineffective respiratory efforts. A ventilator setting with an unnecessarily high level of pressure support can be the cause of patient–ventilator dyssynchrony. Patients who show ineffective triggering are on mechanical ventilation for longer periods, and tracheostomy is also more often indicated in these patients.[46] A subsequent study found a decrease in the number of ineffective respiratory efforts without changes in the work required for breathing and without modifications in the respiratory rate when pressure support levels were reduced.[47] These studies[46,47] indicate that some patients receive excessive levels of mechanical ventilation during the weaning process. These findings are vital, because they indicate that there are modifiable causes (i.e., excessively high levels of assistance) of detrimental patient–ventilator interactions.

The level of external PEEP used in patients with clinically suspected dynamic hyperinflation and dynamic airway collapse should be adjusted with great caution, because the measurement of dynamic intrinsic PEEP in spontaneously breathing patients is not easily performed. To that end, it has been suggested that external PEEP can be titrated according to the changes in airway occlusion pressure.[48]

During weaning, the PSV levels are decreased according to the patient's clinical tolerance, usually by steps of 2–4 cm H_2O at least twice a day. In general, clinical tolerance to a level of PSV of about 8 cm H_2O without PEEP is required before performing extubation, although this level may vary according to a given patient's overall clinical status and endotracheal tube diameter.

NEW MODALITIES

Several novel weaning modalities have been examined, including those that use closed-loop PSV[49–51] or proportional modes, such as proportional assist ventilation (PAV),[52,53] to provide a continuous adaptation of ventilator assistance to the patient's needs 24 hours a day.

Lellouche and colleagues examined automated weaning with the semi-closed-loop PSV system in two groups of patients during the weaning period.[54] In the control group, weaning was performed as per usual care based on written weaning guidelines. In the study group, weaning was performed using a computer-driven weaning protocol. In the study group, weaning time was significantly shorter compared with usual weaning (3 vs. 5 days; $P = .01$). This decrease in weaning time was associated with a decrease in both the total duration of mechanical ventilation (7.5 vs. 12 days; $P = .003$) and ICU length of stay (12 vs. 15.5 days; $P = .02$).

A subsequent study by Rose and colleagues[55] comparing weaning duration with a semi-closed-loop mode versus usual care (weaning managed by experienced specialized critical care nurses using a 1:1 nurse-to-patient ratio) found no differences between the two strategies. Schadler and colleagues[56] found that the semi-closed-loop system decreased the duration of mechanical ventilation in a specific subgroup of patients (cardiac surgery). Finally, a study by Burns and colleagues[57] compared automated weaning with the semi-closed-loop mode versus a standardized protocol in critically ill patients, finding that patients on automated weaning had significantly shorter median times to first successful SBT (1 day vs. 4 days; $P < .001$) and to successful extubation (4 days vs. 5 days; $P = .01$).

In the meta-analysis carried out by Burns and colleagues, the authors concluded that, compared with nonautomated weaning strategies, weaning with semi-closed-loop PSV significantly decreased weaning time without increasing the risk of adverse events.[58] A pilot study compared PAV with conventional PSV and found that PAV is both safe and feasible.[59]

Despite these positive results, in actual clinical practice, the use of these techniques remains quite limited and their success largely a matter of operator skill and familiarity.[4]

SPONTANEOUS BREATHING WITH A T-TUBE

Tolerance to breathing through a T-tube represents a good test to evaluate a patient's capacity to maintain autonomous, spontaneous breathing.[60] The optimal duration of a T-tube trial is at least 30 minutes and no more than 120 minutes.

One disadvantage of the T-tube trial is related to the absence of a connection to a mechanical ventilator. Because patients are not monitored by the alarms on the ventilator, they need to be closely supervised. Moreover, the unassisted breathing through the resistance of the endotracheal tube is a "stress test" for the cardiorespiratory system that, although informative, may itself predispose to weaning failure.

Fernandez et al.[61] showed that in patients who successfully passed the SBT, reconnection to mechanical ventilation for 1 hour, using the same parameters in place before the SBT, significantly reduced reintubation rates in the 48 hours after extubation (5% vs. 14%).

Traditionally, SBTs with pressure support or a T-tube have been considered suitable methods for evaluating a patient's capacity for spontaneous breathing.[7] Nevertheless, Subirà and colleagues recently compared the relative effects of an initial SBT consisting of 30 minutes of PSV with 8 cm H_2O (a less-demanding approach for the patient) to an SBT consisting of 120 minutes of T-tube (a more-demanding approach), finding that the less-demanding strategy resulted in higher rates of successful weaning.[62] These data support the view that in most patients (80%) who are extubated in the first SBT, 30 minutes of PSV may be sufficient to identify those who present a high probability of successful extubation. This concept may hold true in patients whose pretest likelihood suggests a high probability of successful extubation.[63] However, we believe that the use of T-tube weaning trials in difficult-to-wean patients should be considered as an alternative to PSV that induces greater changes in the breathing pattern, inspiratory muscle effort, and cardiovascular response than T-tube in this fragile population.[30]

VENTILATORY SUPPORT AFTER EXTUBATION

Noninvasive Ventilation and High-Flow Nasal Cannula

As discussed earlier, extubation is a crucial event in the management of patients on mechanical ventilation, and extubation failure is associated with higher mortality.[36] Numerous studies published in recent years have evaluated the use of noninvasive ventilation (NIV) and high-flow oxygen therapy as measures to facilitate extubation.

From a practical point of view, there are two different ventilatory support strategies. The first is a facilitative strategy, which permits early extubation in patients who meet criteria for an SBT but who do not pass the test. The second is a preventive strategy, aimed at preventing the emergence of post-extubation respiratory failure. Fig. 57.1 shows our proposed algorithm for ventilatory support.

1. Facilitative Strategy

Currently, NIV is the only approach recommended to facilitate early extubation in selected patients with hypercapnic respiratory failure, and it should only be applied in centers with experience with this technique.

Examples of patients suitable for NIV include those with acute-on-chronic respiratory failure who present with hypercapnia at the end of the weaning test. Various studies have shown that the early application of NIV to facilitate extubation in this patient population reduces the duration of invasive ventilation without increasing the reintubation rate, and it may even reduce mortality rates.[64–66]

At present, there are no firm recommendations on the facilitative use of NIV or high-flow nasal oxygen (HFNO) in patients with non-hypercapnic respiratory failure. Perkins and colleagues, in a group of patients with difficulty weaning and a failed SBT, compared two different approaches: (1) NIV with early extubation (despite the failed SBT) and (2) continued invasive mechanical ventilation until patients were able to pass the SBT.[67] Those authors found that early extubation with NIV did not reduce ventilation time (4.3 vs. 4.5 days in the invasive group, adjusted hazard ratio 1.1; 95% confidence interval [CI], 0.89–1.40). Despite the negative results of this study, these findings imply the wisdom of a change in the current paradigm under which patients who fail to pass an SBT should remain intubated. No studies have been conducted with HFNO in these conditions, but we can expect that such a study will performed in the near future.

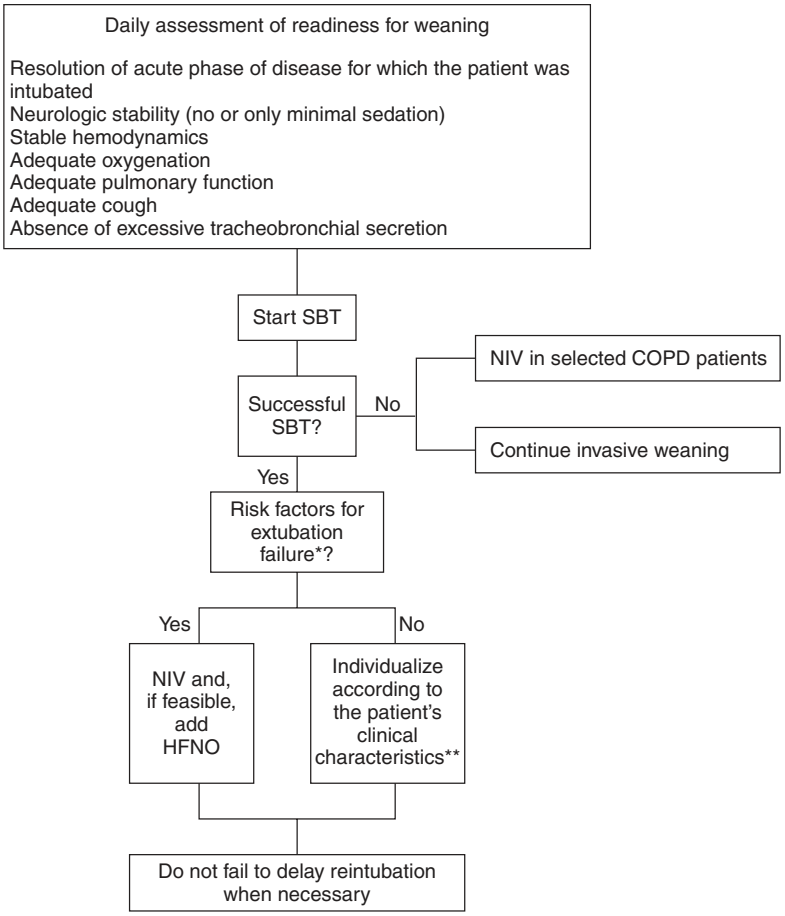

Fig. 57.1 Algorithm for Ventilator Support After Extubation in Critically Ill Medical Patients.
*Risk factors for extubation failure:
– Older than 65 years of age OR
– Presence of any underlying chronic cardiac disease (left ventricular ejection fraction ≤45%; history of cardiogenic pulmonary edema; documented ischemic heart disease; permanent atrial fibrillation).
– Presence of any underlying lung disease (chronic obstructive pulmonary disease; obesity hypoventilation syndrome; restrictive pulmonary disease).
A patient with pancreatitis and fraction of inspired oxygen (FiO_2) 40% is **NOT the same as a simple post-operative patient after 48 hours of ventilation.
COPD, Chronic obstructive pulmonary disease; *HFNO,* high-flow nasal oxygen; *NIV,* noninvasive ventilation; *SBT,* spontaneous breathing trial.

2. Preventive Strategy

In low-risk patients (under age 65 and/or with no underlying respiratory or cardiac pathology), there is evidence that high-flow oxygenation can prevent reintubation. Hernández and colleagues[68] conducted a randomized multicenter trial to compare the efficacy of 24 hours of high-flow versus conventional oxygen therapy after extubation and demonstrated that patients who received HFNO had a lower reintubation rate (5% vs. 12%, $P = .03$). The 12% reintubation rate in the control group in that study is surprisingly high for this population of low-risk patients, which is why we believe that it is premature to recommend the routine use of HFNO for all patients post-extubation. Confirmatory trials will be necessary.

In high-risk patients (older than age 65 or with any underlying chronic heart or lung disease), numerous studies have shown that NIV applied immediately after extubation reduces reintubation rates, which is why this approach is absolutely recommended for this patient population.[65,66,69,70] However, not all patients are able to tolerate NIV well. In this context, HFNO is an alternative strategy proven to be noninferior to NIV in preventing reintubation in high-risk patients.[68] Recently, Thille and colleagues[71] showed that NIV combined with HFNO for ≥48 hours is more effective than HFNO alone in reducing reintubation rates at day 7 (12% vs. 18%, $P = .02$).[71] The results of that study demonstrate, once again, the importance of NIV in at-risk patients and suggest that HFNO could be a complementary treatment that works synergistically with NIV.

CLASSIFICATION OF WEANING

A consensus conference on classification[72] defined three groups of weaning patients: (1) simple weaning (patients who proceed from initiation of weaning to successful extubation on the first attempt); (2) difficult weaning (patients who fail initial weaning and require up to 7 days from the first SBT to achieve successful weaning); and (3) prolonged weaning (patients who require more than 7 days from the first SBT to achieve successful weaning).

The objective of this classification system was to provide greater epidemiologic insight into the weaning process and its association with outcomes.[72] The simple weaning group represents 60%–70% of ventilated patients, whereas the difficult group accounts for 20%–25% of patients, and the prolonged group 5%–15% of patients.[73] Several

studies[74–78] have evaluated this classification system and the distribution of the groups, showing that simple weaning is the most common scenario and that prolonged weaning is associated with poorer outcomes.

Nevertheless, this simple classification system was not designed specifically for this purpose, nor does it tell us exactly what occurs in all patients who receive invasive mechanical ventilation. The WIND study[3]—a prospective, multinational, multicenter study—was designed to answer these questions. The WIND study included all patients on ventilation during a 3-month period, finding that 24% of these patients did not even start the weaning process. The authors classified the remaining patients into three different groups, as follows: simple weaning, comprising the 57% of patients who completed weaning in the first 24 hours; difficult weaning, consisting of the 10% of patients who experienced weaning difficulties lasting more than 1 day but less than 7 days; and prolonged weaning, which included the remaining 9% of patients, who presented with prolonged weaning (>7 days). The ICU mortality rates in the three groups were, respectively, 6%, 17%, and 29%. Clearly, the patients in the third group represent a special population that requires more hospital resources, and a different approach to weaning is probably necessary in these patients.

SUMMARY

The vast majority of intubated mechanically ventilated patients can be successfully liberated from the ventilator after passing an SBT. The best strategy to shorten the total time on mechanical ventilation is a simple clinical approach applied daily to determine the patient's ability to tolerate unassisted spontaneous breathing. Under this approach, at least one daily screening test should be performed, the first early in the day; if this test is positive, then a confirmatory SBT (30–120 minutes in duration) should be performed. In patients who fail multiple SBTs, different techniques for progressive withdrawal of mechanical ventilation can be applied. In this scenario, the most common technique is PSV. Automated systems seem to perform at least as well as usual care, and may even perform better. NIV and HFNO may be useful to hasten the weaning process and avoid reintubation in selected populations. Patients with a long weaning duration (>7 days from the first SBT) have poorer outcomes. Extubation failure is poorly understood and associated with a high mortality rate.

KEY POINTS

- In the vast majority of patients, weaning from mechanical ventilation is a simple process. In this scenario, patients are extubated at the first SBT attempt and outcomes are favorable.
- The implementation of a weaning strategy based on solid clinical and pathophysiologic knowledge improves outcomes in terms of the duration of mechanical ventilation and length of ICU stay. This positive effect is mainly attributable to daily screening to determine the patient's ability to maintain spontaneous breathing.
- A relatively small group of patients require prolonged weaning, which is associated with worse outcomes. These patients need to be carefully evaluated for neuromuscular and cardiovascular dysfunction and could benefit from adjunctive therapy.
- The underlying mechanisms for extubation failure remain poorly understood, and more research is needed in this area. One common cause of extubation failure is acute pulmonary edema, but it is also easy to treat. Patients with extubation failure have a higher mortality rate that varies according to the specific cause of the failure.
- Noninvasive ventilation (NIV) and high-flow nasal therapy are used to facilitate weaning and extubation. In some high-risk cases, NIV plus adjuvant high-flow nasal oxygen (HFNO) may be appropriate.

Adjunctive Respiratory Therapy

Sanjay Manocha and Keith R. Walley

Many critically ill patients are unable to effectively clear secretions that accumulate in the central and peripheral airways. This failure can be the result of factors such as increased secretion production, impaired cough reflex, weakness, and pain. An endotracheal tube prevents closure of the glottis and the high expiratory flows necessary for effective coughing, thereby promoting the retention of secretions. In addition, in critically ill patients, the cilia of the pulmonary tree are impaired in function and reduced in number.[1,2] This leads to an increased risk of aspiration, atelectasis, and pneumonia, which are all detrimental to a critically ill patient.

Adjunctive respiratory therapies aim to prevent and treat respiratory complications that are encountered in critically ill patients (Table 58.1).

METHODS TO IMPROVE PULMONARY MUCOCILIARY CLEARANCE

Percussion

Percussion of the chest can aid in secretion clearance. By clapping cupped hands over the thorax in a rhythmic fashion or using mechanical devices that mimic the same action, the pulsating force so generated is transmitted through the thorax to dislodge airway secretions. Used in conjunction with postural drainage, this action often provides an effective method to mobilize secretions from the pulmonary tract.[3]

High-Frequency Chest Compression

High-frequency chest compression (HFCC) enhances mucus clearance. Using an automated vest device worn by the patient that is attached to an air-pulse generator, small volumes of gas are introduced into the vest bladders at a rapid rate that ranges from 5 to 25 Hz, elevating pressures up to 50 cm H_2O. This technique, primarily used in cystic fibrosis patients, has efficacy equivalent to conventional chest physiotherapy techniques of percussion and postural drainage.[4,5] In an observational study comparing HFCC with percussion and postural drainage in nine long-term mechanically ventilated patients, no difference was seen in the amount of sputum production, oxygen saturation, or patient comfort.[6] HFCC was determined to be safe and felt to save staff time. In a small randomized trial of patients extubated after being ventilated for more than 21 days, the addition of HFCC improved sputum clearance but did not have a significant impact on weaning success rates.[7] In a larger randomized trial conducted in a heterogeneous patient population, HFCC was more comfortable than chest physiotherapy, but did not produce a measurable difference in hospital length of stay, resolution of lobar atelectasis, or risk of nosocomial pneumonia.[8] It is difficult to apply this technique to most critically ill patients because of the size of the vest, as covering the thorax may prevent adequate monitoring.

Manual Hyperinflation

Manual hyperinflation with an inflation bag aims to inflate the lungs slowly to 1.5–2 times the tidal volume or to peak airway pressures of 40 cm H_2O. An inspiratory pause allows for filling of alveoli with slow time constants. This pause is followed by a quick release to allow for rapid deflation. The goals are to recruit atelectatic lung regions, to improve oxygenation, and to improve clearance of airway secretions. Similar to recruitment maneuvers described with mechanical ventilators, manual hyperinflation leads to only transient improvements in oxygenation. Thus it may facilitate secretion clearance but without any identified long-term, clinically significant improvement in patient outcomes.[9–13] It also has the potential disadvantage of requiring a ventilator disconnect—this method can be mimicked by a mechanical ventilator without doing so.[14]

Contraindications to manual hyperinflation include hemodynamic compromise and elevated intracranial pressure. There is also a risk of barotrauma because of preferential inflation of open lung regions that are highly compliant compared with the collapsed regions.

Mechanical Insufflation–Exsufflation

Similar to manual hyperinflation, mechanical insufflation–exsufflation can assist in secretion clearance from the peripheral airways. It is commonly used in patients with chronic neuromuscular diseases to augment the cough. For the critically ill patient population, a recent systematic review judged the quality of evidence to be low.[15] A single small clinical trial found reduced chances of extubation failure when used with noninvasive ventilation and manual cough assistance.[16] Insufflation–exsufflation is generally well-tolerated, but side effects include hypotension, nausea, and abdominal distention. In those with respiratory compromise who require positive pressure ventilation, the disconnect or removal of ventilatory support needed to accomplish this intervention may lead to oxygen desaturation and de-recruitment, thereby limiting its use in the intensive care unit (ICU).

Positioning and Mobilization

Mobilization of patients in the ICU, either through active or passive limb exercises, may improve overall patient well-being and, in the long term, may lead to better patient outcomes. In one report, the addition of early physiotherapy and occupational therapy to daily interruption of sedation resulted in more ventilator-free days and improved functional capacity.[17]

The now standard default positioning of the patient with the head of the bed elevated to at least 30 degrees from horizontal appears to significantly reduce the risk of aspiration and ventilator-associated pneumonia.[18] Upright positioning of patients in whom there is no contraindication increases resting lung volumes and therefore has benefits for gas exchange and work of breathing, especially among

TABLE 58.1 Adjunctive Respiratory Therapies

Methods to Improve Pulmonary Mucociliary Clearance
Chest physiotherapy:
• Percussion
• Postural drainage
• Chest vibration
Suctioning:
• Oropharyngeal suctioning
• Nasopharyngeal suctioning
• Endotracheal suctioning
Continuous lateral rotation
Positive expiratory pressure devices
Forced expiration
Closed chest oscillation
Bronchoscopy
Manual hyperinflation
Mechanical insufflation–exsufflation
Bronchodilators
Mucoactive agents
Methods to Improve Lung Expansion
Deep breathing
Incentive spirometry
Intermittent positive ventilation
Optimum body position
CPAP therapy
Methods to Improve Oxygenation and Ventilation
Inhaled vasodilators:
• Nitric oxide
• Prostaglandins
Helium–oxygen (heliox)

CPAP, Continuous positive airway pressure.

those in whom the supine or semirecumbent position leads to an unusually increased work of breathing. In some individuals with unilateral lung disease, positioning with the affected side up can lead to improved ventilation/perfusion ($\dot{V}/\dot{Q}$) matching, in part by increasing perfusion to the dependent "good" side.[19,20] If atelectasis secondary to retained secretions is the cause, having the affected side up leads to improved drainage of airway secretions.

Postural drainage involves positioning the body to allow gravity to assist in the movement of secretions and is indicated in those rather unusual patients with sputum production volumes of more than 25–30 mL/day and who have difficulty clearing their secretions.[21]

Tracheal Suction

Used in conjunction with other techniques to mobilize secretions from the peripheral to the central airways, suctioning is an effective way of removing secretions to improve bronchial hygiene. Using an open method, the patient's artificial airway is disconnected from the ventilator and a disposable suction catheter is inserted through the tube. A closed system involves a suction catheter within a protective external sheath that is advanced into the trachea while direct connection to the ventilator continues uninterrupted. Because no disconnect is required, the risk of environmental cross-contamination is reduced. Routine changes of the in-line suction catheters are not required, and this restrained practice is cost-effective.[22,23] Overall, the risk of nosocomial pneumonia between the two systems is not different.[24–26]

Because of the anatomic arrangement of the large central airways, a suction catheter most often enters the right main bronchus preferentially, as opposed to the left side. Specially designed curved-tipped "left-sided" suction catheters increase the likelihood of their successful navigation into the left mainstem bronchus.

The uncomfortable practice of nasotracheal suctioning has fallen out of favor and should only be considered in spontaneously breathing patients with ineffective or suppressed cough who are able to protect the glottis. It is perhaps most effective when used in conjunction with assisted coughing and other forms of chest physiotherapy.

Complications with suctioning include hypoxemia (especially in the setting of a ventilator disconnect), increased intracranial pressure, mechanical trauma to the trachea, bronchospasm, and bacterial contamination. All patients should be preoxygenated with 100% oxygen for 1 or 2 minutes before suctioning. To reduce the risk of agitation, the patient should be informed before tracheal suctioning is performed. The suctioning should be limited to $<$15 seconds, and the suction port on the catheter should be opened and closed intermittently—not held closed for longer than 5 seconds at a time.

Continuous Rotation Therapy

Continuous rotational or kinetic therapy extends the practice of regular twice-hourly repositioning of patients from one side to the other by placing the patient on a bed specialized for this purpose that moves to preprogrammed angles on a more frequent basis. Air mattresses that deflate in alternating fashion from side to side also provide postural position changes. Most studies using such equipment demonstrate a lower incidence of nosocomial pneumonia or atelectasis.[27–33] Nonetheless, a systematic review did not demonstrate improvements in mortality or the duration of mechanical ventilation with kinetic therapy.[34]

Bronchoscopy

Fiberoptic bronchoscopy has the advantage of providing direct visualization of the airways and permits suctioning of specific segments where secretions may be retained. Bronchoscopy is a moderately effective technique for the treatment of atelectasis in critically ill patients, with success rates ranging from 19% to 89% depending on the extent of the atelectasis (lobar atelectasis responds better than subsegmental atelectasis).[35] In a recent retrospective review of hospitalized patients with near-complete or complete lung collapse, bronchoscopy is reported to have accelerated radiologic resolution and to have aided in determining causes, such as endobronchial lesions and infectious etiologies.[36] When compared with aggressive multimodal chest physiotherapy in the only randomized trial, no difference in the rate of resolution was observed between the two methods.[37] Bronchoscopy is a semi-invasive procedure that may confer only transient benefit if not followed by respiratory therapy measures directed at preventing recollapse. Furthermore, it is not without associated risks and complications: specifically, sedation required for the procedure, transient increases in intracranial pressure, hypoxemia, and hemodynamic consequences or arrhythmias. Therefore bronchoscopy is not recommended except in situations, such as extensive unilateral atelectasis, that lead to significant difficulties in oxygenating or ventilating and that have not resolved with other methods (e.g., suctioning).

Chest Physiotherapy

Chest physiotherapy is a multimodal therapy with the goal of improving pulmonary function (gas exchange, lung compliance, and pulmonary

mucus clearance). Techniques include percussive therapies (manual or mechanical chest percussion), postural drainage, chest vibration, manual hyperinflation, mobilization, suctioning, and rotational therapy. Overall, chest physiotherapy provides transient improvements in oxygenation and lung compliance, likely secondary to airway clearance and the recruitment of atelectatic regions. In specific situations, it may improve outcome and clinical course, such as preventing ventilator-associated pneumonia[38] or acute lobar atelectasis.[39] But there is insufficient evidence to support routine chest physiotherapy in ventilated patients without primary pulmonary disease.[40]

Aerosol Therapies

Aerosolization

Aerosolization of medications allows direct medication delivery and activity at the site of pathology in addition to the ability to deliver high concentrations with minimal systemic absorption and toxicity.

The two most used methods of delivery by aerosolization are via (1) nebulization or (2) metered-dose inhalers (MDIs). *Nebulization,* commonly with a pneumatic jet, uses a high flow of gas (usually 6–8 L/min) to produce small particles of a liquid medium that contains the medication of interest. In the spontaneously breathing patient, approximately 50% of the nebulized liquid is in the respirable range, with a mass median aerodynamic diameter (MMAD) of 1–5 μm. Approximately 10% reaches the lower respiratory tract and small airways. In mechanically ventilated patients, 1%–15% of the nebulized liquid and medication is delivered to the lower respiratory tract. Ultrasonic nebulization uses high-frequency ultrasonic waves on the surface of the liquid medium to generate high volumes of small, respirable particles.

MDIs are pressurized canisters with the drug suspended as a mix of propellants, preservatives, and surfactants. Upon activation, particles ranging in size from 1 to 2 μm are produced. An MDI used in conjunction with a chamber or spacing device significantly increases drug delivery in spontaneously breathing patients. The same is true when the MDI is attached to the ventilator circuit, either in direct proximity to the endotracheal tube or as part of an in-line device in the inspiratory limb of the Y-piece.

Factors that influence the efficacy of aerosol delivery in mechanically ventilated patients include[41,42]:

1. Administration position in the circuit. An MDI should be positioned closely to the endotracheal tube at the Y-piece and used with a spacer. A pneumatic nebulizer, however, should be positioned at least 30 cm from the Y-piece.
2. Humidification. An excess can decrease aerosol delivery to the respiratory tract because of ineffective deposition of the medication on the ventilator circuit. Higher doses may be required to achieve the desired effect.
3. Timing of delivery. Delivery should occur during the inspiratory phase to maximize drug delivery.
4. Flow rates. Slower inspiratory flow rates (and therefore longer inspiratory time) increase the delivery of nebulized medications. A decelerating flow pattern can also increase the delivery to the lower airways.
5. Tidal volumes. Larger tidal volumes (greater than 500 mL) help optimize delivery.
6. Endotracheal tube size. Tube sizes less than 7 mm reduce drug delivery.
7. Density of inhaled gas. Low-density gases, such as helium–oxygen mixtures, increase deposition to the lower airways by increasing the laminar flow and producing a smaller respirable particle size.

Bronchodilators

Bronchodilators are the most frequently administered aerosolized therapy in critically ill patients. Inhaled beta-2 agonists, such as albuterol or fenoterol, are generally well tolerated in a critically ill patient and improve lung mechanics in many patients with reversible airflow obstruction. In acute lung injury, beta-2 agonists may improve lung edema clearance and have additional antiinflammatory properties.[43,44] However, two multicenter randomized trials in acute respiratory distress syndrome (ARDS) did not show detectable clinical benefit and were associated with more adverse events.[45–47] In a randomized trial of postoperative esophagectomy patients, inhaled salmeterol did not prevent the onset of ARDS.[48] Adverse effects (e.g., arrhythmias, hypokalemia) can occur in patients receiving high doses that encourage significant systemic absorption. Anticholinergic bronchodilators, exemplified by ipratropium bromide, can also be effective in patients with increased airway reactivity, especially when used in conjunction with a beta-2 agonist. Bronchodilators administered via MDI are equally as effective as a nebulizer in spontaneously breathing patients.[41] In mechanically ventilated patients, nebulization is either equally effective[49] or less effective[50,51] than high doses of MDI used with a spacer. MDI administration has the advantage of easier use without the risk of bacterial contamination or the need to adjust flow rates.[41]

Antibiotics

Theoretical advantages of aerosolized antibiotics include directing therapy to the site of infection at higher concentrations with a low risk of systemic absorption and side effects. In chronic pulmonary infective states (e.g., cystic fibrosis and severe bronchiectasis),[52–54] aerosolized antibiotics have a role in reducing bacterial concentrations in the sputum, but they have only been shown to provide clinical long-term benefits in cystic fibrosis.[54] In the acute infective state, aerosolized antibiotics cannot be used alone and have not been shown to add benefit to parenteral antibiotics.[55–57]

In the intubated or tracheostomized patient, the colonization of the airway with potential pathogens routinely occurs, and the attendant risk is high for nosocomial pneumonia. As a preventive measure, a recent meta-analysis of prospective clinical trials of aerosolized aminoglycosides suggested a significant reduction in the development of ventilator-associated pneumonia but no difference in overall mortality.[58] The most recent Infectious Diseases Society of America/American Thoracic Society (IDSA/ATS) ventilator-associated pneumonia guidelines recommend that adjunctive inhaled antibiotic therapy be considered for those with ventilator-associated pneumonia caused by bacteria with susceptibilities limited to aminoglycosides or polymyxins (colistin or polymyxin B).[59] The European Society of Clinical Microbiology and Infectious Diseases ESCMID does not support the use of nebulized antibiotics in mechanically ventilated patients.[60] Bacterial resistance must also be considered. Side effects reported in spontaneously breathing patients treated with inhaled tobramycin include increased cough, dyspnea, and chest pain.[52] Further study is needed to better define the role in inhaled antibiotics as adjuvant therapy in critically ill patients.

Mucoactive Agents

In chronic inflammatory lung conditions such as chronic obstructive pulmonary disease (COPD), cystic fibrosis, bronchiectasis, and intubation/tracheostomy, the overproduction of mucus and impaired clearance results in complications such as airflow obstruction, atelectasis, and infection. Mucus is primarily composed of water, mucin glycoprotein, cellular debris, neutrophil-derived filamentous actin and DNA, and bacteria.[61]

Mucolytic agents reduce the viscosity of mucus by breaking down the mucin glycoprotein network or free DNA strands, thereby altering mucus rheology to improve clearance. Aerosolized *N*-acetylcysteine (NAC) breaks down the disulfide bonds of the mucin glycoprotein network and is associated with improved mucus clearance. However,

because of the increased incidence of bronchospasm with its use, therapy with NAC alone is not frequently initiated, but it may be used in conjunction with an inhaled bronchodilator.[61] Recombinant human DNase (rhDNase, dornase alpha) improves mucus viscosity and pulmonary function in cystic fibrosis patients but has no significant effect on their acute exacerbations.[62,63] In bronchiectasis not resulting from cystic fibrosis, rhDNase is not effective and may be harmful.[64] In mechanically ventilated patients with atelectasis, there is no significant improvement in clinical outcome.[65–67]

This was highlighted in the NEBULAE trial, a large randomized clinical trial that compared "on demand" NAC or salbutamol for thick secretions or wheezing with routine NAC and salbutamol given four times a day. There was no change in ventilator-free days, length of stay, or mortality between the groups. More tachycardia was noted in the routine NAC administration cohort, likely related to the coadministered salbutamol.[68]

Other Aerosol Therapies

Additional aerosol therapies include hypertonic saline, racemic epinephrine (for acute upper airway obstruction because of inflammation), surfactant, and corticosteroids. In the setting of ARDS, inhaled budesonide has been reported to improve oxygenation and reduce peak plateau pressures.[69] Nebulized heparin in smoke inhalation–associated lung injury can improve oxygenation and reduce airway pressures, but the effects on patient outcomes remain to be confirmed.[70,71]

METHODS TO IMPROVE LUNG EXPANSION

Lung expansion techniques that mimic normal sigh maneuvers may help reverse and prevent atelectasis. These techniques are often used in postoperative patients at high risk for pulmonary complications, such as those undergoing thoracic and upper abdominal surgery, and in patients with neuromuscular or chest wall disorders.

Deep breathing and incentive spirometry involve coached inspiratory maneuvers to voluntarily increase lung volumes greater than the vital capacity of the patient. Both are equally effective in reducing postoperative pulmonary complications compared with chest physiotherapy applied without them.[72] Methods to improve adherence can result in clinically important outcomes, as demonstrated in a study involving postoperative bypass surgery patients.[73]

A recent systematic review of continuous positive airway pressure (CPAP) in the postoperative setting for upper abdominal surgery suggested a reduction in atelectasis and the need for reintubation but no improvement in mortality or need for ICU admission.[74]

Intermittent positive pressure breathing to improve lung expansion has fallen out of favor as a preventive measure in postoperative patients because of the expense, lack of a difference in outcomes compared with deep breathing or incentive spirometry, and complications such as abdominal distention.[75]

METHODS TO IMPROVE OXYGENATION AND VENTILATION

Nitric Oxide

Nitric oxide (NO) is a vascular-derived relaxing factor that causes vasodilation via vascular smooth muscle relaxation. The main action of NO is mediated by activating guanylate cyclase, increasing intracellular cyclic guanylate monophosphate (cGMP), thereby causing smooth muscle and subsequent vasomotor relaxation.[76] The beneficial effects observed with inhaled NO are mediated primarily through pulmonary vasodilation that occurs predominantly in patent lung units. Additional observed benefits include a reduction in platelet aggregation and neutrophil adhesion/sequestration in the lungs.[77–79] NO is rapidly inactivated by binding to the heme moiety of hemoglobin. Because of its short half-life, NO does not enter the systemic circulation, making it an ideal selective pulmonary vasodilator.

The most common use of NO in the ICU is in the setting of ARDS. Randomized controlled trials of varying sample size in ARDS have demonstrated improvement in oxygenation by improving $\dot{V}/\dot{Q}$ mismatch. NO initially improved the partial pressure of oxygen (Pao_2) and Pao_2:FIO_2 ratios, but they were no different than control by 24–72 hours.[80,81] A reduction in mean pulmonary artery pressure was also observed in these trials with the use of NO. A beneficial trend was observed in a post hoc analysis in one trial involving higher-severity ARDS.[80] However, a meta-analysis of controlled trials did not support the routine use of inhaled NO in ARDS, and even suggested a possible increase in renal dysfunction.[82–84] With these results in mind, NO is a treatment option primarily in refractory cases of severe ARDS.[83]

NO can be considered a "rescue" therapy to possibly allow for the institution of more protective forms of ventilation, facilitating decreases of fraction of inspired oxygen (FIO_2) and mean airway pressures to maintain acceptable oxygenation. It might also be used in situations in which secondary pulmonary hypertension leads to compromised hemodynamic function from right ventricular failure.

Almitrine bismesylate enhances pulmonary vasoconstriction in areas of hypoxic vasoconstriction, thereby enhancing the redistribution of blood flow from shunt areas to lung units with normal $\dot{V}/\dot{Q}$ ratios.[85,86] This effect of almitrine therefore potentates the effects of inhaled NO on gas exchange. Almitrine is not readily available in North America.

In addition to ARDS, other clinical conditions where NO use may be beneficial are listed in Table 58.2. Inhaled NO has been used after heart and lung transplants as a method to reduce right ventricular afterload in the setting of elevated pulmonary artery pressures.[87] In lung transplants, NO has been described to reduce the risk of ischemia–reperfusion injury. However, this effect was not supported by a randomized clinical trial in which NO was instituted early after lung transplantation.[88]

Inhaled NO is typically initiated at low doses ranging from 1 to 2 ppm and gradually increased until the desired effect is achieved. One method recommended in the United Kingdom (based on American-European Consensus Conference on ALI/ARDS guidelines) is to perform a dose–response test starting at 20 ppm and reduce the concentrations to 10, 5, and 0 ppm to determine the lowest effective dose.[89] A significant response should be considered a 20% increase in the Pao_2:FIO_2 ratio or at least a 5 mm Hg decrease in the mean pulmonary artery pressure (PAP). Improvements in gas exchange are usually observed at lower doses than the reductions in PAP. The usual dose of inhaled NO ranges from 10 to 40 ppm. Doses greater than 80 ppm are associated with a higher risk for adverse effects.

TABLE 58.2 Clinical Conditions Where Inhaled Nitric Oxide May Be Used

Acute respiratory distress syndrome
Severe primary and secondary pulmonary hypertension
Congenital cardiac syndromes
Right ventricular failure in acute pulmonary embolism or after cardiac surgery
Pulmonary ischemic–reperfusion injury after a heart–lung or lung transplant
Sickle cell crisis

Adverse effects of NO include the formation of methemoglobin and spontaneous oxidation to nitrogen dioxide (NO_2). NO_2 is toxic and causes airway irritation and hyperreactivity with levels as low as 1.5 ppm, in addition to pulmonary edema and pulmonary fibrosis after exposure to higher levels. Despite these adverse effects, the development of methemoglobinemia or other toxicities related to NO_2 during acute or prolonged NO inhalation is unusual, especially when NO has been administered at concentrations less than 80 ppm.[90]

To reduce the risk of exposure to NO_2, NO should be stored at concentrations no higher than 1000 ppm in a pure nitrogen environment and only exposed to oxygen at the time of administration. NO should be delivered into the ventilator circuit as close to the patient as possible. NO and NO_2 levels should be monitored closely on the inspiratory side of the Y-piece when using doses above 2 ppm. Rebound pulmonary vasoconstriction can occur with sudden discontinuation, leading to a rapid worsening of $\dot{V}/\dot{Q}$ mismatch and pulmonary hypertension with a significant hemodynamic collapse.[91]

An absolute contraindication to NO therapy is a methemoglobinemia reductase deficiency (congenital or acquired). Relative contraindications include bleeding diathesis (secondary to reports of altered platelet function and bleeding time with inhaled nitric oxide [iNO]), intracranial hemorrhage, and severe left ventricular failure (New York Heart Association [NYHA] grade III or IV).[89]

Inhaled Prostaglandins

Inhaled prostaglandins I2 (PGI2) and E1 (PGE1) have effects similar to iNO, with minimal systemic effects.[92] PGE1 has the advantage of more rapid degradation by pulmonary endothelial cells, providing a selective advantage over PGI2 at higher doses.[93] A recent meta-analysis did not find improved outcome for its routine use in ARDS,[94,95] but the inhaled prostaglandins can be considered rescue therapy[96] when used for conditions similar to those treated with iNO. As with iNO, care must be taken to avoid the abrupt discontinuation of PGI2 or PGE1 because pulmonary hypertension and cardiovascular collapse are possible "rebound"' events.

Heliox

Helium is an inert gas with a significantly lower density than room air (1.42 g/L for oxygen versus 0.17 g/L for helium). By substituting helium for nitrogen, the degree of reduction in the density of the gas is directly proportional to the F_{IO_2} concentration in the mix. Heliox reduces the Reynolds number, increasing the laminar flow and reducing airflow resistance. Consequently, the work of breathing and dynamic hyperinflation associated with high airway resistance are reduced. Clinical situations where heliox may be used include conditions with high airflow resistance, such as severe acute asthma or COPD exacerbations, bronchiolitis, bronchopulmonary dysplasia, and extrathoracic or tracheal obstruction. Heliox has been used to improve lung compliance during noninvasive ventilation in COPD patients, to reduce the work of breathing, to avoid intubation, and to improve aerosolized drug delivery. In the management of moderate to severe asthma exacerbations, routine use of heliox is not supported by systematic reviews of the literature, but can be considered as an adjuvant for short-term use in severe cases not requiring concentrated inhaled oxygen. Most studies use helium/oxygen mixes of 80:20 or 70:30 to achieve a therapeutic benefit. At higher concentrations of oxygen, the effect of helium declines, and therefore heliox is limited to patients who are not severely hypoxemic. In COPD exacerbation, three multicentered trials found no difference in intubation rate or length of stay in the ICU when heliox was added to noninvasive ventilation.[97–99] However, there appeared to be a cost benefit resulting from a shorter overall hospital length of stay.[97] When used in conjunction with nebulized medications, higher flows of heliox may be required to ensure adequate delivery of the medication, though this may be offset by the smaller particle size generated in a heliox mixture. Ventilators also require a recalibration for measured F_{IO_2}, flows, and tidal volumes when using heliox.

SUMMARY

Pulmonary disease and complications are common in critically ill patients, especially those undergoing mechanical ventilation. It is important for the clinician to recognize these potential complications and the many forms of adjunctive respiratory therapies available to prevent further morbidity. Simple therapies, such as chest physiotherapy, suctioning, and positioning, should be used in most patients, with more advanced procedures and therapies used on a selective basis based on the underlying clinical condition.

KEY POINTS

- Inability to effectively clear secretions is common in critically ill patients, increasing the risk of aspiration, atelectasis, and pneumonia.
- Chest physiotherapy, positional therapy, and early mobilization should be considered in all critically ill patients.
- Other adjunctive forms of respiratory therapy should be considered on an individual basis based on the underlying clinical condition.
- Aerosolization of medications is an effective way of providing direct delivery to the lungs.
- MDIs are preferred over nebulization for the delivery of bronchodilators in both the spontaneously breathing and mechanically ventilated patient.
- iNO is associated with improved pulmonary and cardiac physiologic parameters when administered in a variety of clinical conditions encountered in the ICU.
- Heliox can be considered for adjuvant therapy in severe cases of airflow obstruction.

This is the largest clinical trial examining the use of heliox in the management of COPD exacerbations. Despite improvement in some physiologic parameters, there was no difference in noninvasive ventilation failure rate, ICU length of stay, or mortality.

Kreider ME, Lipson DA. Bronchoscopy for atelectasis in the ICU. *Chest.* 2003;124(1):344–350.
A good review of the role of bronchoscopy to manage atelectasis in the ICU describing the effectiveness and complications associated with this procedure.

Rose L, Adhikari NK, Leasa D, et al. Cough augmentation techniques for extubation or weaning critically ill patients from mechanical ventilation. *Cochrane Database Syst Rev*. 2017;1(1):CD011833.
This a systematic review looking at the role of cough augmentation techniques to improve success rates for extubation. The overall quality of the evidence was low, but in the two small clinical trials, there is a suggestion that cough assistance techniques can help with weaning success.

van Meenen DMP, van der Hoeven SM, Binnekade JM, et al. Effect of on-demand vs routine nebulization of acetylcysteine with salbutamol on ventilator-free days in intensive care unit patients receiving invasive ventilation: a randomized clinical trial. *JAMA*. 2018;319(10):993–1001.
This is a large randomized clinical trial examining the use of NAC with salbutamol on an as-needed basis compared with a routine basis. This trial did not show any difference in outcome between the groups, suggesting that on-demand use was noninferior to routine use. There was a higher rate of tachyarrhythmia likely related to routine salbutamol administration.

Intensive Care Unit Imaging

David E. Niccum, Firas Elmufdi, and John J. Marini

RECENT ADVANCES IN ICU IMAGING

Modern advancements in imaging modalities continue to provide an ever-increasing amount of diagnostic and interventional capabilities to aid in the care of critically ill patients. Continued advancement of bedside ultrasound (US) technology and training has allowed for a drastic increase in the availability and ease of performance of these examinations. As a result, guided bedside procedures, including central venous catheter (CVC) placement, arterial line placements, and percutaneous drainage procedures (i.e., thoracentesis or paracentesis), can be performed with relative ease and with a reduction in rates of complications.[1] Bedside US also serves as an indispensable adjunct to a provider's physical examination skills. US facilitates cardiac, vascular, renal, gallbladder, pleural, and lung assessment. The bedside availability of US has made thoracentesis and CVC placement safer and easier.

Additionally, interventional radiology plays an expanding role in performing repairs that once could only be addressed surgically.[1] Embolization of cerebral aneurysms, percutaneous aortic aneurysm grafting, embolization of life-threatening bleeding vessels, placement of intravascular filters, emergent stroke intervention, and pulmonary embolism (PE) lysis can be performed emergently and on patients often at high risk for open surgical procedures. These and many other specialized applications are discussed here and elsewhere in this text in conjunction with the specific diseases they help define. This chapter focuses on imaging applications relevant to the critical care setting: chest x-ray (CXR) and chest computed tomography (CT), abdominal plain film, intensive care unit (ICU) ultrasound, and interventional procedures.

Major advances have occurred in ICU radiology over the last two decades as technological progress has resulted in perfected digital filming techniques, accelerated image acquisition and processing speeds, deployed ultrasonography to the bedside, and dramatically improved imaging communications to and from the ICU point of care.[1] Clinical data and background information can be rapidly reviewed by both clinician and radiologist, and digital images can now be viewed remotely on almost any computer, portable x-ray machine, or handheld electronic device. This technological revolution has brought a host of improvements, including:

1. Physical films are no longer lost or found out of chronological order.
2. Delays in availability have decreased.
3. It is now possible to manipulate image brightness and contrast and to better compare new images side by side with previous ones.
4. Geographically separated physicians can simultaneously view a study.
5. Physicians no longer need to leave the ICU to view studies.

Physicians no longer need to physically travel to the radiology department to access hard copy x-ray films and are therefore less likely to interact directly with a consulting radiologist. As a result, they are more likely to practice in isolation without consulting the radiologist. Although "throughput" efficiency may be enhanced, such isolation is unquestionably detrimental. Failure to connect face to face often deprives the radiologist of important clinical information that would aid in effective consultation, may result in clinicians overlooking subtle but important findings, and eliminates a valuable educational function.

CHEST RADIOGRAPHY

Technique

Although chest CTs offer greater diagnostic capability than plain bedside radiography, there are many applications for which high-quality bedside CXRs retain great utility. Bedside portable anteroposterior (AP) CXR can be strongly affected by patient positioning and exposure technique. In order to obtain the most useful images, care should be taken to reposition devices that overlay the field of view such as electrocardiogram (ECG) leads and wires, pacer pads, intravenous (IV) tubing, and mechanical ventilator tubing. "Gravity-dependent" markers can be used to help identify patient positioning. The patient should be rotated as minimally as possible, as this can greatly affect the dimensions of intrathoracic structures. Rotation can also make diaphragms appear elevated or depressed. Finally, rotation can make diffuse infiltrative processes seem less symmetric by accentuating or diminishing parenchymal lung markings in general.

An AP film magnifies the anterior mediastinal structures and vessels by up to 20%. Obese patients present particular challenges in separating what is normal from what is not, especially when filmed supine (Fig. 59.1).

Positioning: Generally, supine radiographs amplify the heart's dimensions through augmented venous filling, elevated diaphragms, and lung volume reduction. For example, the azygous vein distends in the supine normal subject but collapses in the upright position (Fig. 59.2). Supine radiographs can also make the discovery of a small pneumothorax or effusion difficult or impossible.

Exposure: A properly exposed CXR will reveal vertebral interspaces in the retrocardiac region. If these are not visualized, the film is underpenetrated. Underpenetration will exaggerate parenchymal markings and make it difficult to observe air bronchograms in the setting of consolidation. Consistent exposure on repeat images allows for the day-to-day comparison of films.

Timing: Time films to capture the patient in inspiration, even those acquired on mechanical ventilation. Infiltrates will appear denser in the setting of partial inhalation or exhalation. Likewise, the application of high positive end-expiratory pressure (PEEP) will result in decreased density of infiltrates on a CXR.

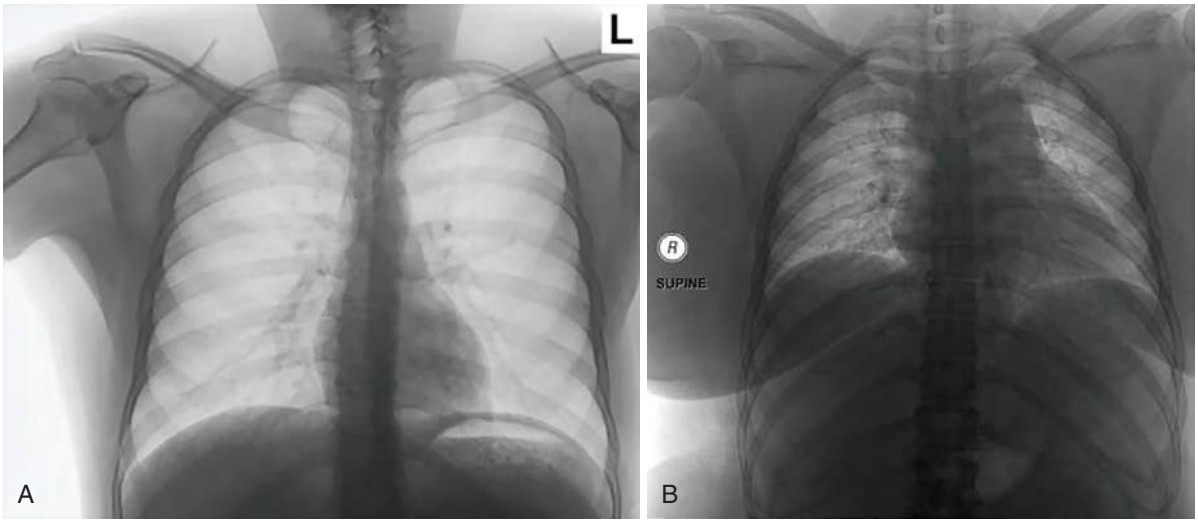

Fig. 59.1 **A,** Normal posteroanterior (PA) upright chest radiograph. Note the definition and dimensions of the heart and vascular structures. **B,** Supine anteroposterior (AP) chest radiograph in massively obese normal subject. Note the widened mediastinum, enlarged heart shadow, and symmetrically elevated hemidiaphragms.

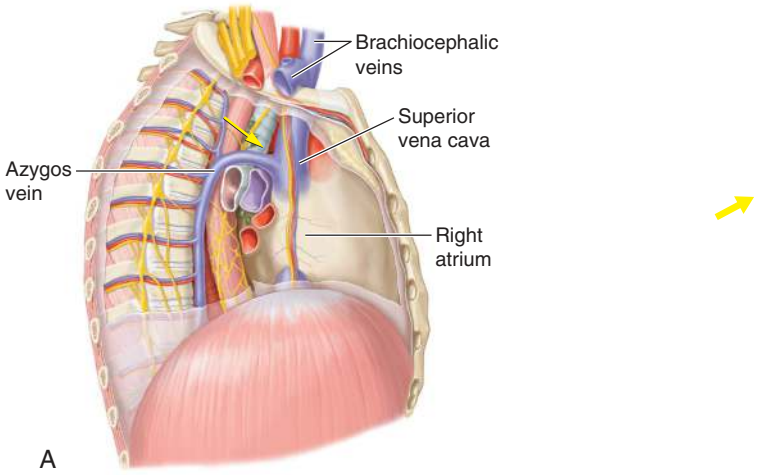

Fig. 59.2 **A,** Lateral view demonstrating the position of the azygous vein in the mediastinum. **B,** Distention of azygos vein, indicating higher-than-normal pressures in the superior vena cava (SVC), is seen on frontal chest film as a circular or lenticular shadow *(arrow)* at its point of anatomic insertion. (A, From Tank PW, Gest TR. *Lippincott Williams & Wilkins Atlas of Anatomy.* Baltimore, MD: Wolters Kluwer; 2009: Plate 4-35b; B, From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig 11.2.)

Consistency: Ideally, compare images from the same patient with the same positioning, ventilator settings, and timing of the respiratory cycle. If this consistency is not possible, keep in mind the differences in technique when comparing films.

The appearance of infiltrates are also often affected by procedures such as bronchoalveolar lavage (BAL). A BAL will leave residual fluid and cause atelectasis (often in sections of the lung with preceding infiltrates) that will result in increased density of infiltrates for several hours postprocedure.

NORMAL PA CXR/NORMAL AP OBESE CXR

Film Timing

A majority of patients should be considered for CXR on arrival in the ICU. Patients who are generally at high risk for endotracheal tube (ET) tube or central line malposition, pneumothorax, or who may have changes in the appearance of their pulmonary parenchyma shortly after initiation of positive-pressure ventilation (such as cardiogenic pulmonary edema) will all benefit from early CXR.

The frequency with which follow-up CXRs are required in the ICU is controversial. Generally, CXRs should be considered after procedures invading the thorax such as ET tube placement, central line placement, feeding tube placement, thoracentesis, or transvenous catheter placement. These images are useful, as they ensure proper placement of the device and that no unintended complications occurred (i.e., pneumothorax). In all but emergency situations, a CXR should follow failed attempts at catheterization via the subclavian route before contralateral placement is attempted to ensure no pneumothorax is present.

Regularly scheduled CXRs are not necessary in all patients with cardiopulmonary disease in the ICU. Despite data indicating that a plurality of routine ICU CXRs demonstrate an abnormality or minor change,

many such findings are nonacute or inconsequential. Observable clinical examination changes typically accompany significant developments that would be observed on a CXR. A prospective study indicates that less than 10% of films demonstrate a new significant finding, and only a fraction of these are not anticipated by clinical examination.[2] Furthermore, meta-analysis of studies examining routine daily CXRs compared with on-demand imaging have failed to demonstrate improvement of patient outcomes, including mortality and ICU length of stay.

A reasonable compromise in practice would be to obtain daily "routine" radiographs on mechanically ventilated patients who have hemodynamic or respiratory instability. Examples would include patients with a significant pneumothorax with a persistent air leak or a patient with progressive hypoxic or hypercapnic respiratory failure. Otherwise, changes in patient clinical condition or procedures dictate the need for additional films. In a stable, mechanically ventilated patient, images can safely be obtained less frequently. Obviously, clinical deterioration should prompt reevaluation.

Placement of Tubes and Catheters

Tracheal Tube Position

ET positioning should be confirmed with a CXR because of the high frequency (25%) of suboptimal ET placements.[3] Ideally the tube should be positioned in the mid-trachea 5 cm above the carina, which is usually located just inferior to the level of the aortic arch. If the carina cannot be visualized on the CXR, the ET tube tip should be positioned overlying the T6 vertebra (Fig. 59.3). Another method to locate an unseen carina uses the intersection of the midline of the trachea with a 45-degree bisecting line, which passes through the middle of the aortic knob. Positioning of the ET tube too deeply usually leads to right mainstem bronchus intubation. This often will result in right upper lobe or left lung atelectasis. Left main intubations are uncommon because the left main bronchus is smaller and angulates sharply from the tracheal axis. If the tube is positioned too high in the trachea (above the level of the clavicles), there will be an increased risk of unintended extubation.

ET tubes move with flexion, extension, and rotation of the neck. An ET tube will generally move in the same direction that the neck flexes or extends (chin down = tip down or chin up = tip up). Head rotation away from the midline will elevate the ET tube tip. Total tip excursion can range up to 4 cm with extremes of head movement.

An ET or tracheostomy tube should occupy one-half to two-thirds of the tracheal width and should not cause bulging of the trachea in the region of the tube cuff. Bulging is indicative of cuff overinflation. This can result in tracheal wall ischemia and subsequent airway stenosis and should therefore be avoided. Gradual dilation of the trachea may occur during long-term positive-pressure ventilation and should be avoided by minimizing both ventilator cycling pressure and cuff sealing pressures.

Fig. 59.3 Location of the main carina on the frontal film. The separation between the right and left main bronchi *(arrow)* almost invariably occurs at the level of the sixth and seventh posterior ribs, directionally "southwest" of the aortic knob. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig 11.3.)

In patients who are post-tracheostomy, a CXR may detect subcutaneous air, pneumothorax, pneumomediastinum, or malposition of the tube. However, routine use of a CXR after both surgical and percutaneously inserted tracheostomy placement is controversial.[4] It may best be reserved for patients with either emergent or technically difficult procedures or who have clinical decompensation after them.[5] The T3 vertebral level is considered the ideal position of the tracheostomy stoma. A tracheostomy tube tip should usually lie halfway between the stoma and the carina. Unlike an ET tube, a tracheostomy tube does not change position with neck flexion or extension.[6] Lateral radiographs are necessary for evaluation of AP angulation. Sharp anterior angulation of the tracheal tube is associated with the development of trachea-innominate fistulas, and continued posterior angulation risks erosion and tracheoesophageal fistula. Massive hemoptysis usually signals the former condition, whereas sudden massive gastric distention with air occurs in the latter. Fortunately, both complications are quite rare in modern practice.[7]

Tracheal Stenosis

Previous intubation or tracheostomy can be complicated by tracheal stenosis. Narrowing of the trachea can be seen at the level of the tracheal tube tip, at the cuff, or, most commonly, at the tracheostomy tube stoma. Stenosis must be substantial (luminal opening <4 mm) to be symptomatic. The typical hourglass-shaped narrowing can be hard to visualize on a single AP radiograph, so CT is best for establishing a definitive diagnosis.

Central Venous Catheters

The tip of a CVC should lie within the thorax, well beyond any venous valves. These valves are typically located in the subclavian and jugular veins, approximately 2.5 cm from their junctions with the brachiocephalic trunk (at the radiographic level of the anterior first rib).[8] Proximal placement will result in an inaccurate measurement of the central venous pressure and is also associated with increased risk of thrombus formation. Distal placement is associated with the risks of cardiac perforation and tamponade. To avoid this, CVCs should be placed with the catheter tip in the middle-superior superior vena cava (SVC), with the tip directed inferiorly. Radiographically, catheter tips positioned above the superior margin of the right mainstem bronchus are unlikely to rest in the atrium. There are some risks to positioning catheters in the middle SVC, including vascular abutment and potential perforation. This is especially notable with left-sided catheters which will enter the SVC at an oblique angle. Caution should be exercised, especially with more rigid hemodialysis lines placed from this approach. Such catheters may benefit from placement in the lower SVC to avoid this complication. Vascular perforation can result in air embolism, fluid infusion into the pericardium or pleural space, hemopneumothorax, and pericardial tamponade.[3]

Postprocedure radiographs reveal complications, including catheter misplacement, in around 10% of CVC placements.[3] For example, catheters inserted via the subclavian route can pass across the midline into the contralateral subclavian vein, or even turn cephalad, entering the internal jugular veins. Similarly, catheters inserted in the internal jugular veins may track into the subclavian vein of either side. This is more commonly seen in patients with proximal stenosis. To minimize this risk, ultrasound should be used to demonstrate collapsibility of the jugular vein before placement. The phenomenon of a subclavian catheter crossing the midline is most common when a triple-lumen catheter is

threaded through a larger-bore channel already in the right subclavian vein. Many clinicians are comfortable leaving CVCs, which terminate in the contralateral subclavian, in place provided there are no clinical effects, but are less at ease with CVCs terminating in the internal jugular vein. In addition to catheter malposition, the complications of CVC insertions include pneumothorax, arterial injury, stroke, and pleural cavity entry. Catheter-associated thrombosis can also occur with CVCs and peripherally inserted central catheter (PICC) lines.

The width of the mediastinal and cardiac shadows should be assessed after placement of CVCs because perforation of the free wall of the right ventricle (RV), although rare, has the potential to result in pericardial tamponade.

Pulmonary Artery (Swan-Ganz) Catheter

A properly inserted pulmonary artery catheter (PAC) should follow the same route as a CVC but continues through the right atrium, RV, and into a pulmonary artery. The tip of the PAC ideally overlies the middle third of a well-centered AP CXR 3–5 cm from the midline, within the mediastinal shadow, or at least not more than 2 cm past the hilum. Ideally, the tip should also lie below the level of the left atrium.

The PAC balloon is used both for placement and obtaining postcapillary wedge pressure (PCWP). Care should be taken to ensure that the balloon is left deflated except during these two procedures, as it can result in pulmonary infarct or pulmonary artery rupture. Unrelieved pulmonary arterial blockage has been a reported complication in 1%–10% of PAC placements. The most common radiographic finding is distal catheter tip migration, with or without pulmonary infarction. Distal migration is common in the first hours after insertion as the catheter softens, adding slack to the line. This slack results in the tip being propelled distally by repeated right ventricular contractions. If pressure tracings suggest continuous wedging, it is important to look for distal migration, a catheter folded on itself across the pulmonic valve, or a persistently inflated balloon (appearing as a 1-cm diameter, rounded lucency at the tip of the catheter). Inflating the balloon of an inappropriately distal PAC can result in immediate catastrophic pulmonary artery rupture or delayed formation of a pulmonary artery pseudoaneurysm. Pseudoaneurysms present as indistinct rounded densities on CXR 1–3 weeks after PAC placement. The diagnosis is easily confirmed by magnetic resonance imaging (MRI) or contrasted chest CT.

In addition to these pulmonary infarct and pulmonary artery rupture issues, PAC insertion can result in knotting or looping and entanglement with other catheters or pacing wires. The risk of knotting or entanglement of PACs can largely be avoided by following two simple steps. First, do not advance the catheter more than 20 cm before observing the next chamber's pressure tracing. For example, a right ventricular tracing should be seen within 20 cm of catheter advancement after obtaining a right atrial pressure tracing. This prevents the catheter from having enough length to form a large loop in the right atrium or ventricle. Second, if the PAC does become knotted or entangled with another device such as a pacing wire, it is essential to resist the temptation to pull on the catheter harder to extract it. Forceful pulling will only tighten the knot, making eventual extraction more difficult. Rather, knotted catheters can be "untied" under fluoroscopic guidance by an interventional radiologist by simply loosening the knot using a stiff internal guidewire.

Pacing Wires

On an AP view of the chest, a properly placed pacing catheter should have a gentle curve with the tip overlying the shadow of the right ventricular apex. To accurately assess the wire's position in three-dimensional space, a lateral film is required. On a lateral view, the tip of the catheter should lie within 4 mm of the epicardial fat stripe and point anteriorly. Posterior angulation suggests coronary sinus placement. Other common areas for malposition include the right atrium or pulmonary artery outflow tract.

In patients with permanent pacemakers, leads can fracture at the entrance to the pulse generator, a site that should be checked routinely. Pacing wires can also result in cardiac perforation, so it is important to examine the CXR for signs of tamponade and perform bedside cardiac US if it is suspected.

Chest Tubes

The optimal position for a chest tube depends on the reason for its placement. Inferior and posterior positioning is ideal for the drainage of free-flowing pleural fluid, whereas anterosuperior placement is preferred for pneumothorax. On an AP chest film, posteriorly placed tubes are closer to the film than those placed anteriorly. This proximity of the chest tube to the film results in a "sharp" or focused appearance of the catheter edge and its radiopaque stripe. Conversely, anteriorly placed chest tubes often have fuzzy or blurred margins. Chest tube location may appear appropriate on a single AP film, even though the tube actually lies within subcutaneous tissues or lung parenchyma. Unexpected failure to re-expand the pneumothorax or drain the effusion should be a clue to extrapleural placement. A chest CT may be necessary to confirm appropriate positioning. In a complicated pleural effusion, a CT can visualize loculations that a plain film can miss. On plain film, another clue to the extrapleural location of a chest tube is the inability to visualize both sides of the catheter. The radiopaque stripe on many tubes includes a break or "sentinel eye," which denotes the proximate port of entry for air or fluid. This should be included within the pleural cavity to achieve drainage and ensure no subcutaneous entry of air into the tube. After removal of a larger chest tube, fibrinous thickening may produce a persisting tube track, which mimics the visceral pleural boundary, suggesting pneumothorax.

Intraaortic Balloon

The intraaortic balloon (IAB) is an inflatable device placed in the proximal aorta to assist a failing ventricle. Diastolic inflation of the balloon produces a distinct, rounded lucency within the aortic shadow, but in systole, the deflated balloon is not visible (unlike its supporting catheter). Ideal positioning places the catheter tip just distal to the left subclavian artery (Fig. 59.4). Placed too cephalad, the IAB may occlude

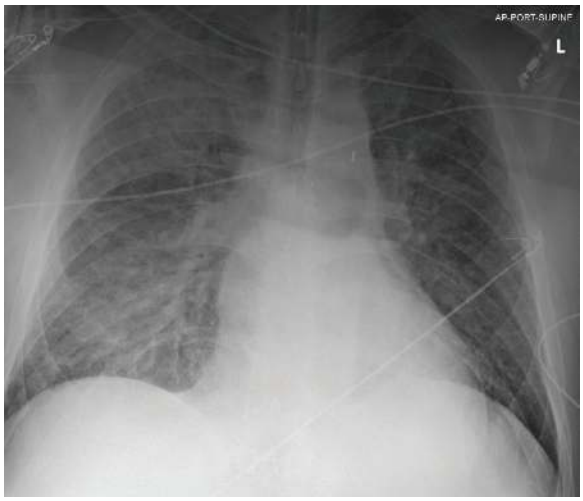

Fig. 59.4 Intraaortic balloon pump on portable anteroposterior (AP) chest x-ray. The position of the tip of the balloon can be seen at the level of the AP window. Note the pulmonary edema pattern in this patient after cardiac arrest in the setting of an ST-elevated myocardial infarction.

the carotid or left subclavian artery. Placed too caudally, the IAB may occlude the lumbar or mesenteric arteries and produce less effective counterpulsation. Daily radiographic assessment is prudent to detect catheter migration or a change of the aortic contour suggestive of IAB-induced dissection.

Temporary Ventricular Assist Devices

Temporary ventricular assist devices (VADs), such as Impella catheters, are also available to assist a failing left ventricle (LV). They are placed via a patient's femoral artery with the catheter extending through the aorta and aortic valve, with the catheter tip being visualized in the LV. Repositioning of the catheter requires visualization beyond a standard CXR, with bedside US or formal echocardiography being required at the time of placement and positioning. Like PACs, slack can develop in a temporary VAD catheter because of a patient's body heat, resulting in an inappropriate position (often too deep in the LV). Clinical signs of catheter malposition include hemolysis (potentially massive) with change in urinary color and blood counts, hypotension, and reduced variability in the motor current monitor tracing.

Gastric Access Tubes

Whether inserted through the nose (nasogastric [NG]) or mouth (orogastric [OG]), it is usually prudent to obtain a CXR or plain abdominal film to confirm appropriate gastric tube position before administration of medication, fluid, or feeding, even when clinical evaluation indicates proper positioning. Tube feeding or medication administration into the airway or pleura can result in severe complications. Even in intubated patients, a small number of tubes intended for the stomach do end up in the lung (usually the right mainstem bronchus). Vigorous insertion technique can force the gastric tube through the lung into the pleural space (Fig 59.5). Inadvertent airway entry is most likely to occur when using a small-bore, stylet-stiffened tube, especially when inserted in comatose or deeply sedated patients.

It is important to confirm that the tip of the tube not only overlies the stomach but also that there is no significant deviation of the tube from the midline esophagus until it has passed the level of the diaphragm. This will help avoid the rare but avoidable complications that can result from tubes that traverse the left mainstem bronchi and into the pleural space. When inserted via the esophagus, the side holes of the enteral tube should be fully advanced past the lower esophageal sphincter to minimize reflux. After similar safety precautions, an abdominal film should be obtained after placement of a percutaneous endoscopic gastric (PEG) tube to search for common complications, such as extragastric migration or peritoneal leakage.

Fig. 59.5 Malpositioning of small-bore nasojejunal (NJ) feeding tube. This was found on abdominal imaging immediately after placement in an intubated patient with SARS-CoV-2 infection. The tube is seen clearly tracking down the right mainstem bronchus and then coiling in the right lower pleural space. Subsequent chest x-ray confirmed the presence of a pneumothorax. This imaging prevented further complications of administering nutrition or medication into the pleural space.

Specific Applications of Chest Radiography

Bedside CXRs retain several important advantages over chest CTs for patients in the ICU despite the greater diagnostic abilities of CTs. CXRs are faster, cheaper, expose the patient to less radiation, and most importantly, avoid a potentially hazardous trip to radiology. Already mentioned at the outset of this discussion, it must be recognized that the chest CT offers far greater diagnostic precision than the bedside radiograph. Yet, for many purposes, the humble bedside chest radiograph remains indispensable, as it is cheaper and quicker to obtain, presents less exposure to ionizing radiation, and spares the patient the hazards associated with transport from the ICU environment.

Atelectasis

Atelectasis is a frequent cause of densities on ICU CXRs. Findings range from invisible microatelectasis, through plate, segmental, and lobar atelectasis, to collapse of an entire lung. Differentiating between segmental atelectasis and segmental pneumonia is often difficult, and these conditions often coexist. Atelectasis can be differentiated by identifying its commonly found features of volume loss, rapid onset, and quick reversal.

Atelectasis tends to develop in dependent regions and by a 2:1 ratio more commonly in the left rather than the right lower lobe. CXR findings will include hemidiaphragm elevation, parenchymal density, vascular crowding (especially in the retrocardiac area), deviation of hilar vessels, ipsilateral mediastinal shift, and loss of the lateral border of the descending aorta or heart. Each lobe has a characteristic pattern of atelectasis that an experienced ICU provider should be able to recognize, and these are summarized in Figs. 59.6 through 59.10. Air bronchograms extending into an atelectatic area suggest that collapse continues without total occlusion of the central airway and that attempts at airway clearance by bronchoscopy or aggressive suctioning are therefore likely to fail to re-expand the involved lobe.

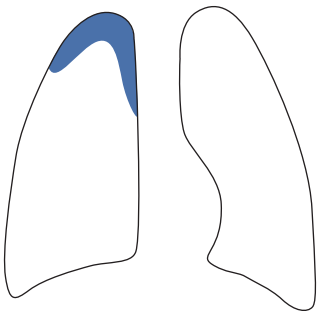

Fig. 59.6 Right upper lobe collapse. Apical density increases as the minor fissure rotates superior medially, producing an easily recognizable curvilinear arch extending to the mediastinum.

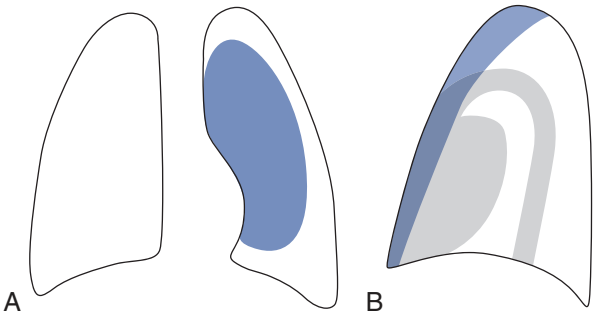

Fig. 59.7 Left upper lobe collapse. A, Because the left lung does not have a middle lobe or minor fissure, upper lobe collapse occurs anteriorly, producing a diffuse haziness of the hemithorax and loss of the upper left cardiac border. **B,** On a lateral film a more distinct region of collapse can be seen running along the anterior portion of the radiograph.

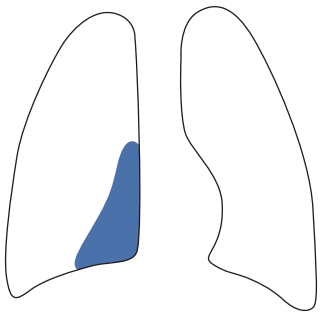

Fig. 59.9 Right lower lobe (RLL) collapse. On an anterior CXR, RLL partial lobar collapse is visualized as diaphragmatic "silhouetting." When lower lobe volume loss is extensive, a triangular posteromedial density can be seen with its base resting on the diaphragm. Contrary to popular belief, the "silhouette sign" is not always reliable on portable films, particularly in the presence of an enlarged heart or when the film was obtained in a lordotic or rotated projection.

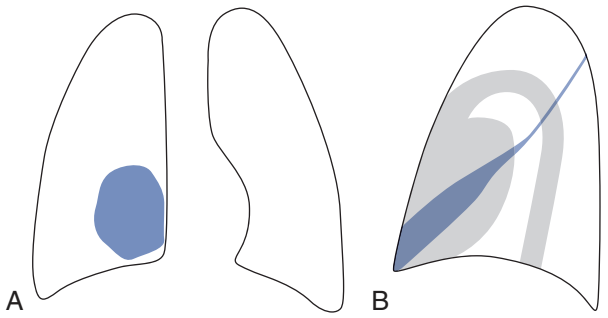

Fig. 59.8 Right middle lobe collapse. On lateral CXR, right middle lobe atelectasis appears as a prominent wedge with its apex directed toward the hilum. The minor fissure and major fissure move toward each other. Findings are more subtle on frontal films, manifesting as obscuration of the right heart border.

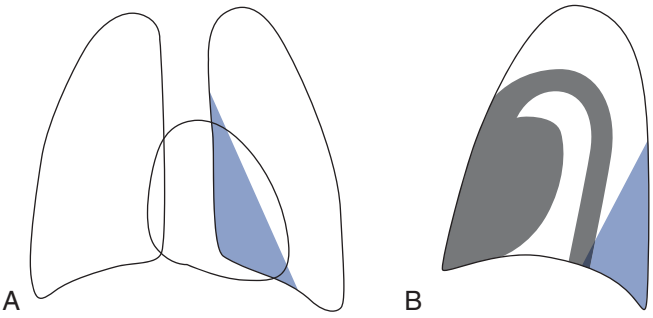

Fig. 59.10 Left lower lobe (LLL) collapse. On an anterior CXR, partial LLL collapse is visualized as diaphragmatic "silhouetting." When lower lobe volume loss is extensive, like in right lower lobe (RLL) collapse, a triangular posteromedial density can be seen with its base resting on the diaphragm.

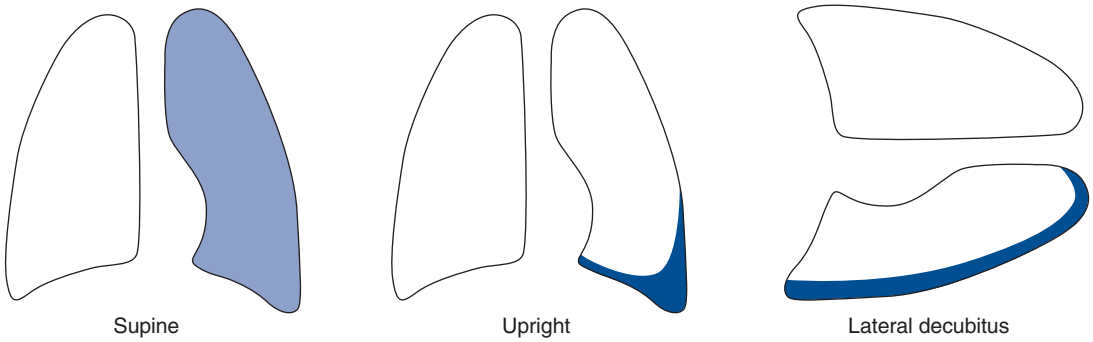

Fig. 59.11 Appearance of a mobile pleural effusion in three positions. In the supine position, a "ground-glass" lateralized diffuse density (with preservation of vascular markings) may be the only sign of layered pleural fluid. A changing appearance with position confirms the diagnosis. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.4.)

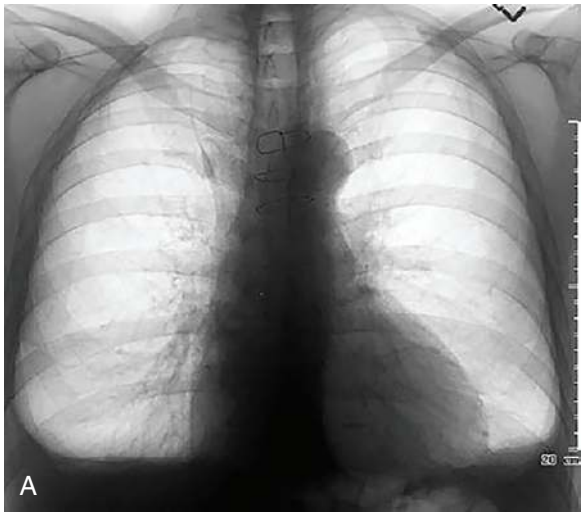
Pleural Effusion and Hemothorax

Pleural effusions occur very commonly among ICU patients. Their appearance varies based on body positioning (Fig. 59.11).

Large effusions can redistribute on a supine AP CXR, causing a hazy density to overlie the entire hemithorax without loss of vascular definition (Fig. 59.12). Apical pleural capping is another radiographic sign of large collections of pleural fluid in the supine patient. Upright or lateral decubitus radiographs may help confirm the presence of an effusion (Fig. 59.13). If a large collection of pleural fluid obscures the lung parenchyma, a contralateral decubitus film often helps visualize the ipsilateral lung. Pleural fluid is not ordinarily visible until several hundred milliliters have accumulated. On lateral decubitus films, 1 cm of layering fluid suggests a volume that can usually be tapped safely. However, in the era of bedside US, the performance of decubitus films is becoming less common as point-of-care US (POCUS) offers a faster and cheaper alternative. US will also be able to provide specific localization and guidance for thoracentesis.

Fig. 59.12 Mobile right pleural effusion supine. Diffuse haziness with well-preserved outlines of the ipsilateral pulmonary arteries is characteristic. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.5.)



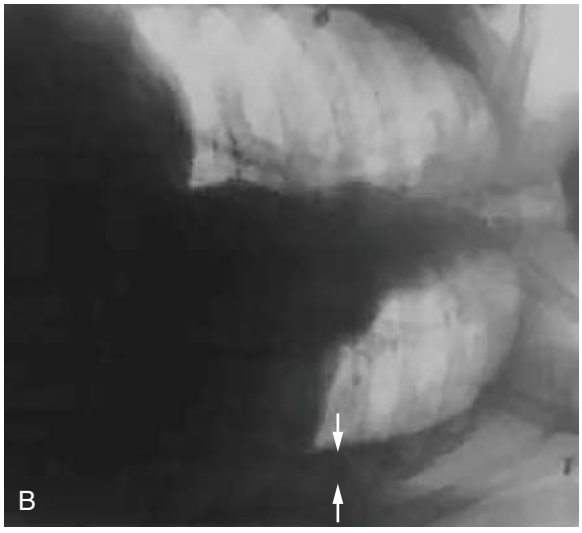


Fig. 59.13 A, Bilateral pleural effusions with characteristic crescentic blunting on the upright PA film. **B,** Mobile effusion in left lateral decubitus orientation. *Arrows* demarcate the fluid separating left lung from ribs.

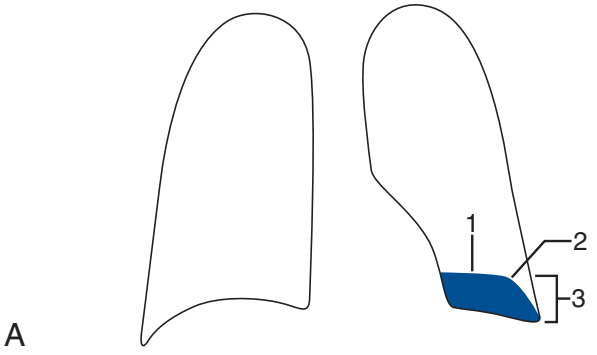
Bilateral Pleural Effusion (Decubitus)

Subpulmonic or loculated fluid may be difficult to recognize on a portable CXR. Hemidiaphragm elevation, lateral displacement of the diaphragmatic apex, abrupt transitions from lucency to solid tissue density, and increased distance from the upper left hemidiaphragmatic margin to the gastric bubble (on an upright film) are all signs of a subpulmonic effusion (Fig. 59.14). US and chest CT are useful adjuncts in detecting the presence of such collections of pleural fluid and in guiding drainage. US has the obvious advantages of portability, repeatability, cost-efficiency, safety, and real-time imaging for drainage.

Extraalveolar Gas/Barotrauma

Extraalveolar gas can manifest as interstitial emphysema, cyst formation, pneumothorax, pneumomediastinum, pneumoperitoneum, or subcutaneous emphysema.

Pulmonary Interstitial Emphysema. This condition is usually associated with positive-pressure ventilation and represents air in the lymphatic and interstitial system. Radiographic signs of gas in the pulmonary interstitium include lucent streaks that do not conform to air bronchograms and new cysts at the lung periphery, usually at the



B

Fig. 59.14 A, Radiographic signs of a subpulmonic effusion: *(1)* hemidiaphragm elevation with separation of lung from gastric bubble, *(2)* lateralization of the diaphragmatic dome, and *(3)* abrupt transition from lucency to soft tissue density. **B,** Left subpulmonic effusion in upright position. Note abrupt transition of density at the lung base and lateral displacement of what appears to be the hemidiaphragmatic dome. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.7.)

bases. Interstitial emphysema may also generate small "target lesions" as air surrounds small peripheral pulmonary arterioles viewed *en face*. These signs, best seen when the parenchyma is densely infiltrated, can indicate the imminent development of pneumothorax.

Subpleural Air Cysts. Subpleural air cysts are a potential sign of impending pneumothorax in mechanically ventilated patients. They appear on a CXR as small (3- to 5-cm wide) basilar, rounded lucencies. They often appear abruptly and tend to rapidly increase in size (sometimes to as large as 9 cm). They can frequently progress to tension pneumothorax in the presence of continued high-pressure mechanical ventilation. When subpleural air cysts are noted, the clinician should reduce airway pressures to the extent possible and maintain a high level of vigilance with preparation to emergently insert chest tubes if needed. Fortunately, such catastrophic developments have become much less likely in the present era of lung-protective ventilation.

Pneumothorax. The identification of pneumothorax in ventilated patients remains of critical importance, despite the decreased incidence of this condition since the introduction of low tidal volume ventilation. When it does occur, pneumothorax commonly complicates the course of patients with necrotizing pneumonias, acute respiratory distress syndrome (ARDS), secretion retention, or expanding cavitary or bullous lesions.

Pneumothorax is often difficult to detect on portable CXRs. Fewer ICU patients exhibit the typical patterns seen on upright CXRs performed in noncritically ill patients. Proper upright positioning is very important in detection. At the bedside, an upright *expiratory* CXR is often the best film for detecting a pneumothorax. This view confines a fixed amount of intrapleural air within a smaller volume, accentuating the proportion of thoracic volume it occupies and the separation of the lung from the chest wall. On supine films or in patients with pleural adhesions, gas may collect exclusively in the basilar (anterior) regions of the thorax. In this case a pneumothorax will be positioned anterior to the heart or may mimic pneumomediastinum or pneumopericardium. Loculated pneumothoraces can be very difficult to detect without CT, and residual localized air collections are often found by CT among patients with one or more chest tubes. Radiographic signs of pneumothorax on the supine CXR include a "deep sulcus sign" and lucency over the upper portions of the spleen or liver. POCUS can greatly facilitate a diagnosis of pneumothorax and should be considered when doubt persists after CXR examination.

When observing a pneumothorax, the visceral pleura provides a specific marker: a radiodense (white) thin stripe of appropriate curvature, with lucency visible on both sides and absent lung markings beyond (Fig. 59.15). Skin folds often mimic the pleural edge but can be distinguished by the following features: (1) lucency present only on one margin, (2) poorly defined limits, and (3) extension beyond the confines of the rib cage. Because pneumothorax reduces blood flow to the collapsed lung, its density may be surprisingly normal, even with an extensive gas collection. Here again, failure to detect dynamic lung sliding and especially the presence of a "lung point" on US nicely complement or even supplant the radiographic evidence (see the section "Ultrasound" later).

Pneumothoraces are often characterized by the percentage of the hemithorax they occupy. This practice is highly imprecise, both because the frontal CXR is only two-dimensional and because apparent percentage changes occur with variations in breathing depth and position. As with pleural fluid, precise determination of the size of a pneumothorax is neither possible nor necessary. A tension pneumothorax is not defined by a specific size of gas collection in the pleural space. Both a tension pneumothorax, regardless of size, and a "large" pneumothorax require drainage—the former because of its immediate physiologic effects, the latter because it creates a pleural pocket that is unlikely to reabsorb spontaneously over an acceptable time. The reabsorption rate of a pneumothorax has been estimated to be 1%–2% per day, a crude rule of thumb that emphasizes the slowness of this process. A 15% pneumothorax would typically take 2 weeks to reabsorb.

Tension Pneumothorax. A tension pneumothorax should be suspected in intubated patients with sudden cardiopulmonary decompensation. This is especially true in patients with high peak inflation pressures. Pneumothorax has been shown to occur in up to 50% of patients with peak airway pressures exceeding 60 cm H_2O. Although action may need to be pursued purely on clinical grounds, imaging, including portable CXR and bedside US, often can be performed in a timely fashion to assist with diagnosis.

Tension pneumothorax can result in shifting of the mediastinum and can flatten or invert with the ipsilateral hemidiaphragm. Tension pneumothorax may not have a typical appearance in a patient's respiratory failure, resulting in uncertainty of diagnosis. Infiltrated or obstructed lungs fail to collapse completely, and an unyielding mediastinum may not shift noticeably, despite a marked pressure gradient. Comparison to past films and clinical correlation may be required. In general, a pneumothorax should be decompressed in a patient with cardiopulmonary decompensation with a new or enlarging pneumothorax. The clinician should rapidly consider and rule out acute hyperinflation (gas trapping) as an explanation before proceeding with any invasive measure.

Tension pneumothorax may be very difficult to distinguish from bullous disease under tension by plain radiograph alone. Although a chest CT can be revealing, patients in extremis cannot wait for a diagnostic CT scan. In such emergent settings, erring on the side of chest

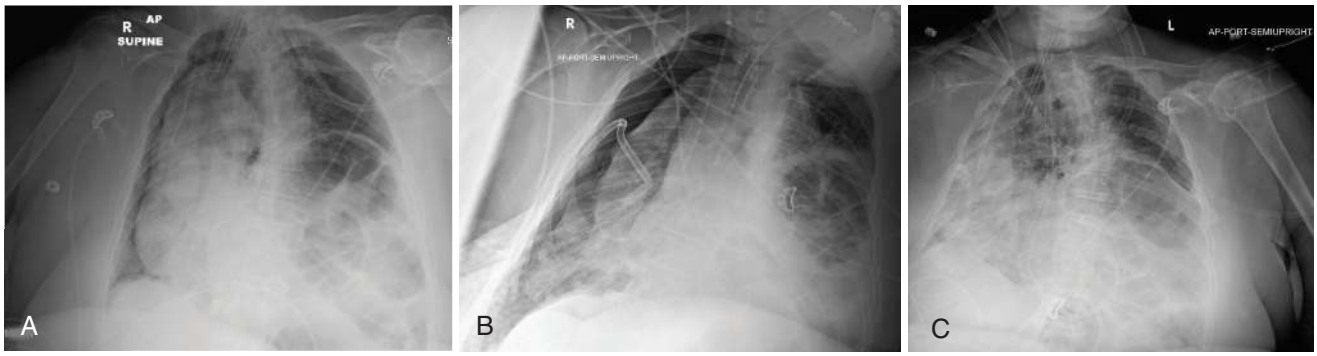


Fig. 59.15 **A,** Pneumothorax seen in a patient with SARS-CoV-2–related ARDS. **B,** Subsequent placement of a small-bore chest tube that, although appearing to be in a good position, has become kinked and is not evacuating the expanding pneumothorax. **C**, Repositioning of the same chest tube has resulted in evacuation of the pneumothorax.

tube insertion is probably the best course of action, even though rupturing a large bulla can create a bronchopleural fistula. A surgically inserted chest tube should be considered in patients with significant bullous disease, as it will help discriminate the pleural boundary better and minimize the likelihood of this complication.

Pneumomediastinum. After gaining access to the mediastinum, gas normally decompresses into adjacent soft tissues. Apart from discomfort or pain, pneumomediastinum itself rarely produces important physiologic effects in adults. Mediastinal gas may arise from neck injuries, from rupture of the trachea or esophagus, or most commonly from alveolar rupture and retrograde dissection of air along bronchovascular bundles. Pneumomediastinum appears radiographically as a lucent band around the heart and great vessels, reflecting gas within the space separating the parietal pleura from the mediastinal contents. On the heart's inferior border, this lucency can extend across the mediastinum, linking the two sides of the chest with a "complete diaphragm sign." An unnaturally sharp heart border is the first indicator of pneumomediastinum, a sign that must be distinguished from the "kinetic halo" seen at the heart or diaphragm border of an edematous lung. The mediastinal pleura, outlined by gas on both sides of a thin radiodense line, can often be detected. On a lateral film, pneumomediastinum usually appears as a thin crescent of gas outlining the ascending aorta. Not uncommonly, extrapleural gas extends from the mediastinum, lifting the parietal pleura off the diaphragm, or outlining the inferior pulmonary ligament. It also can surround and elevate the thymus, resulting in the "thymic sail sign." Pneumomediastinum may indicate, but does not correlate specifically, with pneumothorax, which follows in up to 30% of mechanically ventilated patients.[9] In doubtful cases where progression is feared, definitive diagnosis can be established by CT.

Subcutaneous Gas. Subcutaneous gas, also known as *subcutaneous emphysema,* usually has important diagnostic but little physiologic significance. It produces lucent streaks or bubbles in the soft tissues that contrast with the normal densities of the chest and neck. However, there is almost no limit to the path the gas may take, as it may track into the face, the retroperitoneum, the peritoneal cavity, and the scrotum. During mechanical ventilation, bilateral subcutaneous gas usually results from alveolar or bronchial rupture and medial gas dissection, indicating both a viable decompression pathway and an increased risk of pneumothorax. In patients with pneumothorax, progressive accumulation of subcutaneous gas can indicate the presence of a bronchopleural fistula or a malfunctioning chest tube, especially if the gas is bilateral. Ipsilateral subcutaneous gas detected shortly after chest tube placement generally entered via the tube track itself. Subcutaneous gas detected immediately after blunt chest trauma indicates possible tracheobronchial or esophageal disruption.

Pulmonary Edema

It is important, yet often difficult, to distinguish between normal permeability (fluid overload and congestive heart failure [CHF]) and high-permeability pulmonary edema (ARDS). Although considerable overlap exists in their radiographic findings, certain CXR findings may help distinguish these two etiologies. Patterns of infiltration, the size of the heart and great vessels, and distribution of vascular markings are among the characteristics that should be scrutinized to establish a diagnosis (Table 59.1).

CHF and volume overload are characterized by a widened vascular pedicle, an even or inverted pattern of vascular markings, and a tendency toward a gravitational distribution of edema ("bat wing" or basilar). Pleural effusions, often bilateral and particularly those of substantial size, are also more common with CHF than with ARDS. The vascular pedicle is measured at the point the superior vena cava crosses the right main bronchus to a parallel line dropped from the point of takeoff of the left subclavian artery from the aorta. It should be less than 60 mm in length in 90% of normal CXRs. Kerley B-lines, because of perilymphatic interstitial fluid, are common in established CHF (usually of several days' to weeks' duration), whereas crisp air bronchograms are unusual. Conversely, the less mobile infiltrates of ARDS are widely scattered, patchy, and often interrupted by distinct air bronchograms. These criteria are better for correctly classifying CHF and volume overload edema and less accurate for identifying ARDS.[10] Although useful, when applied with appropriate clinical correlation, widespread application of these criteria has shown them to be less reliable than stated in the original investigations. Because most of the radiographic deterioration seen in ARDS occurs within the first 5 days of illness, a worsening CXR appearance after this time suggests superimposition of pneumonia, fluid overload, CHF, or ventilator-induced lung injury (VILI) (Fig. 59.16).

TABLE 59.1 Radiographic Features of Pulmonary Edema

Characteristics	Cardiogenic or Volume Overload Edema	High-Permeability Edema
Heart size	Enlarged	Normal
Vascular pedicle	Normal/enlarged	Normal/small
Flow distribution	Balanced/cephalad	Basal/balanced
Blood volume	Normal/increased	Normal
Septal lines	Common	Absent
Peribronchial cuffing	Very common	Uncommon
Air bronchograms	Uncommon	Very common
Edema distribution	Even/central/gravitational	Patchy/peripheral/nongravitational
Pleural effusion	Very common/moderate to large	Infrequent/small

Fig. 59.16 Acute pulmonary edema seen in a 62-year-old man with a STEMI. Although pulmonary edema is usually bilateral and symmetric, it may collect asymmetrically when a mediastinal tumor, bronchial cyst, or massive thromboembolism diverts blood flow preferentially to one lung. A recently transplanted lung is also prone to developing unilateral pulmonary edema. Asymmetry may also be observed after unilateral aspiration, re-expansion pulmonary edema or in the presence of extensive bullous disease. Gravity may redistribute edema fluid and atelectasis to newly dependent lung regions over relatively brief periods after patient repositioning. *STEMI*, ST elevation myocardial infarction.

Mediastinal Widening

Mediastinal widening, particularly after chest trauma or an invasive procedure, should raise suspicion of aortic disruption. This should be determined only on a well-centered film, as a rotated or lordotic film may be misleading. In lower-risk patients, vascular anomalies, lobar atelectasis, and masses of the mediastinum should also be considered. Prior chest films should be examined for comparison if available.

A contrast-enhanced chest CT will provide a definitive diagnosis of aortic disruption. Obtaining a high-quality upright posteroanterior (PA) CXR, though desirable, is frequently not possible because of injuries or hypotension. Radiographic clues to aortic disruption include a widened superior mediastinum (the most sensitive sign), a blurred aortic knob, rightward deviation of an NG tube or aortic shadow, and tracheal deviation to the right and anteriorly. Inferior displacement of the left main bronchus, left-sided pleural effusion (with or without apical capping), and displacement of intimal calcifications of the aorta, provide other signs suggestive of aortic disruption. Mediastinal widening with vascular injury is frequently associated with traumatic fractures of the sternum, first two ribs, or clavicle. Widening of the cardiac shadow should prompt careful review of the aortic contour because blood may dissect from the aorta into the pericardium.

Although once considered the gold standard for imaging, catheter-based angiography is rarely used today. More safely performed contrast-enhanced CT scanning, MRI, and echocardiography almost always are sufficient for diagnosis.

Pericardial Effusion

Pericardial effusion is recognized radiographically by enlargement of the cardiac shadow. The classic "water bottle configuration" of the cardiac silhouette, although highly characteristic, is unusual. Serial enlargement of the cardiothoracic ratio can also be seen, as can cardiogenic-appearing pulmonary edema. An epicardial fat pad visible on the lateral CXR is sometimes referred to as the Oreo cookie sign, as it can result in two dense lines, which can be seen both anterior and posterior to the pericardial fat pad. POCUS can be performed to confirm any suspected effusion. Echocardiography is the procedure of choice for the detection and evaluation of pericardial effusions, and it simultaneously affords the opportunity to assess heart chamber size, contractile function, and vena caval diameter. When a transthoracic echocardiogram cannot obtain images of adequate quality because of patient weight or chest hyperinflation, a transesophageal echocardiogram is usually diagnostic. Although echocardiograms can have findings supportive of tamponade, this remains a clinical diagnosis, and cardiovascular compromise in the setting of a large or rapidly accumulating pericardial effusion should raise a high suspicion for this condition.

Air-Fluid Levels (Lung Abscess vs. Empyema)

Although CT scanning more reliably differentiates the location of air-fluid levels, several radiographic features help to distinguish whether an air-fluid level lies within the pleural space or within the lung parenchyma (Fig. 59.17). On an AP film, pleural fluid collections generate wide, moderately dense air-fluid levels. Lung abscesses and liquid-filled bullae are spherical in shape and as such, tend to project similar diameters on both AP and lateral films (Fig. 59.18, *top panels*). Lung abscesses generally have distinct, thick, shaggy walls with irregular contours, unlike most liquid-filled bullae and pleural fluid collections.

Intrapulmonary collections are usually smaller, denser, and rounded. The air-fluid level of pleural fluid collections must abut the chest wall on either AP or lateral film (see Fig. 59.18, *bottom panels*). Fluid collections that cross a fissure line on upright films are located within the pleural space. As body position is altered, pleural fluid collections frequently undergo marked changes in shape or contour.

Postthoracotomy Changes

After pneumonectomy, fluid will accumulate in the vacant hemithorax over days to months. The absolute fluid level is of little significance postpneumonectomy. However, changes in the level of fluid are important. A rapid decline in the fluid level can indicate a bronchopleural fistula, a complication that most commonly develops within 8–12 days of surgery. If a fistula develops earlier, failure of the bronchial closure should be suspected, prompting consideration of reoperation. Bronchopleural fistulas tend to displace the mediastinum to the contralateral side, an unusual occurrence during uneventful postoperative recovery. Small residual air spaces may remain for up to a year after pneumonectomy and do not necessarily imply the presence of a persistent fistula. Very rapid postoperative filling of the hemithorax suggests infection, hemorrhage, or malignant effusion.

Fistulous Tracts

Fistulas between the trachea and innominate artery develop most frequently when a tracheal tube angulates anteriorly and to the right in patients with a low tracheostomy stoma, persistent hyperextension of

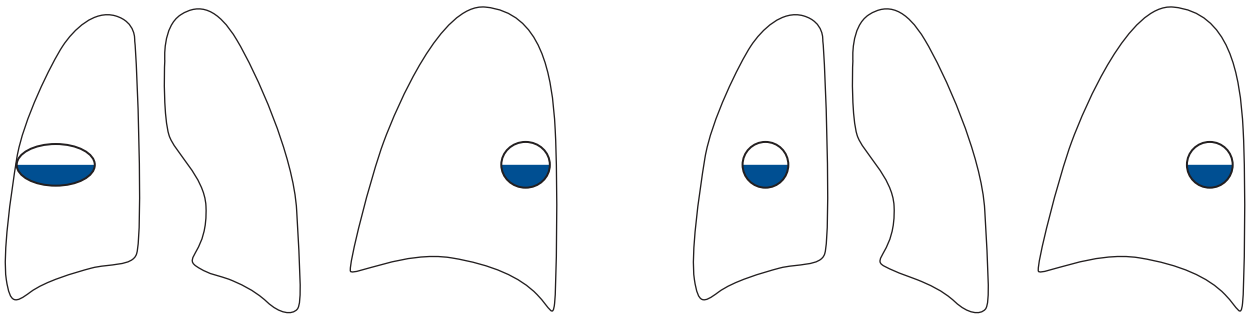

Fig. 59.17 Intraparenchymal versus intrapleural fluid collections. Fluid collections within the pleural space usually have a greater horizontal than vertical dimension, do not cross fissure lines, and may have sloping attachments to the pleural surface on one or more views. Furthermore, pleural collections typically have different dimensions on anteroposterior (AP) and lateral views. By contrast, intraparenchymal collections tend to be more spherical, with equal dimensions on AP and lateral views. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.8.)

Fig. 59.18 Air-fluid levels (lung abscess vs. empyema). *Top:* Large right upper lobe lung abscess with thick cavity wall and air-fluid level indicating communication with the airway. *Bottom:* Loculated empyema of the right posterior pleural space. The lateral view demonstrates that the opacity is not rounded, abuts the ribs, and is not entirely encapsulated by aerated lung. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.9.)

the neck, or asthenic habitus. Because of this association, anteriorly directed tracheal tubes should be repositioned. Fistulas also may form between the trachea and esophagus during prolonged ET intubation. These usually occur at the level of the ET cuff, directly behind the manubrium. Predisposing factors include cuff overdistention with simultaneous presence of an NG tube and posterior angulation of the tracheal tube tip. Tracheal stenosis often coexists. This creates pressure on the tissue separating the ET cuff and NG tube, resulting in ischemia. The sudden occurrence of massive gastric dilation in a mechanically ventilated patient provides an important clue to the presence of a fistula. A radiographic contrast agent may be introduced into the esophagus after cuff deflation or tube removal in an attempt to confirm the presence of a fistula.

Pulmonary Embolism

Although the plain CXR rarely, if ever, diagnoses PE, it is quite useful to detect other conditions in the differential diagnosis, including CHF, pneumothorax, and aspiration. A clear CXR in a patient with sudden cardiopulmonary decompensation should be met with suspicion for PE and warrants further evaluation. Even on plain CXR imaging, large PEs may give rise to suggestive findings: ipsilateral hypovascularity, pulmonary artery enlargement, and very rarely, abrupt vascular cutoff. Local oligemia (the Westermark sign) may be seen early in the course of PE, usually within the first 36 hours in only 10% of cases. "Hampton's hump," a pleural-based triangular density caused by pulmonary infarction, is seldom seen. About 50% of patients with PE have an associated pleural effusion.

For critically ill ICU patients with suspected thromboembolism, it often makes sense to begin the evaluation with a Doppler examination of the limbs, especially in patients too ill to transport or with acute or chronic renal disease. If the US examination reveals what appears to be fresh clots in any deep vein, thromboembolism is diagnosed and therapeutic anticoagulation should be considered. For ICU patients the legs, arms, and neck are potential sites of clots. Roughly half of all CVCs in place for a week or more are associated with at least a partially occlusive thrombus, and approximately 15% of these patients have concurrent PEs.[11] POCUS or formal echocardiography can also be performed in the right clinical context to evaluate for acute right ventricular failure, which can be seen in submassive or massive pulmonary emboli. It is important to note that the McConnell's sign of a dilated, hypoactive RV with relative sparing of the apex also is seen in other conditions that cause severe hypoxic respiratory failure (such as ARDS). Given this, the specificity of this finding is affected by the clinical context. One approach would be to evaluate for deep vein thrombosis (DVT) and the McConnell's sign on bedside US on patients with clinical suspicion for PE who are too unstable to transport or have other contraindications to a CT or ventilation/perfusion (V/Q) scan. If either of these two examinations are positive, one can proceed to treat them empirically for a

pulmonary embolism. When the patient becomes more stable and appropriate, a confirmatory CT angiogram should be pursued.

If the US is negative but the clinical suspicion of PE remains high, V/Q scanning or contrasted chest CT may be performed. The rarity of a normal CXR diminishes the value of V/Q scanning for critically ill patients. Nonetheless, normal perfusion scans are very helpful. The sensitivity and specificity of chest CT for the diagnosis of PE are now well established. In the right clinical context, it is safe to assume that a large filling defect seen in the pulmonary circuit of a technically adequate study represents a clot with ~96% specificity. Primary tumors of the pulmonary artery, primary lung tumors, cancers metastatic to the mediastinum, nonneoplastic mediastinal adenopathy, hydatid disease, and mediastinal fibrosis rarely can mimic PE. By contrast, because the sensitivity of CT varies among institutions, and even in the best centers is not 100% for subsegmental clots, a negative CT does not definitively exclude PE.[12] Sensitivity is optimized by a scanner with many rows of detectors, quick acquisition time, optimal contrast injection technique and gating, adequate breath-holding by the patient, and experienced interpretation of optimally reconstructed images, including three-dimensional views. Although there is controversy about the importance of subsegmental clots in healthy patients, in critically ill patients with impaired cardiopulmonary reserve, it is probably inadvisable to overlook such emboli. Echocardiogram may reveal right ventricular and pulmonary arterial dilation. If the Doppler US is negative, V/Q not practical, echocardiography unrevealing, and CT nondiagnostic while clinical suspicion remains high, angiography is the next, seldom-taken step. Frequently, CT and catheter angiography are both relatively contraindicated by renal insufficiency. Angiography can be safely performed in most critically ill patients, provided that (1) care is used in transport, (2) pulmonary artery pressures are not excessive at the time of contrast administration, and (3) selective injections guided by perfusion scanning are performed. Septic PE should be considered in patients with multifocal cavitary lesions of varying size.

Pneumonitis

Aspiration and Acute Pulmonary Edema

Although bacterial infection sometimes supervenes, gastric aspiration initially produces sterile chemical pneumonitis. When bacterial infection complicates aspiration in the intubated patient, the time from intubation to aspiration can provide valuable clues to the etiologic organism. Events occurring within 4 days of intubation are usually associated with *Staphylococcus, Streptococcus,* and *Haemophilus* infections, whereas later episodes are usually because of gram-negative rods. Massive aspiration, although position and volume dependent, typically appears as bilateral diffuse alveolar and interstitial infiltrates of rapid onset. The extent of the infiltrate does not correlate with outcome, and radiographic improvement often occurs quite rapidly. Aspiration in the supine position usually affects the posterior segments of the upper lobes and superior segments of the lower lobes. Patients who aspirate in a decubitus position often develop unilateral infiltrates (Fig. 59.19A). Patients who are upright tend to have basilar and right middle and right lower lobe opacities. When asymmetrical, the right lung is usually more involved. Significant atelectasis may occur when large pieces of solid food or foreign objects (e.g., teeth, dental appliances) are aspirated.

On occasion, massive symmetric aspiration and/or ARDS can be difficult to distinguish from acute pulmonary edema (see Figs. 59.19B and 59.20). As discussed earlier, several CXR cues may help in making that distinction. Blurred hilar structures and the virtual absence of air bronchograms characterize acute pulmonary edema and fluid volume overload.

Pneumonia

The diagnosis of pneumonia is a clinical one. However, a CXR may give a clue to the organism producing bacterial pneumonia. Bacterial pathogens typically produce patchy segmental or lobar involvement. Bulging fissures, although uncommon, suggest *Klebsiella*. A diffuse, patchy, ground-glass appearance suggests viral pneumonitis (e.g., influenza or COVID-19) or atypical organisms such as *Legionella, Mycoplasma,* and *Pneumocystis* (Fig. 59.21). Small, widely scattered nodular densities suggest miliary *Mycobacterium tuberculosis* as the etiologic organism. Larger nodular densities are associated with *Cryptococcus, Actinomycosis,* or *Nocardia. Aspergillus* often gives rise to peripheral wedge-shaped infiltrates caused by vascular invasion and secondary infarction or cavitary formation. Cavitation suggests neoplasm, tuberculosis, fungal infection (e.g., histoplasmosis, cryptococcosis, coccidioidomycosis), lung abscess, or septic PE. Pneumonitis that develops in preexisting areas of bullous emphysema often produces air-fluid levels that can be confused with lung abscess or empyema. The thinner contour of the cavity wall, the more rapid pace of development and resolution, and premorbid CXRs demonstrating bullae help to identify this problem.

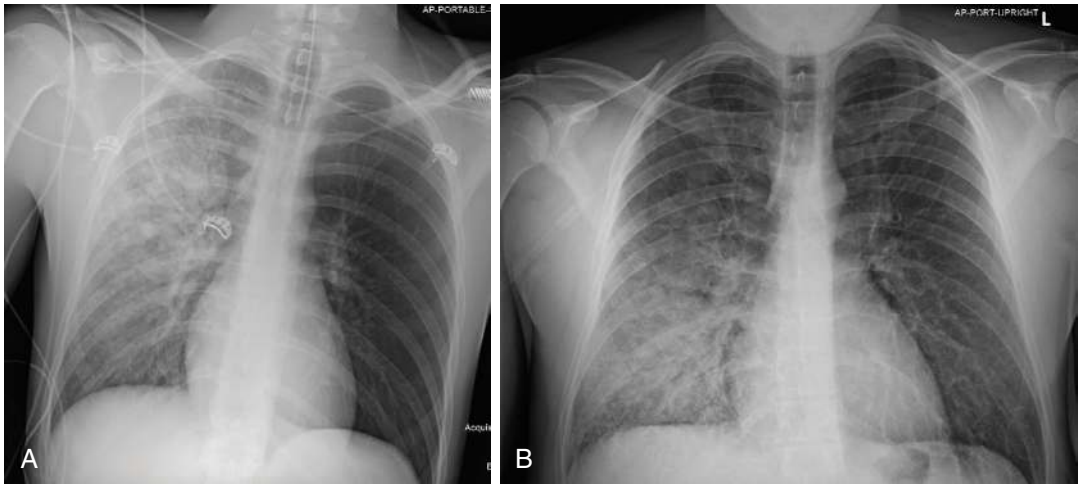

Fig 59.19 Aspiration pneumonitis. A, Aspiration pneumonitis seen in a young male who presented after being found down with an opiate overdose. Note the asymmetric distribution of his infiltrates. **B,** Note the asymmetric distribution of the infiltrates, the presence of air bronchograms, and blurring of the hilar structures.

Fig. 59.21 Radiographic appearance of SARS-CoV-2 pneumonia.

Nosocomial or ventilator-associated pneumonia affects up to 30% of patients with ARDS but is difficult to detect with certainty because focal parenchymal densities may also represent edema, atelectasis, and infarction. Hence, radiographic abnormalities must be interpreted considering the clinical situation. A new unilateral infiltrate in a patient with a previously stable CXR is the best radiographic indicator of a superimposed infection; however, fever, increasing leukocytosis, rising procalcitonin, increased sputum production, and progressive hypoxemia are better indicators than the CXR alone. A focal wedge-shaped infiltrate (especially occurring distal to a PAC tip or in a patient with hemoptysis) is likely to represent pulmonary infarction.

Intraabdominal Conditions

An upright CXR can also help diagnose acute intraabdominal problems. Midline or paraesophageal hiatal hernias are easily visualized. Diaphragmatic disruption may allow abdominal contents to herniate into the chest after abdominal trauma, often displacing a gas-containing viscus into the left chest. Short of a trip to the CT scanner, the upright CXR also provides the most sensitive method of detecting free air within the abdominal cavity. (A cross-table film of the abdomen taken at least 5 minutes after decubitus positioning may serve a similar purpose.) Intubated patients frequently swallow air, producing gastric dilation. In the appropriate setting, massive gastric dilation can suggest the possibility of esophageal intubation or a tracheoesophageal fistula.

CT AND MRI

Reconstruction, Multiplanar, and Subtraction Views

Using a single acquisition of CT data, images obtained (preferably with contrast) can be reconstructed to view multiple planes—not only the traditional axial plane but also the coronal and sagittal ones, allowing improved diagnostic accuracy (Fig. 59.22). Additionally, subtraction techniques may highlight the vasculature (Fig. 59.23). Three-dimensional reconstructions may be developed from the CT

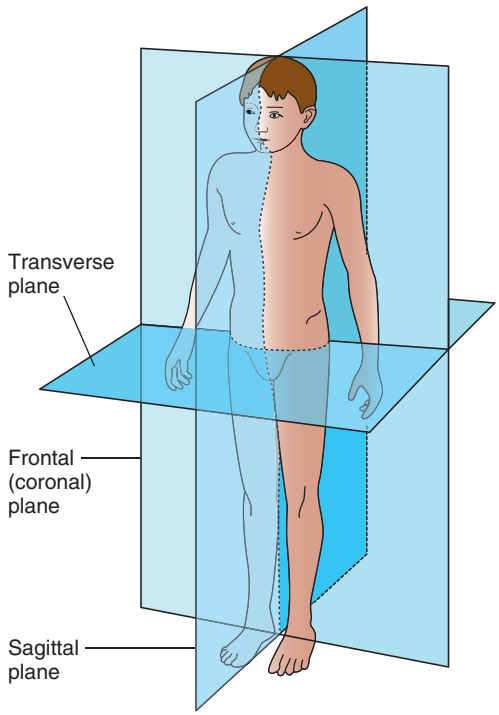

Fig. 59.22 *Top:* The two-dimensional imaging planes. The "transverse" plane is also termed "axial." *Bottom:* Three planes of view for head CT. (From Marini JJ, Dries DJ. *Critical Care Medicine*, 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.11.)

database that are valuable in detailing the anatomy of difficult cases. Such helpful innovations are available because of the accelerated development of digital radiography.

General Preparing of the Patient for Imaging Studies

Radiology staff performing these examinations will facilitate and help implement their preparation, depending on the study being performed. Ensuring accurate diagnostic suspicions on an examination order will help ensure the most beneficial diagnostic protocols are followed. Restricted angulation of the imaging table or gantry is often a limiting factor for patients who are not intubated and receiving mechanical support for ventilation. If the patient is to undergo a sedation-based procedure such as drain placement, then a prior coagulation profile and nothing by mouth (NPO) status are often prerequisites. With elective procedures, the clinician must plan ahead or defer transport in order to comply with these requirements and imaging suite schedules. It is wise to check verbally with the technical staff whenever there is doubt regarding the demands and timing of the study or procedure.

Computed Tomography

Establish urgency of examination (stat vs. routine). The examination protocol is usually determined by the radiologist, and the selected protocol defines the appropriate prep. Depending on the examination, the patient may need oral contrast (e.g., CT abdomen), which can be administered via enteric tube if necessary. Appropriate access for IV contrast administration should be established, provided that it is both indicated and not prohibited by allergy or renal insufficiency. If a computed tomography angiography (CTA) is ordered, then the type (and patency) of IV access catheter may need to be approved by CT staff, as this study requires a relatively high injection rate of the contrast with elevated risk of IV contrast extravasation/infiltration. Communication with the radiology staff before transport is usually advisable.

Magnetic Resonance Imaging

Because it invariably takes a relatively long time to complete, MRI is generally avoided in ICU patients unless both the clinician and radiology team believe it to be absolutely necessary. Unstable and tenuous patients are placed at particular risk because of the relative separation of patient from caregivers. If considering MRI, confer with the MR tech and/or radiologist to discuss how best to proceed. Individual patients may impose unique limitations. For example, metallic foreign bodies or certain medical devices may be incompatible with MRI. Also, the lengthy procedure may create anxiety in patients suffering from claustrophobia. Many ICU patients will require mechanical ventilatory support to remain both still and recumbent for the time required for these examinations.

Ultrasound

US imposes very few limitations other than having physically restricted access to appropriate acoustic windows from binders, wounds, and dressings. For many purposes, high-quality ultrasonic examinations are acquired by technicians at the bedside. Abdominal and pelvic imaging are preferably done in an NPO state to limit bowel gas from interfering with the imaging (see "Ultrasound" section later).

Chest CT and MRI

The chest CT finds many applications in ICU practice. Often CT is the only practical way to image the lung in very obese individuals, as the bedside CXR cannot adequately penetrate the chest wall to reveal the obscured lung characteristics. It is therefore prudent for all critical care unit practitioners to become familiar with the basic elements of axial chest CT interpretation (Fig. 59.24) and to be aware of coronal and sagittal plane reconstructions (Fig. 59.25A and B).

Although indispensable to modern critical care practice, CT scanning (and MRI for that matter) has significant limitations in the critically ill population.[13] Continuing technical advancements in modern

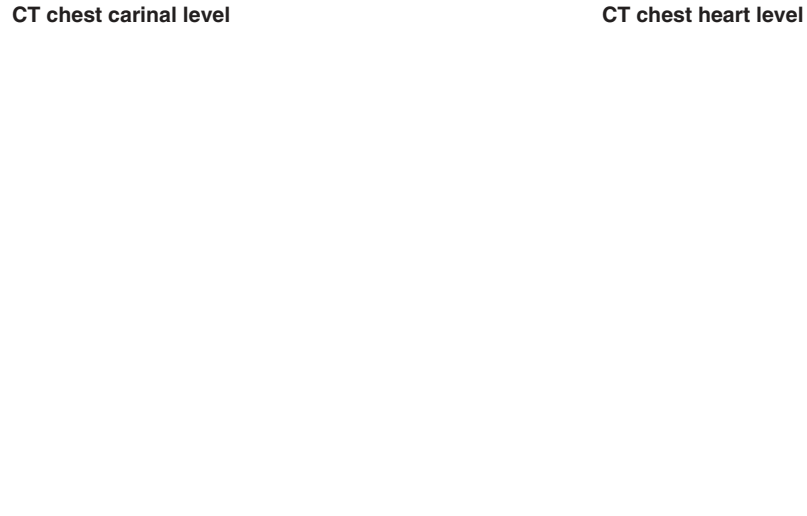

Fig. 59.24 *Left*, The normal structures visualized by a vascular-contrasted axial computed tomography (*CT*) image at the carinal level. *Right*, The normal cardiac structures visualized by a vascular-contrasted axial CT image at the midchest level. *LA*, Left atrium; *LA*, left ventricle; *RA*, right atrium; *RV*, right ventricle; *SVC*, superior vena cava. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.14.)

CT scanners expedite the process of image acquisition and in-suite interpretation. Appropriate concern has been voiced over the risks of moving patients out of the ICU for imaging studies; however, carefully arranged transport is routinely performed reasonably safely. The importance and urgency of any study requiring transport should be weighed against the risk of transport. Alternative studies should be considered that do not require transport if applicable (such as performing an extremity US to locate a DVT rather than CTA chest to evaluate for PE). Portable CT technology can also be used in the right clinical setting. The most important feature of safe transport is to ensure that all vital supports can be effectively maintained and that adequate equipment and personnel are immediately available to cope with any catastrophic event (e.g., accidental extubation or extraction of venous or arterial catheters or chest tubes, interruption of critical infusions, unanticipated cardiac arrest). Patients with bronchopleural fistula needing continual pleural drainage and those requiring vasopressors or high inspired oxygen concentrations or PEEP are at particular risk. It is important to be sure that the intubated patient is able to be adequately oxygenated and ventilated on the transport setup for several minutes before departure. Although now rarely used in transportable patients, interruption of inhaled nitric oxide or nebulized prostacyclin infusions during transport can precipitate calamitous physiologic deterioration. Metallic appliances create artifact on CT scans and may preclude the use of MRI because of the powerful magnetic fields involved. Furthermore, MRI studies are especially time consuming, and the inability of critically ill patients to remain adequately immobile may produce unacceptable motion artifact unless neuromuscular blocking agents are used. If neuromuscular blocking agents are initiated at the time of image acquisition, it is important to ensure that their ventilator settings provide a minute ventilation adequate enough to avoid catastrophic decompensation caused by respiratory acidosis.

CT scanning often requires the use of nephrotoxic contrast material. (Enteral contrast used for abdominal scanning does not carry this risk.) Iodixanol or Nonionix low-osmolality agents can reduce the risk of nephrotoxicity in at-risk patients. Otherwise, administration of IV fluids should be pursued in patients who are intravascularly volume deplete at the time of their examination. Sodium bicarbonate or lactated Ringer's may be preferable to the chloride load of saline. Acetylcysteine is no longer recommended for contrast-induced nephropathy prophylaxis. In years past, MRI was used in place of CT for patients with marginal renal function in an attempt to avoid contrast nephrotoxicity. Unfortunately, the use of some gadolinium-based MRI contrast media may be even more dangerous. Gadolinium has been associated with a rare but progressive and potentially devastating scleroderma-like syndrome known as *nephrogenic systemic fibrosis.* Gadolinium-containing contrast should be avoided in patients with acute kidney injury or who have a baseline estimated glomerular filtration rate (eGFR) of $<$30 mL/min (including patients with end-stage renal disease).

The financial aspects of imaging should not be overlooked. A chest CT scan typically costs three to four times as much as a portable CXR in addition to the costs of transport, which can be substantial. Because patients are placed at higher risk during travel and significant financial and manpower costs are involved, it is logical to plan ahead by bundling studies together when feasible. For example, if an elective head CT is planned tomorrow but an urgent chest CT must be done today, it may make sense to perform both studies today, avoiding the second trip. As a corollary, if an imaging study is likely to yield results that will prompt a radiology-based intervention (e.g., needle or catheter aspiration), it is common sense to confer with the radiologist in advance of the transport, so as to arrange rapid interpretation of the diagnostic study and subsequent intervention in a single trip. Simple preplanning can also avoid wasteful, redundant studies. For example, if a chest CT is to be performed today, there is little reason to do a "routine" morning CXR as well.

In neurocritical care applications, the noncontrasted CT excels for diagnosis of acute intracranial bleeding.[14] It is also helpful when determining if there is an intracranial mass before a lumbar puncture and for detecting sinus cavity opacification. However, detailed anatomic imaging of the brain, spinal cord, and other soft tissues is best performed by MRI (Fig. 59.26). Moreover, detection of acute ischemic strokes by noncontrasted CT is not reliable until many hours have passed after the event (Fig. 59.27A) (though CTAs of the head and neck can identify areas of acute thrombosis, which can be very useful in identifying patients who may benefit from endovascular recannulization), and inflammation of the meninges may evade notice. For these selected problems, MRI is better adapted, as it is immediately sensitive to both (see Fig. 59.27B). With different radiofrequency stimulation and pulsing sequences (so-called "weighting," Fig. 59.28), MRI can reveal inflammation and edema (T2 and fluid-attenuated inversion recovery [FLAIR] weighting) and perfusion adequacy (diffusion weighting). Despite limitations, the chest CT often provides information not otherwise available. It can better differentiate patterns of infiltration or nodularity in the pulmonary parenchyma. It can reveal a small or loculated pneumothorax in patients when previous CXRs are unrevealing. It can well visualize lung abscess or empyema and usually can differentiate between the two conditions. In patients with empyema and atypically distributed pleural effusions or with a persistent pneumothorax, the chest CT is invaluable to evaluate the location and effectiveness of thoracic drainage tubes. A CT better demonstrates the distribution of infiltrates and characteristics of nodules.

In summary, the chest CT represents one of the most useful diagnostic tests available to intensive care practitioners. A short summary list of indications for chest CT scanning includes (1) evaluation of thoracic trauma, (2) searching for occult or persistent sources of fever (empyema, lung, or mediastinal abscess), (3) guiding placement of drainage tubes for loculated or persistent pneumothorax or pleural effusions, (4) detecting

Fig. 59.26 Sagittal magnetic resonance imaging (MRI) of brain and spinal cord. Note the fine anatomic detail provided by T1 weighting. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019; Fig. 11.15.)

The large ischemic zone was not evident on the earlier study. *Arrows* delineate compromised zone (*left*: upon admission; *right*: after 36 hours). **B,** Comparison of near-simultaneously obtained head CT *(top)* and diffusion-weighted magnetic resonance imaging (*MRI*) *(bottom)* of a patient with ischemic (right hemispheric) stroke. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.16.)

Fig. 59.28 **Options for magnetic resonance imaging (MRI) display (normal brain, axial view).** T1-weighted brightness corresponds to fat content and details the anatomy particularly well. T2 weighting tends to highlight pathology associated with higher water content, such as cerebral edema or inflammation. The fluid-attenuated inversion recovery (FLAIR) image attenuates the cerebrospinal fluid (CSF) brightness of the T2 image and therefore is particularly helpful in distinguishing details of pathology. Diffusion-weighted images (DWI, not shown) are the best option for distinguishing well-perfused from ischemic tissues, as in early stroke. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.17.)

mediastinal pathology (especially in the presence of parenchymal infiltrate), (5) searching for PEs, and (6) evaluating distribution and characteristics of opacities in greater detail than a CXR.

ABDOMINAL RADIOGRAPHY

Abdominal CT and Screening Films

Plain abdominal x-rays have largely been replaced by the abdominal CT scan, so it is important to become familiar with its essential elements (Fig. 59.29). The use of abdominal US and CT scanning is discussed in detail, as it relates to specific disease entities in Chapter 25. The standard examination of the abdomen, consisting of supine kidney-ureter-bladder (KUB) or "flat plate" and upright views, can still be useful and does not require a trip outside the ICU. If an upright film cannot be taken, a lateral decubitus view may be substituted.

KUBs still retain great functionality in the ICU, and like the CXR as compared with the chest CT, have the advantage of bedside mobility and lower cost. Line and tube placements can be verified via KUB. General bowel gas patterns can be examined and evidence of obstruction can be found. Systematic review of the KUB may furnish important information, especially after trauma. Fractures of the lower ribs on the left suggest the possibility of a ruptured spleen or lacerated kidney, as does medial displacement of the gastric bubble. Breaks in lower ribs on the right suggest the possibility of renal or hepatic damage. Fractures of the lumbar spine, pelvis, and hips may be seen as incidental findings on plain abdominal radiographs in trauma patients. A ground-glass appearance, displacement of the retroperitoneal fat stripe, or centralization of gas shadows suggests ascites or hemoperitoneum. Free air usually indicates a ruptured, viscus, gas-producing infection; barotrauma-induced pneumoperitoneum; or postoperative change. Free air is much more commonly seen as the result of upper gastrointestinal (GI) (stomach or duodenum) perforation rather than from colonic perforation (diverticulitis, appendicitis, colon cancer).

The KUB view is a poor indicator of liver size, and when in question, should not supplant careful physical examination or CT evaluation. The gallbladder is inadequately defined on the KUB view unless it is very distended or calcified. Less than 15% of gallbladder calculi are visible. Gas appearing in the biliary ducts is highly suggestive of infectious cholangitis but can occur after endoscopic retrograde cholangiopancreatography. The ingestion of massive amounts of carbonated beverages or intake of compounds that can generate gas when mixed with gastric acid (e.g., sodium bicarbonate) can also cause bile duct gas. Hepatic calcifications, although rare, may occur because of healed infection, hemangioma, or metastatic carcinoma. Films taken in different positions may help determine the location of right upper quadrant calcifications. Calcifications within the kidney or liver maintain a relatively fixed position, whereas stones within the gallbladder are usually mobile. Use of the KUB view in the diagnosis of the acute abdomen is discussed in Chapter 25.

Fig. 59.29 Normal anatomic structures visualized on an axial abdominal computed tomography (CT). (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer: 2019: Fig. 11.18.)

Findings Relevant to Specific Organs

Kidneys and Ureters

The visibility of the kidney on the KUB view depends on the amount of perinephric fat and overlying bowel gas. The combination of kidney enlargement and calcification suggests urinary tract obstruction or polycystic kidney disease. Bedside or dedicated renal US should be performed to rule out these conditions if still suspected. If nephrolithiasis is suspected, the renal outlines and course of both ureters should be carefully inspected for calculi (visible in up to 85% of cases). However, a noncontrast CT remains the optimal examination for this condition. Identifying gas in the renal pelvis is uncommon but may indicate emphysematous pyelonephritis, a condition seen most often in poorly controlled diabetics. Gas-producing infections of the bladder are also visualized occasionally.

Pancreas and Retroperitoneum

Asymmetric obliteration of the psoas shadows or retroperitoneal fat lines suggests a retroperitoneal process (most commonly pancreatitis or hemorrhage from a leaking aorta). Similar changes can accompany spontaneous hemorrhage or traumatic disruption. Although the pancreas is not normally seen on the plain radiograph, calcifications may occur in chronic pancreatitis. Localized areas of ileus over the pancreas, such as the "colon cut-off sign" and the "sentinel loop," may also help in the diagnosis of pancreatic inflammation.

Stomach and Bowel

The stomach normally contains some fluid and air. However, massive gastric dilation suggests gastric outlet obstruction, gastroparesis, or esophageal intubation. By contrast, because the small bowel normally contains little air, its gaseous distention indicates ileus or small bowel obstruction. Air-fluid levels of different heights within the same loop of small bowel on an upright film usually indicate mechanical small bowel obstruction and imply residual peristaltic activity. Fluid levels at the same height in a loop of bowel do not necessarily indicate mechanical obstruction. Absence of colonic or rectal gas in patients with small bowel air-fluid levels strongly suggests complete obstruction of the small bowel with distal clearing of gas. Conversely, the presence of gas in the colon (except for small amounts of rectal gas) all but excludes the diagnosis of complete small bowel obstruction. (Ileus or incomplete obstruction may be present, however.)

Colonic obstruction because of a sigmoid volvulus may be diagnosed via a KUB view that shows massive sigmoid dilation; the sigmoid forms an inverted "U" whose limbs rise out of the pelvis. Apposition of the medial walls of these bowel segments produces a midline soft tissue density whose inferior extent approximates the site of torsion. This produces a radiologic finding known as the *coffee bean sign.* A sigmoid volvulus has the bowel loop pointing to the right upper quadrant, whereas a cecal volvulus has the bowel loop pointing to the left upper quadrant. A variety of conditions leading to ICU admission may produce colonic pseudo-obstruction (Ogilvie syndrome) in which massive

colonic dilation occurs because of diminished parasympathetic activity. Radiographically, a CT will demonstrate the absence of a distinct transition point, and unlike the frequently encountered adynamic ileus, affects the small bowel to a lesser degree. Although usually managed conservatively, cecal dilatation to greater than 12 cm suggests the possibility of impending perforation and prompts decompressive interventions.

The frequently observed "thumbprinting" is a useful, highly significant but nonspecific sign of large bowel wall thickening that is most closely associated with ischemia. These nodular indentations appear at regular intervals along the bowel wall and may originate from bowel inflammation from other causes such as Crohn disease, ischemic colitis, *Clostridium difficile,* pseudomembranous colitis, or diverticulitis. Thumbprinting can be seen more chronically in such noninflammatory conditions as lymphoma and amyloid. When seen in conjunction with massive colonic dilation and supportive abnormalities of vital signs, toxic megacolon is highly likely.

Peritoneal Cavity

On the supine abdominal radiograph, ascites is demonstrated by diffuse haze, indistinctness of the iliopsoas stripes, centralization of small bowel segments, and abnormal separation of bowel loops. Increased pelvic density characterizes ascites on the upright film.

Abnormal gas collections are recognized by their nonanatomic location. Therefore all gas densities on supine and erect films require explanation. Each must be assigned to an anatomic segment of bowel. Gas may collect under the diaphragm or overlie the liver on erect or lateral decubitus films, respectively. Free air also allows visualization of both sides of the walls of gas-filled bowel. "Bubbly," curvilinear, or triangular gas collections between segments of bowel suggest abdominal abscess. Bowel ischemia may produce a characteristic pattern known as *pneumatosis cystoides* that represents gas within the bowel wall. Rarely, pneumatosis may rupture to produce free intraperitoneal air, simulating a perforated viscus. Bowel ischemia is more confidently diagnosed when thumbprinting is observed.

ULTRASOUND

Few areas of critical care practice have been adopted as quickly or affected care as profoundly as the bedside application of US imaging. Bedside US has major benefits over other modes of diagnostic imaging, including portability; lack of radiation hazard; speed of data acquisition; low cost; serial repeatability; and the ability to interrogate dynamic properties of the lungs and heart, which helps avoid costly tests, unnecessary delays, and transporting a critically ill patient.

US use in the ICU can be divided into (1) the traditional consultative approach where image acquisition and interpretation are done by providers not involved in bedside patient care and evaluate the organ studied in detail and (2) focused, goal-targeted POCUS, which is usually performed and interpreted by the provider caring for the patient. POCUS use in critical care is becoming more widely adopted because it eliminates clinical and time dissociation in patient care.[15]

Using POCUS for procedural guidance is considered standard of care for many of the procedures performed in an ICU. POCUS can be used as static guidance, such as during thoracentesis or paracentesis where the fluid is identified using POCUS, the skin entry point is marked, and the needle is inserted using the skin mark, or dynamic guidance, such as placement of venous or arterial catheters where the needle is visualized entering the vessel. More recently, POCUS has been used more commonly in the management of patients in shock, respiratory failure, trauma, or cardiac arrest or, less often, for assisting ventilator liberation.

The use of US comes with its own limitations. An adequate ultrasonic window may be obscured or degraded by fat, bone, dressings, or hyperinflated lung. In addition, ultrasonography is a user-dependent technology, and ensuring competence in image acquisition and interpretation is essential to applying POCUS successfully for patient care.[16] Although these skills cannot be acquired without successful hands-on training and practical clinical experience, the range of clinical potential and technical background for US are important to understand.

Organ-Targeted POCUS

Cardiac POCUS

Detailed ultrasonic examination of the stable patient with heart disease continues to be best assigned to consulting cardiologists who formally evaluate detailed echocardiograms acquired with high-capability equipment (Fig. 59.30). In emergency settings and for targeted critical care purposes, however, goal-targeted POCUS can be of high value to direct further steps in management.

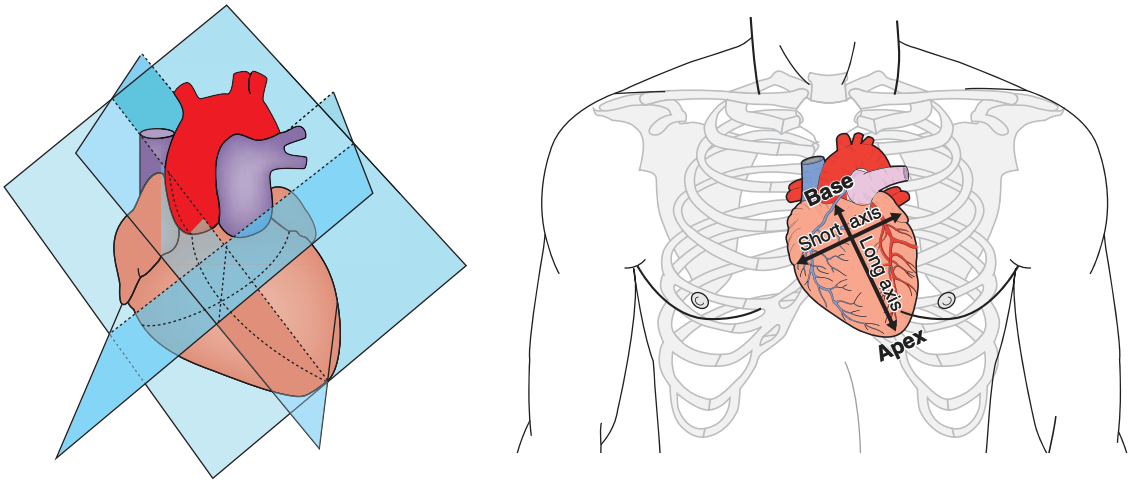

Fig. 59.30 Long and short axes of the heart used in cardiac ultrasound (echocardiography). Knowledge of acoustic windows and structural imaging correlations is quickly becoming an essential skill for the intensivist. (*Left,* from Allen HD. *Moss & Adams' Heart Disease in Infants, Children, and Adolescents, Including the Fetus and Young Adult,* 9th ed. Philadelphia, PA: Wolters Kluwer; 2016; *right,* from Penny SM. *Introduction to Sonography and Patient Care.* Baltimore, MD: Wolters Kluwer; 2015.)

Cardiac POCUS in its most basic form uses five views. Each provides certain information that complements the other views. These views are:

1. Parasternal long-axis view (Fig. 59.31) allows assessment of LV function by assessing myocardial thickening, endocardial excursion, and septal motion of the anterior leaflet of the mitral valve (EPSS) and evaluation of the presence of a pericardial vs. pleural effusion. A posterior pericardial effusion tracks anterior to the descending aorta. It is important to note that epicardial fat pads are hypoechoic and can mimic pericardial effusion. If the hypoechoic area does not move with the heart, it is likely an effusion, whereas if it moves with the heart, it is likely an epicardial fat pad. This view also allows assessment of the left atrial size in comparison with the aortic root and RV outflow tract. Less commonly, large vegetations can be seen clearly on the mitral or aortic valve using this view.
2. Parasternal short-axis view allows assessment of LV function and can visualize the presence of pericardial fluid. This view shows the anterior, lateral, posterior, and septal walls in one plane, which allows identification of wall motion abnormalities in the LV. The presence of the RV in this view allows comparison of right to left ventricular sizes and the assessment of the shape of the septum (flattening of the septum, which gives the LV a D shape, indicates increased RV pressure).
3. Apical four-chamber view is more challenging to obtain in critically ill patients and easier to obtain with the patient in the left lateral decubitus position. In addition to providing much of the same data provided by other views, this view allows measurements of the velocity time integral (VTI) when the aortic outflow tract is in plane. VTI measurement allows the calculation of cardiac output, and repeat measurements help confirm fluid responsiveness. Both are helpful in the management of patients in circulatory shock.
4. Subcostal view visualizes all four chambers and is the easiest way to visualize the heart while resuscitating a patient in cardiac arrest.
5. Inferior vena cava (IVC) view allows IVC measurements and allows the interpreting physician to calculate dynamic changes in IVC size with respiration, which helps identify fluid status and determine fluid responsiveness. When performing this examination, it is essential to ensure the visualized vessel is the IVC and not the aorta.

Experienced POCUS providers can apply advanced echocardiography for assessment of valvulopathy and assessment of diastolic heart disease. As the technical details for performing such studies are readily available in review articles and educational videos, we will not duplicate that work here.

Lung POCUS

Until quite recently, the artifacts on 2D images caused by sonic interactions of tissue and air were disregarded despite their high diagnostic value. Assuming the use of an appropriate probe, depth, and ultrasonic frequency range, normal lung; pneumothorax; and edematous, consolidated, and liquid-filled spaces return characteristic sonograms that vary during tidal breathing (Fig. 59.32). Sliding of the visceral pleura at its interface with the fixed parietal counterpart, in addition to

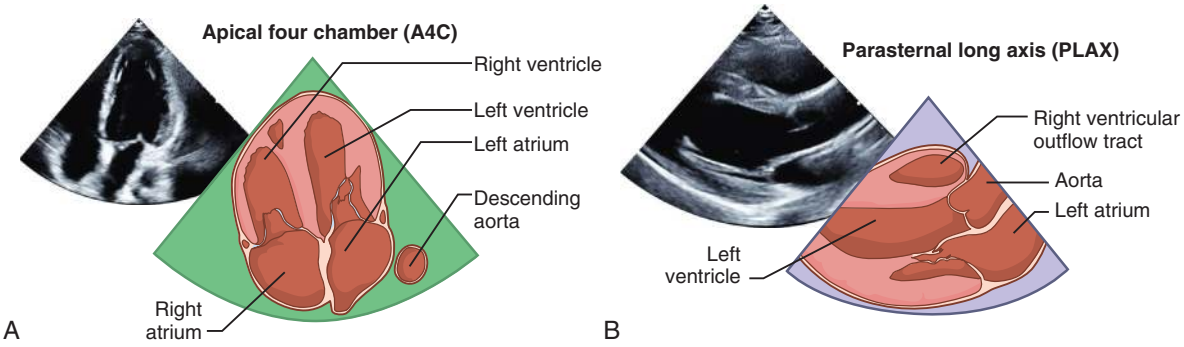

Fig. 59.31 Apical four-chamber **(A)** and parasternal long-axis views **(B)** of the heart with cardiac echo. (Modified from Barnett CF, Sweeney DA, Huddleston LL. Ultrasonography: Advanced applications and procedures. In VC Broaddus, JD Ernst, TE King Jr, et al, eds. *Murray & Nadel's Textbook of Respiratory Medicine,* 7th ed. Philadelphia, PA: Elsevier; 2022: Fig. 24.1.)

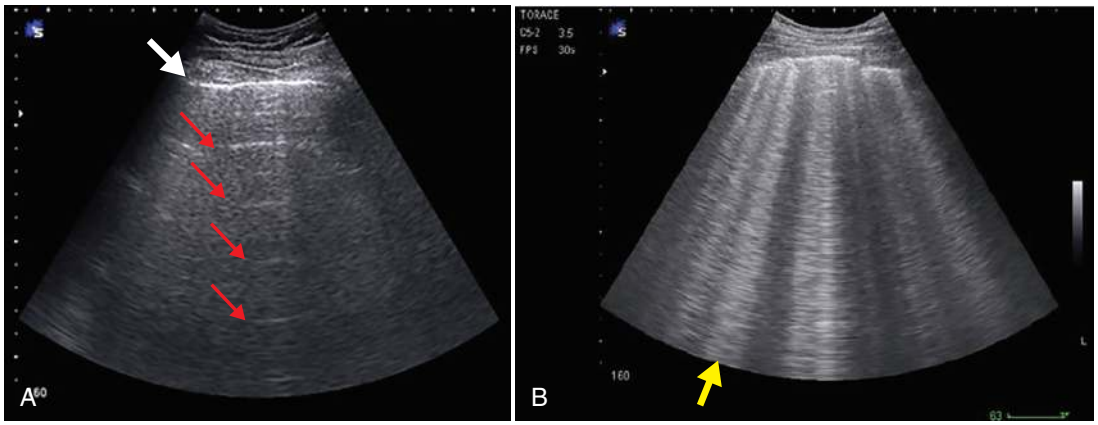

Fig. 59.32 **A,** A-lines *(red arrows)* are the diminishing ultrasonic reverberations of the pleural stripe *(white arrow)* through normal lung tissue. **B,** B-lines are linear streaks *(yellow arrow)* emanating from the pleural boundary. These indicate increased tissue water, such as caused by edema. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.21.)

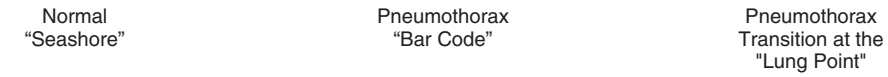

Fig. 59.33 Ultrasonic profiles in M-mode (focal, time based). The stationary transducer in **(A)** and **(B)** paints patterns that indicate blurring caused by lung motion beneath it **(A)** or monotonous reverberation in response to the air barrier caused by pneumothorax **(B)**. When the transducer is positioned at the interface between noncollapsed lung and pleural air, there is an abrupt transition between these ultrasonic M-mode patterns during the phases of the breathing cycle **(C)**. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.23.)

repetitive curvilinear lines that fan out parallel to the pleural surface (A-lines), is characteristic of normal lung. A limited number of hyperechoic, self-erasing lines orthogonal to the pleural plane (B-lines or "lung rockets") are produced by interstitial lung edema. When B-lines are profuse, evenly distributed, and bilateral, alveolar edema likely is present. The homogeneous, sharply demarcated, and distinctly opaque sonographic shadow separating the parietal from the visceral pleura indicates an uncomplicated pleural effusion. Although there is no definite depth to determine safety when sampling pleural fluid, measuring a pleural liquid depth of greater than 1 cm indicates that needle thoracentesis can be safely performed at that site. US is essential to safely perform needle insertion when the patient is receiving mechanical ventilation or when the effusion is loculated.

A pneumothorax is characterized by an echo-free separation between the lung and chest wall. Confirmation is made when a motionless probe detects phasic (tidal) transitions during tidal breathing between echo-free and lung signatures. This "lung point" is confirmed by a "seashore-like" appearance on continuous M-mode tracing (Fig. 59.33).

Use of these characteristics in conjunction with limited cardiovascular ultrasonography directed toward leg clotting and right ventricular dilation is made in systematic protocols designed to rapidly determine the cause of acute dyspnea (e.g., the bedside lung ultrasound in emergency [BLUE] protocol). Thoracic interrogation is performed sequentially at three sites (anterior, lateral, and posterolateral) in the semirecumbent patient as evidence is sought for pneumothorax, lung edema, and consolidation or lung collapse. US of the cardiac and femoral zones completes the appraisal.

Vascular POCUS

As mentioned earlier, POCUS is considered a standard of care for placing vascular catheters. In addition to using the US during the procedure itself, POCUS can evaluate for evidence of a pneumothorax after internal jugular or subclavian central line placement. To do this, first confirm lung sliding in the upper anterior chest before placement. Then repeat the US after the procedure to evaluate the presence or absence of lung sliding. If it was present before and became absent, it suggests a pneumothorax occurred.

Evaluating the presence of DVT using compression ultrasonography is quick and almost as accurate as a radiology-performed full DVT examination in the ICU.[17] It is important to realize that although DVTs can be visualized within the vessel, fresh clots tend to be hypoechoic and cannot be seen. Hence, it is important to perform full vein compression, as lack of vein compressibility indicates the presence of a clot. To perform a lower extremity DVT compression examination, the leg is placed in a frog-leg position (external rotation at the hip with some flexion at the knee), and three to five compression examinations are done over the course of the femoral vein and one to three compression points over the popliteal vein behind the knee. Presence of a DVT could save the patient a trip through the CT scanner if venous thromboembolism (VTE) were suspected.

POCUS can also be used to confirm the presence of flow in the extremities' arteries, which can be helpful when a Doppler signal is not easily obtained. The US can be used to visualize the vessel and can apply color and/or Doppler signal to confirm flow.

Abdominopelvic POCUS

The kidneys are easily accessible with US, and a kidney POCUS examination mainly focuses on the presence or absence of hydronephrosis as an etiology of sepsis or acute renal failure. It is common to see other pathology in the kidneys, including renal cysts during POCUS examinations, and although it is important to be able to differentiate them from hydronephrosis, a detailed examination of the kidneys is still best performed by consultative US examination by a radiography specialist. A renal POCUS examination can be performed on the patient in the supine position by applying the transducer to the flanks, but the left

kidney tends to reside more posteriorly and therefore is more difficult to visualize in a supine patient.

Ultrasound excels in visualizing fluid, which makes it an essential tool to diagnose and treat ascites. Unfortunately, POCUS will not be able to differentiate the type of fluid. Hemoperitoneum and simple ascitic fluid have a similar appearance on US, and if bleeding is suspected, other diagnostic methods may be needed for confirmation. Using a high-frequency linear probe allows visualization of vasculature in the abdominal wall at the needle insertion point. Using this before paracentesis decreases the risk of bleeding complications.

The gallbladder and the biliary ducts can be visualized during POCUS examination either with the patient in the left lateral decubitus (preferred) or supine position. This allows measurement of gallbladder thickness, presence of stones, presence of pericholecystic fluid, and sonographic "Murphy sign." In the right clinical scenario, all can be signs of acute cholecystitis. Obtaining adequate biliary images requires a higher level of skill and expertise to identify pathology correctly. It is often prudent to request consultative US radiology examination to confirm POCUS findings.

Disease-Targeted POCUS

One of the major advantages of POCUS is the ability to evaluate multiple organs rapidly at the bedside with the goal of answering a specific clinical question. Protocols have been published to simplify this concept, combining different organs' ultrasonography to target the treatment of a specific patient presentation.

Trauma FAST Examination

Emergency abdominal US in adults with abdominal trauma (focused assessment with sonography for trauma [FAST] examination) is a widely used management-directing US survey whose results are more reliable after presentations for blunt rather than penetrating trauma (Fig. 59.34). The main goal is to detect newly developed pericardial, intrathoracic, or intraperitoneal free fluid. Acknowledged limitations are that FAST is less sensitive for pelvic bleeding, does not interrogate the retroperitoneum, and cannot reliably differentiate the nature of what caused the pathologic fluid collection (e.g., blood, urine, ascites). Points of sonographic access (windows) are used to evaluate the pericardial, peritoneal, and pleural cavities. Unless a pointed indication interrupts the order, the examination sequence reflects the severity of potential life-threatening risks. The heart is assessed for the presence of cardiac tamponade, global wall motion abnormalities and other evidence of injury, and the adequacy of right ventricular filling.

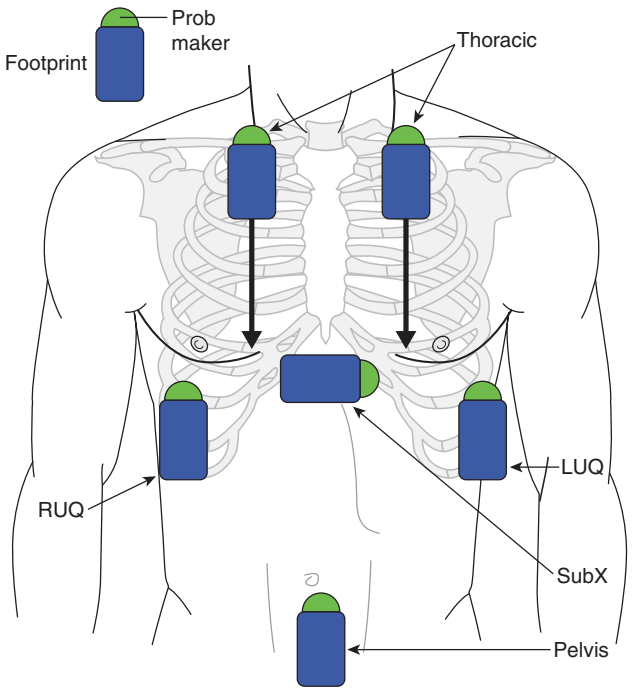

Fig. 59.34 The acoustic ultrasonic windows used in the FAST algorithm. *FAST*, Focused assessment with sonography for trauma. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.24.)

After the heart and pericardium, the right flank (hepatorenal view or "Morison pouch"), left flank (perisplenic view), pelvis, and thorax (pneumothorax and hemothorax) are evaluated. The liver, spleen, and partially filled bladder provide the necessary sonographic windows. The abdominal sequence leads with the right flank and gutter before the left flank and gutter examinations because blood originating from both splenic and hepatic trauma must first pass through the Morison pouch before collecting in the more dependent pelvic cavity.

As in other applications of POCUS, the FAST protocol should be considered to provide very useful, but often not sufficiently definitive, information to preclude radiologic studies or even exploratory surgery. Some serious injuries are seldom visualized confidently by US (e.g., aortic and diaphragm tears, pancreatic lesions, bowel perforations, mesenteric trauma, and injuries that do not produce free fluid in amounts >250 mL). Fluid acutely collected in the pelvis may be either urine or blood. Although important penetrating injuries may go unsuspected with the initial evaluation, overall sensitivity of FAST in these and for all abdominal injuries may improve by performing serial US examinations.[18]

Circulatory Shock RUSH Examination

Using POCUS in a systematic way helps to rule out the major etiologies of shock in an accurate and rapid way. The rapid ultrasound for shock and hypotension (RUSH) examination includes assessment of three cardiac views (parasternal long axis, apical four-chamber, and IVC views) to quickly assess the presence of pericardial fluid/tamponade, evaluate the LV and RV size and function, and determine IVC status.[19] A hyperdynamic LV with small IVC should raise concern for hypovolemic/hemorrhagic shock, but if that hyperdynamic LV was detected in a fluid-resuscitated patient having a large IVC with no respiratory variations, then septic shock should be strongly considered. If an obvious etiology is not identified during the cardiac examination, assessment of both flanks (similar to a FAST examination) allows visualization of any free fluid in hepatorenal and perisplenic views. Typically, the pleural space is evaluated during this time to rule out hemothorax. Unlike a FAST examination, evaluating the kidneys for hydronephrosis is essential to rule out the renal system as an etiology or uncontrolled source of sepsis. Although not commonly encountered in a medical ICU, evaluating the aorta in the epigastric area allows detection of aortic aneurysm, dissection, and even rupture. Lastly, examination of the upper anterior part of the chest to evaluate for lung sliding excludes pneumothorax as an etiology of obstructive shock.

Depending on the clinical circumstances, a RUSH examination also should include a search for ectopic pregnancy and a DVT compression examination.

Acute Respiratory Failure BLUE Protocol

The bedside lung ultrasound in emergency (BLUE) protocol is commonly used for assessment of patients in acute respiratory failure.[20] It uses lung US to categorize the lung signals into different profiles, each associated with a specific diagnosis (Fig. 59.35).

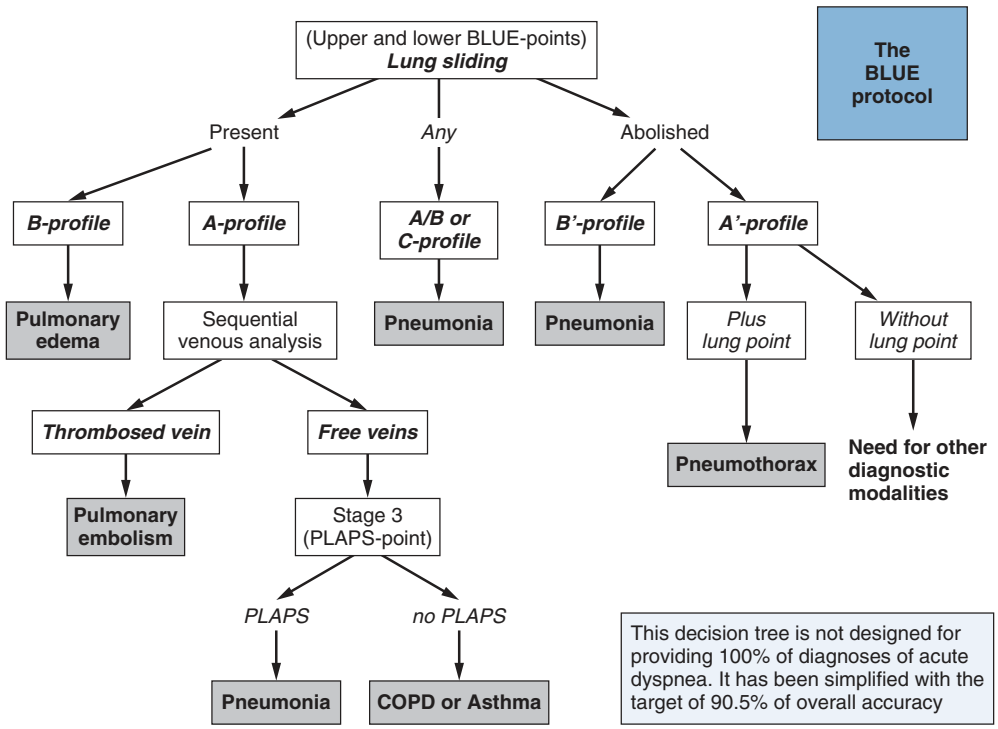

Fig. 59.35 The BLUE protocol. An algorithm using lung ultrasonography to guide diagnosis of severe dyspnea. *BLUE,* Bedside lung ultrasound in emergency; *COPD,* chronic obstructive pulmonary disease. (Modified from Lichtenstein DA, Mezière GA. Relevance of lung ultrasound in the diagnosis of acute respiratory failure: The BLUE protocol [published correction appears in *Chest.* 2013;144(2):721]. *Chest.* 2008;134:117–125, Fig. 7.)

INTERVENTIONAL RADIOLOGY FOR CRITICAL CARE

Interventional radiology (IR) became an indispensable service for critically ill patients in the early 21st century. The ability to perform a wide range of procedures percutaneously enables an ICU physician to pursue therapeutic paths that would have been deemed too risky in many critically ill patients. Dynamic imaging capabilities such as C-arm fluoroscopy and angiography, combined with elegant 3D reconstructions, precise localization, and an ever-expanding arsenal of catheter-based devices and stents, enable physicians to perform high-value, low-morbidity procedures. These include otherwise routine cannulation procedures that cannot be attempted successfully at the bedside, in addition to many sophisticated therapeutic procedures that stabilize hemorrhage and relieve ischemia.

Broadly speaking, the purposes of IR procedures can be classified as vascular and nonvascular in nature. The vascular indications include arterial embolization in patients with uncontrolled bleeding, extraction of thrombi, the placement or manipulation of intravascular catheters, and endovascular stent placements. The latter of these may be lifesaving (e.g., aortic dissection and transjugular intrahepatic portosystemic shunt [TIPS] procedures for portal decompression [Fig. 59.36]). Nonvascular indications for IR generally include drainage of an infected pocket and the placement of stents, feeding tubes, and suprapubic catheters. As noted earlier, these procedures are often performed in lieu of more traditional, invasive surgical procedures. Most IR services perform these procedures, provide consultation, and will assist in the decision-making process. The IR service should be engaged early in this process, particularly when surgical intervention is a contemplated alternative option. Although the range of problems and potential solutions is already vast and continually expanding, several of the more common procedures are highlighted next.

Vascular Interventions

Hemorrhage and Ischemia

A wide variety of life-threatening hemorrhagic events can be effectively addressed by angiography followed by embolization of the culprit vessel (Fig. 59.37). The sources of bleeding commonly involve the bronchial (e.g., submassive or massive hemoptysis), GI/mesenteric (e.g., upper or lower GI bleeding or retroperitoneal bleeding), or solid organ distributions (e.g., splenic rupture or postpartum hemorrhage). Control is routinely achieved, and infarction of the embolized tissue occurs only very rarely. It is important to discuss the findings of an embolization procedure with the interventional radiologist, as often they can provide insight as to whether additional procedures may be necessary to achieve hemostasis.

Type B aortic dissections requiring urgent or emergent correction can frequently be addressed by IR-directed stent placement (Fig. 59.38). End-organ ischemia of cerebral, extremity, mesenteric, or renal systems may often be effectively relieved by thrombus extraction (e.g., stroke) or by stenting, as may symptoms that persist despite optimal medical management. In advanced centers, quite sophisticated manipulations, such as aortic stent graft reconstruction, realignment of true lumen flow, and fenestration, can be successfully accomplished. Traumatic aortic injuries (e.g., pseudoaneurysm, minimal intimal tear, flow-limiting lesions) are evaluated and perhaps better addressed with less morbidity than open surgical repairs. The same principle of endovascular stent graft repair often (but not invariably) is feasible for ruptured thoracic or abdominal aortic aneurysm. These IR procedures carry lower morbidity than invasive surgery and are usually possible, assuming that the anatomy is favorable and the procedure is undertaken emergently. Symptomatically, ischemic smaller vessels of the brain, extremities, and mesentery can also be stented effectively, assuming such preconditions are met.

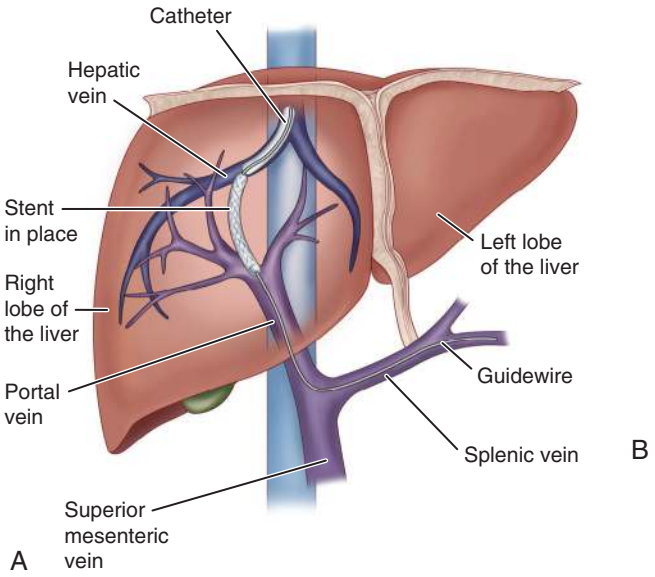

Fig. 59.36 **A,** Schematic depiction of catheter-mediated transjugular intrahepatic portosystemic shunt (TIPS) stenting procedure for portal venous decompression. **B,** TIPS stent inserted via catheter (subtraction fluoroscopic image with contrast). (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.25.)

Fig. 59.37 Colonic bleeding and prehemostatic **(A)** and posthemostatic (**B**) coiling of culprit vessel. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.26.)

Venous Thrombosis

IR has been rapidly developing a useful role for both submassive and massive venothrombosis. Although the role of lytic therapy for hemodynamically stable submassive PE remains controversial, IR should be engaged early for consultation regarding catheter-based lytic infusions into the pulmonary artery or thrombectomy when standard medical management fails and systemic fibrinolysis is relatively or absolutely contraindicated.

IVC filter placement can readily be performed by IR. However, the indications for filter placement remain controversial. Generally, failure or a contraindication for systemic anticoagulation in the setting of known VTE remains a widely accepted indication for this procedure. However, there are some limited observational mortality data that call into question the benefit of this procedure even for this indication. Prophylactic IVC filters, especially in the setting of trauma, are recommended by some, but not all, societies, and their recommendation for use has not been entirely resolved (see later).

Perioperative patients with VTE or long bone and pelvic fractures are often candidates, as are those post-endovascular thrombolysis/thrombectomy with residual DVT. Patients who are immobilized with precarious cardiopulmonary compensation who would not be expected to withstand recurrent embolism are often considered, though

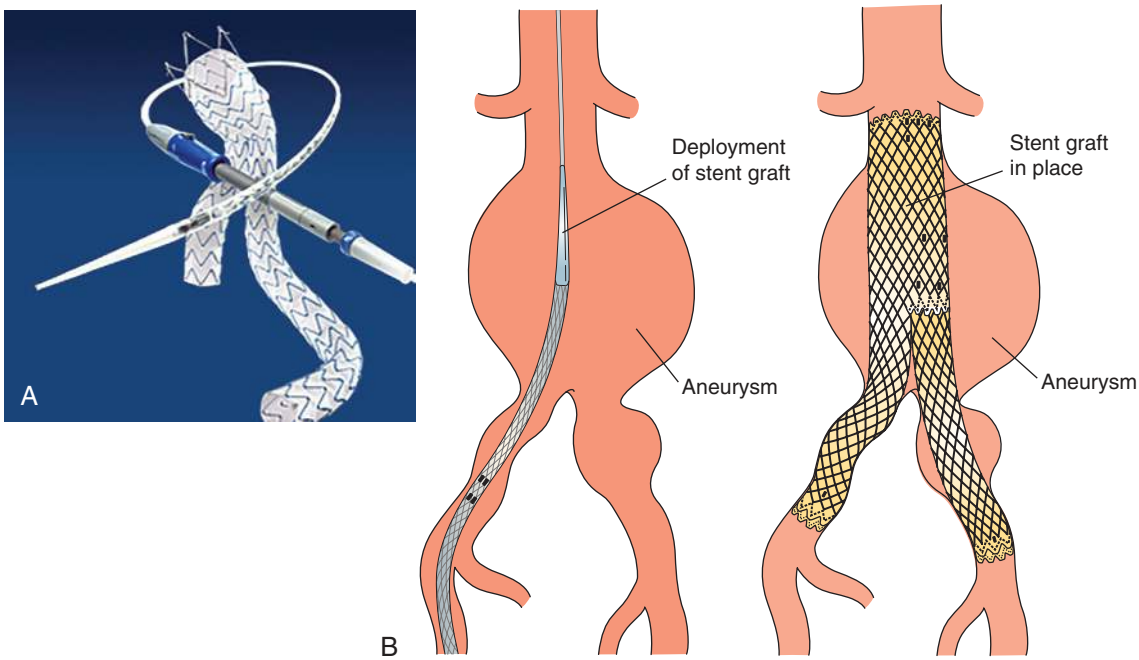

Fig. 59.38 A, Furled and unfurled dimensions of endovascular stent for large vessel. **B,** Insertion and deployment of endovascular stent repair of aortic aneurysm. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.27.)

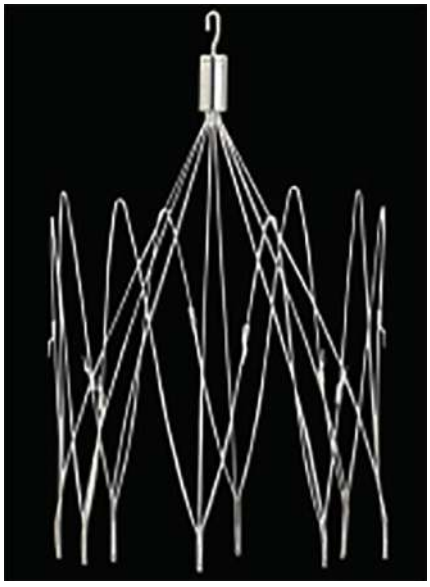

Fig. 59.39 One of many types of IVC filters (VenaTech). After the high-risk period for embolism has passed, the core can be snared by its hook and removed. This allows the cage to remain permanently in place, acting as a stent rather than an occlusive obstruction. *IVC,* Inferior vena cava. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.28.)

again, use of filters in this patient population remains controversial. Overall, the rate of IVC filter placement in the United States has been decreasing since the Food and Drug Administration (FDA) issued a warning for their use in 2010 that was updated in 2014.

Both permanent and retrievable filters (Fig. 59.39) are currently available. Most, if not all, of present-day filters are MRI compatible. Filters can also be convertible over the short term from filtering to nonfiltering functions (see Fig. 59.39).

IR has become a critical part of early stroke management. Endovascular thrombectomy can provide critical restoration of cerebral blood flow in early stroke and carotid artery angioplasty, and stenting can decrease the risk for subsequent events. Likewise, intracerebral vascular stents may be considered to improve jeopardized perfusion of zones with critically compromised blood flow (Fig. 59.40). Cerebral aneurysms can be coiled, as can arteriovenous malformations.

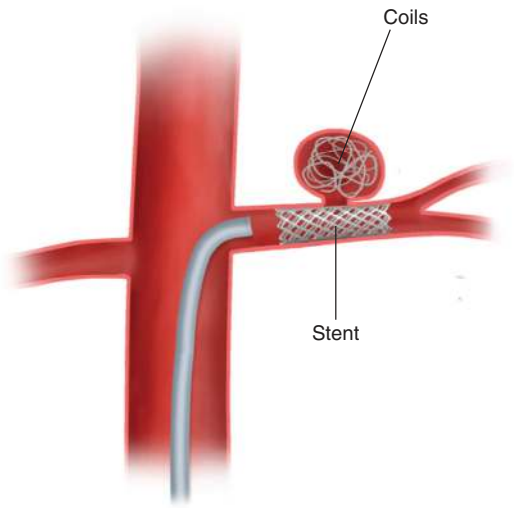

Fig. 59.40 Two useful endovascular interventions for cerebral aneurysm repair: stenting and aneurysm obliteration by coils and clot. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019: Fig. 11.29.)

Catheter-directed thrombolysis and/or percutaneous thrombectomy has gained increasing traction but remains controversial for certain indications. Full-intensity treatment can be directed to the point of interest, with lower total anticoagulant doses carrying the potential of a full therapeutic effect with less risk of bleeding. However, well-designed multiarm trials have yet to be performed to demonstrate this efficacy in common conditions such as life-threatening pulmonary embolism (i.e., massive or high-risk submassive PE). Given this, the costs and risk of cannulation should be weighed against the theoretical benefit of lytic dose reduction. It should be remembered that patients should not simultaneously receive a thrombolytic infusion and full-dose anticoagulation. There are no clear guidelines as to when full-dose anticoagulation should start after cessation of catheter-directed lytics, and discussion with IR regarding the timing of this transition is recommended. Catheter-directed infusion therapy remains a strong consideration for iliofemoral and caval venous clots. The same strategy can be successfully applied to arterial occlusions occurring in circumstances of peripheral vascular disease or embolic, traumatic, and iatrogenic compromise of extremities, mesentery, or brain.

Percutaneous thrombectomy devices are diversifying and proliferating as their indications for use expand at a very rapid rate. Most devices rely on a suction removal mechanism with or without maceration. Such percutaneous procedures carry less morbidity risk than the more complex surgical interventions with which they compete. However, the efficacy of these devices in treating PE as compared with medical management remains uncertain at this time. Consequently, percutaneous thrombectomy of PE should be considered for patients who fail medical management and who have absolute or significant relative contraindications to thrombolysis.

Vascular Access

Bedside ultrasonography of critically ill patients has both improved the rate of successful placement and reduced the complication rate of vascular access. Nevertheless, many critically ill patients continue to present challenges to achieving bedside vascular access because of factors such as massive obesity, vasculopathy, and/or recurrent instances of ICU care. IR can provide valuable expertise in the placement of US-guided central lines, cooling catheters, hemodialysis catheters, ports, and tunneled central venous lines. Misplaced catheters can also be repositioned with relative ease (Fig. 59.41) and, likewise, arterial line access can usually be attained readily.

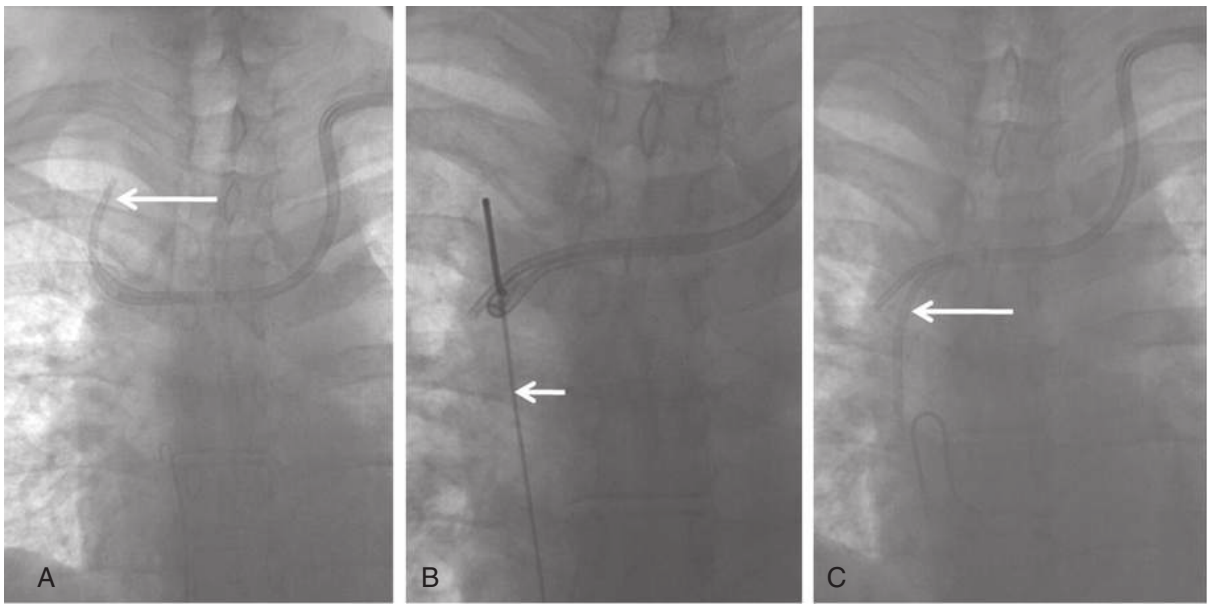

Fig. 59.41 Secondary malposition into the contralateral brachiocephalic vein in a 38-year-old man on hemodialysis. Chest radiograph **(A)** demonstrated the tips *(arrow)* of the left dialysis lines had spontaneously migrated into the right brachiocephalic vein. Fluoroscopy image **(B)** showed the use of a Sidewinder catheter *(arrow)* to pull the lines down into the superior vena cava (SVC). Postintervention image **(C)** showed satisfactory repositioning of the lines *(arrow)*. (From Nayeemuddin M, Pherwani AD, Asquith JR. Imaging and management of complications of central venous catheters. *Clin Radiol.* 2013;68[5]:529–544.)

Management of Pseudoaneurysms

Pseudoaneurysms may form as a result of trauma, infection, penetrating ulcer, or iatrogenesis. Treatment of these depends on location, etiology, and morphology. Infectious (mycotic) lesions generally require vascular surgery. However, IR is particularly well suited to address arterial site access anomalies at the groin, where US-guided thrombin injection may be a good option. Large vessels may be appropriate for stent, graft, or embolization. Traumatic aortic injuries or transections may often be addressed by thoracic stent grafting. Worrisome vascular injuries and tangles in branch vessels of solid organs are generally approached by embolization. Larger feeding vessels are often stented.

Nonvascular Indications for IR

Nephrostomy tubes may be required to address renal obstruction, pyonephrosis, and/or urosepsis if urologic placement of a retrograde stent is not possible or desirable. Abdominal or pelvic drains may best be inserted and positioned radiographically under CT or US guidance. Follow-up imaging is very frequently indicated (e.g., abscessograms and fistula assessment). Complicated abscesses of the lung can be externally drained, but this commonly results in bronchopleural fistula and/or seeding of the pleura with infectious material. Both complications may require later surgical intervention. Given this, thoracic surgical consultation should be pursued before addressing complicated pulmonary abscesses so as to choose the best treatment option. Similarly, though chest tubes are deftly placed into empyema pockets by IR, an open surgical approach is sometimes a better option for complicated spaces. Early surgical consultation is again advised.

Tubes to drain pneumothorax tend to be better positioned, smaller, and more flexible when placed in IR using fluoroscopic or CT guidance, promoting patient tolerance (Fig. 59.42). Poorly functioning drainage tubes that serve any purpose (air/fluid/pus) can be replaced, upsized, or repositioned in IR to optimize performance. After placement, decisions and management of drainage systems can be assigned to the interventional radiologist or to the bedside provider. This decision, if not already assigned by hospital policy, should be made at the time of tube insertion and followed through.

Fig. 59.42 Pigtail catheter inserted by IR into a loculated right apical space *(yellow arrow).* A necrotic abscess is evident on this fluoroscopic image *(red arrow). IR,* Interventional radiology. (From Marini JJ, Dries DJ. *Critical Care Medicine,* 5th ed. Philadelphia, PA: Wolters Kluwer; 2019; Fig. 11.31.)

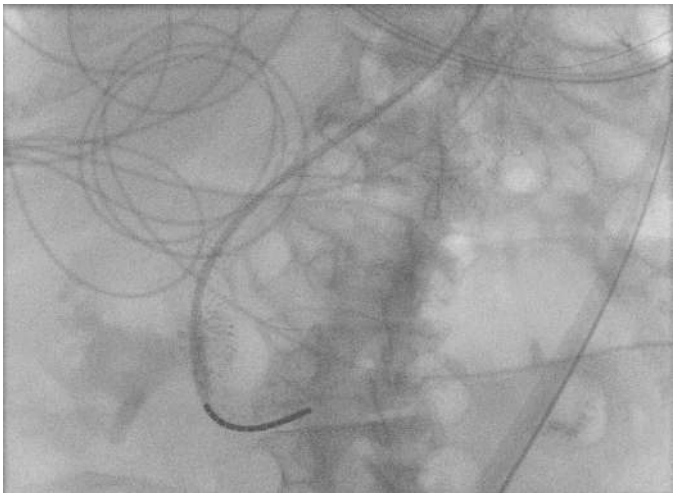

Fig. 59.43 Fluoroscopic placement of a small-bore nasojejunal (NJ) feeding tube transiting the third portion of the duodenum. This placement was performed in the same patient who experienced a previous failed attempt in Figure 59.5.

A variety of indications for IR involvement with tube placement relate to the GI tract. Cholecystostomy tube placement in IR is commonly a first-line intervention for the critically ill at prohibitively high risk for immediate cholecystectomy.

Patients with acalculous cholecystitis may undergo initial drainage, with tube removal occurring 4–6 weeks later, without the need for surgery at all, provided that the cystic and bile ducts are patent. Around two-thirds of patients avoid progressing to cholecystectomy in this way. Drains are also commonly placed when an obstruction cannot be effectively managed by endoscopy.

Feeding tubes, both percutaneous and nasally inserted, are also often placed by IR (Fig. 59.43). Percutaneous feeding tubes include both gastrostomy (G tube) and gastrojejunostomy (GJ tube) variants. The former are placed to vent and drain the stomach and can be used for feeding. The latter may be more appropriate for patients predisposed to reflux and/or inclined to aspirate by gastric dysmotility or outlet obstruction. Insertion of nasal G and GJ tubes is often relegated to IR when this cannot be accomplished at the bedside, for those at unusually high risk for procedural problems or tissue trauma, and for those in whom appropriate tube placement must be unequivocally assured.

Other useful applications of IR services include pain management and suprapubic catheter placement to address bladder outlet obstruction that cannot otherwise be resolved by transurethral insertion. Because challenging anatomy can be addressed, failed attempts at lumbar puncture may sometimes prove successful under IR imaging guidance. Precise site localization before local anesthetic injection may be the only reasonable approach to such intractable pain problems as radiculopathy and abdominal pain addressable by celiac plexus block or ablation (e.g., secondary to pancreatic carcinoma). Finally, intercostal blocks are effectively and safely performed by IR specialists.

KEY POINTS

- The value of a portable CXR usually depends on obtaining an appropriately penetrated, upright exposure in full inspiration. Consistency of technique from day to day is essential to optimize the value of serial films.
- Parenchymal infiltrates have many common potential etiologies, including atelectasis, embolism, edema, and hemorrhage. A minority of infiltrates represents infection; the diagnosis of nosocomial pneumonia requires clinical correlation and microbiologic confirmation.
- Although certain signs may be highly suggestive, the CXR does not reliably distinguish the high-permeability edema of ARDS from the hydrostatic pulmonary edema of volume overload or left heart failure.
- US has burgeoned as an imaging modality for applications by the intensivist, as it poses no risk of contrast or radiation exposure and can provide definitive, dynamic, and high-value information. With its near-immediate availability, US can facilitate an expanding variety of percutaneous bedside procedures and answer emergent questions relating to effusion, lung edema, and pneumothorax.
- Chest CT is quickly completed and often reveals conditions that were not suspected by plain radiographs. Reconstructed images sharply and convincingly define pathoanatomy, especially when contrast agents can be safely given.
- CT is the single best imaging modality for evaluating the abdomen unless the primary working diagnosis is cholelithiasis, ureteral obstruction, or ectopic pregnancy. US may be equally informative in such cases and is often the better choice when contrast exposure for CT is contraindicated.
- MRI is a modality that provides superb soft tissue imaging without ionizing radiation exposure but is time consuming and has relatively few ICU applications that do not relate to neurocritical care.
- IR provides a wide variety of interventions for the critically ill patient that are often of lower risk than traditional surgical interventions.
- Early interactive consultation with the diagnostic or interventional radiologist usually assures the best selection of procedure, optimal patient preparation, and efficient, bundled sequencing of tests and interventions.

Acute Respiratory Distress Syndrome

Julie A. Bastarache, Lorraine B. Ware, and Gordon R. Bernard

Acute respiratory distress syndrome (ARDS) is a common problem in the intensive care unit (ICU) that can complicate a wide spectrum of critical illnesses. First described by Ashbaugh and colleagues in 1967,[1] the syndrome was initially termed *adult respiratory distress syndrome* to distinguish it from the respiratory distress syndrome of neonates. However, with the recognition that ARDS can affect children, the term *acute* has replaced *adult* in the nomenclature in recognition of the typical acute onset that defines the syndrome. Although specific treatments for ARDS have been slow to emerge, new strategies of mechanical ventilation that improve mortality, targeted treatments for severe ARDS that include prone positioning, and fluid management strategies that reduce the duration of mechanical ventilation emphasize the importance of carefully personalized treatment of this condition. Although this point would seem to be straightforward, in practice, ARDS remains underdiagnosed,[2–5] and expert practitioners may disagree on the diagnosis[6–8] and treatment.

EPIDEMIOLOGY

The exact incidence of ARDS has been difficult to determine for a variety of reasons, with estimates ranging from 7 to 85 cases per 100,000 people. In the past, variable definitions of the syndrome were used.[9] The wide variety of causes and coexisting disease processes has also made identification of cases difficult both at the clinical and administrative coding levels.[10] The National Institutes of Health (NIH) first estimated the incidence at 75 per 100,000 population in 1977,[11] whereas a number of studies since then have reported lower incidences.[12] Two prospective studies confirmed the higher original NIH estimate. The first used enrollment logs from the National Heart, Lung, and Blood Institute, which sponsored an ARDS network of 20 hospitals and estimated that the incidence could be as high as 64 cases per 100,000 population. The second was a large, prospective study of residents of King County, Washington. In that study, the crude incidence of ARDS in adults was 78.9 per 100,000 patient years.[10] Several studies in the 1990s and 2000s suggest a decline in the incidence of ARDS over time,[13] including a prospective cohort study of trauma patients at risk for ARDS collected from 1997 to 2004 that showed that the incidence of ARDS decreased from 43% in 1997 to 12% in 2004.[14] A study of almost 3 million patients from the National Trauma Data Bank from 2011 to 2014 showed a further decline in ARDS incidence, with only 1% of all trauma patients developing this condition.[15] Another National Trauma Data Bank study found that among trauma patients who were mechanically ventilated, ARDS incidence decreased from 21.5% to 8.5% from 2007 to 2012.[16] In a population-based study in Olmstead County, Minnesota, the incidence of ARDS declined from 82.4 to 38.9 per 100,000 person-years from 2001 to 2008, despite concurrent increases in severity of acute illness and comorbidities in addition to a higher prevalence of major predisposing conditions.[17] Recent studies suggest that for some risk factors, ARDS incidence may actually be increasing. A large national study of 69 million hospital discharges in the United States from the National Inpatient Sample (NIS) showed that of the almost 1.2 million ARDS discharges, incidence rates increased from 180.7 cases/100,000 US population (2006) to 193.4 cases/100,000 US population (2014).[18] These increased rates were not uniformly distributed, however, with incidence of ARDS in pneumonia, shock, and sepsis increasing steadily over time, whereas rates of trauma- or transfusion-associated ARDS decreased. The global health burden attributed to ARDS is also substantial. A worldwide observational study of 459 ICUs from 50 countries across six continents (the LUNG SAFE study) included high-income European countries, high-income countries from the rest of the world, and middle-income countries. That survey showed wide variation in ARDS cases in the ICU, ranging from 6% to 48% of ICU patients during the 4-week study period.[5] Twenty-five percent of patients met criteria for severe ARDS in the European and middle-income countries, whereas only 18% had severe ARDS in high-income countries elsewhere. Another prospective multinational study of 119 ICUs from 16 countries (the PRoVENT study) found that among ICU patients at risk for ARDS, only 7% of patients developed ARDS.[19] Regardless of the exact incidence, it is clear that ARDS is a major global public health problem that will be encountered frequently by all physicians who care for critically ill patients.

RISK FACTORS

ARDS almost always occurs in the setting of a predisposing factor (Table 60.1), and the likelihood increases with multiple risk factors.[20,21] The commonly associated clinical disorders can be separated into those that directly injure the lung and those that indirectly injure the lung. Although it is not always feasible to determine the exact cause of ARDS in a given patient, direct causes appear to account for approximately one-half of all cases.[22] Regardless of the underlying cause, most patients with ARDS have a systemic illness with inflammation and organ dysfunction that are not confined to the lung.[23] Although the Berlin definition of ARDS requires designation of a risk factor, there is a small group of patients (2.2% of ARDS patients enrolled in ARDS network trials) who clinically have ARDS but do not have an identifiable risk factor.[24] These patients tend to be younger, have lower baseline severity of illness, and experience more ventilator- and ICU-free days.

Sepsis is the most common cause of indirect lung injury, with an overall risk of progression to ARDS of approximately 30%–40% among patients with sepsis requiring ICU admission.[18,20,25–27] In addition to sepsis itself being a risk factor for ARDS, the site of infection may influence the risk of lung injury. Among patients admitted to an ICU with sepsis, patients who had pneumonia as the source of sepsis

TABLE 60.1 Risk Factors Associated With the Development of Acute Respiratory Distress Syndrome

Direct Lung Injury	Indirect Lung Injury
Pneumonia	Sepsis
Aspiration of gastric contents	Multiple trauma
Pulmonary contusion	Cardiopulmonary bypass
Fat, amniotic fluid, or air emboli	Drug overdose
Near-drowning	Acute pancreatitis
Inhalational injury	Transfusion of blood products
Reperfusion pulmonary edema	
Vaping	

had an increased risk of ARDS compared with those with infections at other sites (abdomen, skin, soft tissue, etc.).[28] There is undoubtedly some geographic variation in risk of ARDS by site of infection. In developing countries or those in the tropics, risk factors for ARDS may be very different from those encountered in other parts of the world. For example, a study from India found that the four most common risk factors for ARDS were leptospirosis (18.7%), bronchopneumonia (17.3%), scrub typhus (12%), and dengue (12%).[29] Severe trauma with shock and multiple transfusions also can cause damage indirectly. Although the other causes of indirect lung injury are less common, many, such as transfusion,[30] are common interventions in the ICU setting. The most common cause of direct lung injury, pneumonia, may be of bacterial, viral, or fungal origin. In recent years, new risk factors for direct lung injury have emerged, including novel respiratory viruses such as severe acute respiratory syndrome (SARS),[31] Middle Eastern respiratory syndrome (MERS)[32] and other coronaviruses,[33] and inhaled exposures such as inhalation of vapors from electronic (e) cigarettes or other delivery vehicles.[34,35] Emerging in the summer of 2019, e-cigarette (vaping)–associated lung injury (EVALI) was first described among mostly young adults who presented with a clinical syndrome identical to ARDS.[36,37] Although the chemical composition of vaping liquid is complex, many cases seem to occur in patients using tetrahydrocannabinol (THC)-containing e-cigarettes.[36,38–41] Secondary conditions may also increase the risk. Such factors include chronic lung disease,[27] chronic or acute alcohol abuse,[42,43] cigarette smoking,[30,44,45] air pollution,[46–48] lung resection,[49] and obesity.[50] Interestingly, several studies have shown that patients with diabetes are less likely to develop ARDS.[51–53]

ARDS risk may be modified by the underlying genetic makeup of the individual. A genome-wide association study (GWAS) of African American patients with ARDS showed an association with a single nucleotide polymorphism (SNP) in the P-selectin glycoprotein ligand-1 gene.[54] A larger study of patients of European ancestry with sepsis as the risk factor for ARDS identified associations between variants in fms-related tyrosine kinase (FLT1), which encodes the vascular endothelial growth factor receptor 1 (VEGFR-1) protein, and the risk of ARDS.[55] Blood type, which is genetically regulated, may also be a risk factor for ARDS; blood type A is associated with increased risk of ARDS after sepsis or trauma.[56] Another study identified a variant of the hemoglobin scavenging protein haptoglobin (haptoglobin 2 allele) that is associated with increased ARDS among ICU subjects at risk.[57] Whether genetic risk factors for ARDS will eventually lead to more targeted clinical care for these patients is not yet clear.

Age may also be a risk factor, with some studies indicating higher ARDS risk with increasing age.[50] However, there may in fact be a nonlinear distribution of ARDS risk by age, as demonstrated by a multicenter cohort study of 5584 at-risk patients showing that adults >80 years old had a lower rate of ARDS (3.5%) versus those <80 years old (7.2%).[58] Another somewhat surprising finding is that prehospital vulnerability as measured by the Vulnerable Elders Survey (VES) was not associated with increased risk of ARDS.[59] Although transfusion of blood products is a well-known risk factor for ARDS,[60–63] the risk may differ by indication for transfusion. In the perioperative period, transfusion of blood products is associated with an increased risk of ARDS, particularly among those ventilated with high tidal volumes and driving pressures.[63] However, in an analysis of severely injured trauma patients who were treated with different transfusion regimens (the PROPPR study), infusion of crystalloid, but not blood products, was associated with an increased risk of ARDS, with each 500 mL of crystalloid infused increasing the ARDS rate by 9%.[64] To some extent, almost every patient in the ICU is at risk for developing ARDS, and vigilance is required to recognize the diagnosis and treat appropriately.

PATHOPHYSIOLOGY

The complex pathophysiology of ARDS remains incompletely understood.[65] Microscopically, lungs from afflicted individuals in the early stages typically show diffuse alveolar damage, with alveolar flooding by proteinaceous fluid, neutrophil influx into the alveolar space, loss of alveolar epithelial cells, deposition of hyaline membranes on the denuded epithelial basement membrane, and formation of microthrombi (Fig. 60.1).[66] The alveolar flooding occurs as a result of injury to the alveolar-capillary barrier and is a major determinant of the hypoxemia and altered lung mechanics that characterize early ARDS. The alveolar-capillary barrier is formed of two separate cell layers—the microvascular endothelium and the alveolar epithelium. Injury to the alveolar epithelium is a prominent feature histologically, with loss of alveolar epithelial barrier integrity and sloughing of alveolar epithelial type I cells. Alveolar epithelial apoptosis is widespread and likely contributes to the loss of epithelium seen ultrastructurally.[67,68] Although endothelial injury is less obvious at the microscopic level, ultrastructural studies reveal that it is widespread[69,70] and is accompanied by increased permeability.[65] Endothelial injury allows leakage of plasma from the capillaries into the interstitium and air spaces. The alveolar flooding in ARDS is characterized by protein-rich edema fluid resulting from the increased permeability of the alveolar-capillary barrier, in contrast to the low-protein pulmonary edema that results from hydrostatic causes such as congestive heart failure or acute myocardial infarction.[71–74] Over time, the pathologic changes of ARDS evolve, such that acute inflammation and pulmonary edema become less prominent and fibrosing alveolitis may appear. Recent autopsy studies show that fibroproliferative changes can be seen even early in ARDS and may coexist with exudative changes.[75] These may progress or resolve with time.

Neutrophils play an important role in the initial inflammatory response of ARDS.[76] Early ARDS is characterized by migration of neutrophils into the alveolar compartment.[69,70] Neutrophils can release a variety of injurious substances, including proteases such as neutrophil elastase, collagenase, and gelatinases A and B and reactive nitrogen and oxygen species. In addition, they can elaborate proinflammatory cytokines and chemokines that amplify the inflammatory response in the lung. Recent evidence suggests that neutrophil extracellular traps (NETs) that contain DNA, histones, and other intracellular proteins may act as damage-associated molecular patterns in amplifying the immune response in ARDS.[77,78] Resident alveolar macrophages are also involved in initiating and sustaining a proinflammatory cytokine cascade that leads to recruitment of neutrophils into the lung.[79] Age may be a factor in regulation of the pulmonary host response in ARDS.

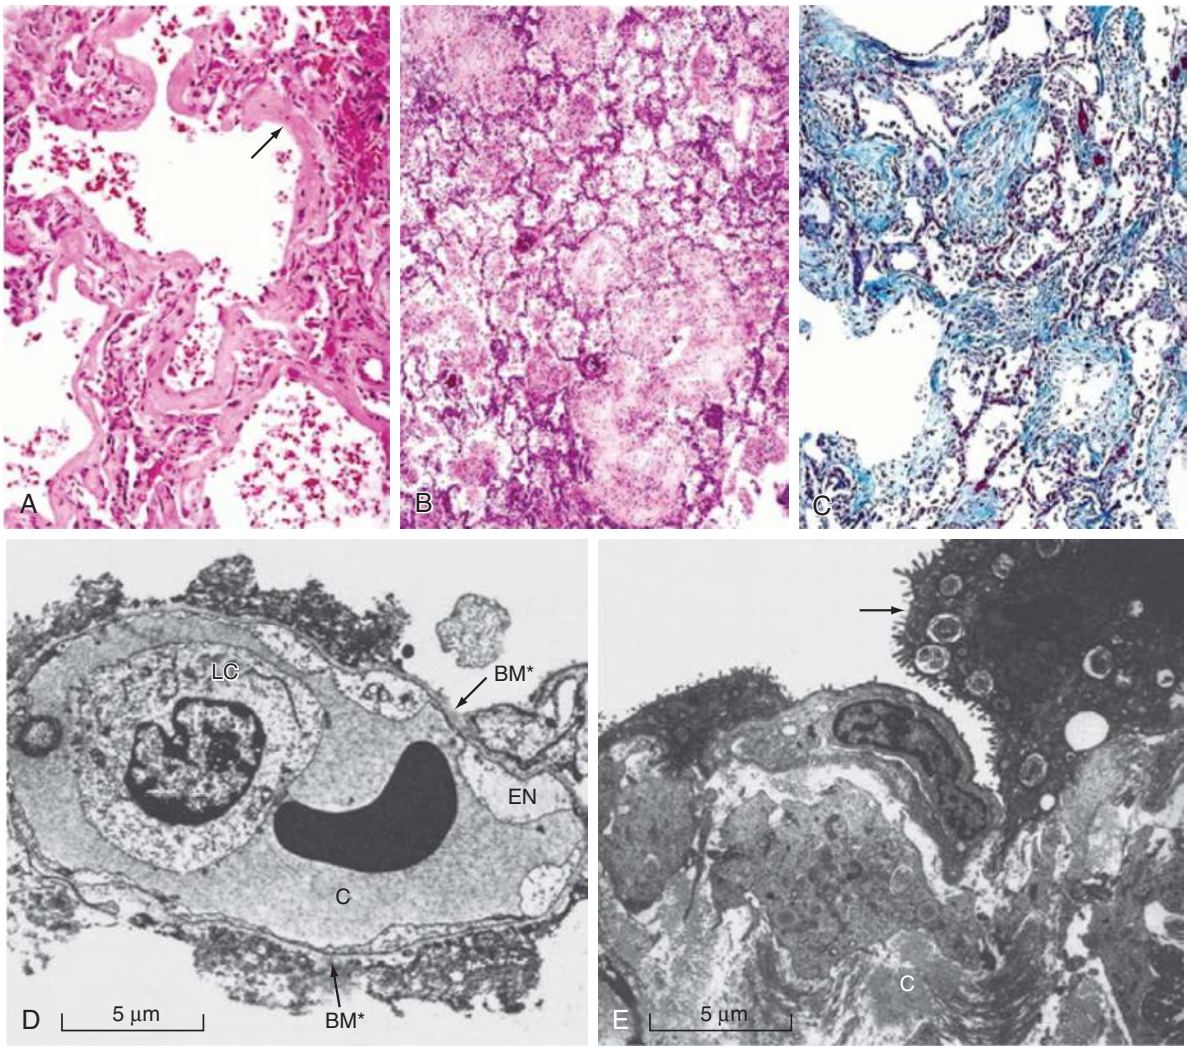

Fig. 60.1 Histologic Findings in Acute Respiratory Distress Syndrome (ARDS). **A,** A lung biopsy specimen obtained from a patient 2 days after the onset of the syndrome as a result of the aspiration of gastric contents. Characteristic hyaline membranes are evident *(arrow)*, with associated intraalveolar red cells and neutrophils, findings consistent with the pathologic diagnosis of diffuse alveolar damage (hematoxylin and eosin, ×90). **B** and **C,** Lung biopsy specimens obtained 14 days after the onset of sepsis-associated ARDS. **(B)** shows granulation tissue in the distal air spaces with a chronic inflammatory-cell infiltrate (hematoxylin and eosin, ×60). Trichrome staining in **(C)** reveals collagen deposition *(dark blue areas)* in the granulation tissue, a finding consistent with the deposition of extracellular matrix in the alveolar compartment (×60). **D,** A specimen of lung tissue from a patient who died 4 days after the onset of ARDS; there is injury to both the capillary endothelium and the alveolar epithelium. An intravascular neutrophil *(LC)* can be seen in the capillary *(C)*. Vacuolization and swelling of the endothelium *(EN)* are apparent. Loss of alveolar epithelial cells is also apparent, with the formation of hyaline membranes on the epithelial side of the basement membrane *(BM*)*. **E,** A specimen of lung tissue obtained from a patient during the fibrosing-alveolitis phase in which there is evidence of reepithelialization of the epithelial barrier with alveolar epithelial type II cells. The *arrow* indicates a typical type II cell with microvilli and lamellar bodies containing surfactant. The epithelial cell immediately adjacent to this cell is in the process of changing to a type I cell, with flattening, loss of lamellar bodies, and microvilli. The interstitium is thickened, with deposition of collagen **(C)**. (Permission from Ware LB, Matthay MA. Medical progress: the acute respiratory distress syndrome. *N Engl J Med.* 2000;342:1334–1349.)

Older adults have more exuberant inflammation in the lung compared with children and younger adults.[80]

In addition to acute neutrophilic inflammation and elaboration of a proinflammatory cytokine cascade, a variety of other abnormalities contribute to the pathogenesis of ARDS. Surfactant dysfunction is characteristic, with abnormalities in both the protein and lipid components.[81–84] This dysfunction likely results from disruption of normal surfactant activity by the influx of plasma proteins into the air spaces, intraalveolar proteolysis, and injury to the alveolar epithelial type II cells. Surfactant dysfunction may have important implications, both for lung mechanics and for host defense.[85] Activation of the coagulation cascade and impaired fibrinolysis are also apparent in patients with ARDS,[86,87] both in the lung[88–90] and systemically.[91] The airspace in ARDS is also characterized by increased oxidative stress with an alteration in the balance of endogenous oxidants and antioxidants with a fall in endogenous antioxidants[92] despite increased oxidant production.[93]

The contribution of ventilator-associated lung injury to the pathogenesis of ARDS has been increasingly recognized. There are several mechanisms by which mechanical ventilation can injure the lung. Ventilation at very high volumes and pressures can injure even the normal lung, leading to increased-permeability pulmonary edema caused by capillary stress failure[94] in conjunction with sustained elevations of circulating plasma cytokines.[95] In the injured lung, even tidal volumes that are normally well tolerated can lead to alveolar overdistention in relatively uninjured areas because the lung available for distribution of the administered tidal volume is greatly reduced and the distribution of inspired gas and stresses is uneven.[96,97] In addition to alveolar overdistention, cyclic opening and closing of atelectatic alveoli can cause lung injury even in the absence of alveolar overdistention. The combination of alveolar overdistention with cyclic opening and closing of alveoli is particularly harmful and can initiate a proinflammatory cytokine cascade.[98] A ventilatory strategy that was designed to minimize alveolar overdistention and maximize alveolar recruitment ameliorated this proinflammatory cytokine release.[99] This fundamental insight into the pathogenesis of clinical ARDS has led to multiple clinical trials of novel ventilatory strategies for patients with ARDS, including the landmark ARDS Network trial of 6 mL/kg versus 12 mL/kg tidal volume ventilation[100] and several trials of higher levels of positive end-expiratory pressure (PEEP) with or without maneuvers intended to maximize alveolar recruitment (see "Treatment" section later).

Although current treatment for all patients with ARDS is similar regardless of cause, emerging evidence indicates that there may be biologically and clinically distinct subphenotypes within ARDS that may respond differently to treatment.[101] One such distinction is between patients who develop ARDS as a result of direct injury to the lung (secondary to pneumonia or aspiration) and those who have primarily indirect injury to the lung because of a systemic insult (secondary to nonpulmonary sepsis or pancreatitis). Whether the distinction between direct and indirect lung injury is clinically useful is unclear,[102,103] but there are biologic differences between direct and indirect lung injury that inform pathogenesis. Patients with direct lung injury have higher circulating markers of lung epithelial injury, whereas those with indirect lung injury have higher levels of markers of endothelial injury.[104] Some investigators have demonstrated reduced respiratory system compliance in patients with ARDS caused by direct pulmonary injury as compared with that of indirect causes,[105] although total respiratory system compliance (including the chest wall) is similar.[106] Improved lung mechanics may be more likely in patients with direct lung injury with the application of PEEP and alveolar recruitment maneuvers.[107,108] However, in the largest cohort of patients studied to date, there was no difference in mortality between those with direct (pulmonary) and indirect (extrapulmonary) causes of lung injury.[22]

A potentially more clinically useful distinction is between ARDS subphenotypes derived using statistical approaches. Calfee and colleagues used latent class analysis to discover two distinct ARDS subphenotypes among patients enrolled in two large clinical trials based on clinical, laboratory, and biomarker measurements.[109] One group was characterized by high levels of proinflammatory cytokines, higher use of vasopressors, a higher prevalence of sepsis, and lower serum bicarbonate (hyperinflammatory endotype). This group had higher mortality and fewer ventilator-free and organ failure–free days compared with the group that had a more hypoinflammatory endotype. Most interestingly, the same two classes with similar defining features were independently derived from five large, heterogeneous patient cohorts.[110–112] Although these initial studies used a multitude of clinical, physiologic, and laboratory measures to identify endotypes, the model has subsequently been refined and simplified, such that excellent classification can be achieved with three variables: interleukin (IL)-8, protein C, and bicarbonate.[113] Although identification of biologically and clinically meaningful subphenotypes has the potential to alter therapeutic approaches to ARDS, it also may lead to significant breakthroughs in our mechanistic understanding of ARDS. For example, the two previously described ARDS subphenotypes have been shown to have distinct gene expression profiles in circulating leukocytes.[114]

DIAGNOSIS

Clinical Criteria

Several clinical definitions have been used for the diagnosis of ARDS since it was first described in 1967. Before 1994, a variety of definitions were used, including the Murray Lung Injury Score.[115] In 1994 the American–European Consensus Conference (AECC) published new clinical definitions for acute lung injury (ALI) and ARDS.[9] A modified version of the AECC definition, the Berlin definition,[116] is currently the primary diagnostic tool for ARDS for both clinical diagnosis and research purposes (Fig. 60.2). To meet the definition, the onset of ARDS, including bilateral infiltrates on chest radiograph, must occur within 1 week of a known precipitant. Patients must be receiving ≥5 cm H_2O of continuous positive airway pressure (CPAP); for mild ARDS, this airway pressure can be delivered by noninvasive positive-pressure ventilation. Severity is classified based on the degree of hypoxemia as mild, moderate, or severe. Mechanical properties of the respiratory system, such as compliance, are not used to grade disease severity. In all patients with suspected ARDS, an underlying cause of ALI (see Table 60.1) should be sought. In the absence of an identifiable underlying cause, particular attention should be given to other causes of pulmonary infiltrates and hypoxemia, such as hydrostatic (cardiogenic) pulmonary edema. Finally, the Berlin definition recognizes that elevated vascular

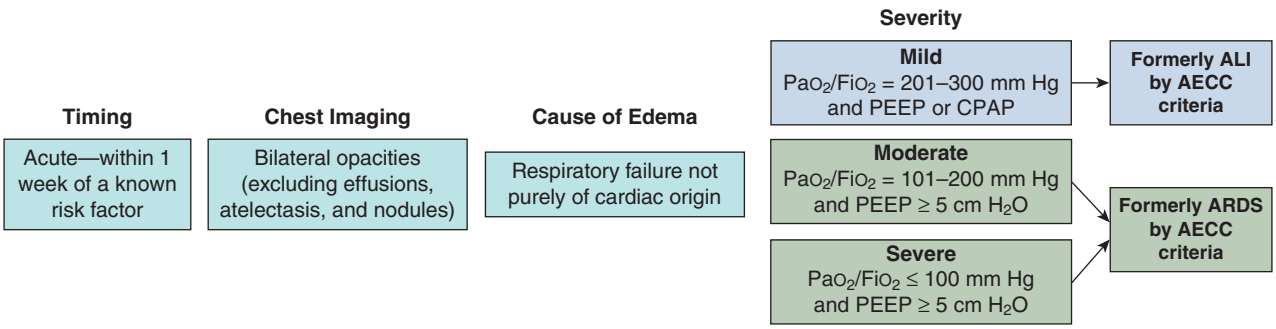

Fig. 60.2 The Berlin definition of ARDS. *AECC*, American–European Consensus Conference; *ALI*, acute lung injury; *ARDS*, acute respiratory distress syndrome; *CPAP*, continuous positive airway pressure; *FiO_2*, fraction of inspired oxygen; *PaO_2*, partial pressure of oxygen *PEEP*, positive end-expiratory pressure.

filling pressures and ARDS can coexist; there is no absolute requirement in the Berlin definition to rule out a cardiac cause of pulmonary edema unless a patient's respiratory failure cannot be explained fully by an ARDS risk factor. In such instances, objective cardiac testing such as echocardiography or pulmonary artery catheterization can be used.

One potential limitation of the Berlin definition is the need for arterial blood gas sampling to calculate a PaO_2/FiO_2 ratio. Recent work has shown good correlation between the SpO_2/FiO_2 ratio (measured by pulse oximetry) and the PaO_2/FiO_2 ratio,[117,118] with an SpO_2/FiO_2 ratio of 235 corresponding to a PaO_2/FiO_2 ratio of 200 and an SpO_2/FiO_2 ratio of 315 correlating to a PaO_2/FiO_2 ratio of 300. These correlations are valid only when the SpO_2 is less than 98% because the oxyhemoglobin dissociation curve is flat above this level. As measurement of oxygen saturation is noninvasive, continuous measurements and the use of the SpO_2/FiO_2 ratio in addition to the PaO_2/FiO_2 ratio may improve the ability of clinicians to diagnose ARDS and monitor its progression.[119]

Differentiation between ARDS and hydrostatic edema can be difficult, and there may be significant overlap in these conditions (Fig. 60.3).[120] A multicenter trial of intravenous catheter–directed fluid management strategies in patients with ARDS showed that 29% of those with clinically defined ARDS had a pulmonary artery occlusion pressure (PAOP) >18 mm Hg at the time of pulmonary artery catheter insertion but that 97% had a normal or elevated cardiac index, suggesting that they did not have clinical heart failure.[121] Other studies have shown similar rates of elevated PAOP in patients with ARDS.[122] There are no specific clinical or laboratory studies that can reliably distinguish between ARDS and hydrostatic edema. A study examining the diagnostic utility of serum levels of B-type natriuretic peptide (BNP) showed that BNP measured at admission could not reliably differentiate between hydrostatic edema and ARDS. Furthermore, BNP levels in these patients did not correlate with invasive hemodynamic measurements.[123] N-terminal BNP levels are also elevated in ARDS[124] but do not necessarily correlate with PAOP.

ARDS is a syndrome, not a specific disease. Therefore although the standardization of ARDS definitions has been of value for both clinical diagnosis and clinical research, the nature of ARDS is such that any definition will have shortcomings. First, the Berlin definition is based solely on clinical criteria because currently there is no laboratory test that allows clinical assessment of the presence or absence of ARDS. Second, the presence or absence of multiorgan dysfunction, an important determinant of outcome, is not specified. Finally, although the presence of bilateral infiltrates has major prognostic significance and is clearly a hallmark of the syndrome, the radiographic findings are not specific for ARDS,[6,125] and a variety of other conditions can produce them (Table 60.2).[126] For these reasons, diagnostic uncertainty in ARDS is common,[127] is a major barrier to initiation of appropriate therapy, and is one of the main reasons why clinicians fail to initiate lung-protective ventilation in clinically appropriate patients.[128]

Invasive Methods

In the majority of patients, the initial diagnosis of ARDS is made clinically. Invasive procedures for the diagnosis of ARDS are of limited clinical utility, and the benefits often do not outweigh the risks.[129] Among the potential invasive diagnostic methods available, bronchoscopy is the one most frequently used. Bronchoscopy may be indicated in the early phases of ARDS in patients for whom there is no identifiable predisposing risk factor and in the immunosuppressed. Bronchoalveolar lavage for cultures and cytologic examination can identify the cause of pneumonia and is particularly useful in the diagnosis of opportunistic infections. Lavage fluid usually has a predominance of

neutrophils, and there may be evidence of diffuse alveolar hemorrhage. Cytologic examination can be used to confirm the presence of diffuse alveolar damage.[130] Rarely, an alternative and directly treatable diagnosis is found, such as acute eosinophilic pneumonia, pulmonary alveolar proteinosis, diffuse alveolar hemorrhage, or unsuspected infection.

In the past, open lung biopsy was obtained more frequently for diagnosis. The degree of histologic abnormality on lung biopsy does not correlate with ultimate outcome as measured by pulmonary function,[131] but is associated with increased mortality.[132] Predictors of diffuse alveolar damage, the pathologic hallmark of ARDS, include duration of ARDS, more severe hypoxemia, increased tidal driving pressure, and more severe radiographic abnormalities.[133] Histologic appearance of the lung is widely varied, even in clinical ARDS, with one retrospective study finding diffuse alveolar damage (48%), lung fibrosis (39%), and organizing pneumonia (24%) on biopsies.[134] Open or thoracoscopic lung biopsy may still be useful in some cases for which the diagnosis remains uncertain and the underlying cause is not apparent. Although open lung biopsy can provide findings that lead to a change in treatment, postoperative complications occurred in 22%–35% of patients.[134,135] Several pathologic studies have shown that biopsy or autopsy can identify unsuspected diagnoses requiring specific therapy such as miliary tuberculosis, pulmonary blastomycosis, aspergillosis, or bronchiolitis obliterans organizing pneumonia in 40%–60% of cases[136–138]; however, the general applicability of these studies may be limited by the fact that they were retrospective case series. In a meta-analysis of published studies, open lung biopsy for well-selected patients altered their management in 73% of cases[135]; biopsy findings that alter management may be associated with better survival.[139]

In addition to familiarity with the Berlin definition of ARDS, the critical care clinician should be aware that ARDS has been called by a variety of other terms, some of which are seen mainly in older literature, but some remain in clinical use. Some of the more common of these terms include adult hyaline membrane disease, postperfusion lung or pump lung, shock lung, and adult respiratory insufficiency syndrome. The terms *reperfusion pulmonary edema, primary graft dysfunction, primary graft failure,* and *transplant lung* have been used to describe ARDS occurring immediately after lung transplantation. In addition, newly defined syndromes such as SARS,[31] MERS,[32] and EVALI[34,39,41] may be used to describe ARDS from specific causes. Regardless of the name applied, ARDS is a clinical syndrome that has prognostic and therapeutic implications above and apart from the underlying cause (i.e., infections, aspiration, trauma). This fact does not diminish the imperative to identify these underlying causes, if present, and treat them appropriately.

CLINICAL COURSE

Early ARDS

The Berlin definition aims to identify ARDS patients early in their course, in the acute or exudative phase. Clinically, the acute phase is manifested by the acute onset of radiographic infiltrates consistent with pulmonary edema, hypoxemia, and increased work of breathing. Radiographic infiltrates are bilateral (by definition) but may be patchy or diffuse, fluffy or dense (Fig. 60.4), and pleural effusions may occur.[140] The chest radiograph can be used to quantify the degree of pulmonary edema by calculating the Radiographic Assessment of Lung Edema (RALE) score, which takes into account both the density of the infiltrate and the distribution in each quadrant of the chest.[141] Furthermore, the RALE score may have predictive or prognostic utility.[141,142] Chest computed tomographic (CT) imaging, though rarely used clinically, has been employed extensively as an investigative tool to better define the nature of the radiographic infiltrates in patients with ARDS. The distribution of infiltrates by CT is surprisingly variable. Although some patients have evidence of diffuse alveolar edema on CT, many patients have more focal infiltrates, with areas of alveolar filling and consolidation occurring predominantly in dependent zones, whereas nondependent regions are relatively spared.[143–145] Studies have attempted to use CT to differentiate ARDS from hydrostatic edema but

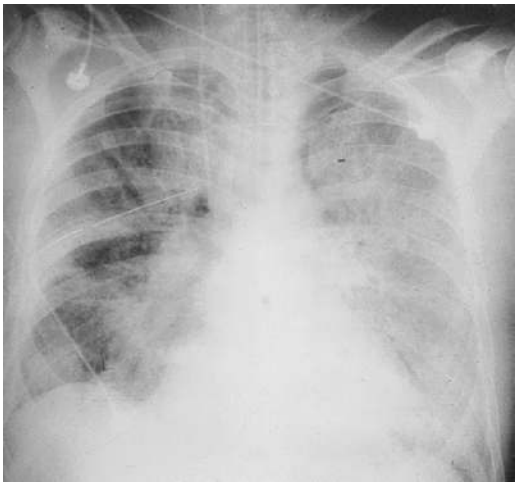

Fig. 60.4 Representative Chest Radiograph from a Patient with Acute Respiratory Distress Syndrome.

have not found useful indicators to differentiate the two.[146] However, even areas that appear spared in conventional radiographic images may have substantial inflammation when sampled using bronchoalveolar lavage[147] or imaged using fluorodeoxyglucose–positron emission tomography (FDG-PET).[148] Patients with more diffuse infiltrates may be more likely to respond to recruitment maneuvers[149]; whether CT imaging could be helpful for guiding ventilator treatment is not yet known, although one recent study attempted to guide ventilator treatment based on CT distribution of infiltrates.[208]

The hypoxemia that characterizes early ARDS usually is relatively refractory to supplemental oxygen. The increased work of breathing in the acute phase of ARDS is caused by decreased lung compliance as a result of fewer available alveolar units, tissue edema, greater airflow resistance,[150] and increased respiratory drive.[151] The combination of hypoxemia and increased work of breathing usually necessitates endotracheal intubation and mechanical ventilation, although occasionally patients can be managed with noninvasive ventilation or very high-flow nasal cannula oxygen (see "Treatment" section later).

In addition to hypoxemia and increased work of breathing, many patients with ARDS develop increased pulmonary vascular resistance, leading to pulmonary hypertension and acute right ventricular (RV) failure. The prevalence of pulmonary hypertension in patients presenting to the hospital with ARDS may be as high as 92%.[152] Even in the era of low tidal volume ventilation, one study used transesophageal echocardiography to show evidence of acute RV failure in 22% of 226 consecutive patients with moderate or severe ARDS.[153] Such findings were associated with an almost twofold increase in 28-day mortality. Attempts to reverse pulmonary hypertension and RV failure with pulmonary vasodilators such as sildenafil have decreased pulmonary artery pressure but produced concomitant increases in shunt fraction and decreases in oxygenation.[154] These findings suggest that although patients with ARDS have evidence of pulmonary hypertension, it may, in some cases, be a compensatory physiologic response that reduces blood flow to areas of severely compromised lung.

Late Fibroproliferative ARDS

In most patients, ARDS will substantially resolve after the acute phase. However, in others, the syndrome progresses to a fibrosing alveolitis. Fibrosing alveolitis usually becomes clinically apparent after 7–10 days, although evidence of deposition of extracellular matrix constituents has been identified in alveolar lining fluid from patients as early as the first day after intubation,[155] and autopsy studies show early fibrotic changes in some patients.[75] Radiographically, linear opacities develop, consistent with the evolving fibrosis. Histologically, pulmonary edema and neutrophilic inflammation are less prominent. A severe fibroproliferative process fills the air spaces with granulation tissue that contains collagen and fibrin in addition to new blood vessels and proliferating mesenchymal cells.[156,157]

Clinically, the late fibroproliferative phase of ARDS is characterized by continued need for mechanical ventilation, often with persistently high levels of PEEP and FiO_2. The lung compliance may fall even further, and pulmonary dead space elevates. If it has not developed in the acute phase, pulmonary hypertension may now emerge as a result of obliteration of the pulmonary capillary bed, and RV failure may occur.[158] This phase of the illness can be prolonged, lasting weeks, and can be very frustrating for the clinician, patient, and family, as small gains in pulmonary function are frequently offset by new problems, such as hospital-acquired infections and nonpulmonary organ dysfunction. Progressive deconditioning can make eventual weaning from mechanical ventilation difficult if the fibrosing alveolitis stage is prolonged. Perhaps in part because the use of lower tidal volumes lessens injury and improves the number of ventilator-free days, the incidence of fibrosing alveolitis seems to be falling. However, a recent autopsy study found more fibrotic changes in patients treated in the low tidal volume era than in patients treated with higher tidal volumes.[75] One possible explanation is that better supportive care has prolonged survival of some patients with more severe lung injury, allowing more time for fibrotic changes to develop and be detected at autopsy.

Resolution of ARDS

After sufficient time has elapsed, lung biopsies from ARDS survivors typically show normal or near-normal lung histology. For such histologically complete resolution of ARDS to occur, a variety of processes must be reversed. Alveolar edema is actively reabsorbed by the vectorial transport of sodium and chloride from the distal airway and alveolar spaces into the lung interstitium, where it can be cleared by the lymphatics or reabsorbed into the vasculature.[159] Water is passively absorbed along the osmotic gradient, probably through water channels, the aquaporins.[160] The majority of patients with early ARDS have impaired alveolar fluid transport; in those with intact alveolar fluid transport, faster rates of alveolar epithelial fluid transport are associated with better outcomes.[71] Soluble and insoluble protein must also be cleared from the air spaces. Soluble protein probably diffuses by a paracellular route into the interstitium, where it is cleared by lymphatics. Insoluble protein probably is removed by macrophage phagocytosis or alveolar epithelial cell endocytosis and transcytosis.[161]

The denuded alveolar epithelium must be repaired. The alveolar epithelial type II cell serves as the progenitor cell for repopulating the alveolar epithelium. Type II cells proliferate, migrate, and differentiate to reconstitute a tight alveolar epithelial type I cell barrier.[162] The inflammatory cell infiltrate must also resolve, but here the mechanisms are less clear. Resolution of neutrophilic inflammation may be predominantly via neutrophil apoptosis and phagocytosis by macrophages. However, one report suggests that neutrophil apoptosis is impaired in the lungs of patients with ARDS.[163] The resolution of fibrotic changes is also not well understood. Clearly, substantial remodeling is necessary to restore a near-normal alveolar architecture. In patients with advanced fibrosis, this process likely takes place over many months; pulmonary function abnormalities continue to improve, sometimes remarkably so, out to the first year and beyond in survivors of ARDS (see later).[164,165]

TREATMENT

Standard Supportive Therapy

Several societies have published comprehensive guidelines to assist clinicians in treating patients with ARDS.[166–171] Encouragingly, there has been a gradual decline in mortality attributable to ARDS over time,[172,173] likely reflecting improvements in standard supportive therapy and adherence to evidence-based guidelines for ventilator and fluid management and supporting care. Although detailed discussion of all aspects of supportive therapy is beyond the scope of this chapter, a few aspects will be considered.

Treatment of Predisposing Factors

First and foremost, a search for the underlying cause of ARDS should be undertaken. Appropriate treatment for any precipitating infection such as pneumonia or sepsis is critical to improving the probability of survival. In the immunocompromised host, invasive diagnostic evaluation, including bronchoscopy, may be warranted to uncover evidence of opportunistic infections. In a patient with sepsis and ARDS of unknown source, an intraabdominal process should be considered. Timely surgical management of intraabdominal sepsis is associated with better outcomes.[174] In some patients, the cause of lung injury will

not be specifically treatable (such as aspiration of gastric contents) or will not be readily identified.[24]

Fluid and Hemodynamic Management

Historically, patients with critical illness and ARDS received a pulmonary artery catheter (PAC) to manage fluid and hemodynamic status. A large, randomized European trial of PAC use (compared with no PAC use) in all patients admitted with ARDS[175] showed no difference in clinical outcomes on either group, suggesting that routine PAC use in ARDS without specified PAC-guided interventions is not beneficial. The ARDS Clinical Trials Network tested the value of pulmonary artery catheterization in the context of specific fluid management protocols and was unable to demonstrate the superiority of PAC over the central venous catheter in directing specific fluid management protocols in ARDS patients, and PAC use did not improve outcomes in these patients.[121] Some investigators have proposed that clinical outcomes in ARDS can be improved by delivery of supranormal levels of oxygen using vigorous volume resuscitation and positive inotropes. However, no benefit to supranormal levels of oxygen delivery has been demonstrated in patients with ARDS.[176,177]

For decades there was disagreement as to the best fluid management strategy in patients with ARDS. Proponents of a liberal fluid strategy reasoned that increased circulating volume would preserve end-organ perfusion and protect patients from the development of nonpulmonary organ failures. Reductions in intravascular volume can have adverse effects on cardiac output and tissue perfusion, factors that could contribute to multisystem organ failure. This concern is legitimate, because mortality in ARDS is usually from nonpulmonary causes, including other organ failures. Others supported a conservative fluid strategy in an attempt to reduce circulating volume, thereby reducing the driving force for pulmonary edema formation. In experimental lung injury, lower left atrial pressures are associated with less formation of pulmonary edema.[178,179] Some limited clinical evidence supported this latter approach.[180–183] Because of conflicting rationales and uncertainty, the ARDS Network conducted a large, multicenter, randomized controlled trial of catheter-driven fluid management in patients with ARDS (central venous catheter vs. PAC).[121] Once patients were out of shock, they were randomized to a liberal fluid treatment strategy that resulted in an average of 1L of fluid accumulation per day or to a conservative fluid treatment strategy with aggressive use of diuretics to achieve a goal central venous pressure (CVP) <4 mm Hg or a goal PAOP <8 mm Hg, resulting in an average of zero net fluid accumulation by day 7. Although there was no difference in mortality at 60 days (the primary outcome of the study), patients in the conservative group experienced improved oxygenation and significantly more ventilator-free days without the development of additional organ failures. In this study it did not matter whether treatment was guided by CVP measurements (derived from a central venous line) or from PAOP measurements (derived from a PAC).[184] These important findings have been confirmed in subsequent studies.[185]

Despite the findings in support of a conservative fluid management strategy in patients with ARDS, there continues to be a great deal of uncertainty about the appropriate goals for hemodynamic therapy in ARDS. Currently, the recommended strategy is to aim to achieve the lowest intravascular volume that maintains adequate tissue perfusion as measured by urine output, perfusion of other vital organs, and metabolic acid-base status using CVP monitoring to direct therapy. In fact, cumulative fluid balance has been shown to predict increased time on mechanical ventilation and mortality in patients with ARDS.[186] If organ perfusion cannot be maintained in the setting of adequate intravascular volume, then vasopressors and/or inotropes should be used to restore end-organ perfusion.[158] Available evidence does not support the use of one particular vasopressor or combination of vasopressors. Once shock has resolved, patients should be managed with a conservative fluid strategy, with the goal of driving the CVP <4 mm Hg when possible so as to keep fluid balance net zero during the ICU stay.

Nutrition

Standard supportive care for the patient with ARDS includes the provision of adequate nutrition. The enteral route is preferred to the parenteral route and is associated with fewer infectious complications.[187] Enteral feeding may also confer other beneficial effects. Experimentally, lack of enteral feeding promoted translocation of bacteria from the intestine.[188] In normal volunteers, administration of parenteral nutrition with bowel rest increased circulating levels of tumor necrosis factor-alpha (TNF-α), glucagon, and epinephrine and increased febrile responses compared with volunteers who received enteral nutrition.[189]

The goals of nutritional support in any critically ill patient include the provision of adequate nutrients for the patient's level of metabolism and the treatment and prevention of any deficiencies in micronutrients or macronutrients.[190] Whether a particular dietary composition could benefit patients with ARDS is unclear. Immunomodulation via dietary manipulation has been attempted by a number of investigators in critically ill patients using various combinations of omega-3 fatty acids, ribonucleotides, arginine, and glutamine. A meta-analysis of these trials suggested a beneficial effect on infection rate but not on overall mortality.[191] However, a large, multicenter, randomized placebo-controlled study of omega-3 fatty acid and antioxidant supplementation in patients with ARDS was stopped early by the data safety monitoring board for a trend towards excess mortality in patients receiving the omega-3 fatty acid supplement.[192] Using a different approach, a high-fat, low-carbohydrate diet reduced the duration of mechanical ventilation in patients with acute respiratory failure.[193] Although the mechanism of this beneficial effect was postulated to be caused by a reduction of the respiratory quotient and a resultant fall in carbon dioxide production, the most common cause of a high respiratory quotient in critically ill patients is not dietary composition but simply overfeeding.[190] A study of clinical outcomes in 1000 ARDS patients randomized to full calorie versus trophic (10 cc/hr) enteral feeds did not show any difference in mortality or other clinical outcomes.[194] Overall, there is still no compelling evidence to support the use of anything other than standard (enteral) nutritional support, with avoidance of overfeeding, in patients with ARDS.[195] How early to attempt institution of feeding remains an unanswered question.

Mechanical Ventilation

Lung-Protective Ventilation

Although historically a tidal volume of 12–15 mL per kg was often used in patients with ARDS, it is now clear that a low–tidal volume, end-inspiratory plateau pressure–limited ventilatory strategy reduces mortality. In 2000 the NIH ARDS Network published the findings of their first randomized, controlled, multicenter clinical trial in 861 patients.[100] The trial compared a lower tidal volume ventilatory strategy (6 mL/kg predicted body weight, plateau pressure <30 cm H_2O) with a higher tidal volume (12 mL/kg predicted body weight, plateau pressure <50 cm H_2O). In this trial, the in-hospital mortality rate was 40% in the 12-mL/kg group and 31% in the 6-mL/kg group, a 22% reduction. Ventilator-free days and organ failure–free days were also significantly improved in the low tidal volume group. Although the twofold separation between the tidal volumes used in the tested cohorts was unusually wide, these findings were truly remarkable, because no prior large randomized clinical trial of any specific therapy for ARDS had ever demonstrated a mortality benefit.

The currently recommended treatment strategy for patients with ARDS is summarized in Table 60.3. Predicted body weight is calculated

TABLE 60.3 Ventilator Management of Patients With ARDS

Calculate Predicted Body Weight (PBW)

- Males: PBW (kg) = 50 + 2.3 [(height in inches) − 60] or
  50 + 0.91 [(height in cm) − 152.4]
- Females: PBW (kg) = 45.5 + 2.3 [(height in inches) − 60] or
  45.5 + 0.91 [(height in cm) − 152.4]

Ventilator Mode

Volume assist/control until weaning

Tidal Volume (Vt)

- Initial Vt: 6 mL/kg predicted body weight
- Measure inspiratory plateau pressure (Pplat, 0.5 sec inspiratory pause) every 4 hours AND after each change in PEEP or Vt.
- If Pplat >30 cm H_2O, decrease Vt to 5 or to 4 mL/kg.
- If Pplat <25 cm H_2O and Vt <6 mL/kg PBW, increase Vt by 1 mL/kg PBW.

Respiratory Rate (RR)

- With initial change in Vt, adjust RR to maintain minute ventilation.
- Make subsequent adjustments to RR to maintain pH 7.30–7.45, but do not exceed RR = 35/min, and do not increase set rate if $PaCO_2$ <25 mm Hg.

I:E Ratio

- Acceptable range, 1:1–1:3 (no inverse ratio)

FiO_2, PEEP, and Arterial Oxygenation

Maintain PaO_2 = 55–80 mm Hg or SpO_2 = 88%–95% using the following PEEP/FiO_2 combinations:

FiO_2	0.3–0.4	0.4	0.5	0.6	0.7	0.8	0.9	1
PEEP	5–8	8–14	8–16	10–20	10–20	14–22	16–22	18–25

Acidosis Management

- If pH <7.30, increase RR until pH ≥7.30 or RR = 35/min.
- If pH remains <7.30 with RR = 35, consider bicarbonate infusion.
- If pH <7.15, Vt may be increased (Pplat may exceed 30 cm H_2O).

Alkalosis Management

If pH >7.45 and patient is not triggering ventilator, decrease set RR but not below 6/min.

Fluid Management

- Once patients are out of shock, adopt a conservative fluid management strategy.
- Use diuretics or fluids to target a central venous pressure (CVP) of <4 mm Hg or a pulmonary artery occlusion pressure (PAOP) of <8 mm Hg.

Liberation From Mechanical Ventilation

- Daily interruption of sedation
- Daily screen for spontaneous breathing trial (SBT)
- SBT when all of the following criteria are present:
  (a) FiO_2 <0.40 and PEEP <8 cm H_2O
  (b) Not receiving neuromuscular blocking agents
  (c) Patient is awake and following commands
  (d) Systolic arterial pressure >90 mm Hg without vasopressor support
  (e) Tracheal secretions are minimal, and the patient has a good cough and gag reflex

Spontaneous Breathing Trial

- Place patient on 5 mm Hg pressure support with 5 mm Hg PEEP *or* T-piece.
- Monitor HR, RR, and oxygen saturation for 30–90 minutes.
- Extubate if there are no signs of distress (tachycardia, tachypnea, agitation, hypoxia, diaphoresis).

based on measured height using the equations provided. This is a key point that is often overlooked by clinicians; use of actual rather than predicted body weight can result in the use of erroneously high and potentially injurious tidal volumes, particularly in female patients who are often treated with tidal volumes that are too high.[196] The tidal volume should initially be set at 6 mL/kg predicted body weight, similar to normal tidal volumes in spontaneously breathing adults at rest. However, if the end-inspiratory plateau pressure (measured during a 0.5-second pause) is still >30 cm H_2O, then the tidal volume must be reduced in a stepwise fashion by 1 mL/kg to a minimum of 4 mL/kg. Ventilation with this tidal volume is generally well tolerated. Some patients may experience breath stacking or dyssynchrony with the ventilator. Increasing the inspiratory flow rate and, if necessary, the level of sedation is usually sufficient to manage these problems. On average, patients receiving lower tidal volume ventilation do not require increases in dose or duration of sedatives compared with patients receiving higher tidal volume ventilation.[197,198] Respiratory acidosis may develop but usually is not symptomatic. Raising the respiratory

rate is usually sufficient to compensate; a rate as high as 35 was used in the aforementioned clinical trial. As with any mode of ventilation in ARDS, patients occasionally will require neuromuscular blockade to alleviate severe dyssynchrony. Although one randomized clinical trial showed a 28-day mortality benefit with use of neuromuscular paralysis with cisatracurium besylate for the first 48 hours in severe ARDS (PaO_2/FiO_2 <150),[199] a subsequent study of early neuromuscular blockade in ARDS (the ROSE trial) was stopped early for futility.[200] Given these recent findings, neuromuscular blockade should be reserved for patients with severe ARDS and refractory hypoxemia.

In the ARDS Network protocol, the level of PEEP and FiO_2 is titrated according to a set of predetermined values (see Table 60.3). The optimal level of PEEP in ARDS has been controversial. Higher levels of PEEP may be beneficial in preventing alveolar collapse and minimizing injurious repeated opening and closing of alveoli. On the other hand, unnecessarily high PEEP may overdistend and injure more compliant areas of the lung and adversely influence RV loading. Several studies have investigated the effects of different levels of PEEP in patients with ARDS.[201] One large multicenter trial conducted by the ARDS Network randomized patients with ARDS ventilated with low tidal volume ventilation to receive lower (mean PEEP levels on days 1–4 were 8.3 ± 3.2) versus higher levels of PEEP (mean PEEP levels on days 1–4 were 13.2 ± 3.5).[202] There were no differences between the groups in clinical outcomes, including ventilator-free days and mortality. Two other studies of the effects of PEEP in ARDS had similar results,[203,204] although one study did show an increase in the number of ventilator-free days and organ failure–free days with application of higher PEEP.[204] None of these trials reported increases in barotrauma related to higher PEEP levels. Although these three large studies have not shown beneficial effects of higher PEEP in ARDS, even in a large meta-analysis,[205] there may be a subset of patients who would benefit from higher PEEP. In a small trial, a ventilator strategy that incorporated low tidal volume and titration of the PEEP level to above the lower inflection point on each individual patient's pressure–volume curve improved mortality in ARDS.[206] However, measurement of the pressure–volume curve in any given patient is not always feasible in practice. Under certain circumstances, higher PEEP may even be harmful. A large, multicenter, randomized trial in 120 ICUs from nine countries found that PEEP titration and aggressive recruitment maneuvers increased mortality in patients with severe ARDS as compared with a low PEEP strategy.[207] Another study of personalized mechanical ventilation based on whether ARDS was focal (tidal volume of 8 mL/kg, low PEEP, and prone position) or diffuse (tidal volume of 6 mL/kg, along with recruitment maneuvers and high PEEP) on imaging did not show a difference in mortality between groups, but significant misclassification could have affected the results.[208] Although imprecise, current recommendations are to adjust the PEEP within an acceptable range (see Table 60.3) to achieve adequate oxygenation at a given FiO_2.

Some patient populations present specific challenges to ventilator management in ARDS. Pregnant or obese patients may be difficult to manage with the standard lung-protective strategy. One study showed that a specially trained team, which they termed a "lung rescue team," improved survival in the obese patient with ARDS.[209] In this study, morbidly obese adults were randomized to usual care (ARDSNet protocol) versus personalized mechanical ventilation with lung recruitment maneuvers, esophageal manometry, and hemodynamic monitoring. Mortality was cut almost in half in the intervention group (16% versus 31%).[209] Pregnant women with ARDS may require a higher driving pressure to achieve the same tidal volume and oxygenation.[210] In addition, studies have examined the use of lung-protective ventilation in at-risk subjects without ARDS with varying results.[211,212] Although most patients with ARDS, and possibly those at risk for ARDS, benefit from a standardized approach using the ARDS Network low tidal volume protocol, it is important to keep individual patient factors in mind when selecting ventilator settings.

Prone positioning was initially studied in several small[213–215] and three large trials[216–218] and was associated with improvements in oxygenation but no reduction in mortality. Subgroup analysis suggested potential benefit in severe ARDS, leading to a multicenter prospective randomized trial of prolonged prone positioning (>16 h/day) in patients with severe ARDS (PaO_2/FiO_2 <150). The impressive results indicated substantial reduction in 28-day mortality in the prone group.[219] Given the results of this trial, prone positioning should be considered in all patients with severe ARDS who do not have contraindications to that position change, such as elevated intracranial pressure, severe hemoptysis, recent sternal surgery, pregnancy, new deep venous thrombosis, or unstable fractures. Despite the evidence supporting prone positioning in patients with ARDS, this therapy has been adopted only reluctantly. A worldwide prospective observational study of 141 ICUs from 20 countries found that the minority of ARDS patients are prone, even in those with severe ARDS (32.9% received prone positioning). The most common reason for not using prone positioning was the impression that hypoxemia was not considered severe enough to require proning.[220]

Noninvasive Ventilation and High-Flow Nasal Cannula

Noninvasive positive-pressure ventilation (NIV) delivered by nasal or full face mask has been highly successful in avoidance of intubation in patients with acute exacerbations of chronic obstructive pulmonary disease (COPD).[221] NIV is commonly used in pediatric patients with ARDS,[222] although there is only one small randomized trial of 50 patients showing that NIV improved oxygenation and prevented the need for endotracheal intubation in children admitted with acute respiratory failure. The role for NIV in adults with ARDS is still unclear. A growing number of small studies suggest that bilevel NIV with pressure support ventilation and PEEP may reduce the need for intubation and improve outcomes in selected patients with ARDS.[223] However, data from large randomized controlled trials is still lacking. Furthermore, it seems likely that the majority of patients with ARDS will still require invasive mechanical ventilation. In one large multicenter study of 354 of 2770 patients with acute hypoxemic respiratory failure *who were not already intubated,* NIV failed in 30% of patients but failed in 51% of patients with ARDS.[224,225] Another multicenter study of early NIV in mild ARDS caused by pneumonia did not reduce the need for mechanical ventilation despite improvement in oxygenation with NIV.[226] Applied broadly to all patients with ARDS, NIV may actually be harmful. In a retrospective analysis of the LUNG SAFE study, NIV was used in 15.5% of ARDS patients and was associated with both a high failure rate (47.1% in severe ARDS) and increased ICU mortality.[227] One group of patients in whom NIV is particularly appealing includes those who are immunosuppressed for various reasons and are at highest risk for nosocomial infections. Encouraging results have now been reported in a variety of patients with acute respiratory failure and immunosuppression.[228–231] With the advent of newer methods for NIV, such as helmet NIV—an interface option that has been reported to reduce intubation rates and mortality[232]—indications and applications of NIV may increase.

More recently, very high-flow nasal cannula oxygen delivery has been tested in patients with acute hypoxemic respiratory failure as an alternative to immediate intubation. In a study of 310 patients with acute respiratory failure, including some patients with ARDS, treatment with high-flow nasal cannula increased ventilator-free days and reduced mortality compared with noninvasive or invasive mechanical ventilation.[233] One benefit of high-flow nasal cannula is that it can provide a small level of PEEP noninvasively. Pending data from larger randomized clinical studies, a trial of noninvasive mechanical ventilation or high-flow nasal cannula oxygen could be considered in a patient with ARDS who does

not have a severe oxygenation defect, hemodynamic instability, or altered mental status, as long as the patient can be closely observed and readily intubated if needed.

Pharmacologic Therapy

There is no specific pharmacologic therapy for ARDS. A variety of treatment strategies have been investigated in large randomized trials, including antiinflammatory strategies, surfactant replacement, vasodilation, novel anticoagulants, antioxidants, and strategies to enhance the resolution of pulmonary edema. Agents that appeared promising in experimental and early clinical studies but failed in large randomized trials include early glucocorticoids,[234–236] anti-TNF antibody fragments,[237] alprostadil,[238,239] surfactant,[240–242] ketoconazole,[243] *N*-acetylcysteine,[244] procysteine,[244] lisofylline,[245] statins,[246,247] albuterol,[248] recombinant activated protein C,[249] site-inactivated recombinant factor VIIa,[250] aspirin,[251] and possibly vitamin C.[252]

Some investigators have suggested that glucocorticoid therapy, although not helpful for the acute phase of ARDS, might hasten the resolution of late fibroproliferative ARDS. One very small randomized study (plagued by crossovers such that only four patients remained in the placebo arm) suggested that glucocorticoid therapy might be beneficial in late ARDS.[253] This question was addressed in a randomized, multicenter study conducted by the ARDS Network of 14 days of methylprednisolone in patients who had persistent ARDS for 7 days.[254] Compared with patients treated with placebo, those treated with methylprednisolone had an increase in the number of shock-free days and ventilator-free days by day 28 and improvements in oxygenation, but did not have improved long-term survival and had higher rates of reintubation after steroids were discontinued, perhaps in part because of neuromuscular weakness. Although there is a large body of evidence suggesting lack of benefit, or even harm, from routinely using glucocorticoids in all etiologies of ARDS, the story is still evolving. A recent open-label, randomized controlled study of early dexamethasone use in ARDS (139 patients) versus placebo (138 patients) resulted in a substantial increase in ventilator-free days (4.8 days) and a 15% reduction in mortality.[255] These provocative findings will need validation and must be considered cautiously, given the serious concern about the safety of high-dose glucocorticoids in critically ill patients, including the possibility of increasing the risk of nosocomial infections or critical illness polyneuropathy/myopathy and the lack of improvement in mortality, with routine use of glucocorticoids.

Despite the dismal findings of the numerous studies of pharmacologic therapy for ARDS to date, new therapeutic strategies are under investigation and may yet prove beneficial. Macrolides hold some promise for ARDS. In an unplanned secondary analysis of patients with ARDS enrolled in two large observational studies in the Netherlands, macrolide therapy was associated with reduced mortality.[256] A recently reported novel approach to sedation in patients with ARDS using inhaled sevoflurane[257] showed a reduction in circulating markers of lung epithelial injury and inflammation and improved oxygenation compared with intravenous sedation, suggesting that there may be some lung-protective effects of inhaled sedation. Currently, three large randomized clinical trials are planned to test the effects of sevoflurane for sedation in ARDS. Because of the failure of pharmacologic therapies in established ARDS, attention has turned to the prevention and early treatment of ARDS, and several trials are in the planning stages or ongoing. For established ARDS, cell-based therapy with intravenous mesenchymal stromal (stem) cells (MSCs) was found to be safe in a phase II clinical trial.[258] In preclinical studies, MSCs have pleiotropic protective and reparative effects in the lung, including secretion of antiinflammatory and antibacterial factors, secretion of epithelial and endothelial growth factors, and direct transfer of mitochondria to restore energy balance in the injured lung epithelium.[259] Another area under active investigation includes strategies to hasten or facilitate the resolution of ARDS. Such therapies might be targeted at increasing the rate of alveolar fluid clearance, encouraging alveolar epithelial repair, or modulating immune regulation of the resolution of inflammation.

One important consideration for future clinical trials is to use predictive and/or prognostic enrichment to tailor therapies to patients who are most likely to benefit.[260] In fact, a prognostic enrichment strategy was used in the recent dexamethasone study,[255] which may be one reason that the benefits of dexamethasone were measurable in this study. Another consideration is the patient with rapidly improving ARDS who may not remain in a study long enough to benefit from a therapy. In clinical trials of ARDS, 10.5%–13.9% of patients were extubated or had P/F ratios >300 on the day after study enrollment.[261] Rates of rapid resolution were even higher (24%) in the multicenter observational LUNG SAFE study.[262] In the future, carefully designed clinical trials using enrichment strategies or platform/adaptive designs may lead to therapeutic breakthroughs.

Rescue Therapies

Despite appropriate treatment, a fraction of patients with ARDS will have profound and refractory hypoxemia. The initial management of these patients includes increased sedation and neuromuscular paralysis to maintain adequate oxygenation, but there is wide variation in practice in the management of refractory hypoxemia.[263] In patients who do not respond to conventional treatment with low tidal volume ventilation and remain persistently hypoxemic, several nonproven rescue therapies can be tried to improve oxygenation in the acute setting (summarized in Table 60.4). Although previously viewed primarily as a rescue therapy, prone positioning improved mortality in moderately severe ARDS in one study[219] and is now being used more frequently in routine care of patients with moderately severe ARDS (PaO_2/FiO_2 <150) in addition to its utility in improving oxygenation in the setting of refractory hypoxemia. Extracorporeal membrane oxygenation (ECMO) has been used in patients with ARDS and severe hypoxemia. In specialized centers ECMO has been used successfully to treat patients with severe ARDS.[264–266] One large trial randomizing 180 patients with severe ARDS to ECMO versus conventional management reported improved survival without disability at 6 months in patients treated with ECMO.[267] In this study, patients randomized to ECMO were transferred to a specialty center to receive therapy. Upon arrival, only 75% of patients in the ECMO group were actually treated with ECMO. The study design makes it difficult to determine whether the transfer to a specialty center for care or the ECMO itself conferred benefit. Although the results of this study are encouraging, the need for transfer to a specialty center and the dropout rate of 25% upon transfer limit the generalizability of this study. The recently completed international EOLIA study randomized 124 patients with very severe ARDS to immediate ECMO or continued conventional treatment and found a trend towards improved 60-day survival in patients randomized to ECMO, with 44 of 124 patients (35%) in the ECMO group and 57 of 125 (46%) in the control group dying (relative risk, 0.76; 95% confidence interval [CI], 0.55–1.04; $P = .09$).[268] More contemporary studies combining ECMO or extracorporeal CO_2 removal with ultra-protective mechanical ventilation[269–271] have some encouraging findings, including improved long-term outcomes.[272–274] High-frequency oscillatory ventilation (HFOV) appeared to be promising in several small randomized trials in patients with ARDS,[275–279] with improvements in oxygenation in patients with severe hypoxemia. However, two large randomized clinical trials in severe ARDS failed to show a benefit,[280,281] and in one of the trials, mortality was higher in the HFOV group.[280] For this reason, HFOV should only be used as a rescue therapy and only by experienced operators. Other rescue therapies include the use of a pulmonary vasodilator, such as inhaled nitric oxide (NO) or inhaled prostacyclin. There have been several small randomized clinical trials of inhaled NO in ARDS; although none has shown improved mortality, its use has been

TABLE 60.4 Summary of Rescue Therapies for Acute Lung Injury and Acute Respiratory Distress Syndrome

Rescue Therapy	Year	How Studied	Number of Patients	Comments	References
ECMO	1979	Phase III	90	In this multicenter trial there was no benefit with the use of ECMO.	284
	2009	Phase III	180	This large randomized trial showed benefit to treatment with ECMO; however, 25% of patients assigned to ECMO did not receive this therapy, and the need for urgent transfer to specialized treatment centers limits general applicability of this trial.	267
	2018	Phase III	124	In this international trial, patients with severe ARDS were randomized to immediate ECMO or continued conventional treatment. There was a nonsignificant trend towards improved 60-day survival in patients treated with ECMO.	268
ECCOR	1994	Phase III	40	This newer form of extracorporeal therapy did not improve mortality.	285
	2019	Phase II	95	Use of ECCOR and ultraprotective ventilation was safe and feasible.	269
Prone positioning	2001	Phase III	304	Although prone positioning improved oxygenation, there was no mortality benefit.	217
	2009	Phase III	342	Patients were randomized according to severity of hypoxemia to receive 20 hours of prone positioning vs. usual care and had no reduction in mortality at 28 days or 6 months.	218
	2013	Phase III	466	Patients with more severe ARDS (PaO_2/FiO_2 <150 mm Hg) were randomized to supine or prone position (>16 h/day). Patients in the prone group had improved 28-day mortality.	219
HFOV	2002	Phase III	148	HFOV group had improved oxygenation but no difference in mortality.	275
	2005	Phase III	61	No significant differences in any outcome between the groups.	279
	2013	Phase III	548	HFOV had higher mortality and more hemodynamic instability.	280
	2013	Phase III	795	No difference in mortality.	281
Inhaled nitric oxide	1998	Phase II	177	Although some patients will have improvement in oxygenation with inhaled nitric oxide, there was no mortality benefit in any of these large studies.	286
	1999	Phase III	203		287
	2004	Phase III	385		288

ARDS, Acute respiratory distress syndrome; *ECMO,* extracorporeal membrane oxygenation; *ECCOR,* extracorporeal CO_2 removal; *FiO_2,* fraction of inspired oxygen; *HFOV,* high-frequency oscillatory ventilation; *PaO_2,* partial pressure of oxygen.

associated with improved oxygenation.[282] Inhaled prostacyclin is another pulmonary vasodilator that may be used as a rescue therapy in severe, refractory ARDS, although there are no randomized trials showing a mortality benefit.[283]

COMPLICATIONS

Complications are common in any critically ill patient population. Supportive care for all critically ill patients must include vigilance in both preventing and diagnosing common complications such as pulmonary embolus, acute myocardial infarction, gastrointestinal bleeding, and nosocomial infection. Certain complications are more common in ARDS patients and deserve special mention. Although not specifically a complication, some patients do suffer from prolonged mechanical ventilation and require prolonged critical care. For those patients who require prolonged ventilation, a tracheostomy is often required. Use and timing of tracheostomy vary widely throughout the world, with patients from high-income European countries being the most likely to get a tracheostomy, with median timing of insertion of 14 days.[289]

Barotrauma

Barotrauma occurs when air dissects out of the airways or alveolar space into surrounding tissues, leading to pneumothorax, pneumomediastinum, pneumatocele, or subcutaneous emphysema (Fig. 60.5). The exact incidence

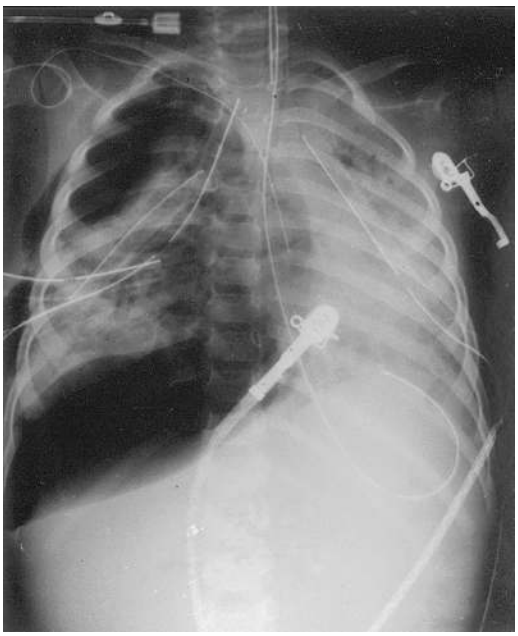

Fig. 60.5 Chest Radiograph Showing Tension Pneumothorax in a Patient with Acute Respiratory Distress Syndrome.

of pulmonary barotrauma in ARDS is unclear but appears to be declining. Data from two large randomized trials of protective ventilatory strategies suggest an incidence of early pneumothorax of 12%–13%.[100] In 861 patients enrolled in the NIH ARDS Network trial, approximately 10% developed some form of barotrauma, regardless of whether they were in the 6- or 12-mL/kg tidal volume arm. Furthermore, PEEP level was the only factor that predicted the development of barotrauma in a multivariate analysis.[290]

Treatment of barotrauma depends on the location of the extravasated air. Pneumothorax can be life threatening, particularly if it is under tension; immediate diagnosis and tube thoracostomy are essential. Pneumothorax should be considered in any mechanically ventilated patient with ARDS who develops sudden, unexplained worsening of hypoxemia, respiratory distress, or hemodynamic instability. A chest radiograph (preferably upright) or bedside lung ultrasound is usually sufficient to make the diagnosis, but in many cases the situation may be too urgent to complete diagnostic imaging (see Fig. 60.5). Pneumomediastinum and subcutaneous emphysema can be painful but do not require specific therapy other than analgesia. Air embolus is a potentially fatal complication of positive-pressure mechanical ventilation that has been reported occasionally in patients with ARDS[285,291,292] and usually occurs in conjunction with other evidence of pulmonary barotrauma, often simultaneously.

Nosocomial Pneumonia

The incidence of nosocomial pneumonia in patients with ARDS is difficult to quantify. Depending on the diagnostic definition and/or strategy employed, estimates range from 15% to 60%.[293,294] There is no consensus regarding the appropriate way to diagnose nosocomial pneumonia in the mechanically ventilated patient. Because patients with ARDS frequently die from uncontrolled infection, recognition and treatment of nosocomial pneumonia is an important component of caring for the ARDS patient. Clinical criteria commonly used in the diagnosis of nosocomial pneumonia include fever, elevated white blood cell (WBC) count, purulent airway secretions, and pulmonary infiltrates. However, these signs are often present in patients with ARDS, even in the absence of nosocomial pneumonia.[295] Autopsy studies of patients who died with ARDS show a high incidence of unsuspected pneumonia.[296–298] An in-depth discussion of diagnostic strategies is presented elsewhere in this text. Regardless of the methods used for diagnosis, early, appropriate, and empiric therapy is the mainstay of treatment for nosocomial pneumonia. The adequacy and timeliness of initial empiric therapy are important determinants of outcome. Knowledge of local resistance patterns is crucial, and a high index of suspicion is required.

Multiorgan System Dysfunction

Although ARDS is often thought of as a primary pulmonary disorder, it is often a systemic disorder with many similarities to sepsis or systemic inflammatory response syndrome (SIRS). Multiorgan system dysfunction is a common complication in ARDS. Organ dysfunction may result from the underlying cause of ARDS, such as sepsis, or occur independently. The exact incidence of multiorgan system dysfunction in ARDS is difficult to quantify. In the ARDS Network trial of low tidal volume ventilation, the mean number of nonpulmonary organ system failures per patient was 1.8.[100] Given the simultaneous occurrence of multiple organ failures, it is often difficult to determine the exact cause of death in ARDS patients, and survival ultimately depends on successful support of the failing organs.

Neuromuscular Weakness

Patients with ARDS are at high risk for developing prolonged muscle weakness that persists after resolution of pulmonary infiltrates is well underway and can complicate weaning from mechanical ventilation and rehabilitation. This clinical syndrome is commonly called *critical illness polyneuropathy* but has components of neuropathy and myopathy that can coexist or occur separately.[299] Although little prospective data are available, several studies suggest that neuromuscular abnormalities persist in many survivors of critical illness, even when studied up to 5 years after ICU discharge.[165,300] Prolonged muscle weakness is most common in critically ill patients who are treated with glucocorticoids. In other studies, neuromuscular blockade has also been implicated. In one study, the sustained use of corticosteroids was shown to be the best independent predictor of ICU-acquired paresis (odds ratio, 14.9; 95% CI, 3.2–69.8).[301] In the absence of a compelling clinical indication such as underlying connective tissue disease or another entity shown to respond, the use of glucocorticoids should not be routine practice. New clinical evidence in support of their clinical utility in certain forms of ARDS may become available.

CLINICAL OUTCOMES AND PROGNOSIS

Once a patient develops ARDS, several prognostic factors can help clinicians predict the outcome. Although the dead space fraction,[302,303] the ventilatory ratio, high driving pressure, and oxygen saturation index may predict mortality,[304–308] none are universally measured or monitored in ICU practice. For this reason, predictive models that use more readily available clinical variables have been developed.[309] In addition to dead space fraction, severe hypercapnia (CO_2 >50 mm Hg)[310] and a positive cumulative fluid balance at day 4 in patients with ARDS predict increased mortality,[311] further supporting the use of a conservative fluid strategy in patients with ARDS.[184] Conversely, body mass index was studied in a post hoc analysis of the OSCILLATE trial and found to have no association with mortality in patients with ARDS.[312]

The reported mortality from ARDS appears to be gradually declining,[172] although this finding has not been consistent between retrospective studies.[313] Before the 1990s, mortality in clinical trials was approximately 40%–60%.[314] Several recent single-center studies suggest that mortality rates measured in the same centers has declined over time.[315–318] In an ARDS Network study that enrolled 861 ARDS patients in the late 1990s, aggregate mortality to hospital discharge was 31% in the 6-mL/kg tidal volume arm and 40% in the 12-mL/kg tidal volume arm. However, mortality data from this study may significantly underestimate overall ARDS mortality because many severely ill patients were excluded, including those with advanced liver disease, bone marrow transplantation, severe chronic respiratory disease, burns greater than 30% body surface area, or any other underlying condition with a likelihood of death greater than 50% within 6 months. As has been observed in other studies, the risk of in-hospital mortality in this study was highest in those with sepsis (43%), intermediate in those with pneumonia (36%) or aspiration (37%), and lowest in those with multiple trauma (11%).[22] Interestingly, developing ARDS in the hospital is associated with a significantly higher mortality compared with at-risk controls (35% versus 5%).[319] The low tidal volume strategy was effective at reducing mortality across all causes of ARDS.[22] Another study has shown that implementation of the ARDS Network low tidal volume ventilator strategy is associated with lower hospital mortality compared with historical controls.[320] In a more recent ARDS Network study published in 2012, the overall 60-day mortality was 23%.[194]

Several recent multicenter studies in France,[321] Sweden,[322] Australia,[323] and Argentina[324] attempted to define mortality and prognostic variables in observational, population-based studies rather than from clinical trial participants. In these studies, mortality was variable, ranging from 32% for mild ARDS to 58%–60% for moderate to severe ARDS. Factors independently associated with mortality from ARDS varied from study to study and included age, Acute Physiology Score, PaO_2/FiO_2 ratio, organ failure or septic shock, immunosuppression,

cardiovascular failure, and chronic liver disease.[197,321,322,324] The large, multinational LUNG SAFE study has significantly informed our understanding of ARDS prognosis and outcomes in more recent years. Analyses from the LUNG SAFE study found that hospital mortality is higher in immunocompromised patients compared with immunocompetent patients[231] and in women with severe ARDS compared with men.[196] Further, analysis of data from LUNG SAFE identified several modifiable (lower PEEP; higher peak inspiratory plateau and driving pressures; and increased respiratory rate) and nonmodifiable (older age, active neoplasm, hematologic neoplasm, and chronic liver failure) risk factors for hospital mortality.[325] Not surprisingly, outcomes in developing countries are worse, with typical mortality rates of 45%.[29] Although most studies have reported short-term mortality from ARDS, a recent study examined 1-year mortality.[326] In a heterogeneous group of 641 patients with ARDS, 1-year mortality was substantially higher than hospital mortality (41% vs. 24%; $P < .0001$). In summary, these studies suggest that although some improvements in ARDS mortality have been made, mortality remains quite high in population-based studies, and improvements in short-term outcomes may not be reflected in better long-term outcomes.

ARDS survivors frequently have long-term functional disability, cognitive dysfunction, and psychosocial problems[327]; are more likely to be discharged to rehabilitation or long-term care facilities compared with controls[319]; and are high users of health care.[328] Many such problems persist even 5 years after the ARDS hospitalization,[329,330]and many patients are never able to return to prior functional status or work.[331,332] There may be distinct subtypes of ARDS survivors that benefit from a more tailored rehabilitation approach.[333] Interestingly, pulmonary function frequently returns to normal or near-normal in survivors. In a report of 1-year follow-up in 109 survivors of ARDS,[164] lung volumes and spirometry had returned to normal by 6 months. However, carbon monoxide diffusing capacity was persistently low throughout the year. Six-minute walk distances were persistently less than predicted at 12 months, largely because of muscle wasting and weakness rather than pulmonary function abnormalities.[164] Treatment with any systemic corticosteroid, the presence of illness acquired during the ICU stay, and the rate of resolution of the lung injury and multiorgan dysfunction during the ICU stay were the most important determinants of the 6-minute walk distance during the first year of follow-up. Other studies report that patients who survive ARDS have reduced health-related quality of life[334] and pulmonary disease–specific health-related quality of life.[335–337] Functional impairment often persists 2 years after ICU discharge.[338] In addition to physical and social difficulties after ARDS, survivors have high rates of depression and anxiety.[339]

KEY POINTS

- ARDS epidemiology, risk factors, and outcomes continue to change over time as new risks and modifiers emerge.
- ARDS is a syndrome with distinct clinical subphenotypes that may have differential responses to treatment.
- Treatment of the underlying cause, lung-protective ventilator management, a conservative fluid strategy, prone ventilation for patients with severe ARDS, and avoidance of complications remain the mainstays of therapy.
- Although survival rates have improved over time, survivors of ARDS experience long-term physical, psychological, and functional impairment.

ANNOTATED REFERENCES

Acute Respiratory Distress Syndrome Network. Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. *N Engl J Med.* 2000;342:1301–1308.
This was a multicenter trial of 6-mL/kg compared with 12-mL/kg tidal volume in 861 mechanically ventilated patients with ALI or ARDS. The major finding was a reduction in hospital mortality in the 6-mL/kg group from 40% to 31%.

Bellani G, Laffey JG, Pham T, et al. Epidemiology, patterns of care, and mortality for patients with acute respiratory distress syndrome in intensive care units in 50 countries. *JAMA*, 2016;315:788–800.
The LUNG SAFE study was a large observational study to understand the global impact of ARDS. It prospectively enrolled 29,144 patients from 459 ICUs in 50 countries. The LUNG SAFE study has provided a wealth of information regarding diagnosis, risk factors, treatment, practice patterns, and outcomes of patients with ARDS.

Calfee CS, Delucchi K, Parsons PE, et al. Subphenotypes in acute respiratory distress syndrome: latent class analysis of data from two randomised controlled trials. *Lancet Respir Med.* 2014;2:611–620.
In this study, unbiased statistical methods applied to data sets from two large clinical trials revealed two distinct subphenotypes among patients with ARDS. Subsequently, these subphenotypes have been identified in multiple large data sets and may have a differential response to ARDS therapy.

Herridge MS, Cheung AM, Tansey CM, et al. One-year outcomes in survivors of the acute respiratory distress syndrome. *N Engl J Med.* 2003;348:683–693.
In this multicenter study, the authors evaluated 109 survivors of ARDS at 3, 6, and 12 months after discharge from the hospital. Notably, functional disability was very common even at 12 months and was largely caused by muscle wasting and weakness. By contrast, pulmonary function was normalized, with the exception of persistent decrements in the diffusing capacity for carbon monoxide.

Force ADT, Ranieri VM, Rubenfeld GD, et al. Acute respiratory distress syndrome: the Berlin Definition. *JAMA.* 2012;307:2526–2533.
This study presents the revised definition of ARDS, called the Berlin definition, which was derived by expert consensus and data analysis. The Berlin definition is a modified version of the prior American European Consensus Criteria definition established in 1994.

National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network. Pulmonary-artery versus central venous catheter to guide treatment of acute lung injury. *N Engl J Med.* 2006;354:2213–2224.

National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network. Comparison of two fluid-management strategies in acute lung injury. *N Engl J Med.* 2006;354:2564–2575.
These companion papers present the main findings from the ARDS Network Fluid and Catheter Treatment Trial (FACTT). The major findings from these two reports are that patients with ARDS who are not in shock should have CVP-directed management of a conservative fluid strategy with a goal CVP of < 4 mm Hg; such patients had more ventilator-free days compared with patients treated with a liberal fluid strategy.

Rice TW, Wheeler AP, Bernard GR, et al. Comparison of the Spo_2/Fio_2 ratio and the Pao_2/Fio_2 ratio in patients with acute lung injury or ARDS. *Chest.* 2007;132:410–417.
This study compares the use of the SpO_2/FiO_2 (S/F) ratio with the more invasive PaO_2/FiO_2 (P/F) ratio, which requires blood gas analysis for the diagnosis of ARDS and should improve the rate of ALI/ARDS diagnosis among clinicians. In this study, an S/F ratio of 235 corresponded to a P/F ratio of 200, and an S/F ratio of 315 corresponded to a P/F ratio of 300.

Ware LB, Matthay MA. Clinical practice. Acute pulmonary edema. *N Engl J Med.* 2005;353:2788–2796.
This case-based review article highlights the pathophysiologic and clinical differences between hydrostatic pulmonary edema and ARDS and provides a clinical algorithm for differentiating between the two.

Drowning

Justin Sempsrott, Joost Bierens, and David Szpilman

DEFINITION

Drowning is the process of experiencing respiratory impairment from submersion or immersion in liquid. This process can be fatal, nonfatal with complications, or nonfatal without complications. This definition is increasingly used in the medical, professional, and research literature to allow consistent and correct data collection and comparison. Terms such as "near," "dry," "wet," "secondary," "active," or "passive" drowning, and "delayed onset of respiratory distress" should not be used, as they lack uniformity, imply spurious understanding of the drowning process, and detract attention from the final common pathway of cerebral anoxia.[1,2]

EPIDEMIOLOGY

Drowning is recognized by the World Health Organization (WHO) as a neglected public health priority. The 2017 WHO Global Burden of Disease reports approximately 300,000 unintentional drowning deaths, of which over 90% occur in low- and middle-income countries (LMICs), with 50% from China, India, Pakistan, and Bangladesh. Globally, drowning accounts for 7% of all fatal injuries and has the fourth highest overall injury mortality rate after road injuries, falls, and interpersonal violence.[3,4] However, exposure-adjusted, person-time death estimates for drowning are 200 times higher than for road injuries.[5]

In 48 out of 85 countries with reliable death registries, drowning is in the top five causes of death for children 1–14 years old, of which those aged 1–4 years old are disproportionately affected.[6] In Eastern European countries, the incidence of fatal unintentional drowning in children <19 years of age is between 5 and 7 per 100,000 compared with 0–1 per 100,000 in most other European countries.[7] Low-income and minority groups carry a higher burden from drowning. American Indians, Alaskan Natives, and African Americans; First Nation people in Canada; indigenous Fijian and Maori in the Pacific region; non-Western immigrants in the Netherlands; and foreign tourists in Spain all have higher risk for drowning mortality compared with their national counterparts.[8–10]

Although dramatic on their own, these national and international estimates vastly underrepresent the true burden of drowning. In addition to varied methodologies for reporting drowning deaths, the standard definition of drowning derives from a public health perspective and excludes drowning as a result of water and land transportation, intentional drowning, and those that occur as a result of floods. These other causes of drowning have a significant magnitude, and their numbers of victims may even be larger than the numbers resulting from unintentional drowning. Over 50% of the fatalities that occur during floods are caused by drowning. In some countries, suicide by drowning occurs more often than unintentional drowning, whereas in other countries the majority of the drowning burden is foreign tourists while snorkeling or scuba diving.

Data on nonfatal drowning are limited and, where reported, subject to diverse inclusion criteria. A study of Brazilian lifeguarded beaches showed a fatal:nonfatal ratio of 1:36,[11] whereas a national Australian data set shows an overall ratio of 1:2.7 with highest ratios in children 0–4 years (1:7.6) and drowning in pools (1:4.4).[12] In the Netherlands, the ratio for hospital admissions is approximately 1:3 for all drowning, but 1:2 for unintentional drowning and 1:0.25 for intentional drowning.[13]

Local context must be considered when treating drowning patients, which helps inform comorbidities or the inciting etiology of the drowning. In Australia, most drownings occur in the ocean and in private pools among children or those engaged in recreation.[14] In Brazil, more than 75% occur in rivers because of incidental and occupational exposures.[15] In Japan, a significant number of drownings occur in elderly patients in traditional hot-water tubs in their homes.[16–18] Water transportation accounts for 38% of all passenger transport in Bangladesh, greatly increasing the burden of incidental and occupational drowning risk.[19] The important common factor is that most drowning occurs in at-risk, economically disadvantaged communities, in the uninformed, and in the unprepared. As such, most drownings are preventable.

PATHOPHYSIOLOGY

The drowning process is a continuum, beginning with respiratory impairment as the person's airway goes below the surface of the liquid (submersion) or when high volumes of water impair the airway by splashing over the face (immersion). If rescued at any time, the process of drowning is interrupted, and this is called *nonfatal drowning*. If they die at any time, this is a *fatal drowning*. Submersion or immersion without evidence of respiratory impairment is a water rescue and not a drowning.[1]

When water is aspirated into the airways, coughing occurs as an initial reflex response. For this reason, prolonged coughing may be considered as a criterion that distinguishes drowning from other stress situations in the water. It is speculative if a brief laryngospasm may occur when the person starts to inhale water, but this is of indeterminate clinical significance. As submersion or immersion continues, with or without aspiration of water, hypoxemia leads to loss of consciousness, apnea, and pulmonary damage. Prolonged apnea and hypoxia precipitate cardiac arrest. Hypoxic cardiac arrest generally occurs after a period of tachycardia, then bradycardia, and ultimately pulseless electrical activity (PEA); only rarely does arrest manifest as ventricular fibrillation.[17] The process from submersion to cardiac arrest occurs in seconds to minutes. The only validated factor that predicts outcome at the scene is duration of submersion.[20] However, the factors that predict who will progress to cardiac arrest within seconds instead of minutes are poorly understood and should be the target of future research. In

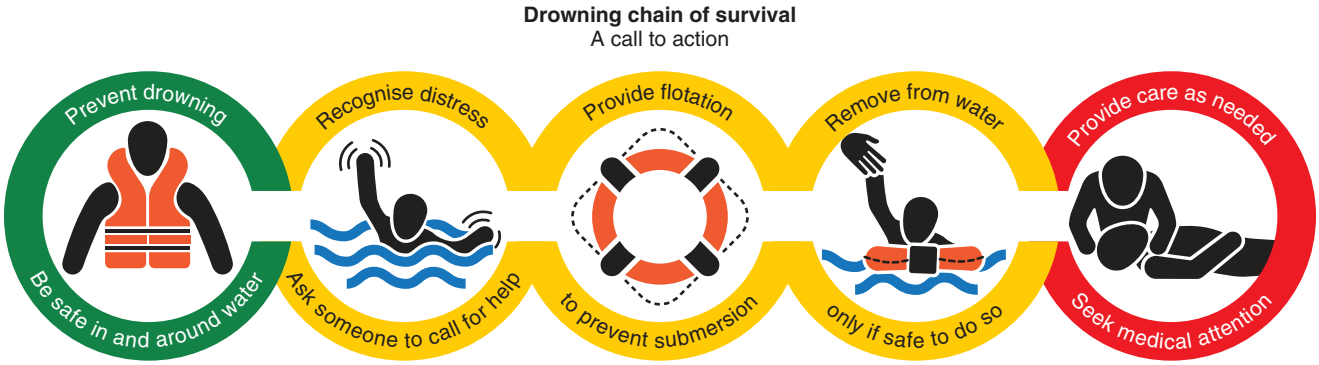

Fig. 61.1 Drowning Chain of Survival. (From Szpilman D, Webber J, Quan L, et al. Creating a drowning chain of survival. *Resuscitation*. 2014;85[9]:1149–1152.)

extraordinarily rare situations, such as when rapid external cooling triggers a mammalian diving reflex, or hypoxia is preceded by hypothermia during submersion in ice-cold water, this process can last for up to an hour. Under typical circumstances, irreversible cerebral damage occurs after 5–10 minutes of submersion.

If the person is rescued in time and the drowning process is interrupted, the clinical picture is determined by the duration of submersion, reactivity of the airways, and the amount of water that has been aspirated. Water in the alveoli causes surfactant destruction and washout. In humans, as little as 1 mL/kg may produce profound alterations in pulmonary gas exchange. Salt and freshwater aspiration cause similar clinical pathology—the symptoms and clinical treatments are identical for both. In either situation, the osmotic gradient can disrupt the integrity of the alveolar-capillary membrane; increase permeability; and exacerbate fluid, plasma, and electrolyte shifts. Regional or generalized pulmonary edema (depending on the amount of water aspirated and airway reactivity) reduces the exchange of O_2 and CO_2.[21–23] Based on the most recent animal and clinical studies from 1960 to 1980, aspiration of 2.2 mL/kg body weight leads to severe disturbance of oxygen exchange and decrease of arterial oxygen pressure (PaO_2) to approximately 60 mm Hg within 3 minutes. The combined effects of fluid in the lungs, loss of surfactant, and increased capillary-alveolar permeability can result in a 10%–40% decrease of lung compliance, increased right-to-left shunting in the lungs, atelectasis, and alveolitis.[24–27]

DROWNING CHAIN OF SURVIVAL

The drowning chain of survival is a visual representation of the relevant factors in the drowning process and shows the five steps to reduce drowning risk and severity (Fig. 61.1).[28]

Prevention

Prevention is unequivocally the most effective way to reduce the burden of fatal and nonfatal drowning. The WHO and other national prevention organizations estimate that 80%–90% of all drownings can be prevented when the appropriate measures are taken. Despite its profound importance, the multifactorial approach to drowning prevention and the layers of protection to prevent drowning are beyond the scope of this chapter. A wide range of reports, publications, and websites, however, are available on the issue.[3,4,29–31]

Recognize Distress and Call for Help

The second element in the drowning chain of survival is to recognize a person in distress and know how to activate help. Sending someone to call for help upon recognizing a person in distress is a key element that ensures early activation of professional rescue and emergency medical services (EMS).

For several decades, it has been assumed that persons exhibiting a surface struggle are generally recognized by the instinctive drowning response (IDR).[32] The IDR is a near-vertical body position, ineffective downward arm movements, ineffective pedaling or kicking leg actions, and little or no forward progress in the water. Video footage of drownings in pools has identified more diverse presentations of visible drowning behavior. All persons in this pilot study submerged completely within 2 minutes without subsequent resurfacing. This limited study and the anecdotal experience of the authors has identified numerous other surface struggle behaviors. Further study is needed to characterize these other movements and inform lifeguard and lay responder training programs.[33]

Provide Flotation to Stop the Process of Drowning

The next priority is to provide flotation as an interim measure to reduce submersion risk. This buys valuable time for those on scene to initiate rescue efforts and for emergency services to arrive. Devices such as ring buoys are purposely designed to provide flotation and can be made available at public locations where they can be deployed by bystanders. Improvised buoyancy aids such as empty plastic bottles or other containers, all kinds of sport balls filled with air, empty ice chests, or driftwood can also be used.

It is critical that laypersons take precautions not to become another drowning victim when attempting to engage in rescue responses. Many drowning persons cling to their would-be rescuer; therefore it is better to approach a struggling person with an intermediary object. When feasible, reaching out, throwing, or dropping the buoyancy aid without entering the water is the preferred method of providing flotation to someone in need of rescue.[11,34–36]

In-Water Ventilation

The drowning process leads first to unconsciousness and apnea, followed by cardiac arrest within several minutes. Between apnea and cardiac arrest, immediate in-water ventilations may provide benefit if provided safely and effectively. For the unconscious person, in-water ventilation can increase the rates of neurologically intact survival to hospital discharge by more than threefold. Effective in-water ventilation is only possible if the rescuer is highly trained. Drowned persons who are only in respiratory arrest may regain consciousness after a few rescue breaths. If there is no response, they should be assumed to be in cardiac arrest and be moved as quickly as possible to a boat or dry land where effective chest compressions can be performed. Chest compressions are

futile while the rescuer and person are in the water, so assessment for a pulse there does not serve any useful purpose.[37,38]

Remove From Water: Rescue Only If Safe to Do So

The attempt to perform a rescue typically involves three phases: approach, contact, and stabilization. Establishing adequate oxygenation is essential to interrupt the drowning process. Professional rescuers may use in-water ventilation as described earlier; otherwise, removing the person from the water as quickly as possible is critical to assist oxygenation and ventilation. Several strategies for removal can be used for bystander rescuers. The person can be helped by directing them to the closest and safest place to exit the water. If this fails, the lay rescuer may consider rescue by throwing a rope, life jacket, or something else that is able to float or reaching with a stick, branch, oar, or wading to them. Entering the water is a personal decision and may depend on the personal relationship with the person in water trouble (e.g., parents and children); distance to swim; swimming skills; and the depth, temperature, and velocity of the water. If available, it is strongly recommended that the rescuer wears a lifejacket or uses some type of flotation. However, sometimes these devices can also increase the risk that well-intentioned rescuers drown by a false sense of invulnerability that results in a rescue for which they are not prepared. If unconscious, the transport to shore should be as rapid as possible to minimize the hypoxic period. The airways should be kept open at all times, if possible.[39] Professional lifeguards can use several types of equipment that may facilitate the rescue[40]

Only a few studies have examined the prevalence of in-water cervical spine injury (CSI).[41,42] A retrospective study of 46,060 water rescues on sand beaches demonstrated an incidence of just 0.009%.[43] In another retrospective review of more than 2400 drowning cases, less than 0.5% had a CSI, and all of these had a history of obvious traumatic mechanism from diving, falling from height, or a motor vehicle collision.[44] Considering the low incidence of CSI and the detriment in delaying oxygenation in order to assure cervical spinal motion restriction, no attempt to immobilize the spine should be made while in the water without a compelling indication. In all cases where the person is unconscious, the priority should be oxygenation, ventilation, and rapid extrication, not cervical spine immobilization. In addition to delaying oxygenation, there is extensive literature showing the potential harms of cervical spine immobilization.

Provide Care as Needed (Resuscitation)

Once on land, the patient should be placed supine with the trunk and head at the same level. On sloped beaches or banks, this is parallel to the shoreline. The standard checks for responsiveness and breathing are carried out. If the patient is unconscious but breathing normally, the recovery position should be used.[45] Cardiopulmonary or isolated respiratory arrest comprises only ~0.5% of all lifeguard rescues. If the patient is not breathing, early oxygenation and ventilation are essential. The drowning process will continue, even out of the water, until the patient receives oxygen. If the patient is in cardiac arrest from drowning, this is primarily because of lack of oxygen. For this reason, cardiopulmonary resuscitation (CPR) by professional rescuers should follow the airway–breathing–circulation (ABC) sequence.[17,39] Because cardiac arrest in drowned persons is caused by asphyxia, cardiac compression only is much less effective and should only occur when there is no other option left.[46–49] For lay persons, the emphasis during training should be to perform breaths AND compressions instead of compression-only CPR.

Early basic life support contributes to better outcomes from drowning and should be initiated as soon as possible. Ventilation should be started with 5 effective initial breaths followed by 30 chest compressions and then continued with 2 breaths to 30 compressions until signs of life reappear, rescuer exhaustion occurs, or Advanced Life Support (ALS) or EMS assistance arrives. The presence of noncardiogenic pulmonary edema fluid (foam), caused by surfactant disruption and alveolar injury, makes initial ventilation often difficult because of decreased pulmonary compliance.[21–23,50] Another frequent complication of drowning resuscitation is regurgitation of stomach contents.[51] The presence of vomitus in the airway can result in further aspiration injury and impaired oxygenation.[52] Active efforts to expel water from the airway (abdominal thrusts or placing the person head down) should be avoided, as they only delay the initiation of ventilation, increase the risk of vomiting by more than fivefold, and lead to a significant increase in mortality.[28,53]

During the COVID-19 pandemic, international CPR guidelines and operational opinions emphasized the role of compression-only CPR for cardiac arrest of presumed cardiac etiology.[54,55] For the same reasons mentioned earlier, the ventilation-first approach for drowning victims has become rather difficult to accept and to apply without further considerations. Ventilation of a person with an active contact or respiratory pathogen in the airways will most certainly infect a person performing mouth-to-mouth ventilation, but this is less likely to occur during chest compressions and use of an automated external defibrillator (AED).[56] Additionally, the use of pocket masks and bag-mask ventilation with or without a HEPA filter are aerosol-generating procedures and will carry some degree of risk of infection to the rescuers. On the other hand, taking into account the young and healthy status of most members of aquatic rescue organizations, it is unlikely that the rescuer will die from participating in a drowning resuscitation that included ventilation. Guidelines have been developed for aquatic rescue organizations that address which elements have to be considered to stratify the risk of COVID-19 to the rescuer during drowning resuscitation.[57,58] These guidelines most of all address how to mitigate the risk to rescuers and relevant public health and ethical aspects (Fig. 61.2).

According to most studies, less than 10% of all drowned persons are in ventricular fibrillation.[38] Given this, the effectiveness of an AED in a drowning resuscitation scenario is low. Oxygenation, ventilation, and cardiac compressions should be optimized during drowning resuscitation before initiation of the AED. If the scenario suggests a sudden cardiac arrest in the water because of presumed ventricular fibrillation (VF) or ventricular tachycardia (VT), the AED should be applied immediately.

PREHOSPITAL ADVANCED LIFE SUPPORT

To save time, medical equipment of the EMS system should be brought to the patient instead of delaying care to transport them to the ambulance. Recommendations for when to start and stop resuscitation differ from cardiac arrest of presumed cardiac etiology (Table 61.1).

In cardiopulmonary arrest for the drowned person, the first priority should be to establish adequate oxygenation and ventilation using the highest concentration available, typically bag-mask ventilations with at least 15 liters per minute of oxygen until an orotracheal tube or a supraglottic airway can be inserted. Effective, high-quality chest compressions should be continued throughout the resuscitation. Once intubated, most patients can be oxygenated and ventilated effectively even in situations where copious noncardiogenic pulmonary edema fluid fills the endotracheal tube. Suctioning can disturb oxygenation and should be balanced against the presence of fluid that makes effective ventilation impossible. Once intubated, positive end-expiratory pressure (PEEP) should be used to optimize oxygenation, either via the ventilator or using a PEEP valve if using a bag-valve mask (BVM).

TABLE 61.1 Drowning: When to Initiate CPR and When to Discontinue

Question	Recommendations
In whom to begin?	Give ventilatory support for respiratory distress/arrest to avoid cardiac arrest. Start CPR in all submersions <60 minutes who do not present with obvious physical evidence of death.
When to discontinue?	Basic life support should continue unless signs of life reappear, rescuers are exhausted, or advanced life support can take over. Advanced life support should be ongoing until the patient has been rewarmed (if hypothermic) and asystole persists for more than 20 minutes.

CPR, Cardiopulmonary resuscitation.

BOX 61.1 Who Needs Further Medical Help After Rescue From the Water

(a) A patient who has experienced or required any of the following should be sent to a hospital:
- Loss of consciousness, even for a brief period
- Foam at the mouth or nose, cough, or dyspnea that persists more than a few minutes after removal from the water
- Rescue breathing was needed
- Cardiopulmonary resuscitation was needed
- A concomitant medical condition such as heart attack, spinal injury, other injury, asthma, epilepsy, intoxication, or delirium
- Any indication of neurologic impairment (e.g., altered mental status, confusion, lethargy)

(b) The following persons may be considered for release from care at the scene if, after 10–15 minutes of careful observation while being warmed with blankets or other coverings as required, the patient has ALL of the following:
- No cough
- Normal rate of breathing
- Normal circulation as measured by pulse in strength and rate and blood pressure (if available)
- Normal color and skin perfusion
- No shivering
- Is fully conscious, awake, and alert

In such cases, it is unwise for the patient to drive a vehicle, and the patient should be so advised. If any of these conditions does not apply or if the lifesaver has any doubt, then the patient should be advised to seek early medical attention.

(c) A small percentage of patients may have minimal symptoms that go unrecognized and become worse over the next several hours. Patients should be advised to seek care if they develop cough, shortness of breath, or any neurologic or respiratory symptoms over the next 6–8 hours.

The presenting rhythm in a drowning resuscitation setting is usually asystole or PEA. VF may occur if there is a history of coronary artery disease, use of epinephrine, or in the presence of severe hypothermia. If VF is present, defibrillation should be attempted. Peripheral venous or intraosseous access is the preferred route for drug administration. Intravenous (IV) administration of medication should follow the algorithms for asystole or PEA. Endotracheal administration of drugs is not recommended during CPR and certainly not for drowning. An orogastric tube can be placed to relieve gastric distention and prevent further aspiration, and this intervention can improve ventilation and circulation.[59,60] If initial resuscitation efforts are not successful, the person should be transported to a hospital where advanced neuroprotective therapies and rewarming can be accomplished while resuscitation is continued during transport. There are emerging data on the benefit of extracorporeal membrane oxygenation (ECMO) in drowning resuscitation, and patients can be transferred to ECMO-capable hospitals where available.[38]

If adequate oxygenation and ventilation have been provided at the scene by bystanders or lifeguards, an isolated respiratory arrest is frequently reversed before EMS arrives. Oxygen administration at the highest concentration available should continue until spontaneous breathing is restored. Once spontaneous ventilation occurs, oxygen should still be administered at the highest concentration available to maintain a saturation above 92%. Some patients may be able to maintain adequate oxygenation despite an elevated respiratory rate. In low- and middle-income or resource-deficit settings, the highest concentration of oxygen available may just be expired air ventilations. This approach is preferable to withholding ventilations until more advanced equipment arrives and may be lifesaving.

Early intubation and mechanical ventilation in spontaneously breathing patients is indicated when saturation remains below 92% or when respiratory fatigue occurs despite adequate oxygenation. Once intubated and sedated, most patients can be oxygenated and ventilated effectively. Mechanical ventilation should provide a tidal volume of 6–8 mL/kg of predicted body weight. Fraction of inspired oxygen (FiO_2) can initially be 1.0 but should be reduced when both indicated and feasible. Ventilation strategies follow the same guidelines and lung-protective principles of the Acute Respiratory Distress Syndrome (ARDS) Network.[61] If hypotension is initially present and not corrected by oxygen or caused by pneumothorax, a rapid crystalloid infusion should be used.[62]

The majority of conscious drowned persons have only mild distress with little or no aspiration. Treatment is to provide supportive care and oxygen at the highest concentration available. These patients can present a disposition dilemma for rescuers who must determine whether or not additional care is needed at a hospital or higher level of care. Simply put, all persons who cough or have other symptoms that do not resolve within a few minutes of rescue should be transported to a hospital (Box 61.1).

Out-of-hospital cardiac arrest (OHCA) caused by presumed cardiac etiologies is far more common than that caused by drowning. Improved training and high-performance CPR programs have led to improved survival. Conversely, drowning resuscitations present many practical challenges for prehospital providers that must be taken into consideration when developing training and response programs. In essence, the difficulties encountered in drowning resuscitation must be anticipated through realistic, high-fidelity training and feedback. Drowning patients frequently vomit, are pediatric, and are found in outdoor settings with sloped surfaces, uneven footing, and varied lighting. Prehospital training scenarios for drowning patients should take these factors into consideration. Many prehospital drowning resuscitations are attended by lifeguards, police, or other nonmedical first responders. Professional response agencies should be aware of the level of training and capabilities of other responders who may attend a drowning resuscitation in their jurisdiction. Improving survival from drowning requires intentional, targeted, realistic training and optimized system performance.[63]

In-Hospital Treatment. Prehospital treatment should continue or be initiated once the patient is admitted to the emergency department (ED). During initial assessment, it is important to recognize that drowning is sometimes precipitated by a trauma, seizure, stroke,

hypoglycemia, or cardiac dysrhythmia. Additional diagnosis and therapies can be required. In some patients a toxicologic screen for suspected alcohol, recreational drug use, or drug overdose maybe justified and may complement other features of the history of the incident, such as depression, suicide, or parental/elder neglect.

Respiratory Concerns. Many drowning patients present with a clinical picture very similar ARDS. Respiratory management should follow updated ARDS guidelines, including efforts to minimize volume trauma and barotrauma.[64,65] Some 10% of ventilated drowning patients develop a pneumothorax secondary to positive-pressure ventilation and local areas of hyperinflation.[66] Any sudden deterioration in hemodynamic stability after the start of mechanical ventilation should be considered to be the result of pneumothorax or other barotrauma until proven otherwise. Ventilation involving permissive hypocapnia or hypercapnia is not suitable for the drowned person and may worsen hypoxic-ischemic brain injury.[62]

In selected conscious, cooperative, and less symptomatic patients, noninvasive ventilation is effective and may prevent endotracheal intubation.[38,67–69]

Vigilance for infectious complications is important.[70] Pneumonia is often initially missed because of the early radiographic appearance of water in the lungs. Pools, rivers, and beaches generally have insufficient bacteria colonization to induce pneumonia in the immediate post-drowning period. Prophylactic antibiotics tend to only select out more resistant and more aggressive organisms and are not indicated. Daily monitoring of tracheal aspirates for Gram stain, culture, and sensitivity is advised. The first sign of pulmonary infection usually occurs in the third or fourth day of hospitalization, when pulmonary edema is expected to be resolving. Unlike the edema, the infection is diagnosed by fever, sustained leukocytosis, persistent or new pulmonary infiltrates, and increased leukocyte numbers in tracheal aspirates. If the patient needs mechanical respiratory assistance, the incidence of ventilator-associated pneumonia increases. Effective antibiotic therapy sometimes needs to be based on information about the predominant organisms in the water where the drowning occurred. If there are reasons to suspect ventilator-associated pneumonia, antibiotics should be directed to the sensitivity of the predominant microorganisms in the intensive care unit (ICU) or by cultures, if available. Early fiberoptic bronchoscopy may be useful for evaluating infection and for occasions when therapeutic clearing of sand, gravel, or other solids is indicated. Corticosteroids for pulmonary injury should not be used except for bronchospasm.[13,71–73]

Circulatory Issues. Cardiac dysfunction with low cardiac output is common immediately after severe drowning. Low cardiac output is associated with high pulmonary capillary occlusion pressure, high central venous pressure, and high pulmonary vascular resistance and can persist for days after correction of oxygenation and perfusion abnormalities. This may add a cardiogenic component to drowning-associated noncardiogenic pulmonary edema. Low blood pressure, if present, can be corrected with better oxygenation, rapid crystalloid infusion, and restoration of normothermia. Vasopressor infusion should be used only in refractory hypotension to improve cardiac output when replacement with crystalloid is inadequate to restore blood pressure. Electrocardiogram (ECG), echocardiography, pulmonary artery catheterization, or noninvasive alternatives may be needed to assess cardiac function, and ejection fraction can help to guide the clinician in titrating inotropic agents, vasopressors, or both if volume crystalloid replacement has failed. Whether pulmonary edema occurs after salt or freshwater drowning, there is no evidence to support the use of any specific IV fluid therapy, diuretics, or water restriction.[70,74–76]

Mixed respiratory and metabolic acidosis occurs in most drowning patients. Acidosis should be corrected when pH is lower than 7.2 or bicarbonate is less than 12 mEq/L despite adequate ventilatory support. Significant depletion of bicarbonate is rarely present in the first 10–15 minutes of CPR, and IV sodium bicarbonate is not indicated during the initial resuscitation. In hypothermic patients, arterial blood gases do not need to be temperature corrected (the alpha-stat or pH-stat concept).[77]

Recently, more data have become available about periods of renal insufficiency and coagulopathies in drowning persons that are secondary to anoxia, shock, or hemoglobinuria. Measurements of electrolytes, blood urea nitrogen, creatinine, and hemoglobin should be considered, but there are no pathognomonic or unique findings in the drowned person.[78–82]

Neurologic System. The most important complication in severe drowning that requires CPR, beyond reversible pulmonary injury, is anoxic-ischemic cerebral insult. Most late deaths and long-term sequelae of drowning are neurologic in origin.[70,83–86] Although the highest priority in resuscitation after drowning is restoration of spontaneous circulation, every effort in the early stages after rescue should be directed at preventing further neurologic damage. These steps include providing adequate oxygenation (High FiO2) to maintain SatO2 > 92% and establishing effective cerebral perfusion (mean arterial pressure around 100 mm Hg). Any patient who remains comatose and unresponsive after successful CPR or deteriorates neurologically should undergo careful and frequent neurologic function assessment. Consensus guidelines on the brain-oriented treatment of comatose drowning victims include head elevation by 15%–30% in hemodynamic stable patients, establishing normal oxygenation and saturation (to prevent hypoxia and hyperoxia), normocapnia, normal body temperature (to prevent hypothermia and treat hyperthermia; however, a temperature between 32°C and 34°C can be considered during the first 12–72 hours). Guidelines also target normal blood pressure (diagnose and treat hypotension and hypertension) and optimized volume, osmotic, and glycemic status. Comatose drowning victims should be transferred to centers with adult or pediatric intensive care expertise. Frequent neurophysiologic and neuroimaging monitoring (ECG, somatosensory evoked potential [SSEP], N_2O, intracranial pressure [ICP], computed tomography [CT], or magnetic resonance imaging [MRI]) and follow-up of serum biomarkers may be needed. The effects of prolonged induced hypothermia after drowning are inconclusive. There is not yet evidence for any pharmacologic therapy that may influence neurologic prognosis.[62]

Ice-Water Drowning. In some drowned patients, a low body temperature is the reflection of slow cooling because of prolonged submersion in water below body temperature and portends a poor prognosis. In others, hypothermia may be the result of rapid cooling in ice-cold (<7°C) water, which presents a diagnostic and prognostic dilemma. Rapidly developed deep hypothermia caused by drowning in ice-cold water can provide a protective mechanism that allows survival despite prolonged submersion episodes. The cold water triggers the mammalian diving reflex and, likely more importantly, decreases the rate of cerebral oxygen consumption by approximately 5% per each °C decrease in temperature within the range of 37°C to 20°C. However, other mechanisms may have an added role, such as the maintenance of intracellular processes. Although the rare cases of survival in cold water receive significant attention both in peer-reviewed and lay media, they represent rare outliers, and the primary determinant of survival is duration of submersion.[20,87–94]

The paradox in drowning resuscitation is that the hypothermic patient must be warmed in order to be effectively resuscitated, but may benefit from induced therapeutic hypothermia after successful

resuscitation. An important dictum that has been developed from experience with ice-water drowning and accidental hypothermia is that patients who appear dead after exposure to very cold temperatures should not be pronounced dead until they are at near-normal core temperature and remain in asystole. Good outcomes have been reported in scattered case reports and in small case studies of postresuscitation drowned patients who were kept hypothermic or treated with therapeutic hypothermia despite predicted poor outcome.[95,96] More recent studies demonstrate, however, that the beneficial effect of low body temperature on neurologic survival is limited.[83,84] Emerging data show benefit from ECMO in hypothermic drowned persons and will likely inform future research.[38]

DECISION TO ADMIT TO THE ICU, GENERAL WARD, OR DISCHARGE

The decision to observe the nonintubated patient in the ED, the ward, or the ICU should be based on a detailed history, trends in monitoring, diagnostic imaging, and laboratory studies. Patients with minimal symptoms after aspiration of small amounts of liquid typically either get better or worse within the first few hours. Patients who have normal respiration, no coughing, normal room air oxygen saturation, and normal mentation during the first 6–8 hours after the event can be safely discharged.

Although the lay media describes drowning persons who develop respiratory complications up to 72 hours after being initially asymptomatic, there are no well-documented published cases of completely asymptomatic patients who later decompensate after early release. Patients presenting more than 8 hours after an aquatic accident with new respiratory or other symptoms should be evaluated for other medical or traumatic etiologies such as spontaneous pneumothorax, viral myocarditis, pneumonia, respiratory syncytial virus, urinary tract infection, or cholecystitis.

Drowning Severity Classification

A classification scheme based on over 85,000 lifeguard rescues was developed to stratify mortality rates and risks among drowned persons based on their presenting symptoms. The six grades of severity can be easily assessed by an on-scene rescuer, EMT, or physician (Fig. 61.3).[97] The algorithm supports and guides prehospital treatment and transport decisions and provides general mortality estimates.[98–100]

OUTCOME

With advances in ICU therapeutics, the clinical outcome of drowning patients has become primarily related to the neurologic outcome after resuscitation.[76,94,99,101]

Patients who have been resuscitated, are comatose, or show other neurologic deficits should undergo intensive assessment and care. Questions such as "How can we know if the effort to resuscitate will be meaningful?" "How long should we continue to resuscitate?" and "What should we expect as life quality after successful resuscitation?" need to be answered. Both at the rescue site and in the hospital, no single indicator appears to be an absolutely reliable predictor of outcome.[76,93,94] Prolonged submersion with successful resuscitation is not only possible in cold or icy water but also (in rare cases) from prolonged warm water drowning.[28,102] A recent systematic review concluded that the outcome of drowning is almost solely determined by one single factor—duration of submersion.[93] Basic and advanced life support enable drowning patients to achieve their best outcome possible when the duration of cardiopulmonary arrest (submersion time included) is minimized. Most patients who show improvement and are alert (or are stuporous or obtunded but respond to stimuli 2–6 hours after the incident) have normal or near-normal neurologic outcomes.

To inform future research and better understand the prognosis of drowned persons, prehospital agencies are advised to use the formal definition of drowning and the Utstein template for reporting data from drowning resuscitation.[1,2]

Treatment in Resource-Deficit Settings

The lack of adequate resources in LMICs or in disaster, remote, wilderness, or resource-deficit settings has significant implications for drowning survival and treatment. At the site of initial resuscitation and rescue, oxygen should still be provided at the highest concentration available, which may just be by mouth-to-mouth or mouth-to-mask. Chest compressions should be initiated in addition to ventilation if the person is pulseless. Understanding the prognosis becomes even more critical if the crucial downstream elements of the chain of survival, especially a functioning EMS system or access to an advanced healthcare facility, are not present. Careful consideration should be given to only starting resuscitation if submersion time is known to be less than 25 minutes and to terminating resuscitation if unsuccessful after 30 minutes of chest compressions and ventilations. Conversely, if consciousness or return of spontaneous circulation is achieved, priority should be given to immediate transport to a hospital, even if it takes several hours or even days. Once in the hospital, the same priorities for oxygenation apply.[4,103]

KEY POINTS

- Drowning is a serious and neglected public health threat, claiming the lives of more than 300,000 people per year worldwide. Exposure-adjusted, person-time estimates for drowning deaths are 200 times higher than traffic accidents. Over 85% of drowning deaths are preventable.
- Prevention is the best treatment for drowning, which is beyond the scope of this chapter.
- The "drowning chain of survival" refers to a series of water-safety interventions that, when put into action, reduce the morbidity and mortality associated with drowning.
- When resuscitation is needed, the first priority is the immediate provision of optimal ventilation and oxygenation.
- Patients not requiring intubation typically improve within 48 hours and do not have long-term sequelae.
- Although intubated patients should be managed according to the most current ARDS protocols, hypercapnia and hypocapnia should be avoided, as this may exacerbate neurologic damage.
- Survival is most dependent on duration of submersion. Patients who arrive at the ED alert typically have a favorable course. Prognosis for patients arriving obtunded is more difficult to predict.

Aspiration Pneumonitis and Pneumonia

Paul E. Marik

Aspiration is defined as the misdirection of oropharyngeal or gastric contents into the larynx and lower respiratory tract.[1] The consequent pulmonary syndromes that follow depend on the quantity and nature of the aspirated material, frequency and chronicity of aspiration, and nature of the host's defense mechanisms. The most important acute syndromes include *aspiration pneumonitis,* characterized in its most severe form and in a predisposing setting as Mendelson syndrome, a chemical pneumonitis caused by the aspiration of gastric contents, and *aspiration pneumonia,* an infectious process caused by the aspiration of oropharyngeal secretions that have been colonized by pathogenic bacteria.[1,2] Although some overlap exists between these two syndromes, they are distinct clinical entities. Consequences of chronic aspiration include bronchiectasis, chronic bronchitis, lipoid pneumonia, interstitial lung disease, organizing pneumonia, bronchiolitis obliterans, diffuse aspiration bronchiolitis, and *Mycobacterium fortuitum* pneumonia.[3] This chapter focuses on acute aspiration, namely, aspiration pneumonitis and aspiration pneumonia. It is critically important to distinguish between these two syndromes, as their management differs considerably. Aspiration pneumonia is a bacterial pneumonia caused by the aspiration of colonized oropharyngeal secretions. It most commonly develops in elderly patients and those with neurologic disorders. By contrast, aspiration pneumonitis is caused by the inhalation of regurgitated gastric contents, causing a chemical pneumonitis.[1] The administration of antibiotics is central to the management of aspiration pneumonia, whereas the treatment of aspiration pneumonitis is largely supportive.[1] The distinction between these two syndromes is based largely on clinical criteria (Table 62.1). Although gastric biomarkers for aspiration are increasingly available (pepsin, amylase, lipid-laden macrophages), none have been clinically validated.[2–4] Serum procalcitonin and other inflammatory markers are unable to distinguish aspiration pneumonitis from aspiration pneumonia.[5] This imprecision is not surprising, considering that proinflammatory mediators play a central role in the pathophysiology of both syndromes and are responsible for the transcription of procalcitonin.[6]

ASPIRATION PNEUMONITIS

Aspiration pneumonitis is best defined as acute lung injury after the aspiration of regurgitated gastric contents.[1] This problem occurs in patients with marked disturbances of consciousness, such as drug overdose, seizures, coma resulting from acute neurologic insults, massive cerebrovascular accident, head trauma, and general anesthesia. Adnet and Baud demonstrated an association between the degree of altered mental status as measured by Glasgow Coma Scale and aspiration, supporting the pathophysiologic link between these entities.[7] In clinical practice, drug overdose is the most common cause of aspiration pneumonitis, occurring in approximately 10% of patients hospitalized after massive drug ingestion. Aspiration pneumonitis also occurs commonly with acute alcohol intoxication and after a generalized seizure.[8] Historically the syndrome most commonly associated with aspiration pneumonitis is Mendelson syndrome, reported in 1946 in obstetric patients who aspirated while receiving general anesthesia.[9]

Although aspiration is a widely feared complication of general anesthesia, clinically apparent aspiration in nonemergent situations is exceptionally rare in modern anesthesia practice, and in healthy patients the overall morbidity and mortality are low. Nevertheless, aspiration pneumonitis is an important perioperative complication and remains the most common cause of anesthesia-associated fatality, accounting for between 10% and 30% of all anesthetic deaths. The risk of aspiration with modern anesthesia is reported to be between 2.9 and 4.7 per 10,000 general anesthetics (about 1 in 3000 anesthetics), with a mortality incidence of approximately 1:125,000.[10,11] Emergency surgery (particularly trauma and abdominal surgery with delayed gastric emptying), procedures performed at night, inadequate anesthesia, obesity, obstetric patients, elderly immobilized patients, and patients with obstructive sleep apnea are considered to be at a higher risk of such aspiration.[11,12]

Pathophysiology

Mendelson emphasized the importance of acid when he showed that un-neutralized gastric contents introduced into the lungs of rabbits caused severe pneumonitis indistinguishable from that caused by an equal amount of 0.1 N hydrochloric acid.[9,13,14] However, if the pH of the vomitus was neutralized before aspiration, the pulmonary injury was minimal. Experimental studies have demonstrated that the severity of lung injury increases significantly with the volume of the aspirate and less directly with its pH; a pH of less than 2.5 is typically required to cause severe aspiration pneumonitis. In experimental models, a two-phase injury results when acid is instilled into the lungs. The initial injury phase (within 1 hour of acid exposure) is primarily because of the acid's direct caustic effects on pulmonary tissue, whereas the second injury phase (beginning at 3–4 hours and peaking at 4–6 hours postexposure) results from the products released by recruited neutrophils.[15,16] The intensity of the alveolar neutrophil infiltration correlates with the severity of the acute lung injury. Once localized to the lung, neutrophils play a key role in the development of lung injury through the release of reactive oxygen species (ROS) and proteases that are injurious to the lung. Nicotinamide adenine dinucleotide phosphate (NADPH) oxidase is the major source of ROS in activated polymorhpho nuclear leukocytes, (PMNs;). Other sources of ROS after gastric aspiration include superoxide anions generated by xanthine oxidase.[17] ROS exacerbate acute lung injury through several mechanisms, including direct cellular injury, nuclear factor-κB (NF-κB) activation, and activation of other proinflammatory mediators such as tumor necrosis factor-alpha (TNF-α) and interleukin-8 (IL-8). The activation of NADPH oxidase in neutrophils is linked to the generation of neutrophil extracellular traps

TABLE 62.1 Contrasting Features of Aspiration Pneumonitis and Aspiration Pneumonia

Feature	Aspiration Pneumonitis	Aspiration Pneumonia
Mechanism	Aspiration of sterile gastric contents	Aspiration of colonized oropharyngeal material
Pathophysiologic process	Acute lung injury from acidic and particulate matter	Acute pulmonary inflammatory response to bacteria and bacteria products
Bacteriologic findings	Initially sterile, with subsequent bacterial infection possible	Gram-negative rods, gram-positive cocci, and rarely, anaerobic bacteria
Major predisposing factors	Depressed level of consciousness	Dysphagia and gastric dysmotility
Age group affected	Any age group, but usually young persons	Usually elderly persons
Aspiration event	May be witnessed	Usually not witnessed
Typical presentation	Patient with a history of depressed level of consciousness in whom a pulmonary infiltrate and respiratory symptoms develop	Institutionalized patient who presents with features of a "community-acquired pneumonia" with an infiltrate in a dependent bronchopulmonary segment
Clinical features	No symptoms, or symptoms ranging from a nonproductive cough to tachypnea, bronchospasm, bloody or frothy sputum, and respiratory distress	Tachypnea, cough, fever, and signs of pneumonia

(NETs). NETs are extracellular strands of decondensed (unwound) DNA in complex with histones and neutrophil granule proteins. NETs contain serine proteases and other antimicrobial products that damage the lung.

The stomach contains a variety of substances in addition to acid. Several experimental studies have demonstrated that aspiration of small, particulate food matter from the stomach may cause severe pulmonary damage, even if the pH of the aspirate exceeds 2.5.[18,19] These studies suggest that cell recruitment and expression of inflammatory mediators are most pronounced after injury with combined acid and small food particles. These data are supported by findings in patients in whom the most severe lung injury was observed after aspiration of gastric fluids with particulate food matter.[20,21] In healthy subjects, gastric acid prevents the growth of bacteria, and the contents of the stomach are normally sterile. Bacterial infection therefore does not play a significant role in the early stages of acute lung injury after aspiration of gastric contents.

Clinical Presentation

Aspiration of gastric contents can present dramatically, with a full-blown picture that includes gastric contents in the oropharynx, wheezing, coughing, shortness of breath, cyanosis, pulmonary edema, hypotension, and hypoxemia, which may progress rapidly to severe acute respiratory distress syndrome (ARDS) and death (Fig. 62.1). However, many patients may not express impressive signs or symptoms associated with aspiration, whereas others may simply develop a new cough or wheeze. In some patients, aspiration may be clinically silent, manifesting only as arterial desaturation with radiologic evidence of aspiration. Warner and colleagues studied 67 patients who aspirated while undergoing anesthesia.[14] Forty-two (63%) of these patients were totally asymptomatic, 13 required mechanical ventilatory support for more than 6 hours, and 4 died.

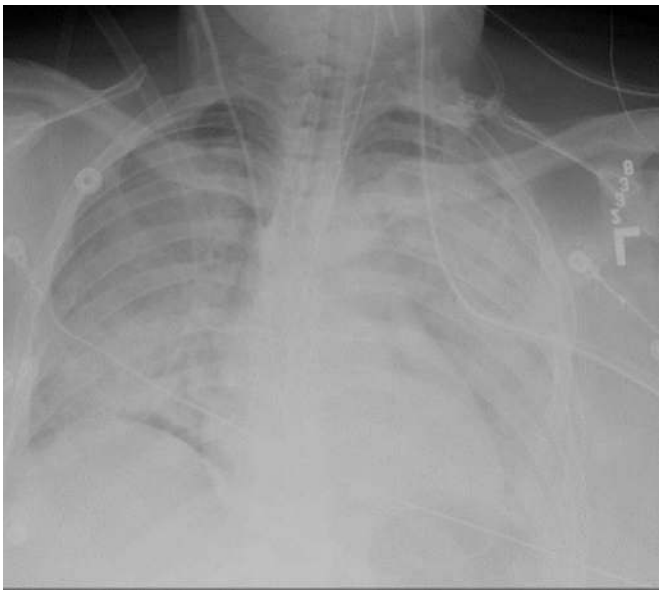

Fig. 62.1 Chest radiograph demonstrating severe bilateral air space disease (ARDS) in a patient who aspirated after anesthesia.

Management of Aspiration Pneumonitis

The upper airway should be suctioned after a witnessed aspiration. Endotracheal intubation should be strongly considered in patients who are unable to protect the airway. Although common practice, the prophylactic use of antibiotics in patients with strongly suspected or witnessed aspiration is not recommended.[1,22] Similarly, the use of antibiotics shortly after an aspiration episode is discouraged in most patients who develop a fever, leukocytosis, and a pulmonary infiltrate, as their use may simply encourage overgrowth of resistant organisms in an otherwise uncomplicated chemical pneumonitis. However, empiric antimicrobial therapy is appropriate in patients who aspirate gastric contents in the setting of small bowel obstruction or in other circumstances associated with colonization of gastric contents. Antimicrobial therapy should be considered in patients with an aspiration pneumonitis that fails to resolve within 48 hours. Empiric therapy with broad-spectrum agents is recommended. Antimicrobials with anaerobic activity are not routinely required.

Corticosteroids are potent antiinflammatory agents that act largely by repression of the transcriptional activity of NF-κB. Glucocorticoids have been used in the management of aspiration pneumonitis since 1955[23–25]; however, their role as monotherapy appears restricted, possibly because of their limited effects on neutrophils and ROS. Vitamin C, acting synergistically with low-dose corticosteroids and thiamine,

has emerged as an important strategy in treating various conditions characterized by widespread and profound inflammation.[26] Vitamin C is a potent antioxidant and inhibitor of NAPDH oxidase and would likely reduce the severity of acute lung injury after acid aspiration.[27] In addition, vitamin C inhibits NETosis.[28] We have previously described two patients with "anesthesia-related" aspiration pneumonitis and severe ARDS who were treated with hydrocortisone, ascorbic acid, and thiamine (HAT therapy) who appeared to respond dramatically to this intervention.[29] Mixed results have been reported from prospective randomized controlled trials that explored the potential benefits of this treatment strategy in the management of sepsis and ARDS. We suggest, however, that this simple, safe, readily available, and cheap intervention be strongly considered in patients with acid aspiration–induced acute lung injury.

Prevention of Aspiration During Anesthesia

In recent years, more liberal preoperative fasting guidelines have been promoted. In heathy adults without an increased risk of regurgitation or aspiration, solids should be avoided after midnight; however, a light meal such as dry toast may be considered up to 6 hours before anesthesia, and clear liquids such as water, coffee without milk, or fruit juice can be ingested up to 2 hours before induction.[30,31] Meta-analyses of randomized controlled trials comparing fasting times of 2–4 hours with more than 4 hours report smaller gastric volumes and higher gastric pH values in adult patients given clear liquids 2–4 hours before a procedure, and this approach is currently endorsed by the American Society of Anesthesiology (ASA).[32]

Preoperative antacids, histamine-2 (H2) receptor blockers, proton pump inhibitors (PPIs), and prokinetic agents have been used to reduce the volume and/or acidity of the gastric contents and hence the risk of aspiration and its consequences. There is, however, a lack of data indicating that any of these drugs reduce the risk of aspiration pneumonia.[33] The routine use of these drugs is not recommended by the ASA guidelines.[32] Standard teaching suggests that rapid-sequence induction with cricoid pressure should be performed when intubating patients at increased risk of aspiration. Although not proven to reduce the risk of aspiration during emergent intubations, cricoid pressure is currently considered the standard of care in this situation.

ASPIRATION PNEUMONIA

Aspiration pneumonia refers to the development of a radiographic infiltrate in the setting of risk factors for increased oropharyngeal aspiration. Approximately half of all healthy adults aspirate small amounts of oropharyngeal secretions during sleep. Presumably the low burden of nonvirulent bacteria in normal pharyngeal secretions, together with forceful coughing, active ciliary transport, and normal humoral and cellular immune mechanisms clear the inoculum without sequelae.[1] However, if normal mechanical, humoral, or cellular mechanisms are impaired or if the aspirated inoculum is large enough, pneumonia may follow. Any condition that increases the volume and/or bacterial burden of oropharyngeal secretions in the setting of impaired host defense mechanisms may lead to aspiration pneumonia. Indeed, the volume of the aspirate correlates strongly with the development of pneumonia in stroke patients undergoing swallow evaluation.[34] Factors that increase oropharyngeal colonization with potentially pathogenic organisms and increase the bacterial load augment the risk of aspiration pneumonia. The clinical setting in which pneumonia develops largely distinguishes aspiration pneumonia from other forms of pneumonia. However, there is considerable overlap. This is illustrated by the fact that otherwise healthy elderly patients with "community-acquired pneumonia" (CAP) have a significantly higher incidence of silent aspiration when compared with age-matched controls.[35]

Epidemiology

The lack of specific and sensitive markers makes the epidemiologic study of aspiration syndromes difficult. Furthermore, most studies do not distinguish between aspiration pneumonitis and aspiration pneumonia. Nevertheless, several studies list "aspiration pneumonia" as the cause of CAP in 5%–15% of cases.[36,37] CAP is a major cause of morbidity and mortality in the elderly, and it is likely that aspiration is the major cause of pneumonia in this advanced age group. Epidemiologic studies have demonstrated that the incidence of pneumonia increases with aging, the risk being almost six times higher in those over the age of 75, compared with those less than 60 years of age.[38,39] The attack rate for pneumonia is highest among those in nursing homes.[40]

Dysphagia in Patients With Aspiration Pneumonia

Impaired swallowing is the major risk factor leading to aspiration pneumonia. In addition, dysphagia contributes significantly to predisposing protein-energy malnutrition and dehydration. Impairment in any component of the swallow mechanism, including anatomic abnormities of the upper airway or esophagus, can lead to dysphagia.[41] Dysphagia has traditionally been associated with brainstem and bilateral cerebral infarction, though it has more recently been shown to occur in isolated cerebral infarctions as well. Furthermore, dysphagia is commonly associated with silent cerebral infarctions.

Dysphagia is remarkably common in Westernized nations and is a major cause of morbidity and mortality. Indeed, aspiration pneumonia is probably the final common pathway by which most chronically ill patients die. It has been estimated that over 16 million senior citizens in the United States suffer from dysphagia.[42] Furthermore, in the United States an additional 300,000–600,000 patients develop swallowing dysfunction each year from neurologic disorders.[43] Dysphagia affects more than 30% of patients who have had a cerebrovascular accident, 52%–82% of patients with Parkinson disease, 84% of patients with Alzheimer disease, up to 40% adults aged 65 years and older, and more than 60% of elderly institutionalized patients.[44] The efficiency of the swallowing mechanism decreases with aging, predisposing to aspiration. Kikuchi and colleagues evaluated the occurrence of silent aspiration in otherwise "healthy elderly patients" with CAP and age-matched control subjects using indium chloride scanning.[35] Silent aspiration was demonstrated in 71% of patients with CAP compared with 10% of control subjects. The impaired swallowing mechanism of the elderly can be attributed to diminished sensation, silent cerebral infarction, cerebral atrophy, a delay in the synapse conduction of the afferent inputs to the central nervous system, and lingual weakness (sarcopenia) caused by aging.[45,46]

Risk Factors for Dysphagia

The major risk factors for dysphagia are listed in Table 62.2. In patients with an acute stroke, the incidence of dysphagia ranges from 40% to 70%.[47] Dysphagic stroke patients who aspirate are at an increased risk of developing pneumonia.[48,49] Although dysphagia gradually improves in most patients after a stroke, in many the swallowing difficulties follow a fluctuating course, with 10%–30% continuing to have dysphagia with aspiration.[50,51]

Factors That Increase the Risk of Pneumonia in Patients Who Aspirate

Although the presence of dysphagia and the volume of the aspirate are key factors that predispose patients to aspiration pneumonia, a number of other influences play an important role.[34] Colonization of the

TABLE 62.2 Risk Factors for Dysphagia and Aspiration Pneumonia

Cerebrovascular disease
Ischemic stroke
Hemorrhagic stroke
Subarachnoid hemorrhage
Degenerative neurologic disease
Alzheimer dementia
Multi-infarct dementia
Parkinson disease

oropharynx is an important step in the pathogenesis of aspiration pneumonia. The elderly have increased oropharyngeal colonization with pathogens such as *Staphylococcus aureus* and aerobic gram-negative bacilli (e.g., *Klebsiella pneumoniae* and *Escherichia coli*).[52] Although this increased colonization may be transient, it underlies their increased risk of pneumonia with these pathogens. Furthermore, colonization of dental plaque may be an important risk factor for aspiration pneumonia.[53] The defects in host defenses that predispose to enhanced colonization with these organisms are uncertain; however, dysphagia with a decrease in salivary clearance and poor oral hygiene may be major predispositions.[54] Residents of long-term care facilities are prone to poor oral health because of a lack of hygiene in addition to conditions of periodontal and/or dental disease. Frequent use of PPIs increases gastric and oropharyngeal colonization with potentially pathogenic organisms. Gulmez and colleagues reported that the concurrent use of PPI in patients over the age of 60 increased the risk for community-acquired (aspiration) pneumonia.[55]

Diagnosis and Management of Aspiration Pneumonia

There is no "gold standard" test to diagnose aspiration. Furthermore, in patients with aspiration pneumonia, unlike the case of aspiration pneumonitis, the critical episode of aspiration is generally not witnessed. The diagnosis is therefore inferred when a patient with known risk factors for aspiration has an infiltrate involving a characteristic bronchopulmonary segment.[52] In patients who aspirate in the recumbent position, the most common sites of involvement are the posterior segments of the upper lobes and the apical segments of the lower lobes (Fig. 62.2).[1,8,52] By contrast, the basilar segments of the lower lobes are favored in patients who aspirate in the upright or semi-recumbent position. The usual picture is that of an acute pneumonic process, which runs a course similar to that of a typical CAP. Untreated, however, these patients appear to have a higher incidence of cavitation and lung abscess formation.[56]

Antimicrobial therapy is indicated in patients with aspiration pneumonia. The choice of antibiotics should depend on the setting in which the aspiration occurred and the patient's premorbid condition. Evaluation includes such considerations as whether the aspiration occurred in the community or in a health care facility and such patient characteristics as alcoholism, oral hygiene, intravenous drug abuse, and recent use of antibiotics or acid suppressive therapy.[57]

Aspiration pneumonia most commonly occurs in a health care facility (health care–acquired pneumonia [HCAP]) or in an acute care hospital (hospital-acquired pneumonia [HAP]). HCAP refers to pneumonia that develops in the growing population of individuals receiving health care in venues outside the hospital, including dialysis clinics, nursing homes, and long-term acute care (LTAC) facilities. Patients with HCAP and risk factors for infection with a drug-resistant pathogen should be treated with broad-spectrum agents. Although commonly prescribed (and often considered the standard of care), antimicrobials with specific anaerobic activity are not routinely warranted.[1,8] In one of the most rigorous studies to date, El-Sohl and colleagues performed protected quantitative bronchial sampling in 95 patients with severe aspiration pneumonia.[58] Out of the 67 pathogens identified, gram-negative enteric bacteria were the predominant organisms isolated (49%), followed by anaerobic bacteria (16%) and *S. aureus* (12%). A single anaerobic bacterium was isolated from 11 patients, usually in association with a gram-negative pathogen. Although seven cases with anaerobic isolates received initially inadequate antimicrobial coverage to address those organisms, six had effective clinical responses. Antimicrobials with specific anaerobic activity may only be indicated in patients with periodontal disease, patients expectorating putrid sputum, and patients with a necrotizing pneumonia or lung abscess on chest radiograph.[1,57,59,60] Prophylactic antibiotics are not recommended for preventing pneumonia in patients with dysphagia who have suffered a stroke.[61]

Assessment and Management of Dysphagia

All elderly patients with CAP and chronic idiopathic lung disease (ILD) in addition to patients with a recent cerebrovascular accident and those with degenerative neurologic diseases should be referred to a speech and language pathologist (SLP) for a formal swallowing evaluation.[49,62] Those patients with dysphagia require the formulation

and implementation of an individualized management strategy. A clinician's bedside assessment of the cough and gag reflex is unreliable in screening for patients at risk of aspiration. Because objective swallowing evaluation can be performed with a nasogastric (NG) tube (or feeding tube) in place, it is not necessary to remove such tubes (and interrupt enteral feedings) to evaluate dysphagia. Similarly, there is no contraindication to leaving an NG tube in place to supplement oral alimentation.[63]

The management of patients with dysphagia requires the coordinated expertise of a number of health care professionals, including the patient's primary care physician, pulmonologist, SLP, clinical dietician, occupational therapist, physiotherapist, nurse, oral hygienist, dentist, and the patient's primary caregivers. The goal is to optimize the safety, efficiency, and effectiveness of the oropharyngeal swallow; to maintain adequate nutrition and hydration; and to improve oral hygiene. Enhanced quality of life, wherever possible, should direct management. Whenever appropriate, emphasis should be placed on encouraging oral versus nonoral nutritional intake and hydration.

A fundamental principle of rehabilitation is that the best therapy for any activity is the activity itself. Therefore because swallowing is logically considered the best therapy for swallowing disorders, rehabilitation should be aimed at identifying ways of ensuring safe and effective swallowing in individual patients. Current treatment for dysphagia includes prevention of aspiration in the form of dietary and fluid modifications, compensatory maneuvers, position changes, and rehabilitation exercises.[64] Diet modification is a common treatment for dysphagia. Modifications in food consistency are individually determined by means of the clinical swallow and/or videofluoroscopic swallow evaluation. Reduction in bolus volume and enhancement of bolus viscosity significantly improve the safety of swallowing and reduce the risk of aspiration.[45] In addition to changes in diet, maintenance of oral feeding often requires compensatory techniques to reduce aspiration risk or to improve pharyngeal clearance. A variety of behavioral techniques are used, including modifications in posture, head position, and breathing efforts, in addition to specific swallowing maneuvers.

Tube Feeding

Tube feeding is not an essential intervention for all patients who aspirate. Short-term tube feeding, however, may be indicated in elderly patients with severe dysphagia and aspiration in whom improvement of swallowing is likely to occur. Nakajoh and colleagues demonstrated that the incidence of pneumonia was significantly higher in stroke patients with dysphagia who were fed orally compared with those who received tube feeding (54.3 vs. 13.2%, $P < 0.001$), despite the fact that the orally fed patients had a higher functional status (higher Barthel index).[65] The FOOD trials consisted of two large randomized studies that enrolled dysphagic stroke patients.[66] In the first trial, patients enrolled within 7 days of admission were randomly allocated to early tube feeding or to no tube feeding. Early tube feeding was associated with an absolute reduction in risk of death of 5.8%. The second trial allocated patients to early NG feeding or early feeding via a percutaneous endoscopic gastrostomy (PEG) tube. PEG feeding was associated with an absolute increase in the risk of death of 1% and an increased risk of death or poor outcome of 7.8%. Patients with a PEG were less likely to be transitioned to oral feeding than the NG group and were more likely to be living in an institution. This may in part explain the higher mortality of the PEG-fed patients. It is interesting to note that PEG-fed patients were more likely to develop pressure sores, suggesting that these patients may have received different (perhaps less attentive) nursing care. The results of the FOOD trials suggest that dysphagic stroke patients should be fed early via an NG or feeding tube and transitioned to oral feeding as their dysphagia resolves. Those patients whose dysphagia does not resolve may be candidates for placement of a PEG tube.

Oral Hygiene

Dental plaque and the "tongue coating" serve as a reservoir of potentially pathogenic organisms.[53] Occupants of residential homes tend to have poor oral hygiene and rarely receive treatment from dentists and oral hygienists.[67] An aggressive protocol of oral care will reduce colonization with potentially pathogenic organisms and decrease the bacterial load, measures that have been demonstrated to reduce the risk of aspiration pneumonia.[68–71] Oral care should not be overlooked in edentulous patients, as "tongue cleaning" is associated with a decreased oropharyngeal bacterial load.[72,73]

Pharmacologic Management

The neurotransmitter substance P is believed to play a major role in both the cough and swallow sensory pathways. Angiotensin-converting enzyme (ACE) inhibitors prevent the breakdown of substance P and may theoretically be useful in the management of patients with aspiration pneumonia. A number of studies have demonstrated a lower risk of aspiration pneumonia in stroke patients treated with an ACE inhibitor compared with other antihypertensive agents.[74,75] This observation was initially noted in Japanese patients, and it has been suggested that this benefit was restricted to Asian populations.[76] Furthermore, it has been postulated that lipophilic ACE inhibitors may be more beneficial than hydrophilic ACE inhibitors.[77] However, a population-based case-control study from the UK demonstrated that the ACE inhibitor currently received was associated with a reduction of the risk of pneumonia in the general population (odds ration [OR] 0.75, 95% confidence interval [CI] 0.65–0.86).[78]

CONCLUSION

Aspiration pneumonia and pneumonitis are common clinical syndromes. Aspiration pneumonitis follows the aspiration of gastric contents, usually in patients with a markedly decreased level of consciousness. Treatment of aspiration pneumonitis is essentially supportive. Aspiration pneumonia occurs in patients with dysphagia and usually presents as a CAP or HCAP with a focal infiltrate in a gravitationally dependent bronchopulmonary segment. Patients with aspiration pneumonia require treatment with antibiotics selected on the basis of the risk of infection with a drug-resistant pathogen in addition to management of the underlying dysphagia.

KEY POINTS

- Aspiration pneumonitis is a chemical pneumonitis that occurs after the aspiration of gastric contents.
- Aspiration pneumonitis occurs in the setting of a marked alteration of the level of consciousness.
- The treatment of aspiration pneumonitis is largely supportive.
- Aspiration pneumonia is a bacterial pneumonia that occurs in patients with dysphagia.
- Aspiration pneumonia is treated with antibiotics, with the choice of antibiotics depending on the setting in which the aspiration occurred.
- Patients with aspiration pneumonia require a comprehensive dysphagia evaluation and a multidisciplinary management strategy.

Severe Asthma Exacerbation in Adults

Thomas Corbridge and James Walter

MAGNITUDE OF THE PROBLEM AND RISK FACTORS

Each year in the United States, acute asthma accounts for approximately 1.8 million emergency department (ED) visits, 190,000 hospitalizations, and 3500 deaths.[1] Although death rates have decreased slightly over the last 20 years, African Americans, women, and older patients continue to be at increased risk.[1] For the subgroup of patients requiring hospital admission, in-hospital mortality is very low in patients not requiring ventilatory support. Mortality in intubated and mechanically ventilated patients is often associated with out-of-hospital cardiopulmonary arrest.[2,3]

Inadequate outpatient asthma control increases the risk of poor outcomes, including death.[4] Risk factors for an exacerbation-prone phenotype include cigarette smoking, medication nonadherence, psychosocial factors, poverty, obesity, severe sinus disease, frequent infections, and alterations in host cytokine response to viral infections.[5–7] However, even patients with mild asthma are at risk for serious exacerbations.[6] Risk factors for fatal or near-fatal asthma are listed in Table 63.1.

PATHOPHYSIOLOGY OF ACUTE AIRFLOW OBSTRUCTION

Rapid-onset exacerbations are a rare but distinct form of acute asthma. These exacerbations are predominantly bronchospastic events that evolve over minutes to hours and follow exposure to allergens or irritants, stress, illicit drugs, or the use of nonsteroidal antiinflammatory agents or beta-blockers in susceptible patients. They are generally not triggered by infection.[8] More commonly, asthma attacks evolve over 24 hours or longer and are associated with increased airway wall inflammation, bronchospasm, and mucous plugs. These exacerbations take longer to resolve and may be triggered by viral infections or *Mycoplasma pneumoniae.*[8]

Regardless of trigger or tempo, the common endpoints of a severe exacerbation include critical expiratory airflow obstruction, inadequate expiratory time, dynamic hyperinflation (DHI), increased work of breathing, and decreased diaphragm force generation. A patient with a respiratory rate (RR) in the high twenties or thirties has less than 2 seconds to exhale the tidal breath. If this time is insufficient to fully exhale, lung volumes increase and tidal breathing occurs at higher lung volumes, where respiratory system compliance is low and the respiratory muscles that drive inflation are less efficient. DHI is self-limiting if hyperinflation increases lung elastic recoil pressure and airway diameter to enhance expiratory flow. At the end of exhalation, incomplete gas emptying elevates alveolar volume and pressure, a state referred to as *auto–positive end-expiratory pressure (auto-PEEP).*[9] Overcoming the effects of auto-PEEP requires increased inspiratory work to drop pleural pressures enough to generate inspiratory flow. Concurrent with increases in resistive and elastic loads is decreased diaphragm force generation from the mechanical effects of DHI, fatigue, and acidemia, increasing the risk of respiratory arrest and death.[10]

Hypoxemia results from a decrease in ventilation ($\dot{V}_A$) relative to perfusion ($\dot{Q}$) in alveolar-capillary units. Hypoxemia severity generally tracks the severity of airflow obstruction, but in recovering patients, spirometry and peak flow may improve faster than partial pressure of oxygen (Pao_2) and $\dot{V}_A/\dot{Q}$ inequality, indicating that larger airways recover faster than smaller airways. Acutely ill asthmatics may also have small areas of high $\dot{V}_A$ relative to $\dot{Q}$ and increased physiologic dead space when blood flow decreases to hyperinflated units. Although elevated physiologic dead space can contribute to hypercapnia, alveolar hypoventilation is the more likely cause in acute asthma.

Large swings in intrathoracic pressure accentuate the normal inspiratory fall in systolic blood pressure, a phenomenon called *pulsus paradoxus* (PP). During forceful inspiration, intrathoracic pressure falls, lowering right atrial and right ventricular (RV) pressures and augmenting RV filling. Enhanced right-sided filling shifts the intraventricular septum leftward. This results in decreased left ventricular (LV) compliance and incomplete LV filling. DHI further impedes LV filling by causing tamponade-like physiology, and it increases LV afterload.

Forced exhalation increases intrathoracic pressures and impedes right-sided filling. The net result of these cyclical changes in pleural pressure is increased PP. A decline in PP generally signals improvement, with the important exception that fatigue and inability to generate large pleural pressure swings also drop PP.[10]

CLINICAL FEATURES

The hallmarks of a moderate to moderately severe exacerbation are tachypnea and respiratory distress. Patients may have difficulty speaking in long sentences and present with wheezing and prolongation of the expiratory phase. Hypoxemia and respiratory alkalosis occur commonly. Severe exacerbations are signaled by upright positioning, diaphoresis, monosyllabic speech, RR over 30/min, accessory muscle use, tachycardia, and a PP greater than 25 mm Hg.[7,11] Hypoxemia with normocapnia or hypercapnia indicates a severe exacerbation. Decreased mental status, paradoxical breathing, bradycardia, absence of PP from fatigue, and a quiet chest signal impending arrest. Severe exacerbations may also be complicated by tachyarrhythmias, RV strain, and myocardial ischemia. Posture, speech, and mental status allow for quick appraisal of severity, response to therapy, and need for intubation. The emergence of wheezes in patients presenting initially with a quiet chest from poor air movement suggests improved airflow rates and clinical status. Additionally, it is worth considering that "all that wheezes is not asthma." Table 63.2 lists other diagnostic considerations.

PEAK FLOW MEASUREMENTS

Early measurement of the peak expiratory flow rate (PEFR) or forced expiratory volume in the first second of expiration (FEV_1) helps characterize exacerbation severity. Severe exacerbations are characterized by a PEFR or $FEV_1 \leq 50\%$ of predicted or personal best, and alternative diagnoses should be considered when lung function is preserved.[7] Failure of pharmacotherapy to improve expiratory flow significantly after the initial 30–60 minutes further predicts a refractory course requiring sustained treatment in the ED or hospitalization. Measurements of expiratory flow are not required in every patient. They are not likely to alter therapy in patients presenting with classic signs and symptoms of acute asthma, and obtaining peak expiratory flow measurements in a tenuous patient can worsen bronchospasm to the point of respiratory arrest.

ACID-BASE STATUS

Arterial blood gases are indicated in patients with severe asthma exacerbations that are not responding significantly to initial therapy. Serial blood gases are generally not required unless the patient is mechanically ventilated. Although a venous blood gas can provide a reasonable approximation of arterial pH and a quick screen for hypercapnia, the poor correlation between arterial and venous partial pressure of carbon dioxide (PCO_2) is a notable limitation of relying solely on venous blood gases in the critically ill patient with asthma.[12] Hypoxemia and respiratory alkalosis are common in mild to moderate exacerbations. Eucapnia and hypercapnia suggest a severe exacerbation, but not necessarily the need for intubation, as even hypercapnic patients may respond to pharmacotherapy and/or noninvasive ventilation.

Renal compensation in response to respiratory alkalosis of adequate duration manifests as a normal anion gap metabolic acidosis. Lactic acidosis can result from increased work of breathing and the use of either high-dose nebulized or parenteral beta-agonist therapy.[13,14]

TABLE 63.1 Risk Factors for Fatal or Near-Fatal Asthma

Frequent emergency department visits and hospitalizations
Intensive care unit admission
Intubation (prior or current)
Hypercapnia
Barotrauma
Psychiatric illness
Poor adherence to medical regimen
Illicit drug use
Poverty
Inadequate access to medical care
Overuse of short-acting inhaled beta-2 agonist
Current or recent use of oral corticosteroids
Not using inhaled corticosteroids
Poor perception of airflow obstruction
Comorbidities (e.g., coronary artery disease)
Food allergy

TABLE 63.2 Differential Diagnosis of Acute Asthma

Chronic obstructive pulmonary disease exacerbation
Vocal cord dysfunction
Intraluminal mass or foreign body
Aspiration
Tracheal stenosis
Infectious bronchitis or pneumonia
Heart failure ("cardiac asthma")

CHEST RADIOGRAPHY

Chest imaging rarely affects management in classic cases of asthma exacerbation. Indications for chest imaging include localizing signs on examination, concerns regarding barotrauma, questions regarding alternative diagnoses, and assessment of endotracheal tube position.

EMERGENCY DEPARTMENT DISPOSITION

Patients demonstrating an inadequate response to albuterol over the first 30–60 minutes of therapy in the ED invariably require hospital admission or prolonged treatment in the ED.[15] Approximately one-third of patients fall into this "nonresponder" category (Fig. 63.1).

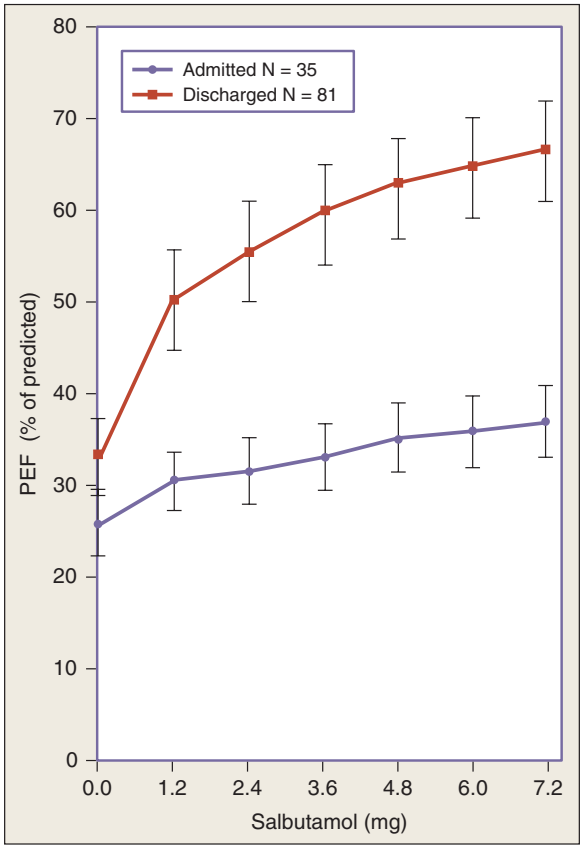

Fig. 63.1 Dose–response relationship to albuterol 4 puffs (400 μg) every 10 minutes in 116 acute asthmatics, of whom 67% obtained discharge criteria after administration of 2.4 mg of albuterol within 1 hour; half of the responders met discharge criteria after 12 puffs. Patients with a blunted cumulative dose–response relationship were hospitalized. (Reproduced with permission from Rodrigo C, Rodrigo G. Therapeutic response patterns to high and cumulative doses of salbutamol in acute severe asthma. *Chest.* 1998;113:593.)

Along these lines, the Global Initiative for Asthma (GINA) report recommends hospital admission for patients presenting with a PEFR less than 50% of predicted or 50% of the patient's personal best on presentation and <60% after initial treatment.[7] Intensive care unit (ICU) admission is required for respiratory failure, the need for frequent albuterol treatments, deterioration despite treatment, fatigue, altered mental status, and cardiac complications. Patients with a PEFR between 60% and 80% of predicted or personal best after treatment may be eligible for discharge from the ED on appropriate therapy, although clinical judgment may favor admission, especially when the outpatient setting is suboptimal or noncompliance favors directly observed therapy. Patients with a good response can be discharged with appropriate maintenance therapy and instructions for follow-up.

OXYGEN

Supplemental oxygen should be administered to maintain oxygen saturations above 90%. Doing so improves oxygen delivery to tissues, including the respiratory muscles, and reverses hypoxic pulmonary vasoconstriction. Oxygen further protects against desaturation consequent to beta-agonist-induced pulmonary vasodilation with increased blood flow to low $\dot{V}_A/\dot{Q}$ units.

PHARMACOLOGIC MANAGEMENT

Selected drugs used in the treatment of acute asthma are listed in Table 63.3.

Beta-2 Agonists

Inhaled short-acting beta-2 agonists (SABAs) treat the bronchospastic component of acute asthma. They can be delivered in a repetitive or continuous fashion, depending on clinical response and side effects, which include tremor, hypersensitivity/paradoxical reactions, cardiovascular effects, and hypokalemia. Recommended doses in acute asthma are higher than approved on the label and are based on clinical judgment, clinical trials, and guideline recommendations. Excessive SABA use has been associated with fatalities. The limits of intensive SABA use should be kept in mind; many asthmatics presenting to the hospital for rescue have done so because their outpatient inhaler was not effective.

A commonly used strategy is albuterol, 2.5 mg by nebulization, every 20 minutes during the first hour. In severe asthma exacerbations, continuous administrations delivering the same total dose may be slightly superior to repetitive doses. Albuterol can also be delivered effectively by metered-dose inhaler (MDI). MDIs with spacers are less expensive and faster; handheld nebulizers require less supervision and coordination. The most recent GINA report recommends albuterol 4–10 puffs by MDI with a spacer every 20 minutes for the first hour.[7] The treatment strategy after the first hour depends on the clinical response and side effects. An as-needed approach may be preferable to scheduled dosing to decrease total drug exposure.

Although albuterol is the most widely used SABA, other SABAs are available, including levalbuterol. A meta-analysis demonstrated that levalbuterol was not superior to albuterol in acute asthma.[16]

Subcutaneous epinephrine or terbutaline should be avoided in patients able to take inhaled therapy. If the patient is refractory to inhaled therapy, subcutaneous treatment may be beneficial, especially if there are concerns regarding anaphylaxis. Subcutaneous treatment is risky, however, particularly in older patients at risk for coronary artery disease, and it should only be used with caution by seasoned clinicians. Long-acting beta-2 agonists (LABAs) are not commonly used to treat severe asthma exacerbations, although they have been studied in this setting.[17] LABAs combined with an inhaled corticosteroid (ICS) are commonly prescribed on discharge to help achieve outpatient control and prevent future exacerbations.

Ipratropium Bromide

The modest bronchodilator properties of ipratropium bromide preclude its use as a single agent in acute asthma, and the addition of ipratropium to albuterol is of limited benefit in patients with mild or moderate attacks. However, in patients with severe attacks, ipratropium added to albuterol is more effective than albuterol alone,[18,19] even though it does not have Food and Drug Administration (FDA)–approved labeling for treatment of asthma. For nebulization in adults, 0.5 mg of ipratropium bromide can be added to 2.5 mg of albuterol; by MDI, 4–8 puffs of ipratropium bromide can be added to 4–10 puffs of albuterol. If a combination albuterol/ipratropium bromide inhaler is used, one recommended dose is 4–10 puffs every 20 minutes. In addition to the warnings and precautions for albuterol, patients receiving ipratropium bromide should be monitored for urinary tract and ocular side effects. Special care should be taken to avoid inadvertently spraying ipratropium into a patient's eyes, which can cause additional toxicity, including mydriasis. Albuterol and ipratropium can be continued for the first 1–3 hours as guided by clinical response and toxicity, after which albuterol can be continued as a single agent.

Corticosteroids

Systemic corticosteroids are invariably recommended for patients with severe asthma exacerbations. A rare exception might be the patient demonstrating an immediate and durable response to initial SABA therapy alone; these patients of course remain candidates for increasing or starting ICS therapy. Corticosteroids treat inflammation by promoting new protein synthesis, and their effects are typically delayed, underlining the importance of early initiation. Systemic steroids decrease hospitalization rates, speed the rate of recovery, and decrease the chance of relapse after discharge. Warnings and precautions pertinent

TABLE 63.3 Selected Drugs Used in the Treatment of Acute Asthma

Albuterol	2.5 mg in 2.5 mL normal saline by nebulization every 15–20 min × 3 in the first hour or 4–10 puffs by MDI with spacer every 10–20 min for 1 hour, then as required; for intubated patients, titrate to physiologic effect and side effects
Levalbuterol	1.25 mg by nebulization every 15–20 min ×3 in the first hour; then as required
Epinephrine	0.3 mL of a 1:1000 solution subcutaneously every 20 min × 3. Terbutaline is favored in pregnancy when parenteral therapy is indicated. Use with caution in patients older than age 40 and in patients with coronary artery disease
Corticosteroids	Methylprednisolone IV or prednisone PO 40–80 mg/day in 1 or 2 divided doses until PEFR reaches 70% of predicted or personal best
Anticholinergics	Ipratropium bromide 0.5 mg (with albuterol) by nebulization every 20 min, or 4–8 puffs by MDI with spacer (with albuterol) every 20 min
Magnesium sulfate	2 g IV over 20 minutes; repeat once as required (total dose 4 g, unless hypomagnesemic)

IV, Intravenous; *MDI,* metered-dose inhaler; *PEFR,* peak expiratory flow rate; *PO,* per os (oral).

to systemic steroids include hyperglycemia, hypertension, steroid myopathy, insomnia, psychosis, hypokalemia, fluid retention, and bone loss.

Oral steroids are as effective as parenteral steroids for patients able to tolerate oral medications. Single-dose formulations of an intramuscular preparation are reasonable in patients deemed unlikely to be compliant with oral steroids after discharge.

Various dosing regimens have been studied, and debate continues regarding the optimal dosing strategy. For hospitalized adults, the Expert Panel Report 3 recommends 40–80 mg/day of prednisone, methylprednisolone, or prednisolone in one or two divided doses until PEFR reaches 70% of predicted or the patient's personal best.[20] GINA recommends 1 mg prednisolone/kg/day or equivalent to a maximum of 50 mg/day. For outpatients, a common strategy is to use prednisone 40 mg/day for 5–10 days, with early follow-up to guide further administration.

There is no clear role for high-dose ICSs in acute asthma. However, as mentioned, ICSs play a pivotal role in achieving outpatient asthma control, and patients should be discharged from the ED or hospital on an ICS-based treatment strategy.

Other Therapies

Aminophylline does not usually provide additional bronchodilation in adults treated optimally with beta-2 agonists, and it increases the frequency of side effects, including tachyarrhythmias. It should not be used routinely in the management of patients with severe exacerbations.

The safety and efficacy of intravenous (IV) magnesium sulfate, $MgSO_4$, in adults treated for acute asthma in the ED has been studied by meta-analysis.[21] The results demonstrate that a single infusion of 1.2 g or 2 g IV $MgSO_4$ over 15–30 minutes reduces hospital admissions and improves lung function in adults with acute asthma who have not responded adequately to supplemental oxygen, SABAs, and IV corticosteroids. There is no established role for inhaled $MgSO_4$ in acute asthma.[22]

There are insufficient data to recommend leukotriene modifiers in acute asthma. The most compelling data come from the use of IV montelukast in adults, but the IV formulation is not available in the United States. There is no benefit to adding oral montelukast to conventional therapy in the management of severe asthma exacerbations.[23] Likewise, mucolytic agents, although usually well tolerated, have limited efficacy in exacerbated asthma and have been associated with a tendency to exacerbate bronchospasm.

Methodologic differences, small patient numbers, and failure to control for upper airway obstruction have plagued studies of heliox. Taken in sum, the data do not support its routine use in acute asthma, but it may be reasonable to try in severe cases in which a high fraction of inspired oxygen is not needed to maintain full oxygenation. Data further suggest that heliox as a driving gas for nebulized SABAs improves PEFRs and decreases hospital admissions in patients with severe exacerbations.[24]

Unlike select exacerbations of chronic obstructive pulmonary disease, antibiotics such as azithromycin do not improve outcomes and are not recommended in acute asthma unless there is clinical concern for bacterial pneumonia.[7,20]

NONINVASIVE VENTILATION

Despite the common and increasing use of noninvasive ventilation (NIV) in patients with acute asthma, limited data are available to define its role in this setting. Additional well-designed, controlled, prospective trials are needed. A systemic review of 13 studies meeting inclusion and exclusion criteria determined a trend towards better outcomes in patients receiving NIV, but the variability of the studies precluded conclusive recommendations.[25] A Cochrane systematic review that included five trials did not demonstrate a clear benefit to NIV for the outcomes of mortality or intubation.[26] A large retrospective cohort study capturing 13,390 US patients showed that NIV was the initial mode of ventilation for 556 patients (4.0%) and that invasive mechanical ventilation was the initial choice for 668 patients (5%).[27] Twenty-six patients (4.7% of NIV-treated patients) were intubated for NIV failure. In-hospital mortality was 0.2%, 2.3%, 14.5%, and 15.4%, respectively, for patients not ventilated, patients receiving NIV, patients requiring invasive mechanical ventilation, and patients intubated after NIV failure. The increased mortality rate seen in patients failing NIV emphasizes the need for close monitoring during NIV to avoid an undue delay in intubation.

NIV includes the use of low levels of nasal continuous positive airway pressure (CPAP) of 5–7.5 cm H_2O or, more commonly, bilevel positive airway pressure (BiPAP). One recommendation for BiPAP is to start 8 cm H_2O inspiratory pressure support and 3 cm H_2O of expiratory positive airway pressure. Pressures are adjusted as required to achieve an RR below 25/min and a tidal volume above 7 mL/kg.[28] NIV should be used only in alert, cooperative, and hemodynamically stable patients, and again, it is mandatory to monitor patients carefully for failure to avoid a delay in intubation.[29] High-flow nasal oxygen does not have a defined role in asthma exacerbations.

INTUBATION AND MECHANICAL VENTILATION

Respiratory arrest or impending arrest (e.g., exhaustion, progressive symptoms despite maximal therapy, a quiet chest, worsening hypercapnia, and altered mental status) are indications for intubation. After intubation, clinicians should be prepared for hypotension, which stems from sedation and paralysis, hypovolemia, positive pressure mechanical ventilation, lung hyperinflation, and potential tension pneumothorax.

Inappropriately fast RRs result in inadequate exhalation time and dangerous levels of DHI. Clues to this include excessive efforts required to deliver manual breathes during Ambu bag ventilation, high airway pressures during mechanical ventilation, hypotension, and tachycardia. When critical DHI is suspected, a trial of hypopnea (two to three breaths per minute) or apnea in a well-oxygenated patient for 30–60 seconds is both diagnostic and therapeutic. This deflation maneuver lowers airway pressures, increases cardiac preload, and helps restore cardiopulmonary stability. Tension pneumothorax is an important additional consideration, even in patients responding to a deflation maneuver.

Initial Ventilator Settings

Expiratory time (Te), tidal volume (Vt), and the severity of airway obstruction determine the level of DHI during mechanical ventilation.[30,31] Expiratory time is determined by minute ventilation and the inspiratory flow rate. Lowering RR and increasing the inspiratory flow rate prolong Te (Fig. 63.2). The magnitude of deflation achieved by these strategies may be small because expiratory flow rates are typically quite low in severe asthma, but even small changes in lung volume may be clinically relevant. Note that high inspiratory flow rates increase peak airway pressures and may worsen patient–machine synchrony and that high inspiratory flow rates may increase RR in spontaneously breathing patients and thereby actually decrease Te.[32]

An initial minute ventilation of 7–8 L/min in a 70-kg patient generally avoids dangerous levels of DHI.[33] This goal can be achieved by choosing volume-controlled ventilation (VCV) with an RR between 12

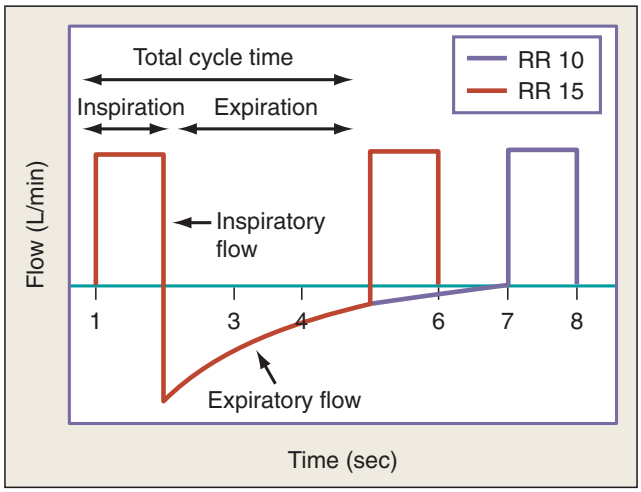

Fig. 63.2 Effects of changing respiratory rate (RR) on expiratory time (Te) with a tidal volume (VT) of 1000 mL and a constant inspiratory flow rate of 60 LPM (1 LPS). Note that with an RR of 15/min, total cycle time (amount of time allowed for one complete breath) is 4 seconds. Inspiratory time (Ti) is 1 second, and Te is 3 seconds, resulting in an I:E of 1:3. Note that the expiratory flow persists at the time of the next delivered breath (as demonstrated by failure of the exhalation flow tracing to return to baseline or zero flow), suggesting the presence of auto-PEEP. By lowering RR to 10/min, total cycle time increases to 6 seconds and Te is 5 seconds, resulting in an I:E of 1:5. Lower RR allows for greater exhalation of the delivered breath and lower end-expiratory plateau pressure (not shown), although effects are modest because of low end-expiratory flow rates.

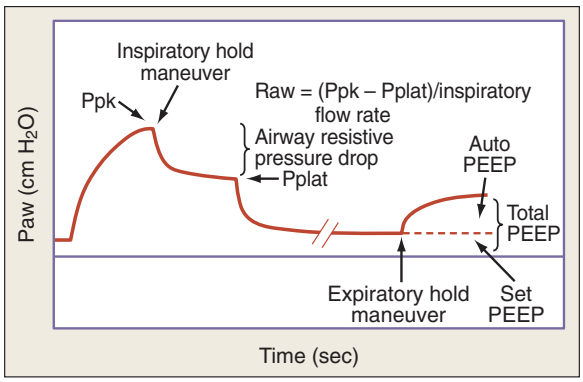

Fig. 63.3 Pressure–time tracing during mechanical ventilation demonstrating measurement of peak inspiratory pressure (Ppk), plateau pressure (Pplat), and auto-PEEP. While delivering a constant inspiratory flow (not shown), airway pressure (Paw) increases to Ppk, the sum of airway resistive pressure and Pplat. Airway resistive pressure and Pplat are determined by an inspiratory pause during which inspiratory flow is temporarily stopped to eliminate airway resistive pressure, allowing Paw to fall from Ppk to Pplat. If inspiratory flow is set at 60 L/min, the resistance pressure drop equals airway resistance (Raw) in units of cm H_2O/L/sec. An end-expiratory hold maneuver is performed to measure auto-PEEP. During this maneuver, Paw increases by the amount of auto-PEEP present. Note that end-inspiratory and end-expiratory hold maneuvers are performed on different breaths.

and 14/min and a VT between 7 and 8 mL/kg. In spontaneously breathing patients, a low level of set PEEP (e.g., 5 cm H_2O) usually reduces the inspiratory work of breathing by decreasing the pressure gradient required to overcome auto-PEEP, without aggravating lung inflation. A constant inspiratory flow rate of approximately 60 L/min or a decelerating flow strategy with an average flow of >40 L/min are reasonable starting points, but decelerating flows may be better tolerated in awake patients. Theoretically, pressure-controlled ventilation (PCV) may deliver more uniform distribution of ventilation than VCV, but the delivered VT is variable with PCV and affected by changes in the degree of bronchoconstriction and hyperinflation.[34] No data support assist control (AC) over synchronized intermittent mandatory ventilation with pressure support (PS) for major clinical outcomes in a broad range of patients.[35]

Assessing Lung Inflation

Avoiding critical DHI is central to ventilator adjustments, but measuring lung volumes is challenging in clinical practice.[3] The only validated method is to measure the volume of gas at end inspiration, termed *Vei*, by collecting expired gas from total lung capacity (TLC) to functional residual capacity (FRC) over 40–60 seconds of apnea. The utility of this measure is limited by the need for paralysis and expertise with monitoring. Although Vei may underestimate air trapping in the presence of slowly emptying lung units, a Vei greater than 20 mL/kg correlates with barotrauma.[33] Surrogate measures of lung inflation include the single-breath plateau pressure (Pplat) and auto-PEEP. Accurate measurements of both of these pressures require ventilator synchrony and absence of patient effort, and neither pressure has been validated to predict outcomes. Pplat is an estimate of maximal average alveolar pressure that is determined by briefly stopping flow at end inspiration (Fig. 63.3). Pplat is affected by the properties of the entire respiratory system, including lung, chest wall, and abdomen. Thus Pplat can vary significantly from patient to patient even for the same degree of DHI. For example, an obese patient will likely have a higher Pplat than a nonobese patient for the same extent of DHI. A common, but unvalidated, recommendation is to maintain a Pplat <30 cm H_2O.

Auto-PEEP is the lowest measurable alveolar pressure achieved during the respiratory cycle. It can be estimated by recording airway opening pressure during an end-expiratory hold maneuver (see Fig. 63.3) in the absence of interference from patient effort. Persistence of expiratory gas flow at the beginning of inspiration (which can be detected by auscultation or from flow tracings) also suggests auto-PEEP (see Fig. 63.2). Auto-PEEP of some units may be rather dramatically underestimated when there is poor communication between alveoli and the airway opening. For this reason, the plateau pressure yields a better estimate of gas trapping during VCV. Significant elevations of auto-PEEP (e.g., >15 cm H_2O) are a sign of severe exacerbation.

Ventilator Adjustments

Although not validated by controlled trials, one logical approach to adjusting the ventilator limits Pplat is a general principle of management (Fig. 63.4). If initial ventilator settings result in Pplat exceeding 30 cm H_2O, then RR should be decreased to drop it below that level. Dropping RR may result in hypercapnia, but doing so may be preferable to hazardous DHI and is generally well tolerated hemodynamically. Anoxic encephalopathy and myocardial dysfunction are relative contraindications to permissive hypercapnia, however, because of the potential for hypercapnia to dilate cerebral vessels, decrease myocardial contractility, and constrict the pulmonary vasculature. Lowering RR may not increase partial pressure of carbon dioxide in the arteries ($Paco_2$) as much as expected if decreasing DHI simultaneously reduces physiologic dead space. If hypercapnia results in a blood pH of less than 7.20 and RR cannot be increased because of the Pplat limit, starting an infusion of sodium bicarbonate is an option, although this has not been shown to improve outcomes. If Pplat is less than 30 cm H_2O

and pH continues less than 7.20, it is reasonable to increase RR until Pplat reaches the 30 cm H_2O limit; however, alveolar ventilation may not benefit in direct proportion to the increase in ventilation, especially if reducing expiratory time generates additional auto-PEEP. As patients improve and DHI diminishes, RR can be safely increased as needed to normalize pH and $Paco_2$.

Whether this strategy decreases the risk of barotrauma is unknown. One study of barotrauma in patients mechanically ventilated with limited V_T and airway pressures included 79 patients with asthma.[36] Five of these patients (6.3%) developed barotrauma. Tidal volumes and airway pressures did not differ between patients with and without barotrauma.

Sedation and Paralysis

Sedation improves comfort, safety, and patient–ventilator synchrony. In patients expected to be extubated quickly (e.g., patients with a more pure form of bronchospasm), propofol is recommended because it allows for rapid reversal of sedation after its discontinuation. Benzodiazepines are less expensive alternatives, but time to awakening is less predictable, particularly after prolonged use, and they may be more deliriogenic. Minimal data are available to inform the use of dexmedetomidine or dissociative-dose ketamine in this setting. For analgesia and to help suppress respiratory drive, an opioid should be strongly considered as an addition to propofol or benzodiazepine. Daily interruption of sedatives and analgesics helps avoid undue drug accumulation in addition to being an important component of best practice for all mechanically ventilated patients.[37]

Short-term paralysis is indicated when safe and effective mechanical ventilation cannot be achieved by sedation and analgesia alone. Cisatracurium is a common choice because it is essentially free of cardiovascular effects, does not release histamine, and does not rely on hepatic and renal function for clearance. Complications associated with paralysis include myopathy, venous thromboembolism, airway secretion retention, ventilator-associated pneumonia, and death from inadvertent machine disconnection.

Use of Bronchodilators During Mechanical Ventilation

Controlled trials are needed to inform the optimal use of bronchodilators in intubated patients and to provide evidence for or against common recommendations. Intubated patients generally require higher drug dosages to achieve a clinical effect. This likely stems from a combination of refractory airflow obstruction and challenges delivering an effective dose to the targeted receptors. Whether bronchodilators are administered by MDI or nebulizer, patient–ventilator synchrony helps to optimize delivery. MDIs require a spacing device on the inspiratory limb of the ventilator, and nebulizers should be administered close to the ventilator. Dropping the inspiratory flow rate during nebulization helps minimize turbulence, but this strategy may worsen DHI and should be time-limited. In-line humidifiers should be stopped during treatments.

At the same constant inspiratory flow and tidal volume, a fall in the peak-to-pause airway pressure gradient demonstrates decreased inspiratory airway resistance, and declines in Pplat and auto-PEEP suggest lung deflation. These favorable changes in mechanics indicate a therapeutic bronchodilator response (Fig. 63.5). Lack of a measurable response suggests that the patient is refractory to bronchodilators, that the delivery and/or dose of drug is suboptimal, or that there is another problem causing fixed airflow obstruction such as a kinked or plugged endotracheal tube.

Other Considerations

Rarely, the management strategies mentioned earlier fail to stabilize the patient. In these situations, general anesthetic bronchodilators may reduce peak pressures and $Paco_2$, but these agents are associated with hypotension and arrhythmias and their benefits are short lived.[38] Heliox delivered through the ventilator circuit may also decrease peak pressure and $Paco_2$, but its use requires significant institutional expertise, planning, expense, and modest fraction of inspired oxygen (FiO_2) requirement. Use of extracorporeal membrane oxygenation (ECMO) may be considered at experienced centers for patients with life-threatening DHI, progressive barotrauma, or respiratory acidosis that worsens despite optimal pharmacologic and ventilator management. In a review of registry data from the Extracorporeal Life Support Organization, survival to hospital discharge for patients with asthma placed on ECMO was 83.5%, suggesting ECMO may be a lifesaving intervention

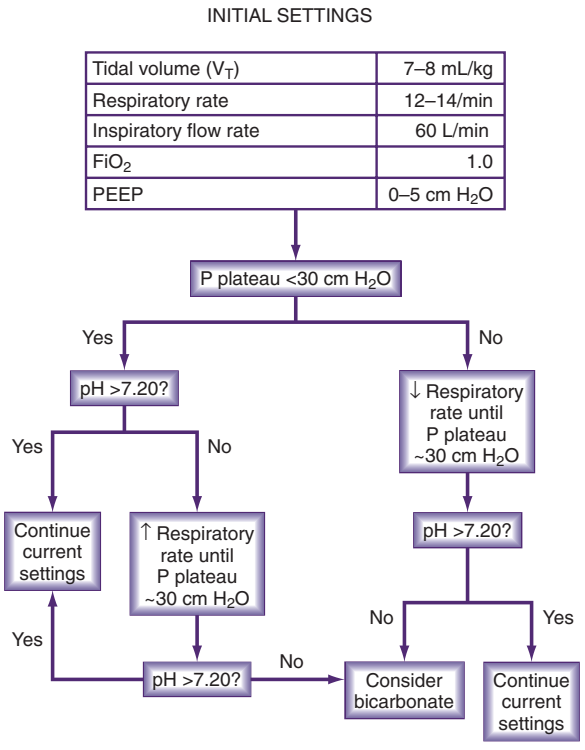

Fig. 63.4 Recommendations for initial ventilator settings and subsequent ventilator adjustments based on Pplat (end-inspiratory plateau pressure) and arterial pH in patients with severe asthma exacerbation.

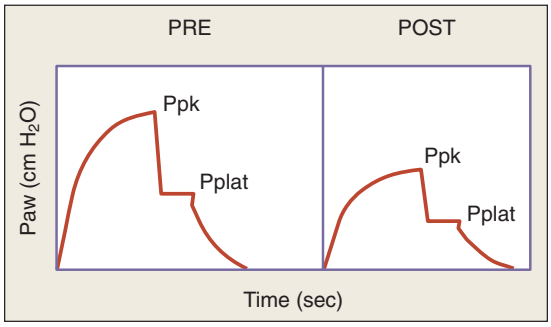

Fig. 63.5 Pressure–time tracings before and after successful administration of a bronchodilator. Note the drop in both airway resistive pressure and end-expiratory plateau pressure (*Pplat*), reflecting increased airway diameter and decreased lung inflation, respectively. *Paw*, Airway pressure; *Ppk*, peak inspiratory pressure.

for carefully selected patients.[39] The use of extracorporeal CO_2 removal ($ECCO_2$-R)—a low-flow extracorporeal support system that requires smaller-bore vascular access than ECMO—has also been described in case reports. Further research is needed to clarify the safety and efficacy of $ECCO_2$-R in the setting of life-threatening asthma.[40]

Extubation

Extubation criteria have not been validated for patients with acute asthma. One approach is to perform a spontaneous breathing trial once $Paco_2$ normalizes, DHI improves, airway resistance is <20 cm H_2O/L/sec, mental status is acceptable, oxygen requirements are minimal, PEEP is ≤ 5 cm H_2O, hemodynamics are stable, and secretions are not excessive. Patients with labile asthma may meet these criteria quickly after intubation; more commonly, 24–48 hours of mechanical ventilation are required. After extubation, observation in an ICU is recommended for an additional 12–24 hours.

POSTEXACERBATION MANAGEMENT

The importance of education, adherence to controller agents (e.g., corticosteroids and long-acting bronchodilators), environmental control measures, and close follow-up cannot be overstated. Patients who have experienced severe asthma exacerbations are at risk for subsequent attacks and asthma-related death. In this regard, a tri-society task force report and GINA have provided recommendations for treatment and follow-up after discharge.[41,42]

KEY POINTS

- Inadequate outpatient control of asthma is associated with poor outcomes.
- Severe exacerbations are characterized by diaphoresis, upright positioning, inability to speak in long sentences, use of accessory muscles, a widened PP, and normocapnia or hypercapnia. Altered mental status, paradoxical breathing, bradycardia, and a quiet chest indicate impending respiratory arrest.
- Acutely ill asthmatics respond variably to inhaled beta-agonists. Frequent (or continuous) administration of albuterol is required in refractory patients. Addition of ipratropium bromide to albuterol may confer additional benefit in patients with severe attacks.
- Systemic steroids are indicated for severe asthma exacerbations.
- Limited data support the use of NIV to decrease the inspiratory work of breathing in acute asthma.
- Postintubation hypotension suggests inadequate expiratory time, causing DHI and decreased cardiac preload. A trial of apnea or hypopnea is both diagnostic and therapeutic in this setting. Tension pneumothorax is an additional important diagnostic consideration for postintubation hypotension.
- During mechanical ventilation, prolong the expiratory phase by setting low minute ventilation and an adequate inspiratory flow rate. Assess DHI by measuring plateau pressure; if necessary, accept moderate hypercapnia to decrease DHI.
- Avoid prolonged paralysis and sedation during mechanical ventilation.
- ECMO should be considered at high-volume centers for patients with life-threatening DHI, progressive barotrauma, or refractory respiratory acidosis despite optimal pharmacologic and ventilator management. Further study is needed to clarify the role of extracorporeal CO_2 removal ($ECCO_2$-R) in the management of life-threatening asthma.
- Discharge planning should focus on asthma education and strategies to achieve and assess asthma control, optimizing controller medications, and ensuring timely follow-up to help prevent future exacerbations.

Chronic Obstructive Pulmonary Disease

Peter M.A. Calverley and Paul Phillip Walker

Chronic obstructive pulmonary disease (COPD), a major cause of death and disability worldwide, is one of the most common reasons for intensive care unit (ICU) admission. Several monographs review this complex disorder in some detail.[1,2] The intensivist's view of COPD is predominantly physiologic, focusing on the impact of disrupted function on the individual's normal homeostatic mechanisms. Although many important insights that have shaped our understanding of COPD have come from ICU studies, other aspects of this disorder must be considered if a rational approach to COPD management is to be developed.

Access to ICU care for sick COPD patients remains relatively inequitable among different healthcare systems. In North America and parts of Western Europe, most patients are offered ICU care, but in other relatively developed healthcare systems, such as in the United Kingdom, this is not the case. Even physicians in the same healthcare system differ significantly in their selection of patients for ICU referral.[3] These choices may be influenced by local resource availability, but they are also conditioned by the generally pessimistic view of the outcome achievable with this treatment intervention. However, poor response to treatment in the ICU is not universal, and extended periods of mechanical ventilation are not invariably required to successfully manage patients with COPD.[4] Nevertheless, intensivists often take a particularly bleak view of the prognosis of COPD patients compared with others entering their units. In one prospective study, intensivists estimated the survival of the sickest COPD patients to be 10% at 180 days post admission, when in fact it was 40%.[5] In one survivor population, 96% were happy to have received ventilator support after being mechanically ventilated, despite their continuing physical problems.[6] Survival appears to relate more to the severity of the acute illness, such as higher acute physiology scores, longer preceding hospital length of stay, level of consciousness, and cardiac dysrhythmia, rather than comorbidity factors such as age, forced expiratory volume in 1 second (FEV_1), and functional capacity.[7] Clearly, decisions about ventilator support should not be made in the emergency department without sufficient medical information or a proper discussion with the family; this was something that was seen in only a minority of cases in past England and Wales national audits of hospitalizations resulting from COPD.[8] The widespread adoption of noninvasive ventilatory support has increased the number of physiologically decompensated patients offered appropriate treatment (see later for further details), although many patients are managed outside of the conventional ICU setting.

DEFINITION AND NATURAL HISTORY

Although the most appropriate definition of COPD has been debated, it has less of an impact in the context of ICU care, where acute hospitalization is usual only in cases of severe and well-established disease. The currently favored definition, developed by the Global Initiative for Chronic Obstructive Lung Disease (GOLD), is:

> *Chronic obstructive pulmonary disease (COPD), a common preventable and treatable disease, is characterized by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities usually caused by significant exposure to noxious particles or gases and influenced by host factors including abnormal lung development. Significant comorbidities may have an impact on mortality and morbidity.*[9]

The emphasis here is on incompletely reversible airflow obstruction that is persistent and often progressive. Comorbidities are very common in patients seen in the ICU and make patient management more difficult. Symptomatic exacerbations contribute significantly to morbidity at all stages of the natural history of COPD and are the usual reason for ICU admission.[9,10] Symptoms and disability usually parallel these processes, although some individuals can apparently cope with a severe degree of airflow limitation without seeking medical help. Such patients tend to present to the emergency room when they develop a severe exacerbation of COPD. In this situation, it is wisest to offer ventilatory support until the patient has at least had a chance to improve with conventional medical therapy. More commonly encountered is a patient whose progressive illness is accompanied by repeated exacerbations, events that identify an accelerated decline in both lung function and health status.[11,12] Such patients have often been hospitalized on previous episodes, and their response to treatment is usually clearly established. Once hospitalization has occurred, it is likely that subsequent exacerbations will lead to further hospital visits.[13]

The usual inhaled particles or gases that produce COPD are a complex mixture of hydrocarbons and particulates derived from tobacco smoke. These are the principal causes of COPD in the United States and Western Europe,[14] although other factors such as poor lung function during childhood and childhood respiratory illness, bronchial hyperresponsiveness, and low birth weight may also be important.[15] The associated inflammatory changes, which persist when smoking stops,[16,17] are thought to explain the airway and parenchymal destruction and fibrosis within the lung.

The natural history of COPD explains why the number of patients presenting for ICU care has not diminished in the last three decades as might be expected, given the overall reduction in tobacco consumption in Western countries. This is illustrated by the classic study of Fletcher and Peto, the results of which were confirmed by longitudinal data from the Framingham study.[18,19] Although the rate of decline of lung function is reduced in individuals who stop smoking, the lung function already lost is never regained, and even if the rate of decline of lung function returns to normal, these patients are still more likely

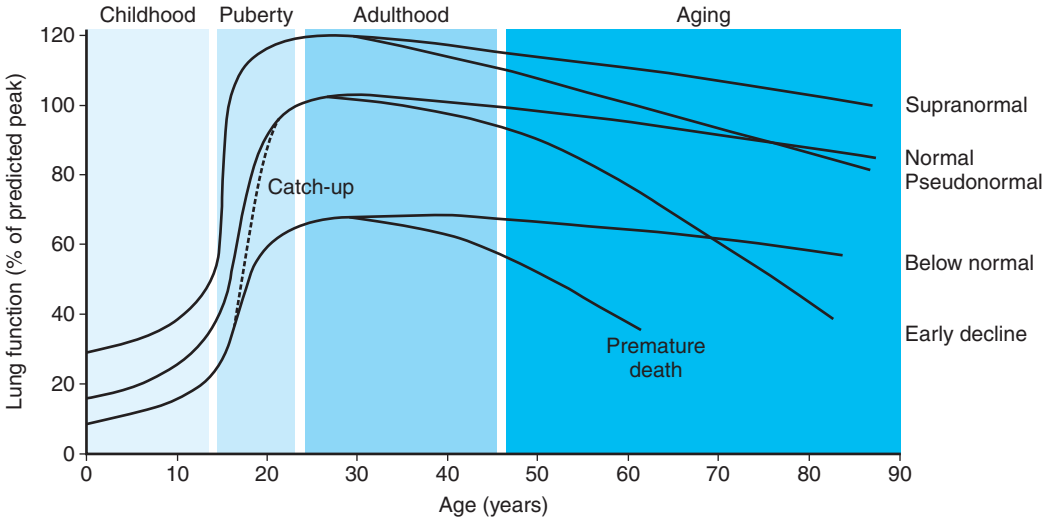

Fig. 64.1 Potential Trajectories of Lung Function, Showing the Effect of Smoking Cessation on Each Cohort. Both abnormal lung development and aging contribute to lung function and determine lung function, which can lead to chronic obstructive pulmonary disease (COPD) in adulthood. This explains the group of never-smokers who develop COPD and why older ex-smokers can present to the intensive care unit with severe disease despite years of abstinence. (Reproduced from Agustí A, Hogg JC. Update on the pathogenesis of chronic obstructive pulmonary disease. *N Engl J Med.* 2019;381:1248–1256.)

to experience disability as they age. Thus in an aging population that contains many former smokers, a significant number will still develop complications of COPD that require ICU care. It is now recognized that many COPD patients experienced inadequate lung growth in early life for a variety of reasons, and this contributes to their chances of developing COPD in later life even though they have little or no history of tobacco exposure (Fig. 64.1).[20] As noted already, comorbidities are common in COPD,[21,22] and most patients with significant symptoms resulting from COPD have at least one, if not multiple, comorbid diseases, especially cardiovascular problems.[23]

PATHOLOGY

The pathologic features of COPD depend on the stage of the illness and the part of the lung examined.[24] In patients likely to need ICU care, the central airways show mucous gland hypertrophy and goblet cell metaplasia, whereas more peripheral airways show variable combinations of smooth muscle hypertrophy, peribronchial fibrosis, luminal occlusion by mucus, and enlarged lymphoid follicles. Alveoli are often, but not invariably, enlarged by the loss of alveolar walls, with an attendant loss of support for the small noncartilaginous airways in this region of the lung. There is evidence of persistent inflammation, with neutrophils in the airway lumen and macrophages in the airway wall. $CD8^+$ T lymphocytes are more prominent in this response than in bronchial inflammation of an asthmatic type, although intermediate states appear to exist.[25] Inflammatory cells are also present adjacent to breaks in the alveolar wall.[26] Overall, as the clinical and spirometric severity of the disease increases, so do the numbers of each cell population involved in the inflammatory process.[27] In addition, extraluminal lymphoid follicles develop containing $CD4^+$ lymphocytes, possibly reflecting a response to repeated infective exacerbations.[27] Recent work has linked elements of this host immune response to the lung microbiome assessed using DNA sequencing.[28] It is now clear from ex vivo airway measurements[29,30] and in vivo observations of the total airway count using CT scanning[31] that there is a significant fall in the number of small airways early in the natural history of smoking-related COPD which precedes the development of emphysema in most cases. Thus irreversible lung damage is present when its functional impact is very limited in most COPD patients. Data obtained during exacerbations, though limited, support an increased role for neutrophils and, surprisingly, eosinophils,[32] which may explain why these events accelerate lung function decline.[33] The utility of blood eosinophil count as a biomarker of exacerbation risk remains contentious,[34] but that indicator does seem to predict the ability of inhaled corticosteroids to prevent COPD exacerbations.[35] Current ideas about the pathogenesis of COPD and its relationship to function have been authoritatively reviewed by Agustí and Hogg.[36]

PHYSIOLOGY

The pathologic changes just described combine to produce the characteristic diagnostic finding of reduced FEV_1 at a given lung volume, which is usually assessed on a time base as an FEV_1/forced vital capacity (FVC) ratio of less than 0.7. Technically, this should be 70% of the age-adjusted normal value for this ratio, because lung elastic recoil declines with age, even in healthy individuals. However, data from large population-based studies suggest that the fixed ratio is generally a better predictor of future mortality and morbidity.

COPD affects all aspects of lung function, but its primary impact is a change in lung mechanics. This is traditionally analyzed in terms of the static (no flow) and dynamic (flow) properties of the respiratory system.[37] Because chest wall mechanics are believed to be structurally, if not functionally, normal in COPD (they are seldom measured directly), changes in the pressure-volume characteristics of the respiratory system are determined by alterations in lung compliance, often attributed to the loss of elastic recoil caused by emphysema. How large a role this plays in changes in tissue compliance is not known. The resulting steeper slope, early-onset inspiratory plateau, and increase in end-expiratory lung volume are typical of the pressure-volume relationships observed in patients with COPD. Changes in end-expiratory lung volume and increases in residual volume change chest wall geometry in favor of a lower, flatter diaphragm and a more horizontally oriented rib cage; these changes, in turn, impair the inspiratory muscles' ability to develop pressure and increase the overall work of

breathing.[38] Expiratory muscle activation is common in severe COPD[39,40] even at rest and provides a useful clinical marker of respiratory distress. The dynamics of the respiratory system are influenced by its static properties but also differ significantly between inspiration and expiration. Maximum inspiratory flow is affected by inspiratory resistance and by the inspiratory muscles' ability to develop pressure (and thus indirectly by chest wall geometry). Maximum expiratory flow is influenced by expiratory pressure generation and, more importantly, by the onset of volume-related airflow limitation, best described by the maximum expiratory flow-volume loop. As lung volume falls during expiration, airways close or become flow limited; hence, the flow at a specific lung volume is reduced. Although an assessment of flow (FEV_1) relative to total volume change during expiration (FVC) is useful in defining COPD, an assessment of tidal flow limitation is more helpful in determining the degree of dyspnea experienced by the patient.[41] More attention is now being paid to the determination of expiratory flow limitation under tidal conditions. In the past, detection was difficult, involving invasive measurements or reliance on body plethysmography, which tended to overestimate the incidence of tidal expiratory flow limitation. The development of the negative expiratory pressure test and, more recently, within-breath variation in respiratory system reactance has changed this.[42] The within-breath method assesses more breaths, is less prone to observer error, and can be automated in the future for ICU application.[43] Abolishing tidal flow limitation detected in this way can be used to minimize intrinsic positive end-expiratory pressure (PEEP) in spontaneously breathing COPD patients.[44]

In general, the lower the FEV_1, the greater the likelihood that expiratory flow limitation is present. However, some COPD patients are not flow limited on every breath and regulate their end-expiratory lung volume to try to minimize this. When respiratory drive rises (e.g., during exercise), during disease exacerbations, or when minute ventilation has to increase to maintain gas exchange during ventilator weaning, this resting variation in expiratory lung volume is likely to decrease. If expiratory flow and hence tidal volume are to increase, end-expiratory lung volume must rise; this further increases the work of breathing and the sensation of respiratory distress. This process, described as *dynamic hyperinflation*, has been clearly demonstrated during exercise and can be lessened by bronchodilator treatment, which aids lung emptying.[45]

In the ICU, patients have a high respiratory drive during weaning and adopt a rapid, shallow breathing pattern. Total respiratory muscle work increases, in part because of the increased operating lung volumes, but also because of the presence of intrinsic positive end-expiratory pressure (PEEPi), also termed *auto-PEEP*. This represents the pressure that must be developed to overcome residual expiratory driving pressure before inspiratory flow can begin.[46] Thus the overall impairment of mechanical function in COPD is substantial, and both static and dynamic properties interact—a concept best captured by the time constant of the respiratory system, which is the product of the total respiratory system resistance and compliance. This parameter is greatly lengthened in COPD and helps explain why lung emptying is delayed and dynamic hyperinflation occurs. There is substantial evidence of regional inhomogeneity in more severe COPD. Differences in the regional time constants explain why COPD patients are prone to barotrauma during mechanical ventilation, despite seemingly acceptable peak inspiratory pressures, and why gas exchange can be quite disordered in this population.

Gas Exchange

Arterial hypoxemia is common in COPD but becomes clinically significant in stable patients only when the partial pressure of oxygen in arterial blood (PaO_2) falls below 60 mm Hg, a problem largely confined to patients with an FEV_1 below 35% of their predicted value. Hypoxemia in COPD is predominantly the result of ventilation-perfusion mismatching, often worsens during exercise, and is readily corrected by a small increase in the inspired oxygen concentration, unless the situation is made worse by secretion retention or severe pneumonia or pulmonary edema.[47] Arterial hypercapnia is seen in some, but not all, hypoxemic patients who are clinically stable, but it is more frequent, at least temporarily, in hospitalized individuals.[48] A combination of ventilation-perfusion mismatching caused by an increase in physiologic dead space and a degree of effective alveolar hypoventilation explains this phenomenon. Acute rises in the partial pressure of arterial carbon dioxide ($PaCO_2$) precipitate respiratory acidosis, a more reliable guide to prognosis and the need for ventilation than the $PaCO_2$ itself.[49,50]

Control of Breathing

Despite years of study, there is no conclusive evidence that ventilatory control is abnormal in COPD patients. However, the response to sustained mechanical loading appears to be variable in healthy subjects[51] and may explain why some individuals with COPD adopt the breathing patterns they do. Traditional techniques of studying respiratory control, which involve stimulation with exogenous CO_2 or nitrogen, suggested that respiratory drive was reduced. However, studies using mouth occlusion pressure techniques or recording the electrical activation of inspiratory muscles suggest that respiratory drive is generally high, even in those COPD patients who tolerate relatively high levels of CO_2.[52–54] Studies of breathing patterns have been more instructive. In general, the lower the tidal volume, the higher the $PaCO_2$.[55] This is because the ratio of the relatively fixed anatomic dead space volume to tidal volume increases as the latter is reduced. Small tidal volumes are accompanied by an increased respiratory frequency to maintain the somewhat higher-than-normal level of minute ventilation. The resulting shortening of inspiratory time is also associated with hypercapnia.[55] The system appears to be regulated to minimize peak inspiratory pressure generation, even at the cost of impaired gas exchange. There are theoretical reasons for believing that this is both energy efficient and likely to minimize the occurrence of inspiratory muscle fatigue.[56] This also explains the usefulness of rapid, shallow breathing as an index of failure of ventilator weaning when neuromechanical coupling in the respiratory system is under stress.[57]

Pulmonary Circulation

In the past, considerable attention was paid to the determination of pulmonary artery pressure in COPD patients, but this is now thought to be less important. Undoubtedly, pulmonary artery pressure increases[58] in hypoxemic COPD patients, reflecting a combination of hypoxic vasoconstriction and pulmonary vascular remodeling. How important this is in the daily limitation of exercise reported by these patients is not clear, but it is known that treatment with domiciliary oxygen retards disease progression[59] and may even reduce pulmonary artery pressure. More specific attempts at therapy, including treatment with vasodilators, phosphodiesterase enzyme type V (PDEV) inhibitors, and nitric oxide—studied inside and outside the ICU—have been unsuccessful, usually resulting in unacceptable worsening of ventilation-perfusion mismatching.[60] Further investigation and treatment are reserved for the small number of patients (<5%) who have severe pulmonary hypertension that is disproportionate to their COPD severity.[61] Assessment of pulmonary hypertension is not part of a routine evaluation in COPD patients, but its occurrence is important to note when interpreting changes in central venous pressure in instrumented patients.

SYSTEMIC EFFECTS

There is good evidence that systemic (extrapulmonary) factors are important in COPD. Patients with a reduced body mass index die sooner than better-nourished individuals with a similar degree of pulmonary function impairment, and those who can gain weight fare better.[62] There are data to show that peripheral muscle function is impaired,[63] fiber type is altered,[64] and exercise is associated with increased oxidative stress.[65] The earlier concept of a specific COPD myopathy has now largely been abandoned, as the major burden falls on the lower limb muscles, with preserved function in the upper limb muscle groups. This likely reflects inactivity, which is worse in those with exacerbated COPD.[66] Weakness of the quadriceps muscle is an independent guide to a poor prognosis,[67] and its occurrence appears to be independent of the presence of cardiovascular problems.[68] In contrast, although the wealth of circulating biomarkers in COPD appear to relate to mortality, their measurement has contributed little to practical management so far.[69]

EXACERBATIONS

An *exacerbation* of COPD is currently defined as sustained worsening of the patient's condition from the stable state (beyond normal day-to-day variation) that is both acute in onset and necessitates a change in regular medication.[9] The key feature is the sustained change from usual daily symptoms. The operational requirement for a change in treatment is more arbitrary but is almost always present in patients referred for ICU care. Disease exacerbation is the principal cause of ICU admission with COPD, and patients commonly have or are at risk of developing significant *respiratory failure,* defined as a PaO_2 below 60 mm Hg with or without an increase in $PaCO_2$.[70] The most common causes of exacerbation are listed in Table 64.1. Viral and bacterial infections are both relevant,[64] with rhinoviruses commonly reported in most series; *Haemophilus influenzae* and *Streptococcus pneumoniae* are the principal bacterial pathogens.[71,72] Some patients, particularly those with a regular cough and green sputum production, develop persistent lower respiratory tract colonization, making the interpretation of qualitative microbiology difficult.[73] Studies of the changing microbiome during acute exacerbations have shown significant reductions in species diversity and increases in the relative importance of *Haemophilus* and *Moraxella* species.[74]

Not all exacerbations of COPD have an infectious precipitant, and changes in the degree of atmospheric pollution can precipitate events in some patients.[75] The frequency of exacerbation rises as spirometric impairment worsens,[76] and although a history of a previous exacerbation can define subsets of patients more likely to exacerbate subsequently, the short-term predictive power of the exacerbation history is modest at best.[77]

The physiologic consequences of increased airflow obstruction secondary to increased inflammation within the bronchial tree are summarized in Fig. 64.2. Whatever the precipitant, the key event appears to be a change in lung mechanics. Previously, attention focused on alterations in respiratory system resistance, but more recent data emphasize that airway narrowing and closure may be more important, particularly by producing changes in operating lung volumes (see earlier discussion). Observations in patients recovering from hospitalized exacerbations have shown progressive improvements in respiratory system reactance (a measure of inspiratory resistance and flow limitation) together with reductions in end-expiratory lung volume that are most evident in patients reporting less dyspnea.[78]

Pneumonia is an important reason for hospitalization in COPD, is more frequently seen in these patients than in others, and is associated with worse outcomes.[79] Pneumonia is diagnosed more frequently in patients taking the inhaled corticosteroid fluticasone propionate,[80] especially older patients with worse airflow obstruction.[81] These pneumonias are not necessarily associated with poor outcome in terms of mortality or health status[80] and are not seen with all types of inhaled corticosteroids.[82,83] At present the benefit of inhaled corticosteroid treatment, especially combined with a long-acting inhaled bronchodilator, outweighs the apparent risk of increased pneumonia events.[84]

TABLE 64.1 Causes of Chronic Obstructive Pulmonary Disease Exacerbation

NEW INFECTION
Bacterial (*Haemophilus influenzae, Streptococcus pneumoniae, Moraxella catarrhalis*)
Change in an existing strain (e.g., *H. influenzae*)
Viral (influenza, rhinovirus, respiratory syncytial virus)
ATMOSPHERIC POLLUTION
Sulfur dioxide, oxides of nitrogen
TEMPERATURE CHANGE
Often related to pollution episodes
INTERCURRENT ILLNESS*
Pneumonia, pulmonary embolus, pneumothorax
POSTOPERATIVE
Especially after upper abdominal surgery

*Clinical presentation is dominated by the primary illness, but respiratory failure can occur.

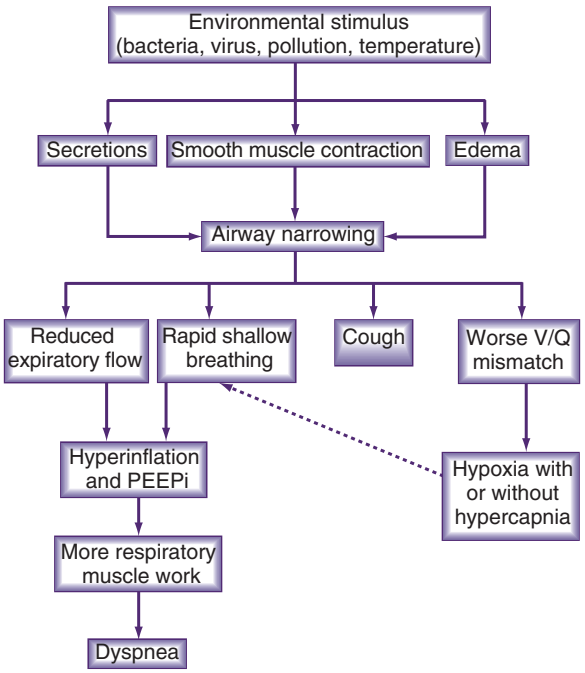

Fig. 64.2 Schematic of Principal Physiologic Changes that Accompany an Exacerbation of Chronic Obstructive Pulmonary Disease. Note that deterioration in one area tends to produce worsening in other areas and leads to a downward spiral in functional abnormality. *PEEPi,* Intrinsic positive end-expiratory pressure; *V/Q,* ventilation-perfusion.

INTENSIVE CARE UNIT REFERRAL

The need for ventilatory support is the primary reason for ICU referral of COPD patients. The various indications for mechanical ventilation (Table 64.2) vary in frequency from institution to institution. Before referring a patient for ICU care, and especially for any form of ventilatory support, it is important to determine what degree of intervention is appropriate.

PRINCIPLES OF TREATMENT

Four general principles guide the management of COPD patients presenting acutely to the ICU, and each should contribute to shortening the duration of illness and stabilizing the patient physiologically until either the natural course of the disease or the effects of therapy lead to its resolution.

Treat Precipitating Factors

Bacterial infection is the most common reason for ICU admission of COPD patients. There is now good evidence that antibiotics shorten the symptomatic period, even when patients are treated with corticosteroids.[85] If given early, antibiotics are associated with lower mortality, fewer episodes of intubation, and shorter hospital stays.[86] Radiographic evidence of pneumonia likely requires a broadening of the antibiotic spectrum, but whether the infection is confined to the airways or involves the alveoli, antibiotic therapy should follow locally established guidelines designed to minimize the development of resistance within the ICU and to address known patterns of drug resistance in the community and the hospital. Broad-spectrum penicillins or, more commonly, cephalosporins are usually recommended, often with an intravenous macrolide. Colonization with methicillin-resistant *Staphylococcus aureus* is a frequent problem and requires particular vigilance in the selection of antibiotics. Likewise, excessive use of broad-spectrum agents can produce superinfection, such as *Clostridium difficile* diarrhea.

The 2009–2010 H1N1 influenza A pandemic made the role of antiviral drugs clearer, and a meta-analysis showed that the early use of neuraminidase inhibitors (within 48 hours) was associated with a lower mortality, though this was not specific for acutely ill COPD patients.[87] In fact, during that pandemic the infection was not a particular problem for COPD patients, possibly reflecting prior partial immunity,[88] but if this virus is diagnosed, the use of antivirals such as oseltamivir is prudent. Similar considerations apply to other viral pneumonias. Whether the new outbreak of coronavirus infection will behave in a similar way is unclear at present.[89]

TABLE 64.2 Indications for Invasive Mechanical Ventilation

Severe dyspnea, with use of accessory muscles and paradoxical abdominal motion
Respiratory frequency >35 breaths/min
Life-threatening hypoxemia (PaO_2 <40 mm Hg or PaO_2/FiO_2 <200 mm Hg)
Severe acidosis (pH <7.25) and hypercapnia ($PaCO_2$ >60 mm Hg)
Respiratory arrest
Somnolence, impaired mental status
Cardiovascular complications (hypotension, shock, heart failure)
Other complications: metabolic abnormalities, sepsis, pneumonia, pulmonary embolism, barotrauma, massive pleural effusion
Noninvasive positive-pressure ventilation failure (or exclusion criteria)

FiO_2, Fraction of inspired oxygen; *$PaCO_2$*, partial pressure of carbon dioxide in arterial blood; *PaO_2*, partial pressure of oxygen in arterial blood.

Reduce Lung Volume and Increase Expiratory Flow

Agents that improve lung emptying, commonly by increasing airway caliber or preventing airway closure, interfere with the vicious circle of pulmonary hyperinflation. This has been demonstrated in stable patients using exercise as a model of hyperinflation,[45] but the data in spontaneously breathing COPD patients during exacerbations are much less satisfactory. Nonetheless, treatment with regular but high doses of short-acting nebulized beta-agonists such as albuterol or ipratropium (2.5–5 mg or 250–500 μg, respectively) is usually recommended. There is no clear evidence that one drug is better than the other,[90] and combination therapy is commonly used. Intravenous theophylline, or one of its derivatives, is often added to these regimens but is no more effective than a placebo infusion.[91,92]

Reduce Pulmonary Inflammation

Several randomized controlled trials have shown that oral corticosteroids shorten the duration of hospitalization and accelerate improvement of post-bronchodilator FEV_1 during an exacerbation of COPD.[93,94] Patients randomized to treatment with oral corticosteroids were less likely to relapse during the subsequent month and showed a number of other benefits, although these did not always reach statistical significance.[95] There is little detriment from giving a short (5-day) course of oral corticosteroids rather than a long (14-day) course. Steroid dose is dramatically reduced,[96,97] and inhaled corticosteroids do not need to be given if systemic therapy is used. In the ICU, corticosteroid treatment is often given to patients on mechanical ventilation. Two studies have given conflicting results. One study using 10 days of tapering-dose methylprednisolone reported a shorter period of ventilation and reduced noninvasive ventilation (NIV) failure,[98,99] whereas a larger study that used up to 10 days of higher-dose prednisolone showed no benefit but higher rates of hyperglycemia.[100] A retrospective review of the dose of systemic corticosteroids used within the first 48 hours of admission to an intensive therapy unit (ITU) showed better lower ITU and hospital length of stay, shorter period of ventilation, less use of insulin, and fewer fungal infections in COPD patients given less than 240 mg methylprednisolone per day.[101] Caution should be exercised because, in addition to the already noted effects, these individuals are often at risk for relatively acute-onset corticosteroid myopathy.[102] In the absence of a large randomized controlled trial and recognizing that 94% of patients in the retrospective review were prescribed systemic corticosteroids, it appears appropriate to use lower doses for shorter periods. It is possible that better targeting of specific endotypes of patients may be effective. A post hoc analysis of systemic corticosteroids used acutely for nonventilated COPD exacerbations found the rate of relapse was lower in patients with higher blood eosinophil counts.[103]

Manage Gas Exchange

It is relatively easy to improve oxygenation in an uncomplicated exacerbation of COPD.[104] Raising the inspired oxygen concentration to 28%–35% is usually sufficient to achieve a PaO_2 greater than 90 mm Hg. However, this can be accompanied by an undesirable increase in $PaCO_2$, with its accompanying respiratory acidosis. Such an increase in $PaCO_2$ impairs respiratory muscle function, at least during loaded breathing,[105] and often precedes more serious clinical deterioration, including impairment of consciousness. The reasons for this effect have been debated for many years, with some advocating a reduction in respiratory drive from the carotid chemoreceptors, and others citing

a worsening ventilation-perfusion match as the cause.[104] Each view has evidence to support it, but the actual cause is likely a combination of both problems, with ventilation-perfusion mismatching being particularly important in severely ill patients, and hypoventilation playing a larger role in those not yet sick enough to require intubation.[106]

Although the phenomenon of oxygen-induced hypercapnia has been recognized for decades, it remains a real problem. In one large center in the United Kingdom, 34% of individuals showed evidence of oxygen-induced hypercapnia.[50] The use of high-flow oxygen in the emergency room is widespread, as is the false sense of security provided by a high oxygen saturation. Many intensivists have legitimate concerns about the failure to adequately oxygenate COPD patients who have a compromised circulation, along with the attendant risk of unanticipated mortality. However, there is growing evidence that clinical outcomes are worse in the ICU when an oxygen saturation of 96% is exceeded. Patients whose problems are predominantly the result of COPD and who have a normal hemoglobin and preserved cardiac output can maintain adequate tissue oxygen delivery with an oxygen saturation as low as 85%, and they will do quite well if an arterial oxygen saturation (SaO_2) of 90%–93% is maintained. The modest increase in inspired oxygen needed to achieve this (often 24%–28%) is accompanied by less hypercapnia and may help avoid the need for ventilatory support. However, if cardiac output is impaired (reduced blood pressure, poor peripheral circulation) or tissue metabolic demands are increased (e.g., in sepsis secondary to pneumonia), a higher SaO_2 may be required to ensure sufficient oxygen delivery; in this case, the consequences of any resultant hypercapnia, including the need for ventilatory support, must be accepted. Oxygen delivery by high-flow nasal cannula provides a new approach that may be helpful in COPD management.[107] As yet, direct comparisons of this approach with either conventional oxygen therapy or NIV as a primary treatment in decompensated COPD patients are lacking.

NONINVASIVE VENTILATION

This topic is reviewed in detail in Chapter 55, but some key issues relevant to COPD are worth emphasizing. Much of the data supporting the use of NIV were obtained in patients with hypercapnic respiratory failure resulting from COPD exacerbations, and several excellent reviews have analyzed these data.[108–111] It is no surprise to see that the widespread use of NIV has led to a substantial increase in the number of COPD patients with decompensated respiratory failure being offered treatment without any increase in the treatment-related mortality.[112]

NIV offers potential benefit in COPD. Intuitively, it seems reasonable to expect that it would increase tidal volume, improve CO_2 elimination, and hence reduce respiratory drive. Studies of gas exchange using a multiple inert gas elimination methodology confirmed that CO_2 elimination is increased, but overall ventilation-perfusion mismatch is not changed during NIV.[113] A more important effect is the unloading of the respiratory muscles, which often approach fatigue conditions in severe episodes of respiratory failure. By assuming some of the additional workload required to overcome PEEPi, NIV directly reduces the drive to breathe, and the respiratory rate falls, a good prognostic feature for NIV success.[114] Data from randomized controlled trials suggest that there is a mean fall of 3.1 breaths per minute (95% confidence interval 4.3–1.9) with the institution of NIV in COPD patients.[115] This allows more effective emptying of the lungs and less dynamic hyperinflation. The resulting improvement in the intensity of breathlessness is usually a much earlier sign of successful NIV treatment in COPD than are changes in blood gas tensions, which often lag behind evidence of clinical improvement.

TABLE 64.3 Efficacy of Noninvasive Ventilation Compared With Usual Care

Outcome	Number of Patients Studied	Relative Risk (95% Confidence Interval)	NNT
Treatment failure	529	0.51 (0.38–0.67)	5
Death	523	0.41 (0.26–0.64)	8
Intubation	546	0.42 (0.31–0.59)	5
Complications	143	0.32 (0.18–0.56)	3

NNT, Number needed to treat—the number of patients who must be treated to prevent this outcome in one individual.

Evidence-based reviews provide a reasonable series of recommendations based on the relative effectiveness of NIV. Key points, including the number of patients needed to be treated to prevent one significant event or complication, are shown in Table 64.3.[108] NIV is associated with less treatment failure, lower mortality, fewer complications, and a lower intubation rate compared with conventional medical treatment. NIV reduces ICU or hospital stay by approximately 3 days and favorably influences gas exchange. With NIV, pH increases by a mean value of 0.03 units (0.02–0.04), $PaCO_2$ falls by 3 mm Hg (5.9–0.23 mm Hg), and PaO_2 rises by 2 mm Hg (−2 to +6 mm Hg). The lower rate of nosocomial pneumonia associated with NIV is a particular advantage. No benefit was seen from the use of a helium-oxygen mixture with NIV compared with oxygen alone.[116]

Treatment failure, which occurs in 10%–15% of cases in many US hospitals,[117,118] reflects an inability to adapt to NIV or progression of the underlying disease. Data suggest that patients likely to subsequently fail with NIV can be prospectively identified by a high blood sugar on admission (irrespective of having diabetes), a raised respiratory rate, or a high APACHE 2 score. All these variables are relatively effective predictors of risk, but combining them increases their discriminant power.[114] Another study confirmed the importance of acute physiology (APACHE 2 score) but also highlighted higher failure rate and mortality risk if the individual had cancer.[117] In addition to its role in the acute phase of respiratory failure, NIV can be valuable as a "bridge" in helping patients wean from intubated positive-pressure ventilation. In an important multicenter prospective trial, Nava and colleagues randomized people who had failed a T-piece weaning trial to either NIV or further mechanical ventilation.[119] NIV was associated with fewer days of ventilatory support (10.2 versus 16.6, respectively), shorter ICU stay (15.1 versus 24 days, respectively), less nosocomial pneumonia, and better 60-day survival (92% versus 72%, respectively). These results were achieved in a unit with experience in NIV. The generic use of weaning by NIV has proven less successful, particularly if patients have significant cardiac disease or established acute respiratory distress syndrome (ARDS).[120] However, further data from Spain have confirmed the value of this approach in hypercapnic patients limited primarily by COPD.[121,122] In a Cochrane review, outcomes were superior in all areas when early extubation followed by NIV was compared with continued mechanical ventilation. It is still unclear whether high-flow nasal oxygen is helpful in this setting. In a large randomized study in which 20% of patients had COPD, high-flow nasal therapy was equivalent to both NIV and conventional therapy as an aid to weaning from mechanical ventilation.[123]

MECHANICAL VENTILATION

Mechanical ventilation should be considered when NIV is not appropriate or has failed. Patients with a pH below 7.25 are more likely to

require this intervention, although in current practice most physicians first offer a trial of NIV unless the patient is hemodynamically unstable or the treatment is contraindicated. Persistent significant hypoxemia despite treatment with NIV, hypotension, and impaired mental state are all predictors of imminent respiratory arrest and the need for intubation and institution of mechanical ventilation.

Ventilation Strategies

A wide range of ventilation strategies have been advocated for use in COPD, each with its own proponents; none has shown a clear advantage over its competitors, however. Familiarity with the equipment used in the context of COPD is probably more important than the relatively minor differences between ventilator modes. The most commonly used approaches, together with their proposed advantages, are summarized in Table 64.4.

Assisted Ventilation and Weaning

As acidosis resolves and oxygen requirements fall, it is possible to reduce the degree of sedation and allow the patient to make some contribution to ventilation before weaning. Several modes of ventilatory support are available in these circumstances, and again, there is no specific advantage of one over another.[124,125] There is an impression, however, that reliance on spontaneous intermittent mandatory ventilation prolongs subsequent weaning. Although not universally accepted, there are good data supporting the use of spontaneous breathing trials in clinically stable COPD patients to determine when they are ready to wean.[126–128] The ability to sustain ventilation in the absence of increasing CO_2, worsening acidosis, or clinical distress (reflected by an increase in blood pressure, heart rate, or restlessness) is generally agreed to be a predictor of future weaning success. Although COPD patients are less likely to achieve these goals as early as other ICU patients, the reintubation rate in those who do meet these criteria is low.[126,127] Unfortunately, breathing through a ventilator circuit delivering continuous positive airway pressure (CPAP) may be associated with significant increases in inspiratory resistance arising largely from the endotracheal tube,[128] and it is sensible to use pressure support to offset some of this additional respiratory work. Evidence in favor of using pressure support instead of unassisted weaning (e.g., via T-piece) continues to accumulate.[129] For those patients who need more prolonged support, postextubation NIV is particularly helpful.

A variety of predictors of weaning success have been developed to try to identify when successful weaning will occur. Unfortunately, none has proved entirely reliable, and relatively few have been assessed prospectively. An empirical approach based on the criteria listed in Table 64.5 is widely used. An aggressive policy toward weaning is justified in COPD patients because failure to wean is invariably associated with a worse prognosis and prolonged ventilation.

TABLE 64.4 Modes of Ventilation

Mode	Method	Comment
Assist-control	Preset tidal volume, patient triggered with backup rate	Patient still performs substantial work of breathing; dynamic hyperinflation worsens this
Spontaneous intermittent mandatory ventilation	Preset number of breaths of a preset volume—patient does the rest	Patient still makes an effort during part of machine breath—involves more patient work, especially at low respiratory rates
Pressure support ventilation	Pressure set to augment each inspiration—tidal volume depends on patient effort, pulmonary mechanics, and pressure applied	Basis of noninvasive ventilation therapy; pressure titrated to a respiratory rate below 27 breaths/min; asynchrony with machine breaths a problem at high pressures
Proportional assist ventilation	Flow and volume generated proportional to patient effort	Experimental technique; requires accurate measurement of elastance and resistance + an intact drive to breathe; proven effective in COPD patients

TABLE 64.5 Criteria for Weaning Failure

Increasing hypercapnia or worsening hypoxemia (<55 mm Hg)
pH <7.32
Increased respiratory rate >35 breaths/min
Increase in heart rate or blood pressure by 20% of baseline
Agitation, sweating, or impaired consciousness

NONVENTILATORY ISSUES

Therapy employed in spontaneously breathing patients is still required in those undergoing mechanical ventilation. High-dose nebulized bronchodilators are commonly used, singly and in combination,[130,131] and it is important to pay attention to the details of drug delivery. If a metered-dose inhaler is used instead, it should always be given with some form of spacer device. Parenteral corticosteroids are commonly administered. This is not without hazard, particularly because of the real risk of myopathy, as reviewed earlier in this chapter.

Clearance of secretions is important in ventilated patients, and it is essential that the patient's hydration state be maintained to facilitate mobilization. Whether specific mucolytic drugs such as *N*-acetylcysteine are helpful is unclear, and no high-quality scientific studies are available to definitively support or reject their use. As with all ICU patients, the psychological impact of the illness and its treatment is considerable, and sensitive support during the recovery phase is needed. As noted, hospitalization with COPD is an important inflection point in the trajectory of this illness. Patience is required, as functional recovery is often slower than is appreciated by the physician or hoped for by the patient.

PROGNOSIS

The prognosis after an exacerbation of COPD is better than the gloomy outlook proposed by some physicians. Nonetheless, patients who experience exacerbations appear to have a more severe clinical course than those who do not, and they report a worse overall quality of life.[132] The associated mortality risk subsequent to ICU admission is significant. In one North American series, 7.4% of patients treated with NIV died, as did 16.1% of those treated with mechanical ventilation.[118] However, some groups do worse, and individuals with COPD treated with long-term oxygen therapy who failed NIV and received mechanical ventilation had 23% in-hospital mortality and 45% 1-year mortality. Twenty-seven percent were discharged to nursing care.[133] Patients with a low FEV_1, significant comorbidity, and a particularly poor performance status at home have the worst outlook.[134] These factors should be considered when decisions about the requirement for

ventilatory support are made. However, as noted already, the physician's view of the very sick COPD patient can be unduly pessimistic. Exacerbations leave patients relatively immobile.[56] The initial encouraging data concerning potential benefits from early rehabilitation have not been confirmed in a large randomized controlled trial of patients hospitalized because of an acute COPD exacerbation but not ventilated. The intervention was robust and included aerobic and resistance training, neuromuscular electrical stimulation, a written self-management plan, and education; however, no reduction in readmission was seen in the following year.[135] As result the European Respiratory Society/American Thoracic Society (ERS/ATS) guidelines for the management of COPD exacerbations made a conditional recommendation against the early use of pulmonary rehabilitation postexacerbation.[111]

Changes in clinical practice continue to improve the outlook for COPD patients. Better prevention, earlier diagnosis, and more specific evidence-based therapy contribute to this.[136] The impact of NIV on acute care has been enormous, as has closer adherence to evidence-based recommendations across the field of intensive care,[137] something about which both practitioners and their patients can feel proud. Despite the increasing age and complexity of the patients with COPD admitted to the ICU, their prognosis and future prospects continue to improve.

KEY POINTS

- The prognosis of patients with COPD admitted to the ICU is better than commonly believed.
- The burden of symptomatic COPD is likely to rise for several decades more, despite effective smoking cessation programs in many countries.
- Small changes in forced expiratory flow are associated with significant impairment in lung mechanics, particularly airway closure and dynamic hyperinflation, and worse gas exchange.
- Common upper respiratory tract pathogens and respiratory viruses precipitate most exacerbations of COPD. Treatment aimed at these agents is useful, but it is not as important as improving lung emptying and maintaining gas exchange until the acute insult resolves.
- Oral and intravenous corticosteroids shorten the duration of an exacerbation and reduce the risk of relapse. However, high-dose treatment beyond 2 weeks provides no advantage and actually poses a risk, especially in ventilated patients.
- Maintaining oxygenation is relatively easy, but there are risks of carbon dioxide retention and acidosis if high-flow oxygen is administered. Keeping oxygen saturation between 91% and 93% ensures adequate tissue oxygen delivery if the cardiac output is stable.
- Respiratory acidosis is a poor prognostic marker in COPD exacerbations and a strong indicator of the need for assisted ventilation.
- Unless contraindicated, NIV is the safest and most effective way of managing acute respiratory failure. More acidotic patients should be managed in an ICU with the option of endotracheal intubation and mechanical ventilation if NIV fails.
- COPD patients meet conventional weaning criteria less frequently than other ICU patients do, but they are more likely to wean successfully when they do meet the criteria.
- Seriously ill COPD patients should be encouraged to make advance directives, particularly after an ICU admission involving any form of ventilatory support.

ANNOTATED REFERENCES

Bafadhel M, Peterson S, De Blas MA, et al. Predictors of exacerbation risk and response to budesonide in patients with chronic obstructive pulmonary disease: a post-hoc analysis of three randomised trials. *Lancet Respir Med.* 2018;*6*(2):117–126.
This study examined data from previous COPD trials where the impact upon exacerbations of a combination inhaled corticosteroid/long-acting beta-agonist inhaler was assessed. Only smoking and eosinophil count predicted the impact of the inhaled therapy, with people with higher baseline eosinophil counts likely to derive greater benefit from treatment. The importance of serum eosinophil count in predicting response by COPD patients to a wide variety of different treatments is becoming clearer.

Hernández G, Vaquero C, Colinas L, et al. Effect of postextubation high-flow nasal cannula vs noninvasive ventilation on reintubation and postextubation respiratory failure in high-risk patients: a randomized clinical trial. *JAMA.* 2016;316(15):1565–1574.
This randomized controlled trial examined 604 patients who were extubated and then randomized to either high-flow nasal oxygen or noninvasive ventilation for 24 hours. The primary outcome was reintubation or development of respiratory failure within 72 hours. High-flow nasal oxygen was found to be equivalent to NIV and felt to offer significant advantage to certain high-risk patients.

Lange P, Celli B, Agustí A, et al. Lung-function trajectories leading to chronic obstructive pulmonary disease. *N Engl J Med.* 2015;373(2):111–122.
This study is one of a number of recent publications examining traditional models of lung function decline leading to the development of COPD. Individuals with a low FEV_1 in early adulthood were more likely to develop a low FEV_1 by early middle age despite no accelerated decline in lung function. The study highlights the importance of early life events in the development of adult lung function and illustrates that accelerated decline in lung function is not necessarily present in people who develop COPD.

Mayhew D, Devos N, Lambert C, et al. Longitudinal profiling of the lung microbiome in the AERIS study demonstrates repeatability of bacterial and eosinophilic COPD exacerbations. *Thorax.* 2018;73(5):422–430.
The study involved lung microbiome assessment in people with COPD at a time of clinical stability and during exacerbations. Specific subgroups were seen, with some COPD patients prone to eosinophil-driven or bacterial-driven exacerbations, and these were often repeated for an individual. Common bacteria included Haemophilus *and* Moraxella. *Viral exacerbations were typically discrete and not repeated.*

Zannin E, Chakrabarti B, Govoni L, et al. Detection of expiratory flow limitation by forced oscillations during noninvasive ventilation. *Am J Respir Crit Care Med.* 2019;200(8):1063–1065.
This is a small study of 10 subjects with COPD who had previously suffered hypercapnic respiratory failure and were treated with bilevel noninvasive ventilation. When stable, the subjects received bilevel ventilation, and forced oscillation measurements were made to detect flow-limited breaths and thresholds for detection of flow limitation established based on expiratory reactance. It is hoped this technique may be useful in ventilator-dependent patients to tailor the level of PEEP, though this requires larger studies in patients who are ventilated acutely.

Pulmonary Embolism

Paul S. Jansson and Christopher Kabrhel

INTRODUCTION

Venous thromboembolism (VTE) encompasses the continuum of disease that includes deep venous thrombosis (DVT; also sometimes referred to as *deep vein thrombosis*) and pulmonary embolism (PE). The prototypical VTE event occurs when a blood clot forms in the deep veins of the legs, detaches, and then embolizes through the vasculature and heart to lodge in the pulmonary arteries, where it is referred to as a PE. The presentation of VTE varies widely, based on the size of the clot and the pathophysiology of the individual. Manifestations range from an incidentally diagnosed PE in an otherwise asymptomatic patient to hemodynamic collapse and sudden death. The diagnosis and management of VTE in the intensive care unit (ICU) present diagnostic and therapeutic challenges that differ from the routine management of VTE in the emergency department or outpatient setting. Overall, the mainstay of treatment for VTE is pharmacologic anticoagulation. For more high-risk VTE, thrombolytic therapy (systemic or catheter-directed) or thromboembolectomy (open-surgical or percutaneous) may be indicated. Adjuvant therapies for the management of VTE may include placement of an inferior vena cava (IVC) filter or extracorporeal life support (ECLS).

EPIDEMIOLOGY

In North America, the incidence has been estimated at 38–112 cases per 100,000, with an estimated global disease burden of approximately 10 million cases per year.[1–3] VTE has a slightly higher incidence in males and increases with the age of the patient.[4–6]

Although the diagnosis of VTE has been increasing over time, primarily because of the use of more sensitive imaging techniques,[7] it may be underdiagnosed in subsets of hospitalized patients. Surveillance studies have found undiagnosed PEs in 24% of trauma patients[8] and 18.7% of patients undergoing mechanical ventilation unrelated to PE.[9] Between 3% and 16% of patients were noted to have undiagnosed PE on routine autopsy.[10–12]

VTE occurs commonly in the ICU, even in the face of routine measures to prevent it. A relatively small percentage (between 0.4% and 2.7%) of patients admitted to the ICU have undiagnosed VTE on arrival,[13,14] but surveillance studies estimate the incidence of DVT in the ICU between 1.0% and 9.6% and the incidence of PE between 0.5% and 2.3%, despite appropriate pharmacologic prophylaxis.[13–15] In critically ill patients without appropriate prophylaxis, VTE is very prevalent, with a 19% incidence of DVT found in one study.[16] PE is the third most common cause of cardiovascular death, with a higher mortality rate than that of myocardial infarction.[17] Overall, PE is responsible for approximately 100,000 deaths per year in the United States.[6,18]

Both the clinical presentation and the mortality risk associated with VTE vary widely, depending on the pathophysiology of the individual patient. Some PEs are asymptomatic and diagnosed incidentally, whereas some cause sudden cardiac arrest. In a large, modern cohort, the 30-day case fatality rate was 2.0% for VTE and 3.9% for PE. The 1-year mortality rate ranges from 12.9% to 30%, although a large proportion of such deaths are attributable to underlying comorbidities.[3,19,20] For patients with a normal blood pressure and no evidence of right ventricular dysfunction, attributable mortality incidence is below 5% and even less than 1% in some studies.[21,22] In contrast, for patients with shock or cardiac arrest, the fatality risk is higher: approximately 30%–53% in shock and up to 95% in cardiac arrest.[23–25] Of fatal events, the initial presentation may be that of sudden death, with approximately 34% of VTE-related deaths presenting as sudden death in one European cohort.[26] For untreated PE, the short-term mortality currently approximates 25%–30%, Historically, studies have reported associated mortality as high as 87%.[27] For obvious reasons, data describing the natural history of untreated VTE are limited.

For many patients, VTE is a chronic disease. Recurrence is common, with the highest risk during the first 6–12 months after diagnosis.[28] In one study cohort, recurrence after 5 years was 20%–25% for all patients and exceeded 25% in those patients with VTE without clear provoking factors.[29] The 10-year recurrence is approximately 30%.[30] The DASH score (e Table 65.1) can be used to predict VTE recurrence in patients without a clear provoking risk factor and uses the patient's age, sex, use of exogenous hormones, and residual D-dimer level to estimate an annual recurrence rate.[31,32]

Return to normal lung structure and function may be a prolonged process. In one study 28% and 15% of patients had residual PE on lung perfusion imaging or computed tomography (CT) imaging, respectively, after 9 months of anticoagulation.[33] Another study found >10% vascular obstruction in 10% of patients after a year of anticoagulation.[34] Although lung function does return to normal in most patients, a small but significant number of patients will develop chronic thromboembolic pulmonary hypertension (CTEPH), and up to 4% of patients have elevated pulmonary artery pressures 2 years after the initial PE diagnosis.[35]

RISK FACTORS

Risk factors for the development of VTE have classically been separated into inherited and acquired categories.[36] Table 65.1 presents a summary of risk factors.

Inherited risk factors typically center around disorders in clotting factor production or activity. The most common genetic risk factors are the factor V Leiden mutation (with a prevalence of 4%–5%) and the prothrombin gene mutation (20210A, seen in 2%–4% of patients).[37–39] Among the other inherited risk factors are antithrombin deficiency, deficiencies of proteins C and S, hyperhomocysteinemia, and a number of single-nucleotide polymorphisms.[40–43] Acquired risk

e TABLE 65.1 DASH Prediction Score for Recurrent VTE

Criterion	Points
D-dimer abnormal 1 month after stopping anticoagulation	+2
Age ≤50 years	+1
Male patient	+1
Hormone use at VTE onset (if female)	−2

Interpretation:

Cumulative Points	Annual Recurrence Risk
≤1	
Consider discontinuing anticoagulation	3.1%
≥2	
Consider continuing anticoagulation	9.3%

TABLE 65.1 Risk Factors for PE

Inherited Risk Factors
Factor V Leiden
Prothrombin mutation
Antithrombin deficiency
Protein C deficiency
Protein S deficiency
Acquired Risk Factors
Vascular Damage
Surgery
Trauma/burns
Previous VTE
Inflammatory or Procoagulant States
Active cancer
Antiphospholipid syndrome
Chronic inflammatory diseases
Pregnancy
Obesity
Nephrotic syndrome
Heparin-induced thrombocytopenia
Venous Stasis
Hospitalization or immobility
Paralysis
Prolonged travel
Factors Common in the ICU
Sepsis
Central venous catheter
Pharmacologic paralysis
Acute renal failure, dialysis
Mechanical ventilation
Blood products
Vasopressors

factors are those developed during a person's lifetime and include surgery, particularly orthopedic and oncologic surgeries, and the presence of trauma, burns, or fractures. VTE occurs after 1% of orthopedic surgeries, despite appropriate thromboprophylaxis.[44]

Active cancer is a major risk factor, with such patients having twice the VTE incidence of patients without cancer. VTE is the second leading cause of death in patients with cancer and cancer-related VTE, accounting for approximately 20% of all VTEs.[45–47] The risk is highest in the first few months after diagnosis, and is especially elevated in adenocarcinomas.[48,49] Cancer cells themselves may provoke inflammation and a procoagulant state,[50,51] and a number of chemotherapeutic drugs increase clotting risk.[52]

Chronic disease states also increase the risk for VTE.[53] Advanced age correlates with increased risk because of both innate factors, such as the relative decrease in the levels of proteins C and S, and the acquisition of other clot-provoking influences.[54–56] Morbid obesity conveys a risk of VTE up to six times that of individuals of normal weight.[57,58] Previous VTE is one of the strongest risk factors for recurrent disease,[59] likely a result of existing risk factors and damage to vessel walls or valves.[60] Poorly controlled inflammatory diseases such as inflammatory bowel disease increase the risk of VTE when compared with their well-controlled peers.[61,62] Lupus, in particular, elevates VTE risk, primarily through the lupus "anticoagulant" (actually a misnomer) and anti–beta-2-glyocoprotein antibodies.[63–65]

High estrogen states increase the risk for VTE.[66] Supplemental estrogen used for oral contraception or taken in the postmenopausal state may increase the risk of VTE by three to four times.[67,68] Pregnancy is another high-estrogen state, which is often coupled with mechanical compression of the gravid uterus on pelvic veins and/or cesarean section surgery. The highest risk of pregnancy-associated VTE occurs in the immediate postpartum period.[69]

Acquired risk factors are particularly common in the ICU population.[14] Immobility is a predisposition that is particularly relevant for ICU patients. Immobility may be intentional, such as in the long-haul traveler,[70] or iatrogenic, such as associated with joint fixation,[71] mechanical ventilation,[9] and pharmacologic paralysis.[72] Central venous catheters increase VTE risk, with femoral catheters being particularly implicated.[73–76] Heparin-induced thrombocytopenia has been associated with a high risk of VTE,[77] as have sepsis[78] and multisystem organ failure.[79]

PATHOPHYSIOLOGY

Normally, a physiologic equilibrium exists regarding hemostasis. Prothrombotic factors are balanced by such naturally occurring anticoagulants as antithrombin III and proteins C and S and by the body's own fibrinolytic system. Acting together, these mechanisms prevent pathologic thrombosis.[80] When disrupted, a procoagulant state can lead to inappropriate thrombosis and the development of VTE. The classical description of the conditions leading to pathologic thrombosis is termed *Virchow's triad*: the combination of endothelial damage, the presence of a hypercoagulable state, and stasis of normal blood flow.

Pathologic thrombosis typically begins around the valves of the veins,[81] regions with slower flow and relative hypoxemia, which in association with predisposing risk factors, can lead to small deposits of thrombus.[82,83] In most patients, skeletal muscle contractions "pump" to displace a nascent thrombus into the bloodstream, where it is degraded by the body's natural fibrinolytic system. However, in the presence of stasis, the thrombus expands, trapping alternating layers of fibrin and red blood cells between aggregated platelets.[84] As the clot expands, venous flow becomes turbulent and slows, further promoting stasis and thrombosis. Eventually, blood flow through the vein stops, and the thrombus propagates proximally until it reaches the next bifurcation of the vasculature. From there, the clot may continue to extend proximally, or it may embolize into the flowing venous bloodstream, which carries it through the right side of the heart to lodge in the tapering pulmonary arterial vasculature as a PE. Air, amniotic fluid, tumor, and foreign bodies can also embolize in a similar manner. Discussion of the pathophysiology and management of these conditions is beyond the scope of this chapter.

DVT occurs most frequently in the lower extremities, with over 90%–95% of DVTs occurring in the leg veins.[85] Most clinically significant DVTs involve the proximal veins of the leg, such as the iliac, femoral, and popliteal,[86] and the vast majority of PEs occur when such proximal DVTs embolize. More than 50% of patients diagnosed with proximal DVT will have evidence of concurrent PE, and up to 70% of patients diagnosed with PE will have a detectable DVT, which in both cases, may be asymptomatic.[87–91] Lower leg DVTs, such as those in the calf veins, rarely embolize, but may extend to the proximal veins if left untreated.[89,92–94]

The individual patient's response to the PE depends on the number of emboli (extent of the clot burden) and the patient's underling cardiopulmonary function and neurohormonal response. When an embolus lodges in the pulmonary vasculature, a complex set of

physiologic responses occur (Fig. 65.1). Acute vascular obstruction leads to increased pulmonary vascular resistance and increased pulmonary artery pressure. Significant increases in pulmonary artery pressure are seen when approximately 30%–50% of the arterial bed is occluded.[95] Shock and cardiopulmonary collapse may occur with large emboli; right ventricular failure may result if the mean pulmonary artery pressure exceeds 40 mm Hg.[96]

Inflammation occurs around the thrombus, with platelets secreting histamine, serotonin, and thromboxane A_2, which act to cause pulmonary vasoconstriction and bronchoconstriction, inducing alveolar hypoxemia.[97] This, in turn, results in a cycle of worsening hypoxic vasoconstriction, further raising pulmonary vascular resistance, pulmonary artery pressures, and right ventricular afterload. Surfactant production is reduced, leading to atelectasis and worsening this hypoxia-driven cycle.

Physiologic dead space increases and V/Q mismatch occurs as involved alveoli are ventilated but not perfused. Minute ventilation is increased, typically by a disproportionate increase in the respiratory rate, resulting in respiratory alkalosis. However, for those patients who are unable to increase their minute ventilation sufficiently, such as those who are mechanically ventilated undergoing pharmacologic paralysis, hypercapnia will result.[96]

The abrupt increase in pulmonary vascular resistance and consequent pulmonary artery pressure is felt most acutely by the right ventricle (RV). As the RV strains against the increase in pressure, its thin wall dilates outward, leading to an increase in wall stress and a decrease in coronary perfusion. RV work increases, predisposing to a mismatch between myocardial oxygen demand and supply. In turn, this can cause acute ischemia and further worsen the function of the RV, particularly with the tachycardia common in acute PE. A decrease in RV cardiac output, whether as a result of ischemia, dilation, or inability to pump against the elevated pulmonary artery pressures, worsens the cycle of hypoxic pulmonary vasoconstriction.

As RV pressure rises, the interventricular septum can bow into the left ventricle (LV). With a bowed septum, the LV encounters impaired relaxation, distensibility, and diastolic filling, reducing preload to the LV and potentially decreasing cardiac output. A decrease in the LV

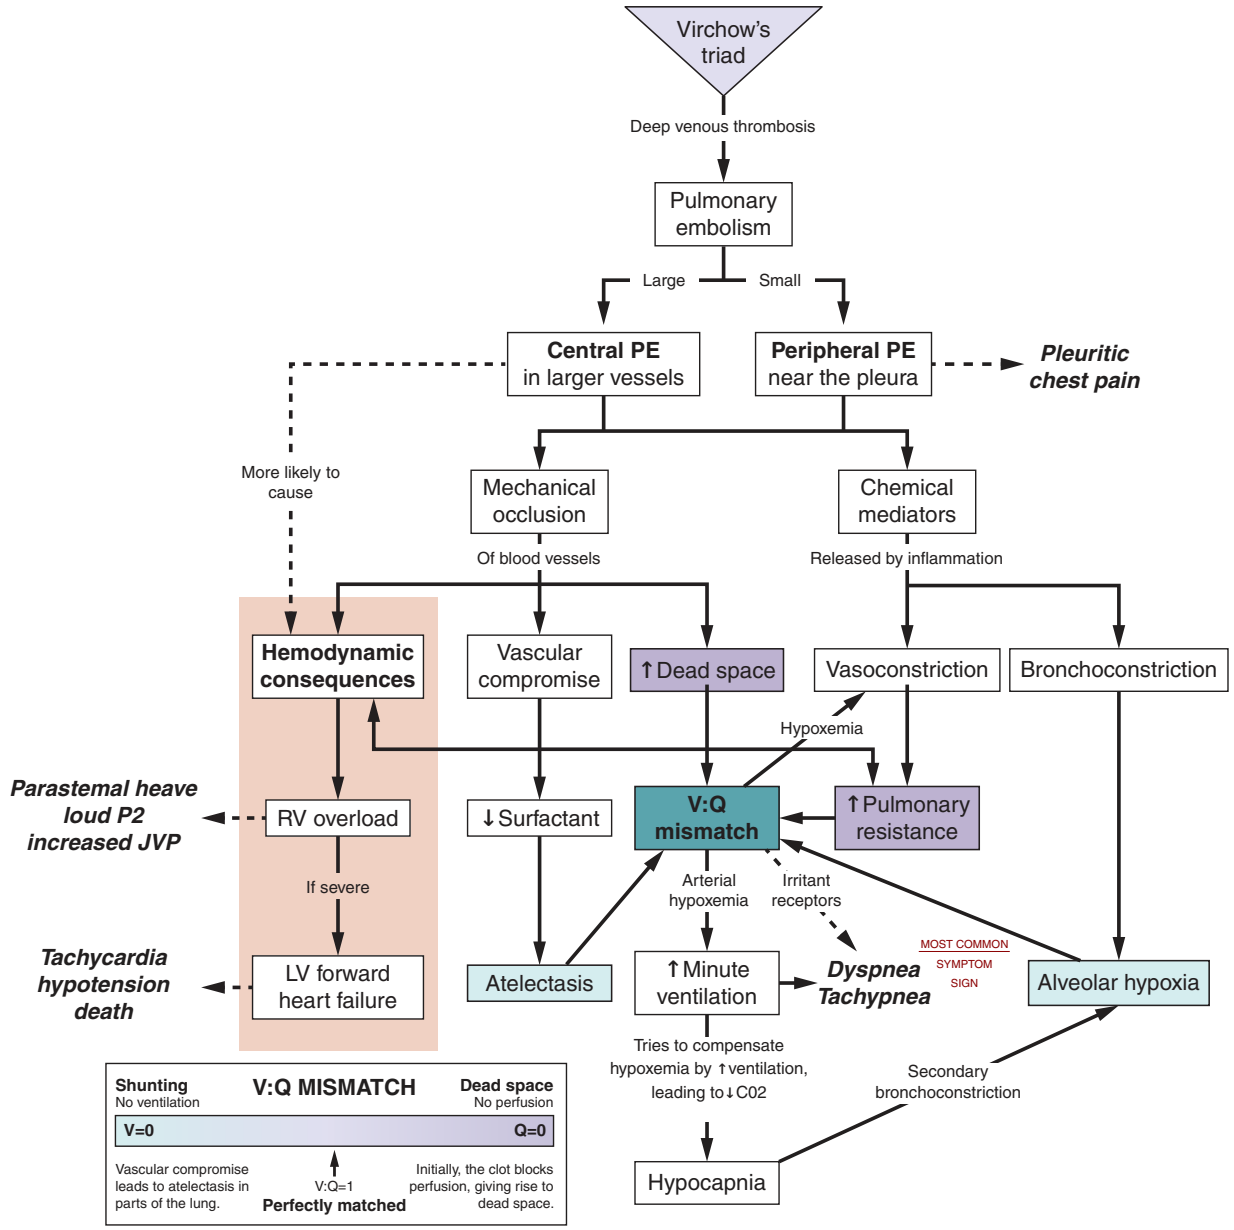

Fig. 65.1 Pathophysiology of Pulmonary Embolism. (From Wong E, Chaudry S. *Venous Thromboembolism. McMaster Pathophysiology Review*. available from: https://pathophys.org/vte). Hamilton, Ontario, Canada.)

cardiac output worsens the hypoxia-driven cycle and contributes to hemodynamic collapse. Increased right atrial pressures may open a patent foramen ovale and lead to intracardiac shunting and worsening hypoxemia.

Myocardial strain and elevated filling pressures may lead to the release of neurohormonal modulators such as the natriuretic peptides (brain natriuretic peptide [BNP] and N-terminal pro-BNP [NT-proBNP]). Ischemia and microinfarctions of the RV can occur, releasing cardiac troponins.[98–100]

DIAGNOSIS

Clinical Presentation

The range of clinical presentations of PE is among the widest of any condition. Symptoms of VTE are nonspecific, and therefore a high index of suspicion must be maintained.

The most common symptom in acute PE is dyspnea. (e Table 65.2 lists the prevalence of common signs and symptoms of PE.) Dyspnea is typically rapid in onset, within seconds in 46% of patients or minutes in another 26%.[101–103] More peripherally located PEs may result in lung infarction. Pleuritic chest pain accompanies these in up to 74% of cases.[104] A minority of these patients exhibit hemoptysis, commonly attributed to hemorrhage of the infarcted lung. Other findings include a cough, orthopnea, or wheezing. Given the common coexistence of DVT, many patients will also exhibit associated signs and symptoms, including calf or thigh pain and lower extremity swelling or edema. Although syncope has been traditionally described as a presenting symptom of PE, it is relatively rare—reported at less than 2% of instances.[105] PE is a relatively common cause of sudden cardiac arrest, however, and precipitates approximately 8% of all such events. Symptoms preceding cardiac arrest may include sudden dyspnea.[106,107]

Many patients are asymptomatic, even with large PE.[103,108] Therefore the first clinical clue may come from the physical examination. Tachypnea is the most common sign, seen in 54% of patients. Physical signs of DVT are detected in approximately 47%. Although traditionally taught as a common finding, tachycardia is only present in 24% of patients. Auscultation may reveal rales, wheezes, decreased breath sounds, or an accentuated second heart sound, but these findings are nonspecific and occur more commonly in alternative conditions.[103]

Differential Diagnosis

The differential diagnosis in patients with suspected PE includes cardiopulmonary disorders for each mode of presentation (see Clinical Presentation). For patients presenting with dyspnea, tachypnea, or hypoxemia, possible alternative diagnoses include atelectasis, pneumonia, pneumothorax, pleural effusion, aspiration, pulmonary edema, bronchial obstruction, alveolar hemorrhage, and other pulmonary disorders. For patients who present with pleuritic chest pain or hemoptysis, possible diagnoses include pneumonia, pneumothorax, pericarditis, aortic dissection, neoplasm, pleurisy, and musculoskeletal disorders. For patients who present with right-sided heart failure or cardiovascular collapse, possible diagnoses include myocardial infarction, acute massive hemorrhage, sepsis, cardiac tamponade, heart failure, hypovolemia, and tension pneumothorax. Other considerations related to PE include sepsis, fat, air, amniotic fluid, tumor emboli, and in situ thrombosis (e.g., sickle cell chest syndrome).

Diagnostic Testing

Because the common signs and symptoms lack specificity for VTE, diagnostic testing is required. DVT and PE are not separate and unrelated disorders, but rather represent a continuous syndrome of VTE in which the initial presentation may suggest DVT, PE, or both. Therefore strategies for diagnosis typically include testing for both PE and DVT. In addition, many patients will undergo simultaneous diagnostic testing for other potentially life-threatening disorders.

Assessment of Probability

The initial step in diagnosing PE involves the use of a probability assessment to calculate a pretest probability of disease. The two most commonly used clinical prediction rules are the Wells Score and the revised Geneva Score[109,110] (e Table 65.3). Other less commonly used scores include the Pisa Score, the Revised Pisa Score, and the Charlotte Score.[111–113] Experienced clinical gestalt performs similarly to clinical scoring symptoms, although scoring systems may have slightly higher specificity.[114,115] However, all of these decision rules were developed and validated primarily in the outpatient and emergency department settings. Although the scores generally perform well in the hospitalized patient, they may show poor performance in the ICU.[116,117]

Laboratory Testing

Laboratory testing plays either a supporting or exclusionary role in the diagnosis of PE, as there is no specific blood test for the disease. However, such testing can alter pretest probability, provide alternative diagnoses, and help with the risk stratification of PE once diagnosed.

Arterial Blood Gas Testing

Arterial blood gas testing, although commonly performed in the ICU, is no longer routinely used for the diagnosis of PE. In one study of patients with PE, 74% of patients had hypoxemia (defined as a partial pressure of oxygen [PaO_2] of <80 mm Hg) and 86% of patients had an abnormally elevated alveolar-arterial oxygen gradient.[101] These findings are neither sufficiently sensitive nor specific to rule in or rule out the presence of PE.[118–120]

Cardiac Markers

BNP and its precursor, NT-proBNP, are released from the myocardium in response to distention and theoretically could serve as markers for acute RV strain because of acute PE. However, they are neither sensitive nor specific for diagnosis and are better used to grade severity and prognosis.[121–123]

Similarly, cardiac troponins may be released from the RV from the pathologic dilation and microinfarction that occur in response to PE, particularly in larger or more hemodynamically significant PEs. Like BNP, however, troponin cannot be used to rule out the disease and is best deployed as a marker of severity and prognosis.[124–126]

Emerging Biomarkers

Early clinical studies may show evidence that circulating micro RNA (miRNA) may be used to detect pulmonary embolism, but this option has not yet entered clinical practice.[127]

D-Dimer

D-dimer is a fibrin degradation product produced by the plasmin-catalyzed lysis of cross-linked fibrin. Although it is highly sensitive for VTE, it is nonspecific, especially in ICU patients.[128] For low- and moderate-risk patients, as determined by a clinical decision rule or experienced clinician gestalt, a D-dimer below the assay's diagnostic cutoff (often <500 ng/mL) can be used to rule out VTE, although the negative predictive value drops as the pretest probability increases. Some authors advocate for a more liberal threshold of <1000 ng/mL in low-risk individuals,[129,130] whereas other studies advocate an "age-adjusted D-dimer," where a "negative" D-dimer corresponds to a value less than the patient's age × 10 (e.g., for a low-risk 65-year-old, a negative D-dimer would be

e TABLE 65.3 Common Prediction Scores

Wells Criteria for Pulmonary Embolism (PE)

Criterion	Points
Clinical signs or symptoms of deep venous thrombosis (DVT)	3
PE is the #1 diagnosis or equally likely	3
Heart rate >100	1.5
Immobilization for at least 3 days or surgery within the previous 4 weeks	1.5
Previous PE or DVT	1.5
Hemoptysis	1
Malignancy with treatment within 6 months or palliative treatment	1

Interpretation:

Three-Tier Group	Prevalence of PE
Low risk (<2 points)	1.3%
Moderate risk (2–6 points)	16.2%
High risk (>6 points)	37.5%
Two-Tier Group	
PE unlikely (0–4 points)	12.1%
PE likely (>4 points)	37.1%

Revised Geneva Score for Pulmonary Embolism

Criterion	Points
Age >65	1
Previous DVT or PE	3
Surgery (under general anesthesia) or lower limb fracture in the last month	2
Active malignancy	2
Unilateral lower limb pain	3
Hemoptysis	2
Heart rate:	
<75	0
75–94	3
≥95	5

Pain on lower limb palpation and unilateral edema	4

Interpretation:

Point Summary	Prevalence of PE
Low risk (<3 points)	9%
Moderate risk (4–10 points)	27.5%
High risk (>10 points)	71.7%

<650 ng/mL).[131] These approaches have been validated in outpatients, but not yet in the ICU population.

Despite extensive validation and study of the D-dimer assay to rule out VTE in the outpatient setting, it does not have much utility in the ICU.[132,133] Because of the high prevalence of VTE in the ICU, the preponderance of factors that increase the risk of both VTE that generates a positive D-dimer on that basis, and the poor performance of the test in the relevant patient population, D-dimer is unlikely to prove useful in ruling out PE in many ICU patients.[134,135]

Electrocardiography

Electrocardiography (ECG) is routinely performed in the diagnostic evaluation of PE because the wide differential diagnosis includes many cardiopulmonary etiologies. Unfortunately, the ECG findings of PE are nonspecific. Sinus tachycardia is reported as the most common abnormality in acute PE, even though some studies report as few as 29% of patients display that finding.[128] RV dilation and strain may manifest on ECG as a new or incomplete right bundle branch block, right axis deviation, or RV hypertrophy. The classic triad of S1Q3T3 (that is, an S wave in 1, Q wave in III, and T-wave inversion in III) is another marker of RV strain that occurs only in a minority of PE patients.[136] A wide variety of additional ECG findings have been described in acute PE, but none are specific for the disease, and many patients with acute PE will have a normal ECG.[137,138]

Diagnostic Imaging

Given the poor sensitivity and specificity of the history, physical examination, laboratory, and ECG testing in acute PE, imaging is typically required to diagnose or exclude VTE in the ICU. The particular study chosen will depend on specific characteristics of the patient and the capabilities of the hospital. For example, a CT scan may be indicated, but to undergo this, a patient must be clinically stable enough to travel outside of the ICU to the radiology department and must be able to lie flat, take a deep breath, and receive IV contrast. Fig. 65.2 suggests a diagnostic algorithm for imaging in the ICU.

Chest Radiograph

Plain radiography of the chest is commonly performed in the ICU, but is typically not useful to confirm the diagnosis of PE. The chest radiograph may display nonspecific signs in acute PE, such as atelectasis, pleural effusion, or reduced pulmonary vascularization,[96] but normal studies are also common.[139] Classically described findings such as the Westermark sign (a sharp transition from an enlarged pulmonary artery to an area of oligemia) or Hampton hump (a pleural-based hyperdense area representing a pleural infarction) are rarely seen.[140] Chest radiography is therefore most useful to quickly establish an alternative diagnosis for the patient in whom PE is being considered. A normal chest x-ray in the presence of significant dyspnea, hypoxia, chest pain, or tachycardia should increase the suspicion for PE and may also help in assessing suitability for a ventilation/perfusion (V/Q) scan.

Chest Computed Tomography

CT scanning of the chest using a PE protocol (typically referred to as CT angiography [CTA], CT-PE, or CT-PA [pulmonary angiography]) is the most commonly used and important test in the modern diagnosis of PE.[141] CTA uses a multidetector CT scanner to acquire

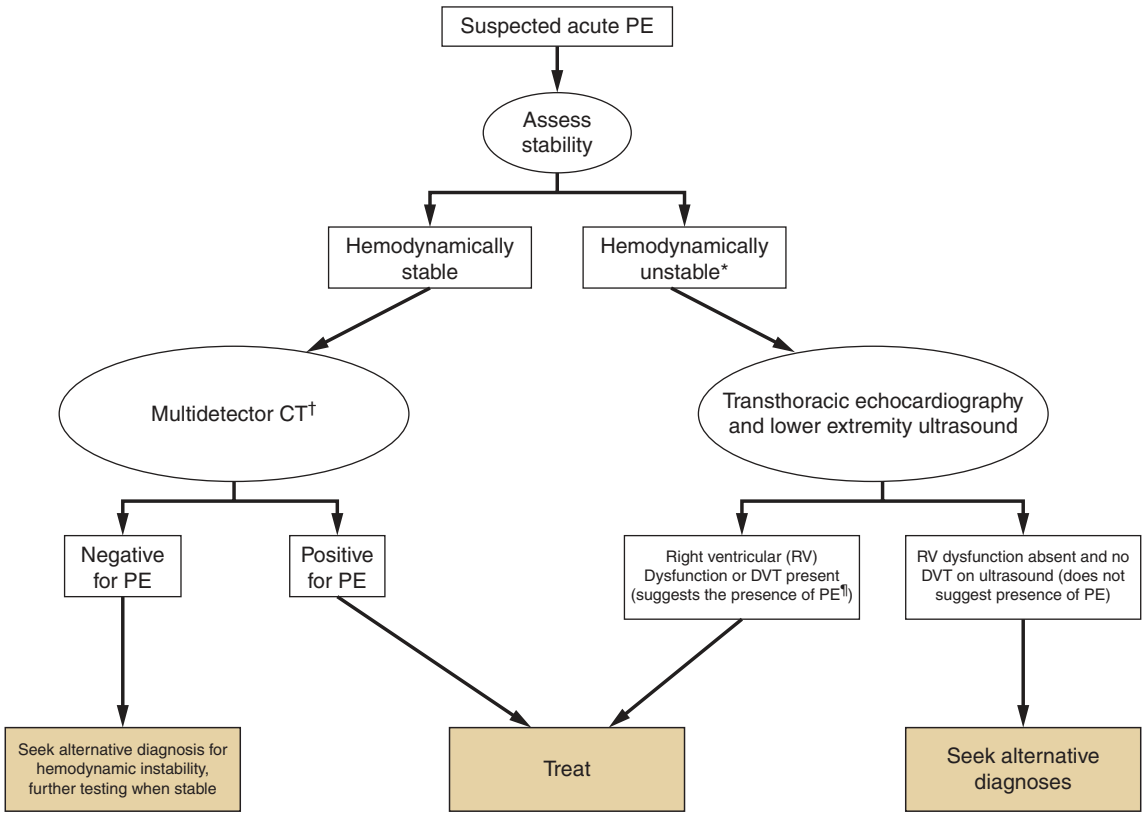

Fig. 65.2 Diagnosis of Pulmonary Embolism. *CT,* computed tomography; *DVT,* deep venous thrombosis; *ICU,* intensive care unit; *PE,* pulmonary embolism. *Search for alternative and concomitant diagnoses. †If contraindication to intravenous (IV) contrast exists, consider ventilation-perfusion scintigraphy, lower extremity venous compression ultrasound, or MR angiography. ¶Try to confirm the presence of PE with additional testing. Proximal lower extremity DVT serves as a surrogate to PE in the appropriate clinical setting.

thin sections of the chest, with the addition of a bolus of IV contrast dye to opacify the pulmonary arteries. Improper timing of the contrast bolus, patient motion, body habitus, artifact, or poor cardiac output may render the study nondiagnostic.

In 15%–20% of patients, CTA provides an alternative diagnosis, such as the presence of pneumonia, pneumothorax, lung tissue disease, or aortic dissection.[142,143] CT may also assist in the grading of PE severity by assessing for the presence of right heart strain (Fig. 65.3A and B).

In an early validation study, CTA had a sensitivity of 83% and a specificity of 96%, with 6% of studies labeled nondiagnostic.[144] With a high probability for PE (as assessed by the Wells criteria), the positive predictive value was 96%, and with a low probability, the negative predictive value was 96%. However, poor diagnostic accuracy accompanied discordance between the pretest probability and the imaging results. Refinements in technology have resulted in a sensitivity and specificity for PE that exceed 90%, even as radiation doses have decreased.[145] Although increasingly diagnosed by newer higher-resolution scanners,[146] the presence of small subsegmental PEs has substantial interrater variability and may lead to overdiagnosis.[147,148] Furthermore, the clinical significance of these small clots is debated.[149]

Radionuclide Lung Scanning

With the advances in CTA technology, the utilization of V/Q scanning has decreased. Nevertheless, given the numerous contraindications to CTA and the presence of nondiagnostic CT scans, there remains a role for V/Q imaging.[104] The perfusion (Q) aspect of the V/Q scan involves an IV injection of technetium (Tc)-99m–labeled macroaggregated albumin particles. The ventilation (V) aspect involves inhaled tracers (e.g., aerosolized Tc-99m–labeled agents or noble gases such as krypton-81 and xenon-133).[150] Gamma camera images of the patient's chest are then obtained.

The diagnostic ability of the V/Q scan stems from its ability to detect mismatches in ventilation and perfusion. Classically, a wedge-shaped perfusion defect may be seen in the perfusion images, corresponding to an area of the pulmonary vasculature that has been blocked by the presence of an embolus. Therefore normal perfusion imaging suggests the absence of an acute PE; if perfusion scanning is performed and normal, the ventilation aspect of the imaging may be omitted. However, the presence of a perfusion deficit can occur as a result of other diseases that cause the shunting of blood away from a diseased portion of lung. Therefore a decrease in perfusion should be correlated with the absence of a coexisting ventilation deficit (e.g., a "mismatch") to diagnose acute PE. V/Q imaging is correlated with a contemporaneous chest radiograph. "Normal" chest radiographs are typically required for certainty, as abnormal chest radiographs raise the probability of false-positive V/Q results. Because the diagnosis depends on secondary signs of a PE and not direct visualization of a thrombus, results are given as a probability.[151] Overall, the sensitivity of V/Q for the diagnosis of acute PE ranges from 85% to 93%, with a specificity of 80%–97%.[152,153] Unfortunately, only 23% of inpatients have normal perfusion imaging and the majority of hospitalized patients have nondiagnostic examinations.[104,154,155]

Compared with CTA, V/Q scanning exposes the patient to significantly less ionizing radiation, particularly to the breast.[156,157] For these reasons, V/Q scanning may be preferred in patients with contrast dye allergy, renal insufficiency, pregnancy, or for younger patients. However, many patients require additional imaging (e.g., CTA) after a nondiagnostic V/Q scan, and for these patients, the overall radiation dose will be greater than if CTA was performed as the first test. Given the low prevalence of normal chest radiography in the ICU patient population, the high rate of nondiagnostic scans, and the lack of ability to diagnose other disease processes, V/Q scanning remains a secondary study to CTA in the modern diagnosis of acute PE.

Magnetic Resonance Imaging

Magnetic resonance imaging using an angiography protocol (MRA) has limited utility in the diagnosis of acute PE. Unfortunately, images are technically inadequate in 25%–52% of studies.[158] MRA has excellent specificity for the diagnosis of PE, approaching 100% in most studies, but its sensitivity varies based on the location of the PE. Central and lobar PE are routinely diagnosed with sensitivities nearing 100%, but sensitivity for subsegmental PE may be as low as 40%.[159,160] In addition to directly showing the filling defect of a thrombus, MRA can provide information about the morphology of the RV.[96,161] The addition of MR perfusion imaging increases the sensitivity to 93% for subsegmental PEs and 100% for larger emboli.[162] The main advantage of MR imaging is the lack of ionizing radiation, but the longer study time, limited diagnostic ability for other thoracic pathologies, and traditional contraindications (such as the presence of a metallic implant) do not support its routine adoption for the diagnosis of PE.

Pulmonary Angiography

Traditional pulmonary angiography was once the gold standard for the diagnosis of acute PE but has largely been supplanted by multidetector CTA. The sensitivity of pulmonary angiography is similar to that of CT imaging,[163] and reliability significantly drops at the subsegmental level.[164,165] The risks are similar to those of other cardiac catheterizations,

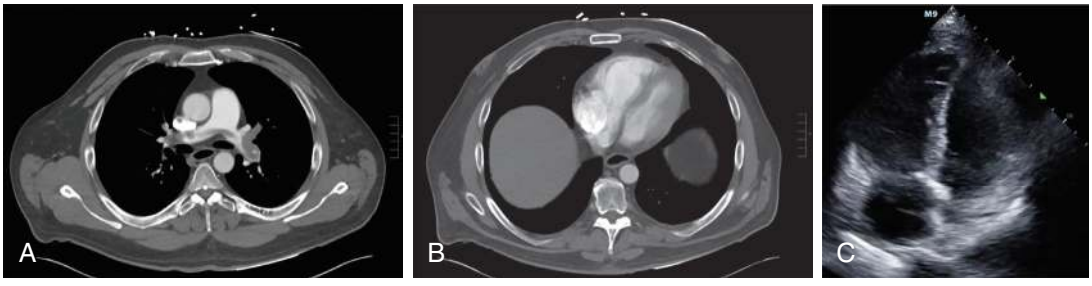

Fig. 65.3 Suggested Management of the Patient with Acute PE. **A,** Acute pulmonary embolism. Cross-sectional computed tomography angiography (CTA) using a pulmonary angiography protocol showing a large bilateral acute pulmonary embolism overlying the main pulmonary bifurcation ("saddle PE"). **B,** Acute right heart strain. Cross-sectional CTA using pulmonary angiography protocol reveals an enlarged right ventricle in the setting of acute pulmonary embolism, suggestive of acute right heart strain. **C,** Acute right heart strain on ultrasound. Ultrasonographic apical four-chamber view of the heart showing acute right heart strain. The right ventricle (left side of the image) is larger than the left ventricle, a pathologic finding. and the procedure has been reported to carry risks of 2% mortality and 5% morbidity.[166] Now typically only used during the performance of endovascular therapy such as catheter-directed thrombolysis, catheter angiography also allows hemodynamic measurements which may be useful in management.

Echocardiography

Echocardiography plays an important role in the workup of suspected and proven PE in the ICU and is most useful diagnostically for assessing secondary signs of PE. The most common findings that suggest acute PE include RV dilation and hypokinesis, an increase in the ratio between the RV and the LV (see Fig. 65.3C), tricuspid regurgitation, paradoxical septal motion (movement of the septum into the LV during systole), interventricular septal shift toward the LV, McConnell sign (hypokinesis of the free wall of the RV with normal motion of the apex), decreased tricuspid annulus plane systolic excursion (TAPSE), and pulmonary artery dilation.[167–169]

In acute PE, a sudden increase in right-sided pressures often occurs, leading to RV dilation and strain. Elevated RV pressures without commensurate RV hypertrophy suggest an acute event such as PE; conversely, RV hypertrophy suggests a preexisting condition.

Although a number of echocardiographic findings have been identified that correlate with the presence of acute PE, echocardiography is poorly sensitive for the diagnosis of PE, particularly in the hemodynamically stable patient. Therefore for a hemodynamically stable patient with suspected acute PE, echocardiography can neither rule in nor rule out the disease.[170–172] However, for the hypotensive patient, an echocardiogram that does not show signs of right heart dysfunction almost certainly excludes PE as the primary cause of the hemodynamic decompensation. Helpfully, echocardiography assists with evaluating alternative etiologies for hypotension (such as pericardial tamponade, valvular heart disease, LV dysfunction, aortic dissection, and hypovolemia) and can easily be performed at the bedside.[173–175] Therefore for an unstable patient in the ICU with contraindications to other diagnostic imaging studies, transthoracic echocardiography (TTE) may help support the presumptive diagnosis of acute PE. Transesophageal echocardiography (TEE) is highly specific for the diagnosis of PE, particularly when combined with the presence of RV overload on TTE.[176,177] Rarely, TEE may reveal a clot in the right side of the heart or thrombus in transit.[178–184] TEE requires specialized equipment and is operator dependent. Therefore it is not routinely used in the diagnosis of acute PE.

For the ICU patient diagnosed with PE via other imaging studies, echocardiography can provide valuable information about cardiopulmonary function and reserve. Particularly important to the diagnosis of PE is the ability of echocardiography to diagnose right heart strain, which is important in the risk stratification of PE.[185–187] Despite its value in prognostication and risk stratification, echocardiography is not recommended as a routine test in the hemodynamically stable and normotensive patient.[188,189]

Venous Compression Ultrasonography

Venous compression ultrasonography ("ultrasound") is the modern standard for diagnosis of ongoing DVT.[190,191] Ultrasound may directly visualize thrombus in the blood vessel or may show secondary signs of DVT such as incomplete compressibility of the vein, suggesting the presence of intraluminal thrombus. Additional ultrasound techniques include the use of Doppler imaging and flow augmentation with manual calf compression. The combination of these sonographic techniques leads to a sensitivity and specificity well over 95% for the presence of proximal DVT.[190] Several studies have confirmed excellent performance of point-of-care ultrasonography by trained intensivists, emergency physicians, and hospitalists, with sensitivity between 86% and 100% and specificity of 90%–96% compared with radiology-performed ultrasound.[192–194]

Although venous ultrasound cannot directly identify PE, and the absence of demonstrable DVT does not exclude the presence of PE, ultrasonography remains helpful in supporting the diagnosis of PE. Because most PE originates from lower extremity DVT and many patients with acute PE will have concomitant DVT,[195,196] a new DVT diagnosis in the setting of symptoms suggestive of acute PE is considered diagnostic.[197] Detection of proximal DVT provides an indication for treatment regardless of the presence or absence of PE and reduces the need for further diagnostic testing.[198,199] As such, ultrasound is particularly helpful in the presence of inconclusive CT results, nondiagnostic V/Q scan results, or in patients with contraindications to other diagnostic imaging.

Particularly important for ICU patients, DVT may occur in non–lower extremity sites such as the arms, head and neck, or trunk.[200,201] Major risks for the development of upper body DVT include the presence of central venous catheters and cancer.[79,85] Because DVT of the upper body is less common, research on diagnostic techniques and protocols is more limited.[202] Additionally, ultrasonography of the proximal upper extremity veins is technically limited because of the clavicle overlying the subclavian vein and superior vena cava.[203]

Venography

Although ultrasonography has become the primary diagnostic modality for DVT, a number of other methods of venography exist. CT venography (CTV) can be performed at the same time as CT pulmonary angiography. Like CTA, CTV can also provide an alternative diagnosis beyond vascular structures and can show larger venous structures (such as the iliac veins and inferior vena cava [IVC]) that ultrasonography may not be able to image.[204] The addition of CTV to CTA increases the sensitivity for VTE, and further improvements in sensitivity may be obtained by direct contrast injection to the affected limb.[205] However, the improvement in sensitivity comes at the expense of increased exposure to radiocontrast media and significant increases in radiation.[206] Given these risks, ultrasound is generally preferred over CTV.

MR venography (MRV) has excellent sensitivity and specificity, nearly 100% in some studies,[207] can give information about the age of thrombosis,[208] and can provide an alternative diagnosis. MRV imparts no radiation, and some protocols do not require contrast media.[210] Expense and duration preclude its use for most ICU patients, but MRV can be useful in specific scenarios, such as the pregnant patient with concern for pelvic or IVC thrombus.[211]

Catheter-based venography was previously regarded as the gold standard for the diagnosis of DVT but has been almost entirely replaced by ultrasound.[212] Direct venography is invasive, requiring catheterization of the venous system of the leg, exposure to contrast dye, and radiation.[213,214] Because of the technical problems with its use and the availability of safe and reliable alternatives, it is rarely used in contemporary practice, except in very limited circumstances, such as during placement of an IVC filter.

Diagnostic Summary

A diagnostic pathway for PE in the ICU is presented in Fig. 65.2. The specific approach used should depend on individual patient circumstances and available diagnostic modalities. Stable patients may undergo transport for testing outside of the ICU. For unstable patients or those at high risk of complications during transport, bedside testing is recommended. Unstable patients should also undergo testing to work through the differential diagnosis list of life-threatening illnesses and to allow for rapid intervention. Given the number of risk factors for PE and the high prevalence of the disease in the ICU population, imaging via CTA will typically be the first diagnostic test in the hemodynamically stable

patient. For hemodynamically unstable patients, TTE and ultrasonography should be performed first.

CLASSIFICATION, PROGNOSTIC ASSESSMENT, AND SEVERITY

Although there is an important distinction between acute and chronic PE, acute PE has the most relevance to the ICU and therefore will be discussed here. Acute PE severity is stratified based on physiologic, laboratory, and radiologic measurements. Hemodynamically stable patients without evidence of RV dysfunction are considered "low-risk" PE, and have low (about 1%) mortality. The presence of right heart strain places the acute PE into the "submassive" or "intermediate-risk" PE category. Right heart strain is defined by the radiologic presence of RV enlargement on CTA or by characteristic echocardiographic findings.[167,215,216] RV dysfunction on echocardiography has been associated with a 2.5-fold (95% confidence interval [CI] 1.2–5.5) increased risk of mortality,[217] and RV dysfunction on CT has been associated with a 1.8-fold (95% CI 1.3–2.6) increased risk of mortality.[218] The presence of right heart dysfunction can also be defined by the presence of laboratory biomarkers, such as the presence of an elevated troponin or NT-proBNP/BNP.[124] A recent meta-analysis found that an elevated troponin is associated with a 4.3-fold (95% CI 2.1–8.5) increase in mortality after PE.[126]

The most severe category of PE is defined as "massive" or "high-risk" PE. Massive PE is described as acute PE with either shock or persistent hypotension (where hypotension is defined as a systolic blood pressure <90 mmHg or a decrease of >40 mg Hg from baseline) not resulting from another etiology like sepsis or dysrhythmia.

The European Society of Cardiology (ESC) recently updated their recommendations for PE risk stratification (Table 65.2)[219] to include a risk score, either the Pulmonary Embolism Severity Index (PESI)[220,221] or the simplified Pulmonary Embolism Severity Index (sPESI).[222] The PESI and sPESI use a number of elements from the history (age, history of cancer, and history of cardiopulmonary disease) and physical examination (tachycardia, hypotension, and hypoxemia) to prognosticate all-cause 30-day mortality. However, because of their lack of association with PE-specific mortality, it is not clear whether these scores should be used to guide advanced treatments such as thrombolysis.

In the current ESC classification system, "low-risk" PE includes patients without any evidence of right heart strain (defined by radiologic criteria or laboratory biomarkers) and a low-risk PESI/sPESI. "Intermediate-risk" PE includes patients with "high-risk" classification on the PESI/sPESI and is further subdivided into "intermediate-high" if there is both radiographic and biomarker evidence of right heart strain or "intermediate-low" if either one or neither is positive. Finally, "high-risk" PE includes patients with evidence of shock or hypotension. Importantly, patients are classified as "high-risk" in the presence of shock or hypotension, regardless of the presence of an elevated risk score or laboratory biomarkers.

A number of additional prognostic scoring systems also exist, including the Geneva risk score,[223] Hestia criteria,[224] Shock Index,[225] Global Registry of Acute Coronary Events (GRACE) score,[226] PREP score,[227] PROTECT multimarker index,[228] Bova score,[229] and RIETE score.[230] Of note, none of these clinical prediction tools have been developed or validated specifically for patients in the ICU.

Although not included in most diagnostic scores or classification systems, thrombus burden and the presence of coexisting DVT are also associated with increased mortality in acute PE.[231–233] D-dimer levels, which reflect thrombus burden, are also correlated with morbidity and mortality.[234–239] However, there is only a loose relationship between the anatomic location of a PE and its physiologic consequences. For example, the term "saddle" PE has classically been used to describe a large PE overlying the bifurcation of the pulmonary artery trunk. Although "saddle" PE has colloquially been used to imply a large, potentially hemodynamically significant PE, patients with acute saddle PE are often asymptomatic and hemodynamically stable, so the term has little use in classifying the severity of PE.[8,240]

TREATMENT OF ACUTE PE

The management of acute PE depends on a number of factors, including the clinician's confidence in the diagnosis of PE, the hemodynamic status of the patient, the degree of RV dysfunction, bleeding risk, non PE-related prognosis, patient preferences, and patient-specific factors that could affect treatment safety and efficacy. The fundamentals of treatment for acute PE include initial resuscitation, prompt therapeutic anticoagulation with drug monitoring (if necessary), consideration of thrombolysis or thrombectomy, and avoidance of complications. Assuming there are no contraindications, patients for whom there is a high suspicion of acute PE should receive empiric anticoagulation before completion of diagnostic testing, especially if a delay in testing is expected. A management algorithm is shown in Fig. 65.4.

Initial Resuscitation

Volume Administration

For hypotensive patients, a cautious fluid challenge with administration of IV crystalloid in small-volume boluses (such as 250–500 mL) may improve cardiac output.[241,242] A volume status examination should occur before and after administration of fluid and should be tailored to the hemodynamics of the patient. Aggressive administration of IV fluids should be avoided, as this may result in RV overdistention, compression of the LV by the septum, decreased cardiac output, and myocardial ischemia.[243,244]

Vasopressors

If the administration of an initial bolus of IV fluids does not improve the patient's hypotension, vasopressors should be administered. There are limited experimental data on the appropriate initial vasopressor,[245] but expert consensus suggests that norepinephrine should be the initial agent in blood pressure support.[219] Dobutamine has been used in selected cases but may worsen hypotension via peripheral beta-2 agonism unless coadministered with norepinephrine.[246,247] Vasopressin may play an accessory role as a vasopressor that does not raise pulmonary vascular resistance.[248]

Vasodilator Therapies

Pulmonary arterial vasodilators may decrease pulmonary vascular resistance and pulmonary arterial pressure, thereby decreasing RV afterload.[249] The successful use of inhaled nitric oxide and epoprostenol have been reported in several case series.[250–254] However, a recent clinical trial failed to show benefit of inhaled nitric oxide in hemodynamically stable patients with PE and RV dysfunction.[255,256]

Supplemental Oxygen

Hypoxemia occurs commonly in hemodynamically significant acute PE, and hypoxemic vasoconstriction may worsen acute pulmonary hypertension. Expert consensus recommends the administration of supplemental oxygen to target a pulse oximetry saturation of 90% or greater.

Intubation and Mechanical Ventilation

Great caution should be exercised in the intubation and ventilation of a patient with acute PE, as these procedures may precipitate

TABLE 65.2 Risk Stratification

Early Mortality Risk		RISK PARAMETERS AND SCORES			
		Shock or Hypotension	PESI Class III–V or sPESI ≥ 1	RV Dysfunction on Imaging	Cardiac Biomarkers
High		+	(+)	+	(+)
Intermediate	Intermediate-high	−	+	Both positive	
	Intermediate-low	−	+	Either one or none positive	
Low		−	−	Assessment optional: if assessed, both negative	

- Any shock or hypotension is classified as high risk, regardless of PESI/sPESI class or biomarkers.
- RV dysfunction on imaging characterized by RV dilation or increased RV/LV ratio (usually greater than 1.0) on CT or echocardiography and hypokinesia of RV wall or increased tricuspid regurgitation jet on echocardiography.
- Cardiac biomarkers = elevated cardiac troponin or natriuretic peptide.

hemodynamic collapse and cardiac arrest. Because the increased intrathoracic pressure brought by mechanical ventilation can further lower preload and worsen RV failure, preintubation hemodynamics should be optimized and an infusion of vasopressors should be considered for those patients needing intubation.[257–259] Many induction and sedative agents cause hypotension and transient hypoxemia during the apneic period of an intubation, which can increase pulmonary vascular resistance and worsen RV failure. Therefore intubation should be rapidly accomplished by a skilled operator, using induction medications that preserve cardiovascular stability. Careful attention should also be paid to postintubation ventilator management to optimize RV function.[260]

Anticoagulation

Anticoagulation is the mainstay of treatment for acute PE. Anticoagulation prevents new clot formation and extension of clots and recurrence of disease. Selection of the appropriate anticoagulant medication depends on a number of individual factors, including availability and ease of administration, onset of action and time to peak, patient-specific

features such as metabolism and excretion, bleeding risk, drug interactions, and reversibility. Upcoming procedures or anticipated thrombolysis may favor a medication with a shorter half-life, whereas patients at high risk of bleeding may benefit from an anticoagulant with a readily available reversal agent. The choice of anticoagulant in the ICU should focus on short-term management, whereas long-term treatment choices can be deferred until after the patient leaves the ICU. (e Table 65.4 provides information on the dosing of commonly used anticoagulant medications.)

Patients with a high clinical suspicion for PE should undergo empiric parenteral anticoagulation while awaiting diagnostic imaging unless the bleeding risk is prohibitively high. Initial anticoagulation after the diagnosis of PE is usually accomplished with a parenteral agent in the immediate management period before transitioning to an oral agent. However, the development of direct-acting oral anticoagulants, which are both effective and safe for the treatment of VTE, are viable alternatives for initial treatment in most cases.

All patients should undergo a bleeding risk assessment and evaluation for contraindications before anticoagulant therapy is initiated. Risk factors for bleeding with anticoagulation are listed in Table 65.3. Major contraindications to anticoagulant treatment include intracranial bleeding, severe active bleeding, or recent neurologic or spinal surgery. Relative contraindications include recent major surgery, ischemic stroke, nonsevere active bleeding, thrombocytopenia, or bleeding diathesis. Nonsteroidal antiinflammatory drugs increase the risk of bleeding on anticoagulation, so their use should be minimized.[261] Although studies have identified risk factors for anticoagulant-associated bleeding in patients with VTE, for most patients admitted to an ICU with PE, the benefits of anticoagulation outweigh the risks.[262,263]

Unfractionated Heparin

Despite the development of new anticoagulant medications, unfractionated heparin (UFH) remains the initial parenteral medication of choice for many patients with acute PE in the ICU. Though endogenously produced, commercial UFH is isolated from porcine or bovine intestines as a mix of different-length polysaccharides.[264] These long chains bind to antithrombin III (AT), potentiating the inactivation of factors Xa and IIa (thrombin).[265]

After an initial bolus, the infusion rate of UFH is commonly titrated using a nomogram based on the activated partial thromboplastin time (aPTT) or the anti-Xa level and monitored every 6 hours until a steady state is reached.[266] Typically, the minimum therapeutic threshold of UFH corresponds to 1.5 times the mean control value or the upper limit of normal of the aPTT range, so many institutions will target 1.5–2.5 times the upper limit of the test's normal range. For anti-Xa, this corresponds to a range of 0.3–0.7 unit/mL. The actual aPTT range will vary between institutions based on the assay used. Each aPTT reagent should be correlated to an anti-Xa assay, particularly when switching manufacturers.[265]

The efficacy of UFH depends partly on achieving a therapeutic level of UFH within the first 24 hours of treatment.[96,267] Unfortunately, the anticoagulant response to a standard dose of UFH varies widely among patients, and numerous studies have demonstrated difficulties in clinical practice with reliably administering therapeutic doses of IV UFH, even despite the use of a dosing protocol and nomogram.[265,268–271] Because of its short half-life, utility with renal dysfunction, and availability of a reversal agent, UFH is often the first medication used for treatment of acute high-risk PE in the ICU. However, given its unreliability in anticoagulation, a different anticoagulant should be chosen for those patients for whom thrombolysis or interventional procedures are not immediately planned.

Heparin-induced thrombocytopenia (HIT) occurs within 5–10 days of the initiation of heparin in about 5% of patients. HIT type I (HIT-I), characterized by a transient decrease in platelet count, occurs within the first 2 days of therapy because of a direct effect of heparin that causes platelet aggregation. HIT-I is not clinically significant and does not require a change in therapy.[272] HIT type II (HIT-II) is much more concerning and is an immune-mediated disorder caused by antibodies targeting the platelet–heparin complex (specifically, platelet factor 4 [PF4]).[273] Recognition of the PF4–heparin complex by immunoglobulin G (IgG) leads to both thrombocytopenia and an activation of the clotting cascade, leading to arterial and venous thrombosis, which can be life-threatening. Patients with HIT-II have a 30-fold increased thrombotic risk.[274]

The diagnosis of HIT-II is made clinically using the 4T score while awaiting laboratory confirmation[275] (e Table 65.5). Laboratory diagnosis is typically accomplished using the highly sensitive immunoassay for the PF4–heparin complex and confirmed using the highly specific serotonin release functional assay.[274] For patients in whom there is a high suspicion for HIT-II, heparin therapy should be discontinued immediately and the patient transitioned to an alternative form of anticoagulation, typically a parenteral direct thrombin inhibitor.[276] Although fondaparinux and factor Xa inhibitors have increasingly been used for alternative anticoagulation in HIT-II, they have not yet entered guidelines as recommended therapy.[277–279]

Low-Molecular-Weight Heparin

Low-molecular-weight heparin (LMWH) is obtained by the chemical or enzymatic degradation of UFH from approximately 45 saccharides to 15 saccharides.[280] Similarly to UFH, LMWH binds to AT to inactivate factors Xa and II (thrombin). The decreased length of the LMWH chains decreases the ability of AT to bind thrombin compared with UFH, and therefore its major mechanism of action is from the inactivation of Xa.[281] Several different formulations of LMWH are commercially available with similar characteristics.[282]

LMWH is given subcutaneously and has excellent bioavailability (>90%) and a longer half-life when compared with UFH. LMWH is renally cleared and thus is contraindicated in renal failure. It is administered once or twice a day in weight-based dosing and does not require laboratory monitoring. Nonetheless, anti-Xa levels can be used to measure its efficacy, if needed. When compared with UFH, LMWH has a more predictable anticoagulant response.[280,282]

Overall, LMWH appears to have fewer serious complications, more reliable anticoagulation, lower rates of recurrent thrombus, a lower risk of bleeding, and requires less monitoring than UFH.[283] LMWH also appears to have a lower rate of heparin-induced thrombocytopenia.[284–287] Protamine can be used to reverse LMWH, but its efficacy in reversing Xa blockade is limited.[288,289] Therefore in the patient for whom an invasive intervention is not immediately planned and who can otherwise tolerate the medication, LMWH appears superior to UFH. Limitations include subcutaneous administration; among patients in the ICU receiving DVT prophylaxis with LMWH, patients receiving vasopressors had lower anti-Xa activity than those not on vasopressors[290,291] and anti-Xa activity is also variable in the setting of subcutaneous edema.[292,293] The appropriate dose of LMWH in morbid obesity is also unclear.[294]

Fondaparinux

Fondaparinux is a heparinoid that contains only the biochemically active pentasaccharide sequence of UFH. It binds to AT to inhibit factor Xa but has no activity against thrombin. Fondaparinux has nearly 100% bioavailability after subcutaneous injection and a relatively long half-life when compared with UFH and LMWH.[295] Renally cleared, it should not

e TABLE 65.4 Initial Anticoagulant Therapy for VTE

Medication	Route	Initial Dosing*	Monitoring	Maintenance Dosing
Unfractionated heparin	IV	80 units/kg bolus, then 18 units/kg/hr infusion	aPTT 1.5–2.5 normal *or* anti-Xa 0.3–0.7	–
Low-molecular-weight heparin	SQ	Enoxaparin 1 mg/kg BID Dalteparin 200 units/kg daily Tinzaparin 175 IU/kg daily	None	Same as initial
Fondaparinux	SQ	5–10 mg daily (based on patient weight)	None	Same as initial
Warfarin	PO	5 mg daily (generally) with heparin bridge	INR 2.0–3.0	Adjusted by INR
Apixaban	PO	10 mg BID × 1 week	None	5 mg BID
Rivaroxaban	PO	15 mg BID × 3 weeks	None	20 mg daily

TABLE 65.3 Risk Factors for Bleeding With Initial Anticoagulant Therapy

RISK FACTORS	
Age >65 years	Diabetes
Age >75 years	Anemia
Previous bleeding	Antiplatelet therapy
Cancer	Poor anticoagulant control
Metastatic cancer	Comorbidity and reduced functional capacity
Renal failure	Recent surgery
Liver failure	Frequent falls
Thrombocytopenia	Alcohol abuse
Previous stroke	Nonsteroidal antiinflammatory drug

Interpretation:

ESTIMATED ABSOLUTE RISK OF MAJOR BLEEDING			
	Low Risk (0 Risk Factors)	**Moderate Risk (1 Risk Factor)**	**High Risk (≥2 Risk Factors)**
Anticoagulation (0–3 months)			
Baseline risk (%)	0.6	1.2	4.8
Increased risk (%)	1.0	2.0	8.0
Total risk (%)	1.6	3.2	12.8
Anticoagulation (after 3 months)			
Baseline risk (%/year)	0.3	0.6	≥2.5
Increased risk (%/year)	0.5	1.0	≥4.0
Total risk (%/year)	0.8	1.6	≥6.5

be used in renal dysfunction. Dosing is weight-based and does not require monitoring. Fondaparinux does not appear to cause HIT.[296,297] Its safety and efficacy appear to be similar to UFH in PE and LMWH for DVT.[298,299] Given its longer half-life and the lack of a reliable reversal agent,[300] fondaparinux is not typically the initial anticoagulant utilized in the ICU but may be a reasonable choice in selected patients.

Vitamin K Antagonists

The vitamin K agonists (VKAs or coumarins) block the function of vitamin K epoxide reductase, depleting the necessary cofactor for activation of the vitamin K–dependent coagulation factors II, VII, IX, and X (and the anticoagulant proteins C and S).[301] Because of the delay in onset of action caused by the presence of circulating coagulation factors and the potential for procoagulant activity at the initiation of therapy resulting from the initial depletion of the anticoagulant proteins, VKAs are typically given alongside a "bridge" of another anticoagulant medication, typically a heparinoid.[302] The VKAs are given orally, and therapeutic monitoring is required to achieve a targeted international normalized ratio (INR) range of 2.0–3.0. Because of a large number of medication interactions and patient-specific variability, there is significant lability in anticoagulation efficacy, and the dosing requires close laboratory monitoring.[303] Given the delay in anticoagulation, large number of interactions, and variable anticoagulation, in addition to the development of newer direct-acting anticoagulant medications with more favorable safety profiles, the use of VKAs in PE is more relevant to chronic anticoagulation.

Direct Oral Anticoagulants

The development of the direct oral anticoagulant (DOAC) medications has quickly changed the management of VTE. In contrast to the VKAs, the DOACs have a more rapid onset, shorter half-life, wider therapeutic window, and more predictable pharmacokinetics without the need for therapeutic monitoring.[304] The DOACs are categorized into two major categories, the direct factor Xa inhibitors and the direct thrombin inhibitors.

Orally administered, the factor Xa inhibitors directly bind factor Xa to prevent the cleavage of prothrombin to thrombin.[305] Unlike heparin, they do not require the presence of antithrombin. The two DOACs approved for the initial treatment of VTE, rivaroxaban and apixaban, both require a higher dosage in the first week(s) of therapy before decreasing to a maintenance dose (see e Table 65.4). Edoxaban, a third approved DOAC, requires at least 5 days of overlapping parenteral therapy before being used as monotherapy, whereas the fourth medication, betrixaban, is approved only for VTE prophylaxis.

When compared with LMWH and VKAs in large clinical trials, the factor Xa antagonists have shown equivalent efficacy for the treatment of VTE, while offering a more favorable safety profile.[306–309] Although these medications have become the first-line treatment for most patients in the outpatient setting because of their reliable anticoagulant effect without the need for routine monitoring, a number of factors limit their use in the ICU, including oral dosing, limitations of use in renal dysfunction, and until recently, limited options for anticoagulation reversal.[310]

The only oral direct thrombin inhibitor is dabigatran, which directly inhibits circulating and clot-bound thrombin.[311] In large clinical trials dabigatran has shown equivalent performance to warfarin with a favorable safety profile[312,313] and has the benefit of a reliable reversal agent, idarucizumab.[314] Dabigatran requires at least 5 days of parenteral therapy with another anticoagulant before its use in VTE, which limits its use in the ICU.

Parenteral direct thrombin inhibitors include bivalirudin, argatroban, and desirudin. They are not approved for the treatment of PE and are typically used off-label for anticoagulation in patients with HIT.[276]

Thrombolytic Therapy

In contrast to anticoagulant medications, which prevent clot propagation, thrombolytic (or fibrinolytic) drugs lead to rapid clot lysis by converting plasminogen to plasmin.[315] Earlier thrombolytic drugs such as streptokinase and urokinase have largely been replaced by more fibrin-specific agents modeled on the naturally occurring enzyme tissue plasminogen activator (tPA). Recombinant genetic engineering has led to the development of three major thrombolytic medications: alteplase (recombinant tissue-type plasminogen activator or r-tPA), reteplase (recombinant plasminogen activator, rPA), and tenecteplase (TNK-tPA). Alteplase is given as a 100-mg IV bolus over 2 hours, reteplase is given as 10 units IV over 2 minutes and then repeated 30 minutes later, and tenecteplase is given as a single weight-based bolus dose.[316]

Thrombolytic therapy provides more rapid lysis of PE than anticoagulation.[317] This clot resolution can restore pulmonary perfusion and promptly lower pulmonary artery pressure and resistance, thereby improving RV function.[318] Over 90% of patients will show a response with thrombolysis.[319] The benefit of thrombolysis appears to be highest when initiated within 48 hours of symptom onset but may remain for up to 2 weeks afterwards.[320] Meta-analyses of thrombolysis have shown lower rates of mortality[321–323] and lower rates of clinical deterioration and recurrent PE, though at the expense of higher rates of major and

e TABLE 65.5 4T Score for Heparin-Induced Thrombocytopenia

Criterion	Points
Thrombocytopenia

Intermediate probability (4–5 points)	~14%
High probability (6–8 points)	~64%

intracranial bleeding.[324] The benefit-to-risk ratio of thrombolysis therefore seems to be highest in those patients with hemodynamic instability in the setting of acute PE (e.g., high-risk or "massive" PE) and intermediate- and high-risk patients who are showing signs of hemodynamic worsening despite appropriate anticoagulation.[325] Younger patients also seem to benefit more than older patients. The long-term benefit of thrombolysis is uncertain, as studies have yet to demonstrate clear improvement in long-term mortality, dyspnea, or RV function.[326] Lower-dose systemic thrombolysis has shown promise in early trials for intermediate-risk PE and for some patients with relative contraindications to thrombolysis. Because these studies have not been replicated in well-designed, large-scale trials, such use is still experimental.[327–329]

The primary risk of thrombolytic therapy is major bleeding. Studies have suggested rates of major bleeding as high as 22%, with a 3% risk of intracranial hemorrhage, although a more recent meta-analysis showed rates of 9.2% and 1.5%, respectively.[23,321] Bleeding associated with thrombolytic treatment can be catastrophic and lead to death; therefore careful patient selection is crucial. Contraindications to thrombolytic therapy are given in Table 65.4.

Expert consensus recommends that UFH be stopped during the administration of r-tPA and TNK-tPA, though it can be continued if rPA is used. Anticoagulation is generally resumed after thrombolysis, typically with UFH in case urgent reversal is needed.[219]

Although no mortality benefit has been demonstrated with empiric thrombolysis in undifferentiated cardiac arrest, fibrinolysis is generally recommended in cardiac arrest resulting from presumed or known PE.[330,331] Alteplase may be given as a 50-mg bolus,[332] and tenecteplase, although technically weight-based, is typically given as a 50-mg bolus for ease of administration.[333] When fibrinolytics are given in cardiac arrest, consensus recommendations suggest cardiopulmonary resuscitation (CPR) should be continued for at least 60–90 minutes before terminating resuscitation attempts.[334]

Interventional Techniques

Inferior Vena Cava Filter

Insertion of an IVC filter is indicated for patients with acute PE with an absolute contraindication to anticoagulant therapy or for patients with recurrent PE despite adequate anticoagulation.[219] Many clinicians also favor insertion of an IVC filter for patients with large PE and residual iliofemoral DVT that could result in sudden cardiac arrest if it were to embolize. IVC filters prevent the embolization of thrombus to the heart and pulmonary vasculature but do not aid in resolution of the thrombus; therefore the patient should receive anticoagulation if the contraindication to anticoagulation resolves. The routine placement of IVC filters for patients with proximal DVT without PE is not supported,[335] as it does not reduce mortality[336] and increases the risk of subsequent DVT.[337]

Permanent IVC filter insertion has largely been replaced by the development of retrievable filters, which have a high rate of successful placement and removal.[338,339] Removal should take place within several weeks of insertion, although most "retrievable" IVC filters are never retrieved.[340] Coordination with specialists who can remove an IVC filter after discharge from the ICU is very important. The most common complications of IVC filter placement are IVC penetration and occlusion; other complications include filter movement or migration and fracture.[341] Because the complication rate increases with time[340] and the success of retrieval decreases with time,[342] IVC filters should be removed as soon as clinically appropriate.[339]

Catheter-Directed Treatment

Catheter-directed treatment includes a variety of endovascular treatments for acute PE, including thrombolysis and thrombectomy.[343] Catheter-directed thrombolysis involves the insertion of a catheter into affected pulmonary arteries to directly deliver fibrinolytic into the thrombus, theoretically avoiding the shunting of blood away from the occluded artery and into nonoccluded vessels.[344] Some catheters include ultrasound to facilitate the entry of thrombolytics into the thrombus, though the clinical benefit of this functionality is unknown.[345] Catheter-based techniques allow the delivery of much lower doses of thrombolytic medications over a longer period, theoretically reducing the risk of major bleeding.[344,346] Catheter-directed thrombolysis appears to be as effective as systemic thrombolysis in high-risk PE with a lower risk of bleeding[347–349] and may be superior to anticoagulation alone in intermediate- and high-risk PE, though large clinical trials comparing catheter-directed thrombolysis with either anticoagulation alone or with systemic thrombolysis have not yet been performed.[350] Other percutaneous catheter-based techniques include fragmentation, aspiration thrombectomy, and mechanical thrombectomy. These procedures are only available at specialized centers, and data supporting these techniques are limited to case series.[351–353]

Surgical Embolectomy

Surgical embolectomy (thrombectomy) has a role for patients who have high-risk PE and a contraindication to thrombolytic therapy or

TABLE 65.4 Contraindications to Fibrinolytic Therapy

Major Contraindications
Structural intracranial disease
Previous intracranial hemorrhage
Recent ischemic stroke (3 months)
Active bleeding
Recent brain or spinal surgery
Recent head trauma with fracture or brain injury
Bleeding diathesis
Relative Contraindications*
Systolic blood pressure >180 mm Hg
Diastolic blood pressure >110 mm Hg
Recent (nonintracranial) bleeding
Recent surgery
Recent invasive procedure
Noncompressible vascular puncture
Remote ischemic stroke (>3 months)
Therapeutic anticoagulation
Traumatic cardiopulmonary resuscitation
Pericarditis or pericardial fluid
Diabetic retinopathy
Pregnancy
Age >75 years
Low body weight (<60 kg)
Female
Black race

*Relative contraindications are those that have been associated with increased bleeding risk in retrospective studies of thrombolysis. Severity of condition and clinical judgment should determine importance of relative contraindications.

Adapted from Kearon C, Akl EA, Ornelas J, et al. Antithrombotic therapy for VTE disease: CHEST guideline and expert panel report. *Chest*. 2016;149(2):315–352.

failed thrombolytic therapy.[219] Additionally, embolectomy should be considered for thrombus-in-transit through the right heart or crossing a patent foramen ovale.[354] Surgical embolectomy requires general anesthesia, cardiopulmonary bypass, and available personnel and equipment. Because standard technique involves a median sternotomy and pulmonary artery incision, embolectomy is technically most feasible for large, central PEs. Intraoperative TEE should be performed because of the high prevalence of extrapulmonary thromboembolism in this patient population.[355]

Traditionally, surgical embolectomy has had a prohibitively high mortality rate, over 50% in early trials[356] and 59% when performed after cardiac arrest.[357] However, this was most likely the result of selection bias and the use of surgical embolectomy only after cardiac arrest and other efforts, such as thrombolysis, had failed.[358] With improved patient selection and surgical technique, a more recent, large meta-analysis found in-hospital all-cause mortality of 26.3%,[359] and some centers have reported mortality rates lower than 11%.[360,361]

For patients with massive, high-risk PE, surgical embolectomy leads to more rapid decreases in pulmonary artery pressure and RV diameter with a lower complication rate than systemic thrombolysis.[362–364] Surgical embolectomy appears to have similar mortality to catheter-based therapies with a lower failure rate in the treatment of massive, high-risk PE, but available data are subject to selection bias, as surgical techniques have been traditionally reserved for the most critically ill.[365] The decision to proceed with either surgical embolectomy or catheter-directed techniques will depend on the available personnel, equipment, and specific conditions of the patient.

Extracorporeal Life Support

ECLS (also called *extracorporeal membrane oxygenation* or *ECMO*) can be used in acute high-risk PE to unload the RV, increase cardiac output, and provide oxygenation.[358] ECLS can be used either as a bridge to surgical embolectomy or as definitive (destination) therapy with anticoagulation alone.[354] Most data on ECLS are from published case series, but a systematic review showed an overall survival rate of 70.1% with similar mortality for catheter-directed thrombolysis, surgical embolectomy, and systemic thrombolysis in patients with massive, high-risk PE.[366] ECLS requires significant institutional infrastructure, including equipment, physician specialists, perfusionists, and well-established protocols. These requirements limit its utility to specialized centers.[344]

Team-Based PE Therapy

Similar to the management of acute coronary syndromes, stroke, and trauma, pulmonary embolism response teams (PERTs) have been developed to coordinate care for patients with higher-risk acute PE.[367,368] PERTs can assist with the early management, triage, and coordination of advanced interventional techniques such as catheter-directed thrombolysis, surgical embolectomy, or ECLS, in addition to facilitating follow-up. As the management of intermediate- and high-risk PE is complex, PERT may rapidly coordinate expertise from diverse disciplines to develop a plan of care.[369–371]

KEY POINTS

- VTE includes both DVT and PE, which occurs when a DVT embolizes and travels through the heart to lodge in the pulmonary arterial vasculature.
- The critically ill patient is at high risk for the development of PE because many risk factors for thrombus formation are common in the ICU.
- History, physical examination, and traditional scoring systems are unreliable in the ICU patient; therefore diagnostic imaging is the test of choice for the diagnosis of acute PE in the ICU.
- Patients suspected of acute PE should promptly undergo CT using an angiography protocol (CTA) as the initial diagnostic study of choice; a subset of patients with contraindication to CTA may undergo V/Q scanning. The hemodynamically unstable patient should be expediently examined by echocardiography and compressive venous ultrasonography.
- Anticoagulation is the mainstay of treatment for acute PE. For patients diagnosed with acute PE or with high pretest probability, anticoagulation should be promptly administered, often using a parenteral heparinoid.
- Unstable patients with high-risk PE should be assessed for definitive therapy by thrombolysis (either systemic or catheter-directed) or surgical embolectomy. A PERT may help coordinate advanced therapies.
