Patients at highest risk for severe infection and influenza complications requiring ICU care are those with a history of chronic lung disease and/or severe immunosuppression. Underlying lung disease occurs in approximately 20% of patients with influenza in the ICU, most commonly asthma and chronic obstructive pulmonary disease (COPD). Other special populations at increased risk of severe disease and mortality are elderly patients (>65 years of age), women who are pregnant or recently postpartum, residents of long-term care facilities, those with obesity, and Indigenous populations.[25,43] Additional risk factors include patients with other chronic medical conditions, including neurologic diseases (12%), hematologic or oncologic conditions (9.9%), and cardiac conditions (4.6%).[38] However, approximately half of hospitalized patients during pandemic years might otherwise be healthy.[28,29,38]

Whereas most patients with influenza do not develop critical illness, 11%–19% of patients hospitalized with laboratory-confirmed influenza require treatment in the ICU.[29,44] Those who develop critical illness often deteriorate rapidly, and severe illness may be protracted. For patients requiring mechanical ventilation, the mean duration is approximately 5–12 days. Many patients are difficult to oxygenate, and patients often require ancillary therapies such as extracorporeal membrane oxygenation (ECMO) and nitric oxide therapy, leading to increased length of ICU stay and excess mortality.[28,38,45]

Similar to prior pandemics, the primary cause of death remains complications from secondary bacterial infection, including multisystem organ failure and cardiovascular collapse.[31,46] However, mortality rates have significantly improved in recent years (~17%)[47] as a result of better oxygen delivery, supportive ICU care, vaccination, antibacterial agents, and antiviral medications. Unfortunately, sophisticated ICU care remains out of reach for many patients in developing countries, and case-fatality rates remain regrettably high.[48]

Clinical and Laboratory Diagnosis of Influenza

Clinicians should suspect and test for influenza in all patients who present to the hospital during influenza season with an acute respiratory illness, acute decompensation of chronic medical conditions, or any immunocompromised patients.[49] Importantly, a history of current-season influenza vaccination does not exclude the diagnosis of influenza because of variable vaccine effectiveness from year to year. Uncomplicated disease does not typically result in significant respiratory compromise, but shortness of breath should raise concern for severe disease. Other clinical signs indicating severe infection include hemoptysis, frothy pink sputum, and purulent sputum with diffuse lung crackles. Percutaneous oximetric assessment of oxygenation or arterial blood gas evaluation of PO_2 should be performed when assessing a patient with suspected severe influenza. Relative hypoxia should trigger further assessment, including a chest radiograph. Laboratory findings commonly found at presentation with severe disease typically include normal to low leukocyte count and elevated creatine kinase.[25,47,50] A leukocyte shift to immature forms is unusual in the absence of bacterial coinfection. An approach to the diagnosis and treatment of influenza is presented in Fig. 119.3.

Early laboratory diagnosis of influenza infection is greatly facilitated by the use of rapid reverse transcriptase–polymerase chain reaction (RT-PCR) testing.[51] Clinicians should collect nasopharyngeal specimens using flocked swabs.[49] In patients who require mechanical ventilation, endotracheal aspirates should be collected in addition to the nasopharyngeal specimens in order to maximize diagnostic yield.[49,52,53] Virus may only be detected in lower tract samples in patients with severe pneumonitis. For critically ill patients, the use of multiplex nucleic acid amplification tests to detect a panel of other respiratory viruses is recommended. The use of immunofluorescent techniques, enzyme-linked immunoassays, and other rapid diagnostic tests is discouraged because of lack of diagnostic sensitivity.[49,51,54–57] Viral cultures require up to 1 week for processing and should only be considered to provide isolates for further characterization.

Lessons From the 2009 Influenza A H1N1 Pandemic

Starting March 2009, a novel strain of a human-adapted influenza virus, influenza A(H1N1)pdm09, spread from an initial large outbreak in Mexico to virtually all countries of the world. By September 27, 2009, there were over 340,000 cases with 4100 deaths worldwide.[11,58] Over the period of June to September 2009, there were dramatic spikes in Australia, New Zealand, and South America that breached the capacity for ICU care in some regions.[47] Ultimately, 18,500 lab-confirmed influenza deaths occurred worldwide, but modelling data estimate that >300,000 respiratory or cardiovascular deaths attributed to influenza occurred globally, predominantly in patients under 65 years of age and in low- to middle-income countries.[59] This led to lessons that have advanced our current understanding of influenza and control of other emerging global pandemics. Public health officials

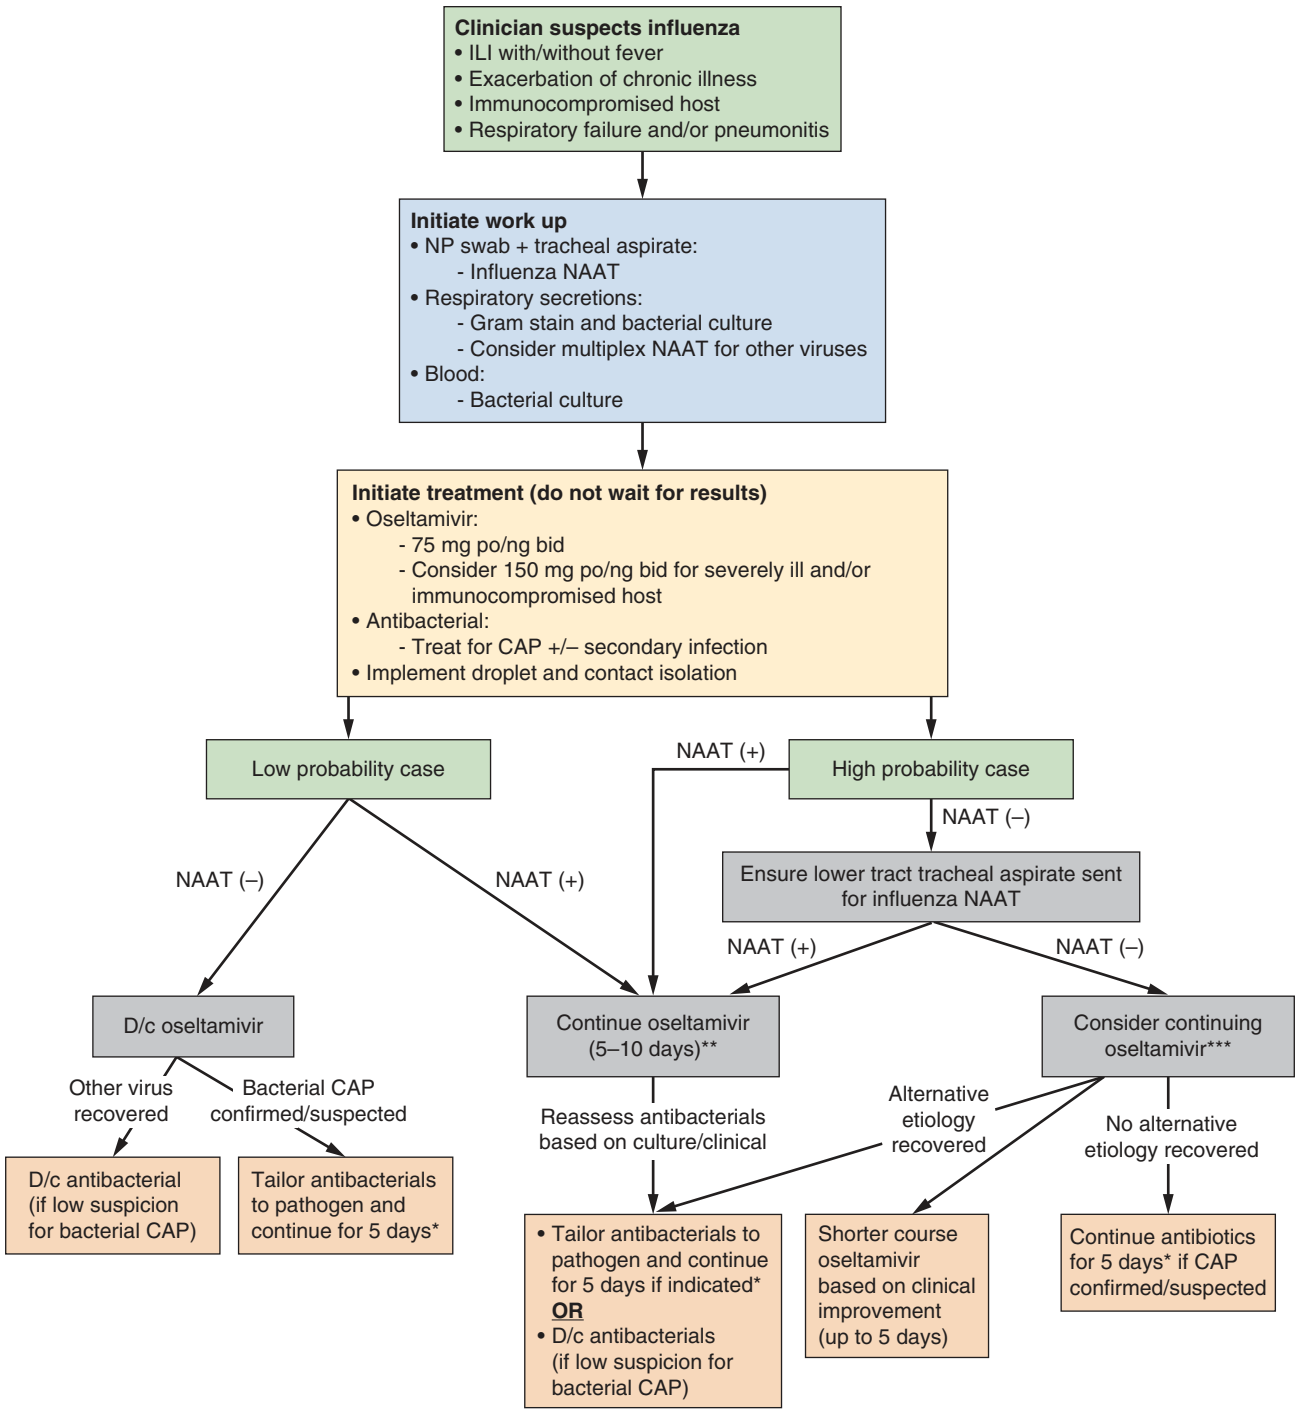

Fig. 119.3 Approach to the workup and management of a patient with suspected influenza pneumonia in the ICU. * A longer course may be needed if CAP) is complicated by meningitis, endocarditis, or other deep-seated infection; suspected or proven *MRSA* or *P. aeruginosa* pneumonia may require a 7-day treatment course; less common specific pneumonia pathogens may require longer courses (e.g., *Mycobacterium tuberculosis, Burkholderia pseudomallei*). ** Because of prolonged viral shedding with primary influenza pneumonia, treatment durations longer than 5 days may be warranted, particularly for ARDS, immunocompromised, and/or severely ill patients, to a maximum of 10 days. *** Results of most NAAT testing are highly sensitive and very highly specific. If influenza is highly suspected clinically during times of high influenza activity and NAAT results are negative, the NPV remains low, and a negative NAAT may reflect a false-negative result. If symptoms present >4 days, diagnostic yield is lower and may also result in a false-negative result. *CAP,* Community-acquired pneumonia; *d/c;* discontinue; *ILI,* influenza-like illness; *NAAT,* nucleic acid amplification test; NP, nasopharyngeal.

were not prepared to quickly assess the transmissibility, severity, and impact of disease. Implementation of risk management plans and global communications were delayed. Despite blunting of the North American spread by widespread deployment of an effective, inactivated, monovalent vaccine program,[60] as many as 61 million Americans were infected, with 274,000 hospitalizations and approximately 12,500 deaths between April 2009 and April 2010.[61]

The events that transpired in Canada were illustrative of the influenza situation in much of the Northern Hemisphere. Among critically ill Canadian patients with influenza A(H1N1)pdm09, the mean age was 32 years, with a possible predilection for more severe disease in women (67% of patients).[25] Pregnant women, obese patients, and Indigenous Canadians were overrepresented and suffered from a disproportionate high level of disease severity, but only 30% suffered from serious comorbid illness.[25,43,62,63] Similar clinical findings were reported in other regions of the world.[47,50,58,64] Nosocomial transmission occurred in approximately 10% of patients. Transmission to healthcare workers occurred early in the outbreak, but this was minimized once the pandemic was recognized and appropriate infection-control safeguards were instituted. A summary of clinical risk factors, comorbidities, and severe complications associated with the latest influenza pandemic is found in Table 119.2.

The most common specific symptoms with influenza A(H1N1) pdm09 included high fever and respiratory symptoms in greater than 90% of patients. Weakness and myalgias were less common. A variety of severe clinical syndromes necessitating ICU care were observed, including:

1. Rapidly progressive, diffuse pneumonitis associated with severe, refractory hypoxemia in relatively healthy teens or adults
2. Secondary bacterial pneumonia, or influenza-bacterial coinfection, frequently with gram-positive pathogens including *S. pneumoniae* and *S. aureus*
3. Acute and prolonged exacerbation of asthma or COPD in those with preexisting disease
4. Life-threatening decompensation of chronic underlying disease in those patients with serious comorbidities, including congestive heart failure, chronic renal failure, end-stage liver disease, poorly controlled diabetes, or immune compromise
5. Bronchiolitis and croup in infants and young children, which frequently required hospitalization, but not ICU care

During pandemic periods, relatively young patients with few serious comorbidities can be affected because of widespread lack of immunity to novel circulating viruses and vigorous intrinsic inflammatory responses.[31] Additionally, vulnerable populations with usual risk factors can be greatly affected, similar to nonpandemic years. The impact on hospital care and costs can be dramatic and necessitates thoughtful critical care resource management in modern ICUs that have limited surge capacity to meet sudden demand for a future pandemic.[25–27,31,47] Establishing a pandemic preparedness plan is imperative to ensure institutions have the capacity to respond to emerging pandemics and mitigate health impact.[65]

Supportive Care Considerations With Influenza

Almost all patients with severe influenza in the ICU will have deficits in oxygenation, leading to acute respiratory distress syndrome (ARDS) and requiring ventilatory support.[25,47] Shock and renal failure are also common, often exacerbated by efforts to optimize oxygenation through diuresis, coupled with high intrathoracic pressures and limited venous return.[25,50,66]

Despite ARDS standard treatment with lung-protective low tidal volume ventilation and open lung strategy with high positive end-expiratory pressure (PEEP),[67] primary influenza pneumonia often results in a relative insensitivity to usual measures of oxygenation and markedly abnormal lung compliance. Control mode ventilation with appropriate sedation and use of neuromuscular blockade to avoid ventilatory dysynchrony and high airway pressures are often needed. Avoidance of volume overload (and judicious diuresis) may also reduce duration of ventilation and length of stay in the ICU for most patients with ARDS.[27,68] Because some patients worsen despite these standard measures, early consideration of transfer to a referral center with experience in rescue therapies should be considered, particularly if severe hypoxemia is encountered.

TABLE 119.2 Prognostic Indicators and Risk Factors for Severe Influenza Complications

Risk Factors and Comorbidities	Comments
**Age <5 years	Especially children <2 years; those with chronic cardiopulmonary disease; <6 months of age associated with higher hospitalization and mortality
Age >65 years	Poor vaccine response; reduced host response to influenza infection
**Chronic cardiopulmonary diseases	Chronic pulmonary disease at highest risk; includes COPD, asthma, cystic fibrosis; cardiac disease includes congestive heart failure, coronary artery disease
Metabolic disease and chronic liver disease	Diabetes mellitus; cirrhosis
Chronic neurologic illness	Includes disorders of the brain, spinal cord, and peripheral nerves; seizures, epilepsy; stroke; developmental delay and institutionalization
Pregnancy	Includes all stages of pregnancy, up to 2 weeks postpartum; women in the third trimester at particular increased risk
Obesity	Particularly with extreme obesity; BMI >35 kg/m^2
Hemoglobinopathy	Sickle cell disease
**Immunosuppression	Glucocorticoids, chemotherapy, malignancy, HIV, organ transplant recipients; lung transplant and advanced HIV at highest risk
Indigenous populations	Increased prevalence of some chronic health conditions; social determinants of health; healthcare access
Access to healthcare services	Nursing home and long-term care residents; hospitalized patients
Secondary bacterial pneumonia	Longer ICU and hospital stays; more nosocomial complications; greater mortality rate

**Comorbidities associated with highest risk of influenza complications, including hospitalization and mortality.

Ancillary strategies may be required to improve refractory hypoxemia, minimize ventilator-induced lung injury, and improve cardiothoracic dynamics. Strategies include prone ventilation, lung recruitment maneuvers, inhaled nitric oxide, and ECMO. These strategies require considerable resources and expertise and offer variable impacts on clinical outcomes.

Early prone ventilation has been demonstrated to be an effective strategy to improve oxygenation and mortality for most causes of ARDS.[69,70] Although little is known about influenza-specific outcomes with prone ventilation, it is recommended for those with severe ARDS in the appropriate experienced facility and in the absence of contraindications. Lung recruitment maneuvers may be used to recruit collapsed alveoli, but because of a lack of convincing benefit, it should not be done routinely.[71] Use of inhaled nitric oxide has demonstrated improvements in oxygenation; however, studies have failed to show improvement in morbidity or mortality, and some studies suggest there may be an increased risk of renal injury.[72–76] Inhaled nitric oxide should not be considered standard therapy. Since the 2009 pandemic, there has been a considerable rise in the use of venovenous ECMO in patients with refractory ARDS from influenza. Although data are limited, pooled analyses suggest that this modality may reduce mortality and should be considered for severe influenza where other options do not exist.[24,27,77–80]

Septic shock is common in critically ill patients with influenza and typically results in refractory hypotension and need for moderate to high doses of vasopressors.[41] Optimal fluid resuscitation strategies remain unknown in this setting and must be balanced with fluid-restrictive strategies that aim to improve oxygenation. It is recommended that all patients with severe influenza, ARDS, and septic shock be treated in accordance with international guidelines and receive at least 30 mL/kg of crystalloid via bolus dosing.[81] The development of AKI often necessitates renal replacement therapy to correct bicarbonate deficiencies to allow for increased tolerability of hypercapnia when poor lung compliance prohibits effective ventilation.

For patients with influenza-associated critical illness, clinical improvement is slow and ICU length of stay is typically prolonged.[82] Clinicians should focus on minimizing the complications of critical illness, including ICU-acquired weakness, delirium, and psychosocial disturbances. Long-term ventilation weaning is often needed, and tracheostomy may be required.

Antiinfluenza Therapy

In severely ill patients with suspected influenza, early initiation of antiviral therapy is predicated on clinical presenting features and epidemiologic data. Therapy must not be delayed pending laboratory confirmation, as initiation within the first 48 hours of illness is most likely to provide benefit.[25,83] For critically ill individuals, early initiation of antiviral therapy may improve survival,[83–88] but antivirals should be administered for all those with severe illness, regardless of the duration of symptoms before hospitalization.[49] The choice of antiviral therapy is dependent on circulating influenza subtypes and local surveillance data examining the risk of oseltamivir resistance.

The NA inhibitor oseltamivir is the preferred agent for severe influenza. Oseltamivir works by selectively binding to the influenza envelope protein NA, inhibiting its enzymatic activity and preventing spread to other uninfected cells. It reduces the duration and severity of symptoms and reduces viral shedding.[83,88–90] It may also reduce the risk of secondary bacterial infection[91–93] and reduce mortality in critically ill patients, though data are limited to pooled analyses of studies that included less severe cases.[44,84–86] The typical dosing for oseltamivir is 75 mg orally twice daily, which must be adjusted for renal dysfunction. Doubling or tripling the dose (150–225 mg orally twice daily) is typically well tolerated, but unnecessary in hospitalized patients without severe illness[94,95]; however, this strategy may benefit severely ill patients, particularly with immunocompromise or patients infected with H5N1 avian influenza.[95–97] In patients with primary influenza pneumonia, viral shedding is often prolonged, with viral clearance occurring after a median of 11 days while on oseltamivir.[52] In these severely ill patients, an extended duration beyond 5 days may be warranted, particularly for those with ARDS or immunocompromise. Current recommendations suggest continued use until adequate clinical response or infection resolution, but formal studies on optimal duration are lacking.[49] Oseltamivir is very well tolerated, but occasionally associated with nausea and vomiting, which rarely requires discontinuation of therapy.

Rare oseltamivir-resistant viruses were isolated during the 2009 H1N1 pandemic but remain very uncommon in current circulating subtypes. The majority of influenza B and influenza A (H3N2) remain susceptible to NA inhibitors. The resistance mutation H275Y, which renders oseltamivir and peramivir ineffective, has rarely been detected (<1.0%) in influenza A (H1N1), but sensitivity to zanamivir is preserved.[98,99] This is in contrast to the seasonal H1N1 subtypes circulating before the 2009 pandemic year, which were often resistant to oseltamivir.[100–102]

Alternative NA inhibitors may be available, including peramivir and zanamivir. These agents are not currently recommended because of limited data in patients with severe lower respiratory tract disease. Peramivir is given by intravenous (IV) route at a typical single adult dose of 600 mg, but duration may be extended to once daily for 5 days in critically ill patients.[103] In studies of ambulatory patients with lab-confirmed influenza, peramivir was shown to reduce time to symptom resolution compared with placebo and to be noninferior to oseltamivir.[104,105] In one study of critically ill patients, similar mortality and ICU length of stay were observed when peramivir was compared with oseltamivir; therefore IV peramivir may be a reasonable alternative to oseltamivir in patients who are unable to tolerate enteral agents.[106,107] Although GI absorption of oseltamivir among critically ill patients had been questioned, comparable blood concentrations have clearly been demonstrated in critically ill influenza patients compared with healthy volunteers.[108,109] Zanamivir by inhalation is not recommended in critically ill patients because of the risk of bronchospasm, lack of efficacy data, and lack of systemic absorption; however, it may be an alternative option for ambulatory patients without asthma or COPD to reduce the duration of symptoms.[110–112]

Baloxavir marboxil is a newer antiviral that selectively inhibits cap-dependent endonuclease, preventing initiation of influenza messenger RNA (mRNA) synthesis and blocking viral proliferation. It is effective in reducing duration of symptoms in acute uncomplicated influenza,[113] but its role in severe infection, in critically ill patients, or in combination therapy with oseltamivir has not been studied. The adamantane family of antivirals, including amantadine and rimantadine, are no longer routinely recommended because of their limited spectrum of activity (only effective against influenza A) and high levels of circulating resistance.[99]

Adjunctive Pharmacologic Therapy for Severe Influenza

The most important adjunctive pharmacologic treatment in critically ill patients with influenza is empiric broad-spectrum antibiotics to cover possible secondary bacterial pneumonia or influenza-bacterial coinfection.[49] Antibiotics should be selected according to local antibiograms to cover the most common pathogens involved, namely *S. pneumoniae, S. aureus* (including methicillin-resistant *S. aureus*

[MRSA]), *S. pyogenes,* and occasionally, gram-negative bacteria. De-escalation of antibiotics is appropriate as lower tract respiratory cultures are finalized. If secondary decompensation occurs after a period of initial clinical improvement, additional antibiotic treatment may be warranted while investigating for newly acquired bacterial or fungal nosocomial infections, examining for empyema, lung abscess, sepsis, or other causes of deterioration.

Many other potential adjunctive therapies for the treatment of severe influenza have been studied. Use of IV immunoglobulins, convalescent serum or plasma, and hyperimmune globulin derived from donors who have recovered from influenza have demonstrated mixed results.[114–116] Meta-analyses suggest that early administration of such products may be associated with improved outcomes, but the effect on survival remains uncertain.[117,118] In addition, case series suggest that similar therapies may be of use in severe influenza A (H5N1) infection,[119,120] but more data are needed before recommending these therapies.

Glucocorticoids have been used to reduce inflammatory responses in influenza, septic shock, and a variety of other infectious conditions.[121–127] Although few randomized trials have been performed, meta-analyses of largely observational studies demonstrated prolonged viral replication, more frequent superinfections with bacterial and fungal pathogens, and increased mortality.[128–133] Because of the very low quality of evidence, potential benefits of glucocorticoid treatment remain uncertain. But extreme caution is needed, and their use in primary influenza pneumonia should be avoided in the absence of a clear alternative indication.

The effect of statins in reducing inflammation and improving illness severity with influenza has been studied in small observational studies. Although there is a suggestion that these may improve outcomes, further trials are needed to assess the risks and benefits before recommending their use.[134] One small open-label trial examined the role of clarithromycin and naproxen in combination with oseltamivir for the treatment of hospitalized patients with influenza. Although this trial demonstrated a reduction in mortality, patients who were already critically ill were not included.[135] This combination merits further investigation.

Infection Control in the ICU to Mitigate the Spread of Influenza

Influenza is transmitted from person-to-person primarily through large-particle respiratory droplets; thus patients with suspected influenza should be instructed to use appropriate hand hygiene, cough etiquette, and be given a face mask to wear upon entry into healthcare facilities. Patients with suspected influenza should be in single-patient rooms, if available, during the initial phase of hospital admission. If clinical demand exceeds the availability of single rooms, cohorting patients with influenza into common rooms may be necessary. Patients who must be transported outside of the room should wear a mask if tolerated, or when necessary, an oxygen delivery system that limits the spread of aerosols. Influenza vaccination is the best way to prevent or mitigate the severity of influenza illness, and in the absence of contraindications, is recommended annually for the entire population, particularly those with risks for severe disease.[49] Vaccination and postexposure chemoprophylaxis are recommended for close contacts who are at very high risk of influenza complications.[49]

Healthcare personnel (HCP) should apply droplet precautions by wearing standard surgical tie masks and use appropriate hand hygiene. Studies have found N95 masks offer no additional protection compared with surgical masks, yet many still advocate their use during cough-inducing procedures.[136] HCPs should also consider contact precautions with gloves when anticipating contact with bodily fluids or touch with contaminated surfaces. Protective eyewear is recommended when providing direct care in close proximity to the patient.[49] The annual influenza vaccine should be mandatory for all HCPs unless specific contraindications exist. Ill HCPs with fever and respiratory symptoms should be instructed not to work until fever has dissipated for >24 hours. For additional information regarding infection prevention strategies in healthcare settings, the reader is directed to updated recommendations from the Centers for Disease Control and Prevention (CDC) at https://www.cdc.gov/flu/professionals/infectioncontrol/healthcaresettings.htm.

OTHER CRITICAL RESPIRATORY VIRAL INFECTIONS

Coronaviruses: SARS, MERS, COVID-19

Coronaviruses are ubiquitous around the world and frequently cause mild to moderate upper respiratory tract infections in humans. These infections seldom cause critical illness; however, three notable severe syndromes were noted with coronaviruses emerging in the twenty-first century: severe acute respiratory syndrome (SARS), Middle East respiratory syndrome (MERS), and coronavirus disease-19 (COVID-19). SARS is caused by the SARS-associated coronavirus (SARS-CoV), which emerged in November 2002. The first cases were discovered in China, with subsequent clusters occurring in countries around the world. Its somewhat unusual lengthy prodrome of fever and constitutional symptoms typically lasted 3–7 days without respiratory symptoms. Subsequently, dry cough would ensue with potential progression to ARDS and case fatality rates of 9.6%. Ultimately, SARS occurred in localized epidemics in several countries, infecting approximately 8000 people and 774 deaths globally.[137] Because of intensive infection-control strategies, it disappeared as quickly as it emerged by July 2003.[138]

MERS has become an endemic viral pathogen in the Middle East, first appearing in June 2012. Over 2400 lab-confirmed cases have been reported, predominantly from the Arabian Peninsula.[139] Although transmission specifics are not fully understood, person-to-person transmission has occurred, and contact with camels appears to be an important risk factor. MERS predominantly causes a severe, acute, febrile, respiratory syndrome that frequently is accompanied by shock and AKI.[140] The vast majority of patients require ICU care and mechanical ventilation.[141] Hospital mortality appears to be the highest of the coronaviruses, approaching 25% in hospitalized patients and 50% in those who require ICU care.[142]

In December 2019, a novel coronavirus emerged, causing a cluster of pneumonia cases in Wuhan, China. This novel coronavirus, named *severe acute respiratory coronavirus 2* (SARS-CoV-2), is genetically similar to that of SARS-CoV.[143] At the time of this writing, the emerging epidemic is rapidly spreading throughout Southeast Asia, and emerging in many other countries, threatening a global pandemic.[144] Genetic sequencing indicates that the virus probably "jumped" animal species from snakes to bats and then to human hosts. Person-to-person spread of SARS-CoV-2 has been demonstrated from epidemiologic studies, and healthcare workers have been disproportionately affected, similar to prior outbreaks of serious viral respiratory illnesses.

The incubation period of SARS-CoV-2 is thought to last up to 14 days, but most symptoms appear within 5 days of exposure. Clinical manifestations of COVID-19 vary from asymptomatic to severe respiratory compromise. Most patients experience an abrupt onset of fever and respiratory symptoms. Approximately 15% develop severe disease with lower respiratory tract involvement, 5% develop critical illness, and 2.3% of patients die. Mortality rates are much higher in elderly adults and approach 50% for patients in the ICU.[145] Strict isolation precautions and extreme infection control measures have been important in attempts to limit the spread of this outbreak.[146] Work on

vaccines, immunotherapy, and antiviral chemotherapies are underway, but currently treatment is simply supportive.[144]

Paramyxoviruses: Morbillivirus (Measles)

Although a highly effective vaccine has dramatically reduced the incidence of measles in the past decades, recent social and political factors have contributed to low vaccination rates and resurgence of disease in some areas.[147] The World Health Organization (WHO) recently announced a staggering statistic that measles accounted for more than 140,000 deaths worldwide in 2018.[148] The mortality rates are particularly high in children under 5 years of age. Measles typically causes a relatively mild childhood exanthem in otherwise healthy children. This highly contagious virus causes rapid spread of fever, rash, cough, conjunctivitis, and coryza. Regrettably, unvaccinated, malnourished children in developing countries, often with other concomitant respiratory illnesses, fare much worse and can die from measles-induced pneumonia or encephalitis or suffer from permanent blindness and/or deafness.

Pneumonia is the most common life-threatening complication of severe measles infection, often resulting in death, particularly in patients <5 years or >20 years of age. Additionally, measles may cause persistent morbidity and mortality after naturally acquired infection secondary to immunosuppression and risk for secondary infection.[149] Rarely, measles can be complicated by encephalitis, acute demyelinating encephalomyelitis, or, years later, with subacute sclerosing panencephalitis (SSPE). Treatment is largely supportive; however, vitamin A may reduce morbidity and mortality, and ribavirin may be given for life-threatening infection.

CRITICAL VIRAL INFECTIONS CAUSING VESICULAR SKIN LESIONS

Herpesviruses: HSV, VZV, Herpes B Virus

Herpes simplex virus (HSV), varicella-zoster virus (VZV), and herpes B virus are large, enveloped DNA viruses that exhibit lifelong latent infection.[150,151] They all cause vesicular skin lesions but may cause other systemic manifestations. In the ICU, these viruses may be encountered as part of a life-threatening clinical syndrome with primary infection or as a result of secondary reactivation of latent infection, typically causing mild breakouts of skin lesions.

Herpes Simplex Virus

HSV infections are common, with an estimated two-thirds of the world's population latently infected. Characteristically, HSV-1 is associated with orolabial disease, and HSV-2 is associated with genital infection, although this is not a rigid distinction. Primary infections are usually associated with mucosal lesions and systemic signs and symptoms.[152] Localized reactivation of HSV is common in critically ill patients and may require episodic treatment. The diagnosis is usually suspected clinically with clusters of vesicular lesions on an erythematous base, usually in the orolabial or anogenital areas. A precise diagnosis can be established easily by PCR on scrapings from the lesions. Patients with atopic eczema or severe burns may develop extensive infections.

Primary infection with HSV-2 is commonly accompanied by aseptic meningitis and may recur with secondary flares (Mollaret meningitis). Meningeal symptoms usually start 3–12 days after the onset of genital lesions. Transverse myelitis and autonomic nervous system dysfunction may also occur.[153]

Reactivation of latent HSV-1 infection, potentially from the trigeminal or autonomic nerve roots, may cause extension of the virus into the central nervous system (CNS) and cause encephalitis in adults. HSV-1 encephalitis is frequently seen in the ICU. Patients typically present with acute neurologic change and fever, including altered mental status, focal deficits, and/or seizures. There is a notable absence of vesicular lesions or rash. The cerebrospinal fluid (CSF) is typically lymphocytic and can be tested by PCR for HSV-1. MRI of the brain characteristically demonstrates temporal lobe enhancement.[154] Other potential serious complications of primary HSV infection include hepatitis, pneumonia, or thrombocytopenia. In immunocompromised hosts, reactivation of HSV-1 or HSV-2 may be associated with disseminated infection or severe local esophagitis, hepatitis, or pneumonia. Neonatal herpes, occurring in infants of mothers with primary or reactivated infection at the time of delivery, carries a high risk of disseminated fatal infection.

Varicella Zoster Virus

Primary VZV infection causes chickenpox, whereas reactivation of VZV causes shingles (herpes zoster). Chickenpox is typically a mild pediatric disease, but primary infection by VZV in adults or immunocompromised patients may lead to severe, life-threatening infection. The typical primary illness is usually associated with fever, constitutional symptoms, and a vesicular skin rash. Most skin lesions are small vesicular lesions with an erythematous base. Successive crops of lesions occur over 2–4 days, leading to clusters of lesions at all stages of development (from fresh vesicles to crusted lesions).[155] Secondary bacterial infections of vesicular lesions are relatively common, usually involving *S. aureus* and *S. pyogenes*.[156] This should be suspected with recrudescence of fever after an initial period of improvement after the systemic manifestations of chickenpox. Clinicians should monitor for signs of severe infection as a result of toxic shock syndrome.[157]

Chickenpox is associated with pneumonia in 1 in 400 cases of infection.[150] A larger proportion of people may have some pulmonary involvement, but it is typically asymptomatic. Pregnant women and immunocompromised patients are at high risk of severe pneumonia. Chickenpox pneumonia is generally manifested by cough and shortness of breath 3–5 days after the onset of the rash. Chest radiography typically shows a reticulonodular infiltrate, and respiratory failure may occur. Neurologic complications of chickenpox include encephalitis, acute cerebellar ataxia (1 in about 4000 cases), and cerebral angiitis. Encephalitis resulting from VZV is less common than pneumonia. The typical manifestations occur within 2 weeks of the chickenpox rash, and CNS symptoms are indistinguishable from HSV encephalitis. Typical features include small to large vessel vasculopathy, ischemic or hemorrhagic strokes, demyelinating lesions, and/or ventriculitis.[158]

Shingles is caused by reactivation of latent VZV and is characterized by a unilateral vesicular eruption that follows a distinct dermatomal distribution. Rash is frequently accompanied by neuritis, but systemic manifestations are uncommon. Diagnosis is made by clinical assessment and/or confirmation by PCR of vesicular scrapings. Immunocompromised patients with shingles may develop disseminated cutaneous infection resembling chickenpox and spreading to other organ systems.

Herpes B Virus (Cercopithecine Herpesvirus 1)

Herpes B virus (Macacine herpesvirus 1) infection is a relatively benign disease in macaque monkeys that resembles HSV-1 in humans. Rarely, herpes B virus may infect humans, causing a life-threatening encephalitis. Those at risk of herpes B virus are typically immunocompetent laboratory workers in close contact with macaque monkeys that are exposed via monkey bites, scratches, or mucous membrane exposure to monkey secretions. Monkeys of the *Macaca* genus (rhesus and cynomolgus monkeys) are considered to be at the highest risk.[159] An incubation period of 2–14 days is usually observed after the bite or

scratch. Initial symptoms are nonspecific but include fever, malaise, and headache. A cluster of small vesicles may occur at the bite site. Severe encephalomyelitis may ensue, with death occurring in days. In the United States, only one reference laboratory is equipped to identify the virus. Prompt and exhaustive cleaning of wounds, followed by early initiation of postexposure acyclovir or valacyclovir, may prevent the occurrence of severe disease.[160]

Poxviruses: Smallpox and Monkeypox

The global effort to eliminate the scourge of Variola virus (smallpox) from the earth in 1979 remains one of the greatest medical accomplishments of humankind.[161] This double-stranded DNA virus is still relevant today only because of concerns regarding its potential in bioterrorism.[162,163] Jenner's vaccination strategy using a closely related cowpox virus to provide cross-species protective immunity to smallpox eventually eradicated the last human cases of smallpox. A recent added level of protection to smallpox is now available as a novel, oral, antiviral agent called *tecovirimat*. The drug inhibits final cell membrane assembly and release of viral particles.[164]

The classic smallpox eruption starts in the oropharynx and spreads to the face, palms, soles, and centrifugally. Initially macules evolve to papules, and ultimately vesicles and pustules over a 1-week period. All lesions are typically at the same stage of development, and fever and systemic symptoms predate the onset of rash. In contrast, the lesions of chickenpox are present at different stages of development, and fever occurs with the onset of the rash. The rash of smallpox could also be confused with monkeypox, generalized vaccinia, eczema vaccinatum, coxsackievirus infection, HSV infection (especially eczema herpeticum), rickettsialpox, insect bites, drug eruptions, and acne. The poxviruses and their major clinical manifestations are listed in Table 119.3.

Monkeypox

Monkeypox was first recognized in 1958 as a disease of primates and subsequently recognized in rodents. Beginning in 1970, cases in humans were reported in Central Africa. In 2003 cases occurred in the United States in residents of the Midwest who had contact with imported prairie dogs.[165] Patients developed vesicular skin lesions and fever with diaphoresis. Although case fatality rates of 4%–22% have been observed in outbreaks of the infection in Africa, none of the 11 patients in an American outbreak died.[165] There is no clear evidence as yet that tecovirimat is an effective treatment for monkeypox.

TABLE 119.3 Common Clinical Manifestations of Poxviruses

Virus	Clinical Manifestations
Variola (smallpox)	Diffuse vesicular rash; systemic disease; eliminated from the world by vaccination, but still a possible agent of bioterrorism
Monkeypox	Vesicular rash; lymphadenopathy may help differentiate from smallpox; increased risk after African monkey and rodent exposures
Vaccinia (cowpox)	Vesicular, sometimes hemorrhagic rash; may leave black eschar; postinfectious encephalitis may occur; historic use in smallpox vaccination; increased risk after exposure to infected cats
Parapoxvirus	Orf (localized vesicular lesion); increased risk after exposure to infected goats or sheep
Molluscipoxvirus	Molluscum contagiosum; may cause chronic genital lesions and other vesicular skin lesions
Tanapox virus	Vesicular rash; often a presenting as a single pox lesion; endemic to regions in sub-Saharan Africa

CRITICAL NEUROTROPIC VIRUSES

Flaviviruses: WNE, Zika, Japanese Encephalitis, St. Louis Encephalitis, Tickborne Encephalitis

West Nile Encephalitis Virus

West Nile encephalitis (WNE) virus is a neurotropic flavivirus that has circulated for several decades but re-emerged in North America in the 1990s.[166,167] Currently, the virus and its complications are found around the world. The majority of cases are transmitted by mosquitos, particularly in the presence of crows and/or blue jays, but transmission by blood transfusion or organ allograft have been reported.[168,169] Symptoms are nonspecific, but infected patients may experience high fevers, influenza-like illness, retroorbital pain, headaches, and confusion. Conjunctivitis, rash, and lymphadenopathy may be present. Although severe neurologic symptoms occur in <1% of infections, they can be serious, including acute flaccid paralysis (myelitis), a diversity of neuropathies, and meningoencephalitis. Case fatalities are highest in elderly patients.[170]

Zika Virus

Zika virus is a flavivirus first isolated in the 1950s, but it has come to significant attention after epidemics in the Americas, Caribbean, and Pacific in 2015 and 2016. The virus is endemic in tropical climates and transmitted by the *Aedes aegypti* mosquito. The vast majority of symptoms in adults are mild and self-resolving, including fever, maculopapular rash, and arthralgias. Zika virus is neurotropic to the developing fetus, and in utero transmission may result in microcephaly and significant developmental problems. Rarely, adult patients may suffer serious complications necessitating ICU care, including GBS, myelitis, and meningoencephalitis.[171]

Other Flaviviruses

Many other flaviviruses have neurotropic clinical manifestations, predominantly causing encephalitis that might cause serious complications. These viruses are distributed throughout diverse geographic locations around the world. The Japanese encephalitis (JE) virus is endemic in Southeast Asia and transmitted via the *Culex* mosquito, particularly in rural areas near rice paddies and pigs. St. Louis encephalitis (STE) has been found in virtually all U.S. states, Canada, and Mexico. Transmission also occurs via the *Culex* mosquito. Tickborne encephalitis (TBE) virus is found throughout Western Europe, Russia, China, and Japan. Unique to the flavivirus family, this disease is the only one transmitted by ticks *(Ixodes)*. Vaccinations are available for JE and TBE and are only recommended for those with potential for significant exposure and at serious risk of complications. Like WNE, the majority of infections with these agents are subclinical; however, severe systemic and neurologic manifestations can occur, particularly in older patients. Diagnosis is predominantly confirmed by clinical, serologic, and molecular methods. Treatment is supportive without approved specific antiviral therapy.

Paramyxoviruses: Hendra and Nipah Virus

Hendra and Nipah viruses have been associated with high mortality as a result of encephalitis or an acute pulmonary syndrome in Australia (Hendra virus) and Malaysia, Singapore, India, and Bangladesh (Nipah virus). The reservoir for these closely related viruses appears to be fruit bats. Viral transmission appears to occur from bats to horses (Hendra virus) or pigs (Nipah virus). Humans exposed to ill horses or pigs have

developed this potentially fatal infection. In Bangladesh, nosocomial transmission of Nipah virus may have occurred.

VIRAL HEMORRHAGIC FEVERS

Hemorrhagic fevers are caused by Filoviridae, Bunyaviridae, Arenaviridae, or Flaviviridae. Dengue hemorrhagic fever and yellow fever are reviewed in Chapter 123. Other less common, but life-threatening hemorrhagic fevers are reviewed here.

Filoviruses: Marburg and Ebola

Marburg and Ebola viruses are distinct genera in the Filoviridae family and are among the world's most virulent pathogens. Marburg virus appears to have originated in Uganda and Western Kenya, where it infected monkeys and subsequently humans. *Marburg* refers to a town in Germany where monkeys from Uganda infected medical researchers, who subsequently infected hospital staff.

The major subtypes of Ebola virus (Zaire, Sudan, Bundibugyo, Tai Forest) have occurred in Central Africa. Recent large epidemics have occurred and threatened global spread. The West African epidemic with the Zaire species in 2014 infected nearly 29,000 individuals with case-fatality rates of approximately 40%. Cases predominantly occurred in Guinea, Liberia, and Sierra Leone; however, imported cases occurred in the United States, United Kingdom, Italy, Spain, Mali, Nigeria, and Senegal. Additional secondary infections occurred in these countries, mainly nosocomial spread to healthcare workers.[172] The most recent epidemic continues in the North Kivu province of Democratic Republic of the Congo (DRC) (2018), where military conflict has presented significant challenges for treatment and prevention. An additional subtype (Reston) was discovered in Reston, Virginia, among infected monkeys imported from the Philippines but does not cause disease in humans.[173]

Marburg and Ebola virus infections have a typical incubation period of 5–10 days (range 2–21 days) and begin with the abrupt onset of fever, myalgia, and headache. Somnolence and delirium usually follow. Most patients have abdominal pain and diarrhea. Many have a maculopapular rash on the trunk. Hemorrhagic manifestations such as bleeding around needle puncture sites and from the mucous membranes become prominent. Most patients have significant thrombocytopenia, leukopenia, and elevated transaminase levels. Viral culture, serology, and PCR have all been used to establish the diagnosis. At present, management is purely supportive and predominantly geared to fluid replenishment from GI loses and use of broad-spectrum antibiotics in late and severe cases to treat secondary bacterial infection from mucosal translocation. Several investigational therapies are under development, including monoclonal antibodies (mAb114, REGN-EB3, ZMapp), nucleotide analogues (remdesivir), and immunizations. Additionally, strict contact isolation precautions are necessary.

Bunyaviruses: Hantavirus and Nairovirus (Crimean-Congo Hemorrhagic Fever)

Hantavirus and Crimean-Congo hemorrhagic fever (CCHF) virus are from the Bunyaviridae family of viruses. Hantaviruses cause hemorrhagic fever with renal syndrome (HFRS) and hantavirus pulmonary syndrome (HPS). There are over a dozen human pathogenic strains of hantavirus. The subtypes Hantaan, Dobrava, and Seoul cause moderate to severe HFRS in Asia and Europe, whereas Puumala causes a mild form of HFRS.[174] Unlike other Bunyaviridae, hantaviruses do not appear to have an arthropod vector and are usually transmitted via aerosols of virus-contaminated rodent urine or feces. The incubation period is typically 2 weeks. Initially, patients develop fever, headache, dizziness, blurred vision, abdominal pain, and back pain. Petechiae may be evident on the palate and the trunk; most patients have significant thrombocytopenia. After 4–7 days, significant shock can occur. In patients who survive, oliguria and mucosal hemorrhage occur, followed by polyuria. Sin Nombre virus and Andes virus cause HPS in North America and South America, respectively.[174] HPS is characterized by fever and severe vascular permeability with capillary leak, leading to shock and pulmonary edema.

CCHF is a severe hemorrhagic fever with a mortality rate ranging from 3% to 30%; it has been described in parts of Africa, Asia, Eastern Europe, and the Middle East.[175] It has the most extensive geographic distribution of medically important tickborne viral diseases. CCHF occurs through tick bites, by contact with blood or tissues from viremic livestock, and after contact with patients with CCHF during the acute phase of infection.[175] Patients have severe thrombocytopenia, disseminated intravascular coagulation, and extensive bleeding, with hepatitis and rhabdomyolysis. Diagnosis is made by enzyme-linked immunoassay (ELISA) and/or PCR. The clinical course of CCHF includes an incubation period (3–7 days), a pre-hemorrhagic period (3–7 days) with flulike symptoms, a hemorrhagic period (2–3 days), and a convalescence period. Supportive therapy is the most essential part of the management of CCHF. Ribavirin (30 mg/kg as an initial dose, then 15 mg/kg 6-hourly for 4 days, then 7.5 mg/kg 8-hourly for 6 days) is the recommended antiviral agent for severe CCHF, although its mechanism of action is unknown.[175]

Arenaviruses: Lassa Fever and South American Hemorrhagic Fevers

Lassa fever and South American hemorrhagic fevers are caused by Arenaviridae. Lassa fever occurs in West Africa. South American hemorrhagic fevers occur in Argentina, Bolivia, and Venezuela. Lassa fever is transmitted via rodents, but subsequent nosocomial transmission has been extensive. Many cases of Lassa fever are only mildly symptomatic. Some patients develop high fever, pharyngitis, and retrosternal chest pain accompanied by significant mucosal bleeding. Hypotension, renal failure, and pulmonary edema may follow. Serology can be used to establish the diagnosis, but the virus is also easily isolated from blood during the first week of illness, when viremia is often striking. Use of ribavirin has been associated with a decrease in mortality.[176]

South American hemorrhagic fevers (Argentine, Bolivian, and Venezuelan) usually present with unremitting fever accompanied by a variety of nonspecific symptoms. Petechiae are often present on the palate and the skin, especially the axilla; mucosal bleeding may result. Pulmonary edema may occur. Management is extremely difficult owing to the combination of hypotension and refractory pulmonary edema. The diagnosis can be established by serologic tests. No specific therapy is available.

OTHER SYSTEMIC CRITICAL VIRAL INFECTIONS

Herpes Viruses: CMV, EBV, HHV 6, HHV 8

Aside from the vesicular herpes viruses (HSV-1, HSV-2, VZV, and herpes B virus), five other herpes viruses may cause life-threatening infection, by primary or latent reactivation, particularly in immunocompromised hosts. These include cytomegalovirus (CMV); Epstein-Barr virus (EBV); and the human herpesviruses (HHV) types 6, 7, and 8.

Cytomegalovirus

CMV infection is a classic cause of severe infection in immunocompromised hosts, especially transplant recipients and patients with human immunodeficiency virus (HIV) infection.[177–179] Infection can be primary or the result of reactivation. The risk of end-organ CMV

infection depends on the degree of immunosuppression and whether the infection is primary or reactivated. For solid organ transplant recipients, there is a significant risk of primary infection in patients who were seronegative for CMV before transplantation and received an organ from a seropositive donor.[177] The organs commonly affected by CMV infection include the esophagus, colon, retina, and lungs. Virtually any organ can be infected, including the CNS. Some patients present with fever, malaise, and hematologic abnormalities (cytopenias), without specific end-organ abnormalities.

Given the high risk of CMV infections in transplant recipients, strategies should be employed to prevent CMV infections.[177,180,181] Two options are prophylaxis or preemptive therapy. *Prophylaxis* implies the administration of preventive therapy to all persons at risk.[177] In contrast, *preemptive* therapy is the administration of antiviral therapy only to persons at highest risk, as determined by a positive result on a regularly monitored serum PCR to detect CMV viremia.[177] Such therapy is given even if the patient is asymptomatic.

Epstein-Barr Virus

Primary EBV infection may be associated with fever, malaise, and hematologic abnormalities in immunocompromised patients (and also in some immunocompetent individuals). EBV infection may be associated with the development of malignancies such as posttransplant lymphoproliferative disorder.[182–184] In some transplant populations, regular quantitative monitoring of EBV in peripheral blood by PCR is performed to determine the risk of significant EBV infection.[185]

Human Herpes Virus-6

HHV-6 is a ubiquitous viral infection that usually occurs in infancy. Primary HHV-6 infection and possibly reactivation of infection in immunocompromised patients can be associated with serious disease.[186,187] HHV-6 seems to have neurotropism—in addition to fever, HHV-6 infection may be associated with confusion, coma, and seizures.[188,189] Occasionally, CSF examination is normal except for increased protein and the finding of HHV-6 by PCR.

Human Herpes Virus-8

HHV-8 is associated with Kaposi sarcoma, primary effusion lymphoma, and Castleman syndrome.[190,191] It may be transmitted via organ allograft in solid organ transplantation. Primary infection in immunosuppressed patients may be associated with high fever, thrombocytopenia, other severe cytopenias, and mental state abnormalities.[192] Detection of HHV-8 by PCR in whole blood can establish the diagnosis.

Other Systemic Viruses

Adenoviruses

Adenoviruses have a myriad of presentations in immunocompetent and immunocompromised hosts. Adenovirus infection in immunocompetent individuals is rarely associated with severe disease.[193] Although adenovirus infection in immunocompromised hosts may have trivial manifestations, severe diseases may certainly occur. In recipients of hematologic stem cell transplantation, adenoviruses may cause interstitial pneumonitis, hepatitis (including ascending cholangio-hepatitis), hemorrhagic cystitis, nephritis, hemorrhagic colitis, CNS disease, and disseminated infection.[193] In solid organ transplant recipients, the primary site of adenovirus disease is usually related to the transplanted organ. Clinical manifestations of adenovirus infections described in solid organ transplantations include pneumonia, hepatitis, nephritis, hemorrhagic cystitis, enteritis, and disseminated disease.[193] Adenovirus infection in patients with HIV may cause pneumonia, hepatitis, meningoencephalitis, nephritis, and GI and disseminated disease.[193]

Polyomaviruses: JC and BK Virus

The most commonly encountered polyomaviruses are JC virus and BK virus. JC virus may be associated with progressive multifocal leukoencephalopathy, a progressive and ultimately fatal neurologic disease occurring in profoundly immunosuppressed individuals, such as patients with advanced HIV infection. BK virus is associated most commonly with renal infection in renal transplant recipients.[194] This infection is usually not accompanied by systemic manifestations such as fever but is frequently associated with nephropathy and rising serum creatinine. The mainstay of therapy is to reduce immunosuppressive medications. Without resolution of infection, patients are at higher risk of allograft dysfunction and loss.[195] Patients with hematopoietic stem cell transplants and BK virus infection are at risk of hemorrhagic cystitis after engraftment.

Other Acute Viral Syndromes

Many other viruses can cause life-threatening complications such as aseptic meningitis, encephalitis, pneumonia, or hepatitis. Because they are less common than those described in this text, they are not discussed in detail but are summarized in Tables 119.4 and 119.5 and elsewhere in this text. Viruses are continually evolving and because of their genetic plasticity, modified or entirely new pathogens may emerge. In the right setting, viruses may become more contagious and transmissible and/or develop increased virulence with serious health repercussions.

ANTIVIRAL DRUGS

Because of the increasing recognition of viruses in the ICU and the potential for some of the viruses to cause life-threatening infection, it is imperative that ICU clinicians maintain an understanding of antiviral drug regimens and their indications. This section reviews commonly used antivirals in the ICU, with the exception of HIV and viral hepatitis therapies. Antivirals for influenza are reviewed earlier in the text.

Acyclovir

Acyclovir is a deoxyguanosine analog that inhibits viral DNA polymerase. When incorporated into viral DNA, it acts as a chain terminator. Acyclovir has its greatest clinical utility against HSV-1, HSV-2, and VZV. It has only minor activity against CMV; therefore ganciclovir is preferred. There are rare strains of acyclovir-resistant HSV, whereas acyclovir-resistant VZV is very uncommon. Acyclovir is available in oral and IV formulations. It penetrates the CSF reasonably well, and CSF levels are about 50% of plasma levels.[196] Acute mucosal HSV is typically treated with 200 mg orally five times per day; however, valacyclovir may be preferred because of its higher oral absorption and lower dosing intervals. VZV infections can be treated with 800 mg orally five times per day. In HSV encephalitis, acyclovir is usually given by IV at 10 mg/kg every 8 hours. Dose reduction is required in the presence of renal dysfunction. Patients should be monitored for neurotoxicity, usually manifesting as confusion, hallucinations, and tremors. As acyclovir can cause crystalline nephropathy, patients receiving the drug should be well hydrated.

Valacyclovir

Because the bioavailability of orally administered acyclovir is low, valacyclovir (the l-valyl ester prodrug of acyclovir) was developed. It is usually administered twice daily for non–life-threatening HSV infections and three times daily for VZV infections.

Famciclovir

Famciclovir is a prodrug of penciclovir, which is active against HSV and VZV. Similar to acyclovir, penciclovir is an inhibitor of viral DNA synthesis. In general, acyclovir-resistant strains are also resistant to penciclovir. Dose adjustment of famciclovir is needed in renal insufficiency.

TABLE 119.4 Viruses That Cause Aseptic Meningitis or Encephalitis

Virus	Clinical Manifestations
Enteroviruses	Common cause of aseptic meningitis; rapid diagnosis available via PCR of CSF
HSV-1/2	In adults usually the result of reactivation; rapid diagnosis available via PCR of CSF; HSV-1 commonly causes herpes encephalitis; HSV-2 often causes aseptic meningitis
VZV	May cause encephalitis after chickenpox or in immunocompromised hosts; relatively uncommon; diagnosis made via PCR of CSF
HHV-6	Uncommon cause of encephalitis in immunocompromised hosts, particularly in solid organ transplant recipients
JC virus	May cause progressive multifocal leukoencephalopathy in immunocompromised hosts, particularly HIV-infected patients
Japanese encephalitis	Endemic cause of encephalitis in Southeast Asia, particularly after exposure to rural rice paddies, near farms with pigs
St. Louis encephalitis	Outbreaks have occurred throughout the United States; spread by *Culex* mosquito; spectrum of disease including headache, aseptic meningitis, and encephalitis
West Nile virus	Endemic globally, most common cause of encephalitis in United States and Canada; spread by mosquitos; most cases asymptomatic; causes ILI, and some may develop encephalitis
Tickborne encephalitis	Occurs mostly in Europe, Siberia, and the Far East; related North American TBE caused by Powassan virus; causes acute febrile illness, aseptic meningitis, meningoencephalitis, and acute flaccid paralysis
Nipah virus	Occurs in Southeast Asia; severe and often fatal meningoencephalitis; increased risk after zoonotic exposure
Hendra virus	Occurs in Australia; causes ILI leading to fatal respiratory illness or encephalitis; increased risk after zoonotic exposure
Rabies virus	Global zoonosis transmitted after bite from rabid animals (racoons, dogs, bats, etc.); postexposure with active and passive immunotherapy is important
California encephalitis	Caused by La Crosse, Jamestown Canyon, and other related viruses; second most common cause of encephalitis in the United States and Canada
Human immunodeficiency virus	Can cause encephalitis during the early/acute phase of HIV infection

CSF, Cerebrospinal fluid; *HHV-6,* human herpesvirus 6; *HSV,* herpes simplex virus; *ILI,* influenza-like illness; *PCR,* polymerase chain reaction; *TBE,* tickborne encephalitis; *VZV,* varicella-zoster virus.

TABLE 119.5 Viruses That Can Cause Severe Pneumonia

Virus	Clinical Manifestations
Respiratory syncytial virus	Common cause of lower respiratory tract infection in infants; circulates seasonally with influenza; can cause ARDS and other systemic manifestations in adults
Influenza	Well-known cause of endemic and epidemic upper and lower respiratory tract infection
Parainfluenza virus	Among most common URTI globally; causes croup in children; may cause severe pneumonia or exacerbation of chronic pulmonary disease
Measles virus	Common cause of pneumonia in children in developing nations; re-emerging in areas with low vaccine uptake
Coronaviruses	Severe acute respiratory syndrome (SARS), Middle East respiratory syndrome (MERS), coronavirus disease 2019 (COVID-19); emerging in epidemics
CMV	Cause of pneumonia only in immunocompromised hosts
VZV	Pneumonia can complicate chickenpox
Adenovirus	Ubiquitous virus; may cause severe pneumonia in immunosuppressed hosts
Hantavirus	Most severe form related to Sin Nombre virus (SNV); febrile illness with severe capillary leak and pulmonary edema; increased risk after exposure to rodents
Hendra virus	Occurs in Australia; may cause fatal pneumonia; increased risk after zoonotic exposure

CMV, Cytomegalovirus; *URTI,* upper respiratory tract infection; *VZV,* varicella-zoster virus.

Ganciclovir

Similar to acyclovir, ganciclovir is a deoxyguanosine analog that inhibits viral DNA polymerases. Its primarily used in the treatment of CMV infections but also has activity against HSV and VZV. Patients with tissue-invasive CMV are treated initially with induction ganciclovir, 5 mg/kg IV every 12 hours. Alterations in dose and frequency are required in patients with renal dysfunction. Typically, maintenance therapy is given at a reduced frequency in patients who have received 2–3 weeks of induction therapy. Myelosuppression is the major toxicity of ganciclovir. Neutropenia typically begins to occur in the second week of ganciclovir therapy. Regular monitoring of hematologic parameters is mandatory for patients receiving ganciclovir. CNS abnormalities such as headaches and confusion have been well described in patients receiving ganciclovir. Ganciclovir also can be administered into the eyes via an ocular implant.[197,198] Resistance of CMV to ganciclovir can occur after mutations in the *UL97* phosphotransferase gene.[199] Risk factors for ganciclovir resistance include prolonged exposure to ganciclovir (usually several months), ongoing active viral replication because of severe immunosuppression, lack of prior CMV immunity, and inadequate antiviral drug delivery with oral ganciclovir.[199]

Valganciclovir

The oral bioavailability of ganciclovir is poor. Valganciclovir, a prodrug of ganciclovir, can be used to enhance bioavailability. Valganciclovir may be used as a prophylaxis against CMV infections in those undergoing solid or hematopoietic transplantation[180] or as a reasonable step-down alternative to ganciclovir in maintenance therapy for CMV disease.

Foscarnet

Foscarnet is an alternative anti-CMV antiviral, typically reserved for CMV-resistant infections (or for those intolerant of ganciclovir). Foscarnet also has activity against HSV and VZV, including acyclovir-resistant and ganciclovir-resistant strains. Although foscarnet and ganciclovir may have synergistic activity against CMV, there is greater toxicity and no proven benefit to using them in combination.[200] Foscarnet is available in an IV formulation only. Toxicity is common with foscarnet. Nephrotoxicity is a major dose-limiting side effect. Electrolyte abnormalities are also common, especially hypocalcemia, hypophosphatemia, hypomagnesemia, and hypokalemia, which may be symptomatic. Foscarnet may produce painful genital ulcerations; saline loading may diminish the likelihood of nephrotoxicity or ulceration.

Cidofovir

Cidofovir is a broad-spectrum nucleotide analog that is active against many DNA viruses, including herpesviruses, polyomaviruses, poxviruses, and adenoviruses. It is active against acyclovir-resistant and ganciclovir-resistant HSV and CMV. Cidofovir is administered via IV once a week or once every 2 weeks. Its use is accompanied by high rates of nephrotoxicity. Neutropenia occurs in 20% of patients receiving this drug.

Ribavirin

Ribavirin was widely used in combination therapy for hepatitis C virus infection before the advent of direct-acting antivirals, but it is discussed here in the context of its use against other viruses. In vitro, ribavirin has activity against a wide range of DNA and RNA viruses. Ribavirin (aerosolized) is approved by the U.S. Food and Drug Administration for the treatment of bronchiolitis and pneumonia caused by respiratory syncytial virus (RSV). It has been used systemically in the treatment of some hemorrhagic fevers. Systemic ribavirin administration is associated with hemolytic anemia and is highly teratogenic. Use of aerosolized ribavirin in patients with mechanical ventilation or aerosolizing procedures is controversial because of potential exposure to healthcare workers; thus use of aerosol containment systems is recommended.

KEY POINTS

- Influenza has exacted an enormous cost to civilization since antiquity and continues to cause annual epidemics and excess deaths to the present day.
- Influenza A is responsible for periodic pandemics when influenza viruses from birds reassort with human-adapted viruses to generate novel, hybrid viruses to which the entire human population is susceptible.
- Secondary bacterial pneumonia is common with or after influenza infection, usually caused by *S. pneumoniae* or *S. aureus.*
- The mainstay of treatment for severe influenza includes supportive ICU care, neuraminidase inhibitors (oseltamivir), and often ancillary treatments for refractory hypoxemia.
- Annual influenza vaccination is the best way to prevent and/or minimize illness severity and is recommended for patients at risk and all healthcare workers.
- Coronaviruses have a propensity to emerge into highly transmissible pathogens causing potentially severe pneumonia, including SARS, MERS, and COVID-19; treatment is supportive, and prevention with appropriate infection control strategies is imperative to limit spread.
- Measles is re-emerging because of lack of herd immunity and low vaccination rates; the typical manifestations include fever, rash, coryza, and conjunctivitis and can be associated with severe pneumonia in otherwise healthy adults.
- Flares of latent herpesvirus infection are common in the ICU, vesicular rashes in the oropharynx or genital region should be swabbed and treated for HSV; dermatomal vesicular rashes should be checked for herpes zoster (VZV).

Human Immunodeficiency Virus Infection

Piotr Szychowiak, Élie Azoulay, and François Barbier

INTRODUCTION

The burden of human immunodeficiency virus (HIV) infection remains a global public health issue, with an estimated 1.8 million new infections and almost 800,000 acquired immunodeficiency syndrome (AIDS)–related deaths in 2018.[1] Around 38 million people are currently living with HIV worldwide (including 8 million patients not aware of their seropositive status), corresponding to a ~50% increase over the past two decades that reflects both the continuous dissemination of the virus and a striking improvement of life expectancy in patients with sustained viral replication under combination antiretroviral therapies (cARTs). Indeed, since their advent in 1996, dramatic progresses in the efficacy and safety of cART schemes have converted HIV infection from a rapidly fatal disease to a chronic condition requiring long-term care. Though access to cART remains a major challenge in low-income countries and certain sociologic clusters in middle- and high-income regions,[2] roughly two-thirds of the global seropositive population are now receiving these drugs.[1] This proportion is growing steadily, which translates into a continuous decrease in the incidence of opportunistic infections (OIs) and other AIDS-related events compared with the early years of the HIV pandemic.[3,4] Meanwhile, lifelong residual viral replication and/or cART-related toxicities may result in HIV-associated non-AIDS (HANA) conditions, especially chronic obstructive pulmonary disease (COPD), atherosclerosis, renal dysfunction, certain neoplasms, and liver diseases.[4]

HIV-infected patients are at high risk for critical illness because of the occurrence of severe OI in those with advanced immunosuppression, a marked susceptibility to bacterial sepsis and tuberculosis at every stage of HIV infection, and a rising prevalence of HANA conditions in patients aging under cART. Along with a steady decline in AIDS-related admissions and an opposite trend in those for exacerbated comorbidities, several patterns of intensive care have changed in this population over the late cART era, notably the emergence of new mechanisms of immunosuppression not directly resulting from AIDS (e.g., antineoplastic chemotherapy or solid organ transplantation [SOT]), the management of cART at the acute phase of critical illness, and a dramatic enhancement in short-term survival that mainly ensues from general advances in ICU practices.[5,6]

Here, we seek to provide a comprehensive overview of intensive care in HIV-infected patients, including current epidemiologic features, reasons for intensive care unit (ICU) admission, use of life-sustaining therapies, and determinants of short-term outcome. We also summarize the available evidence regarding the management of cART in the ICU, with a focus on severe adverse events, administration issues, and timing of initiation in patients admitted for AIDS-related OI.

THE CONTINUUM OF HIV INFECTION: IMPACT ON CLINICAL PRESENTATION AT ICU ADMISSION

Acute HIV Infection

Acute HIV infection is characterized by a rapid rise in plasma HIV RNA levels and may trigger a myriad of nonspecific clinical signs such as fever, myalgia, disseminated lymphadenopathy, and rash that mimic mononucleosis syndrome.[7] Yet severe forms with acute encephalitis, myocarditis, or multiple organ failure caused by hemophagocytic lymphohistiocytosis (HLH) have been reported occasionally and may require ICU admission.[8–11]

Progression to AIDS

After 3–4 weeks, the viremia level plateaus because of the appearance of HIV-specific antibodies. The disease then becomes chronic, with a gradual decline in $CD4^+$ T lymphocytes (hereafter referred to as CD4 cells) resulting in the occurrence of AIDS-defining conditions within 2–20 years after seroconversion. Of note, both innate and humoral immune alterations occur upon early HIV infection, explaining the high risk of bacterial infection and tuberculosis at this stage. Without cART, HIV infection nearly always progresses to end-stage AIDS with wasting, recurrent OIs, and other ultimately fatal complications (e.g., HIV encephalitis).

Late-stage HIV infection remains a common reason for ICU admission in settings or sociologic clusters with limited access to diagnosis, cART, and specialized aftercare—migrants, homeless people, and other individuals without adequate health insurance coverage are particularly affected in high-income countries. These patients primarily present with severe AIDS-related OIs against a background of poor nutritional status and advanced immunosuppression, similarly to the early years of the HIV pandemic (1980–1995). *Pneumocystis jirovecii* pneumonia (PCP), cerebral toxoplasmosis, and tuberculosis are the leading diagnoses, especially for inaugural admissions.[5,6] Such patients account for 10%–30% of all ICU admissions of HIV-infected individuals (Table 120.1), though this proportion appears to be dwindling over the past decade.[12–18] Of note, severely immunosuppressed hosts—that is, those with CD4 cells $<100/\mu L$—may have two or more concurrent OIs accounting for clinical presentation at ICU admission.

Severe AIDS-defining conditions may also occur in patients with uncontrolled viral replication despite cART. However, the contemporary therapeutic armamentarium enables achieving viral suppression and immunologic restoration within 6 months in more than 90% of cases—even those involving resistant strains—with maintenance of OI prophylaxis (e.g., sulfamethoxazole plus trimethoprim [SXT] for PCP) until a protective CD4 cell threshold is achieved.[4,28] Beside compliance flaws, virologic failure in 2020 is mainly linked with procurement issues

TABLE 120.1 Critically Ill HIV-Positive Patients in the cART Era: Selected Recent Cohort Studies

Setting and Period (reference)	Patients, Number	Age, y[a]	Prior cART	Inaugural Admission	OI[b]	IMV	RRT	Vasopressors	Mortality

TABLE 120.2 Expected Rise in CD4 Cell Count After cART Initiation

Time Frame	CD4 Cell Count
First month	Increase by 50–75 cells/μL after initiation of cART
Each ensuing year	50–100 cells/μL per year
After several years	>500 cells/μL provided HIV replication remains suppressed (undetectable viral load)

cART, Combination antiretroviral therapy.

(i.e., stock-outs, defective supply, or lack of financial resources) in low- and middle-income countries, as in other environments with restricted access to cART.

Immune Recovery and Aging Under cART

cART initiation is mandatory in patients with acute infection or established AIDS; however, these drugs are beneficial and now recommended upon the early stage of asymptomatic HIV infection.[28] In patients with sustained treatment adherence, cART rapidly controls HIV replication, thereby elevating the CD4 cell count (ideally above 500/μL), although substantial interindividual variations exist regarding the pace and magnitude of recovery. Table 120.2 indicates the expected rise in CD4 cells after treatment introduction in cART-naïve patients.

Importantly, compared with age- and gender-matched seronegative individuals, cART-treated patients aging with sustained viral control are at increased risk for a broad spectrum of chronic HANA conditions that predispose to life-threatening complications,[12] including COPD, atherosclerosis (e.g., coronary heart disease or cerebrovascular disease), non–AIDS-defining cancers (especially lung, liver, and anal carcinoma), and renal or liver impairment.[29–34] Lifetime low-level inflammation caused by silent HIV replication in sanctuary sites, coinfections (e.g., cytomegalovirus [CMV], Epstein-Barr virus [EBV] or hepatitis B and hepatitis C virus [HBV/HCV]), habitus (e.g., tobacco or intravenous drug use), sequelae of past infectious processes, and long-term toxicity of certain antiretroviral medications may be implicated to varying degrees in the pathogenesis of these conditions.[4,35] A role for intestinal dysbiosis has also been suggested by recent metagenomics-based studies in cART-treated patients.[36] Overall, chronic HANA diseases now account for over 75% of deaths in HIV-positive patients living in high-income countries.[37]

Up to 70% of HIV-infected patients nowadays managed in the ICU are receiving long-term cART (see Table 120.1).[13,15,17,18,24–26] This epidemiologic shift translates into a continuous rise in non–AIDS-related ICU admissions—mostly for bacterial sepsis or exacerbated HANA conditions—which broadly exceeded those for severe OIs in the most recent cohorts. Furthermore, on the basis of encouraging outcomes, HIV infection is no longer a definite contraindication for SOT in patients with chronic kidney, liver, or heart failure, thereby enlarging the scope of critical illnesses in this population.[38–41]

CONVERGENCE OF CLINICAL PRESENTATION AND OUTCOMES IN CRITICALLY ILL HIV-INFECTED AND SERONEGATIVE PATIENTS

As a result of easier access to cART and sequential improvements in intensive care practices, critically ill HIV-infected individuals now share several similarities with the general population of ICU

patients. First, the reasons for ICU admission are evenly distributed between seropositive and HIV-uninfected patients, with acute respiratory failure (ARF, 40%–60% of all admissions), bacterial sepsis (10%–20%, mostly resulting from respiratory, intraabdominal, and bloodstream infections), and impaired consciousness (10%–20%) being the main clinical vignettes in both subgroups.[13,14,21,25] Admissions for acute kidney injury (AKI), gastrointestinal bleeding, acute-on-chronic liver failure, or scheduled postoperative management become more regular over time,[27] which merely reflects the increasing prevalence of at-risk comorbidities in HIV-infected individuals—for instance, HIV/HCV-coinfected patients are more prone to developing AKI.[5]

More than two-thirds of current admissions are not directly related to AIDS,[13,27] a proportion that is expected to amplify in the years to come. For a given reason of ICU admission, the etiologic spectrum is increasingly analogous to what is observed in HIV-uninfected subjects. Indeed, bacterial pneumonia, COPD exacerbation, complicated lung cancer, and pulmonary edema caused by congestive heart failure have become major causes of ARF, and stroke or *Streptococcus pneumoniae* meningitis are overtaking classic OIs of the central nervous system (CNS) in patients admitted for life-threatening neurologic disorders.[5,6] Again, chronic HIV infection stands out as an independent risk factor for most of these AIDS-unrelated conditions.

Notwithstanding a manifest propensity to these diseases, the clinical presentation of common community-acquired infections does not differ between HIV-infected patients with mild-to-moderate immunosuppression and their seronegative counterparts. This is notably shown for pneumonia caused by *S. pneumoniae* and *Legionella pneumophila,*[42,43] severe COVID-19,[44,45] or bacterial meningitis.[46] Excepting those with profound immune deficiency,[15,47] HIV-infected patients with sepsis exhibit no discrepancies in terms of plasma levels of host response biomarkers, disease severity, and survival when compared with HIV-uninfected controls.[48,49] Therefore the diagnostic workflow and initial management of HIV-infected patients with a protective CD4 cell count for usual OIs (i.e., above 200–250/μL) has no relevant particularities and should follow standard procedures and guidelines.[50]

The spectacular improvement of life expectancy in cART-treated patients offers long-term perspectives that justify maximizing the level of supportive care when indicated. Invasive mechanical ventilation (MV, 40%–50% of all admissions), vasopressors (15%–30%), and renal replacement therapy for AKI (8%–15%) are now used as frequently in seropositive individuals as in the general ICU population (see Table 120.1),[13,14,16,27,51,52] with comparable prognoses, including in patients at high risk of death, such as those admitted after cardiac arrest or with acute respiratory distress syndrome (ARDS).[53,54] Last-resort venovenous or venoarterial extracorporeal membrane oxygenation can be discussed in selected patients, with promising results in available reports.[55,56]

Strikingly, overall in-hospital mortality rates have fallen from more than 80% in the early 1980s to 20%–40% in the most recent Western cohorts, a shift that likely reflects general improvement in intensive care such as direct admission from the emergency department, prompt antibiotic initiation and hemodynamic interventions in patients with sepsis, or protective MV settings for ARDS.[13,24–27,51] Short-term outcomes of critically ill HIV-infected patients tend to equal those of seronegative subjects with similar demographics, chronic health status, and underlying diseases (e.g., HCV or malignancy), reason for admission, and extent of organ dysfunction.[21] CD4 cell count, HIV viral load, prior cART use, and an admission for an AIDS-related event (versus other diagnoses) are no longer associated with hospital survival.[14,15,57–59]

DIAGNOSTIC WORKFLOW AND THERAPEUTIC APPROACHES IN CRITICALLY ILL HIV-INFECTED PATIENTS

In HIV-positive patients, the CD4 cell count, which is the most readily available surrogate marker of immune deficiency, is essential to guide the etiologic work-up, notably in patients with ARF or neurologic disorders (Fig. 120.1).[5,6,60] Except tuberculosis, severe OIs occur almost exclusively in patients with CD4 cells below 200/μL. Some rare conditions, such as severe CMV infection or invasive aspergillosis, may occur at counts below 50/μL. Because a transient drop in CD4 cells is usual at the acute phase of sepsis, diagnostic algorithms should be based on a recent steady-state count, when available, rather than on the count measured at admission. Other baseline features to consider include a prior history of OI at risk for recurrence (e.g., tuberculosis), a geographic origin that predisposes to specific imported OIs (e.g., histoplasmosis), adherence to cART and anti-PCP prophylaxis when prescribed, and comorbidities.

Admission for Acute Respiratory Failure

In HIV-positive patients, community-acquired bacterial pneumonia (CAP) accounts for 35%–50% of all cases of ARF and is the main reason for ICU admission. The risk of CAP is markedly higher at all stages of HIV infection, but is greatest in patients with profound CD4 cell depletion and decreases with long-term cART use.[61,62] *S. pneumoniae* is the causative agent in 20%–40% of cases.[58,62] As previously mentioned, the clinical presentation and outcomes of *S. pneumoniae* CAP are the same in HIV-positive patients and in their HIV-negative counterparts matched on demographics and comorbidities.[43] Bacteremia is more common in HIV-positive patients, probably because of impaired alveolar macrophage and neutrophil functions.[61] *Haemophilus influenzae, Staphylococcus aureus,* and Enterobacteriaceae are involved in less than 10% of cases.[58,63] *L. pneumophila,* a major pulmonary pathogen in other immunocompromised patients, is uncommonly responsible for severe CAP in HIV-positive individuals.[58] Of note, *Pseudomonas aeruginosa* may cause CAP in patients with very low CD4 cell counts or underlying structural lung damage and should be considered when selecting empirical antibiotics in patients with these predisposing factors.[15,58,64] Lastly, lower respiratory tract infections caused by respiratory viruses (e.g., influenza, rhinovirus, adenovirus, human metapneumovirus, or respiratory syncytial virus) are now commonly diagnosed through multiplex molecular assays in HIV-infected patients, including those admitted to the ICU for ARF, whatever the extent of CD4 cell deficiency.[65,66] The incidence, clinical presentation, and outcomes of severe COVID-19 in cART-treated HIV-infected individuals appear similar to those reported in seronegative patients.[44,45]

PCP continues to decline in frequency but still accounts for 10%–20% of ARF cases and remains the most common AIDS-related OI encountered in the ICU, especially in patients without a previous diagnosis of HIV infection.[13,17,27,67] In HIV-positive patients, PCP manifests as fever, dry cough, and worsening dyspnea culminating in ARF within 2 or 3 weeks. Overall, about a third of all patients with AIDS-related PCP require initial ICU management.[68,69] Extrarespiratory failures (e.g., shock) suggest bacterial coinfection or another concurrent OI. The radiologic presentation evolves from reticular infiltrates to diffuse or patchy bilateral ground-glass opacities with alveolar consolidations (Fig. 120.2). By computed tomography (CT), parenchymal cysts and sparing of subpleural regions are usual at advanced stages of the disease, whereas lymph node enlargement and pleural effusion are not attributable to PCP and should trigger a search for a concurrent OI. The diagnosis of AIDS-related PCP is far easier than in other immunocompromised patients and relies on the visualization of *P. jirovecii* trophozoites or cysts

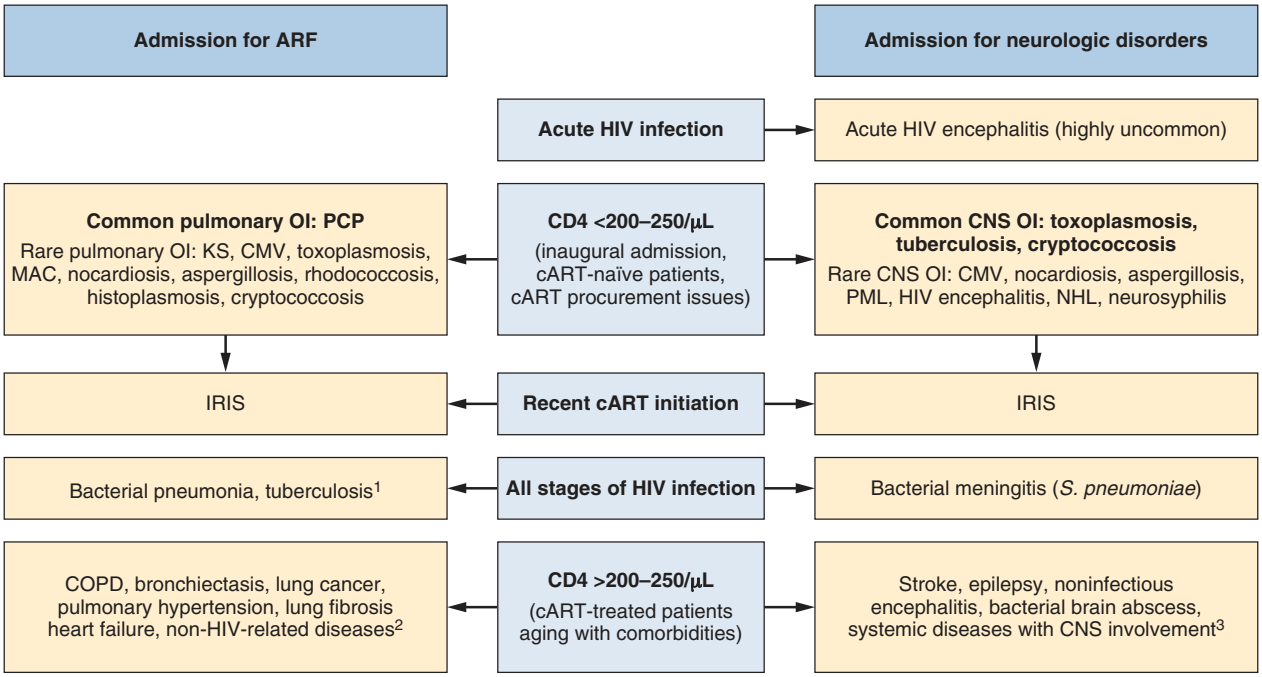

Fig. 120.1 Admission of HIV-Infected Patients for Acute Respiratory Failure or Acute Neurologic Impairment: Etiologic Panel According to Immune Status. *ARF,* Acute respiratory failure; *cART,* combination antiretroviral therapy; *CNS,* central nervous system; *COPD,* chronic obstructive pulmonary disease; *IRIS,* immune reconstitution inflammatory syndrome; *KS,* Kaposi sarcoma; *MAC, Mycobacterium avium* complex; *NHL,* non-Hodgkin lymphoma; *OI,* opportunistic infection; *PJP, Pneumocystis jirovecii* pneumonia; *PML,* progressive multifocal encephalopathy (JC virus encephalitis). [1]Pulmonary tuberculosis is also a major cause of IRIS that may lead to ARF; [2]Interstitial pneumonitis, drug toxicity, asthma, pulmonary embolism, others; [3]Sepsis, endocarditis, anoxia, metabolic disorders, drug toxicity or overdose, malignancies, thrombotic microangiopathy, others. (From Barbier F, Mer M, Szychowiak P, et al. Management of HIV-infected patients in the intensive care unit. *Intensive Care Med.* 2020;46[2]:329–342, Fig. 1.)

in bronchoalveolar lavage (BAL) fluid stained with Gomori-Grocott or Giemsa and immunofluorescence, which has greater than 90% sensitivity.[70] Induced sputum is only 50%–90% sensitive, may be challenging to perform in patients with ARF, and does not allow an exhaustive search for the bacterial or opportunistic coinfections seen in up to 20% of patients with pronounced immunosuppression.[70] The qualitative polymerase chain reaction (PCR) assay is valuable for diagnosing non–AIDS-related PCP,[71] notably in patients on prophylactic therapy, but lacks specificity in HIV-positive patients because of their 14%–69% prevalence of colonization. PCR may, however, be occasionally useful in ruling out PCP, given its greater than 95% negative predictive value.[72] A high fungal load by quantitative PCR supports infection as opposed to colonization,[73,74] but appears to be of limited added value, given the high performance of staining and immunofluorescence. Last, blood 1,3 β-D-glucan elevation (>80 pg/mL) is highly sensitive (92%–95%) but lacks specificity (78%–82%) because this component of the *P. jirovecii* cell wall increases in several other AIDS-related fungal infections (e.g., esophageal candidiasis).[75,76] SXT remains the first-line treatment (Table 120.3). Whether dihydropteroate synthase gene mutations hamper the clinical efficacy of sulfamethoxazole remains controversial,[77] and standard SXT dosages are still recommended in patients with PCP despite prophylaxis.[70] Adjunctive corticosteroid therapy reduces the risk of invasive mechanical ventilation (IMV) and in-hospital death and should be started within 72 hours in all patients with suspected or definite severe PCP (arterial partial pressure of oxygen [PO_2] <70 mm Hg while breathing room air).[70,78,79]

Pulmonary tuberculosis is responsible for up to 10% of ARF cases in Western cohorts of HIV-positive patients and remains a common inaugural AIDS-defining condition, notably in immigrants from endemic areas.[58,80] The presentation is usually typical at the early stages of HIV infection, whereas patients with CD4 cells below 200/μL more often have atypical radiologic patterns (miliary or diffuse alveolar infiltrates without upper lobe cavitation), extrapulmonary localizations, and no acid-fast bacilli (AFB) visible in sputum smears (see Fig. 120.2). Nucleic acid amplification tests (NAATs) should be performed on at least one respiratory sample in all HIV-positive patients with suspected tuberculosis, both to distinguish *Mycobacterium tuberculosis* from other mycobacteria in patients with AFB-positive sputum smears and to allow earlier identification of *M. tuberculosis* in AFB-negative sputum smears—in this last situation, NAATs are positive in 50%–80% of patients with culture-proven tuberculosis.[70] Some NAATs, such as Xpert MTB/RIF, also detect *rpoB* mutations conferring rifampicin resistance several weeks before the availability of conventional susceptibility test results.[81,82] Of note, interferon-gamma release assays may be negative in up to 30% of patients with active tuberculosis and should therefore not be used as a pivotal decision-making tool.[70] The first-line regimen for suspected or definite pulmonary tuberculosis in HIV-positive patients is a four-drug combination of isoniazid, rifampin, ethambutol, and pyrazinamide for 2 months (see Table 120.3). A growing amount of evidence supports benefits from corticosteroids in ARF caused by tuberculosis[83,84]; however, data from HIV-positive patients are lacking, and this adjunctive treatment is currently recommended only in patients with involvement of the CNS or pericardium.

A vast array of other pulmonary AIDS-related diseases may cause ARF in patients with fewer than 50–100/μL CD4 cells, albeit only very rarely. Examples include nontuberculosis mycobacterial diseases (e.g.,

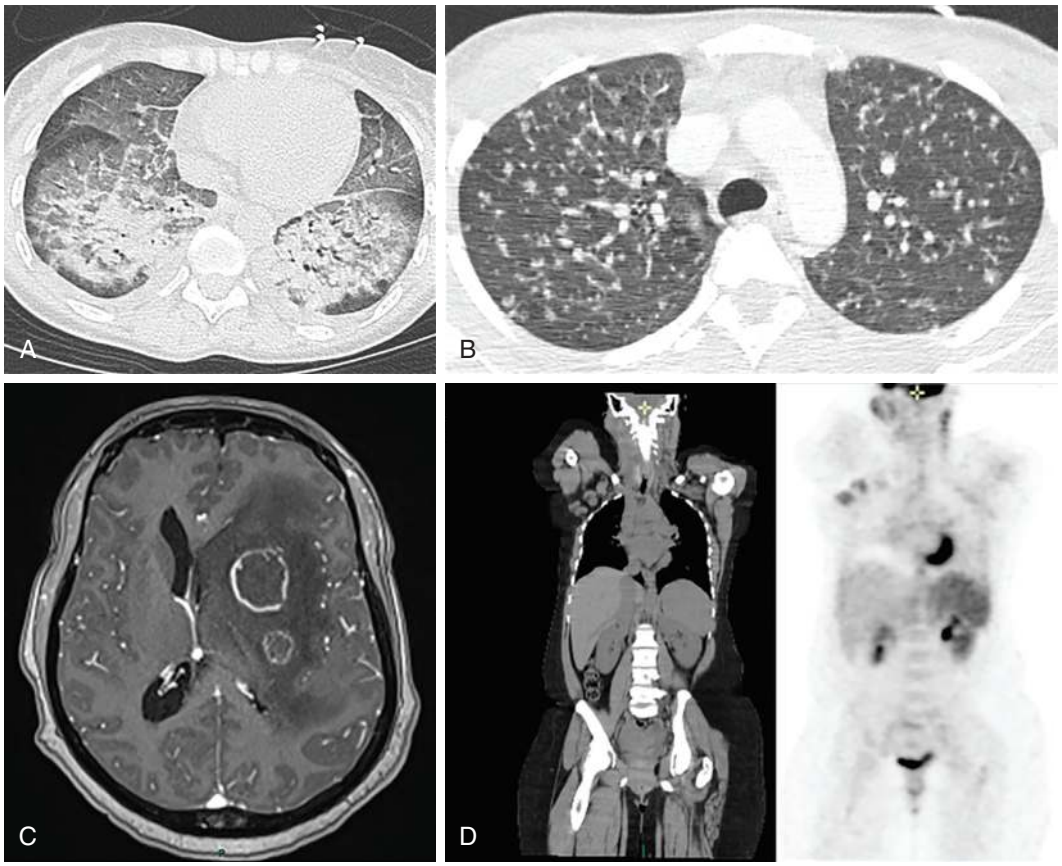

Fig. 120.2 AIDS-related opportunistic infections in the ICU: typical imaging features. **A,** *Pneumocystis jirovecii* pneumonia (chest CT scan showing diffuse ground-glass opacities with focal alveolar consolidations, thickened septal lines, relative sparing of the subpleural regions, and absence of pleural effusion). **B,** Lung involvement secondary to miliary tuberculosis (chest CT scan showing bilateral disseminated nodules without typical excavation in a patient with CD4 cell count <100/μL). **C,** Cerebral toxoplasmosis (T1-weighted cerebral magnetic resonance imaging showing gadolinium-enhanced lesions of the hemispheric grain matter with peripheral edema and mass effect). **D,** Multicentric Castelman disease (positron emission tomography showing enlarged liver, spleen, and axillary/cervical lymph nodes with hypermetabolic patterns). (From Barbier F, Mer M, Szychowiak P, et al. Management of HIV-infected patients in the intensive care unit. *Intensive Care Med.* 2020;46[2]:329–342, Fig. 2.)

Mycobacterium avium complex), pneumonia caused by opportunistic bacteria (e.g., *Rhodococcus equi* or *Nocardia* spp.) or fungi (e.g., *Aspergillus* spp., *Cryptococcus neoformans, Histoplasma capsulatum,* coccidioidomycosis, and mucormycosis), disseminated toxoplasmosis, and Kaposi sarcoma (see Fig. 120.2). Also, CMV has been detected by molecular assays in 5%–10% of patients with PCP or another OI, although CMV pneumonitis appears rare and should be diagnosed only in patients with nuclear inclusions in BAL fluid or lung biopsies or with diffuse interstitial infiltrates or other suggestive patterns by chest CT (e.g., ground-glass opacities, focal consolidation, or parenchymal micronodules).[70]

At last, the prevalence of ARF caused by exacerbated HANA conditions (especially COPD, lung cancer, and, to a lesser extent, pulmonary hypertension) will probably continue to rise in the near future in cART-treated patients aging with sustained viral control. In these patients, the diagnostic work-up does not differ from that in HIV-negative subjects (see Fig. 120.1).[5,6]

Admission for Neurologic Disorders

The incidence of AIDS-related diseases involving the CNS has dropped sharply in high-income countries since the introduction of cART.[70] In a single-ICU study, AIDS-related diseases accounted for only 42% of admissions for altered consciousness, with the most common diagnoses being cerebral toxoplasmosis, tuberculous meningitis, and cryptococcal meningitis.[57] Other OIs such as CMV encephalitis, progressive multifocal leukoencephalitis caused by JC virus, neurosyphilis, cerebral aspergillosis, nocardiosis, and histoplasmosis are exceedingly rare causes of neurologic failure in HIV-positive patients.[27,57] Contrast-enhanced CNS imaging—preferentially magnetic resonance imaging (MRI)—is a key component of the diagnostic work-up in patients with deep CD4-cell depletion and must be performed before lumbar puncture to rule out a mass effect responsible for a high risk of cerebral herniation.

AIDS-related cerebral toxoplasmosis is nearly always the result of reactivation of latent intraparenchymal *Toxoplasma gondii* cysts rather than to primary infection. In a multi-ICU study, altered consciousness, focal deficits, and seizures were observed in 67%, 59%, and 22% of patients, respectively, and fever was absent in almost half the cases.[85] Brain MRI shows multifocal, ring-enhanced, and sometimes hemorrhagic lesions in the cortex and/or basal ganglia region with a mass effect from peripheral edema that may require corticosteroid therapy.[86] Solitary lesions and diffuse encephalitis are far less common. The PCR assay for *T. gondii* in cerebrospinal fluid (CSF) is highly specific (>95%) but is no more than 50% sensitive after a few days of therapy.[86] *T. gondii* PCR in blood is even less sensitive but may provide

TABLE 120.3 Treatments for the Most Common Opportunistic Infections in Critically Ill HIV-Positive Patients

Opportunistic Infection	First-Line Regimen for Severe Cases	Main Alternatives	Adjunctive Therapies	Timing of cART Introduction
PCP pneumonia	TMP (15–20 mg/kg/d) and SMX (75–100 mg/kg/d) IV q6h or q8h Switch to PO after clinical improvement Total treatment duration: 3 weeks (then switch to secondary prophylaxis dosing[a]) No leucovorin supplementation[b]	Pentamidine 4 mg/kg IV once daily (patients with TMP or SMX adverse events such as allergy or hemolysis because of glucose-6-phosphate dehydrogenase deficiency)	Corticosteroids if PaO_2 <70 mm Hg (room air) Prednisone PO: Days 1–5: 40 mg BID Days 6–10: 40 mg daily Days 11–21: 20 mg daily Alternative: methylprednisolone IV (75% of prednisone dose)	Within 2 weeks
Tuberculosis (drug-susceptible *M. tuberculosis*)	• Intensive phase (2 months): isoniazid + rifampin or rifabutin + pyrazinamide + ethambutol • Continuation phase: isoniazid + rifampin or rifabutin • Total treatment duration: Pulmonary TB: 6–9 months Extrapulmonary TB with CNS involvement: 9–12 months Extrapulmonary TB with bone or joint involvement: 6–9 months Extrapulmonary TB at other sites: 6 months	Consult an ID specialist	• CNS disease: dexamethasone 0.3–0.4 mg/kg/d for 2–4 weeks, then taper by 0.1 mg/kg per week until 0.1 mg/kg, then 4 mg/d and taper by 1 mg/wk; total duration of 12 weeks • Pericardial disease: prednisone or prednisolone (e.g., 60 mg PO daily with weekly tapering over 6 weeks)	• Active TB without CNS involvement: • Within 2 weeks for patients with CD4 cells <50/μL • Within 8 weeks for patients with CD4 cells ≥50/μL • Active TB with CNS involvement: deferred initiation (high risk of severe IRIS) • Close collaboration with ID specialists
Toxoplasmosis	• Pyrimethamine 200 mg PO once, then pyrimethamine 50–75 mg PO daily + sulfadiazine 1000–1500 mg PO q6h + leucovorin 10–25 mg PO daily • Total treatment duration: at least 6 weeks (then switch to chronic maintenance therapy[a])	• Pyrimethamine (with leucovorin) plus clindamycin 600 mg IV or PO q6h • TMP 5 mg/kg and SMX 25 mg/kg IV or PO BID	• Corticosteroids if cerebral lesions with mass effect • Anticonvulsants only if seizures (no primary prevention)	• No recommendation, because of insufficient data (usually within 2–3 weeks)
Cryptococcus infections	• Induction therapy (at least 2 weeks): liposomal amphotericin B 3–4 mg/kg IV daily plus flucytosine 25 mg/kg QID • Consolidation therapy (at least 8 weeks) after clinical improvement and sterilization of CSF cultures: fluconazole 400 mg PO or IV once daily • Maintenance therapy (at least 1 year): fluconazole 200 mg PO	Induction therapy: fluconazole (400–800 mg/d) may replace either liposomal amphotericin B or flucytosine	Corticosteroids may be deleterious in patients with CNS disease and are not recommended.	CNS involvement: 2–10 weeks after initiation of specific therapy (longer delay if high intracranial pressure) Other localizations: 2–4 weeks after initiation of specific therapy
Histoplasmosis	Induction therapy (at least 2 weeks): liposomal amphotericin B 3 mg/kg/d IV – *If confirmed meningitis: increase dosage to 5 mg/kg/d and extend induction to 4–6 weeks* Maintenance therapy: itraconazole 200 mg PO TID for 3 days, then BID for at least 12 months	Fluconazole (400 md/d PO) may replace itraconazole for long-term suppressive therapy	–	As soon as possible

TABLE 120.3 Treatments for the Most Common Opportunistic Infections in Critically Ill HIV-Positive Patients—cont'd

Opportunistic Infection	First-Line Regimen for Severe Cases	Main Alternatives	Adjunctive Therapies	Timing of cART Introduction
Disseminated MAC disease	Clarithromycin 500 mg PO twice daily + ethambutol 15 mg/kg PO daily or azithromycin 500–600 mg + ethambutol 15 mg/kg PO daily Addition of a third or fourth drug (rifabutin, amikacin, fluoroquinolone) should be considered for patients with CD4+ T cells <50/μL, high mycobacterial loads (>2 log CFU/mL of blood), or in the absence of effective cART	Consult an infectious disease specialist	–	After completion of the second week of MAC-directed therapy
CMV infection	Ganciclovir 5 mg/kg IV q12h Role of oral valganciclovir: not established Optimal treatment duration: not established	Foscarnet 60 mg/kg IV q8h or 90 mg/kg IV q12h	–	No recommendation, because of insufficient data (usually within 2 weeks)
PML	cART	–	–	As soon as possible

BID, Twice a day; *cART,* Combination antiretroviral therapy; *CFU*, colony-forming unit; *CMV,* cytomegalovirus; *CNS,* central nervous system; *CSF,* cerebrospinal fluid; *HIV*, human immunodeficiency virus; *IRIS,* immune reconstitution inflammatory syndrome; *IV*, intravenous; *IV,* intravenously; *MAC, Mycobacterium avium* complex; PaO_2, arterial partial pressure of oxygen; *PCP*, Pneumocystis jirovecii; *PML,* progressive multifocal encephalopathy (caused by JC virus); *PO,* per os; *SMX,* sulfamethoxazole; *TB,* tuberculosis; *TID*, three times a day; *TMP,* trimethoprim.

[a] Consider discontinuation in patients with CD4 cells >200/μL under cART.

[b] Leucovorin supplementation does not efficiently prevent myelosuppression and may be associated with treatment failure.

Adapted from the guidelines of the Centers for Disease Control and Prevention, the National Institutes of Health, and the Infectious Diseases Society of America for the management of opportunistic infections in adults with HIV.[70]

valuable information if positive in a patient with contraindications to lumbar puncture. The first-line regimen for suspected cerebral toxoplasmosis is combined pyrimethamine, sulfadiazine, and leucovorin (see Table 120.3). The diagnosis must be confirmed by a clinical and radiologic response to empirical toxoplasmosis therapy within 10–14 days. A brain biopsy should be considered promptly in patients who fail to respond, have negative immunoglobulin G (IgG) serology or PCR results, or have imaging study findings suggesting another etiology (notably CNS lymphoma).[70] Of note, disseminated disease with septic shock, multiorgan failure, myocarditis, and HLH appears less common in patients with AIDS compared with other causes of immunodeficiency.[87]

Tuberculous meningitis is present in up to 20% of HIV-positive patients admitted to the ICU with active tuberculosis.[88] The clinical presentation is usually subacute and may include fever, headache, focal abnormalities, consciousness impairments, and seizures. Meningeal inflammation in a predominantly basal location, tuberculomas, hydrocephalus, and vasculitis are common MRI patterns, whereas CSF analysis usually shows lymphocytic pleocytosis with variable cell counts (10–500/μL), low glucose levels, and elevated protein levels (0.5 to >3 g/L).[89] The low mycobacterial inoculum translates into poor sensitivities of CSF staining (10%–20%), cultures (~70%), and NAATs (~50%). However, NAATs are highly specific (>95%) and may remain positive for days after the empirical initiation of tuberculosis treatment, thus documenting the diagnosis in patients without initial CSF sampling.[86,90] A large volume of CSF (i.e., >4–5 mL) should be sampled to improve culture sensitivity.[91] The first-line regimen combines rifampicin, isoniazid, ethambutol, and pyrazinamide. No convincing evidence exists that intensified therapies, including fluoroquinolone or high-dose rifampicin, are clinically beneficial.[92] Adjunctive corticosteroid therapy (dexamethasone 0.3–0.4 mg/kg/day for 2–to 4 weeks, followed by tapering, for a total of 12 weeks) should be considered routinely, given the evidence of lower short-term mortality rates in patients with tuberculous meningitis,[70] with no decrease, however, in the prevalence of residual neurologic impairments in survivors.[93]

Most cases of cryptococcal meningitis and meningoencephalitis are caused by the ubiquitous species *Cryptococcus neoformans,* although *Cryptococcus gattii* infections also occur in subtropical regions. Patients present with fever, headaches, and impaired mental status caused by intracranial hypertension. Moderate lymphocytic pleocytosis, mild protein elevation, low-to-normal glucose levels, and encapsulated yeasts by Gram or Indian ink staining are the most common CSF findings. CSF cultures are positive in over 90% of patients.[86] Cryptococcal antigen testing on CSF and serum is both sensitive and specific and allows earlier confirmation of the diagnosis, including in cases of disseminated disease. An initial combination of amphotericin B and 5-fluorocytosine is recommended for at least 2 weeks,[94] followed by an azole-based consolidation regimen after clinical improvement and CSF culture sterilization (see Table 120.3).[70] Adjunctive corticosteroid therapy does not appear beneficial and may even be deleterious in this indication.[95] CSF depletion by repeated lumbar punctures is an essential component of care in patients with intractable intracranial hypertension caused by severe forms of the disease.

The diagnostic work-up for neurologic failure is similar in cART-treated patients with CD4 cells above 200/μL and in HIV-negative patients (see Fig. 120.1). Nonetheless, intensivists should keep in mind the high risk of bacterial meningitis (notably caused by *S. pneumoniae*) in HIV-positive patients.[46] Also, stroke may become an increasingly common reason for ICU admission, as an independent association has

been reported between long-term HIV infection and stroke resulting from accelerated vascular senescence.[96]

Admission for Sepsis

Sepsis remains a major reason for ICU admission in HIV-positive patients.[14,16,47] HIV infection increases the risk not only of bacterial pneumonia and meningitis but also of skin and soft tissue infections, notably the result of community-acquired methicillin-resistant *S. aureus* in endemic areas (e.g., USA300 strain in North America), because of a combination of both immune impairments and social risk factors.[97] HIV-positive patients are also at increased risk of primary bloodstream infection caused by nontyphi *Salmonella* species, *S. aureus,* and *Escherichia coli,* whose incidence correlates with the depth of immune deficiency.[98] Other severe bacterial infections, such as endocarditis or urinary tract infection, are also more common in patients with advanced HIV infection.[99] Again, the management of sepsis in HIV-positive patients has no specific characteristics and should follow general guidelines.[50] However, the higher risk of infection by multidrug-resistant bacteria caused by repeated antibiotic exposure and frequent contacts with the healthcare system should be considered when selecting empirical antimicrobials. Septic shock and multiorgan failure occur occasionally during the course of disseminated OIs, notably toxoplasmosis, tuberculosis, and histoplasmosis. These infections commonly trigger HLH, which may substantially worsen organ dysfunctions.[100] Lastly, *Clostridioides difficile* (formerly *Clostridium difficile*) infection is the leading cause of bacterial diarrhea in HIV-positive patients.[101] However, it remains unclear whether HIV infection is associated with an increased incidence of severe presentations or adverse outcomes.[102]

Other Clinical Situations

CMV Infection

CMV reactivation, detected by quantitative PCR in peripheral blood, is commonly observed in critically ill HIV-infected patients, especially in those with low CD4 cell counts and/or intercurrent OIs. Careful assessment should be made for identification of rare end-organ diseases (e.g., retinitis, encephalitis, esophagitis, colitis, or pneumonitis) that require treatment with intravenous ganciclovir or foscarnet.[70]

Non–HHV8-Associated Lymphoma

Non-Hodgkin and Hodgkin lymphomas (NHL and HL, respectively) remain a major cause of mortality in the late cART era, with 33%–76% of affected patients having undetectable HIV viral load at diagnosis.[103,104] NHL is almost constantly aggressive and is often EBV-related.[105] Diffuse large B-cell lymphoma (DLBCL) is still the most frequent type, but Burkitt lymphoma (BL) has gained an overgrowing place in recent years and now accounts for 40% of lymphoma-related ICU admissions in seropositive individuals.[104] Primary CNS EBV-induced lymphoma, a hallmark AIDS-defining disease until the early nineties, is now occasional.[106]

The reported prevalence of NHL and HL in HIV-infected patients admitted to the ICU may reach 8% and 1.5% Respectively in recent cohorts, with inaugural admission in up to 75% of cases.[106] Patients may be admitted for lymphoma-induced HLH, tumor lysis syndrome, organ infiltration or compression, or chemotherapy-related complications such as sepsis in neutropenic patients.[106,107] Preserving renal function is crucial to optimize subsequent chemotherapy schemes, notably in BL, that often require high-dose methotrexate. NHL at high risk for tumor lysis syndrome—notably DLBCL with large tumor volume and BL—may require preventive ICU admission at the time of induction chemotherapy for fluid management, rasburicase administration, and prompt renal replacement therapy when necessary.[108]

In addition to supportive care, the cornerstones of management of HIV-associated lymphoma in the ICU include adequate tissue sampling for diagnostic procedures, whole-body imaging (either CT scan or fluorodeoxyglucose [FDG] positron emission tomography) to appraise tumor burden and localizations, biologic evaluation for HLH and tumor lysis syndrome, cardiac evaluation (as most chemotherapy regimens are anthracycline-based), prompt administration of etoposide in case of HLH, and timely chemotherapy induction with prevention of tumor lysis syndrome in high-risk patients.[109,110] Of note, rituximab should not be included in the chemotherapy regimen in patients with CD4 cells $<50/\mu L$ because of excess toxicities without survival benefit.[111] The management of cART in this context requires a close collaboration between ICU, hematology, and infectious diseases physicians.[112] Overall survival rates depend on tumor characteristics rather than on HIV infection, which does not affect the outcome of lymphoma managed in the ICU.[113–115]

HHV8-Related Diseases

The most frequent human herpesvirus-8 (HHV-8)–related disease is Kaposi sarcoma (KS), an endothelial cell–derived tumor that may affect various organs and tissues, especially the skin, mucosa, lymph nodes, lungs, and intestinal tract.[116,117] The severity of KS depends on the presence of life-threatening localizations (e.g., the lower respiratory tract), its extension, and the degree of immune deficiency.[116] The treatment of AIDS-related KS rests on immune restoration through cART and, occasionally, chemotherapy for aggressive presentations. Steroids should be avoided in patients with KS, as they can exacerbate the course of the disease. Multicentric Castleman disease is an HHV-8–induced polyclonal B lymphoproliferative disorder characterized by recurrent bouts of fever with lymphoid hyperplasia and severe systemic inflammatory symptoms linked to inappropriate release of interleukin (IL)-6, IL-10, and other cytokines, ultimately resulting in HLH and transformation to NHL.[118,119] Etoposide is the first-line drug for severe associated HLH, whereas long-term outcomes have markedly improved with the use of rituximab.[120] Primary effusion lymphoma (as diagnosed through positive HHV-8 PCR and presence of large B cells in pleural or peritoneal fluid) and DLBCL may also complicate the course of HHV-8 infection in seropositive patients.

MANAGEMENT OF ANTIRETROVIRAL THERAPY IN THE ICU

Immune Reconstitution Inflammatory Syndrome

Immune recovery may induce paradoxical worsening of an already treated or previously undiagnosed OI within weeks or months after cART initiation. Relevant examples include the occurrence of ARF in patients with an initially mild to moderate pulmonary OI (e.g., PCP with no baseline indication for corticosteroids) or neurologic deterioration caused by the enlargement of cerebral tuberculomas, *Toxoplasma* abscesses, or cryptococcal lesions. Immune reconstitution inflammatory syndrome (IRIS)–induced HLH has also been reported. IRIS has an estimated crude incidence of 16%, and the main risk factors are a high baseline viral load, low baseline CD4 cell count, and rapid CD4 cell count elevation after cART initiation.[121,122]

IRIS drives substantial morbidity and mortality, with a fatality rate of up to 20% in patients with cryptococcal meningitis.[121] IRIS as the main reason for ICU admission was uncommon in recent cohorts of critically ill HIV-positive patients, suggesting better anticipation and management by infectious disease specialists.[14,16,21] Nonsteroidal

antiinflammatory drugs and corticosteroids are the cornerstones of therapy for severe IRIS, without requirement for interrupting cART in most cases.[70]

ICU Admissions for Non-IRIS cART-Related Events

ART-related toxicity accounts for approximately 5% of ICU admissions in this population.[16,26,60] Old antiretrovirals are notably associated with lactic acidosis (e.g., azathioprine [AZT], didanosine) or pancreatitis (e.g., didanosine), whereas proximal tubulopathy with AKI and toxic epidermal necrolysis are well-described adverse events of tenofovir and nevirapine, respectively. New drugs may also cause critical complications such rhabdomyolysis from raltegravir (Table 120.4).

Starting cART in the ICU

Early cART initiation reduces all-cause mortality and the incidence of new AIDS-defining conditions in non–critically ill HIV-positive patients with an active OI, notably those with PCP or pulmonary tuberculosis and less than 50/μL CD4 cells.[123–127] Accordingly, current US and European guidelines recommend cART initiation at 2 weeks after the start of specific OI treatment, except for those with cryptococcosis or CNS tuberculosis because of the risk of severe IRIS that may outweigh potential benefits from rapid immune recovery—in these situations, cART initiation must be deferred until at least 4 weeks and with proven disease control.[28,127]

In contrast, whether antiretroviral drugs should be introduced in cART-naive patients admitted to the ICU for an active OI remains

TABLE 120.4 cART Management in the ICU: Main Toxicities, Drug–Drug Interactions, and Administration Issues

Drug	Most Common Severe Toxicities	Main Drug–Drug Interactions to Consider in the ICU	Alternatives for Administration in the ICU	Dosage Adjustment If Renal Failure
Nucleoside/nucleotide reverse transcriptase inhibitors				
Abacavir	Hypersensitivity syndromes in patients with HLA-B*5701	–	Liquid formulation	No (avoid if end-stage renal failure)
Emtricitabine	Neutropenia	–	Liquid formulation, crushable pills	Yes
Lamivudine	Rash	–	Liquid formulation, crushable pills	Yes
Zidovudine	Lactic acidosis, myopathy, bone marrow toxicity, hepatitis	Rifamycins, valproic acid, fluconazole	Liquid formulation, crushable pills, IV formulation	Yes
Tenofovir	Nephrotoxicity (proximal tubular acidosis with Fanconi-like syndrome, acute renal failure), rash, hepatitis	–	Crushable pills	Yes
Nonnucleoside reverse transcriptase inhibitors				
Efavirenz	Hepatitis, rash	Rifamycins, voriconazole, posaconazole, phenytoin, phenobarbital, carbamazepine, calcium channel blockers, statins, warfarin, midazolam	Crushable pills	No
Etravirine	Bone marrow toxicity, hypersensitivity syndromes, hepatitis	Rifamycins, fluconazole, voriconazole, posaconazole, phenytoin, phenobarbital, carbamazepine, digoxin, amiodarone, warfarin, statins, clopidogrel, dexamethasone	Crushable pills	No
Nevirapine	Neutropenia, hypersensitivity syndromes, hepatitis	Rifampicin (switch to rifabutin), fluconazole, warfarin	Liquid formulation	Yes
Rilpivirine	Bone marrow toxicity, hepatitis, rash	Rifamycins, PPIs, anti-H_2, phenytoin, phenobarbital, carbamazepine, dexamethasone	IV formulation	No
Integrase inhibitors				
Raltegravir	Rash	Rifampicin	Liquid formulation, crushable pills	No
Dolutegravir	Rash, hepatitis	Rifampicin, phenytoin, phenobarbital, carbamazepine, apixaban, metformin	Crushable pills	No
Protease inhibitors (all ritonavir-boosted)				
Atazanavir	Hyperbilirubinemia, renal lithiasis, QT prolongation	Rifamycins, voriconazole, PPIs, phenytoin, phenobarbital, carbamazepine, fentanyl, midazolam, calcium channel blockers, amiodarone, warfarin, statins	–	No

TABLE 120.4 cART Management in the ICU: Main Toxicities, Drug–Drug Interactions, and Administration Issues—cont'd

Drug	Most Common Severe Toxicities	Main Drug–Drug Interactions to Consider in the ICU	Alternatives for Administration in the ICU	Dosage Adjustment If Renal Failure
Darunavir	Rash, peripheral neuropathy	Rifamycins, voriconazole, fluconazole, posaconazole, phenytoin, phenobarbital, fentanyl, midazolam, calcium channel blockers, beta-blockers, amiodarone, digoxin, warfarin, apixaban, rivaroxaban, dabigatran, ticagrelor, metformin, statins, salmeterol	Liquid formulation	No
Fosamprenavir	Rash	Rifamycins, phenytoin, phenobarbital, fentanyl, midazolam, amiodarone, statins, warfarin	Liquid formulation	No
Lopinavir	QT prolongation, bone marrow toxicity, hypersensitivity syndromes, hepatitis	Rifamycins, voriconazole, phenytoin, phenobarbital, valproic acid, fentanyl, midazolam, calcium channel blockers, amiodarone, digoxin, warfarin, rivaroxaban, statins, salmeterol	Liquid formulation	No
Tipranavir	Hepatitis, rash	Rifamycins, voriconazole, phenytoin, phenobarbital, carbamazepine, fentanyl, midazolam, PPIs, amiodarone, digoxin, warfarin, statins	Liquid formulation	No
Fusion inhibitors				
Enfuvirtide	Myalgia, lung toxicity, peripheral neuropathy, pancreatitis, renal lithiasis	-	Subcutaneous formulation	No
CCR5 inhibitors				
Maraviroc	Anemia, rash	Rifamycins, phenytoin, phenobarbital, carbamazepine	Liquid formulation	Yes

CCR5, C-C motif chemokine receptor 5; *HLA*, human leukocyte antigen; *ICU*, intensive care unit; *IV*, intravenous; (HLA) complex; *PPIs*, proton pump inhibitors.

unsettled. Indeed, there are no prospective evaluations of the safety, efficacy, and timing of cART initiation in the ICU. A few retrospective single-ICU studies suggest that early cART initiation may improve both short-term and long-term survival rates.[23,26,51] A recent meta-analysis found that initiation or maintenance of cART in the ICU was associated with a lower short-term risk of death (random effects odds ratio 0.53, 95% confidence interval 0.31–0.91, $P = .02$); however, heterogeneity was high (I^2 77%), precluding firm conclusions.[128] Given the declining incidence of ICU admissions for inaugural OIs, it is unlikely that a large-scale randomized controlled trial (RCT) could solve this issue in the near future. Therefore the appropriateness of starting cART in the ICU should be discussed on a case-by-case basis in a framework of close collaboration between intensivists and infectious disease specialists.[5,6] Fig. 120.3 shows the algorithm recently proposed by a panel of intensivists and infectious disease physicians for using cART in the ICU.[60]

Continuing cART in Previously Treated Patients

Stopping cART in virally suppressed patients has been shown to increase the hazard of breakthrough OIs and all-cause death.[129] The possible emergence of resistant HIV mutants (requiring new genotyping before cART reintroduction) should also be considered, although the risk is presumably limited after a short interruption. Hence, in patients treated before admission, cART should be continued in the ICU whenever possible (see Fig. 120.3). Factors that may complicate the continuation of cART in critically ill patients include adverse drug reactions; drug–drug interactions; impaired enteral absorption; the need to deliver drugs via a nasogastric tube; avoidance of proton pump inhibitors, H_2 antagonists, and other antacids if cART contains components such as atazanavir or rilpivirine (which require gastric acidity for absorption); avoidance of enteral nutrition products containing iron, calcium, magnesium, or aluminum to prevent malabsorption of integrase inhibitors; and dose adjustment because of renal and/or hepatic impairment (see Table 120.4). Several solutions exist, such as switching to liquid drug formulations, dosing adjustment based on plasma-level monitoring, and occasionally, parenteral administration. Again, close cooperation with infectious disease specialists is fundamental when deciding to continue, modify, or interrupt cART during the ICU stay.[60]

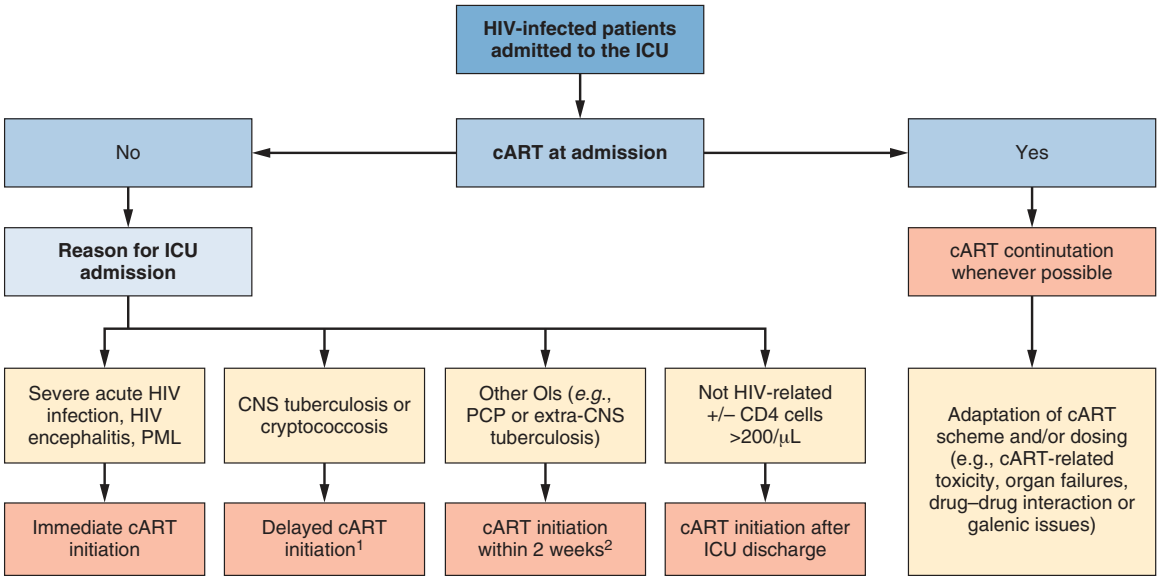

Fig. 120.3 Proposed Algorithm for use of Combination Antiretroviral Therapy in the ICU. *cART,* Combination antiretroviral therapy; *CNS,* central nervous system; *HIV,* human immunodeficiency virus; *ICU,* intensive care unit; *OI,* opportunistic infection; PCP *Pneumocystis jirovecii* pneumonia; *PML,* progressive multifocal encephalopathy. [1] Delayed cART initiation because of the substantial risk of severe immune reconstitution inflammatory syndrome (e.g., up to 10 weeks in cryptococcal meningoencephalitis with elevated intracranial pressure and delayed clinical improvement or cerebrospinal fluid [CSF] culture sterilization); [2] cART initiation may be deferred for up to 8 weeks in patients with pulmonary tuberculosis and CD4 cells >50/μL. (From Barbier F, Mer M, Szychowiak P, et al. Management of HIV-infected patients in the intensive care unit. *Intensive Care Med.* 2020;46[2]:329–342, Fig. 3 and based on the guidelines of the Centers for Disease Control and Prevention, the National Institutes of Health, and the Infectious Diseases Society of America for the use of antiretroviral agents in adults and adolescents with HIV. Note than no academic dedicated guidelines exist for the management of antiretroviral drugs in the specific context of critical illnesses. Close collaboration with an infectious disease physician is mandatory in every case.

CONCLUDING REMARKS AND POTENTIAL RESEARCH AXES

ICU admission for life-threatening OIs continues to occur in patients with previously undiagnosed HIV infection or with failure to respond to cART because of viral resistance or poor adherence. Yet HIV-positive patients with controlled viral replication and CD4 cell count above 200/μL under cART account for a growing proportion of ICU admissions, of which the main reasons are bacterial pneumonia and exacerbation of chronic HANA conditions. Regardless of the depth of immune deficiency, HIV-positive patients now tend to have similar hospital survival rates, as do HIV-negative ICU patients with the same comorbidities, reasons for admission, and severity of organ failures. Hence, the HIV status should no longer be viewed as a pivotal criterion for ICU admission decisions, which should instead be based on frailty, performance status, comorbidities, and other clinical features associated with mid- and long-term outcomes, as with all critically ill patients.

Several domains should be explored to further improve the management of critically ill HIV-positive patients. First, there is a crucial need for longitudinal studies of the long-term impact of critical illness on HIV-specific care, progression of HANA conditions, cognitive decline, functional status, and quality of life. Second, the conversion of HIV infection to a chronic manageable disease has ethical implications. Although major interventions such as IMV, vasopressor therapy, and renal replacement therapy are now equally used in HIV-positive and HIV-negative ICU patients, the determinants of end-of-life decisions in the specific setting of critical illness have not been reappraised in detail. Third, solid and hematologic malignancies act as new immunosuppression vectors in patients with controlled HIV replication. How the coexistence of malignancy may influence the management and post-ICU outcomes of HIV-positive patients deserves to be addressed specifically. Along this line, SOT is increasingly performed in selected HIV-positive patients with end-stage renal or heart failure: the reasons for and prognosis of ICU admission have not yet been investigated in this emerging subpopulation.

KEY POINTS

- In recent Western cohorts, up to 70% of HIV-infected patients admitted to the ICU were receiving long-term cART.
- Bacterial sepsis and exacerbated comorbidities such as COPD, non–AIDS-defining neoplasms, atherosclerosis, and chronic renal diseases have become the leading reasons for ICU admission.
- Admissions for severe AIDS-defining OIs continue to occur in patients with previously unknown HIV infection or restricted access to cART.
- PCP, tuberculosis, and cerebral toxoplasmosis are the most common OIs in the ICU.
- The management of cART in the ICU requires a close collaboration between intensivists and HIV specialists.
- In-hospital mortality mostly depends on age, underlying comorbidities, and extent of organ dysfunction rather than on HIV-related characteristics (i.e., CD4 cell count, viral load, admission for AIDS-related diagnoses, and prior cART use).
- Lymphomas, solid neoplasms, and SOT are emerging drivers of immunosuppression in cART-treated patients with otherwise controlled HIV replication.
- Ethical issues and long-term outcomes warrant dedicated investigations in this patient population.

Infections in the Immunocompromised Patient

Steven A. McGloughlin and David L. Paterson

Many immunocompromised patients are managed in intensive care units (ICUs) every year, with infection being a leading cause of ICU admission. Common examples of such infections include community-acquired pneumonia, bacteremia, and central nervous system (CNS) infections. The incidence of infections acquired by immunocompromised patients during ICU admissions is also significant.[1] Mortality from certain infections in immunocompromised patients exceeds 50%.[2] Early diagnosis, initiation of appropriate antimicrobial and supportive therapy, and reduction in immunosuppression where possible can improve outcomes significantly.

COMMONLY ENCOUNTERED IMMUNOCOMPROMISING CONDITIONS

Immunocompromise can be broadly defined as a state in which the response of the host to a foreign antigen is subnormal. It can be congenital (primary) or acquired. Congenital immunodeficiencies are now much less common than acquired immunodeficiencies. In general, congenital immunodeficiency is observed more frequently in patients in pediatric ICUs than in those in adult ICUs. Patients with congenital immunodeficiencies usually have repeated infections, especially infections affecting the sinuses and lower respiratory tract. Congenital immunodeficiencies are usually "pure," in that the defects in the host response to foreign antigens are usually specific and well defined. For example, Bruton X-linked agammaglobulinemia is associated with a defect in the normal maturation process of immunoglobulin-producing B cells. As a result, mature circulating B cells, plasma cells, and serum immunoglobulin are absent. The patient is susceptible to organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae,* normally dealt with by immunoglobulins. Other congenital immunodeficiency syndromes are listed in Table 121.1.

Most immunocompromised patients managed in adult ICUs have acquired immunocompromise. Although the response of host defenses in the elderly, people with diabetes, and people with alcohol use disorder is compromised, this chapter deals primarily with four categories of immunocompromised patients: (1) patients receiving therapy for hematologic malignancies and solid tumors; (2) patients receiving immunosuppressive therapy in the context of solid organ transplantation; (3) patients receiving corticosteroids, methotrexate, monoclonal antibodies to tumor necrosis factor, and other disease-modifying agents for rheumatoid arthritis, Crohn disease, and autoimmune disorders; and (4) patients with human immunodeficiency virus (HIV) infection.

Hematologic Malignancies and Solid Tumors

Prolonged neutropenia from chemotherapy carries a significant risk of bacterial and fungal infection. Classically, gram-negative organisms such as *Pseudomonas aeruginosa* and fungal organisms such as *Aspergillus* species have been associated with severe neutropenia. It has long been known that the severity and duration of neutropenia influence the risk of infection.[3] It has also been well established that aggressive chemotherapy and radiotherapy for Hodgkin disease coupled with splenectomy significantly impair humoral defense against encapsulated organisms such as *S. pneumoniae, H. influenzae,* and *Neisseria meningitidis*.[4] Stem cell transplantation (particularly allograft transplantation) is associated with a substantial risk of graft-versus-host disease (GVHD). Prophylaxis and treatment for GVHD may involve use of drugs such as cyclosporine or tacrolimus plus corticosteroids. Cyclosporine and tacrolimus inhibit calcineurin, an enzyme important in the lymphocyte activation cascade. Corticosteroids also affect lymphocyte function and depress functions of activated macrophages. As a result, patients receiving therapy for GVHD may be prone to fungal, viral, and mycobacterial infections, in addition to bacterial infections associated with prolonged neutropenia. Chimeric antigen receptor (CAR) T-cell therapy is an additional treatment modality used to treat some blood cancers.[5] Patient lymphocytes are engineered to produce CARs, which are directed towards tumor cells. Patients receiving CAR T-cell therapy experience multifactorial immune suppression related to their cancer and its prior treatment, pretreatment chemotherapy, depletion of B cells, and the effects of cytokine release syndrome. Additionally, management of severe cytokine release syndrome often involves administration of interleukin (IL)-6 inhibitors (e.g., tocilizumab) and high-dose corticosteroids, both of which themselves carry an additional risk of infection.[6]

Solid Organ Transplantation

Solid organ transplant recipients are uniquely susceptible to infection.[7] They undergo significant surgery, breaching the defenses provided by the skin. Furthermore, they can remain in ICUs for prolonged periods, requiring intravenous access and mechanical ventilation—here, cutaneous and pulmonary barriers to infection are breached. Finally, solid organ transplant recipients receive immunosuppressive therapy to prevent graft rejection. The commonly used immunosuppressive medications are listed in Table 121.2. Immunosuppressive regimens are in a constant state of flux—more recent trends have been toward aggressive "pretreatment" immediately before transplantation, coupled with decreased immunosuppression in the posttransplant period.[8]

In the early posttransplant period, transplant recipients are susceptible to nosocomially acquired bacterial infections such as pneumonia, catheter-related bloodstream infection associated with usual ICU care, and wound and intraabdominal infections associated with surgical procedures. Opportunistic infections may be acquired from the organ graft; cytomegalovirus (CMV) is the most pertinent example,[9] but a wide variety of infections (e.g., rabies, histoplasmosis, tuberculosis, and West

TABLE 121.1 Congenital (Primary) Causes of Immunodeficiency

Condition (Immunodeficiency)	Organisms With Increased Tendency to Cause Infection in This Condition
T-Lymphocyte Deficiencies	
DiGeorge syndrome (thymic aplasia with reduced CD4 and CD3 cells)	Viruses (especially HSV and measles), sometimes *Pneumocystis jirovecii,* fungi, or gram-negative bacteria
Purine nucleoside phosphorylase deficiency (marked T-cell depletion)	*P. jirovecii* and viruses
B-Lymphocyte Deficiencies	
Bruton X-linked agammaglobulinemia (absence of B cells, plasma cells, and antibody)	*Haemophilus influenzae, Streptococcus pneumoniae, Staphylococcus aureus, Pseudomonas aeruginosa, P. jirovecii* (after the first 4–6 months of life when maternal antibody has been consumed)
Selective IgG subclass deficiencies	Variable
Selective IgA deficiency	*S. pneumoniae, H. influenzae*
Hyper-IgM immunodeficiency (elevated IgM but reduced IgG and IgA)	*S. pneumoniae, H. influenzae, P. jirovecii* (rarely)
Mixed T- and B-Lymphocyte Deficiencies	
Common variable immunodeficiency (leads to various B-cell activation or differentiation defects and gradual deterioration of T-cell number and function)	*S. pneumoniae, H. influenzae,* CMV, VZV, *P. jirovecii*
Severe combined immunodeficiency (severe reduction in IgG and absence of T cells)	*P. jirovecii,* viruses, *Legionella*
Wiskott-Aldrich syndrome (decreased T-cell number and function, low IgM, occasionally low IgG)	*S. pneumoniae, H. influenzae,* HSV, *P. jirovecii*
Ataxia-telangiectasia (decreased T-cell number and function; IgA, IgE, IgG_2, and IgG_4 deficiency)	*S. aureus, S. pneumoniae, H. influenzae*
Disorders of Complement	
C3 deficiency (congenital absence of C3 or consumption of C3 caused by deficiency of C3b inactivator)	*S. pneumoniae, H. influenzae,* enteric gram-negative bacilli
Phagocyte Defects	
Chronic granulomatous disease (defect in NADPH oxidase in phagocytic cells)	*S. aureus, Escherichia coli, Klebsiella pneumoniae, Enterobacter cloacae, S. marcescens, P. aeruginosa, Aspergillus*
Chédiak-Higashi syndrome (impaired microbicidal activity of phagocytes)	*S. aureus, H. influenzae, Aspergillus*
Kostmann syndrome, Shwachman-Diamond syndrome, cyclic neutropenia (low neutrophil count)	*S. aureus,* enteric gram-negative bacilli, *P. aeruginosa*

CMV, Cytomegalovirus; *HSV,* herpes simplex virus; *Ig,* immunoglobulin; *NADPH,* nicotinamide adenine dinucleotide phosphate; *VZV,* varicella-zoster virus.

TABLE 121.2 Immunosuppressive Drugs Used in Solid Organ Transplantation and Their Mechanisms of Activity

Immunosuppressive	Mode of Action
Corticosteroids	Negative regulation of cytokine gene expression
Azathioprine	Inhibits DNA and RNA synthesis; inhibits T- and B-cell function
Cyclosporine	Calcineurin inhibitor; inhibits cytokine expression
Tacrolimus	Calcineurin inhibitor; inhibits cytokine expression
Sirolimus (rapamycin)	Prevents translation of mRNAs encoding cell cycle regulators
Mycophenolate mofetil	Blocks purine biosynthesis; inhibits T- and B-cell proliferation
Polyclonal antilymphocyte	Lymphocyte depletion antibodies (e.g., Atgam, Thymoglobulin)
Muromonab-CD3 (OKT3)	Anti-CD3 monoclonal antibody
Alemtuzumab (Campath)	Anti-CD52 monoclonal antibody
Daclizumab, basiliximab	Anti-CD25 monoclonal antibody

Nile virus) have also been rarely acquired from grafts. Solid organ transplant recipients, by virtue of their iatrogenic immunosuppression, are also susceptible to reactivation of latent infection (e.g., CMV infection, tuberculosis, or histoplasmosis) or to infections acquired through the hospital environment (e.g., aspergillosis, legionellosis, or tuberculosis).

Rheumatoid Arthritis and Autoimmune Disorders

Therapy for rheumatoid arthritis and other autoimmune disorders may be with simple analgesics or nonsteroidal antiinflammatory drugs. Drugs with the potential to cause significant immunocompromise are also frequently used. Classically, therapy has been with corticosteroids or disease-modifying antirheumatic drugs such as azathioprine, cyclosporine, penicillamine, gold salts, hydroxychloroquine, leflunomide, methotrexate, or sulfasalazine. The effects of corticosteroids, azathioprine, and cyclosporine on host defenses have been noted previously (see Table 121.2). Methotrexate reversibly inhibits dihydrofolate reductase and interferes with DNA synthesis and repair and cellular replication. In addition to its use in rheumatoid arthritis, it can be used as an antineoplastic agent. Methotrexate, however, can cause significant neutropenia, and low-dose methotrexate is generally less likely to increase the infection risk in patients with rheumatoid arthritis.[10,11]

A variety of "biologic" agents are now widely used for rheumatoid arthritis. These include tumor necrosis factor (TNF)-alpha inhibitors (for example, etanercept, infliximab, adalimumab, certolizumab, and golimumab), IL-6 inhibitors (for example, tocilizumab and sarilumab), IL-1 beta inhibitors (anakinra), CD80/86 inhibitors (abatacept), and an antibody against the CD20 protein (rituximab) (Table 121.3). The indications for the use of these biologic agents are also increasing—for example, they may also be used in treatment of Behçet disease, Crohn disease, GVHD, hairy cell leukemia, psoriasis, pyoderma gangrenosum, sarcoidosis, and ulcerative colitis. Considerable attention has been paid to the possibility of tuberculosis developing after treatment with such agents.[12] The risk is sufficiently high that it is recommended that tuberculin skin testing or interferon gamma (IFN-γ) release assays be performed to detect latent tuberculosis before the initiation of anticytokine agents. Invasive infections with *Histoplasma, Candida, Pneumocystis jirovecii, Aspergillus, Cryptococcus, Nocardia, Salmonella, Listeria, Brucella, Bartonella,* nontuberculous mycobacteria, *Leishmania,* and *Toxoplasma* have also been reported to be associated with the use of "biologics."[13–16] As is the case with transplant-associated immunocompromise, these infections may represent reactivation of latent infection or new acquisition of organisms through environmental exposure.

Human Immunodeficiency Virus Infection

HIV infection remains a relatively common infection, but acquired immunodeficiency syndrome (AIDS) has become less frequently encountered in ICUs since the advent of highly active antiretroviral therapy. A decline in CD4 counts creates a predisposition to *P. jirovecii* pneumonia, mycobacterial infection, fungal infection (e.g., cryptococcal meningitis), and viral infection (e.g., CMV infection). Many patients with HIV infection are coinfected with hepatitis C virus, and as a result, liver failure is now a relatively common reason for ICU admission in HIV-infected patients. In some centers, liver transplantation is performed in HIV-infected patients with hepatitis virus–induced liver diseases.[17,18]

TABLE 121.3 Commonly Used Anticytokines for Management of Rheumatoid Arthritis

Drug	Mechanism of Action	FDA-Approved Indications
Adalimumab (Humira)	Recombinant, fully human anti-TNF monoclonal antibody	Ankylosing spondylitis Crohn disease Psoriatic arthritis Rheumatoid arthritis
Anakinra (Kineret)	Recombinant human interleukin-1 receptor antagonist	Rheumatoid arthritis
Etanercept (Enbrel)	TNF receptor p75 Fc fusion protein	Ankylosing spondylitis Juvenile rheumatoid arthritis Plaque psoriasis Psoriatic arthritis Rheumatoid arthritis
Infliximab (Remicade)	Chimeric monoclonal antibody to TNF	Ankylosing spondylitis Crohn disease Psoriatic arthritis Plaque psoriasis Rheumatoid arthritis Ulcerative colitis
Tocilizumab (Actemra)	IL-6 receptor–inhibiting monoclonal antibody	Rheumatoid arthritis

FDA, US Food and Drug Administration; *IL-6,* interleukin-6; *TNF,* tumor necrosis factor.

GENERAL DIAGNOSTIC APPROACH TO IMMUNOCOMPROMISED PATIENTS WITH SEVERE INFECTIONS

Immunocompromised patients are a heterogeneous group. The infections commonly encountered by a patient with neutropenia as a consequence of chemotherapy may be different from infections observed in a patient with rheumatoid arthritis who is receiving infliximab. Even within a particular category, different renal transplantation recipients, for example, may have a different degree of immunocompromise and a different susceptibility to infection. In solid organ transplant recipients, the "net state of immunosuppression" (i.e., the cumulative burden of immunosuppression with a special weighting toward recent T-cell ablative therapy) influences the risk of infection. A renal transplant recipient who is receiving tacrolimus monotherapy twice per week would be less susceptible to opportunistic infection than a patient with recent acute cellular rejection who is receiving OKT3 or alemtuzumab. There have been attempts to quantify immune function in solid organ transplant recipients,[19] although it has not yet been definitively proved that such tests predict infection risk. In contrast, with HIV infection, CD4 lymphocyte count and HIV RNA quantification ("viral load") predict risk of infection.[20] Patients with CD4 counts greater than 500 cells/mm^3 are unlikely to be infected with an opportunistic pathogen, whereas those with CD4 counts of 200–500 cells/mm^3 may be infected with organisms such as *Mycobacterium tuberculosis,* but they are unlikely to be infected with opportunistic pathogens such as CMV or *Mycobacterium avium* complex. Patients with CD4 counts less than 200 cells/mm^3 have an increased risk of a wide variety of opportunistic infections.

Specific environmental exposures may be potentially important for immunocompromised patients. A travel history to the deserts of the southwestern United States and northern Mexico, for example, may increase the likelihood that an immunocompromised patient has coccidioidomycosis[21]; histoplasmosis is endemic in the Ohio River Valley.[22] Alternatively, there may be environmental risks within the ICU. Outbreaks of invasive pulmonary aspergillosis have been linked to construction activity within the hospital. Outbreaks of legionellosis may be waterborne via air conditioning cooling units, drinking water, or aerosolization from showers.[23] Furthermore, it is possible that many fungal and bacterial infections are waterborne.[24,25] Tuberculosis transmission has been well described in ICUs caring for transplant recipients or HIV-infected patients.[26] In summary, the net state of immunosuppression must be considered in the context of recent environmental exposures.

Although elements of history taking and physical examination may narrow the differential diagnosis of the causative agent of infection in immunocompromised patients, some of the "rules" applied to diagnosis in immunocompetent patients do not apply. Caution must be exercised in use of the diagnostic principle that follows Occam's razor: "entities are not to be multiplied without necessity." In an immunocompetent patient, given all the patient's symptoms, signs, and noninvasive laboratory test results, one unifying diagnosis usually explains all. Importantly, in contrast, immunocompromised patients may have more than one infection at any given time. A neutropenic patient may have bacterial pneumonia and invasive pulmonary aspergillosis simultaneously, whereas an immunocompromised patient with HIV infection may have *P. jirovecii* pneumonia and pulmonary infiltrates because of human herpesvirus (HHV)-8 infection (Kaposi sarcoma).

BOX 121.1 Diagnostic Approach for Severe Infections in Immunocompromised Patients

History Taking and Review of Prior Records

Likely degree of immunocompromise
- Recent CD4 lymphocyte count and HIV viral load
- Time since transplantation
- Recent acute cellular rejection or GVHD and treatment thereof
- Current or recent receipt of immunosuppressive medications
- Current or recent receipt of antiretroviral medications

Prophylaxis against opportunistic infections
- Receipt of antimicrobial prophylaxis against *Pneumocystic jirovecii,* HSV, or CMV
- Vaccination status (pneumococcus, influenza, *Neisseria meningitidis*)

Family history
- Personal or family history of tuberculosis or chickenpox

Potential environmental exposures
- Travel history to southwestern United States
- Exposure to hospital construction activity (aspergillosis)
- Exposure to hospital water supply (legionellosis, aspergillosis)
- Exposure to patients with tuberculosis or chickenpox
- Donor and recipient serostatus for CMV or *Toxoplasma gondii*

Physical Examination

Skin
- Presence of cutaneous nodules consistent with cryptococcosis or nocardiosis
- Presence of cutaneous manifestations of GVHD
- Kaposi sarcoma
- Line insertion site erythema or pus
- Peripheral embolic phenomena
- Scars consistent with prior surgery

Mouth and other mucous membranes
- Presence of candidiasis

Respiratory system
- Presence of signs of focal versus multilobar pneumonia

Cardiovascular system
- Murmurs, prosthetic heart sounds

Abdominal examination
- Signs of peritonitis
- Hepatomegaly or splenomegaly
- Tenderness of renal allograft

Neurologic examination
- Nuchal rigidity
- Cranial nerve signs

Noninvasive Laboratory Tests

White blood cell count and differential
Blood and urine cultures
Serum cryptococcal antigen
Serum galactomannan antigen (aspergillosis)
Serum and urine *Histoplasma* antigen
Urinary *Legionella* antigen

Invasive Laboratory Tests

Bronchoalveolar lavage
Pleural fluid aspiration
Upper gastrointestinal endoscopy
Colonoscopy
Biopsy of liver, kidney, bone marrow

CMV, Cytomegalovirus; *GVHD,* graft-versus-host disease; *HIV,* human immunodeficiency virus; *HSV,* herpes simplex virus.

The potential for multiple diagnoses underscores the need for early invasive testing in immunocompromised patients with severe infection. Patients with unexplained severe community-acquired pneumonia may be best managed by early bronchoalveolar lavage performed before antimicrobial therapy has commenced. Bronchoalveolar lavage could be sent for Gram stain, Ziehl-Neelsen stain, modified acid-fast stain, calcofluor stain, direct fluorescent antibody tests, polymerase chain reaction (PCR), and cytologic analysis to enable rapid diagnosis of infection with bacteria, mycobacteria, *Nocardia*, fungi, *Legionella,* CMV, community-acquired respiratory viruses, and *P. jirovecii*. Close liaison with the microbiologic laboratory is vital to ensure that appropriate attempts are made to identify the causative pathogens as rapidly as possible. For example, newer microbiologic techniques such as mass spectrometry, matrix-assisted laser desorption/ionization (MALDI-TOF) and DNA sequencing have been demonstrated to be useful in identifying fungal isolates rapidly.[27] The bronchoalveolar lavage should be inoculated onto solid media, and molecular diagnostic testing should be used as appropriate. An outline of the diagnostic approach in immunocompromised patients is given in Box 121.1.

MAJOR MANIFESTATIONS OF INFECTION IN IMMUNOCOMPROMISED PATIENTS

The organism causing infection in an immunocompromised patient sometimes can be inferred by the specific host defect in the immunologic defense or the specific clinical manifestation. In most circumstances, the differential diagnosis is too broad, however, to make a definitive clinical diagnosis.

Pulmonary Infection

Pneumonia is a significant cause of morbidity and mortality in immunocompromised patients. In contrast to a normal host, the impaired responsiveness of the immune system means that the disease presents in unusual ways, which may lead to challenges in establishing a diagnosis.

Infectious microorganisms usually gain access to the respiratory tract through inhalation, although hematogenous spread sometimes may occur. Mechanical defenses remove the bulk of potentially harmful agents from the lungs (Table 121.4); inhaled particles greater than 10 μm in diameter usually become trapped in the upper airways or are removed by coughing or mucociliary clearance. Most bacteria range from 0.5 to 2 μm in size and are able to reach the terminal airways/alveoli and potentially cause infection. In the alveoli, the alveolar macrophages are the first line of defense. Subsequently, an inflammatory response consisting of polymorphonuclear neutrophils is important. Finally, specific T-cell and B-cell immune responses are essential for successful defense against many pathogens.

As noted earlier, although it may be possible to pinpoint a major immunologic deficiency, most immunocompromised individuals have an assortment of deficiencies in host defenses working together. An organ transplant recipient may be intubated, have multiple intravenous lines, be diabetic, and be on corticosteroids and tacrolimus. All

TABLE 121.4 Host Defenses Against Respiratory Infections and How They Are Affected in Immunocompromised Patients

Location	Host Defense	Defect
Upper airway	Filtration	Endotracheal intubation
	Mucociliary apparatus	CF, cigarette smoking
	Cough	Impaired consciousness
Lower airway (nonspecific)	Alveolar macrophages	Immunosuppressive medication, corticosteroids
	Polymorphonuclear leukocytes	Corticosteroids, malnutrition, chemotherapy, malignancies
Lower airway (specific)	B lymphocytes	Hypogammaglobulinemia, CLL, MM
	T lymphocytes	AIDS, malignancies, immunosuppressants

AIDS, Acquired immunodeficiency syndrome; *CF,* cystic fibrosis; *CLL,* chronic lymphocytic leukemia; *MM,* multiple myeloma.

these factors contribute to the overall degree of immunity, each paving the way for its own peculiar array of susceptibilities to pulmonary infection. In solid organ transplant recipients, specific causes of pulmonary infection are most frequent at certain times posttransplantation (Table 121.5). In a similar manner, specific causes of pulmonary infection are more frequent at different CD4 lymphocyte counts for patients with HIV infection (Table 121.6).

A normal chest radiograph does not rule out pulmonary infection in immunocompromised patients. Additionally, although some diseases have suggestive radiologic findings (e.g., apical cavitations in tuberculosis), most radiographic findings have to be interpreted in light of all other data available. Frequently, computed tomography (CT) is required (e.g., evaluation of pulmonary nodules). Pulmonary nodules have a broad differential diagnosis in immunocompromised patients, including infections caused by fungi (especially *Cryptococcus neoformans, Coccidioides immitis,* and *Aspergillus fumigatus*), *Nocardia,* mycobacteria, *Rhodococcus equi,* and *Bartonella*. Additionally, carcinomas and posttransplant lymphoproliferative disorders may present with pulmonary nodules. The differential diagnosis of cavitary lesions includes mycobacteria, invasive pulmonary aspergillosis, legionellosis, and infection with *R. equi*. As noted earlier, the broad differential diagnosis of pulmonary infection in immunocompromised patients mandates early and aggressive diagnostic strategies such as bronchoscopy, with the bronchoalveolar lavage sent for a comprehensive battery of microbiologic investigations.

Central Nervous System Infections

Most infectious agents reach the CNS via hematogenous dissemination from an extraneural site. Exceptions include retrograde propagation of infected thrombi within emissary veins, spread along olfactory nerves, and spread from a contiguous focus of infection. The blood-brain barrier presents a natural and an efficient barrier to hematogenous infection. The function of the blood-brain barrier in immunocompromised patients has not been well studied. It is well known, however, that when a CNS infection is established, immune defenses (even in immunologically competent hosts) are inadequate to control the infection.[28] Local opsonization is deficient within the brain. In animal models of bacterial brain abscess, corticosteroid administration led to a reduction in macrophage and glial response, with an increased number of viable bacteria in the abscess.[29]

TABLE 121.5 Occurrence of Pulmonary Infection After Solid Organ Transplantation Stratified by Time From Transplantation

Time After Transplant (mo)	Organism
<1	Nosocomial bacteria (e.g., MRSA, ESBL-producing Enterobacteriaceae, *Pseudomonas aeruginosa, Acinetobacter baumannii*)
	Legionella spp.
	Respiratory viruses (e.g., influenza virus, parainfluenza virus, RSV, adenovirus, rhinovirus, human metapneumovirus)
	Aspergillus spp.
1–6	Nosocomial bacteria (if still mechanically ventilated)
	Legionella spp.
	Nocardia spp.†
	Mycobacterium tuberculosis
	Herpesviruses (e.g., HSV, VZV, CMV)‡
	Respiratory viruses (e.g., influenza virus, parainfluenza virus, RSV, adenovirus, rhinovirus, human metapneumovirus)
	Pneumocystis jirovecii†
	Cryptococcus neoformans
	Aspergillus spp.
	Coccidioides spp.
	Histoplasma spp.
>6	Bacteria associated with community-acquired pneumonia (e.g., *Streptococcus pneumoniae, Haemophilus influenzae, Legionella* spp., *Mycoplasma pneumoniae*)
	Nocardia spp.*†
	*Rhodococcus equi**
	Mycobacterium tuberculosis
	Atypical mycobacterium
	Aspergillus spp.*
	Zygomycetes*
	*Cryptococcus neoformans**

*These organisms should be considered when immune suppression is still substantial.
†These organisms are less likely in patients on prophylactic cotrimoxazole.
‡These viruses are less likely in patients on prophylactic ganciclovir or valganciclovir.
CMV, Cytomegalovirus; *ESBL,* extended-spectrum beta-lactamase; *HSV,* herpes simplex virus; *MRSA,* methicillin-resistant *Staphylococcus aureus; RSV,* respiratory syncytial virus; *VZV,* varicella-zoster virus.

Bacterial meningitis caused by *N. meningitidis* is relatively uncommon in immunocompromised patients, except if they have undergone splenectomy. In contrast, pneumococcal meningitis seems to occur with increased frequency in patients who have undergone stem cell transplantation[30–32] and in those with HIV infection.[33,34] Meningitis caused by *Listeria monocytogenes* is classically associated with immunocompromise, reflecting the need for adequate T-cell function and IFN-γ production to kill this intercellular pathogen.[35] In addition to meningitis, *Listeria* infection may be associated with a brain abscess, particularly that occurring in the brainstem.[36,37] Enteric bacteria (e.g.,

TABLE 121.6 Etiology of Pulmonary Infections in Patients Infected With Human Immunodeficiency Virus Stratified by CD4 Lymphocyte Count

	CD4 COUNT (cells/mm³)			
	>500	200–500	50–200	<50
Organism	*Streptococcus pneumoniae* *Haemophilus influenzae*	*S. pneumoniae* *H. influenzae* *M. tuberculosis*	*Pneumocystis jirovecii* *Mycobacterium tuberculosis* *Cryptococcus*	*P. jirovecii* *Cryptococcus* CMV MAC *Aspergillus*

CMV, Cytomegalovirus; *MAC, Mycobacterium avium* complex.

Escherichia coli) are rare causes of bacterial meningitis in immunocompromised patients. A classic association exists, however, between meningitis with such organisms and disseminated infection with *Strongyloides stercoralis.*[38,39] In the presence of immunosuppression (e.g., large doses of corticosteroids), *Strongyloides* can migrate from the gastrointestinal (GI) tract to the CNS, carrying enteric bacterial flora into the CNS. Mortality is high without prompt recognition and treatment. *Nocardia* and mycobacteria must also be considered in the differential diagnosis of CNS infections in immunocompromised patients; diagnostic samples should be sent for inoculation onto appropriate media for isolation of these organisms.[40–42]

Fungal infection of the CNS may cause meningitis or space-occupying lesions. Cryptococcal meningitis is associated with advanced HIV infection (CD4 lymphocyte count <100 cells/mm³) but can also occur in transplanted patients.[43] The presentation is usually subacute, although dangerous elevations in intracranial pressure are sometimes observed. Space-occupying lesions in the brain may occur with disseminated mold infections; these infections usually arise in the lung, but dissemination to the brain is part of multiorgan spread. Mortality is extremely high in these cases. Any of the pathogenic molds[44,45] such as *Aspergillus,* zygomycetes,[46,47] *Scedosporium,*[48] or *Fusarium*[49] can undergo dissemination to the brain. The dimorphic fungi (e.g., *Histoplasma, Coccidioides*) may also disseminate from the lung, causing infection of the CNS. Zygomycetes may also be associated with frequently fatal infection arising within the nose or sinuses (rhinocerebral mucormycosis).[46,47]

The most common protozoal pathogen to affect the CNS is *Toxoplasma gondii.* The classic association is between *T. gondii* infection and advanced HIV infection, although cases have shown associations with other forms of immunocompromise.[50–52] Amebic encephalitis has been reported occasionally in conjunction with advanced HIV infection or organ transplantation.[53]

Additionally, a variety of viruses can cause CNS infections in immunocompromised patients. Perhaps as a result of the widespread use of anti-herpesvirus prophylaxis in many immunocompromised populations, herpes simplex virus (HSV) encephalitis is rare.[54] Some of the newer herpesviruses, such as HHV-6, have been associated with neurologic infection in transplant recipients.[55–57] Lack of diagnostic capabilities for these viruses may partially explain their apparent infrequency. CMV meningoencephalitis is well described in patients with advanced HIV infection[58] and occasionally has been reported in transplant recipients.[59] Further, disseminated infections with varicella-zoster virus (VZV) in immunocompromised patients may result in CNS infection; West Nile virus may also be acquired from transplanted organs or blood transfusions and is associated with a significant meningoencephalitis in transplant recipients.[60,61] Table 121.7 summarizes the agents capable of causing CNS infections in an immunocompromised host.

The wide variety of organisms that could be responsible for CNS infection presents a need for a broadly based diagnostic work-up before empiric therapy is begun. If the cerebrospinal fluid (CSF) is collected, it should be sent for Gram stain and Ziehl-Neelsen stain for rapid diagnosis of bacterial and mycobacterial infections. PCR can be performed for the diagnosis of most viral infections such as HSV, CMV, and VZV. Cryptococcal antigens can be detected rapidly in the CSF, enabling a quick diagnosis of this form of meningitis, but for patients with space-occupying lesions of the brain, collection of the CSF may not be possible. Aspiration may be performed in some circumstances. Before invasive diagnostic testing of the brain is performed, however, the patient's skin is examined for lesions (such as that which may occur with cryptococcosis or nocardiosis) and the

TABLE 121.7 Central Nervous System Infections in the Immunocompromised Host

Etiologic Agent	Special Considerations
Meningitis	
Streptococcus pneumoniae	Especially in HIV-infected individuals
Listeria monocytogenes	Predilection for brainstem
Enteric bacteria	Associated with disseminated *Strongyloides* infection
Cryptococcus neoformans	Rapid diagnosis by cryptococcal antigen or India ink stain
Mycobacterium tuberculosis	Consider PCR for rapid diagnosis
Meningoencephalitis	
HSV	Rare in immunocompromised patients
HHV-6	May be associated with lack of CSF pleocytosis
VZV	Skin lesions yield diagnosis
West Nile virus	Transmitted via transplanted organ or blood
Space-Occupying Lesions	
Nocardia	Pulmonary lesions usually also present
Toxoplasma gondii	Especially in HIV-infected individuals
Fungi	Pulmonary lesions usually also present

CSF, Cerebrospinal fluid; *HHV-6,* human herpesvirus-6; *HIV,* human immunodeficiency virus; *HSV,* herpes simplex virus; *PCR,* polymerase chain reaction; *VZV,* varicella-zoster virus.

lungs are carefully reviewed by CT. Because most CNS lesions arise from infection in other parts of the body, a diagnosis may often be made more easily by microbiologic sampling of these body sites.

Gastrointestinal Infections

Severe GI infections in immunocompromised patients may occasionally warrant ICU admission because of dehydration or visceral perforation. As with respiratory and CNS infections, the differential diagnosis is usually broad, and a precise diagnosis rarely can be made based on clinical suspicion alone. Immunocompromised patients have an increased predisposition to GI infections, depending on the type and degree of immunocompromise and exposure to certain pathogens.

The most commonly involved organisms in the etiology of infective esophagitis or gastritis are *Candida,* CMV, and HSV, although a variety of other organisms (e.g., mycobacteria and zygomycetes) occasionally are implicated. Candidal esophagitis is a common opportunistic infection in patients with AIDS. Approximately 13.3 events of candidal esophagitis per 100 person-years occur in HIV-infected patients with CD4 counts less than 300 cells/mm^3.[62] A study of renal transplant patients in the United States showed that esophageal candidiasis is the most common fungal infection in these patients, making up 22% of all fungal infections.[63] Other predisposing factors for severe esophageal candidiasis include broad-spectrum antibiotic therapy, steroid therapy, cancer chemotherapy, diabetes mellitus, cutaneous burns, radiotherapy, and hematologic stem cell transplant. Although *C. albicans* is the most frequently diagnosed organism, there is an increase of other species, including *C. krusei* and *C. glabrata*—this is notable because of the increase in resistance to fluconazole in these species. Finally, as noted previously, immunocompromised patients may have a combination of pathogens causing infection at any one time. Upper GI endoscopy with biopsy is the gold standard for making the diagnosis.

Diarrhea is a common problem in immunocompromised patients with multifactorial etiologies. It may lead to the diagnosis of immunosuppression in a previously undiagnosed patient when an opportunistic pathogen is found and appropriately investigated. Severe complications such as malabsorption leading to malnutrition, dehydration, and wasting can occur. Occasionally, intestinal perforation may result from a GI infection. In an immunosuppressed patient, it is important to differentiate diarrhea caused by opportunistic infections from diarrhea caused by neoplasms, GVHD, drugs, and other therapeutic agents. GVHD accounts for more diarrhea in blood and bone marrow transplant patients than infective organisms.[64] In these patients, organisms that cause mild self-limiting disease in the normal host may cause severe and life-threatening infections.[64]

Prolonged use of multiple antibiotics in high doses predisposes patients to colonization with *Clostridium difficile* and development of pseudomembranous colitis. Antibiotic prophylaxis to prevent *P. jirovecii* pneumonia or spontaneous bacterial peritonitis has been associated with *C. difficile.* In addition to the classic antibiotic risk factors of clindamycin or cephalosporin use, fluoroquinolones may predispose to epidemic strains of *C. difficile* (BI/NAP1/027 strain).[65] Enteric bacterial pathogens such as *Salmonella* occur at increased frequency in immunocompromised patients, especially HIV-infected individuals. In some regions of Africa, nontyphoidal *Salmonella* infections are among the most common causes of bacteremia.[66] Severe *Salmonella* infections may be associated with intestinal perforation. *Shigella, Campylobacter jejuni, E. coli* (enterotoxigenic, enteroadherent, and enteroaggregative), and *Yersinia* species are other bacterial causes of diarrhea, although they are less commonly associated with bacteremia.

Protozoal infections are seen more commonly in HIV-infected patients than in other immunocompromised groups. At CD4 counts less than 200 cells/mm^3, patients with HIV infection may present with unusual protozoa (e.g., *Cryptosporidium* and *Microsporidium*). Occasionally, these pathogens are also seen in transplant recipients.[67,68] Such pathogens are not detected on routine microscopic examination for ova, cysts, and parasites. Special stains and microbiologic techniques are needed. A routine examination usually detects *Giardia lamblia, Entamoeba histolytica,* and other more common pathogenic protozoa.

CMV can cause significant colitis in all immunocompromised populations. CMV colitis may occur in the absence of systemic evidence of infection (i.e., PCR finding on peripheral blood may be negative[69,70]). An intestinal biopsy may be required to make the diagnosis. A CMV intestinal infection may present with diarrhea, but may have more profound presentations such as intestinal perforation.[71,72]

Finally, mycobacterial infections such as tuberculosis occasionally can be associated with colitis.[73] *M. avium* complex can be grown readily from the feces of patients with HIV infection and CD4 counts less than 50 cells/mm^3, but it is not always the cause of diarrhea in such patients.

SEPSIS WITHOUT A DEFINED SITE OF INFECTION

Immunocompromised patients may be referred for ICU admission because of signs of sepsis despite no localizing source of infection being found. Classically such patients have gram-negative bacteremia (including with *Pseudomonas aeruginosa*), and antipseudomonal therapy needs to be commenced empirically. However, gram-positive cocci (for example, *Staphylococcus aureus*), gram-positive bacilli (for example, *Listeria monocytogenes*), and gram-negative cocci (for example, *N. meningitidis* after splenectomy or use of eculizumab) may sometimes be responsible for presentations with sepsis.

CAR T-cell therapy may be associated with a syndrome resembling sepsis called *cytokine release syndrome (CRS).* CRS is caused by the production of inflammatory cytokines by the CAR T cells themselves and by other activated immune cells.[74] It presents with high-grade fever, hypotension, hypoxia, and reduced cardiac function and usually manifests within 7 days after CAR T-cell infusion.[75] CRS has been reported in up to 93% of patients receiving CAR T-cell therapy and causes significant morbidity and poor outcomes and can be extremely difficult to distinguish from sepsis.

THERAPEUTIC DIFFICULTIES IN IMMUNOCOMPROMISED PATIENTS

Empiric Therapy

The choice of empiric antimicrobial therapy is often difficult in immunocompromised patients because of the broad differential diagnosis involved and the substantial risk of antimicrobial resistance (stemming from prolonged hospitalization and frequent prior use of antibiotics). As emphasized earlier, management of infection in an immunocompromised patient can be simplified by narrowing the differential diagnosis by thorough history taking, review of prior medical records, and careful physical examination. Aggressive early diagnostic maneuvers before beginning empiric antimicrobial therapy can enable a definitive diagnosis to be made. Failure to collect specimens before beginning empiric therapy can lead to prolonged, expensive, and unnecessary therapy.

Empiric antibiotic therapy in suspected bacterial infections should be tailored to the individual to maximize the chance that the therapy is microbiologically adequate. There is a clear link between microbiologically adequate empiric therapy and successful outcomes from infections in the ICU.[76] In settings such as severe pneumonia in an immunocompromised patient, empiric regimens comprising vancomycin, ciprofloxacin,

meropenem, amphotericin (or voriconazole), ganciclovir, and trimethoprim/sulfamethoxazole may be necessary to cover potentially lethal infections with methicillin-resistant *S. aureus, P. aeruginosa, Legionella,* fungi, CMV, and *P. jirovecii*. However, increasing resistance to carbapenems may necessitate consideration of newer antibiotics such as ceftazidime-avibactam, cefiderocol, and ceftolozane-tazobactam. Nephrotoxic antibiotics such as colistin, polymyxin B, or amikacin may be problematic in immunocompromised patients with baseline renal impairment, despite the activity of these antibiotics against many carbapenem-resistant organisms.

There is no established role of combination empiric therapy with antifungal agents. The decision to start empiric mycobacterial therapy is never an easy one. In general, it is only advised when there is a substantial risk of tuberculosis. Empiric therapy for disseminated *Strongyloides* infection may have a role in immunocompromised patients coming from an endemic area and with the classic presentation of disseminated infection.

Immunocompromised patients presenting with acute meningitis should receive treatment that covers *S. pneumoniae* and *L. monocytogenes*. The combination of vancomycin, ampicillin, and ceftriaxone may be necessary (vancomycin and ceftriaxone for multidrug-resistant *S. pneumoniae* and ampicillin for *Listeria*). The combination of liposomal amphotericin and 5-flucytosine is recommended empirically for meningitis in which antigen testing or India ink stain of the CSF reveals encapsulated fungi consistent with *C. neoformans*. Immunocompromised patients with space-occupying lesions of the brain can be treated empirically with an antifungal drug (amphotericin or voriconazole) if the suspicion of disseminated fungal infection is high, although nocardiosis, toxoplasmosis, or mycobacterial infection would not be covered without specific therapy.

For immunocompromised patients with severe diarrhea requiring ICU admission, empiric therapy with metronidazole or oral vancomycin (for *C. difficile)* and ganciclovir (for CMV) may be given after fecal samples have been collected. Colonic biopsy may be necessary if it can be safely performed. For immunocompromised patients with intestinal perforation, antibiotic coverage against gut flora (i.e., treatment of peritonitis) plus treatment of the most likely causes of perforation (e.g., ganciclovir for CMV) may be chosen.

Pathogen-Directed Therapy

The importance of appropriate specimen collection is that empiric therapy can be streamlined (de-escalated) if cultures or other diagnostic tests reveal positive findings. With immunocompromised patients, antimicrobial therapy is often complicated by drug interactions or adverse reactions. Transplant recipients taking calcineurin inhibitors (e.g., cyclosporine or tacrolimus) or HIV-infected patients taking protease inhibitors are most at risk because these drugs may be metabolized by the cytochrome P-450 system.[77] Significant interactions may occur between rifampin, macrolide antibiotics, azole antifungal drugs, and calcineurin inhibitors.[78] Aggressive treatment of infections in immunocompromised hosts (e.g., with amphotericin, pentamidine, or foscarnet) may be associated with renal dysfunction, compounding the nephrotoxic effects of calcineurin inhibitors. Antimicrobial agents such as linezolid or ganciclovir frequently cause neutropenia, potentially adding further host defense defects.

COVID in the Immunocompromised

The COVID-19 pandemic has had a disproportionate effect on immunocompromised patients. Recent studies suggest that immunocompromised patients have typical manifestations of COVID-19; however, they are at an increased risk of poor outcomes and prolonged viral replication. Hematopoietic cell transplant (HCT) recipients diagnosed with COVID-19 at a median time from transplant of 17 months had increased rates of mechanical ventilation and a 30-day postdiagnosis survival of only 68% for recipients of allogeneic transplants and 67% for autologous recipients.[79] A review in Sweden of solid organ transplant recipients demonstrated a 30-day all-cause mortality of 9.6% in patients with COVID-19, which was higher than the general Swedish population over the same period (3.1%). Worse outcomes were demonstrated in those with older age, male, and a high body mass index (BMI).[80] COVID-19 has also been demonstrated to lead to a poorer prognosis in patients living with a diagnosis of HIV, with increased mortality and an increased rate of hospitalization, particularly among those without viral suppression and lower CD4 counts.[81] Importantly, prolonged COVID-19 symptoms and viral shedding have also been demonstrated in immunocompromised patients. Studies have demonstrated this in patients with HCT, CAR T-cell therapy, and hematologic neoplasms and solid tumors. However, the risk of transmitting infection despite persistent viral shedding remains uncertain, and decisions to remove infection control precautions should be made in consultation with infection prevention experts and local guidelines.[82]

CONCLUSION

Infection is likely to be one of the most significant problems an immunocompromised patient faces. These patients may present with severe infection or acquire infection while critically ill resulting from other causes. Prevention of infection in the ICU is of primary importance. Pneumonia can be readily prevented by many strategies. Ventilator-associated pneumonia may be prevented by a bundle of interventions.[83] Aspiration of subglottic secretions and selective digestive tract decontamination, although supported by some trials, are still controversial. Opportunistic pneumonia with *P. jirovecii* can be prevented by use of prophylaxis with trimethoprim/sulfamethoxazole, dapsone, or nebulized pentamidine. Environmental exposure to *Legionella* and *Aspergillus* spp. can be prevented by ensuring water purification techniques (e.g., copper-silver ionization) and by preventing exposure of patients to construction activity. Infections caused by pathogens transmitted human to human, such as *M. tuberculosis,* can be prevented by isolation precautions.

Many extrapulmonary infections can also be prevented. CMV infection can be prevented by universal prophylaxis with ganciclovir, valganciclovir, valacyclovir, or a preemptive approach using serial PCR of peripheral blood.[84,85] A similar preemptive approach may be useful in preventing aspergillosis by monitoring peripheral blood for the galactomannan antigen, although this remains controversial.[86,87] *C. difficile* infection is difficult to prevent because there is a clear need for antibiotic therapy for immunocompromised patients with infection. The increasing incidence, severity, and high rate of recurrence of *C. difficile* infection have become significant problems.[88] A randomized controlled study demonstrated that the addition of monoclonal antibodies against *C. difficile* toxins to antibiotic agents significantly reduced the recurrence of *C. difficile* infection, even among patients with the epidemic BI/NAP1/027 strain.[89] Finally, attention to classic infection control practices such as appropriate immunizations,[90–92] hand hygiene, and contact isolation is paramount in immunocompromised patients.

ACKNOWLEDGMENT

The contributions of Dr. Yoshiro Hayashi to a previous edition of this book are gratefully acknowledged.

KEY POINTS

- The degree of immunocompromise in a patient is a guide to the likelihood of particular opportunistic infections and may be indicated by the type and timing of immunosuppressive therapy and, in HIV-infected patients, by the CD4 lymphocyte count and viral load.
- Environmental exposures can be important predictors of infection type. Travel history and exposure to *M. tuberculosis, Aspergillus,* or *Legionella* are important considerations.
- The differential diagnosis of opportunistic lung infection in immunocompromised hosts is so broad that bronchoscopy with bronchoalveolar lavage, before antimicrobial therapy, is highly desirable.
- CNS lesions in immunocompromised hosts are often the result of disseminated infection. Careful examination of the skin, with biopsy of suspicious lesions, and CT of the lungs may obviate the need for brain biopsy.
- Antimicrobial therapy in immunocompromised hosts is beset by difficulties with antimicrobial resistance (especially carbapenem resistance), drug interactions, and adverse effects. Increased frequency of monitoring of immunosuppressive drug levels is essential.

Tuberculosis

Melissa L. New and Edward D. Chan

EPIDEMIOLOGY

The World Health Organization (WHO) estimates that 1.7 billion people are latently infected with *Mycobacterium tuberculosis* worldwide.[1] Approximately 10 million active tuberculosis (TB) cases emerge annually, resulting in 1.2 million deaths and making TB the leading cause of death by an infectious agent worldwide.[1–3] The majority of TB cases occurs in the developing world, with nearly 90% of cases emerging from 30 countries with a high TB burden.[1] The global incidence rate is 132 cases per 100,000 persons; however, this rate is much higher in much of sub-Saharan Africa and South Asia, with many countries having rates of over 300 cases per 100,000 persons, with some areas such as certain townships in South Africa with much higher incidences.[2,4] Countries with the most cases per year include India (2.7 million cases per year), China (866,000 cases per year), and Indonesia (845,000 cases per year). Over the past two decades, global incidence and mortality from TB have declined, thanks to efforts for screening and prevention in countries with a high TB burden; however, because of the growing global population, the number of active TB cases has not gone down.

In the United States, the TB rate continues to decline, with 2.8 new cases per 100,000 reported in 2018, the lowest rate recorded since national reporting began in 1953.[5] Foreign-born persons and racial/ethnic minorities bear a disproportionate burden of TB in the United States. In 2018 more than 70% of new TB cases were in foreign-born persons, with non-Hispanic Asians and Hispanics representing most of this group.[5,6]

Four states (California, Florida, New York, and Texas) account for around half of all TB cases in the United States. Among US-born racial and ethnic groups, TB disproportionately affects racial and ethnic minorities, with blacks/African Americans, Native Americans/Alaska Natives, and Native Hawaiians/Pacific Islanders having TB incidence rates 6.5 times, 10 times, and 14 times higher than US-born whites, respectively.[5] Other groups at increased risk of active TB include prisoners, homeless persons, residents of long-term care facilities, and human immunodeficiency virus (HIV)–positive individuals.[5]

The acquired immunodeficiency virus syndrome (AIDS) epidemic has contributed significantly to the rise in TB cases worldwide, with approximately 9% of new cases developing in people living with HIV, mostly in Africa.[1] HIV increases the risk of developing TB by 21-fold in countries where the prevalence is more than 1% in the general population.[7]

The bacille Calmette-Guérin (BCG) vaccine has been widely used in TB-endemic areas for decades. Its efficacy against TB resides mainly in its excellent protection against disseminated and meningeal TB in children.[8] Although its efficacy against pulmonary TB has an overall rate ratio of ~0.50—translating to an efficacy of 0%–80% in different trials—its effectiveness varies widely depending on age at vaccination (better protection when given at school age and to neonates), tuberculin skin test (TST) status (better protection when TST is negative), and distance from the equator (better protection the farther away the recipient lives from the equator).[8,9] BCG is given subcutaneously, but a recent report indicated that in macaques, BCG given intravenously provides much greater protection.[10] Results from the trial of a TB vaccine ($M72/AS01_E$) are promising and raise the hope for a reduction in the global incidence of active TB.[11]

DRUG-RESISTANT TUBERCULOSIS IS A FOREBODING PROBLEM

Drug-susceptible TB is readily curable, provided adherence to medications is followed. However, TB caused by *M. tuberculosis* strains with resistance to one or more first-line agents often requires a significantly longer course of antibiotics; second-line agents have more difficult-to-tolerate side effects, and the treatment of drug-resistant TB is significantly more challenging. More important, multidrug-resistant TB (MDR-TB)—defined as resistance to at least both isoniazid (INH) and rifampin (RIF), two of the most powerful first-line anti-TB drugs—is associated with significant increase in morbidity and mortality.[12–14]

It is estimated that of the 10 million new cases of TB per year worldwide, approximately 500,000 are caused by MDR-TB.[1] Most cases of drug-resistant TB are in India, China, and Russia.[1,15] Although cases of MDR-TB are well known to spawn from inappropriate treatment of drug-susceptible TB, the Baltic countries of the former Soviet Union have very high rates of MDR-TB among new, not previously treated TB cases. Additionally, new molecular epidemiologic techniques have demonstrated direct transmission as a significant contributor to new cases of drug-resistant TB.[16] Fortunately, the percentage of MDR-TB cases in the United States decreased between 1991 and 2006 from 3.5% to 1.1%.[17,18] MDR-TB disproportionately affects foreign-born individuals, with 86% of cases coming from non–US-born persons.[6]

Extensively drug-resistant tuberculosis (XDR-TB) is defined as resistance to INH, RIF, any fluoroquinolone, and a second-line injectable (amikacin, kanamycin, or capreomycin). XDR-TB has emerged with a wide geographic distribution, including the United States, and is associated with poorer treatment outcomes than MDR-TB, especially in those coinfected with HIV.[15,19–25] There are strains of TB with resistance beyond XDR; however, it is debated how to define and treat these strains.[16,26] Fortunately, new drugs and treatment regimens for MDR-TB and XDR-TB have emerged in the past decade, including a change in the recommended treatment strategy put forth by the World Health Organization (WHO). New regimens raise the hope for shorter courses of treatment, better adherence, fewer adverse effects, and improved outcomes in treating drug-resistant TB.[27–33]

TUBERCULOSIS IN THE INTENSIVE CARE UNIT

Tuberculosis patients requiring intensive care unit (ICU) care represent 1%–3% of all patients hospitalized with active TB. Most studies of TB patients requiring ICU admission are retrospective and frequently include a disproportionate number of HIV-positive individuals. TB should be considered in the differential diagnosis of critically ill patients, particularly in foreign-born individuals who emigrated from countries with a high prevalence of TB. With the increased use of tumor necrosis factor-alpha (TNF-α) antagonists and other immunosuppressive agents, ICU physicians are more likely to encounter patients with nonclassical features of TB. In this chapter, selected critical care issues in TB are discussed. Some disease forms, such as renal and peritoneal TB, are omitted because they are less likely to be seen in the ICU.

PULMONARY TUBERCULOSIS

Pulmonary disease is by far the most common manifestation of active TB and of TB requiring ICU admission. Lung disease from TB may be the result of progression of a primary infection or of reactivation disease.

Primary infection occurs after airborne implantation of tubercle bacilli into the lungs. *M. tuberculosis* is transported by infected dendritic cells from the lungs to hilar lymph nodes and then throughout the bloodstream, resulting in secondary occult infections at extrapulmonary sites (Fig. 122.1). Although primary infection is usually asymptomatic in adults, it can present with fever, hilar adenopathy, lung opacifications, pleural effusion, and even severe pulmonary disease that can mimic viral or bacterial pneumonia, potentially delaying the diagnosis of TB. In severely immunocompromised patients, primary TB may be aggressive and become disseminated. Pleural TB, which can present as pleuritis or empyema, is usually a manifestation of primary TB, although it may also occur with reactivation disease. Pleural biopsy specimens are more likely to yield positive cultures than pleural fluid.

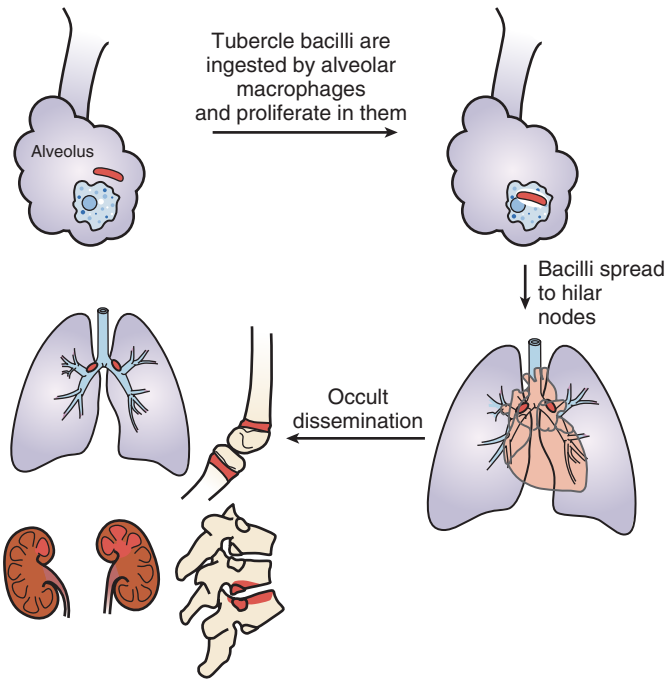

Fig. 122.1 Cartoon representation of a primary infection of TB and occult dissemination. Largely asymptomatic, dissemination of *M. tuberculosis* after primary infection occurs when infected mononuclear cells migrate throughout the body, particularly to the lung apices, kidneys, bone growth plates, and vertebrae, resulting in latent infection.

In non–TB-endemic countries, most cases of active TB are caused by reactivation of latent TB infection (LTBI). Risk of reactivation from LTBI is about 5% within the first 18 months of the initial infection and about 5% for the remaining lifetime for immunocompetent individuals.[34] Typically, reactivation TB is a subacute fibrocavitary pneumonia involving the upper lobes and/or superior segments of the lower lobes. However, reactivation TB can involve any organ system and can present in a fulminant fashion with respiratory failure.[35]

Both primary and reactivation TB can cause bilateral alveolar infiltrates, hypoxic respiratory failure, and acute respiratory distress syndrome (ARDS).[35,36] Consolidation is the most frequent radiographic pattern of patients with pulmonary TB who are admitted to the ICU.[37,38]

Because this radiographic pattern is highly nonspecific, chest x-rays are often not helpful in raising suspicion for TB. Nevertheless, in patients with active TB, consolidation on initial chest radiographs was found to be a stronger, independent predictor for in-hospital mortality than the presence of nodules, interstitial infiltrates, or cavities.[38,39] One possible reason for this is a delay in diagnosis, as clinicians may be more prone to favor nontuberculous bacterial pneumonia in the absence of cavitation or a miliary pattern. Another reason is that consolidation may be an indication of a suboptimal immune response to the infection. Pulmonary gangrene, which carries a mortality of up to 75%, can ensue when rapid progression of infiltrates causes vascular damage and death of lung tissue.[40] Other life-threatening complications of pulmonary TB include hemoptysis, spontaneous pneumothorax, bronchopleural fistula, and empyema. Not unexpectedly, delayed recognition and treatment of nosocomial pneumonia complicating TB patients requiring mechanical ventilation have significant adverse effects on survival.[41,42]

Perhaps the best safeguard to prevent missing a diagnosis of pulmonary or disseminated TB in critically ill patients is to maintain a high index of suspicion for it in at-risk individuals—for example, the foreign-born, immunosuppressed, and/or those known to have a history of untreated LTBI. Studies have shown that the presence of diffuse infiltrates consistent with ARDS and/or acute respiratory failure may cause physicians to inappropriately dismiss the diagnosis of TB, especially as TB remains a rare cause of ARDS.[43–46] Older individuals (≥65 years old) or patients with AIDS may also have a delayed diagnosis of TB resulting, in part, from atypical presentations.[47,48]

In-hospital mortality among TB patients who require ICU admission is high, at 26%–73%, and may be higher among those requiring mechanical ventilation, at 48%–81%.[39,41,42,49–56]

Delayed initiation of anti-TB treatment has been shown to increase mortality.[53] Other risk factors for death among TB patients in the ICU are less specific to TB, such as severity of illness; hypoalbuminemia; anemia; lymphopenia; alcoholism; advanced age; and organ failure requiring life support, including mechanical ventilation, renal replacement therapy, and use of vasopressors.[39,41,42,49,50,57,58] Despite being a relatively rare cause of respiratory failure, pulmonary TB requiring ICU care carries a poor prognosis. Early recognition of the infection is essential in reducing mortality and preventing the nosocomial spread of *M. tuberculosis*.[45]

DISSEMINATED TUBERCULOSIS

Disseminated, or "miliary," TB is more likely to occur in the very young, the very old, and patients with underlying diseases such as AIDS. It may result from either primary or reactivation TB. Disseminated TB typically presents subacutely with symptoms present for days to months, but it can manifest fulminantly with ARDS, septic shock, and multiorgan failure.[59,60] Typical presenting signs and symptoms include fever, malaise, weight loss, dyspnea, and hypoxia.

The chest radiograph (Fig. 122.2A) and computed tomography (CT) scan (see Fig. 122.2B) may show a typical miliary pattern manifested by

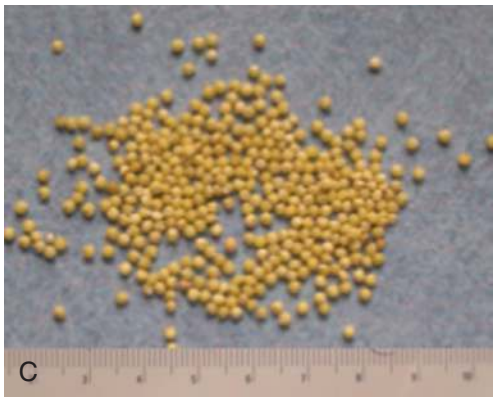

Fig. 122.2 Miliary TB. **A**, Chest radiograph of a patient with miliary TB. **B**, The chest CT scan of the same patient. Both show the characteristically small nodules (less than 2 mm) that are supposed to resemble **(C)** millet seeds.

a profusion of diffuse small (<2 mm) nodules that resemble the size and uniformity of millet seeds (see Fig. 122.2C). In some cases of disseminated disease, the chest x-ray may appear normal. Virtually any organ may be involved, including the adrenals, brain, meninges, spleen, liver, gallbladder, pancreas, eyes, kidneys, and skin. Bone marrow involvement by TB commonly manifests with anemia, leukemoid reaction, and thrombocytosis. The diagnosis of miliary TB can be difficult. If disseminated TB is suspected, sputum acid-fast smear and culture should be obtained even if lung disease is not apparent. Biopsy and culture of affected tissues such as the bone marrow are often required. Culture of blood, urine, and/or stool may be positive, especially in AIDS patients.[60,61]

NEUROLOGIC TUBERCULOSIS

Tuberculous Meningitis

TB meningitis is rare, accounting for more than 1% of global TB cases and with only 107 cases reported in the United States in 2013.[62] It occurs via rupture of a subependymal tubercle that seeded and formed during primary infection or disseminated disease. Individuals at high risk of TB meningitis include very young children with primary TB and older patients with immunodeficiency disorders such as HIV. Most will have no known history of TB, but evidence of extrameningeal disease (e.g., pulmonary, urinary) can be found in about half of the patients.[63,64]

TB meningitis is typically a subacute disease. Symptoms can be present for 1 day to 9 months, with a median of 10–14 days before diagnosis.[63,65] A prodromal phase of low-grade fever, malaise, headache, dizziness, vomiting, and/or personality changes may be present for 2–3 weeks before patients seek medical care. Typical findings at presentation include worsening headache, altered mental status, stroke, hydrocephalus, and cranial neuropathies. These clinical features are the result of basilar meningeal fibrosis and vascular inflammation.[66] Classic manifestations of bacterial meningitis, such as stiff neck and fever, may be absent. When allowed to progress, seizures and coma may ensue.[67]

The diagnosis of TB meningitis can be difficult and may be based only on clinical findings without definitive microbiologic proof. The TST is positive in only about 50% of patients with TB meningitis. Certain clinical characteristics such as longer duration of symptoms (>6 days), moderate cerebrospinal fluid (CSF) pleocytosis, and the presence of focal deficits increase the probability of TB meningitis.[68,69] Characteristic CSF findings of TB meningitis include the following:

- Leukocytosis with predominance of lymphocytes. White blood cell counts are usually between 100 and 500 cells/μL. Lower white blood cell counts and neutrophil predominance may be seen very early in the course of the disease.
- Elevated protein levels, usually between 100 and 500 mg/dL.
- Low glucose levels, typically less than 45 mg/dL.

CSF samples should be sent for acid-fast smears, but this has low sensitivity. Because TB meningitis is a paucibacillary disease, centrifuging larger quantities of CSF (10–15 mL) from several lumbar punctures can increase the sensitivity. Culture is also associated with low sensitivity and can take weeks to become positive. A stereotactic biopsy can be performed if tissue samples are needed. Mycobacterial antigens by enzyme-linked immunosorbent assay (ELISA) or radioimmunoassay have been detected in the CSF of patients with TB meningitis.[70] A large study cited sensitivities of 90% for interferon-gamma (IFN-γ) release assay performed on whole blood, 82% for CSF in automated culture systems, 73% for CSF in Lowenstein-Jensen medium, 30% for CSF adenosine deaminase, and 27% for Ehrlich-Ziehl-Neelsen acid-fast staining of the CSF.[71]

In recent years, the use of nucleic acid amplification assays (NAAs) has been shown to aid in the diagnosis of TB meningitis. These tests can detect *M. tuberculosis* in a few hours with a sensitivity of 56%–80% and a specificity of 95%–98%.[72–75] The sensitivity of CSF microscopy and culture falls rapidly after the start of treatment, whereas mycobacterial DNA may remain detectable within the CSF up to a month after the start of treatment.[76] Given the high morbidity and mortality associated with TB meningitis, the WHO recommends use of Xpert MTB/RIF, an NAA, to test CSF in preference to conventional microscopy and culture as the initial diagnostic test in patients with suspected TB meningitis.[1] The novel loop-mediated isothermal amplification (TB-LAMP) assay, which is an NAA technique, has some advantages over polymerase chain reaction (PCR) in that it is performed at a constant temperature and produces a high amount of DNA amplification. This technology has been used on CSF in some settings to diagnose TB meningitis.[77] Regardless of which diagnostic test is used, a negative test neither excludes the diagnosis nor obviates the need for continued empiric treatment if the clinical suspicion is high.[78]

Magnetic resonance imaging (MRI) often reveals a basilar meningeal enhancement (Fig. 122.3) and/or hydrocephalus.[64] Hypodensities indicating cerebral infarcts and ring- or nodular-enhancing lesions can also be seen. MRI is superior to CT for evaluating the brainstem and the extent of lesions.

The outcome of TB meningitis is improved by timely treatment. Thus empiric treatment is warranted when risk factors and clinical features are suggestive of TB meningitis, even before microbiologic confirmation. Chemotherapy for TB meningitis follows the model of short-course chemotherapy for pulmonary TB—an induction phase, followed by a continuation phase. However, unlike pulmonary TB, the optimal drug regimen and duration of each phase of treatment are not

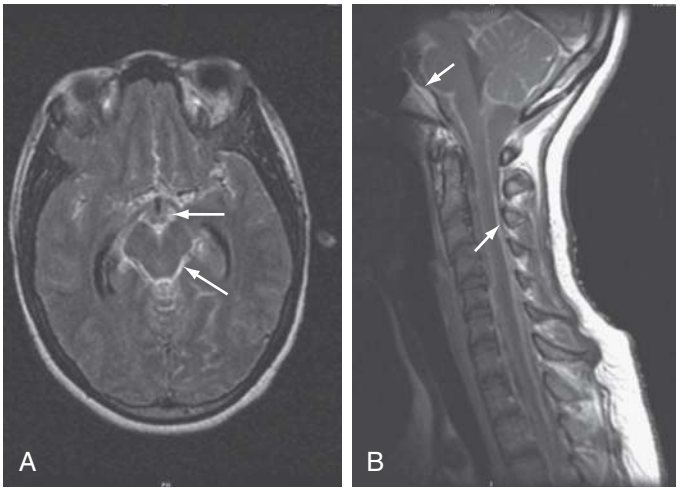

Fig. 122.3 Tuberculous meningitis. T1-weighted **(A)** transverse MRI of the brain and **(B)** sagittal MRI of the base of the brain and the spinal cord in a patient with tuberculous meningitis. Note the enhanced meninges (*arrows*) in the basilar regions of the brain, brainstem, and spinal cord.

clearly established. INH and RIF remain the most essential drugs. INH penetrates the CSF freely and has potent early bactericidal activity.[79–81] RIF penetrates the CSF less well (maximum concentrations around 30% of plasma), but the high mortality from RIF-resistant TB meningitis has confirmed its central role in the treatment of central nervous system (CNS) disease.[82] One study compared standard oral doses of RIF (450 mg) with higher doses of RIF (600 mg) administered intravenously. The higher-dose RIF group had three times higher CSF concentrations than the standard oral dose group and improved mortality (35% vs. 65%).[83] Increased CSF concentrations of RIF have also been achieved with high oral doses (1350 mg, approximately 30 mg/kg) of RIF.[84] INH, RIF, and pyrazinamide are considered mandatory at the beginning of TB meningitis treatment, and some centers use all three drugs for the duration of therapy.[85] There are no data from controlled trials to guide the choice of the fourth drug. Most authorities recommend either streptomycin or ethambutol, although neither penetrates the CSF well in the absence of inflammation, and both can produce significant adverse reactions. Although fluoroquinolones have good CNS penetration, their addition to a standard regimen did not improve outcomes in treatment of drug-susceptible TB meningitis; fluoroquinolones are recommended for treatment of RIF-resistant and MDR-TB strains.[86] Linezolid, which also has good CNS penetration, may be beneficial for severe TB meningitis, though data are few.[86,87] Therapy should be continued for 9–12 months.

Adjunctive glucocorticoid treatment of TB meningitis has been recommended for more than 50 years. There has been long-standing concern that glucocorticoids may reduce the penetration of anti-TB drugs into the CNS; however, data increasingly point toward their benefit in TB meningitis.[66] A Cochrane systematic review and meta-analysis of seven randomized controlled trials involving 1337 participants concluded that glucocorticoids improved survival from TB meningitis by 25%; however, this analysis included few HIV-infected individuals.[88] Currently, the WHO recommends initial adjuvant glucocorticoid therapy in patients with TB meningitis.[89]

Because there are no controlled trials comparing different glucocorticoid regimens, the choice of regimen should be based on those found to be effective in published trials. One recommended regimen for adults is dexamethasone 12 mg a day for 3 weeks, followed by a gradual taper over the next 3 weeks.[90] In a large study from Vietnam, patients with mild disease received intravenous dexamethasone 0.3 mg/kg/day × 1 week, 0.2 mg/kg/day × 1 week, and then 4 weeks of tapering oral therapy.[91] For patients with severe TB meningitis, intravenous dexamethasone was given for 4 weeks (1 week each of 0.4 mg/kg/day, 0.3 mg/kg/day, 0.2 mg/kg/day, and 0.1 mg/kg/day), followed by 4 weeks of tapering oral dexamethasone therapy.[91]

The prognosis of TB meningitis largely depends on the neurologic status at the time of presentation and time to treatment initiation. Various case series indicate a mortality rate between 7% and 65% in developed countries and up to 69% in underdeveloped areas.[63,64,92] Most patients will die in 5–8 weeks if not treated. Mortality risk is the highest in those who are elderly and with comorbidities, severe neurologic involvement on admission, and rapid progression of disease. Neurologic sequelae occur in up to 50% of survivors.[92]

Other Central Nervous System Manifestations of Tuberculosis

Other CNS manifestations of TB include brain abscesses, intracranial tuberculomas, vasculitis, radiculomyelitis, and spinal arachnoiditis. These can occur in conjunction with TB meningitis but are less likely to be seen in the ICU when isolated. Intracranial tuberculomas are more common among pediatric patients, especially infants, and can occur in any region of the brain. They result from hematogenous spread of TB. Tuberculous radiculomyelitis is a paradoxical reaction to the treatment of TB meningitis and may respond to glucocorticoids. Signs and symptoms include subacute paraparesis, radicular pain, bladder disturbance, and paralysis.[93]

CARDIOVASCULAR TUBERCULOSIS

Tuberculous Pericarditis

Pericarditis is an uncommon, but important, manifestation of TB. In countries with a low incidence of TB, it is primarily a disease among the elderly and those with HIV, but it should be considered as a differential diagnosis of any patient with pericarditis and/or pericardial effusion. Tuberculous pericarditis can result from local spread from the lungs, tracheobronchial tree, lymph nodes, or adjacent bones or by disseminated infection. The onset is usually insidious. Presenting signs and symptoms can be nonspecific (fever, dyspnea, and weight loss) and/or more specific to the pericardium, such as characteristic chest pain that is relieved with sitting up and leaning forward. Large hemorrhagic effusions may develop, resulting in cardiac tamponade. Pericardial inflammation and thickening may eventually cause constrictive pericarditis. The presence of both pericardial effusion and constrictive pericarditis is physiologically characterized by the continued elevation of diastolic pressure after pericardiocentesis. Such a finding should raise suspicion for tuberculous pericarditis.

The diagnosis of tuberculous pericarditis can be difficult to prove. Culture of pericardial fluid is positive in only 30% of cases, and pericardial biopsy has a yield of approximately 60%. Biopsy of the pericardium may reveal granulomatous changes consistent with TB or stain positive for acid-fast bacteria. The presence of elevated adenosine deaminase levels in the pericardial fluid has been shown to indicate tuberculous pericarditis, but confirmation is needed.[94] PCR holds promise as a more sensitive test in the diagnosis of tuberculous pericarditis.[95,96] Many individuals are treated empirically for tuberculous pericarditis based on clinical suspicion, positive TST results, imaging studies, and exudative pericardial fluid with high protein and mononuclear white count. Treatment involves standard four-drug regimens as for other manifestations of TB. Glucocorticoids have been used as adjunctive treatment for TB pericarditis to reduce the need for operative intervention.[97] However, a more recent study of 1400 adults with TB pericarditis did not have a lower mortality or frequency of cardiac tamponade with corticosteroid treatment. Additionally, the steroid-treated group had a

higher frequency of AIDS-related malignancy.[98] Thus there is no consensus on whether to administer adjunctive glucocorticoids for TB pericarditis patients with corticosteroids.[89,99]

Other Cardiovascular Manifestations of Tuberculosis

In addition to the pericardium, TB may affect the endocardium, myocardium, and epicardium (coronary arteries). These disorders are very rare. Endocardial involvement may manifest as endocarditis or as mural thrombi with entrapped *M. tuberculosis*. Tuberculous myocarditis occurs via direct spread from pericardial or mediastinal lymph nodes or from disseminated disease.[100] TB may also affect the coronary arteries, resulting in coronary arteritis with granulomatous inflammation of the arterial wall and obliterative intimal fibrosis.[101]

The aorta can be affected by TB, causing aortitis, aortointestinal fistula formation, or rupture.[102,103] The pathogenesis of aortitis includes septic embolization from endocarditis, seeding of a preexisting aneurysm from bacteremia, or extension from a contiguous site of infection. Signs and symptoms include fever, abdominal or back pain, and a palpable abdominal mass. Blood cultures are positive for *M. tuberculosis* in approximately 15% of cases. CT findings include air in the aortic wall, a periaortic nodularity, a saccular aneurysm in a noncalcified aorta, and a rapidly increasing aortic diameter. A primary mycotic aneurysm of the aorta may be a sequela of chronic tuberculous aortitis.[104,105]

TUBERCULOSIS IN HUMAN IMMUNODEFICIENCY VIRUS–POSITIVE PATIENTS

HIV is the most important host risk factor for active TB.[106] In many developing countries, TB is the most common opportunistic infection associated with HIV. The estimated annual risk of active TB among persons with LTBI in the general population is 12.9 per 1000 person-years. In contrast, rates of progression to active TB among HIV-infected persons with LTBI range from 35 to 162 per 1000 person-years. More recent estimates for reactivation TB in HIV-positive individuals shows a rate ratio of 57 (95% confidence interval [CI], 27–120) compared with HIV-negative individuals with LTBI.[107] Because TB may be an initial manifestation of HIV infection, all patients with TB should be tested for HIV. The WHO estimates that globally, 8.6% of TB patients in 2018 were coinfected with HIV and that HIV coinfected patients accounted for over 20% of deaths from TB.[1]

The mechanism of increased TB susceptibility in HIV-positive persons is incompletely understood. Unlike other AIDS-related opportunistic infections, the $CD4^+$ count is not always a reliable predictor of increased risk of TB disease, although $CD4^+$ lymphopenia does reduce IFN-γ production, impairing macrophage and dendritic cell activation. Alveolar macrophages (AMs) are important components of an effective immune response to TB,[108] and AM apoptosis represents a critical host defense mechanism that promotes *M. tuberculosis* elimination. In this context, another possible mechanism by which HIV increases susceptibility to TB is that HIV-infected AMs have a reduced apoptotic response to *M. tuberculosis* compared with AMs from healthy individuals.[109,110]

When the $CD4^+$ count is above 350 cells/μL, pulmonary TB in AIDS patients is more likely to present with typical chest radiographic findings of upper lobe fibrocavitary disease.[111] However, as the $CD4^+$ count decreases, pulmonary TB tends to manifest with more atypical radiographic manifestations, such as mediastinal adenopathy, diffuse miliary or nodular infiltrates, focal lower zone opacifications, and lack of cavitation.[111] Among HIV-positive persons, death from TB was significantly associated with low $CD4^+$ counts.[41,112]

Although coinfection with HIV is considered to contribute significantly to TB-related mortality, a study showed no difference in mortality in TB patients requiring ICU care between those who were HIV negative and those with advanced AIDS in a low-burden, resource-rich country where state-of-the-art intensive care is available, suggesting that the severity of illness has a greater influence on mortality than the HIV status per se.[41] Extrapulmonary TB is more common among HIV-positive patients, occurring in up to 70%. Disease involving the lymph nodes is especially common. Other extrapulmonary manifestations include miliary disease, sepsis, and CNS disease.[47,113] Empiric treatment may be necessary before the diagnosis is confirmed. If rapid diagnosis is needed, NAAs can be used, although they are more accurate in smear-positive cases.

After initiating antiretroviral therapy (ART) in severely immunosuppressed patients, those with subclinical or recently diagnosed TB may display a paradoxical reaction, where there is an apparent clinical worsening of TB while on appropriate anti-TB treatment.[114–116] This phenomenon, also known by the more descriptive name of *immune reconstitution inflammatory syndrome* (IRIS), can manifest as early as 7 days after starting ART. Signs and symptoms include fever, weight loss, and evidence of local inflammatory reactions such as lymphadenitis and worsening pulmonary disease such as increased pulmonary consolidation, nodules, and effusions. Histologically, a vigorous suppurative and necrotizing granulomatous reaction occurs, with or without caseation; cultures of infected material are almost invariably positive.

TUBERCULOSIS AND IMMUNOMODULATORY THERAPIES

TNF-α plays a central role in the pathogenesis of various inflammatory disorders and in the pathophysiologic response to many infections. TNF-α is produced predominantly by macrophages and lymphocytes and is active both as a membrane-bound and soluble protein.[117,118] In several animal models, TNF-α plays an essential part in the host response to TB.[119] One mechanism by which it potentiates the host defense is by its ability to induce apoptosis of *M. tuberculosis*–infected cells. Macrophage apoptosis helps contain *M. tuberculosis* by maintaining granuloma integrity, increasing the efficiency of antigen presentation, and promoting the killing of intracellular *M. tuberculosis*.[120] Administration of antibodies neutralizing TNF-α resulted in the reactivation of TB in a mouse model.[121] Interruption of the normal TNF-α–controlled response to TB reduces apoptosis, disrupts granuloma integrity, and predisposes to disseminated infection.

TNF-α antagonists are increasingly used for the treatment of various chronic inflammatory disorders. Currently licensed TNF-α antagonists fall into two main types: monoclonal neutralizing anti–TNF-α antibodies and the soluble p75 subunit of the TNF-α receptor (TNF-α–R). The soluble TNF-α–R antagonizes TNF-α function by acting as decoys to bind TNF-α. Four monoclonal anti–TNF-α antibodies (infliximab, adalimumab, certolizumab pegol, and golimumab) and one soluble TNF-α–R (etanercept) are in clinical use. Patients treated with TNF-α blockers have a TB incidence rate of 1.17 per 1000 patient-years—12.2 times that of the general population[122]; almost all these cases are caused by reactivation of LTBI. A consensus statement reported that the relative risk for reactivation TB is increased 25-fold in individuals who use TNF-α antagonists compared with nonusers.[123]

Important differences have emerged among the TNF-α antagonists in regard to the risks of reactivation TB. Consistently, the excess risk is associated with infliximab and adalimumab rather than with etanercept. For example, compared with etanercept, infliximab is associated with a twofold to sevenfold greater risk of TB, shorter time to TB onset (17 vs. 48 weeks), and higher proportion of TB cases with disseminated or extrapulmonary disease (25% vs. 10%).[124,125] It is not entirely clear why the neutralizing antibodies to TNF-α put people at greater

risk of reactivation TB than soluble TNF-α receptors. Possible reasons include a longer duration of action of infliximab and adalimumab and their ability to bind to membrane-bound TNF-α with greater affinity than etanercept.[117] As a result, infliximab can induce death in T cells that express the membrane-bound TNF-α, whereas etanercept cannot. In addition, anti–TNF-α antibodies can inhibit T-cell activation and IFN-γ production, whereas etanercept cannot. Thus the pharmacokinetic and biologic differences between the two main types of TNF-α antagonists may account for the greater susceptibility to intracellular pathogens with the use of the anti–TNF-α antibodies.[117,126] As might be anticipated, when anti–TNF-α antibodies are used in combination with other immunosuppressive medications such as methotrexate or azathioprine, the risk of TB reactivation is higher than that with the use of anti–TNF-α antibodies alone.[127]

DIAGNOSIS OF TUBERCULOSIS

When TB is suspected, the first diagnostic test should be a microscopic examination and culture for mycobacteria of relevant body fluids or tissues. Several specimens are often required, especially for CNS disease.

Patients with suspected pulmonary TB should be placed in respiratory isolation until two to three sputa, collected with at least 8 hours between samples, are negative for acid-fast bacteria. Because patients with extrapulmonary disease may also have occult pulmonary disease, it is generally recommended that sputum smears be sent for these patients regardless of chest radiographic findings.

Acid-fast smear does not differentiate between *M. tuberculosis* and nontuberculous mycobacteria, so culture is used to confirm species and determine drug susceptibility. Simultaneous culture on both liquid and solid media is recommended. Liquid medium such as the BACTEC systems allow growth of the organism in about 14 days, whereas growth takes 3–6 weeks on solid media (Lowenstein-Jensen or Middlebrook 7H11). Once sufficient growth is obtained, species identification can be obtained via conventional biochemical tests or more rapid tests such as nucleic acid probes, high-performance liquid chromatography, the NAP test (*p*-nitro-α-acetylamino-β-hydroxypropiophenone), or molecular tests. Only experienced laboratories should complete susceptibility testing on culture-positive specimens. Molecular fingerprinting by restriction fragment-length polymorphism can be used to distinguish strain types when laboratory contamination is suspected.

Although rapid and inexpensive, acid-fast smear microscopy is limited by its poor sensitivity (approximately 50% sensitivity in culture-confirmed pulmonary TB cases) and suboptimal specificity (50%–80%) in settings where nontuberculous mycobacteria are commonly isolated.[128–130] NAAs have become a routine procedure in many settings because they can reliably detect *M. tuberculosis* in specimens 1 or more weeks earlier than culture and can report the presence of genes that confer rifampin resistance.[129] Because of the increasing use of NAAs and the potential impact on patient care and public health, the Centers for Disease Control and Prevention (CDC) and the Association of Public Health Laboratories made recommendations for using NAAs for laboratory confirmation of TB. The CDC recommends that NAAs be performed on at least one respiratory specimen from each patient in whom a diagnosis of TB is being considered but has not yet been established and for whom the test result would alter case management or TB control activities.[131,132] A newly available assay, TB-LAMP, has a sensitivity of 98% in smear-positive and 53% in smear-negative/culture-positive patients. TB-LAMP can be used instead of or in addition to microscopy for the diagnosis of pulmonary TB, which can reduce the time to diagnosis to several hours. The sensitivity of TB-LAMP is close to that of NAAs, and the amount of laboratory infrastructure is much less, making it an appealing technology for more remote and resource-limited settings.[133]

TREATMENT OF TUBERCULOSIS

Standard treatment of adults with drug-susceptible TB is a three- or four-drug regimen for at least 6 months.[134,135] The typical course of therapy for drug-susceptible disease is 2 months of INH, RIF, pyrazinamide (PZA), and ethambutol (EMB) (initial phase), followed by 4 months of INH and RIF (continuation phase) (Tables 122.1 and 122.2). A 9- to 12-month regimen is suggested for TB meningitis; for pulmonary TB that is slow to respond to therapy, such as those with cavitary lesions and persistent sputum culture positivity even after 2 months of an appropriate four-drug regimen; or when PZA is not used in the induction regimen. EMB can be discontinued when drug susceptibility studies show sensitivity to INH and RIF. Streptomycin can be used instead of EMB if resistance is unlikely or susceptibility is shown. The continuation phase can be daily therapy, twice-weekly therapy, or thrice-weekly therapy for drug-susceptible TB (see Table 122.1). Specific guidelines, including information on first- and second-line agents, have been published by the CDC.[136]

Treatment of TB in patients with HIV is similar to that in HIV-negative patients but is often complicated by drug interactions between TB medications and antiretrovirals.[139] Protease inhibitors and nonnucleoside reverse transcriptase inhibitors can either induce or inhibit activity of the P-450-3A (CYP3A) system. RIF can increase the activity of CYP3A, leading to decreased levels of several antiretrovirals. Rifabutin is a less potent inducer of the CYP3A system and is associated with fewer drug–drug interactions, but dose adjustments may be needed. Despite these potential drug interactions, a RIF-based regimen should be used whenever possible. Patients with liver disease caused by hepatitis C virus may be at increased risk of drug-induced hepatotoxicity. Another treatment issue in HIV-TB coinfection is that patients may fail to properly absorb the anti-TB drugs, which may increase the risk of treatment failure, relapses, and acquired drug resistance.[140]

Because of the increased risk of RIF resistance, patients with HIV should *not* receive once-weekly INH-rifapentine in the continuation phase of treatment. Twice-weekly INH-RIF or INH-rifabutin should be avoided when the $CD4^+$ cell count is less than 100 cells/μL. Treating drug-susceptible pulmonary TB in HIV-positive individuals for 9 months

TABLE 122.1 Current Regimens for Treatment of Drug-Susceptible TB

Regimen	Initial Phase	Continuation Phase
Daily or 5 days per week	8 weeks of INH, RIF, PZA, ± EMB	18 weeks of INH and RIF
Intermittent	(a) 2 weeks of daily INH, RIF, PZA, and EMB (or SM), then 6 weeks of INH, RIF, PZA, EMB BIW or TIW	18 weeks of INH and RIF BIW
	(b) 8 weeks of thrice-weekly INH, RIF, PZA, and EMB (or SM)	18 weeks of INH and RIF TIW

BIW, Twice weekly; *EMB,* ethambutol; *INH,* isoniazid; *PZA,* pyrazinamide; *RIF,* rifampin; *SM,* streptomycin; *TIW,* thrice weekly.
The daily regimen is employed when patients self-administer their drugs. There is enough redundancy that if patients miss some of their doses, the outcome will remain acceptable.
The intermittent regimens are intended for directly-observed therapy (DOT) Regimen (a) entails a total of 62 doses and has yielded over 95% success rates.[137] Regimen (b) involves 78 doses and has also resulted in success rates of approximately 95% in Hong Kong, where it is the standard regimen.[138]

TABLE 122.2 Dosages of First-Line Antituberculosis Drugs in Adults and Major Adverse Effects

Drug	Daily Dosage	Twice- or Thrice-Weekly Dosage	Adverse Effects
Isoniazid	5 mg/kg oral (max: 300 mg)	900 mg BIW 600 mg TIW	Hepatitis, peripheral neuritis, drug-induced lupus, seizures, and hypersensitivity with rash and fever. Drug interactions with Dilantin and disulfiram. Pyridoxine can decrease neurotoxicity.
Rifampin	5 mg/kg oral (max: 300 mg)	10 mg/kg 600 mg BIW 600 mg TIW	Orange body secretions, flulike syndrome, hepatitis, pruritus, thrombocytopenia, nausea, anorexia, diarrhea, renal failure, and **multiple drug interactions**.
Rifabutin*	10 mg/kg oral (max: 300 mg)	5 mg/kg	Neutropenia, uveitis, hepatotoxicity, orange discoloration of body fluids
Rifapentine**	10 mg/kg ***once weekly*** (max: 600 mg)		Similar to rifampin
Pyrazinamide	15–30 mg/kg oral (max: 2.0 g)	30–35 mg/kg	Hyperuricemia, hepatitis, rash, nausea, and anorexia
Ethambutol	25 mg/kg initial 2 months, then 15 mg/kg oral	50 mg/kg BIW 30 mg/kg TIW	Optic neuritis and gastrointestinal discomfort

BIW, Twice weekly; *TIW,* thrice weekly.
*Rifabutin and rifapentine are considered first-line agents when intolerance to rifampin precludes its use or concerning drug interactions exist.
**Rifapentine is only used in a once-weekly dose in HIV-negative patients with noncavitary and uncomplicated disease. It is not approved for use in children.

rather than the standard 6 months is associated with lower relapse rates and is recommended for patients who are not receiving ART treatment or who have delayed response to therapy.[141,142] Recommendations regarding the treatment of TB in HIV patients are frequently revised as new drugs and information become available. The following websites can assist with treatment decisions and information on drug–drug interactions:
http://www.cdc.gov/tb/publications/guidelines/TB_HIV_Drugs/default.htm
http://www.medscape.com/updates/quickguide
https://www.currytbcenter.ucsf.edu/

If a patient develops IRIS while on ART, it is generally recommended that HIV therapy be continued during TB treatment whenever possible because IRIS is usually self-limited. However, more severe IRIS may require the addition of corticosteroids and/or temporary discontinuation of ART. Patients with the lowest $CD4^+$ counts, less than 50 cells/μL, are at highest risk of severe IRIS with the initiation of ART, though they also have the greatest mortality benefit with early ART initiation.[143–145] Although there has been debate as to the safest time for the initiation of ART relative to starting TB treatment, mounting evidence demonstrates that early initiation is associated with improved survival.[143,146,147] The WHO currently recommends the initiation of ART, for those not already on it, within 8 weeks of TB treatment initiation, and within 2 weeks for those with $CD4^+$ count[89] <50 cells/μL.

When MDR-TB is suspected or confirmed, a specialized treatment regimen should be used. Whenever possible, treatment for an MDR-TB strain should be guided by drug susceptibility testing to EMB, PZA, and the second-line anti-TB drugs.[148] New drugs have been developed over the past few years that can now be used for the treatment of drug-resistant TB. Typical regimens for MDR-TB will include a fluoroquinolone (levofloxacin or moxifloxacin), bedaquiline, and linezolid, in addition to other medications, including clofazimine and cycloserine or terizidone. Other medications that may be used, depending on a resistance profile, may include EMB, delamanid, PZA, imipenem-cilastatin, meropenem, amikacin, streptomycin, ethionamide, prothionamide, or para-aminosalicylic acid.[16,27,30] Local public health departments should be contacted to meet reporting requirements and will usually be responsible for treatment monitoring, including for medication adverse events. Directly observed therapy should be implemented. Patients with MDR-TB require longer therapy (generally 18 months of treatment after the last negative sputum culture). Surgical resection after 2–3 months of treatment may improve outcome.[136]

There is increasing evidence that regimens that contain some of the newer agents is highly efficacious against drug-resistant TB. A 6 month of treatment with bedaquiline, pretomanid, and linezolid resulted in a 90% favorable clinical outcome in 109 South Africans with highly-drug resistant TB, comprised of both multi-drug resistant TB (MDR-TB) and extensively drug-resistant TB (XDR-TB).[149a] A multi-drug regimen that included bedaquiline (63%), delamanid (27%), or both (10%) resulted in an 85% sputum conversion rate within 6 months in a multi-national study of over 1,000 individuals with rifampin-resistant TB or MDR-TB.[149b]

Parenteral therapy may be required in ICU patients and is recommended for patients with fulminant disease (Table 122.3). When delivered

TABLE 122.3 Selected Parenteral Medications Used in Treating Tuberculosis[136]

Medication	Preparation	Initial Dosage in Adults (maximum dosage)
Isoniazid	PO, IV, IM	5 mg/kg/day (300 mg)
Rifampin	PO, IV	10 mg/kg/day (600 mg)
Streptomycin	IV, IM	10–15 mg/kg/day or 750–1000 mg/day
Amikacin	IV, IM	10–15 mg/kg/day or 750–1000 mg/day
Kanamycin	IV, IM	10–15 mg/kg/day or 750–1000 mg/day
Capreomycin	IV, IM	10–15 mg/kg/day or 750–1000 mg/day
p-Aminosalicylic acid	PO, IV	8–12 g/day in 2 or 3 doses
Levofloxacin	PO, IV	500–1000 mg/day
Moxifloxacin	PO, IV	400 mg/day
Linezolid	PO, IV	600 mg/day

IM, Intramuscular; *IV,* intravenous; *PO,* oral.
Table shows routine daily dosing (taken from https://www.currytbcenter.ucsf.edu/sites/default/files/tb_sg3_chap5_medications.pdf). Dosages may differ in children and in patients in intermittent therapy. Persons over age 59 should receive the lower dose for aminoglycosides (750 mg).

enterally, half of the ICU patients have subtherapeutic levels of RIF.[149] INH and RIF are available in parenteral forms; EMB and PZA are not. Other active medications available for intravenous use include aminoglycosides, fluoroquinolones, capreomycin, and linezolid. In patients with renal failure, dose adjustments are required for those taking EMB, PZA, cycloserine, an aminoglycoside, capreomycin, or a fluoroquinolone. INH and PZA should probably be withheld in the setting of severe liver failure. An expert in the treatment of TB should be consulted when treating complicated ICU patients or those with MDR-TB.

Glucocorticoids are generally recommended in the adjunctive treatment of TB meningitis and possibly pericarditis, as discussed earlier.[150] There is some evidence that use of glucocorticoids in patients with acute respiratory failure from pulmonary TB may be beneficial; however, data regarding HIV-infected patients are lacking.[151,152] Typical therapy includes prednisone at 40–80 mg per day, tapered over a few weeks.

RISK TO HEALTHCARE WORKERS

The awareness that caring for TB patients poses a risk to healthcare workers (HCWs) did not emerge until the 1950s and 1960s, when studies established that *M. tuberculosis* infection was transmitted by the airborne route.[153] However, occupational transmission received little attention until numerous outbreaks of TB and MDR-TB occurred in US and European hospitals in the late 1980s and early 1990s.[154] At that time, more than 20 HCWs became ill with MDR-TB and at least 10 died.[155] Hundreds of HCWs may be latently infected with MDR-TB and thus represent a relatively large reservoir of individuals at risk of future reactivation MDR-TB.

Pulmonologists are at higher risk of occupational exposure to TB than other medical specialists. Atypical presentations of TB can put providers at increased risk when TB is not suspected and proper precautions are not taken.[156] Bronchoscopy requires close contact with patients and provokes coughing, which likely contributes to the TST conversion rate of 11% among pulmonary fellows.[156] DMF-HEPA respirators should be used when performing bronchoscopy on patients with known or suspected TB.[156]

In HCWs with negative TST reactions who undergo repeat testing, an increase in reaction size of more than 10 mm within a period of 2 years should be considered a skin-test conversion indicative of recent infection with *M. tuberculosis*. Because TST conversion typically occurs 3–8 weeks after primary infection, skin testing should be performed at 3 weeks after exposure.

HCWs with potential exposure should be monitored for symptoms, and unless they are known to have a positive TST at baseline, skin testing or an IFN-γ release assay should be performed as soon as possible after the exposure to establish a baseline. If initial screening is negative, testing should be repeated 8–10 weeks after exposure, and if found to be positive, treatment for LTBI is recommended.

KEY POINTS

- Although pulmonary TB classically develops cavitary lung disease, it can present in many ways, including ARDS and respiratory failure.
- Tuberculous meningitis typically has a subacute presentation and has a high mortality rate, which is improved with prompt treatment.
- Tuberculous pericarditis is rare but can result in constrictive pericarditis or cardiac tamponade from a hemorrhagic effusion.
- Disseminated TB can affect nearly any organ and is most common in very young or old patients and those who are immunocompromised.
- Patients with HIV and those on anti-TNF therapies are at increased risk of developing active TB.
- Culture remains the cornerstone of diagnosis of TB and is important for drug resistance testing. However, NAA assays can provide a much more rapid diagnosis and are especially recommended for use with CSF and other fluids where culture positivity is classically low, such as pericardial and pleural fluid.
- Treatment of TB requires several drugs given over many months, though the exact regimen will vary depending on the site of disease and the susceptibility of the cultured organism.
- Treating with a course of glucocorticoids is recommended to reduce morbidity and mortality from TB meningitis and possibly TB pericarditis.

ANNOTATED REFERENCES

Chan ED, Strand MJ, Iseman MD. Treatment outcomes in extensively resistant tuberculosis. *N Engl J Med.* 2008;359:657–659.
This study compared the outcomes of MDR-TB vs. XDR-TB patients at a referral hospital in the United States. Odds ratios for long-term treatment success was 21.1 (MDR-TB vs. XDR-TB). The hazard ratio of death from TB was 7.9 (XDR-TB vs. MDR-TB). Despite aggressive treatment, XDR-TB was associated with significantly poorer long-term outcome and survival than MDR-TB.

Erbes R, Oettel K, Raffenberg M, et al. Characteristics and outcome of patients with active pulmonary tuberculosis requiring intensive care. *Eur Respir J.* 2006;27:1223–1228.
Retrospective study from Germany looking at 58 TB patients admitted to the ICU. The in-hospital mortality was 15 of 58 (25.9%); 13 (22.4%) patients died in the ICU. The factors independently associated with mortality were acute renal failure, need for mechanical ventilation, chronic pancreatitis, sepsis, acute respiratory distress syndrome, and nosocomial pneumonia.

Nahid P, Gonzalez LC, Rudoy I, et al. Treatment outcomes of patients with HIV and tuberculosis. *Am J Respir Crit Care Med.* 2007;175:1199–1206.
The optimal length of tuberculosis treatment in patients coinfected with HIV is unknown. HIV-infected patients who received a 6-month rifamycin-based course of tuberculosis treatment or who received intermittent therapy had a higher relapse rate than HIV-infected subjects who received longer therapy or daily therapy, respectively. Standard 6-month therapy may be insufficient to prevent relapse in patients with HIV.

Thwaites GE, Nguyen DB, Nguyen HD, et al. Dexamethasone for the treatment of tuberculous meningitis in adolescents and adults. *N Engl J Med.* 2004;351:1741–1751.
This is a prospective, randomized, placebo-controlled trial of adjunctive dexamethasone in 545 patients over 14 years of age with tuberculous meningitis in two hospitals in Vietnam. The results showed that adjunctive treatment with dexamethasone reduced mortality, but there was no demonstrable improvement in the combined endpoint of death or severe disability after 9 months.

Tubach F, Salmon D, Ravaud P, et al. Risk of tuberculosis is higher with anti-tumor necrosis factor monoclonal antibody therapy than with soluble tumor necrosis factor receptor therapy: the three-year prospective French Research Axed on Tolerance of Biotherapies registry. *Arthritis Rheum.* 2009;60:1884–1894.
This is a case-control study investigating the risk of newly diagnosed TB associated with the use of anti-TNF agents. The authors identified 69 cases of TB in patients treated for various inflammatory diseases with infliximab (n = 36), adalimumab (n = 28), and etanercept (n = 5). In the case-control analysis, exposure to infliximab or adalimumab versus etanercept was an independent risk factor for TB (odds ratio [OR] 13.3 [95% CI, 2.6–69.0] and OR 17.1 [95% CI, 3.6–80.6], respectively).

Malaria and Other Tropical Infections in the Intensive Care Unit

Taylor Kain, Andrea K. Boggild, Frederique A. Jacquerioz, and Daniel G. Bausch

Malaria infections are classified broadly into three clinical categories: (1) *asymptomatic parasitemia,* which generally does not require treatment for those living in endemic areas; (2) *uncomplicated malaria,* defined as parasitemia (typically low, though perhaps elevated in those who are semi-immune or immune) and fever without evidence of end-organ damage or other signs of severe disease (these patients may often be treated as outpatients with oral antimalarials); and (3) *severe and complicated malaria,* defined as parasitemia of any value in conjunction with vital organ damage or other signs of severe disease. Patients with severe and complicated malaria require hospitalization, often in an intensive care unit (ICU), and parenteral antimalarials. This third category is the focus of this chapter.

Although the spectrum of possible "tropical" infections (i.e., infections that are prevalent in tropical and subtropical regions, especially those that are resource-poor) in a patient with exposures in tropical areas may initially seem daunting, a detailed history of the travel itinerary, activities, and exposures can often significantly narrow the differential diagnosis (Table 123.1). This must include more than simply recording the countries to which the patient traveled; exposures of a traveler staying at upscale hotels and dining in fine restaurants may differ drastically from those of someone backpacking through rural areas of the same country. General knowledge of the diseases endemic to a given area and their incubation periods and drug resistance patterns is vital (Fig. 123.1 and Table 123.2). In addition, most routine "nontropical" infections common in industrialized countries are also common in low-resource settings, and thus must be considered in the differential diagnosis.

Of all tropical diseases potentially manifesting as acute, life-threatening illness, malaria is the most prevalent globally and should be considered in any patient reporting travel in malaria-endemic areas or with exposure to unscreened blood products ("transfusion malaria") or blood-contaminated needles. Increased travel and migration over the past several decades have resulted in increases in imported malaria in most industrialized countries.[18–23]

Patients at risk of malaria can be divided into three groups: (1) nonimmune persons, either because they have no history of exposure to malaria—primarily nonexpatriate travelers—or because immunity has waned, such as in young children, regardless of geographic origin, after the waning of maternal antibodies (around age 6 months). Pregnant women, who are transiently relatively immune-suppressed, are also included in this category. (2) Immune or semi-immune persons residing in malarious areas who are repeatedly exposed. (3) Those originally from malaria-endemic countries but now residing elsewhere who, in the absence of continued exposure, have waning immunity. The degree of immunity may exert profound effects on the clinical presentation and severity of illness. For example, a returning traveler may develop severe malaria at a relatively low parasitemia, whereas a resident of an endemic area in sub-Saharan Africa who has had repeated infection may have the same degree of parasitemia but be asymptomatic. Various human genetic traits relate to mutations in red blood cells (RBCs) and confer resistance to malaria, such as reduced susceptibility to *Plasmodium vivax* in populations across Africa because of genetic absence of the Duffy antigen, which serves as a key *P. vivax* receptor, or the relative protection from severe malaria of any species afforded to those carrying the sickle cell trait or with thalassemia.[24–29] Parasite strain differences may also play a role in the ultimate course of any given malaria infection.

In returning travelers, knowledge of pretravel vaccinations and both prescribed and taken chemoprophylaxis (which often turn out not to be the same) is imperative. Both physicians and patients frequently err in the prescribing of and adherence to appropriate prophylactic regimens.[30,31] Furthermore, these preventive measures do not confer 100% protection and should not be used to discard a given entity from the differential diagnosis. There is also increasing evidence that failure of prophylaxis may occur because of malabsorption of oral medications rather than resistance.[32] Chemotherapy, complete or partial, may prolong the incubation period or alter the presentation of the illness. Those initially from tropical countries are often less likely to seek pretravel medical advice before making a visit home and also often have considerably more exposures to tropical pathogens during their visit than do short-term travelers from industrialized countries.[33–35]

People living in resource-constrained tropical countries may be more likely to have complicating health problems but less likely to have them previously diagnosed or controlled. Underlying diabetes, hypertension, malnutrition, chronic anemia, intestinal parasites, tuberculosis, human immunodeficiency virus (HIV), or hepatitis virus infection may be discovered at the time of the acute illness.[36,37] Infection with multiple tropical pathogens is common in those living in endemic areas. Thus the finding of a given pathogen cannot automatically be assumed to be causally related to the patient's current illness.

EPIDEMIOLOGY

Malaria parasites are spread to humans by the bite of anopheline mosquitoes. Five species of *Plasmodia* commonly cause malaria in humans: *Plasmodium falciparum*, *P. vivax*, *P. ovale*, *P. malariae,* and *P. knowlesi* (see Table 123.2).[38–41] Furthermore, recent evidence suggests that there may be distinct species of *P. ovale. vivax.* Simultaneous infections with multiple strains of *P. falciparum* are common in some areas of sub-Saharan Africa and also occur with *P. vivax* in Southeast Asia and Latin America.[42–44]

The most prevalent and dangerous form of malaria is that due to *P. falciparum*. The risk of acquiring *P. falciparum* is highest in sub-Saharan

TABLE 123.1 Selected Tropical Diseases That May Merit Management in an Intensive Care Unit*

Disease and Organism	Distinguishing Clinical Features	Incubation Period	Geographic Distribution	Mode of Transmission and Typical Risk Factors
Nonspecific Febrile Syndromes				
African trypanosomiasis, hemolymphatic stage (*Trypanosoma brucei gambiense* and *T. b. rhodesiense*)	Lymphadenopathy, HSM, edema, rash, 30% have history of chancre, rarely DIC and thrombocytopenia	3–21 days	Sub-Saharan Africa	Tsetse fly bite; camping, safari
Babesiosis (*Babesia* spp.)	Hemolytic anemia, HSM	3–28 days	North America, Europe, sporadic cases worldwide	Tick bite, blood transfusion (rare); especially severe in asplenic persons
Brucellosis (*Brucella* spp.)	Subacute presentation over weeks/months, HSM, weight loss, may involve large bones, joints, spine	2–8 weeks	Worldwide, especially Mediterranean, Middle East, and Latin America	Ingestion of contaminated dairy products; respiratory, skin, or conjunctival inoculation from contact with farm animals; abattoir workers, butchers, farmers
Candidiasis, disseminated (*Candida* spp.)	May involved any organ; skin or mucosal lesions not always present	1–4 weeks	Worldwide	Usually in IH or after administration of long-term antibiotics or maintenance of indwelling catheters
Cat scratch disease *(Bartonella henselae)*	Papule or eschar at site of inoculation, regional lymphadenopathy, fever may be mild, may progress to CNS involvement or endocarditis	1–2 weeks	Worldwide	Cat scratch or bite, severe disease most often seen in IH
Coccidioidomycosis *(Coccidioides immitis)*	May see pneumonia with cavities, meningeal, skin, and bone involvement, eosinophilia	1–4 weeks, often RD† in IH	Desert areas of the Americas	Inhalation of spores from soil; disseminated disease more common in black persons and those of Filipino or Hispanic descent, IH, and in pregnancy
Echinococcal cyst, leak, or rupture *(Echinococcus granulosus)*	Allergic symptoms: urticaria, pruritus, anaphylaxis	Years	Worldwide	Ingestion of eggs in feces of infected carnivores such as dogs and wolves; raising of domestic livestock
Ehrlichiosis (*Ehrlichia* spp.)	Rash (<50%), leukopenia, thrombocytopenia, HSM; may progress to GI, renal, pulmonary, or CNS involvement	7–21 days	Sporadic foci worldwide	Tick bite; camping, safari
Histoplasmosis, disseminated *(Histoplasma capsulatum)*	Mucocutaneous lesions, lymphadenopathy, HSM, DIC; any organ may be involved	1–4 weeks, usually RD	Tropics worldwide	Inhalation of spores from soil; severe disease usually IH
Leptospirosis (*Leptospira* spp.)	Icterus, jaundice, conjunctival suffusion, rash, HSM; may be biphasic; may develop hepatorenal syndrome ("Weil disease"), CNS involvement, or pulmonary disease with hemorrhage	2–20 days	Worldwide	Contaminated urine of many types of small mammals, either directly or through soil or standing water; hunting, military exercises
Malaria (*Plasmodium falciparum, P. vivax, P. ovale, P. malariae*, and *P. knowlesi*)	See text	Table 123.2	See Fig. 123.1 and Table 123.2	Mosquito bite, transfusion
Measles	Conjunctivitis, coryza, cough, rash, Koplik spots	5–14 days	Worldwide	Person-to-person via aerosol
Melioidosis *(Burkholderia pseudomallei)*	May develop pneumonia or local suppurative infection, shock (especially if IH)	2–21 days	Southeast Asia (especially Thailand), Australia, sporadic foci in tropics worldwide	Exposure to contaminated soil or infected animals, person-to-person (rare), often IH
Monkeypox (monkeypox virus)	Diffuse vesicular rash resembling chickenpox but involving palms and soles, lymphadenopathy	3–21 days	Central and West Africa	Person-to-person and from exposure to infected small mammals and monkeys; exotic pets; rule out smallpox/bioterrorism

Continued

TABLE 123.1 Selected Tropical Diseases That May Merit Management in an Intensive Care Unit—cont'd

Disease and Organism	Distinguishing Clinical Features	Incubation Period	Geographic Distribution	Mode of Transmission and Typical Risk Factors
Mycobacterium avium-intracellulare, disseminated	Usually subacute, HSM, weight loss	Months to years	Worldwide	Environmental organism causing opportunistic infection in IH
Oroya fever *(Bartonella bacilliformis)*	Acute anemia, jaundice, HSM, lymphadenopathy	2–3 weeks	Peru, Ecuador, and Colombia	Sandfly bite; hiking, camping
Paracoccidioidomycosis *(Paracoccidioides brasiliensis)*	May involve lungs, bones, skin, lymph nodes, adrenal glands, or mucous membranes	1–4 weeks, often RD	Tropical America	Inhalation of spores from soil; more severe in IH
Talaromycosis *(Talaromyces marneffei)*	Mucocutaneous lesions, HSM, lymphadenopathy, may have skeletal or pulmonary involvement	Unknown, probably >1 week	Southeast Asia	Reservoir unknown, most often IH
Plague *(Yersinia pestis)*	Localized tender lymphadenitis ("bubo"), pneumonia, shock	2–8 days	Worldwide	Flea bite or person-to-person; areas of heavy rat infestations, R/O bioterrorism
Q fever (*Coxiella burnetii*)	HSM; may develop pneumonia, endocarditis, hepatitis, osteomyelitis, or neurologic abnormalities	2–29 days	Worldwide	Inhalation of organism from products of infected livestock or pets, especially birth products but also milk, urine, and feces; farmers, ranchers
Rat bite fever (*Spirillum minor* or *Streptobacillus moniliformis*)	Peripheral rash, sometimes with desquamation, polyarthritis in *S. moniliformis*, eschar or ulcer at site of bite in *S. minor*	2–28 days	Worldwide, especially Asia and North America	Bite of rat or other animal that preys on rats; ingestion of food contaminated by rat
Relapsing fever (*Borrelia* spp.)	Recrudescent fever pattern, HSM, petechiae, epistaxis, neurologic abnormalities	4–18 days	Worldwide (especially East Africa)	Body louse (*B. recurrentis*) or tick bite (various *Borrelia* species); conditions of poor hygiene, outdoor exposures, refugee camps, camping, safari
Rickettsiosis, spotted fever group (*Rickettsia rickettsii, R. conorii, R. africae, R. australis, R. sibirica, R. japonica, R. honei, and R. akari*)	Peripheral skin rash, eschar at site of tick bite may be seen ("tache noire"), may progress to GI, renal, pulmonary, or CNS involvement	7–14 days	Worldwide (with circumscribed distributions of each specific organism)	Tick bite (mite for *R. akari*); camping, safari
Rickettsiosis, typhus group (*Rickettsia prowazekii, R. typhi, and R. felis*)	Centripetal rash (~50%), no eschar	7–14 days	Worldwide, especially cold climates	Feces from infected louse (*R. prowazekii*) or flea (*R. typhi* and *R. felis*) rubbed into broken skin; crowding, poor hygiene, abundant rodents, refugee camps, flea-infested cats
Scarlet fever (group A *Streptococcus pyogenes*)	Pharyngitis, "sandpaper" rash, cervical adenopathy	1–4 days	Worldwide	Person-to-person via aerosolization/droplets
Schistosomiasis, Katayama fever (*Schistosoma* spp., especially *S. japonicum*)	Lymphadenopathy, HSM, eosinophilia	1–2 months	Africa, Asia, Caribbean, Middle East, South America, Caribbean	Skin penetration of cercaria; swimming or bathing in contaminated water
Scrub typhus *(Orientia tsutsugamushi)*	Centripetal rash, conjunctival suffusion, lymphadenopathy, eschar at site of chigger bite (~50%), hearing loss in one-third of cases	6–18 days	Asia, Australia, Pacific Islands	Chigger bite; outdoor rural or suburban exposures
Strongyloidiasis, disseminated *(Strongyloides stercoralis)*	Abdominal pain and distension, shock, pulmonary and CNS involvement common	2–3 weeks; may be maintained via autoinfection for decades	Tropics worldwide	Skin contact with contaminated soil; miliary exercises; dissemination may occur in IH (AIDS, steroid treatment)
Toxic shock syndrome (*Staphylococcus aureus*, group A *S. pyogenes*)	Rash, extremity or abdominal pain, skin desquamation, soft tissue infection (70%)	2–10 days	Worldwide	Wound or vaginal colonization with toxin-producing bacteria; history of minor trauma (often without break in skin), previous surgery, or varicella infection; staphylococcal syndrome often associated with menses

TABLE 123.1 Selected Tropical Diseases That May Merit Management in an Intensive Care Unit—cont'd

Disease and Organism	Distinguishing Clinical Features	Incubation Period	Geographic Distribution	Mode of Transmission and Typical Risk Factors
Trench fever *(Bartonella quintana)*	Rash, HSM, shin pain, may develop endocarditis and angioma-like lesions	1–2 weeks	Worldwide	Body louse bite; areas of crowding or poor sanitation, more severe in IH
Trichinellosis (*Trichinella* spp.)	Diarrhea followed by myalgias, periorbital edema, eosinophilia, may involve heart or CNS	7–30 days	Worldwide	Ingestion of contaminated meat, including pork (*T. spiralis*), wild boar, horse, bear, and walrus
Tularemia, typhoidal form *(Francisella tularensis)*	Pulse-temperature dissociation, diarrhea (~40%); may develop pneumonia	1–21 days	Sporadic foci worldwide, mostly Northern Hemisphere	Tick or fly bite or direct exposure to small mammals; hunting, camping, military exercises; R/O bioterrorism
Typhoid/paratyphoid fever (*Salmonella enterica* serotypes typhi or paratyphi)	Pulse-temperature dissociation, abdominal pain, rash, intestinal perforation and bleeding, HSM, 10% with extraintestinal manifestations	8–28 days	Worldwide	Fecal-oral
Vibrio infection, nonepidemic type (*Vibrio vulnificus*)	Bullous skin lesions, DIC, thrombocytopenia, GI bleeding, shock	1–2 days	Worldwide	Contaminated saltwater or seafood; severe disease mostly in IH, history of alcoholism, liver disease
Viral hemorrhagic fever (dengue, yellow fever, Ebola, Marburg, Lassa, Junin, Machupo, and Rift Valley fever viruses, many others)	Capillary leak syndrome; may or may not exhibit frank hemorrhage, GI hemorrhage, shock	3–21 days, depending on specific virus	Select areas worldwide	Depending on specific virus: exposure to rodent excreta, infected nonhuman primates, person-to-person, tick or mosquito bite, some unknown; R/O bioterrorism
Viral hepatitis (hepatitis A, B, C, D, and E; Epstein-Barr virus; cytomegalovirus; others)	HSM, light-colored stools, dark urine, jaundice	2 weeks to 5 months, depending on specific organism	Worldwide	Fecal-oral or ingestion of seafood from contaminated sea beds (hepatitis A, E); percutaneous (blood exposure), sexual, or mother-to-child transmission (hepatitis B, C, D); hepatitis D requires coinfection with hepatitis B virus
Visceral leishmaniasis (*Leishmania* spp.)	Weight loss, HSM, neutropenia	Months to years	Tropics worldwide, especially Indian subcontinent, Middle East, and North Africa	Sandfly bite; military exercises, outdoor exposures
Gastrointestinal Syndromes				
Amebic dysentery (Entamoeba histolytica)	Abdominal pain and diarrhea, sometimes bloody, minority may develop ameboma, toxic megacolon, peritonitis, or abscesses in solid organs (usually liver)	2–4 weeks (usually longer for solid organ involvement)	Worldwide	Fecal-oral; may be transmitted through anal sex
Anthrax, gastrointestinal or oropharyngeal *(Bacillus anthracis)*	Abdominal pain and bloody diarrhea, neck swelling, pharyngitis, mucosal lesions, shock	2–10 days	Worldwide	Ingestion of spores; exposure to domestic animals or animal by-products; R/O bioterrorism
Ascending cholangitis (*Clonorchis sinensis* and *Opisthorchis* spp.)	May be recurrent and accompanied by pancreatitis	Months to years	Asia, former USSR	Ingestion of raw infected freshwater fish; sushi consumption
Bacterial dysentery (*Shigella* spp., *Campylobacter* spp., invasive and hemorrhagic *Escherichia coli,* non-typhi *Salmonella* spp., *Vibrio parahaemolyticus,* others)	Abdominal pain and diarrhea, sometimes bloody	10 hours to 7 days, depending on specific organism	Worldwide	Fecal-oral
Cholera (*Vibrio cholerae*)	Copious "rice water" diarrhea, abdominal pain, severe hypovolemia, fever minimal or absent	1–3 days	Tropics worldwide	Contaminated water or food, especially seafood; ceviche consumption

TABLE 123.1 Selected Tropical Diseases That May Merit Management in an Intensive Care Unit—cont'd

Disease and Organism	Distinguishing Clinical Features	Incubation Period	Geographic Distribution	Mode of Transmission and Typical Risk Factors
Clostridial gastroenteritis *(Clostridium difficile)*	Abdominal pain and diarrhea, sometimes with mucus or blood, toxic megacolon	≈ 1 week to months	Worldwide	Alteration of GI flora through previous antibiotic administration and/or GI manipulation
Eosinophilic gastroenteritis *(Angiostrongylus costaricensis)*	Mimics appendicitis or inflamed Meckel diverticulum, right lower quadrant abdominal pain and mass, eosinophilia	Estimated 3–4 weeks	Latin America	Ingestion of larvae in undercooked mollusks, crustaceans, or frogs
Hemolytic uremic syndrome (*Escherichia coli* O157:H7)	Bloody diarrhea followed by hemolysis and renal failure	2–5 days	Worldwide	Ingestion of poorly cooked meat, fecal-oral
Neurologic Syndromes				
African trypanosomiasis, meningoencephalitic stage (*Trypanosoma brucei gambiense* and *T. b. rhodesiense*)	Headache, HSM, cervical lymphadenopathy, somnolence, change in mental status, extrapyramidal and cerebellar signs	Months to years	Sub-Saharan Africa	Tsetse fly bite; camping, safari
Antiretroviral syndrome (human immunodeficiency virus-1)	Usually asymptomatic or mild flu-like illness, meningoencephalitis occurs rarely	2–4 weeks	Worldwide	Sexual transmission or percutaneous blood exposure; unprotected sex, IV drug use
Arboviral encephalitides (eastern equine, Japanese encephalitis, West Nile, Murray Valley encephalitis, St. Louis encephalitis, and Venezuelan equine encephalitis viruses, many others)	Encephalitis, focal neurologic deficits, seizures, change in mental status	3–21 days	Sporadic foci worldwide	Mosquito bite, seasonal
Bacterial meningitis (*Neisseria meningitides, Streptococcus pneumoniae, Haemophilus influenza* type B, *Listeria monocytogenes*, others)	Petechiae, ecchymoses, and bleeding suggest *N. meningitides*	2–10 days, depending on specific organism	Worldwide; *N. meningitides* more frequent in African "meningitis belt"	Person-to-person, asymptomatic carrier states, seasonal fluctuations
Botulism (*Clostridium botulinum*)	Bilateral cranial nerve deficits with symmetric descending weakness, fever absent	1–3 days	Worldwide	Toxin ingestion or wound contamination; home-canned foods, soil contamination
Brain abscess (various bacteria, fungi, and parasites)	Focal neurologic signs	Days to months, depending on specific organism	Worldwide	Varies with infecting organism
Cryptococcosis *(Cryptococcus neoformans)*	Mild meningitis with low-grade fever, nonfocal neurologic examination, sometimes seizures or pulmonary involvement	1–4 weeks	Worldwide	Inhalation of spores from soil and bird and bat excreta; usually IH
Eosinophilic meningitis *(Angiostrongylus cantonensis)*	Headache, meningitis, sometimes cranial nerve involvement, fever minimal	1–7 days	Southeast Asia, South Pacific, sporadic foci worldwide	Ingestion of larvae in undercooked mollusks, crustaceans, or frogs
Gnathostomiasis (*Gnathostoma* spp.)	Migratory skin and subcutaneous swellings, epigastric pain and vomiting, eosinophilia, may invade any organ, especially CNS	Weeks to years	Southeast Asia, with sporadic cases from Central and South America	Consumption of raw freshwater fish, frogs, snakes, crustaceans, or poultry; sushi consumption
Herpes encephalitis (various herpesviruses)	Encephalitis, focal neurologic deficits, seizures, change in mental status, may show vesicular eruption	2–20 days, depending on specific virus	Worldwide; herpes B virus via monkey exposure in Asia and North Africa (wild monkeys) or captive monkeys worldwide	Person-to-person, often more severe in IH; herpes B virus via bite or other exposure to monkeys of the genus *Macaca*; person-to-person transmission reported; researchers, animal handlers

TABLE 123.1 Selected Tropical Diseases That May Merit Management in an Intensive Care Unit—cont'd

Disease and Organism	Distinguishing Clinical Features	Incubation Period	Geographic Distribution	Mode of Transmission and Typical Risk Factors
Mucormycosis (various fungi from the order Mucorales)	CNS infiltration with loss of consciousness, black exudate around mucous membranes of face, pulmonary infiltrates	1–7 days	Worldwide	Inhalation of spores from soil, traumatic inoculation of wound; usually IH (diabetes mellitus or steroid use)
Neurocysticercosis *(Taenia solium)*	Seizures, headache, change in mental status, muscle pain	Years	Worldwide, especially Latin America and India	Ingestion of cysticerci in contaminated pork; areas where pigs roam freely
Paragonimiasis, cerebral (*Paragonimus* spp.)	Meningoencephalitis, often accompanied by pulmonary disease	Years	Sporadic foci worldwide, especially East Asia, Peru, Ecuador, West Africa	Ingestion of raw infected crustaceans; sushi consumption
Poliomyelitis (poliovirus)	Acute flaccid paralysis, meningeal signs, muscle pain	9–12 days	Sporadic foci in Africa, Asia, and eastern Mediterranean	Fecal-oral
Primary amebic meningoencephalitis *(Naegleria fowleri)*	Fulminant meningoencephalitis	3–7 days	Sporadic foci worldwide	Entry of trophozoite through the nose; swimming in contaminated fresh warm water; hot springs
Rabies (rabies virus)	Change in mental status, autonomic instability, photophobia, aerophobia, paralysis	20–90 days	Worldwide	Animal bite or bat exposure; spelunking, caring for injured animals
Schistosomiasis, CNS (*Schistosoma* spp.)	Encephalopathy, meningoencephalitis, transverse myelitis, seizures	Weeks to months	Africa, Asia, Caribbean, Middle East, South America, Caribbean	Skin penetration of cercaria; swimming or bathing in contaminated water
Tetanus (*Clostridium tetani*)	Diffuse muscle spasms, opisthotonos, trismus, autonomic dysfunction	3–21 days	Worldwide	Soil contamination of wound, commonly involves umbilical stump in neonates
Tickborne encephalitis (tickborne encephalitis virus)	Encephalitis, focal neurologic deficits, seizures	7–14 days	Central and East Asia, Europe, North Africa, North America	Tick bite
Toxoplasmosis, cerebral *(Toxoplasma gondii)*	Meningoencephalitis, HSM, focal neurologic deficits, seizures, change in mental status	Usually RD	Worldwide	Ingestion of cysts in undercooked meat or oocysts from exposure to cat feces; usually IH
Variant Creutzfeldt-Jacob disease (prion)	Change in mental status, myoclonus, spasticity, rigidity, extrapyramidal and cerebellar signs and symptoms, occasionally seizures	Months to years	United Kingdom, with sporadic cases elsewhere in Europe, Canada, and United States	Recipients of cadaveric transplants or injections of biomedical products derived from infected patients, contaminated surgical apparatuses, person-to-person(?), ingestion of contaminated beef or lamb(?)
Visceral larva migrans *(Toxocara canis)*	Cough, wheezing, HSM, eosinophilia; may develop CNS or other solid organ involvement	Weeks to years	Worldwide	Ingestion of eggs in puppy feces
Pulmonary Syndromes				
Anthrax, inhalation *(Bacillus anthracis)*	Pulmonary infiltrates with widened mediastinum, shock, CNS involvement	2–60 days	Worldwide	Inhalation of spores, exposure to domestic animals or animal by-products; R/O bioterrorism
Aspergillosis (*Aspergillus* spp.)	Pulmonary "fungus ball," (aspergilloma), transient infiltrates and allergic symptoms in allergic bronchopulmonary aspergillosis	1–4 weeks	Worldwide	Inhalation of spores from soil
Bacterial pneumonia (*Streptococcus pneumoniae, Legionella pneumophila, Mycoplasma pneumoniae, Haemophilus influenza, Chlamydophila* spp., others)	Extrapulmonary findings frequent in Legionnaires' disease and psittacosis	2–21 days, depending on specific organism	Worldwide	Person-to-person spread; Legionnaires' disease associated with colonized air/water systems; psittacosis associated with bird exposure
Blastomycosis *(Blastomyces dermatitidis)*	Subacute pneumonia; bone, skin, and GU tract involvement	1–4 weeks, usually RD	Sporadic foci worldwide	Inhalation of spores from soil

Continued

TABLE 123.1 Selected Tropical Diseases That May Merit Management in an Intensive Care Unit—cont'd

Disease and Organism	Distinguishing Clinical Features	Incubation Period	Geographic Distribution	Mode of Transmission and Typical Risk Factors
Diphtheria *(Corynebacterium diphtheriae)*	Low-grade fever, cough, pharyngitis, oropharyngeal membrane, neck swelling, mucosal bleeding, myocarditis, polyneuritis	3–7 days	Worldwide, especially temperate areas	Person-to-person through respiratory route and breaks in the skin
Eosinophilic pneumonia (various parasites, helminthes and filaria)	Eosinophilia, asthma-like condition, elevated IgE	Days to weeks, depending on specific organism	Worldwide, depending on specific organism	Lung passage of larvae or adult helminthes, mosquito bite (filaria), filarial disease occurs primarily in those living in endemic areas with continued exposure
Hantavirus pulmonary syndrome (various hantaviruses)	ARDS, thrombocytopenia, leukocytosis, hemoconcentration, circulating immunoblasts	1–5 weeks	Americas	Contaminated rodent urine or feces; outdoor exposures
Pertussis *(Bordetella pertussis)*	Low-grade fever, coryza, rhinorrhea, paroxysmal dry cough	5–21 days	Worldwide	Person-to-person; adults vaccinated as children are susceptible to milder disease
Pneumocystosis *(Pneumocystis jiroveci)*	Dyspnea, dry cough, hypoxemia, often only mild findings on pulmonary auscultation and CXR	Usually RD	Worldwide	Inhalation; usually IH
Tuberculosis *(Mycobacterium tuberculosis)*	Upper lobes infiltrates and cavities; miliary TB, meningitis, and GU involvement all also common	Usually RD	Worldwide	Person-to-person via aerosol/droplet; increased frequency and likelihood of extrapulmonary involvement in IH
Tularemia, pneumonic form *(Francisella tularensis)*	Pulse-temperature dissociation, diarrhea (~40%)	1–21 days	Sporadic foci worldwide, mostly Northern Hemisphere	Tick or fly bite, or direct exposure to small mammals; hunting, camping, military exercises, R/O bioterrorism
Viral pneumonia (influenza, parainfluenza, respiratory syncytial, and SARS coronavirus, many others)	May be complicated by bacterial suprainfection	Days to weeks, depending on specific organism	Worldwide, depending on specific organism	Person-to-person spread and zoonotic, depending on specific virus; contact with farms or live animal markets, birds, or pigs (zoonotic influenzas); civet cats suspected to be a reservoir of SARS coronavirus
Localized Infections				
Mycetoma (various fungi and bacteria)	Chronic swollen limb with nodules, sinus tracts, drainage of pus and "grains"	Weeks to months	Tropics worldwide	Traumatic implantation of organism into skin; soil exposure
Necrotizing fasciitis (group A strep *S. pyogenes, Clostridia* spp., *S. aureus*)	Rapid progression of edema, erythema, tenderness, bullae, necrosis, and gangrene	~24 hours	Worldwide	Posttraumatic or surgical

ARDS, Acute respiratory distress syndrome; *CNS,* central nervous system; *CXR,* chest x-ray; *DIC,* disseminated intravascular coagulopathy; *GI,* gastrointestinal; *GU,* genitourinary; *HSM,* hepatosplenomegaly; *IH,* immunocompromised host; *IV,* intravenous; *RD,* reactivation disease; *R/O,* rule out; *TB,* tuberculosis.

*Only diseases that typically have acute or subacute presentations and may cause severe disease are included. Diseases are classified by the most typical associated severe syndrome. In practice, significant variation may exist.

†Initial infection is usually asymptomatic or mild. Reactivation with severe disease may occur years later, usually in immunocompromised hosts.

Africa, in particular West Africa,[45] and in New Guinea; moderate in India; and comparatively low in Southeast Asia and Latin America.[46–48] There is increasing recognition that *P. vivax,* the second most common cause of malaria and previously considered to be benign, can also cause severe disease and death.[49,50] *P. vivax* malaria is especially frequent in travelers returning from Oceania, although the parasite exists in all malaria-endemic regions except Haiti and the Dominican Republic.[51,52] The dormant liver stage parasites (hypnozoites) that characterize *P. vivax* sometimes result in primary disease or relapse even years after infection. *P. knowlesi* is found in rainforests of Southeast Asia, including parts of Cambodia, China, Indonesia, Laos, Malaysia, Myanmar, the Philippines, Singapore, Thailand, and Viet Nam.[53,54] *P. knowlesi* is now the most common cause of malaria in Malaysia and parts of Indonesia. Although quite rare, deaths resulting from *P. ovale* or *P. malariae* infection have been reported.[55,56]

Although rare, malaria has been reported in persons without documented travel, usually resulting from the carriage of malaria-infected passengers (who may be asymptomatic) or anopheline mosquitoes on aircraft arriving from endemic areas.[57–59] The parasite may then be

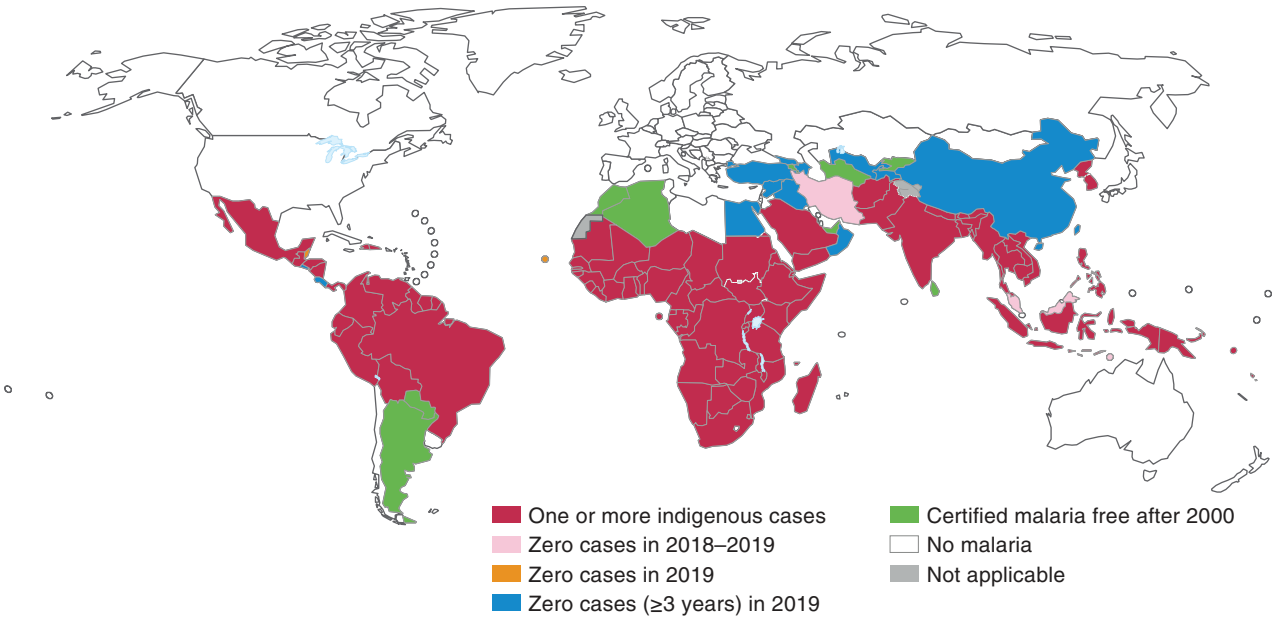

Fig. 123.1 Population at risk in malaria-endemic countries in the Western and Eastern Hemispheres. The risk of malaria may vary within specific regions of each country. (From the World Health Organization [2020]. Available at https://www.who.int/teams/global-malaria-programme.)

TABLE 123.2 Features of the Five Species of Malaria Known to Cause Disease in Humans

	Plasmodium falciparum	Plasmodium vivax	Plasmodium ovale	Plasmodium malariae	Plasmodium knowlesi
Incubation period (days)	6–25	8–27	8–27	16–40	12–13
Asexual cycle (hours)	48 (tertian)	48 (tertian)	48 (tertian)	72 (quartan)	24 (tertian)
Relapse	No	Yes*	Yes*	No†	No
Chloroquine resistance	Yes‡	Rare§	No	No¶	No
Characteristic on thin blood film	Rings predominate, multiply infected RBCs, high parasitemia, rings with threadlike cytoplasm, double nuclei, banana-shaped gametocytes	Enlarged RBCs, Schüffner dots, trophozoite cytoplasm ameboid, 12–24 merozoites in mature schizont	Oval RBCs with fringed edges, Schüffner dots, trophozoites cytoplasm compact, 6–16 merozoites in mature schizont	Trophozoite cytoplasm compact (band forms), 6–12 merozoites in mature schizont, RBC unchanged	Similar to *P. malariae*, 8–10 merozoites in mature schizont, often in rosette pattern with central clump of pigment

*Relapses may appear months to years after initial infection because of dormant hypnozoites in the liver.
†Although relapse does not occur, *P. malariae* can produce persistent infections that remain below detectable limits in the blood for 20–30 years or more.
‡*P. falciparum* resistance to sulfadoxine/pyrimethamine, mefloquine, halofantrine, and artemisinin has also been reported in some areas, along with partial resistance to quinine and quinidine.[1–3]
§*P. vivax* resistance to chloroquine now reported in some areas of Southeast Asia, Oceania (Ethiopia, Madagascar), and South America.[4–16]
¶Chloroquine-resistant *P. malariae* has also been reported in south Sumatra, Indonesia.[17]

secondarily transmitted by anopheline mosquitoes endemic in some industrialized countries, including the United States, Canada, and Southern Europe.

PATHOPHYSIOLOGY

P. falciparum accounts for the vast majority of severe malaria because of (1) its ability to infect RBCs of all ages, resulting in overwhelming parasitemia (up to 70% of RBCs); (2) its induction of adherence of parasitized RBCs to the microvascular wall, with consequent obstruction; (3) its induction of severe metabolic derangements, both directly through glucose consumption and lactate production and indirectly through the induction of cytokines; and (4) the high prevalence of chloroquine and multidrug resistance to *P. falciparum* in many parts of the world (see Table 123.2). Unlike the other species of malaria, *P. falciparum* causes decreased RBC deformability and the production of small protrusions, or "knobs," on parasitized RBC membranes that mediate their adhesion to the venular endothelium (Fig. 123.2). These knobs are high-molecular-weight (>200 kD), strain-specific molecules displayed on the surface of infected RBCs. The best described of these is *P. falciparum* erythrocyte membrane protein 1 that plays a critical role in malaria pathogenesis, including in evasion of the host immune system.[60,61]

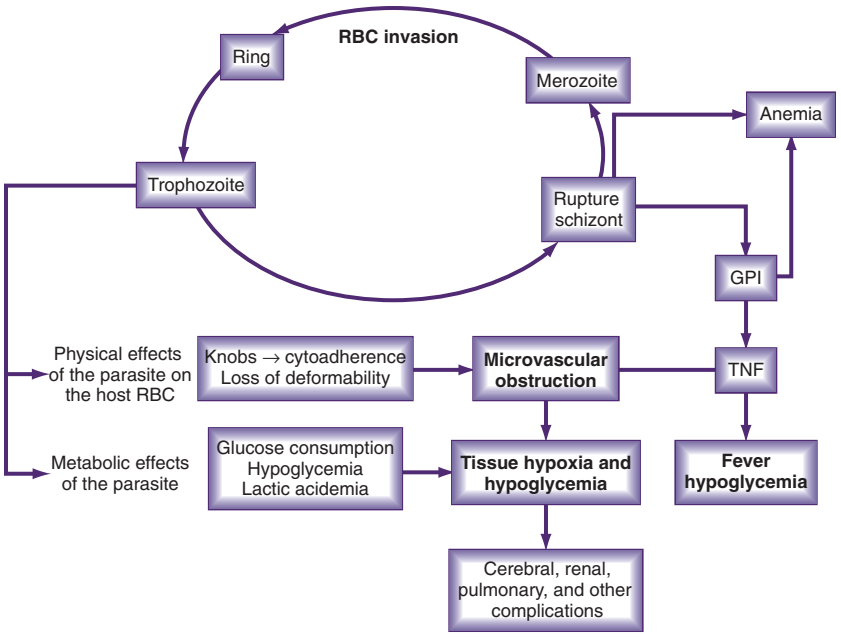

Fig. 123.2 Pathogenesis of severe and complicated *Plasmodium falciparum* malaria. *GPI,* Glycosylphosphatidylinositol; *RBC,* red blood cell; *TNF,* tumor necrosis factor. (Modified from Krogstad D. Plasmodium species (malaria). In Mandell GL, Bennett JE, Dolin R, eds. *Principles and Practice of Infectious Diseases,* 5th ed. Philadelphia, PA: Churchill Livingstone; 2000.)

The rupture of schizont-stage parasites exposes glycosylphosphatidylinositol anchors on the parasite and RBC surface that induce macrophages and other inflammatory cells to release a host of inflammatory mediators, including tumor necrosis factors, interleukin-1, and various kinins and reactive nitrogen intermediates.[62–65] These cytokines play a role in up-regulation and activation of endothelial adhesion molecules such as ICAM-1 and E-selectin, enhancing cytoadherence of parasitized cells and mediating pathologic processes such as hypoglycemia, lactic acidemia, shock, gut mucosal damage, and increased permeability and neutrophil aggregation in the lung.

The sum total of this cascade is sequestration of parasitized RBCs in the microvasculature, where they are not only sheltered from removal but cause sluggish flow and obstruction, resulting in impaired oxygen delivery and organ dysfunction.[62,65–67] The most profound effects are usually on the cerebral capillaries, although a host of tissues may be affected, including the kidney, liver, spleen, placenta, intestine, lung, bone marrow, heart, and retina. Histopathologic changes are usually minimal, but ring hemorrhages and perivascular infiltrates sometimes develop at the sites of obstructed vessels, perhaps facilitated by thrombocytopenia because of splenic sequestration of platelets. Although subendocardial and epicardial hemorrhages have been noted at autopsy, myocarditis does not occur, and primary cardiac events are relatively rare in malaria.

In *P. falciparum* infection, acute pulmonary hypertension can be precipitated by nitric oxide consumption by free plasma hemoglobin released from intravascular hemolysis.[68] Endothelial injury leading to increased alveolar permeability and noncardiogenic pulmonary edema also contributes. Autopsy studies have shown increased markers of endothelial activation (vWF and ANG-2) in patients with acute malaria-associated respiratory distress syndrome (MA-ARDS) compared with infected and uninfected controls.[69] Interstitial edema and inflammatory cell infiltrates are seen at autopsy, but sequestration of parasitized RBCs in the lung is not common.[70] There is evidence, however, that *P. falciparum* erythrocyte membrane protein 1 interaction with host endothelial cell receptors (e.g., ICAM-1 and endothelial protein C receptor) plays a role in cytoadherence and pathogenesis of MA-ARDS.[71]

Parasitemia usually reaches a lower level in *P. vivax* infection because of a strong predilection for reticulocytes. Chronic exposure to *P. vivax* parasites may be sufficient to destroy the new reticulocytes and, over time, to reduce the population of mature RBCs, thereby contributing to severe anemia. This, combined with a lack of cytoadhesive properties of the infected cells, results in reduced microvascular obstruction and suggests different pathogenetic mechanisms to severe infection.[72,73] The main pathogenesis of *P. vivax* is the result of higher cytokine production and endothelial activation caused by an increased guanine-cytosine DNA content in its genome and a higher associated content of Toll-like receptor 9-stimulating GpG motifs.[74–76]

The returned traveler exposed to *P. vivax* for a short period will rarely present with a severe or fatal infection unless there is an underlying condition. However, in endemic regions, children with prolonged *P. vivax* infection resulting from frequent exposures and relapsing infections from the liver hypnozoites can present with profound anemia with subsequent high morbidity and mortality, particularly in the presence of malnutrition and other causes of anemia.[77] *P. vivax* anemia is exacerbated by splenic removal of uninfected RBCs, which occurs at a higher proportion compared with *P. falciparum,* although the removal mechanism is not well understood.[50,78,79]

In *P. vivax* infection, a cytokine-mediated inflammatory response in the pulmonary microvessels leads to increased alveolar permeability and fluid buildup. Because of a lower parasitic biomass, the effect of the hemolysis-associated nitric oxide depletion on pulmonary pressures is minimal.[72,76] There is greater inflammatory and endothelial activation per parasite in *P. vivax* compared with *P. falciparum* infections, and this likely contributes to MA-ARDS in the absence of other

risk factors specific to *P. falciparum*.[80] In addition to the acute hemolytic destruction of parasitized RBCs, the more chronic processes of removal of parasitized cells from circulation by the spleen and cytokine inhibition of erythropoiesis may contribute.[81]

CLINICAL PRESENTATION

Malaria classically produces three stages of symptoms that progress over an 8- to 12-hour period, comprising a "paroxysm." These correspond and are attributable to the period of schizont rupture and appearance of ring forms (merozoites) in the blood, accompanied by the release of numerous host inflammatory mediators. The paroxysm classically begins suddenly with a "cold stage" in which the patient experiences rigors and chills, often accompanied by headache, nausea, and vomiting. Intense peripheral vasoconstriction may result in pale, goosepimpled skin and cyanosis of the lips and nail beds. Within a few hours, the "hot stage" ensues, with high fever, flushed skin, throbbing headache, and palpitations. The paroxysm concludes with the "defervescent stage," consisting of a drenching sweat and resolution of the fever. The exhausted patient often then sleeps. Clinical deterioration with *P. falciparum* usually appears 3–7 days after onset of fever.

Although a classic periodicity is described for the different malaria species (see Table 123.2), this occurs only when the infection has persisted untreated long enough to allow for synchronization of schizont rupture. Furthermore, schizont rupture tends to be asynchronous in *P. falciparum* and in most primary infections of any *Plasmodium* species. Therefore malaria may often result in persistently spiking fevers difficult to distinguish from fever produced by many other infections, and the absence of a classic paroxysm and periodicity should not be used to exclude the diagnosis. Paroxysms may be accompanied by cough, sore throat, myalgias, back pain, postural hypotension, abdominal pain, nausea, vomiting, diarrhea, and weakness. These flulike symptoms are more common in children and may lead to misdiagnoses. Rash and lymphadenopathy are not typical of malaria and suggest another diagnosis.

Severe and Complicated Malaria

Although all species of malaria may produce severe consequences in a debilitated patient, potentially fatal malarian which merits attention in an ICUn can be grouped into three categories: (1) severe complications of *P. falciparum* and, less commonly, *P. vivax* and *P. knowlesi* in nonimmune children and adults; (2) splenic rupture, which occurs most frequently with *P. vivax;* and (3) chronic nephrotic syndrome caused by immune-complex nephritis associated with *P. malariae,* usually seen in children and often complicated by overwhelming bacterial infection. The first category is responsible for the vast majority of severe disease worldwide (Box 123.1). There is emerging evidence that *P. knowlesi* can also cause severe fatal malaria and should be treated in an ICU setting.[33]

Cerebral Malaria

Cerebral malaria is the most frequent severe complication of plasmodium infection, accounting for most fatalities and chronic sequelae. It is most frequent in children of 3–5 years of age. Strictly defined, cerebral malaria implies unarousable coma caused by *P. falciparum.* Hyperpyrexia and febrile convulsions in young children may produce transiently altered mental status without true involvement of the cerebral microvasculature and do not constitute cerebral malaria. However, in clinical practice, seizures or persistent changes in sensorium that cannot be attributed to other disease processes should be considered cerebral malaria until proven otherwise. Although cerebral malaria is classically attributed to cytoadhesion and microvascular obstruction in the brain, other ongoing processes, including hypoglycemia, metabolic acidosis, and impaired oxygenation caused by anemia and pulmonary edema, also contribute.

Box 123.1 Clinical and Laboratory Features That Classify a Patient as Suffering From Severe *Plasmodium falciparum* Malaria* According to the World Health Organization

Clinical Features

Impaired consciousness (including unarousable coma); Glasgow Coma Score <11 in adults or a Blantyre coma score <3 in children
Prostration: generalized weakness so that the patient is unable walk or sit up without assistance
Multiple convulsions (more than two episodes in 24 hours
Pulmonary edema: radiologic evidence or oxygen saturation <92% on room air with a respiratory rate >30/min
Respiratory distress (severe acidosis): rapid, deep, labored breathing
Circulatory collapse or shock, systolic blood pressure <80 mm Hg in adults and <70 mm Hg in children, with evidence of impaired perfusion (cool peripheries or prolonged capillary refill)
Clinical jaundice plus evidence of other vital organ dysfunction
Abnormal spontaneous and significant bleeding

Laboratory Findings

Hypoglycemia (blood glucose <2.2 mmol/L or <40 mg/dL)
Metabolic acidosis; base deficit of >8 mEq/L, plasma bicarbonate <15 mmol/L, or venous plasma lactate >5 mmol/L.
Severe normocytic anemia (hemoglobin ≤5 g/dL, hematocrit ≤15% in children <12 years of age (<7 g/dL and <20%, respectively, in adults) with a parasite count >10,000/μL;
Jaundice: plasma or serum bilirubin >50 μmol/L (3mg/dL) with a parasite count >100,000/μL
Hyperparasitemia: >10%
Renal impairment: serum creatinine >265 μmol/L (3mg/dL) or blood urea >20 mmol/L)

(From World Health Organization. (2012). Management of severe malaria: a practical handbook, 3rd ed.. World Health Organization. https://apps.who.int/iris/handle/10665/79317

* For severe *P. vivax* malaria, the same criteria are used as for *P. falciparum* malaria but with no parasite density thresholds. Likewise, severe *P. knowlesi* malaria is defined as for falciparum malaria but with two differences: (1) P. *knowlesi* hyperparasitemia: parasite count >100,000/μL and (2) jaundice and parasite count >20,000/μL.

The altered sensorium of cerebral malaria may develop gradually within a few days of onset of illness or manifest as persistent coma after a generalized convulsion. Compared with adults, children with cerebral malaria have a shorter history of fever before progressing to coma (average about 2 days). The most common neurologic picture is of a diffuse symmetric encephalopathy with hypertonia and hyperreflexia. Pupils are usually symmetric with intact pupillary, corneal, oculocephalic, and oculovestibular reflexes. Gag reflex is usually intact. In severe cases, clonus, opisthotonos, disconjugate gaze, nystagmus, sixth nerve palsy extensor Babinski responses, occasional signs of frontal lobe release such as a pout reflex or bruxism, and decorticate or decerebrate posturing can occur.[82,83] Mild neck stiffness may occur, but meningismus, severe neck rigidity, photophobia, and papilledema are almost never seen.[83]

Seizures may occur in up to 50% of cases of cerebral malaria. Among children ages above 3–4 years, seizures are increasingly likely to represent cerebral malaria rather than febrile convulsions.[84] Although generalized seizures are typical, partial motor seizures, with or without secondary generalization, may occur.[85] Electroencephalogram (EEG) studies may sometimes reveal underlying status epilepticus even when it is not clinically evident.[82]

Pulmonary Edema and Malaraia-Associated Acute Respiratory Distress Syndrome

Pulmonary complications occur in up to 30% of patients with severe malaria, especially pregnant women, nonimmune persons, and patients already suffering from other complications.[70] The onset may be any time during the course of illness, even if the patient appears to be improving and parasitemia has decreased. Symptoms include dyspnea and cough, with rapid progression to hypoxia and respiratory distress. Pulmonary edema, which may progress to MA-ARDS, is frequent and typically the most lethal of the complications of malaria globally. MA-ARDS is most commonly associated with *P. falciparum, P. vivax,* and *P. knowlesi*, but has been seen with all malaria species.[84,86] Pulmonary complications are seen in about 5% of hospitalized patients with *P. vivax* infection.[87]

Anemia and Hematologic Perturbations

Although some degree of anemia is common in all types of malaria, severe anemia (hemoglobin less than 5 g/100 mL) occurs mostly with *P. falciparum* and *P. vivax*. In *P. falciparum* infection, it is most common and often severe in pregnant women and young children (<1 year), in whom it may be the presenting sign.[88,89] In addition to the acute hemolytic destruction of parasitized RBCs, the more chronic processes of removal of parasitized cells from circulation by the spleen and cytokine inhibition of erythropoiesis may contribute.[81] Nonimmune subjects may develop anemia within days after infection, but usually more slowly in those who are semi-immune.

In *P. vivax* infection, profound anemia is seen in young children from high-endemic areas and results from several pathogenic processes, including frequent hemolysis because of relapsing infection, increased fragility of infected and uninfected reticulocytes, high splenic removal rate of uninfected RBCs (four times higher than in *P. falciparum*), and recrudescence of chloroquine-resistant parasites.[78]

The degree of anemia generally correlates with bilirubin level and level of parasitemia. It may be exacerbated by underlying glucose-6-phosphate dehydrogenase deficiency in the setting of administration of oxidant antimalarial drugs (e.g., quinine, sulfadoxine) and iron-deficiency anemia resulting from malnutrition or soil-transmitted helminthiases. Delayed hemolytic anemia can also occur in patients treated with parenteral artesunate.[89] Significant jaundice and hemoglobinuria may result. Thrombocytopenia, although frequent, is not usually associated with bleeding or correlated with disease severity. Disseminated intravascular coagulation (DIC) has been reported, but in less than 10% of severe cases.

Acute Kidney Injury

Acute kidney injury (AKI) is seen in about 30% of nonimmune adult patients with cerebral malaria and may result in electrolyte abnormalities such as hyponatremia, hypocalcemia (usually related to albumin loss), hypophosphatemia, and metabolic acidemia, in addition to fluid overload with pulmonary edema. For unclear reasons, AKI is rare in semi-immune persons. It is usually the result of acute tubular necrosis, is oliguric in nature (<400 mL urine/24 hr for adults), and is most often reversible. Renal ischemia caused by hypovolemia, renal vasoconstriction, microvascular obstruction, and pigment nephropathy from hemolysis may all contribute. AKI occurs mainly with *P. falciparum,* but it is also described with *P. vivax* and *P. malariae*. It was previously thought to be uncommon in children, but this idea has been challenged by more recent studies showing almost two-thirds of children to have AKI on presentation or to develop AKI while hospitalized with severe malaria.[90] Classically, AKI has been a sign of poor prognosis,[84,91,92] but this may be the result of underrecognition and limited resources, because smaller studies have shown good renal recovery with limited excess mortality.[93]

Blackwater fever refers to a severe syndrome characterized by low or absent parasitemia, intravascular hemolysis, hemoglobinuria, and AKI. It is classically seen in people of Northern European descent chronically exposed to *P. falciparum* and irregularly taking the quinoline antimalarial drugs quinine or quinidine (see later), which together are known as the *cinchona alkaloids*. The syndrome virtually disappeared after 1950 when chloroquine superseded quinine. However, it is now said to be resurgent, albeit with lower mortality, in relation to mounting chloroquine resistance and consequent increased use of quinine, and other newer antimalarials.[94]

Hypoglycemia, Lactic Acidosis, and Other Metabolic Perturbations

Severe metabolic derangements are frequent, especially in pregnant women and young children. Although sometimes asymptomatic in pregnancy, malaria-induced hypoglycemia (blood or plasma glucose <2.2 mmol/L) often causes convulsions and impaired consciousness and may be confused with cerebral malaria. The pathogenesis is not completely known and likely multifactorial, but direct glucose consumption by the malaria parasite and cytokine inhibition of gluconeogenesis seem to be the main mechanisms. Decreased oral intake, depletion of liver glycogen, and insulin release stimulated by quinine or quinidine may also contribute.[95,96] Hypoglycemia has been found to be less frequent with artesunate treatment compared with quinine.[97] Serum insulin levels are low, and lactate, alanine, and counterregulatory hormones are appropriately elevated. Although rarely clinically significant, mild hepatocellular damage may occur and be manifested by elevated hepatic transaminases and jaundice. At least theoretically, such hepatic dysfunction could result in impaired metabolic clearance of antimalarial medications and lactate and deficits in the production of coagulation factors and albumin.

Shock and Bacterial and Other Suprainfection

So-called *algid malaria,* referring to hypotension and shock, may resemble and indeed sometimes be the result of gram-negative sepsis from impaired flow in intestinal capillaries, with resultant mucosal erosion. Algid malaria is often seen in the setting of hyperparasitemia, with concomitant hypoglycemia and lactic acidemia, and may progress to multiorgan system failure and death. As with most malaria complications,

severe hemodynamic derangements are most often seen in nonimmune persons.[98] Whether bacteria are isolated or not, a classic septic shock picture is typical, with elevated cardiac index and decreased systemic vascular resistance.[99] Hypovolemic shock resulting from splenic rupture may mimic algid malaria.

A host of infectious complications, including sepsis, aspiration pneumonia, and parvovirus infection, may be related to *P. falciparum* malaria. Nontyphoidal *Salmonella* septicemia, exacerbated by the iron-rich intravascular environment of hemolysis, is specifically associated with *P. falciparum*.[100] Malaria occurs with increasing frequency and severity in those who are HIV-infected, especially during pregnancy, and can also transiently up-regulate HIV replication.[101–107] An association between severe malaria infection and hepatitis B virus carriage has also been noted.[108] Other infections, such as dengue virus and bacteremia, or noninfectious processes may trigger relapses of *P. vivax and P. malariae* infections.

Tropical Splenomegaly and Splenic Rupture

Splenomegaly is common in infection with all species of malaria. The *tropical splenomegaly syndrome,* also sometimes termed *hyperreactive malarial syndrome,* refers to a condition of massive splenomegaly, high titers of total serum immunoglobulin M (IgM) and malaria-specific antibodies, and scant or absent parasitemia. It is seen in individuals with a history of residence in an endemic area and can be associated with any malaria species. Host genetic factors appear to play a role.[109–111]

Unlike virtually all the other complications of malaria that are most often associated with *P. falciparum,* acute splenic complications occur most commonly in *P. vivax,* especially with the first infection. Although the term *spontaneous splenic rupture* has traditionally been used, in reality a range of hematomas or tears of varying severity may occur. The rupture or tear usually occurs 2–3 months after infection, presumably because of increased intrasplenic tension, often precipitated by varying degrees of trauma or mechanical ventilation.[112] Fever, tachycardia, vomiting, prostration, abdominal pain or guarding, tender splenomegaly, hypovolemia, and rapidly worsening anemia are common presenting features. Abdominal pain may be localized or diffuse, mild or severe. Shock may ensue. Diaphragmatic irritation after rupture may cause referred pain to the left shoulder, supraclavicular, or scapular regions, known as the *Kehr sign.* This is present in about one-half of cases and is said to have good specificity for rupture.

Malaria in Pregnancy and Neonates

In addition to being more susceptible to infection, malaria is particularly dangerous in pregnant women and their fetuses, with increased risk of pulmonary edema, hypoglycemia, severe anemia, premature delivery, low birth weight, and maternal and fetal death. Malaria parasites can often be found in the placenta and may impair oxygen and nutrient transport to the fetus. Placental thickening and decreased transplacental nutrient and hormone production occur, which can result in uterine and placental blood flow reduction and intrauterine growth restriction.[113] Disease is most severe in primiparae, especially if nonimmune. In contrast, women from endemic areas are often asymptomatic, with the exception of the effects of anemia, which are more severe in primiparae.

Congenital malaria is vertically transmitted when malaria parasites cross the placenta, or via direct contact at the time of delivery. Congenital malaria is not as rare as previously thought in endemic areas, with a recent meta-analysis showing a rate of 6.8%, but with significantly higher prevalence in areas of unstable malaria prevalence.[114] Malaria may be symptomatic or asymptomatic in newborns with nonspecific signs requiring a high index of suspicion and appropriate testing.[115]

DIAGNOSIS

Clinical

Malaria often presents with nonspecific signs and symptoms, so making a clinical diagnosis may be difficult. Furthermore, although almost all patients have a history of fever, they may be afebrile at the time of examination.[116–118] Physicians in industrialized countries who are unfamiliar with the disease may initially neglect to include malaria in the differential diagnosis, resulting in delayed diagnosis, which is associated with a poor outcome.[33,119] Only slightly more than half of severe malaria cases in the United States receive appropriate treatment.[120] Most patients with *P. falciparum* malaria present within 1 month of exposure (see Table 123.2). Longer incubation periods may be seen in semi-immune persons or in those who have taken partial chemoprophylaxis. *P. vivax* and *P. ovale* infections can manifest later, months or even years after initial infection, because of reactivation of liver hypnozoites.[121–124]

The differential diagnosis includes most febrile illnesses found in the tropics (see Table 123.1). Babesiosis may present both clinically and microscopically similar to malaria in patients with travel to Lyme-endemic areas. Cerebral malaria must be distinguished from bacterial meningitis, viral meningoencephalitides, metabolic coma, and intoxications, usually necessitating a lumbar puncture.[125,126] Lumbar puncture has been shown to be generally safe in comatose patients with suspected cerebral malaria, even if there are signs of raised intracranial pressure.[127] In cerebral malaria, the cerebrospinal fluid (CSF) opening pressure is usually normal, although a few lymphocytes and moderate elevation of protein may be seen. High CSF lactate and low glucose indicate a poor prognosis.

Conventional Microscopy

Laboratory diagnosis has traditionally been via light microscopy of thick and thin Giemsa-stained smears. Thick smears are more sensitive, whereas thin smears allow identification of the specific parasite and accurate staging of visible forms. Either smear can be used to quantify the level of parasitemia, but thick smears are theoretically more sensitive for this purpose.[128,129] In addition to diagnosis, parasite quantification, and species identification, microscopy allows the clinician to monitor the response to treatment via decreased parasitemia and evaluate parasitic markers of disease severity, such as the presence of schizonts in *P. falciparum* infection.[130,131]

Smears should be taken as soon as the diagnosis of malaria is considered, without waiting for manifestation of a classic paroxysm. Blood obtained by pricking a fingertip or earlobe is preferred because parasite densities are higher in these capillary-rich areas, although blood obtained by venipuncture collected in heparin or ethylenediaminetetraacetic acid (EDTA) anticoagulant-coated tubes is acceptable if used shortly after being drawn before possible alteration in the morphology of white blood cells and malaria parasites.[132,133]

Parasitemia may be undetectable in the early stages of the illness in those with partial immunity and/or who have already taken antimalarials, a common practice in malaria-endemic areas.[134] Levels of parasitemia may fluctuate over time, necessitating repeated smears for diagnosis. Furthermore, *P. falciparum*–parasitized RBCs may be sequestered in the deep capillaries of the spleen, liver, and bone marrow and thus not visible in peripheral blood. In these cases, a positive antigen test (see later) may yield the diagnosis.

Although a blood film is unlikely to be falsely negative in a patient with severe disease, negative smears should not prevent prompt administration of antimalarial therapy if the diagnosis is strongly suspected.[48] Nonimmune individuals may be symptomatic at low parasitemia, and so blood smears should be repeated every 12–24 hours for a total of

three sets before malaria can be excluded.[135] Conversely, asymptomatic parasitemia is common in children from endemic areas, and thus a positive smear does not necessarily signify malaria as the cause of disease under these circumstances.

Considerable expertise at reading malaria smears may be necessary to detect and distinguish the parasites (see Table 123.2). An experienced technician can detect parasitemia as low as 4–20 parasites/μL of blood (0.0001%–0.0005% parasitemia).[136,137] *P. knowlesi* may often be misdiagnosed as *P. falciparum* or *P. malariae* because of similar morphology.[138] Superimposed platelets, particles of stain, pits in the slide, RBC inclusions such as Howell-Jolly bodies and those seen in siderocytes, and other intracellular pathogens such as *Bartonella* and *Babesia* must also be distinguished from malaria parasites. Alterations in parasite morphology may occur related to strain variation, drug pressure, and blood collection methods.

Rapid Diagnostic Tests and Other Newer Laboratory Methods

Various new diagnostic techniques for malaria have been developed in recent years, including dipstick antigen detection (i.e., rapid diagnostic test [RDT]), microscopy with fluorescent stains, DNA probes, polymerase chain reaction (PCR) assays, and automated blood cell analysis.[128,129,139–144] Use of one of these new diagnostic modalities should be considered when a high suspicion of malaria remains despite repeatedly negative blood smears, especially if the microscopist has limited experience with reading malaria smears. Each technique has unique advantages and disadvantages, but the sensitivity and specificity for *P. falciparum* are generally similar or better than conventional microscopy. Because of its greater sensitivity (as low as 5 parasites/μL), PCR may be a particularly valuable tool in nonimmune persons. PCR also allows evaluation for possible infection with multiple malaria strains and determination of drug resistance.

Although they have not completely replaced microscopy in low-resource settings, RDT use is increasingly common in many areas of the world.[145] RDTs are fast (usually have a result in less than 30 minutes) and easy to perform, with sensitivities and specificities comparable to microscopy for *P. falciparum,* depending on the specific product and level of parasitemia. Sensitivity and specificity are lower for *P. vivax* and when the parasitemia is less than 100 parasites/μL, regardless of the species.

RDTs generally detect one or more of three malaria antigens: *P. falciparum* histidine-rich protein 2 (*Pf*HRP2), *Plasmodium* lactate dehydrogenase (pLDH), and aldolase. *Pf*HRP2 is specific for *P. falciparum,* whereas pLDH and aldolase are common to all *Plasmodium* species. RDTs that rely on lactate dehydrogenase or aldolase are not sufficiently sensitive for detecting *P. vivax* and may miss infections because of lower parasitemia.[146] No RDT reliably detects *P. knowlesi.* RDT sensitivity for any *Plasmodium* parasite is diminished when parasitemia is less than 100 parasites/μL. RDTs based on pLDH detection can be used to determine the efficacy of drug therapy because this antigen disappears rapidly after parasite clearance relative to other antigens detected by RDTs. However, most licensed and available RDTs should not be used for patient monitoring, given the longevity of serum antigenemia even with adequate treatment.[147] False-negative malaria RDT results may occur because of a prozone-like effect in high parasitemia, or because of PFHRP2 mutations or deletions leading to reduced or absent production of this antigen by *P. falciparum,* the incidence of which is rising and worrisome. There is currently no RDT specific for *P. knowlesi* detection, and cross-reaction with *P. falciparum* and *P. vivax* pLDH antibodies has been described. No RDT has sufficient negative predictive value to justify withholding treatment in severe illness.[148–150]

In the United States, both microscopy and RDTs are recommended. Although a large number of malaria RDTs have been approved for use globally in recent years, only one is currently approved in the United States: BinaxNOW Malaria (Inverness Medical, Princeton, NJ), which detects both PFHRP2 and aldolase, with a reported sensitivity of 94% for *P. falciparum* and 84% for non–*P. falciparum* malaria.[151,152]

Molecular testing (e.g., PCR) is generally limited to research and epidemiologic purposes, but it does have a role in select clinical situations.[153] The U.S. Centers for Disease Control and Prevention offers PCR testing for species confirmation and identification of drug-resistance mutations. It should be requested if *P. knowlesi* is suspected, given the challenges with diagnosis outlined earlier, in the case of microscopy-RDT discordance, and in situations where aberrant morphologies are noted microscopically. PCR has a theoretical limit of detection of 0.02–1 parasite/μL, far better than conventional microscopy.[154] It therefore can serve an important role in nonimmune patients with low parasitemia or in placental malaria, in which there is significant sequestration and sensitivity of light microscopy is low.[155,156] Research continues on a number of biomarkers that could help distinguish malaria from bacterial and viral diseases.

Imaging

Computed tomography (CT) or magnetic resonance imaging (MRI) scanning of the abdomen is the usual diagnostic modality when splenic rupture is considered, although ultrasonography, angiography, or exploratory laparotomy sometimes may be needed. Findings such as increased brain volume and occasionally brain swelling have been noted in CT and MRI studies in cerebral malaria, but these tests are generally unhelpful clinically and are indicated only to rule out suspected mass lesions when the diagnosis of cerebral malaria is uncertain.[157] Chest imaging may be helpful for identification of MA-ARDS, but there are generally no specific features on imaging to help narrow the diagnosis.

CLINICAL MANAGEMENT

Indications for Admission to the Intensive Care Unit and General Management

Features that indicate severe disease meriting admission to an ICU and urgent intravenous (IV) therapy are noted in Box 123.1. Treatment should follow current septic shock guidelines in terms of fluid resuscitation and vasopressor use.[158] For patients in profound shock, blood cultures should be drawn and broad-spectrum antibiotics begun unless the diagnosis of severe malaria has already been confirmed and bacterial coinfection ruled out.

Careful attention to fluid balance is imperative, especially considering the very poor prognosis once pulmonary edema or MA-ARDS develops. Monitoring of central venous pressure should be considered in critically ill patients. In patients with stable blood pressure and cardiac output, careful fluid maintenance with regular assessment of tissue perfusion as a therapeutic endpoint seems to be more beneficial than liberal fluid resuscitation to minimize the risk of acute pulmonary edema.[159,160]

Hemofiltration or hemodialysis or peritoneal dialysis are indicated for severe AKI and may aid not only through improved fluid and electrolyte balance and control of acidemia but also via removal of circulating cytokine mediators of inflammation.[161,162] Increasing evidence suggests peritoneal dialysis may be a safe and effective alternative to hemodialysis in resource-limited settings.[163–165] Cautious transfusion of packed cells is usually indicated when the hematocrit falls below 20% or Hb <7 g/dL, as extrapolated from other large trials around the topic.[166] In addition to improved oxygen transport, blood transfusion

may reduce the parasite load and cytokine mediators of inflammation.[116,167] Concurrent administration of diuretics with blood products may be warranted to avoid fluid overload. Use of low-dose dopamine and epinephrine have not been associated with significant improvement in renal oxygen metabolism or function, but these or other intravascular vasoactive medications may be needed to support patients with hypotension and/or signs of shock.[168]

Increasing respiratory distress may indicate the onset of MARDS. Arterial blood gas or pulse oximetry measurements may reveal hypoxemia, and chest imaging (x-ray, ultrasound, CT) may reveal bilateral infiltrates. Evidence of cardiogenic pulmonary edema suggests an alternative diagnosis. Supplemental oxygen and mechanical ventilation may be required. Lung-protective ventilation, with tidal volume of 6 mL/kg predicted body weight and plateau pressures less than 30 cm H_2O, are indicated for improved survival.[70,169] Extracorporeal oxygenation has also been employed.[170–173] Metabolic acidosis should be treated by improving pulmonary gas exchange, correcting hypovolemia and hypoglycemia, and treating associated septicemia. Careful monitoring of serum potassium with appropriate supplementation is warranted, especially when correcting acidosis. Blood glucose should be checked at least every 6 hours, especially in pregnant patients, and 50% dextrose administered when needed. Results of studies on the efficacy of continuous IV infusion of 5% dextrose have been mixed.[174,175] If a quinoline is the selected antimalarial, it should be administered with dextrose to avoid quinine-induced hypoglycemia.[176] Once hypoglycemia is ruled out as the etiology, acute seizures should be treated with IV benzodiazepines as preferred first-line therapy. Phenobarbital is an alternative if benzodiazepines are unavailable but has a slower administration time and potentially longer duration of action. Prolonged seizures can be treated with phenytoin, fosphenytoin, valproic acid, or levetiracetam, with phenobarbital as an alternative second-line agent if none of the other agents are available.[82,177,178] Prophylactic anticonvulsants are not recommended and may be harmful.[158] Although the risk of bleeding is low, aspirin and nonsteroidal antiinflammatory drugs should be avoided in the presence of thrombocytopenia. Many patients with splenic rupture can be managed conservatively with supportive therapy, although splenectomy may be necessary.[109,179]

When malaria occurs during pregnancy, an ultrasound should be performed to assess amniotic fluid volume, fetal size, and fetal well-being (i.e., biophysical profile). In late pregnancy, fetal monitoring should be initiated before treating with quinoline therapy so that the effects of the disease can be distinguished from those of drug toxicity.[180] Early obstetric intervention may be considered for the benefit of both mother and fetus at the discretion of the obstetrician. Although fetal distress is usually the result of placental insufficiency, it may sometimes be related to high maternal temperature and hypoglycemia. Thus these parameters should be carefully monitored and treated accordingly. Fluid balance is particularly crucial in pregnant patients because the sudden increase in peripheral vascular resistance postpartum may precipitate pulmonary edema. In young children prone to febrile convulsions, extra efforts should be made to control fever by the use of acetaminophen, cooling blankets, and baths.

Antimalarial Chemotherapy

Because delay of therapy is associated with increased mortality, empirical parental treatment should be implemented immediately in all suspected cases of severe malaria after obtaining appropriate blood specimens. Infection with chloroquine-resistant *P. falciparum* should be assumed unless specifically ruled out. Treatment regimens for severe *P. falciparum* are also effective for the more infrequent cases of severe malaria caused by other species.

Two classes of medicines are indicated for parenteral treatment: the artemisinin derivatives (artesunate, artemether) and the cinchona alkaloids (quinine, quinidine) (Table 123.3). Large randomized trials and a Cochrane systematic review have shown that artesunate is superior to quinine for severe malaria in both adults and children.[181,182] IV or intramuscular (IM) artesunate is the World Health Organization (WHO) first-line recommended drug for severe malaria and should be administered for at least 24 hours even if there is early improvement. If IV or IM artesunate is not available, IM artemether should be considered in preference to quinine for both adults and children with severe malaria. After 24 hours, and if patients are able to tolerate oral therapy, they may be transitioned to one of three recommended oral artemisinin-based combination therapies (ACTs) to complete a total of 3 days (see Box 123.1). If not possible to treat with one of the three recommended ACT regimens, oral artesunate can be combined with either clindamycin or doxycycline, or oral quinine plus either clindamycin or doxycycline can be used for a total of 7 days for both drugs. Doxycycline is preferred to other tetracyclines because it can be given once daily and does not accumulate in renal failure. Doxycycline is contraindicated, and thus clindamycin preferred, in children and pregnant women (see Box 123.1). The dosage of artemisinin compounds does not need to be adjusted for patients with AKI or hepatic dysfunction, and artemisinin compounds do not need dose adjustment with hemodialysis or hemofiltration. This is not true of quinine, which accumulates in renal failure and must be dose adjusted.

Despite its use throughout much of the world, artesunate has not been licensed in many industrialized countries. In the United States, artesunate was approved for use in 2020 but is not widely available.[183] The drug can be procured through the U.S. Centers for Disease Control and Prevention (770-488-7788).[184,185] If artemisinin is unavailable, parenteral quinine or quinidine gluconate can be used as an alternative, although these drugs are no longer widely available in the United States.[183,185,186]

There is increasing artesunate resistance in the Greater Mekong area after first being described in Western Cambodia in 2008.[187–190] Cinchona alkaloids may also be considered in patients infected from countries where resistance to artemisinin compounds has been documented. Currently, guidance is to administer both IV artesunate and IV quinine for severe malaria from the Greater Mekong region, although this is based on expert opinion rather than evidence.[191] Combination therapy with dihydroartemisinin and piperaquine for resistant malaria has been used, with mixed results.[192,193] Chloroquine and sulfadoxine/pyrimethamine are not recommended for treatment of severe malaria.

Adverse Effects of Therapy

Artemisinin compounds are generally well tolerated. Infrequent adverse effects include mild abdominal pain, diarrhea, contact dermatitis, decreases in reticulocyte and neutrophil counts, and elevated hepatic transaminases.[194,195] Severe allergic reactions and cerebellar dysfunction have been rarely reported.[196] In nonimmune adult travelers with high parasitemia, delayed hemolysis has been described after administration of parenteral artesunate, and thus patients treated with this compound should be monitored for anemia for 1 month post-treatment.[88,197–199]

Adverse effects of quinine and quinidine, known as *cinchonism,* are common and typically include nausea, vomiting, headache, dysphoria, vasodilation, tinnitus, and changes in auditory and visual acuity. These alterations are dose related and reversible. Less common side effects include rash, urticaria, angioedema of the face, pruritus, agranulocytosis, hepatitis, blackwater fever, and psychiatric disorders.[200] Overdoses are associated with depressed respiration, circulatory collapse, and

TABLE 123.3 Treatment Guidelines for Severe *Plasmodium falciparum* Malaria

Drug	Dose	Comments
Artemisinin Compounds		
Artesunate Artemether	2.4 mg/kg IV bolus at 0, 12, 24 hr, then daily until patient is able to transition to the following oral regimen: 1. Artemether + lumefantrine: tablets containing 20 + 120 mg, or 40 + 240 mg of artemether and lumefantrine, respectively • Adults: ≥35 kg: 80 + 480 mg twice daily for 3 days • Children: 5 to <15 kg: 20 + 120 mg twice daily for 3 days 15 to <25 kg: 40 + 240 mg twice daily for 3 days 25 to <35 kg: 60 + 360 mg twice daily for 3 days 2. Artesunate + amodiaquine: A fixed dose of combination tablets containing 25 + 67.5 mg, 50 + 135 mg, or 100 + 270 mg of artesunate and amodiaquine, respectively • Adults ≥36 kg, 200 1 540 mg daily for 3 days • Children: 4.5 to <9 kg: 25 + 67.5 mg daily for 3 days 9 to <18 kg: 50 + 135 mg daily for 3 days 18 to <36 kg: 100 + 270 mg daily for 3 days 3. Dihydroartemisinin (DHA) + piperaquine (PPQ): tablets containing 20 + 160 mg, or 40 + 320 mg of DHA and PPQ, respectively • Adults: 36 to <75 kg: 120 + 960 mg daily for 3 days ≥75 kg: 160 + 1280 mg daily for 3 days (no data on dose recommendation above 100 kg) • Children: 5 to <7 kg:10 + 80 mg daily for 3 days 7 to <13 kg: 20 + 160 mg daily for 3 days 13 to <24 kg: 40 + 320 mg daily for 3 days 24 to <36 kg: 80 + 640 mg daily for 3 days 4. Artesunate or quinine PO to complete 7 days PLUS doxycycline, 100 mg PO BID × 7 days 5. Artesunate or quinine PO to complete 7 days PLUS clindamycin, 20 mg base/kg/d PO, TID × 7 days Initial dose: 3.2 mg/kg intramuscularly (IM) (anterior tight); maintenance dose: 1.6 mg/kg IM daily until patient is able to transition to oral regimen as describe earlier for artesunate	Artesunate has recently been approved by the FDA in the United States, but until widely stocked, it remains available from the CDC (770-488-7788) via expanded use investigational new drug protocol. Eligibility requirements include inability to take oral medications, high levels of parasitemia, clinical evidence of severe malaria, intolerance of or contraindication to quinidine, failure of quinidine therapy, and lack of rapid access to quinidine.[86] Where available, artesunate rectal suppositories (10 mg/kg) may be used in children <5 years of age if IV or IM administration is not possible. Doxycycline is contraindicated in children <8 years of age and in pregnancy. Atovaquone/proguanil is packaged in the United States in fixed-dose combination tablets of 250 mg atovaquone/100 mg proguanil for adults and 62.5 mg atovaquone/25 mg proguanil for children. Safety of atovaquone/proguanil in pregnancy has not been established.
Cinchona Alkaloid Regimens		
Quinine dihydrochloride	20 mg salt/kg IV or IM on admission, then 10 mg/kg q8h. Can be given IM if IV administration is not possible. One of the following drugs should also be given concurrently: 1. Artemisinin combination therapy as noted earlier 2. Doxycycline as noted earlier. If patient unable to take PO, give 100 mg IV q12h and switch to PO when possible. Avoid rapid IV administration. 3. Clindamycin as noted earlier. If patient unable to take PO, give 10 mg base/kg loading dose IV followed by 5 mg base/kg IV q8h and switch to PO when possible. Avoid rapid IV administration.	The infusion rate of IV quinine should be rate controlled and not exceed 5 mg salt/kg/hr. The drug is usually diluted in 5% dextrose and infused over 4 hours. IV quinine is not available in the United States. When administering IM, the dose should be split and diluted to a concentration of 60–100 mg/kg delivered to each thigh. Reduce the quinine dose by one-third (to 10 mg salt/kg every 12 hours) after 48 hours in patients with severe renal and/or hepatic dysfunction. Doxycycline is contraindicated in children <8 years old and in pregnancy.
Quinidine gluconate	6.25 mg base/kg (=10 mg salt/kg) IV on admission over 1–2 hours, then 0.0125 mg base/kg/min (=0.02 mg salt/kg/min) continuous infusion. An alternative regimen is 15 mg base/kg (=24 mg salt/kg) loading dose IV infused over 4 hours, followed by 7.5 mg base/kg (=12 mg salt/kg) infused over 4 hours q8h, starting 8 hours after the loading dose. A second drug should be given concurrently as listed earlier for quinine.	The loading dose should be omitted if the patient received >40 mg/kg quinine in the preceding 48 hours or mefloquine in the previous 12 hours. Reduce the dose by one-third after 48 hours in patients with severe renal and/or hepatic dysfunction.

central nervous system (CNS) alterations, including seizures and coma, which may be difficult to distinguish from cerebral malaria.[201] Simultaneous use of two quinolines or retreatment with the same quinoline within a short period may predispose to severe side effects.[202] The cinchona alkaloids are metabolized in the liver and excreted in the urine. Monitoring blood levels is recommended for persons with impaired renal or hepatic function, and dose reduction is necessary in those with severe renal impairment. Quinine metabolism appears to be decreased in children with kwashiorkor but increased in those with marasmus.[203]

Although often not clinically significant, prolongation of the electrocardiographic QT interval with IV quinoline therapy is common.[204] Severe conduction abnormalities may occur along with hypotension, blindness, and deafness.[204] Dysrhythmias and hypotension may also result from overly rapid infusion and can be fatal. Coma may result when serum quinoline levels exceed 20 mg/L. Cardiac monitoring should be performed with IV quinoline use, especially with quinidine, which although more potent against the malaria parasite is also generally more toxic.[204] Infusion rates of quinidine should be decreased if the QT interval increases by more than 25% of its baseline level.

Quinoline-induced stimulation of insulin release may elicit significant hypoglycemia, especially in pregnancy.[175,205] Hypophosphatemia may also be precipitated by both quinoline and IV dextrose, causing CNS dysfunction.[116] Levels of digoxin, mefloquine, neuromuscular blocking agents, and oral anticoagulants may all be increased with quinoline administration. Quinine can cause hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency. Because of their curarelike effect on skeletal muscle, quinolines are contraindicated in patients with myasthenia gravis. An extensive list of drug interactions reported for recommended antimalarial drugs is available in the WHO guidelines for the treatment of malaria.[158]

Ancillary Therapies

Various ancillary therapies have been proposed for severe malaria, but in most cases controlled data are not available to determine their efficacy. Exchange transfusion and erythrocytapheresis have been employed in cases of severe malaria with high parasitemia with anecdotal benefit.[206–211] However, multiple studies reviewing case series and controlling for confounding have shown no benefit of exchange transfusions on mortality, parasitemia, and ICU or hospital length of stay.[212–214] In an era of artemisinin-based therapy, which is characterized by rapid clearance of parasitemia, the biologic plausibility of benefit from conventional exchange transfusion is becoming less relevant. However, there is ongoing research studying the role of exchanging malaria-resistant RBCs (T-REX) in cases of severe artesunate-resistant malaria.[215,216] Treatments such as heparin, prostacyclin, deferoxamine, pentoxifylline, low-molecular-mass dextran, urea, high-dose corticosteroids, aspirin, antitumor necrosis factor antibody, cyclosporine A, dichloroacetate, adrenaline, hyperimmune serum, N-acetylcysteine, inhaled nitric oxide, and bolus administration of albumin are not recommended because their effectiveness is not proven or they have shown to be detrimental in severe malaria.[158,217]

Laboratory Monitoring

Findings in severe malaria may include profound hemolytic anemia and thrombocytopenia, leukocytosis with a left shift (although milder cases may show leukopenia), prolonged coagulation times with increased fibrin degradation products and low fibrinogen reflecting DIC, hyponatremia, hypoalbuminemia, hypophosphatemia, hypoglycemia, lactic acidemia, and elevated hepatic enzymes, LDH, bilirubin, blood urea nitrogen (BUN), and creatinine. Urinalysis may reveal proteinuria, RBCs and RBC casts, and hemoglobinuria. Coagulation defects and thrombocytopenia often correlate with the degree of parasitemia. The level of parasitemia should be monitored via blood smear every 12 hours after initiation of therapy. A decrease of 75% should be noted within 48 hours of starting artemisinin therapy. If this does not occur, drug resistance should be suspected, and the regimen should be changed accordingly (see Table 123.3).

PROGNOSIS AND SEQUELAE

Case fatality rates of severe malaria vary by geographic context and quality of care from 2% to 50%.[82,85,218–220] Factors that correlate with a poor prognosis include the infecting species and resistance profile, choice of parenteral therapy, CNS involvement, pulmonary edema, shock, hypoglycemia, lactic acidosis, renal failure, severe anemia, younger age, pregnancy, and treatment in a rural health facility as opposed to an ICU.[91,116,221–230] There is a semi-quantitative relationship between level of parasitemia and risk of death, especially in nonimmune patients.

Although less than 10% of adults with cerebral malaria have persistent neurologic sequelae, this number may be as high as 40% in children, especially if associated with hypoglycemia.[174,218,231] Commonly seen sequelae include psychosis, hemiparesis, cerebellar ataxia, blindness, and extrapyramidal rigidity.[82,85,231] Children who survive without obvious neurologic sequelae often still have behavioural or cognitive impairments, in some studies in over 50%.[232] A postmalarial neurologic syndrome, usually associated with mefloquine use, of an acute confusional state, psychosis, convulsions, and tremors, has been described but is usually self-limited.[82]

ACKNOWLEDGMENTS

The authors thank Andrew Bennett, Jenna Iberg, Emily Jentes, Rob Fowler, Donald Krogstad, Nikki Maxwell, Corina Monagin, Laura Morgan, Obinna Nnedu, Christina Styron, Torrey Theall, and Kent Wagoner for their advice and assistance preparing the manuscript.

KEY POINTS

- A detailed history of the patient's travel itinerary, activities and exposures, and any pretravel prophylaxis, in addition to general knowledge of the prevalent diseases and their incubation periods and drug-resistance patterns in the region of travel, are imperative when evaluating patients with exposures overseas.
- Most "nontropical" infections are also common in low- and middle-income countries and thus need to be considered.
- Assessing the patient's immune status based on history of exposure to malaria is essential in directing the diagnostic workup and management.
- Infection with multiple tropical pathogens is common in those living in endemic areas, and malaria may not be the primary causative pathogen even if identified.

Risk of Infection and Uncomplicated Malaria

- Malaria is the most common serious infection in the majority of tropical countries and in returning travelers and therefore should be considered in any patient reporting travel in malaria-endemic areas or exposure to unscreened blood products ("transfusion malaria") or blood-contaminated needles.
- Malaria classically produces a three-stage "paroxysm" progressing over an 8- to 12-hour period, consisting of rigors and chills ("cold stage"), followed by fever ("hot stage"), followed by sweating with resolution of all symptoms

("defervescent stage"). In practice, neither the classic paroxysm nor the periodicity is invariably seen.

Severe and Complicated Malaria

- The overwhelming majority of severe and complicated malaria is caused by *P. falciparum* in nonimmune children, adults, and pregnant women, but *P. vivax* and *P. knowlesi* can also cause severe disease.
- The risk of acquiring *P. falciparum* is highest for those traveling to sub-Saharan Africa (especially West Africa) and New Guinea; the risk is moderate in India and comparatively low in Southeast Asia and Latin America. *P. vivax* is widely distributed, with the highest risk in Oceania. *P. knowlesi* is only found in Southeast Asia.
- The most frequent severe complication is cerebral malaria, mostly seen in children. It manifests as coma, convulsions, changes in sensorium, or focal neurologic signs. Other severe complications include severe anemia (especially in young children and pregnant women), hypoglycemia, lactic acidosis, AKI, pulmonary edema and ARDS, shock, and bacterial suprainfection.
- Other potentially severe complications caused by non–*P. falciparum* malaria include splenic rupture and severe anemia *(P. vivax)* and chronic nephrotic syndrome *(P. malariae).*

Diagnosis

- Malaria often presents with nonspecific signs and symptoms, and the differential diagnosis is broad, so making a clinical diagnosis may be difficult.
- The vast majority of malaria cases will present within 1 month of exposure. *P. vivax* and *P. ovale* infections can present months or even years after infection because of the possibility of dormant forms (hypnozoites) in the liver.
- Laboratory diagnosis is traditionally made through microscopy of thick and thin Giemsa-stained smears. Low or fluctuating parasitemia or altered parasite morphology may complicate diagnosis, especially with an inexperienced microscopist. Asymptomatic parasitemia is common in children from endemic areas.
- Various new diagnostic techniques for malaria (e.g., dipstick antigen detection, PCR) have been developed in recent years, with sensitivities and specificities for *P. falciparum* generally superior to conventional microscopy. Use of one of these new modalities can be considered when the diagnosis of malaria is unclear if local resources are available.
- Radiographic imaging of the abdomen is indicated when splenic rupture is suspected.

Clinical Management

- Patients with evidence of severe or complicated malaria should be assumed to have chloroquine-resistant *P. falciparum* and admitted to the ICU for aggressive supportive care and urgent antimalarial drug therapy. Therapy should consist of IV artesunate followed by oral ACT for 3 days. Parenteral artesunate should be given for at least 24 hours and until the patient is able to tolerate oral medication. Acceptable alternatives when parenteral artesunate is unavailable include IM artemether, IV quinidine gluconate, or IV quinine (transitioned to oral artesunate or quinine according to the same criteria as noted earlier), given simultaneously with oral/IV doxycycline or clindamycin for 7 days.
- Artemisinin compounds are usually well tolerated. Side effects with cinchona alkaloid therapy are frequent, but are usually mild, dose related, and reversible. Cardiac toxicity and arrhythmias are common in the case of overadministration of cinchona alkaloids.
- Many patients with splenic rupture can be managed conservatively with supportive therapy, although splenectomy may be necessary.
- The hemoglobin/hematocrit, electrolytes, platelet count, glucose, lactate, arterial blood gas, BUN/creatinine, liver function and coagulation enzymes, and the level of parasitemia in response to therapy should be monitored closely.
- The case fatality rates of severe malaria treated in an ICU vary by geographic context and quality of care and may be up to 50%.

ANNOTATED REFERENCES

Balikagala B, Fukuda N, Ikeda M, et al. Evidence of Artemisinin-resistant malaria in Africa. *New Engl J Med.* 2021;385(13):1163–1171.
This is a longitudinal study in Uganda looking at in vivo and ex vivo susceptibility of malaria strains to artemisinins. The authors found that from 2017 to 2019, 14/240 (5.8%) of patients treated with IV artesunate had in vivo evidence of artemisinin resistance (parasite clearance half-life >5 hours); 13/14 (93.6%) of these malaria parasites had mutations in the kelch13 *gene. This is evidence of independent emergence of clinical artemisinin-resistant* P. falciparum *in Africa.*

Blanshard A, Hine P. Atovaquone-proguanil for treating uncomplicated *Plasmodium falciparum* malaria. *Cochrane Database Syst Rev.* 2021;1(1):CD004529.
This is a Cochrane review to assess the safety and efficacy of atovaquone-proguanil compared with other antimalarials for treatment of uncomplicated P. falciparum *malaria in both adults and children. The review showed that atovaquone-proguanil was effective for uncomplicate malaria, although failure rates were 5%–10% and could be decreased with the addition of artesunate to the regimen.*

Conroy AL, Hawkes M, Elphinstone RE, et al. Acute kidney injury is common in pediatric severe malaria and is associated with increased mortality. *Open Forum Infect Dis.* 2016;3(2):ofw046.
This study looked at 180 children in rural Uganda with malaria. The investigators found that 81 (45.5%) had AKI. There were higher rates of AKI than anticipated in children, and AKI was associated with increased rates of mortality and neurodisability.

Khuu D, Eberhard ML, Bristow BN, et al. Malaria-related hospitalizations in the United States, 2000-2014. *Am J Trop Med Hyg.* 2017;97(1):213–221.
This review identifies all U.S. malaria cases from 2000 to 2014 from hospital discharge records. There were an estimated 22,029 malaria-related hospitalizations (4.88 per 1 million population) in the United States, with 4823 severe cases and 182 in-hospital deaths. The rate of malaria-related hospitalizations did not change significantly over the study period. On average, malaria patients were hospitalized for 4.36 days with charges of $25,789. Enhanced primary and secondary prevention measures, including strategies to increase the use of pretravel consultations and prompt diagnosis and treatment, are needed.

van der Pluijm RW, Tripura R, Hoglund RM, et al. Triple Artemisinin-based combination therapies versus Artemisinin-based combination therapies for uncomplicated *Plasmodium falciparum* malaria: A multicentre, open-label, randomised clinical trial. *Lancet.* 2020;395(10233):1345–1360.
Investigators compared treatment of uncomplicated P. falciparum *malaria in 18 hospitals across eight countries. They found that dihydroartemisinin-piperaquine plus mefloquine and artemether-lumefantrine plus amodiaquine triple artemisinin-based combination therapies are efficacious, safe, and well-tolerated treatments for uncomplicated* P. falciparum *malaria even in areas with developing artemisinin resistance.*

Clostridioides difficile Infection

Massimo Sartelli

INTRODUCTION

Clostridioides difficile is an anaerobic, spore-forming, gram-positive bacillus that may be part of the normal intestinal microbiota in healthy babies.[1–4] It was officially renamed in 2016 to *Clostridioides difficile*. The new name reflects the taxonomic differences between this species and other members of the *Clostridium* genus.[5] It is spread via the oral-fecal route, and in hospitalized patients may be acquired through the ingestion of spores from other patients, healthcare personnel's hands, or environmental surfaces.[6,7] *C. difficile* is the main pathogen associated with nosocomial infections and is the most common cause of diarrhea in hospitalized patients.[8] *C. difficile* infection (CDI) can present as a spectrum of symptoms ranging from an asymptomatic carriage to fulminant disease with toxic megacolon. Extracolonic manifestations of CDI are rare and most commonly involve small intestine infiltration, reactive arthritis, and bacteremia.[9] The mortality rate directly attributable to CDI is estimated at 5%, whereas mortality associated with CDI complications reaches 15%–25%, and up to 34% in intensive care units (ICUs). Mortality doubles in ICU patients with CDI as compared with ICU patients without CDI.[9,10]

PATHOGENESIS

CDI occurs via the fecal-oral route as a result of ingestion of spores that are resistant to their environment. During gastrointestinal passage, bile acids and other substances stimulate the germination of vegetative growth forms; these produce toxins, depending on the surrounding microflora (microbiota) The primary toxins produced by this bacterium are toxins A and B.[11] Toxins A and B act as glucosyltransferases, promoting the activation of Rho GTPases and leading to disorganization of the cytoskeleton of the colonocyte and eventual cell death.[12] Because CDI is a toxin-mediated infection, nontoxigenic *C. difficile* strains are nonpathogenic. The increased incidence, severity, and mortality of CDI have been largely attributed to the epidemic strain ribotype 027 (formerly referred to as *NAP1/BI/027*). The *C. difficile* BI/NAP1/027 epidemic strain is characterized by two mutations in the toxin regulatory gene *tcdC*, an 18–base-pair (bp) deletion, and deletion at position 117, which leads to increased production of toxins A and B.[9,13]

RISK FACTORS

Risk factors for CDI may be divided into three general categories: host factors (immune status, comorbidities), exposure to *C. difficile* spores (hospitalizations, community sources, long-term care facilities), and factors that disrupt normal colonic microbiome (antibiotics, other medications, surgery).[14]

PATIENT FACTORS

Risk factors identified to date include age >65 years, comorbidity or underlying conditions, inflammatory bowel diseases, immunodeficiency (including human immunodeficiency virus (HIV) infection), malnutrition, obesity, female sex, and low serum albumin level.[14]

Exposure to *Clostridium difficile* Spores

Factors that increase risk of exposure to *C. difficile* spores, such as increased duration of hospital stay, increase the risk of CDI. A length of stay >2 weeks has been shown to be a risk factor for CDI.[14] During the first days of hospitalization, the incidence of *C. difficile* colonization ranges from 2% to 20%[15–19] and increases with longer hospital stays.[20–21] It must be noted that colonization does not necessarily mean symptomatic infection; it is suggested that only 25%–30% of asymptomatic colonized patients develop diarrhea. *C. difficile* spores survive in the environment for several months.[22]

Normal Flora Disruption

The indigenous gut microbiota is a complex community of microorganisms that populates the gastrointestinal tract in a healthy person. This micro-ecosystem plays a crucial role in protecting the gut by providing resistance to colonization and infection by pathogenic organisms.[23] Gut microbiota also has immeasurable effects on homeostasis of the host.[24] Under normal conditions, the human gut microbiota impedes pathogen colonization through general mechanisms such as direct inhibition through bacteriocins, nutrient depletion (consuming growth-limiting nutrients), or stimulation of host immune defenses. However, the exact mechanism by which the microbiota protects against CDI is unknown.[25] Disruption of the normal balance of colonic microbiota as a consequence of antibiotic use or other stressors is of major importance.[26]

In 1974 Tedesco and colleagues published a prospective study of clindamycin-associated colitis, which had become endemic in many hospitals.[27] In 200 consecutive patients, administration of clindamycin resulted in diarrhea in 21% and the incidence of endoscopy-diagnosed pseudomembranous colitis was 10%. The study led to a search for an infectious cause of colitis, and it identified *C. difficile* as the main causative agent.[28] Nearly every antibiotic has been associated with the development of CDI, including the antibiotics used for treatment of CDI such as metronidazole and vancomycin. Broad-spectrum penicillins and cephalosporins, clindamycin, and fluoroquinolones possess a higher risk for CDI induction than other antibiotics.[14] The risk for development of CDI is eightfold to tenfold higher during antibiotic therapy and 4 weeks thereafter and threefold higher in the next 2 months.[29]

DIAGNOSIS

CDI should be considered in patients who have diarrhea (≥3 loose stools in 24 hours) with or without abdominal pain, especially if they have a recognized risk factor (including recent antibiotic use, hospitalization, or advanced age) with no obvious alternative diagnosis (including laxative use in the past 48 hours). Nausea, vomiting, and fever are often, but not always, present.

Several diagnostic options are available; however, no single test is considered to be the best laboratory testing method. The most common diagnostic option for CDI is based on detection of *C. difficile* toxins directly in a stool sample, most commonly with an enzyme immunoassay (EIA), which provides rapid turnaround time (about 1–2 hours), in addition to sensitivity of 75%–85% and specificity of 95%–100%.[9] Because of its low cost and ease of use, this is the most popular test in all laboratories. Tests detecting *C. difficile* antigens are based on the detection of glutamate dehydrogenase (GDH) and are characterized by ease of use and rapid turnaround time in addition to a specificity of almost 100%. However, they do not distinguish whether the strain is toxigenic (specificity of 59%).[9] In 2009, nucleic acid amplification tests (NAATs) were introduced. NAAT has higher sensitivity (80%–100%) and specificity (87%–99%) compared with an EIA test. The specificity is especially high, reaching 95%, when a negative result is obtained. In this situation, another cause of diarrhea should be considered.[9] The NAAT has also limitations: namely, high cost and some interpretation difficulties. NAAT detects the presence of a toxin-encoding gene and thus confirms the presence of a *C. difficile* toxin–producing strain, but it does not necessarily mean that the strain produces any toxins at the moment. A multistep algorithm to diagnose CDI (GDH plus toxin EIA, GDH plus toxin EIA with NAAT confirmation if results are discordant, or NAAT plus toxin EIA) is generally suggested in clinical practice.

In certain clinical settings, adjunct testing methods such as radiologic diagnostic imaging may be useful for diagnosing CDI. Diagnostic computed tomography (CT) imaging can assist with an early diagnosis and may help determine the severity of disease in patients with CDI.[14] Typical CT findings of CDI include colonic wall thickening, dilation, pericolonic stranding, "accordion sign" (high-attenuation oral contrast in the colonic lumen alternating with low-attenuation inflamed mucosa), "double-halo sign, target sign" (intravenous contrast displaying varying degrees of attenuation caused by submucosal inflammation and hyperemia), and ascites.[14] However, the most common finding, colonic wall thickening, is nonspecific and can be found in other forms of colitis, although it may be more pronounced with CDI.

TREATMENT

Treatment should only be started in patients with CDI symptoms; presence of the *C. difficile* toxin without symptoms of the infection is not an indication for treatment. When antibiotic therapy is indicated for symptomatic cases with a positive *C. difficile* toxin result, options include metronidazole, oral or intraluminal vancomycin, and oral fidaxomicin. Although metronidazole may be associated with more frequent side effects and there has been a significant increase in treatment failures (especially in patients infected with the emergent 027/BI/NAP1 strain), oral metronidazole 500 mg three times per day for 10 days has been used for treating mild to moderate cases of CDI.[30] Repeated or prolonged courses of metronidazole should be avoided because of the risk of cumulative and potentially irreversible neurotoxicity.[31]

In 2017 the Infectious Diseases Society of America (IDSA) and Society for Healthcare Epidemiology of America (SHEA) updated their guidelines, pointing out that vancomycin and fidaxomicin are the cornerstone of CDI treatment, suggesting metronidazole only for patients with an initial episode of nonsevere CDI in settings where access to vancomycin or fidaxomicin is limited.[32] Vancomycin orally 125 mg four times daily for 10 days is considered superior to metronidazole in severe *C. difficile* disease.[33–36] This may reflect the superior pharmacokinetic properties of vancomycin, which is concentrated in the gut lumen. Doses of up to 500 mg have been used in some patients with severe or fulminant disease, defined as hypotension or shock, ileus or megacolon,[14] although there is little evidence for this in the literature. Unlike vancomycin delivered enterally, intravenous vancomycin has no effect on CDI because the antibiotic is not excreted into the colon. Vancomycin enemas may be an effective therapy for patients who cannot tolerate the oral preparation or patients with ileus who have delayed passage of oral antibiotics from the stomach to the colon.[37]

Fidaxomicin orally 200 mg twice daily for 10 days is a valid alternative to vancomycin in patients with CDI.[38,39] Fidaxomicin was noninferior to vancomycin for initial cure of CDI in two prospective trials.[40,41] It may be useful for treating patients who are considered at high risk for recurrence (elderly patients with multiple comorbidities who are receiving concomitant antibiotics). However, it is important to note that no data on the efficacy of fidaxomicin in severe life-threatening disease are available.[14] The use of other antibiotics such as tigecycline,[14] fusidic acid, teicoplanin, rifamixin,[14] and nitazoxanide[14] has been described in the literature, but they are not currently recommended for general use.

Patients with fulminant colitis who progress to systemic toxicity require surgical intervention.

These patients are likely to have serious comorbidities, and delaying surgery in these patients leads to increased likelihood of adverse outcomes. Total colectomy is the surgical procedure of choice. However, diverting loop ileostomy with antegrade colonic lavage may be a colon-preserving alternative to total colectomy.[42,43] A prospective, nonrandomized, historical control group study was performed at the University of Pittsburgh Medical Center and the Veterans' Administration Healthcare System in Pittsburgh between June 2009 and January 2011.[44] Forty-two patients with fulminant colitis were managed by a loop ileostomy, intraoperative colonic lavage with warmed polyethylene glycol 3350/electrolyte solution via the ileostomy, and postoperative antegrade instillation of vancomycin flushes via the ileostomy. There was no significant difference in age, sex, pharmacologic immunosuppression, and Acute Physiology and Chronic Health Evaluation-II (APACHE II) scores between the studied cohort and historical controls. The operation was accomplished laparoscopically in 35 patients (83%). This treatment strategy resulted in reduced mortality compared with their historical controls. Preservation of the colon was achieved in 39 of 42 patients (93%). Of note, vancomycin antegrade enemas were continued via the ileostomy every 6 hours for 10 days, and this likely augmented the effect of the defunctioning surgery.

A retrospective multicenter study conducted under the sponsorship of the Eastern Association for the Surgery of Trauma to compare loop ileostomy with total colectomy as surgical treatment for CDI was published in 2017.[44] Data from 10 centers of patients who presented with CDI requiring surgery between July 1, 2010, and July 30, 2014, were collected. When comparing colectomy with loop ileostomy, there was no statistical difference between these two operative strategies. Univariate preprocedure predictors of mortality were age, lactate, timing of operation, vasopressor use, and acute renal failure. There was no statistical difference between the APACHE score of patients undergoing either procedure (total colectomy, 22 vs. loop ileostomy, 16). Adjusted mortality (controlled for preprocedure confounders) was

significantly lower in the loop ileostomy group (17.2% vs. 39.7%; $P=.002$).

TREATMENT OF RECURRENT CDI

Recurrence is diagnosed when CDI recurs <8 weeks after the resolution of a previous episode, provided the symptoms from the previous episode resolved after completion of the initial treatment and other causes have been excluded. Symptomatic recurrent *C. difficile* infection (RCDI) occurs in approximately 20% of patients and is challenging.[14] Therefore patients with RCDI should be treated by experienced clinicians. Antibiotics that may be used to treat the first recurrence of CDI include vancomycin (particularly if metronidazole was used for the first episode) or fidaxomicin. Antibiotic treatment options for patients with more than one recurrence of CDI include oral vancomycin therapy using a tapered and pulsed regimen.[14]

Fecal microbiota transplantation (FMT) has been considered as an alternative therapy to treat RCDI.[14] It involves infusing intestinal microorganisms (in a suspension of healthy donor stool) into the intestine of patients to restore the intestinal microbiota. The rationale of FMT is that disruption of the normal balance of colonic flora allows *C. difficile* strains to grow and produce CDI. By reintroducing normal flora via donor feces, the imbalance may be corrected and normal bowel function re-established.[42,43] Although FMT has high success rates with long-term durability,[44] a few disadvantages still exist. In particular, the manipulation of feces and the classical enteral administration methods are not only laborious but also tend to make the procedure rather unattractive for physicians and patients. FMT may be administered via enemas or as a slurry given via a nasogastric tube.

In 2016 the Food and Drug Administration (FDA) approved bezlotoxumab to reduce the recurrence of CDI in adult patients receiving antibiotic therapy for CDI who are at high risk of recurrence. Bezlotoxumab (MK-6072) is a human monoclonal antibody that reduces recurrent CDI by blocking the binding of *C. difficile* toxin B to host cells, thus limiting epithelial damage and facilitating recovery of the microbiome.[14]

Coadjuvant treatment with bezlotoxumab is generally suggested to prevent recurrences of CDI, particularly in patients with a history of CDI, caused by the 027 epidemic strain, in immunocompromised patients and in patients with severe CDI.[14]

INFECTION PREVENTION AND CONTROL

Prompt identification of patients with CDI is essential so that appropriate isolation precautions can be put into effect.[45] This is particularly important in reducing environmental contamination, as spores can survive for months in the environment,[46] despite regular use of environmental cleaning agents. An infection control "bundle" strategy should be used to successfully control CDI outbreaks. The "bundle" approach should include multifaceted interventions, including hand hygiene, isolation measures, and environmental disinfection.[14] In a healthcare setting, transmission of *C. difficile* spores occurs primarily via the contaminated hands of healthcare workers, but contact with a contaminated environment, utensils, or medical devices has also been implicated. Hand hygiene with soap and water and the use of contact precautions, along with good cleaning and disinfection of the environment and patient equipment, should be used by all healthcare workers in contact with any patient with known or suspected CDI. Hand hygiene is a cornerstone of prevention of nosocomial infections, including infection caused by *C. difficile*. Alcohol-based hand sanitizers are highly effective against non–spore-forming organisms, but they do not kill *C. difficile* spores. Though disposable glove use during care of a patient with CDI may be effective in preventing the transmission of *C. difficile*,[14] these must be removed at the point of use and the hands thoroughly decontaminated afterwards through soap and water handwashing. Patients with known or suspected CDI should ideally be placed in a private room[14] with en-suite handwashing and toilet facilities. If a private room is not available, known CDI patients may be cohort nursed in the same area,[14] though the theoretical risk of transfection with different strains exists.

CONCLUSIONS

In the last three decades the frequency and severity of *C. difficile* infection have been increasing worldwide to become one of the most common hospital-acquired infections. Appropriate management of infection requires an understanding of the various diagnostic assays and therapeutic options in addition to measures relevant to infection prevention.

KEY POINTS

- Proper antibiotic stewardship in both selecting an appropriate antibiotic and optimizing its dose and duration to prevent and cure an infection may prevent the emergence of *C. difficile.*
- The diagnosis of CDI should be based on clinical signs and symptoms in combination with laboratory tests.
- When antibiotic therapy is indicated, options include metronidazole (only in mild cases), oral or intraluminal vancomycin, and oral fidaxomicin.
- Patients with severe CDI who progress to systemic toxicity should undergo early surgical consultation and should be evaluated for potential surgical intervention.
- Resection of the entire colon should be considered to treat patients with fulminant colitis. However, diverting loop ileostomy with colonic lavage may be a useful alternative to resection of the entire colon

Anemia and RBC Transfusion

Erin L. Vanzant and Alicia M. Mohr

Anemia remains common in the critical care population, and its etiology is multifactorial, related to hemorrhage, hemodilution, diagnostic phlebotomy, acute inflammation, and functional iron deficiency. These factors result in decreased red blood cell (RBC) production and reduced RBC survival. This chapter will explore the problem of anemia in the critically ill patient, its causes and effects, and the use and risk of RBC transfusions in the management of anemia, with a focus on evidence-based studies. The physiologic effects of anemia are covered elsewhere.

EPIDEMIOLOGY

Anemia is defined as a hemoglobin (Hb) level of <130 g/L in men and <120 g/L in nonpregnant women.[1] In the intensive care unit (ICU) population, modest anemia is generally accepted to be a hemoglobin level of ≤100 g/L in both men and women. Large observational studies in all admitted ICU patients have demonstrated that the vast majority will experience an appreciable drop in hemoglobin. In a 2006 European study of over 1000 patients, anemia, as defined by a hemoglobin level of <130 g/L in men or <115 g/L in women, was observed in more than 80% of the patients, and by the time of discharge almost 25% had a hemoglobin level of <90 g/L.[2] Similar observations were made in a 2003 North American critical care study that involved 4892 patients.[3] In this study, 70% of patients developed a hemoglobin level of <120 g/L within 2 days of ICU admission, and 50% had a hemoglobin level of <100 g/L. By the end of the first week at least 97% of patients had a notable decrease in their hemoglobin levels.[3]

Anemia develops early within the first 2 days of ICU admission. In nonbleeding patients, an average hemoglobin drop of 5 g/L/day has been observed, with the largest decline seen in the first days after admission.[4] Persistent anemia is common after ICU discharge, with 77% of patients anemic at hospital discharge and 50% remaining anemic for up to 6 months.[3–5]

ETIOLOGY

The cause of anemia in critical illness is complex and often multifactorial. Primary mechanisms include problems with decreased RBC production, hemodilution from large-volume resuscitation, and increased RBC losses. Production issues include a suppression of bone marrow secondary to a blunted erythropoietin response during critical illness, lack of substrate availability (including iron, vitamin B_{12}, and folate), and the presence of renal failure, which leads to an absolute erythropoietin deficiency.[5,6] The blunted erythropoietin response is in part secondary to the host inflammatory response. This can lead to dysregulation of iron metabolism homeostasis, impaired proliferation of erythroid progenitor cells, and increased inflammatory mediators (interleukin [IL]-1, tumor necrosis factor [TNF]-alpha, increased hepcidin concentrations) causing an iron-restricted anemia.[7,8] The elevated hepcidin levels lead to iron sequestration in macrophages and reduce iron absorption from the gut, leading to an iron-restricted erythropoiesis.

Anemia caused by blood loss can be subdivided into disease-related and secondary causes. Disease-related causes of anemia include traumatic blood loss, coagulopathy, hemolysis, and gastrointestinal losses. Other secondary losses are primarily iatrogenic and include losses caused by diagnostic sampling, hemolysis, vascular cannulation, renal replacement therapy, and surgical procedures. Daily diagnostic sampling can be an important contributor to anemia. The average volume of blood draws in the ICU results in an average of 40 mL of blood loss per day, and up to 70 mL per day are lost as the patient's illness progresses.[6,8] Phlebotomy-related blood loss has been decreased with the introduction of new conservative techniques, with pediatric tubes, reinfusion of the discarded sample from indwelling lines, and reducing the frequency of blood tests.

CONSEQUENCES OF ANEMIA

Anemia is associated with poor outcomes, especially in the elderly and those with chronic disease.[9,10] The compensatory response of the body in acute or chronic anemia is an extra burden on critically ill patients. The supply/demand balance is particularly stressed in the critically ill anemic patient who has increased cardiac and peripheral oxygen consumption. In patients with ischemic heart disease, coronary flow may be fixed, thereby creating a mismatch between blood supply and oxygen demand. In a large retrospective administrative database study of over 75,000 patients over the age of 65 with myocardial infarction, lower hematocrit (Hct) levels were associated with significantly higher rates of shock and heart failure, in-hospital and 30-day mortality, and increased length of hospital stay.[11]

RED BLOOD CELL TRANSFUSION

Epidemiology

Anemia in critical care populations is common. The physiologic effects not only affect oxygen delivery to vital organs and tissues but also

increase cardiac workload as a consequence of natural compensatory mechanisms. These effects are further accentuated in certain high-risk populations. RBC transfusion is one of the most common therapies ordered in the ICU. It is estimated that the incidence of RBC transfusion in the ICU varies between 20% and 50%.[12] Although anemia appears to be a risk factor for both morbidity and mortality, the benefit of the augmentation of hemoglobin levels with RBC transfusion is less clear and is the focus of the discussion ahead.

PHYSIOLOGIC EFFECTS OF RBC TRANSFUSION

The negative effects of anemia on oxygen delivery are clear. Although the improved delivery of oxygen after RBC transfusions in these patients has been demonstrated in several studies, an increase in oxygen uptake and consumption by the end organs and tissue beds is less evident and is not a consistent finding. This can be explained by the various adverse factors of stored blood, like low levels of 2,3-diphosphoglycerate (2.3-DPG), with decreases in the ability of hemoglobin to unload oxygen to the tissues, the structural changes in stored blood, and the accumulation of proinflammatory cytokines. Therefore despite a strong physiologic rationale to treat anemia in critically ill patients, particularly those with evidence of end-organ ischemia, studies have failed to demonstrate reliable benefits with respect to oxygen utilization.

TRANSFUSION-RELATED COMPLICATIONS

There are infectious and noninfectious risks from RBC transfusions (Table 125.1). RBCs are tested for an extensive number of pathogens, including syphilis, hepatitis B, human immunodeficiency virus (HIV), human T-cell lymphotropic virus, hepatitis C, West Nile virus, Chagas disease, and Zika virus. In addition, storage of blood in refrigerators makes bacterial infection rare. Because of significant enhancements in donor screening and blood testing, the direct transmission of infection through a contaminated blood supply is exceedingly rare (see Table 125.1).

TABLE 125.1 Complications Associated With Allogeneic RBC Transfusion

	Complication	Risk per RBC Unit Transfused
Infectious complications	Symptomatic bacterial sepsis	1:250,000
	Death from bacterial sepsis	1:500,000
	Hepatitis:	
	A	1:2 million
	B	1:153,000
	C	1:2.3 million
	HTLV	1:4.3 million
	HIV/AIDS	1:7.8 million
	West Nile virus	<1:1 million
	Parasitic infection	1:4 million
Noninfectious complications	Urticarial reaction	1:100
	Febrile nonhemolytic reaction	1:300
	Transfusion-associated circulatory overload	1:700
	Transfusion-related acute lung injury	1:10,000
	Delayed hemolytic transfusion reaction	1:7000
	Acute hemolytic transfusion reaction	1:40,000
	Anaphylactic reaction	1:40,000
	Posttransfusion purpura	Rare

Data from Callum JL, Lin Y, Pinkerton PH, et al. *Bloody Easy 3: Blood Transfusions, Blood Alternatives and Transfusion Reactions: A Guide to Transfusion Medicine*. 3rd ed. Ontario: Ontario Regional Blood Coordinating Network; 2011.

AIDS, Acquired immunodeficiency syndrome; *HTLV,* human T-cell lymphotropic virus; *HIV,* human immunodeficiency virus; *RBC,* red blood cell.

Although changes in donor screening and blood testing have led to a significant decline in direct RBC transfusion-related infections over the past 30 years, indirect RBC transfusion-related infections have been the focus of many more recent studies. A systematic review and meta-analysis of 20 randomized trials with 7456 patients evaluated the risk of healthcare–associated infections linked to RBC transfusions and compared different liberal and restrictive transfusion strategies.[13] They found that although a restrictive transfusion strategy was not significantly associated with fewer overall healthcare–associated infections, there was a significant risk reduction in serious infection rates even when controlling for leukoreduction (number needed to treat 48, 95% confidence interval [CI] 36–71).[13] This significance was not observed in a subgroup analysis of 1475 critically ill patients. Another systematic review of randomized trials by the *British Medical Journal* to study the effect of restrictive versus liberal transfusion strategies used a subgroup meta-analysis of eight trials deemed at lower risk of bias by the authors that included 5107 patients.[14] The authors also showed a lower associated risk of infection with a restrictive transfusion strategy (relative risk [RR] 0.73, 95% CI 0.55–0.98).[14]

Noninfectious complications of RBC transfusions are far more common (see Table 125.1). These represent a spectrum from relatively benign (fever) to more severe (acute lung injury) and imminently life-threatening (hemolytic reactions).[15] With increased surveillance and studies focused on complications of transfusions, it has been recognized that transfusion-associated circulatory overload (TACO) is becoming one of the most common risks associated with RBC transfusion.[15] Patients at high risk of volume overload have the greatest danger for developing TACO. The leading cause of RBC transfusion-related morbidity is from transfusion-related acute lung injury (TRALI). This pathophysiologic process is characterized by noncardiogenic pulmonary edema leading to hypoxia. TRALI is secondary to increased lung endothelial permeability and can be caused by immune-mediated and nonimmune-mediated mechanisms.[16] Immune-mediated TRALI is caused by the presence of leukocyte antibodies in the plasma of donor blood that are directed against human leukocyte antigens and human neutrophil antigens.[17,18] Nonimmune mediation is thought to be the result of biologically active substances such as lipids and cytokines. Any blood product can trigger TRALI, but it is most commonly associated with the transfusion of products containing high plasma content, and the risk increases with the number of products transfused. In the critically ill patient, the clinical picture of TRALI is difficult to distinguish from other causes of acute lung injury. Therefore there has been a proposed update to define TRALI by an expert panel.[18] The authors used the Delphi methodology to split TRALI into two types based on a patient's risk factor for acute respiratory distress syndrome (ARDS) (Table 125.2).[18] Type I includes those without risk factors for ARDS and is defined similarly to the traditional definition. Type II includes those who may have mild ARDS or risk factors for ARDS, but have had a stable respiratory status for at least 12 hours before their transfusion and otherwise meet the definition of type I.

The exact mechanisms by which these complications occur are not understood, but are likely at least in part attributable to host immune and inflammatory responses. Central to immune-mediated reactions are donor ILs and the TNF, in addition to antibodies or activated neutrophils, fragments of cellular membranes, and soluble human leukocyte antigen, which play important roles in transfusion-induced immunomodulation

TABLE 125.2 New Consensus TRALI Definition

TRALI type I	Patients have no risk factors for ARDS and meet the following criteria: a. i. Acute onset ii. Hypoxemia (P/F <300 or SpO_2 <90% on room air) iii. Clear evidence of bilateral pulmonary edema iv. No evidence or contribution of left atrial hypertension to hypoxemia b. Onset during or within 6 hours of transfusion c. No temporal relationship to an alternative risk factor for ARDS
TRALI type II	Patients who have risk factors for ARDS (but have not been diagnosed with ARDS) or who have P/F of 200–300 but respiratory status deteriorates because of transfusion based on: a. Findings as described in a and b of TRALI type I b. Stable respiratory status in the 12 hours before transfusion

Data from Vlaar APJ, Toy P, Fung M, et al. A consensus redefinition of transfusion-related acute lung injury. *Transfusion.* 2019;59(7):2465–2476. *ARDS,* Acute respiratory distress syndrome; *P/F,* partial pressure of oxygen (PaO_2)/fraction of inspired oxygen (FiO_2); *TRALI,* transfusion-related acute lung injury.

(TRIM). TRIM is purported to predispose patients to infections and cancer recurrence.[19–21] Many Western countries across Europe and North America have adopted leukoreduction programs to reduce the effects of TRIM. TRIM may contribute to indirect infectious complications from RBC transfusions, like healthcare–associated infections that occur downstream from the point of transfusion.

Complications from massive transfusions, including coagulopathies, electrolyte disturbances, acid-base imbalances, temperature dysregulation, and citrate toxicity, are also of significant importance but are beyond the scope of this chapter.

RBC STORAGE

RBC storage encompasses the numerous physiologic and morphologic changes that occur in RBCs during storage that are a potential consequence of the storage medium.[22] Biochemical changes include depletion of 2,3-DPG (causing a reduction in oxygen unloading) and adenosine triphosphate (intracellular energy stores), *S*-nitroso-hemoglobin, and calcium. Morphologic changes include membrane phospholipid loss and redistribution, protein oxidation and lipid peroxidation, release of free hemoglobin, and microvesicle formation, which lead to RBC membrane deformation, altering the biconcave shape to a deformed spheroechinocytes.[23] Consequently, the rheologic properties of blood are altered, potentially affecting the normal passage of these deformed RBCs through the capillary microvasculature. Prolonged storage significantly impairs the ability of stored RBCs to deliver to the tissues. The effect of the storage lesion on clinical outcome has been reported in several observational studies, but these findings were not validated in more rigorous study designs.

The Canadian-led Age of Blood Evaluation (ABLE) international randomized trial was conducted to study the effect of blood storage time on clinical outcome. ABLE included 2430 patients from 64 centers across Canada and Europe and tested the effect of transfusion of fresh (stored <8 days) RBCs compared with standard-issue RBCs (oldest available compatible blood) on 90-day mortality and clinically important morbidity.[24] The investigators found no significant difference in the primary outcome of 90-day mortality among those patients who received fresh RBCs (mean age 6.1 ± 4.9 days) compared with those who received the older units (mean age 22.0 ± 8.4 days).[24] Further, there were no appreciable differences between the two groups in all of the secondary outcomes, including major illnesses, duration of life supports (respiratory, hemodynamic, and renal), and length of hospital stay or transfusion reactions.

A secondary analysis of the INFORM trial, a multicenter randomized controlled trial (RCT) that looked at all-cause hospital mortality in those with RBC transfusions greater than 35 days to those less than 7 days again found no effect between the two groups.[25] A similar study to the ABLE trial was conducted by an Australian group called the TRANSFUSE-RCT (standard issue transfusion versus fresher RBC use in intensive care). This large multicenter study included 59 centers in five countries with 4919 patients undergoing randomization.[26] The investigators compared the effect of transfusion of the freshest available versus the oldest available RBCs and the impact on 90-day mortality. They also evaluated 28-day mortality, persistent organ dysfunction, and new bloodstream infections over 180 days. The authors found no significant difference in those who received the freshest RBCs versus older blood.[26]

WHEN TO TRANSFUSE BLOOD IN THE CRITICALLY ILL

RBC transfusion remains the treatment of choice for anemia in the ICU. Various studies and trials have shown that restrictive blood transfusion protocols that use a hemoglobin trigger of <70 g/L for most critically ill patients have been found to beneficial in lowering total mortality, infections, and cardiac events. The evidence supporting a restrictive transfusion strategy for general critically ill patients is shown in Fig. 125.1. Published in 1999, the landmark Transfusion Requirements in Critical Care (TRICC) trial found no difference in 30-day mortality for critically ill patients with euvolemia, and patients should be managed with a restrictive (Hb <70 g/L) transfusion threshold.[27] This RCT included 838 ICU patients with a hemoglobin concentration of ≤90 g/L within 3 days of admission who were randomized to either a restrictive or liberal (70 g/L vs. 100 g/L) transfusion threshold strategy. The investigators found no significant difference in 30-day mortality between the groups (18.7 vs. 23.3%, $P = .11$).[27] Further, subgroup analyses showed that 30-day mortality was significantly lower in the less sick subpopulation (patients with an APACHE II score of <20) and in those critically ill patients who were less than 55 years of age.

In the euvolemic critically ill patient, improving oxygen delivery is the most common reason for administering an RBC transfusion. Specifically, in the American CRIT study,[3] a cohort of 4892 patients from 284 ICUs in 213 hospitals were observed, and low hemoglobin, active bleeding, and hemodynamic instability/hypotension were the most common indicators for transfusion (90%, 24%, and 21%, respectively). These observations were consistent with the findings of the European ABC study[9] (3534 patients, RBC transfusion rate 37%), where active bleeding (56%), anemia with diminished physiologic reserves (28%), altered tissue perfusion (17%), and ischemic heart disease (8%) were the most common reasons for transfusion.

A 2008 systematic review of 45 observational studies demonstrated an association between RBC transfusions and poor outcomes, including an increased risk of death, infection, organ dysfunction, and ARDS.[28] More recently, a systematic review of large-scale observational studies of mixed medical, surgical, ICU, and trauma patient populations (minimum 1000 patients) published between 2006 and 2010 demonstrated that RBC transfusions (as compared with no transfusion) were associated with adverse events, including mortality.[29] All of these studies, however, are subject to potential bias significantly limiting the interpretation and generalization of the results.

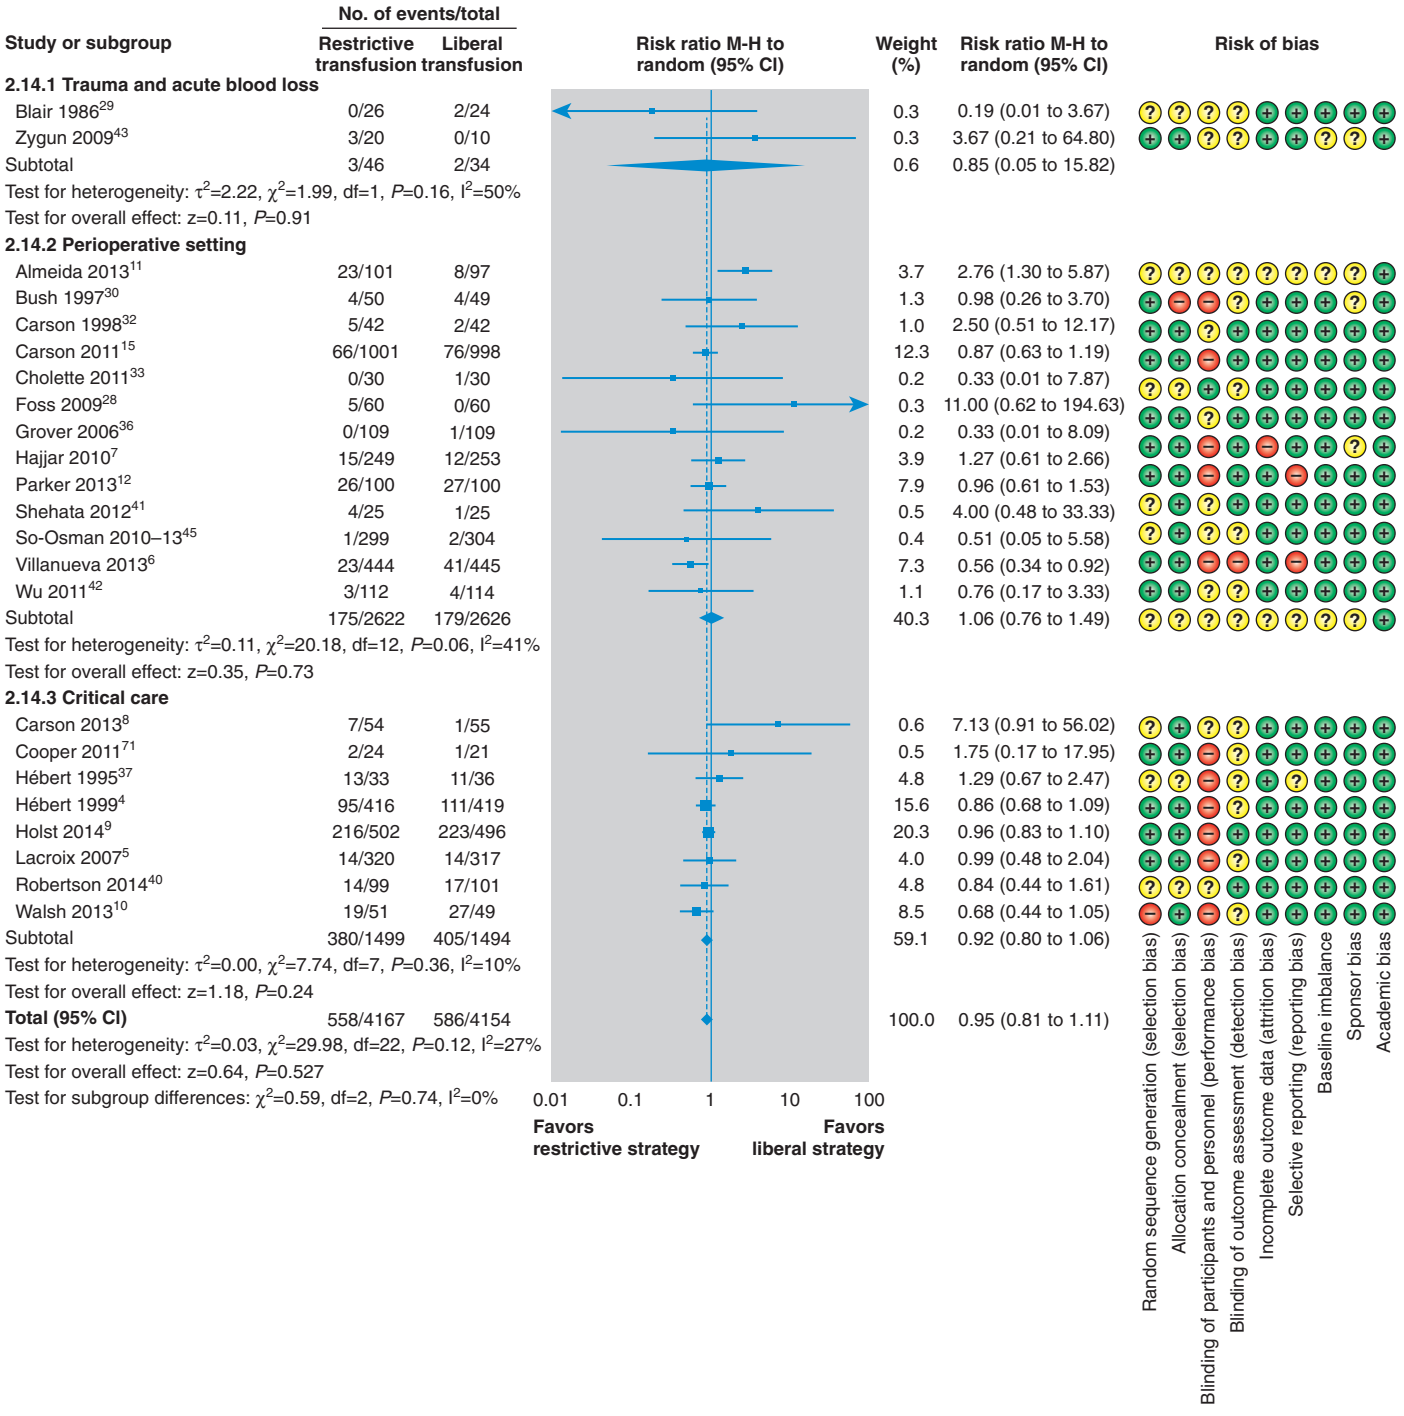

Fig. 125.1 Forest plot of the effect of restrictive versus liberal transfusion strategy on mortality stratified by patient population, presented as risk ratios with 95% confidence intervals (*CI*) and presented with risk of bias assessment. The size of the *square* represents the weight of the trial in the pooled analysis. (From Holst L, Petersen M, Haase N, et al. Restrictive versus liberal transfusion strategy for red blood cell transfusion: Systematic review of randomised trials with meta-analysis and trial sequential analysis. *BMJ.* 2015;350:h1354.)

Several systematic reviews of randomized trials of RBC transfusion in critical care and other populations exist. A comprehensive 2012 Cochrane systematic review of 19 RCTs by Carson and colleagues[30] examined transfusion thresholds and other strategies to guide transfusion. A restrictive transfusion strategy significantly decreased the exposure risk for RBC transfusion. Although the authors found that a restrictive RBC transfusion threshold was associated with reduced hospital mortality (5 studies, RR 0.77, 95% CI 0.62–0.95), no statistical significance was observed for 30-day mortality (11 studies, RR 0.85, 95% CI 0.70–1.03).[30] Furthermore, there was no statistically significant reduction in medical complications, including pneumonia (five studies), pulmonary edema (five studies), stroke (five studies), cardiac (seven studies), or venous thromboembolic events (three studies). The authors also noted the lack of literature to guide transfusion practices in certain patient populations, like those with acute

cardiac ischemia. More recently, a systematic review of restrictive versus liberal transfusion strategies for RBC transfusion by Holst and colleagues included 31 trials from a number of different clinical settings.[14] They concluded that a restrictive strategy resulted in less RBC transfusion and was not associated with less risk of death, either overall or in any of the population subgroups (see Fig. 125.1). Differences in overall mortality or fatal or nonfatal myocardial ischemia were also not observed.

A recent subanalysis of the Intensive Care Over Nations audit noted that transfusion rates in multiple regions across the world were notably lower than those reported in the ABC and CRIT studies.[31] The authors proposed that this is the result of the adaptation of a more restrictive approach to transfusion, reflecting recent literature. It is still too early to see if this trend will continue, as additional studies are being performed.

In summary, a restrictive RBC transfusion strategy leads to fewer transfusions, decreased exposure risks, and appears to not be associated with worse clinical outcomes and may in fact result in better outcomes as compared with a liberal transfusion strategy. Consequently, evidence favoring restrictive transfusion strategies has been translated into clinical practice for nearly two decades. As a result, the 2018 Patient Blood Management International Consensus Conference recommended a hemoglobin transfusion threshold of 70 g/L for stable critically ill patients.[32]

TRANSFUSION THRESHOLDS FOR SPECIFIC SUBPOPULATIONS

There are certain critical care subpopulations with distinct physiology or pathophysiologic processes that are underrepresented in the trials discussed earlier, limiting the generalization of the existing evidence to guide their anemia management with RBC transfusions.

Sepsis

A more liberal approach to RBC transfusion was previously suggested in septic shock patients with evidence of hypoperfusion/end-organ ischemia. A target hematocrit >30% was based on the significant effect on survival when introduced as part of an early goal-directed therapy bundle demonstrated by Rivers and colleagues.[33] Since this study, two other RCTs of a goal-directed therapeutic approach to patients with severe sepsis/septic shock failed to demonstrate the same survival benefit.[34,35] Transfusion rates in both of these studies were under 15%.

The specific effect of transfusion strategies on outcome in septic shock has recently been tested (liberal vs. restrictive) in the TRISS RCT.[36] In this multicenter RCT of 1005 ICU patients, the effect of a liberal (Hb trigger <90 g/L) versus a restrictive (Hb trigger <70 g/L) transfusion strategy in patients with septic shock on 90-day mortality was examined. There was no appreciable difference in the primary outcome between the two groups (RR 0.94, 95% CI 0.78–1.09) and no significant difference in ischemic events.[36] Similarly, no differences were found in subgroup analyses for age, chronic cardiovascular disease history, or illness severity. Therefore for patients with septic shock, a restrictive transfusion strategy imparts no increased risk of mortality or negative outcome and is associated with fewer RBC transfusions. The 2016 Surviving Sepsis Guidelines suggest a hemoglobin transfusion trigger of <70 g/L in the absence of extenuating circumstances, such as myocardial ischemia, severe hypoxemia, or acute hemorrhage.[37]

Acute Coronary Syndrome

Decreased myocardial oxygen delivery is the major concern in acute coronary syndrome caused by impaired coronary blood flow. In a subgroup analysis of patients with cardiovascular disease ($n = 357$) enrolled in the TRICC trial,[38] no significant difference in hospital and 30-day mortality and length of stay were found between the restrictive (Hb trigger of 70 g/L) and liberal (Hb trigger of 100 g/L) transfusion strategies. An insignificant trend toward harm was seen in those patients with severe ischemic heart disease ($n = 257$) in the restrictive strategy.[38]

The more recent FOCUS RCT of high-risk patients undergoing hip surgery ($n = 2016$, patients ≥50 years of age with a history of or risk factors for cardiovascular disease) randomized participants to either a restrictive (Hb trigger of 80 g/L) or a liberal (Hb trigger of 100 g/L) transfusion strategy.[39] The investigators found no difference between the groups for the primary outcome of death or inability to walk across the room without human assistance at 60 days. However, in a higher-risk population of patients with acute coronary syndrome or stable angina undergoing angiography, in a small pilot RCT of a restrictive versus liberal transfusion strategy, a trend toward a decrease in the primary composite outcome of death, myocardial infarction, or unscheduled need for revascularization at 30 days was observed in the liberal strategy group (risk difference: 15.0%, 95% CI 0.7–29.3%, $P = .054$).[40] Currently, the MINT trial (myocardial ischemia and transfusion) (NCT02981407) is ongoing and will aim to enroll 3500 patients with myocardial infarction and evaluate the effect of a restrictive (<80 g/L) or liberal transfusion (<100 g/L) threshold on all-cause mortality or nonfatal myocardial reinfarction within 30 days.

Cardiac Surgery

Evidence in RBC transfusion strategies in the cardiovascular surgery population is more conflicting. In the TRACS noninferiority trial[41] involving patients who had undergone cardiac surgery, a restrictive (Hct trigger <24%) compared with a liberal (Hct trigger <30%) transfusion strategy was noninferior with respect to their primary composite outcome of 30-day all-cause mortality and severe morbidity (10% vs. 11%). More recently, the large multicenter TITRe2 trial enrolled 2007 patients undergoing nonemergency cardiac surgery and examined the effect of a liberal (Hb trigger <90 g/L) versus restrictive (Hb trigger <75 g/L) transfusion strategy on a composite of serious infections or ischemic events at 3 months.[42] Although there was no significant difference in the primary outcome between the two groups, a significant increase in mortality was observed in the restrictive arm (hazard ratio 1.64, 95% CI 1.00–2.67, $P = .045$). The authors were careful not to overinterpret these secondary findings, but this strengthens the need for further trials in this higher-risk population in which a restrictive transfusion strategy may not be safe.

The subsequent Transfusion Requirements in Cardiac Surgery (TRICS)-III trial was the largest RCT of 5243 cardiac surgery patients and confirmed that a restrictive transfusion strategy was not inferior to a liberal strategy.[43] The 2019 Patient Blood Management International Consensus Conference recommends a hemoglobin threshold of 75 g/L for patients undergoing cardiac surgery.[32]

Acute Neurologic Injury

The decreased oxygen delivery associated with anemia may have more significant effects in those patients with stroke, subarachnoid hemorrhage (SAH), and traumatic brain injury (TBI). Evidence to guide RBC transfusions in these populations is lacking because both anemia and transfusion have been associated with worse outcomes. In the TRICC trial, only 67 patients with a primary neurologic diagnosis were included in the original trial.[27] A subgroup analysis of these limited patients showed no difference in outcome between the liberal and restrictive transfusion strategies.[44]

A recent systematic review of six comparative studies of RBC transfusion in a neurocritically ill population[45] found only one additional small RCT in an adult population. This small RCT included 44 patients with SAH who were randomized to either a liberal (Hb trigger of <115 g/L) or a restrictive (Hb trigger <100 g/L) RBC transfusion

strategy.[46] The study was underpowered to detect any clinically relevant outcome and used triggers that are higher than those currently practiced, which resulted in the majority of the patients receiving at least one RBC transfusion in both arms. There are no RBC transfusion strategy trials specific to an ischemic stroke population.

A RCT of 200 patients with TBI compared a liberal (Hb trigger of <100 g/L) with a restrictive transfusion strategy (Hb trigger of 70 g/L) and erythropoietin versus placebo on outcome, as measured by the Glasgow Outcome Scale (GOS), at 6 months.[47] There was no statistically significant difference between the two transfusion strategies ($P = .28$), but fewer thromboembolic events in the restrictive threshold group were reported (odds ratio [OR] 0.32, 95% CI 0.12–0.79).[47] This study does not completely answer the clinical question of the utility of liberal transfusion strategies in this patient population, as the study was underpowered to detect smaller yet clinically important outcome differences between the two transfusion groups. Although RBC transfusion rates differed in the two groups, the difference in median hemoglobin level was less than 20 g/L by day 9 and increasingly smaller by days 16, 23, and 30.

Currently two multicenter RCTs are in process, looking at transfusion thresholds in patients with TBI. The first is by a European group—the TRAIN trial (transfusion strategies in acute brain injured patients) will enroll 4610 patients with TBI, SAH, or intracranial hemorrhage to study the effect on a liberal (<90 g/L) versus restrictive (<70 g/L) transfusion trigger on neurologic outcomes (NCT02968654). A similar study is being conducted by a Canadian group—the HEMOTION trial (hemoglobin transfusion threshold)—where they plan to enroll 712 patients with moderate to severe TBI and evaluate the effect of hemoglobin thresholds (<100 g/L versus <70 g/L) on neurologic functional outcomes (NCT03260478). Although current studies do not demonstrate harm from a restrictive transfusion strategy, it remains unclear if any benefit results from a more liberal strategy in these unique patient populations.

Gastrointestinal Bleeding

In one large trial, patients with severe acute upper gastrointestinal bleeding were randomized to restrictive (Hb <70 g/L) versus liberal (Hb <90 g/L) transfusion strategies. The restrictive strategy had significantly better 6-week survival, less rebleeding, no increase in portal-pressure gradient, and reduced need for additional transfusion.[48] The 2012 American College Gastroenterology upper gastrointestinal bleeding guidelines recommend a hemoglobin greater than or equal to 70 g/L, with higher targets in patients with intravascular volume depletion or comorbidities.[49]

Alternatives to Transfusion

The knowledge of adverse effects of blood transfusion has focused current research on finding alternatives to transfusion or methods to reduce transfusion.

Erythropoiesis-Stimulating Agents

In critically ill patients, the erythropoietin response to anemia is abnormal. The bone marrow has a decreased response to erythropoietin. Corwin and colleagues,[50] in a prospective, randomized, placebo-controlled trial including 146 medical, surgical, and trauma patients, concluded that treatment with erythropoietin did not reduce the number of RBC transfusions. The use of erythropoietin was associated with a greater incidence of thrombotic events.[50] This may be caused by the fact that erythropoiesis-stimulating agents require high dosages or have delayed effect. Currently, erythropoiesis-stimulating agents are only indicated in patients with chronic kidney disease.

Iron Therapy

In critically ill patients there is an iron-restricted erythropoiesis caused by iron sequestration and decreased absorption from the gut. This suggests a role for intravenous (IV) iron therapy, but this has been challenged because of the role of iron in the growth and virulence of microbes. In a meta-analysis of five RCTs of iron supplementation (four IV, one oral iron) in adult critical care with 665 patients, the researchers found no difference in RBC transfusions, hemoglobin level, mortality, in-hospital infection, or length of stay.[51] Most recently, the IRONMAN study compared IV iron with placebo in 140 critically ill patients.[52] This study was unable to demonstrate any reduction in RBC transfusion, but patients did have higher hemoglobin levels on discharge.[52] Current evidence suggests that iron supplementation does not increase infections or adverse events, but improved patient-focused outcomes are lacking.

Blood Substitutes

The quest for blood substitutes or artificial oxygen carrier solutions as alternatives to RBC transfusions has spanned decades. Blood substitutes have not shown promising results. Cell-free hemoglobin-based oxygen carriers have various adverse effects, including nephrotoxicity, impaired perfusion, and increased rates of myocardial infarction and death.[53] Other challenging product development issues relate to the safety and cost-effectiveness of these products.

CONCLUSION

The occurrence of anemia is nearly inevitable in critically ill patients and because of its multifactorial etiology, it has impact both on morbidity and mortality. The primary etiologies include blood loss caused by bleeding and phlebotomy and defective erythropoiesis caused by systemic inflammation. The evidence supports the restrictive strategy of RBC transfusion (transfusion at Hb <70 g/L) preferably over a liberal transfusion strategy (transfusion at Hb <10 g/L) in the majority of critically ill patients. Careful consideration to individual cases must be taken in specific populations, including patients with severe cardiovascular disease and brain injury, where there is a need for more evidence. Although alternatives to RBC transfusion are lacking in the critically ill, the avoidance of unnecessary diagnostic phlebotomy should be evaluated daily.

KEY POINTS

- Anemia is common and affects almost all critically ill patients and may negatively affect organ function and patient outcome.
- Persistent anemia is common after ICU discharge, and 50% of patients remain anemic for up to 6 months.
- The etiology of anemia is multifactorial, related to hemorrhage, hemodilution, diagnostic phlebotomy, acute inflammation, and functional iron deficiency.
- RBC transfusion, the most common treatment for anemia, comes with associated infectious risks and more common noninfectious risks, including TACO, TRALI, and TRIM.
- The best evidence suggests a practice of restrictive RBC transfusion (hemoglobin trigger <70 g/L) for the majority of critically ill patients.
- Certain subpopulations of critically ill patients, such as those with cardiac disease or neurologic injury, may benefit from a more liberal trigger, but further research is still needed.
- Alternatives to blood transfusion in critically ill patients with anemia are not proven, but careful consideration of the need for diagnostic phlebotomy can be implemented daily.

ANNOTATED REFERENCES

Cable CA, Razavi SA, Roback JD, et al. RBC transfusion strategies in the ICU: a concise review. *Crit Care Med.* 2019;47(11):1637–1644.
This is a critical review of high-level studies evaluating RBC transfusion strategies with a focus on hemoglobin thresholds in the ICU. Current literature supports the use of restrictive transfusion strategies in the majority of critically ill populations, but a slightly higher threshold is recommended in cardiac surgery and those with cardiovascular disease.

McIntyre L, Tinmouth AT, Fergusson DA. Blood component transfusion in critically ill patients. *Curr Opin Crit Care.* 2013;19(4):326–333.
A good review article.

Napolitano LM. Anemia and red blood cell transfusion: advances in critical care. *Crit Care Clin.* 2017;33(2):345–364.
This is a review of the etiology of anemia in the ICU and current transfusion practices. Significant advances have been made in understanding the pathophysiology of anemia in the ICU. The anemia is related to high hepcidin concentration resulting in iron-restricted erythropoiesis and abnormal erythropoietin concentrations. Although a restrictive transfusion strategy is recommended to ICU patients in need of therapy for anemia, all strategies to reduce anemia and blood loss in the ICU should be implemented.

Guidelines for Blood Component Therapy

Alexandra L. Dixon and Martin A. Schreiber

Blood component therapy is generally supportive for the correction of one or more hematologic deficiencies until the basic disease process can be controlled or corrected. Anemia is pervasive in the intensive care unit (ICU), with over 30%–50% of critically ill patients receiving a transfusion during their ICU stay.[1–3] Transfusions do not come without risk, and thus the past decade has seen a drastic shift from a product-centered focus to one of patient blood management (PBM). Defined by the AABB (previously the American Association of Blood Banks) as "an evidence-based, multidisciplinary approach to optimizing the care of patients who might need transfusion," PBM consists of a three-pillar approach: optimizing red cell mass, minimizing blood loss, and tolerating anemia. Accurate diagnosis of hematopoietic deficiencies, minimizing blood loss and unnecessary laboratory draws, and tolerance of deficiencies within limits is important. Perioperatively, this can be achieved by identifying patients at high risk of bleeding, giving close attention to surgical and anesthetic techniques (e.g., permissive hypotension, normothermia, reduction of venous pressure at the operating site) and using pharmacologic agents to minimize blood loss (eFig. 126.1). Additionally, cell salvage and hemostatic agents such as fibrin glue can be employed to avoid transfusion.

RED BLOOD CELL CONCENTRATES

Transfusion of red blood cells (RBCs) is one of the most common medical interventions performed in the United States, with over 11 million units of RBCs transfused annually.[4] RBCs are typically packed (pRBCs) with a preservative solution that allows refrigerated storage for up to 42 days. Each unit has a hematocrit of approximately 60%, and transfusion of one unit of pRBCs is typically expected to result in a hemoglobin (Hgb) increase of 1 g/dL in an adult with stable blood volume. Despite previous published guidelines, there remains significant variation in the practice of transfusing patients.[5–9] Whereas some clinicians base the decision to transfuse solely upon Hgb level, many guidelines maintain that transfusions should be given for overall clinical status, patient preference, and availability of alternative therapies.[10,11]

A recent systematic review and meta-analysis evaluating the efficacy of RBC transfusion included 31 randomized clinical trials (RCTs) with over 12,000 patients who were randomized to a higher Hgb concentration as the threshold for transfusion (referred to as *liberal transfusion;* Hgb <10 g/dL) or to a lower Hgb concentration (referred to as *restrictive transfusion;* Hgb <7–8 g/dL).[12] Patients in the restrictive group were 43% less likely to receive an RBC transfusion than those in the liberal group. Overall, there was no difference in 30-day mortality between the two groups, and results were similar among trials with thresholds of 7 and 8 g/dL. Other outcomes did not differ significantly between restrictive and liberal transfusion groups, including infection (pneumonia, wound, bacteremia), myocardial infarction, and congestive heart failure.

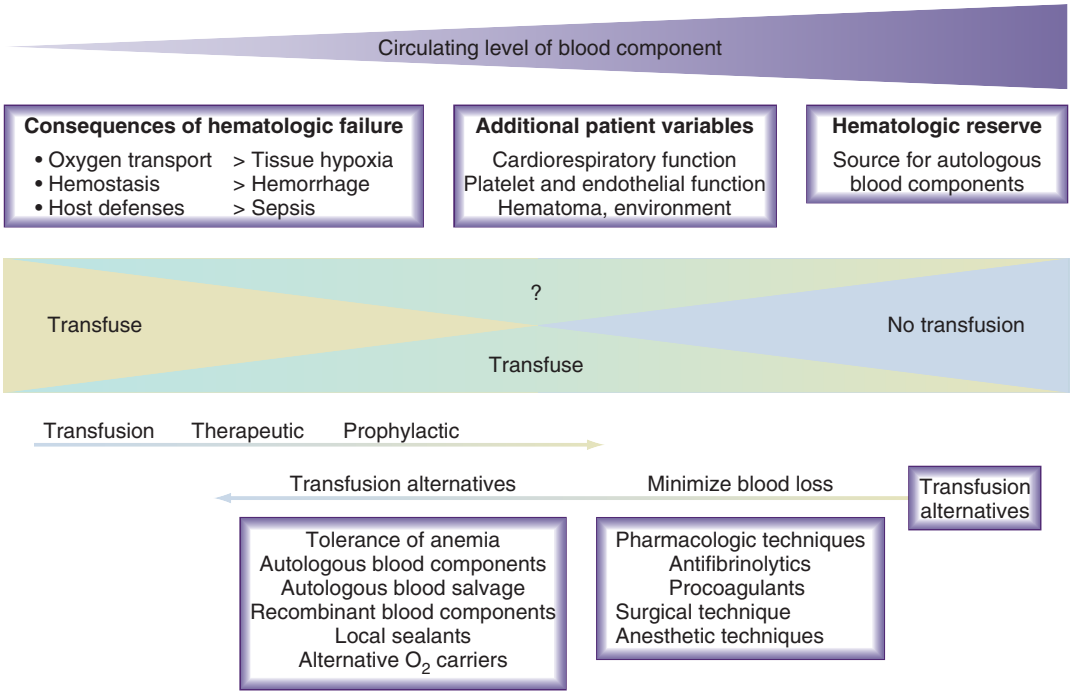
With these data in mind, the AABB recommends a restrictive RBC transfusion threshold in which transfusion is not indicated until the Hgb falls below 7 g/dL for the majority of hemodynamically stable patients, including those who are critically ill. For patients undergoing orthopedic or cardiac surgery and those with cardiovascular disease, the AABB recommends a restrictive transfusion threshold with an Hgb goal of 8 g/dL. Although they do comment that the restrictive threshold of 7 g/dL is likely comparable with 8 g/dL, RCT evidence is not available for all patient categories. These recommendations do not apply to patients with acute coronary syndrome, severe thrombocytopenia, and chronic transfusion-dependent anemia, as the evidence is insufficient in these disease processes.[10]

PLATELET CONCENTRATES

Platelet concentrates can be prepared by apheresis or from whole blood using either the buffy-coat or platelet-rich plasma methods. Whereas apheresis platelets are obtained from one donor, the buffy-coat and platelet-rich plasma methods require pooling of platelets from several donors (usually four to six). Unlike other blood components, platelets are stored at 22°C with continuous agitation and have a shelf-life of up to 5–7 days out of concern for possible bacterial growth during storage.

Thrombocytopenia is correlated with increasing illness severity, sepsis, and organ dysfunction; however, the effect of thrombocytopenia on clinically significant spontaneous hemorrhage remains unclear. Platelet transfusion strategies are driven by the need to stop (therapeutic) or prevent (prophylactic) bleeding. Although an increased risk of bleeding has been demonstrated with a platelet count below 5×10^9/L and spontaneous hemorrhage rarely occurs above 10×10^9/L, there is a general lack of evidence to support specific platelet thresholds in most critical care and surgical settings.

In patients undergoing surgical or invasive procedures, relative factors that contribute to the decision to transfuse platelets perioperatively include the type of procedure, preoperative platelet counts, degree of active or anticipated hemorrhage, and presence of antiplatelet medications or disorders that affect platelet function. For major surgeries or invasive procedures that carry an inherently elevated risk of bleeding, the platelet count should be maintained at greater than 50×10^9/L. As a significant number of patients who undergo cardiac surgery experience platelet dysfunction related to cardiopulmonary bypass, hypothermia, hemodilution, and platelet activation, prophylactic platelet transfusion should not be performed unless the patient is on antiplatelet therapy. Postoperatively, platelets should be transfused in the setting of active bleeding with a platelet count less than 50×10^9/L



eFig. 126.1 Overview of Blood Management and Where Blood Component Therapy May be Appropriate.

with no obvious source of hemorrhage.[13] For minor surgeries and minimally invasive procedures (central line placement, angiography, endoscopy, lumbar puncture, paracentesis), the platelet count should be maintained above 20–30 $\times$ 10^9/L.[14] For neurosurgical procedures and other procedures that occur within a closed, defined space (including ocular procedures), a platelet count above 100 $\times$ 10^9/L is recommended.[15]

Prophylactic platelet transfusions are recommended only for platelet counts below 10 $\times$ 10^9/L unless other factors that increase the risk of bleeding are present. In patients with qualitative defects in platelet function, platelet count is not a reliable indicator for transfusion, and transfusion decisions and monitoring of efficacy should be based on the setting and clinical features. In the setting of massive hemorrhage, the platelet count should be maintained above 50 $\times$ 10^9/L, and above 75 $\times$ 10^9/L with any associated injury to the central nervous system.[16] The transfusion of platelet concentrates is not generally considered appropriate when thrombocytopenia is the result of immune-mediated destruction or in patients with thrombotic thrombocytopenic purpura and hemolytic uremic syndrome.

FRESH FROZEN PLASMA

Fresh frozen plasma (FFP) has a shelf-life of up to a year at −18°C but requires 30 minutes or more to thaw, limiting immediate availability. Once thawed, it has a 5-day shelf-life before it must be discarded. FFP is widely used, but there are limited specific indications for its use, and there is a dearth of evidence for its efficacy in many clinical settings. FFP is frequently used to correct an abnormal international normalized ratio (INR) in nonbleeding patients. In this setting, many patients have adequate coagulation function and transfusion is unnecessary.[17] FFP may be appropriate in patients with a known coagulopathy who are bleeding or at risk of bleeding when a specific therapy or factor concentrate is not appropriate or is unavailable. This includes patients with a vitamin K deficiency or who require reversal of warfarin therapy. Additionally, FFP is generally indicated in acutely hemorrhaging patients as part of a massive transfusion protocol.

The benefit of plasma transfusion extends beyond its hemostatic effects to include reduction of vascular permeability and mitigation of inflammation after hemorrhagic shock. Severe trauma, in addition to other inflammatory conditions such as ischemia-reperfusion injury, diabetes, and sepsis, are known to result in vascular endothelial dysfunction. In vitro[18–20] and in vivo[21,22] models of hemorrhagic shock demonstrate that plasma restores microvascular integrity, in part by repair of the endothelial glycocalyx. The mechanisms of action of FFP are the subject matter of current research, but may be attributed to soluble factors, of which over 1000 are found in plasma. Many of these soluble proteins are biologically active and have unknown functions.[23]

CRYOPRECIPITATE

Cryoprecipitate is collected as the precipitate of plasma after a freeze-thaw cycle and is enriched in factors VIII and XIII, von Willebrand factor, fibronectin, and fibrinogen. Administration of cryoprecipitate is principally indicated for fibrinogen deficiency or dysfibrinogenemia when there is clinical bleeding, trauma, acute disseminated intravascular coagulation, or before invasive procedures. Currently, the American College of Surgeons Committee on Trauma recommends transfusion of cryoprecipitate to maintain fibrinogen at 180 mg/dL or greater during massive transfusion in bleeding patients.[24]

PLASMA-DERIVED PRODUCTS

Table 126.1 summarizes commonly used fresh and plasma-derived blood products. Prothrombin complex concentrate (PCC) contains concentrated vitamin K–dependent coagulation factors stored as a lyophilized powder. PCC comes as three-factor (containing factors II, IX, and X) and four-factor products (containing factors II, VII, IX,

TABLE 126.1 Blood Products

Blood Product	Main Indications
Whole blood*	Increasingly used for acute traumatic hemorrhage.
Red blood cell concentrates*	Hemorrhage and anemia.
Leukocyte-depleted blood*	In patients having febrile reactions, to avoid leukocyte immunization in selected patients (especially patients with hematologic malignancy). Universal prestorage leukodepletion is more widely used and has the added benefit of minimizing storage lesions.
Platelet concentrates*	Thrombocytopenia caused by marrow hypoplasia or platelet functional defect.
Granulocyte concentrates*	Occasionally in patients with sepsis associated with profound and prolonged neutropenia secondary to marrow suppression.
Fresh frozen plasma*	Specific or multiple plasma protein deficiencies (especially coagulation).
Cryoprecipitate*	Hypofibrinogenemia and rarely in factor VIII and von Willebrand disease, when concentrates are unavailable.[26]
4% or 5% albumin solutions†	Plasma volume expansion. Use is controversial, and the role of albumin solutions in critically ill patients remains under debate.[27]
Concentrated albumin†	Severe hypoalbuminemic states with complicating hypovolemia.
Concentrate of coagulation factors II, VII, IX, and X†	Vitamin K–dependent factor II, IX, and X deficiency and reversal of oral vitamin K antagonists.
Specific factor concentrates†	Factor VIII and IX concentrates have an established role in the management of hemophilia, but others are in the process of establishing their clinical efficacy and indications.[28–30]
	Fibrinogen concentrates for hypofibrinogenemia and dysfibrinogenemia.[28]
	Antithrombin concentrates are available for thrombophilia caused by antithrombin deficiency and are increasingly recommended in other disorders in which antithrombin may be depleted (e.g., DIC, MODS).[31]
Gamma globulin†	Generally used intravenously for replacement in hypogammaglobulinemia or in high dosages as an immune-modulating therapy.[32]
Specific immune gamma globulins†	Rhesus prophylaxis, specific infection prophylaxis and treatment.[33]

DIC, Disseminated intravascular coagulation; *MODS,* multiorgan dysfunction syndrome.
*Fresh products.
†Fractionated plasma products.

and X, in addition to the anticoagulant proteins—protein C, protein S, antithrombin, and heparin). Both three- and four-factor PCC have been shown to be superior to FFP for urgent reversal of acquired coagulation factor deficiency induced by vitamin K agonists and in correcting the coagulopathy of trauma, with four-factor PCC correcting elevated INRs more rapidly than three-factor PCC.[25] Currently, there is extensive and increased use of PCC for off-label applications, such as reversing direct oral anticoagulants.

In addition to FFP and cryoprecipitate, fibrinogen concentrate is increasingly used in the management of hypofibrinogenemic states, depending on local availability. However, because of the low quality of published clinical evidence,[34] the beneficial effect of fibrinogen concentrate remains under debate.

RECOMBINANT BLOOD PRODUCTS

Recombinant growth factors such as erythropoietin and granulocyte stimulating factor have had a major impact on managing anemia and neutropenia. Recombinant hemostatic factors, such as recombinant activated factor VII (rFVIIa), have improved the management of acquired hemophilias and other inherited bleeding diatheses. As rFVIIa tends to localize to areas of vascular injury once administered and may decrease the overall need for blood products in trauma patients, it has also been used off-label in the treatment of severe bleeding despite a lack of high-quality evidence for efficacy, as most experience has been observational and anecdotal.

BLOOD SUBSTITUTES

Significant efforts have long been ongoing to develop substitutes for RBCs and platelets. Unfortunately, neither hemoglobin-based oxygen carriers nor chemical-based products such as perfluorocarbons have yielded optimistic results, and safety concerns have plagued clinical development. However, new research does suggest that these artificial oxygen carriers may have beneficial application in other areas, such as organ preservation for transplant surgery,[35] sickle cell crisis,[36] and brain oxygenation during circulatory arrest.[37]

TRANSFUSION MANAGEMENT OF MASSIVE ACUTE TRAUMATIC HEMORRHAGE

Early definitive hemorrhage control and, when indicated, initiation of a massive transfusion protocol (MTP), have long been the tenets of treatment of severe hemorrhagic shock; however, the composition of an MTP has changed significantly in recent years. The recent conflicts in Iraq and Afghanistan led to the emergence of damage control resuscitation. This is defined as early transfusion of a balanced ratio of blood products along with the prevention and correction of coagulopathy and minimization of crystalloid fluids to prevent the known complications associated with massive crystalloid resuscitation, including acute respiratory distress syndrome, abdominal compartment syndrome, multiple organ failure, and mortality.[38] As shown by the PROMMTT study, patients transfused with plasma and platelet:RBC ratios more than 1:2 had significantly decreased 6-hour to 24-hour mortality.[39] The ideal resuscitation ratio was further validated by the PROPPR trial, which demonstrated that early transfusion of plasma, platelets, and RBCs in a 1:1:1 ratio led to improved hemostasis and fewer deaths from exsanguination than a 1:1:2 ratio.[40]

Massive transfusion (MT) is usually defined as the transfusion of ≥10 units of pRBCs within a 24-hour period. Early identification of the trauma patient who will require MT is difficult, though necessary, as early activation of an MTP is associated with decreased blood waste and improved outcomes. Although several scoring systems exist to identify trauma patients who will require an MTP, early iterations rely on laboratory values that are not available until well after the resuscitation process has begun. One scoring system that requires no laboratory data and thus can be determined almost immediately upon patient arrival is the Assessment of Blood Consumption (ABC) score, which gives 1 point for each of the following: penetrating mechanism, systolic blood pressure (SBP) <90 mm Hg, heart rate (HR) >120 bpm, and positive Focused Assessment with Sonography for Trauma (FAST) exam. A score of 2 or more is predictive of MT, with a sensitivity of 75%–90%, specificity of 67%–88%, and overall accuracy of 84%–87% for trauma patients.[41]

Although blood transfusion may be lifesaving for exsanguinating patients, it is increasingly recognized that transfusion may be an independent risk factor for delayed morbidity and mortality. Transfusion can thus be minimized with tolerance of hypotension, termed *permissive hypotension,* until hemorrhage is controlled.

Failure of hemostasis is common in acutely bleeding patients and may be complex and multifactorial. Trauma-induced coagulopathy (TIC) develops in approximately one-third of all trauma patients. Initially thought to be only the result of the iatrogenic secondary effects of hemodilution, hypothermia, and acidosis, TIC is now known to also result from multiple distinct but highly integrated pathways. Tissue hypoperfusion secondary to hypovolemic shock leads to activation of protein C, ultimately resulting in unopposed fibrinolysis and depletion of fibrinogen. Significant fibrinolysis heralds increased mortality. Conversely, fibrinolysis shutdown, or overinhibition of fibrinolysis, has also been demonstrated to be an independent predictor of adverse outcomes, including mortality, after trauma. The combination of tissue trauma and acidosis has been associated with disruption of the endothelial glycocalyx, the shedding of which appears capable of triggering systemic thrombin production and protein C activation.

NOVEL CONCEPTS FOR DAMAGE CONTROL RESUSCITATION IN TRAUMA

Never-Frozen Liquid Plasma

There is increasing interest in the use of never-frozen, or liquid, plasma to reduce waste and improve rapid availability of plasma in MTPs. Liquid plasma is approved for storage at 1°–6°C for up to 26 days with minimal degradation of clotting factor function. In vitro studies demonstrate that liquid plasma has a better coagulation profile than thawed plasma.[42] In high-volume centers, liquid plasma has the potential to replace FFP because of its superior coagulation profile, its immediate availability for MT, and its potential to reduce waste. FFP that is thawed and never used over its 5-day shelf-life is a major source of waste in most large centers.

Freeze-Dried Plasma

Freeze-dried (or lyophilized) plasma (FDP) is stored at room temperature and can be reconstituted within minutes. It can be stored for at least 1 year in the powder form. Although used extensively during World War II, US production of FDP was halted in the 1960s because of concern for pathogen transmission. FDP may be single donor or it may be pathogen reduced and come from multiple donors. There is currently no approved FDP product in the United States, though FDP is used abroad and by the deployed US military. Products are currently undergoing phase II trials in the United States.

Cold Storage Platelets

Cold storage platelets (CSPs) can be kept at 1°–6° C for up to 21 days and do not require agitation, thus reducing the burden of storage on blood banks. They undergo a spherical shape change when stored cold and are thus cleared from the circulatory system more rapidly than platelets stored at room temperature. CSPs have been shown to aggregate better and produce stronger clots than platelets stored at 20°–24°C.[43,44] CSPs are approved for military use by the Food and Drug Administration (FDA) in deployed settings and have the potential to ease platelet shortage scenarios and make platelets available in rural settings.

Whole Blood

As demonstrated by the PROPPR study, the ideal resuscitation for a trauma patient in hemorrhagic shock is a balanced 1:1:1 transfusion of plasma, platelets, and pRBCs. This "reconstituted whole blood" contains a significant amount of preservative, creating an anemic, thrombocytopenic, and coagulopathic solution even without the addition of crystalloids or artificial colloids. Contrasting this, a single 500-mL unit of fresh whole blood (WB) is diluted with only 70 mL of preservative, yielding an Hgb concentration of 13–14 g/dL, 150,000–400,000 platelets/μL, 1500 mg of fibrinogen, and nearly 100% activity of clotting factors.[45] WB provides a balanced resuscitation that simultaneously addresses oxygen debt and coagulopathy while logistically simplifying the process of transfusion by requiring only one bag as opposed to three. The use of fresh WB has been associated with decreased mortality in the military setting, and transfusion with uncrossmatched, cold-stored, low-titer group O–positive or –negative WB is currently being investigated as an alternative to component therapy in civilian trauma centers.

GOAL-DIRECTED CORRECTION OF COAGULOPATHY

There has been increased interest in viscoelastic coagulation assays such as thromboelastography (TEG) and rotational thromboelastometry (ROTEM) for the monitoring of TIC and guidance of blood product resuscitation. These assays provide real-time information on various viscoelastic properties, including time to clot initiation, clot propagation, clot strength, and clot breakdown (fibrinolysis). Many studies have validated TEG and ROTEM against standard coagulation tests, including prothrombin time (PT), INR, and activated partial thromboplastin time (aPTT). Viscoelastic assays have been shown to reduce mortality and blood product utilization in MT compared with conventional coagulation tests.[46]

HAZARDS OF ALLOGENEIC TRANSFUSION

Noninfectious risks have become the leading concern of transfusion and include the following: transfusion-associated lung injury (TRALI), transfusion-associated circulatory overload (TACO), transfusion reactions (including but not limited to allergic/anaphylactic, acute and delayed hemolytic, febrile, hypotensive, and septic transfusion reactions), alloimmunization, immunomodulation, bacterial contamination (especially of platelets), and graft-versus-host disease (GVHD). Although more detailed discussion of the complications of allogeneic blood transfusions are discussed in other chapters, TRALI and TACO deserve special mention, as they are the leading causes of transfusion-associated morbidity and mortality. Characterized by acute pulmonary edema occurring within 6 hours of transfusion, TRALI consists of pulmonary permeability (noncardiogenic) edema, whereas TACO is defined by pulmonary hydrostatic edema (cardiogenic) with signs of circulatory overload. Both syndromes are difficult to diagnose and underscored by complex and incompletely understood physiologies.

The pathophysiology of transfusion reactions can be divided broadly into the following four categories:

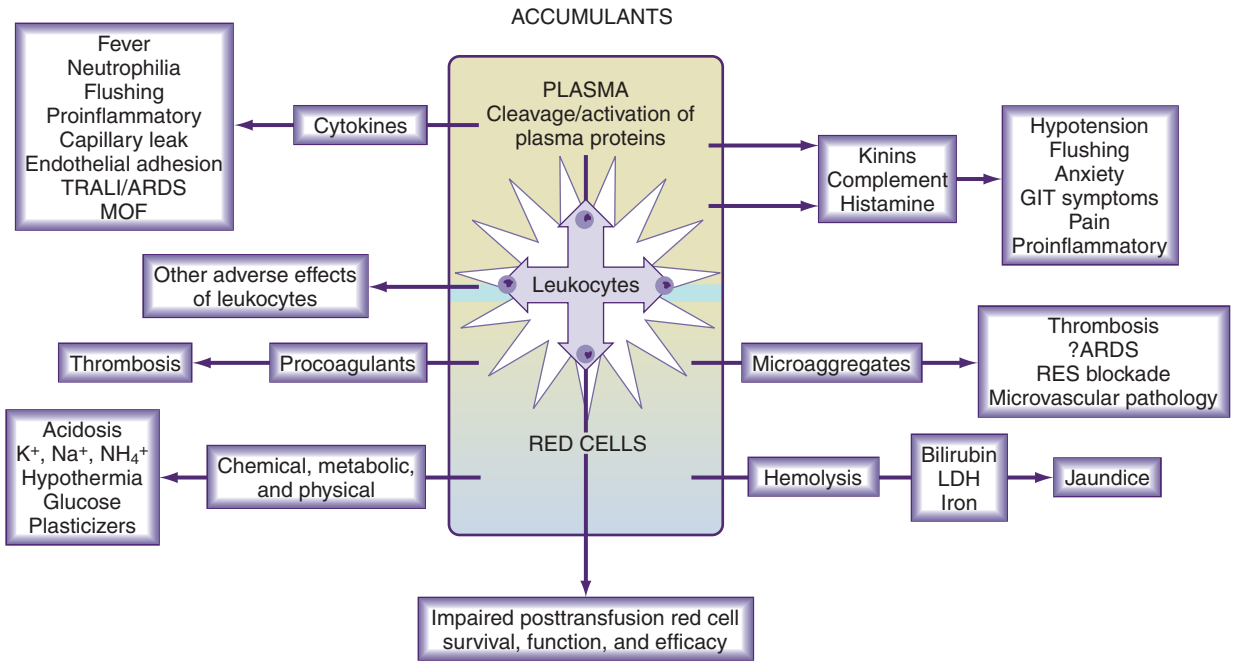
1. Reactions may occur because of *immunologic differences* between the donor and recipient, resulting in varying degrees of blood component incompatibility. In general, for a reaction to occur, the recipient needs to have been previously immunized to a cellular or plasma antigen.
2. A wide range of *infectious agents* may be transmitted by allogeneic blood component therapy. With advances in donor screening and blood product testing, the risk of transmission of infections such as human immunodeficiency virus (HIV) and viral hepatitis have been reduced to less than 1 per 10 million units of blood in developed nations. Despite this, transmission of emerging pathogens is always a threat, with the most recent example being the Zika virus, as potential donors may be viremic at the time of donation—though asymptomatic and thus not detected by donor screening.
3. *Alterations in blood products caused by preservation and storage* may result in quantitative or qualitative deficiencies in the blood components that reduce transfusion efficacy and expose the patient to potentially adverse consequences from substances that accumulate during storage (Table 126.2).
4. *Clinical, technical, and clerical errors* resulting from incorrect patient identification, failure of cold chain management, or administration errors may result in a range of hazards. Included in this group are patients who are at particular risk from lung injury and circulatory overload because of comorbidities such as cardiac compromise, poor clinical assessment of fluid and volume status, and sepsis.

A multitude of experimental and clinical studies have linked blood transfusions to a long list of unfavorable outcomes, including increased ICU admission rates, increased hospital length of stay, sepsis and infection, multiorgan dysfunction, respiratory distress and failure, venous thromboembolism, cardiac complications, stroke, renal injury, and mortality. The implication of RBC transfusion as part of the problem rather than optimal therapy has challenged long-held views about the safety of allogeneic blood transfusion. For these reasons, a precautionary approach should be adopted, with avoidance or minimization of allogeneic transfusion and the use of appropriate patient blood conservation techniques whenever possible.

BLOOD STORAGE LESIONS AND POTENTIAL CLINICAL CONSEQUENCES

In addition to the transfusion reactions and infectious risks discussed earlier, transfusion of large volumes of blood product may expose the patient to "storage lesions," or the collection of biochemical and morphologic changes that occur because of degradation of pRBCs and platelets while stored. This has been postulated to lead to deleterious effects on microvascular circulation and oxygen delivery. Storage lesions progress throughout the duration of storage, and the extent of these changes is determined by the specific blood component, preservative medium, container, storage time, and storage conditions (eFig. 126.2). RBCs stored for longer periods have alterations of the membrane resulting in increased rigidity and adherence to the endothelium, decreased levels of 2,3-bisphosphoglycerate, and decreased nitric oxide metabolism.[47,48] The storage medium itself may contain increased amounts of iron, potassium, free Hgb, and inflammatory mediators, all of which can have significant consequences.[49]

Although there is a growing literature confirming the presence of the storage lesion in vitro, the clinical significance of this continues to be debated. Previous data suggesting adverse outcomes with transfusion of older RBCs were predominantly obtained via uncontrolled observational studies. Contrasting this, a recent meta-analysis of multiple



eFig. 126.2 **Red Blood Cell Storage Lesions.** *ARDS,* Acute respiratory distress syndrome; *GIT,* gastrointestinal tract; *LDH,* lactate dehydrogenase; *MOF,* multiple organ failure; *RES,* reticuloendothelial system; *TRALI,* transfusion-related acute lung injury.

TABLE 126.2 Red Blood Cell Storage Lesions and Possible Clinical Consequences

Storage Lesion	Potential Clinical Consequences
Alterations in blood cell structure and function	
ATP depletion	Echinospherocyte formation, increased osmotic fragility, impaired RBC deformability with adverse effects on oxygen transport and delivery
Microvesiculation and loss of membrane lipid, lipid peroxidation and hemolysis, and irreversibly damaged RBCs	Reduced RBC viability and cell death Hyperbilirubinemia, LDH, increased serum iron, free radical generation, hyperkalemia
Reduced 2,3-DPG	Increased hemoglobin affinity for oxygen and impaired unloading
Decreased CD47 antigen (integrin-associated protein) expression	Reduced posttransfusion survival caused by premature clearance post transfusion
RBC adhesion to endothelial cells	Adverse effects on microcirculatory hemodynamics
Storage temperature	Hypothermia unless pretransfusion warming
Additives	
Citrate	Hypocalcemia, acid-base imbalance, initial acidosis alkalosis
Glucose	Hyperglycemia
Sodium	Hypernatremia
Cytokines: IL-1, IL-6, IL-8, TNF	Fever, hypotension, flushing
Enzymes: Myeloperoxidase, elastase, arginase, secretory phospholipase A_2	Transfusion-related immunomodulation, neutrophilia
Reactive proteins: Defensins, annexin, soluble HLA, Fas ligand, soluble endothelial cell growth factor, and others	Proinflammatory, potential "priming" for ARDS, TRALI, and MODS
Histamine and kinin accumulation	Hypotension, anxiety, flushing, pain syndromes, proinflammatory
Microaggregates and procoagulants	Blockade of reticuloendothelial system Risk factor for development of ARDS, MODS, TRALI Activation of hemostasis > DIC (?), VTE (?), arterial thrombotic events (?)

ARDS, Acute respiratory distress syndrome; ATP, adenosine triphosphate; *DIC,* disseminated intravascular coagulation; *2,3-DPG,* 2,3-diphosphoglycerate; *HLA,* human leukocyte antigen; *IL,* interleukin; *LDH,* lactate dehydrogenase; *MODS,* multiorgan dysfunction syndrome; *RBC,* red blood cell; *TNF,* tumor necrosis factor; *TRALI,* transfusion-related acute lung injury; *VTE,* venous thromboembolism.

large RCTs with over 5000 patients enrolled found that patients transfused with fresher blood (<10 days old) had no difference in adverse events outcomes or mortality when compared with patients transfused with standard-issue blood.[12] Interestingly, a trend toward increased risk of nosocomial infection was demonstrated with fresher blood (risk ratio [RR] 1.09; 95% confidence interval [CI] 1.00–1.18; $P = .04$).[12] Little data exist on transfusion of end-of-storage RBCs (older than 28 days). Further information about the storage lesion and the possible clinical implications is summarized in Table 126.2.

HYPERBILIRUBINEMIA IN THE SETTING OF MASSIVE TRANSFUSION

Hyperbilirubinemia after massive transfusion is common and deserves special mention. A significant portion of the transfused RBCs may not survive, and the resulting bilirubin load causes varying degrees of hyperbilirubinemia. Hypovolemia and shock contribute to impairment in biliary transport functions, particularly in the presence of sepsis or multiple organ dysfunction. An important rate-limiting step in bilirubin transport is the energy-requiring process of transporting conjugated bilirubin from the hepatocyte to the biliary canaliculus. Delayed excretion may lead to conjugated hyperbilirubinemia. A hemolytic transfusion reaction and resorbing hematoma also must be considered as possible causes of hyperbilirubinemia. A later increase in bilirubin at 5 days post shock may reflect ongoing injury to the liver as part of multiple organ failure.

BASIC IMMUNOHEMATOLOGY

RBC serology is a specialized area of knowledge, and with the International Society of Blood Transfusion (ISBT) now recognizing 36 human blood group systems and 346 antigens, it is not possible to expect clinicians to have more than a basic working knowledge essential for patient safety. The most well-known and important antigens for safe transfusion are ABO and D (Rh).

REGULAR AND IRREGULAR (ATYPICAL) ANTIBODIES

The four major ABO blood groups are defined by the presence or absence of the two carbohydrate antigens integral to the RBCs, A and/or B, and by the presence or absence of the naturally occurring antibodies (isoagglutinins) anti-A and/or anti-B. An individual with an antigen will lack the corresponding antibody (e.g., an individual with group A antigen will have anti-B antibodies). Of note, group A RBCs cause the most common and most dangerous ABO-incompatible hemolytic reactions.

The D antigen of the rhesus (Rh) blood group system is common and highly immunogenic, and is the second-most important antigen with regard to safe transfusion. When an Rh-negative (i.e., D-negative) patient is exposed to D-positive blood, there is a high likelihood of forming an anti-D antibody. D-negative females of childbearing age who receive D-positive blood may be at risk for hemolysis of the newborn or fetus. For this reason, the D antigen is taken into account when providing blood for transfusion to young females. Beyond the A, B, and (Rh)D antigens, it is not practical or necessary to take notice of other blood group antigens unless an atypical antibody is detected during antibody screening procedures.

Atypical antibodies are not normally present in the plasma but may be found in some people as naturally occurring antibodies or immune antibodies. Immune antibodies result from previous exposure due to blood transfusion or pregnancy. Naturally occurring antibodies are generally of minimal clinical significance. In contrast, many of the immune atypical antibodies are of major clinical significance and thus their recognition is imperative and drives pre-transfusion compatibility testing and antenatal antibody screening.

ANTIBODY SCREEN

On receipt of a blood sample by the transfusion service, the RBCs are ABO and Rh(D) typed while the serum is screened for atypical antibodies. The antibody screen is performed by incubating the patient's

serum with group O screening cells, which are RBCs obtained from two- or three-group O donors and express combinations of commonly encountered and clinically significant RBC antigens. If an atypical antibody is detected on the antibody screen, further serologic investigations are done to identify the specificity of the antibody.

CROSSMATCH (COMPATIBILITY TEST)

The crossmatch is the final compatibility test between the donor cells and the patient's serum, acting as a last check for ABO compatibility and unexpected antibodies. It can be done electronically or serologically. For a patient with a negative antibody screen with no history of a clinically significant antibody and with at least two prior ABO types performed, an electronic crossmatch (EXM) can be performed. In EXM, a computer algorithm ensures the correct ABO/RhD type blood is issued.

If the patient does not meet these criteria or EXM is not available at the institution, immediate spin crossmatch (IS XM) is performed. In IS XM, the donor RBCs are suspended in a saline solution, which is then gently mixed with the patient's serum and centrifuged before being resuspended. The presence of any hemolysis or RBC agglutination suggests possible ABO mismatch. If IS XM or antibody screen is positive, or if the patient has a history of clinically significant antibodies, an immunoglobulin G (IgG) crossmatch must be performed. In this indirect Coombs test, the donor RBCs are added to the patient's serum and incubated to allow for any immunoglobulins to coat the donor RBCs. The RBCs are then washed and treated with an antibody to human IgG before being inspected for hemolysis or agglutination.

Emergency uncrossmatched blood can be given in times of significant exsanguination with concern for possible loss of life. Group O Rh(D)-negative donors are referred to as "universal" blood donors and are ABO compatible with all recipients. This emergency uncrossmatched blood is also screened for high-titer A or B hemolysins. Although group O Rh(D)-positive blood can be used in severe hemorrhage, if the recipient is a female of childbearing age, every attempt should be made to give Rh(D)-negative blood until the patient's blood type is known.

KEY POINTS

- In general, a restrictive RBC transfusion strategy is recommended (transfuse when Hgb falls below 7 g/dL). For patients with acute coronary syndrome, RBC transfusion should be considered when Hgb is below 8 g/dL.
- The decision to transfuse RBC concentrates should be supported by the need to relieve clinical signs and symptoms of impaired oxygen transport and to prevent morbidity and mortality, with the aim of improving clinical outcomes.
- For the acutely hemorrhaging patient, resuscitation should consist of early transfusion of plasma, platelets, and RBCs in a balanced 1:1:1 ratio or liquid, cold-stored, type O WB.
- In patients undergoing surgical or invasive procedures, the decision to transfuse platelets should take into account the type of procedure, preoperative platelet counts, degree of active or anticipated hemorrhage, and presence of antiplatelet medications or disorders that affect platelet function.
- The benefit of plasma transfusion extends beyond its hemostatic effects to include reduction of vascular permeability and mitigation of inflammation after hemorrhagic shock.
- Prothrombin complex concentrate is superior to FFP in reversal of acquired coagulation factor deficiency induced by vitamin K agonists such as warfarin.
- Allogeneic transfusion can be associated with infectious and noninfectious risks, such as allergic, hemolytic, and febrile reactions, in addition to TRALI, TACO, transfusion-related immunomodulation, and GVHD.

Venous Thromboembolism

Simone Langness, Caitlin Collins, and M. Margaret Knudson

INTRODUCTION

Venous thromboembolism (VTE), which includes both deep vein thrombosis (DVT) and pulmonary embolism (PE), is a source of significant morbidity and mortality for the critically ill patient.[1] The development of DVT alone in the intensive care unit (ICU) is associated with a longer length of stay, more ventilator days, and an increased mortality rate compared with similar patients without DVT.[2] The annual costs for VTE in the United States is >$10 billion,[3] with a total economic burden as high as $69 billion.[4]

DEEP VEIN THROMBOSIS

Incidence

It is estimated that approximately 10% of patients in medical or surgical ICUs will have a DVT on admission.[5,6] The incidence of DVTs developing during ICU care is much harder to estimate but has been cited to be between 10% and 80%, depending on the patient population, predisposing factors, diagnostic method used, and prophylactic choice.[6–9] More recent studies place the estimates closer to 10%–15%[10,11] if appropriate prophylaxis is given.

Risk Factors

Several factors predispose critically ill patients to DVT (Table 127.1). Some risk factors are caused by an underlying illness, whereas others are acquired during the stay in the ICU. Each risk factor, whether intrinsic or acquired, relates to Virchow's triad of venous thrombosis: stasis, endothelial injury, and hypercoagulability.

Diagnosis

The diagnosis of DVT in critically ill and injured patients is challenging. Less than 15% of ICU patients diagnosed with DVT have associated clinical signs,[26] and many are unable to communicate symptoms because of factors such as altered mental status, sedation, or mechanical ventilation. Additionally, classically described signs such as unilateral leg swelling, local calf tenderness, dilated superficial veins, and erythema may not be present in the critically ill patient or are confounded by accompanying diseases or traumatic injuries. As such, physical examination has been shown to have little utility in the diagnosis of DVT in the ICU patient.[26]

Compression Ultrasound

Compression ultrasound (US) is the most commonly employed modality in the diagnosis of DVT, with a sensitivity of 85% and specificity of 96%[27] (Fig. 127.1). Given that DVTs in the critical setting are often clinically silent, some have advocated for routine screening of patients with US.[6] Although screening results in more DVTs diagnosed, it is also associated with increased costs and the potential for inaccurate results. Based on data from the Prophylaxis for Thromboembolism in Critical Care Trial (PROTECT), weekly screening US is not recommended.[28]

Prophylaxis

The incidence of DVT among medical-surgical ICU patients without any form of prophylaxis is estimated at around 30%.[8,11] Mechanical prophylaxis with intermittent pneumatic compression devices (PCDs) has been shown to reduce the development of DVT by approximately 30% when used in isolation compared with no prophylaxis.[29] However, when PCDs are combined with appropriate chemical prophylaxis, there appears to be no additional benefit.[30] Currently, PCD is recommended for all ICU patients in whom chemical prophylaxis is contraindicated.[31,32]

In multiple prospective randomized controlled trials and meta-analyses, chemical prophylaxis reduces the incidence of VTE in critically ill patients by approximately 50%.[33,34] The number of patients needed to receive prophylaxis in order to prevent one DVT is 20 and to prevent one PE is 52.[35] The American College of Chest Physicians (ACCP) gives a strong recommendation (Level I) for chemical thromboprophylaxis in all ICU patients.[36]

Medication Choice

Options for chemical prophylaxis for VTE prevention include unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), and argatroban. For surgery and medically ill patients, LMWH and UFH have similar efficacy and safety for DVT prophylaxis,[37,38] but LMWH is superior in the prevention of PE.[35,39] Given these findings and the lower risk of heparin-induced thrombocytopenia (HIT), LMWH should be considered the first-line approach for chemical prophylaxis for all ICU patients with adequate renal function.

For trauma patients, LMWH shows better efficacy than UFH with a risk reduction of an additional 30%.[40] LMWH administered twice daily (30 mg BID subcutaneously), typically in the abdominal fatty tissue, is the preferred medication for DVT prophylaxis for trauma patients from the ACCP and the Eastern Association for the Surgery of Trauma (EAST).[41,42]

Fondaparinux is an indirect factor Xa inhibitor. The advantage of fondaparinux is that it does not interact with platelets and therefore is a safe alternative in patients with HIT.[43]

Dosing

The optimal dosing of heparin for VTE prophylaxis in the ICU population has received recent attention. Standard dosing for UFH is 5000 U administered subcutaneously twice or three times daily. Meta-analyses evaluating the effectiveness and safety of twice-daily regimens compared with three-times-daily regimens for hospitalized patients have been mixed. Two studies suggest equivalent rates of VTE and

TABLE 127.1 Risk Factors Associated With VTE in Critically Ill Patients

Risk Factor	Pathophysiology	Notes
Age	Increased plasma concentration of specific clotting factors, impaired fibrinolytic activity.[12]	DVT risk doubles for every decade after 40[13]* *Risk of DVT for 40–49 years old = 2.5
Sepsis	Marked proinflammatory state results in dysregulated cellular responses and deposition of platelet-fibrin thrombi within vessels.[14]	RR of VTE in sepsis: 3–10.[15] *VTE incidence of 37% for patients with severe sepsis and septic shock despite >80% receiving appropriate prophylaxis.
Prolonged immobility/ neuromuscular blockade	Decreased venous blood flow from no/minimal extremity muscle contraction.	Neuromuscular blockade independently associated with incidence of DVT in multivariate analysis (OR 8.8).[16]
Central venous catheter	Direct damage to endothelium. *Polyethylene catheters, increased number of lumens, catheter size, and location all increased risk of catheter-associated VTE.[17]	Rate of catheter-associated DVT (per 1000 CVC days).[18] Internal jugular = 61 Femoral = 36 Peripheral = 27 Subclavian = 9
Genetic/acquired hypercoagulability	Reduced ability to degrade activated clotting factors.[12]	Antithrombin deficiency, proteins C and S deficiency, factor V Leiden, antiphospholipid syndrome
Obesity	Mechanical impairment of deep vein valve system. Metabolic syndrome can lead to decreased production of nitric oxide and prostacyclin, which can alter endothelial function.	RR DVT[19] (versus nonobese): 2.5 RR PE (versus nonobese): 2.2
Surgery/trauma	Direct injury to blood vessel → release of tissue factor → activation of clotting cascade.[20] Hemorrhagic shock results in hypoperfusion and stasis. Trauma → increased production of thrombin.[21]	DVT OR[22]: Femur or tibial fracture = 4.8 Spinal cord injury = 8.6 Surgery for trauma = 2.3 VTE odds ratio[23]: Lower extremity fracture with abbreviated injury score (AIS) ≥3 = 1.9 Head injury + AIS ≥3 = 1.24 Venous traumatic injury = 3.56 Surgery for trauma = 1.53
Malignancy	Direct compression of or invasion into veins. Tumors can promote the release of tissue factors → activation of clotting cascade.[24]	
Pregnancy	Increased concentration of procoagulant factors. Impairment of fibrinolytic system.[25]	

CVC, Central venous catheter; *DVT,* deep vein thrombosis; *OR*, odds ratio; *PE,* pulmonary embolism; *RR,* relative risk; *VTE,* venous thromboembolism.

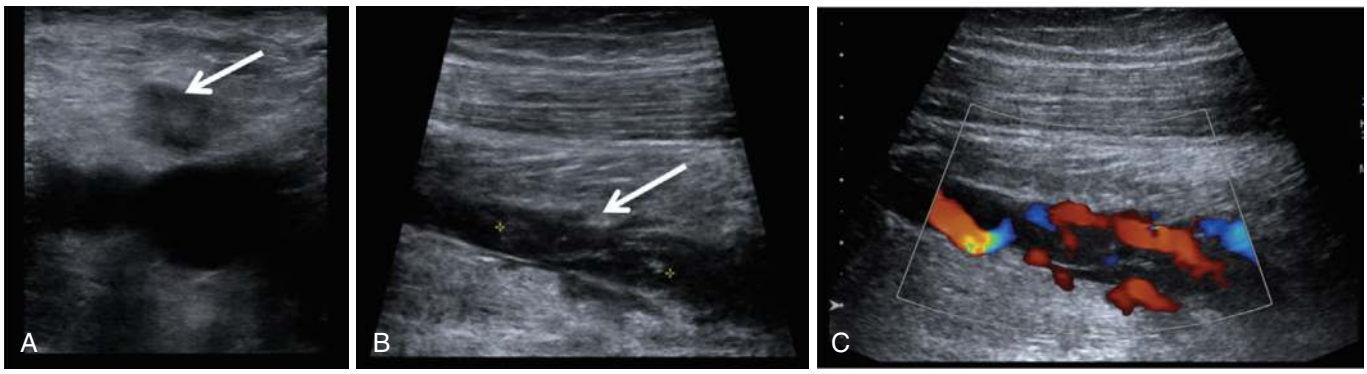

Fig. 127.1 Occlusive **(A)** and nonocclusive **(B)** deep vein thrombus (*arrows*) on compression ultrasound. Doppler ultrasound confirms nonocclusive nature of thrombus **(C)**.

major bleeding between the dosing regimens,[44,45] and a third found three times daily to be more effective (relative risk [RR] 0.27) with no increase in the incidence of major bleeding.[46]

Anti-factor Xa (anti-XA) levels can be used to evaluate the degree of thromboprophylaxis after LMWH administration. The therapeutic target for VTE prophylaxis is 0.3–0.5 IU/mL.[47] Several reports have demonstrated that approximately 50% of critically ill patients have inadequate anti-Xa levels with standard LMWH dosing (30–40 mg daily).[48–50] This has led some to argue for twice-daily dosing[51,52] or dosing based on weight,[53] thromboelastogram,[54] and/or goal anti-Xa.[55]

The etiology of subtherapeutic levels with standard LMWH in the ICU population is multifactorial but may include decreased absorption

caused by vasopressors, altered metabolism with organ dysfunction, variable albumin binding, and differences in volume of distribution caused by edema.[50,56] Obesity also plays a role in the bioavailability of heparin. There is a strong, and seemingly dose-dependent, relationship between body mass index (BMI) and failure of thromboprophylaxis. One study found a 60% increased risk of VTE for patients with BMI ≥30, suggesting that higher doses of prophylaxis may be necessary.[57] In trauma patients with massive fluid shifts, clearance of heparin-based drugs may actually increase, thus providing a rationale for more frequent dosing.

Timing of Prophylaxis

VTE prophylaxis in the critically ill patient should be initiated as soon as feasible based on the risk of hemorrhage. For the majority of patients admitted to the ICU, administration should occur at the time of admission, as delayed initiation of VTE prophylaxis by as little as 24 hours is associated with a threefold increase in VTE rates[58] in addition to increased mortality.[59] Trauma patients represent a particularly challenging population with respect to managing the risk of bleeding against the risk of VTE. The risk of VTE after injury ranges from 5% to 60% depending on injury type and patient risk.[22,23,60] PCD should be initiated immediately unless otherwise contraindicated. In patients with polytrauma, chemical VTE prophylaxis is initiated as soon as bleeding is controlled and coagulopathy corrected, as the risk of VTE increases significantly with every day it is withheld. For patients with traumatic brain injury, it is safe to start chemical VTE prophylaxis within 72 hours of injury as long as there is no expansion of bleeding on repeat imaging.[61,62] For patients with spinal cord injuries, new evidence suggests that it may be safe to initiate anticoagulants within 24–48 hours of the injury.[63] Early chemical prophylaxis is also safely given at 24–48 hours after injury in patients with solid organ injuries being managed without operation.[64,65]

Inferior Vena Cava Filter

For those who have a relative or absolute contraindication to chemical DVT prophylaxis because of high-risk bleeding, a prophylactic inferior vena cava (IVC) filter may be indicated. Additional indications for IVC filter placement include failure of or poor compliance with anticoagulation or for patients with VTE and limited cardiopulmonary reserve. Although IVC filters are highly effective at preventing PEs from lower extremity DVT, they also substantially increase the risk of DVT formation and are not effective against the formation of in situ PE or embolism from an upper extremity thrombus.[66,67] There are conflicting recommendations on the use of IVC filters in patients without a current DVT/massive PE, with some advocating their use in "high risk" trauma patients who are unable to receive chemical prophylaxis.[41]

Treatment of DVT

Although anticoagulation is the mainstay of treatment of DVT, the type and duration of anticoagulation can vary significantly, depending on the status and compliance of the patient and the perceived risk for recurrent VTE. The purpose of anticoagulation is to prevent extension of the thrombosis, embolization to the pulmonary arterial system, and the complications from chronic venous outflow obstruction.

Lower Extremity DVT

Lower extremity DVT can be classified as proximal or distal. Proximal DVTs are located in the popliteal, femoral, or iliac veins, whereas distal DVTs are confined exclusively to the calf veins (peroneal, posterior tibial, and anterior tibial). Proximal DVTs, regardless of symptomatology, are treated with anticoagulation, unless otherwise contraindicated, as they are associated with an increased rate of embolism and mortality.[68] Distal DVTs have approximately half the risk of embolization,[69] and some will resolve without intervention.[70] Management can range from observation alone to full anticoagulation, considering such factors as symptomatology, prior VTE episodes, and/or prolonged immobility. If observation is employed, routine surveillance to monitor for extension into proximal veins is recommended.[71]

Upper Extremity DVT/Catheter-Associated DVT

Upper extremity DVTs account for 5%–10% of all DVTs and include thrombus within the radial, ulnar, brachial, axillary, and subclavian veins. Thrombosis within the internal jugular vein is occasionally included as an upper extremity DVT, although rigorous definition is lacking. The incidence of PE caused by upper extremity DVT embolism is approximately 6%[72] compared with 15%–30% for lower extremity DVT.[73] Anticoagulation is recommended for upper extremity DVT in proximal vessels (axillary, subclavian, internal jugular) regardless of the etiology.

The majority of upper extremity DVTs are associated with intravenous catheter use. The increased use of peripherally inserted central catheters (PICC lines) in the management of ICU patients is associated with a corresponding increase in the incidence of upper extremity DVT. DVTs can occur as early as 1 day after central venous catheter (CVC) placement and are frequently asymptomatic. Risk factors for the development of catheter-associated DVT include catheter type, anatomic site of placement, the presence of infection, and the duration of use.[74] Data on the optimal management of CVC-related DVT are limited. Consensus opinion recommends systemic anticoagulation for a minimum of 3 months,[17,75] although 6 weeks may be adequate if the clot is small and nonocclusive.[75,76] The decision to remove the CVC should be based on whether or not the catheter is still required. Additional recommendations regarding catheter removal with associated DVT include poor positioning, infections, arm or neck swelling, and when anticoagulation is contraindicated.[75,77]

Anticoagulant Options

Initial anticoagulant therapy for DVT may include continuous heparin infusion, subcutaneous, fondaparinux, or oral factor Xa inhibitors such as rivaroxaban or apixaban. Warfarin cannot be used alone as the initial treatment of DVT because of the risk of warfarin-induced skin necrosis.[78] The determination of which anticoagulant to initiate will be dictated by comorbidities and risk of bleeding.

Intravenous heparin is the preferred initial anticoagulant for patients with renal failure (creatinine clearance [CrCl] <30), hemodynamic instability, extensive clot burden, and those with a high risk of bleeding. Rivaroxaban and apixaban are the only direct oral anticoagulants approved for initial treatment of VTE. These agents do not require pretreatment with heparin and can be useful for lower-acuity patients with low bleeding risk profiles.

All VTE events, regardless of etiology, require anticoagulation treatment for at least 3 months.[68] A transition from the initial anticoagulation regimen to a maintenance therapy is often required. Maintenance agents may include LMWH, warfarin, direct oral factor Xa inhibitors, or direct thrombin inhibitors. According to the 2016 CHEST guidelines, for patients with VTE in the absence of cancer, direct oral anticoagulants are preferred over warfarin (grade 2B), and warfarin is preferred over LMWH (grade 2C).[68]

Thrombolysis

Anticoagulation alone is sufficient treatment for the majority of patients who develop an acute DVT. However, a subpopulation of patients may benefit from reducing the venous clot burden through the administration of thrombolytic agents or with a mechanical thrombectomy. Patients who should be considered for thrombolytic therapy include those with phlegmasia cerulean dolens or massive iliofemoral

DVT. Ideal candidates for thrombolysis/thrombectomy have symptoms for <14 days, have good functional status, and have a low risk of bleeding.[68] Thrombolysis can be systemic or catheter-directed, but catheter-directed therapy is associated with a lower risk of bleeding.[79]

PULMONARY EMBOLISM

Incidence

The prevalence of PE in critically ill patients remains largely unknown. A systematic review of ICU patients reported that PE was discovered in 7%–27% of patients upon postmortem examination.[80] PE was believed to have contributed to the patient's death in 0%–12% of the cases; however, clinical suspicion of PE was present in only 30% before death, highlighting the likelihood of significant inaccuracy in current prevalence estimates. Historical estimates of PE prevalence in critically ill patients range from 7% to 50% but are largely based on autopsy studies performed between the 1960s and early 1980s.[7,81,82]

Risk Factors

PE can be considered part of a VTE spectrum, with DVT representing the requisite precursor to PE.[83] Kakkar and colleagues examined the natural history of postoperative DVT and found that approximately 20%–30% of untreated calf DVTs will eventually propagate into the thigh, at which point they pose a 40%–50% risk for PE.[84–86] Approximately 95% of pulmonary emboli arise from lower extremity DVTs.[83]

Predictive factors for the development of PE include acute medical illness, presence of meningeal hemorrhage, spine fracture, hypoxemia with partial pressure of oxygen (PaO_2)/fraction of inspired oxygen (FiO_2) <300, and absence of pharmacologic VTE prophylaxis. Additionally, the use of epinephrine or norepinephrine is associated with a particularly poor prognosis among patients diagnosed with PE.[87]

Symptoms and Physiologic Derangements

Symptoms

Common symptoms of PE include pleuritic chest pain, acute-onset shortness of breath, palpitations, cough, and hemoptysis.[88,89] However, these symptoms are nonspecific and are often entirely absent in sedated and mechanically ventilated patients. The relevant clinical signs (hypoxemia, tachypnea, and tachycardia) are similarly nonspecific and frequently explained by the preexisting conditions driving their critical illness.[88] The atypical presentation in ICU patients necessitates that providers maintain a high degree of suspicion for PE with any relevant, acute changes in clinical status. More subtle clinical scenarios in which one should suspect PE include failure to wean from mechanical ventilation and persistent pyrexia without evidence of infection.[90]

Physiologic Derangements

Hypoxemia and hypocarbia are the most common signs of PE. PE causes an increase in dead space, as the corresponding lung parenchyma is ventilated but no longer perfused. Additionally, the remaining lung receives a higher proportion of blood flow but does not receive a concomitant increase in ventilation.[91] This ventilation-perfusion (V/Q) mismatch results in hypoxemia during the acute phase of PE.

Intrapulmonary shunting is a second driver of hypoxia after PE and occurs as a result of atelectasis and other causes of lung volume loss.[92] In patients with a patent foramen ovale, intracardiac shunting might also play a role. The application of positive end-expiratory pressure (PEEP) or continuous positive airway pressure can worsen the intracardiac shunting by exacerbating right and left atrial pressure gradients. Importantly, hypoxemia secondary to shunt physiology will not correct with supplemental oxygen.[91,93]

PE can result in sudden cardiovascular collapse. Acute PE decreases the cross-sectional area of the pulmonary vascular bed, thereby increasing pulmonary vascular resistance (PVR) and right ventricular (RV) afterload.[91] If severe, this can lead to RV enlargement followed by hypokinesis, ischemia, and subsequent RV failure.[93,94] In patients with already restricted cardiopulmonary reserve, even small increases in PVR can result in RV dysfunction and hemodynamic compromise.[95]

Diagnosis

When diagnosing PE, reliance on clinical impression alone is profoundly unreliable. Studies demonstrate that the sensitivity and specificity of empiric diagnosis of PE based on clinical impression alone are only 85% and 51%, respectively.[96] These data reiterate the importance of ancillary testing when PE is suspected, especially considering the potentially grave risks of therapeutic anticoagulation in a critically ill patient.

Chest X-Ray, Electrocardiogram, and D-Dimer

Chest x-ray (CXR) is most useful for quickly identifying (or ruling out) other possible conditions that mimic PE (e.g., pneumonia, atelectasis, pulmonary edema, pleural effusion, pneumothorax) but provides no utility in the diagnosis of PE.[89] Electrocardiogram (ECG) abnormalities, such as sinus tachycardia and nonspecific ST-segment and T-wave abnormalities, are frequently present in patients with acute PE.[89,97] These findings, however, lack specificity, particularly in the critically ill patient. Additional irregularities, such as atrial arrhythmias, right axis deviation, right bundle branch block, the S1Q3T3 pattern, and p-wave pulmonale, more commonly accompany a large PE and are equally nonspecific.[89,94,97] In the outpatient setting, D-dimer is routinely used as a screening test for PE, as it is associated with a negative predictive value of 99.6%.[98] However, its effectiveness in the inpatient setting, and moreover the ICU, is diminished by the fact that most patients will have elevated D-dimers for unrelated reasons, especially those who have sustained major trauma.[99]

Echocardiography

The role of transthoracic echocardiography (TTE) in the diagnosis of PE has gained momentum in the last decade. Although unable to specifically assess clot formation within the pulmonary vasculature, TTE can evaluate the physiologic consequences of PE. PE should be considered when new RV dysfunction is identified on TTE as evidence by RV dilation, hypokinesis, tricuspid regurgitation, elevated systolic pulmonary artery pressure, and paradoxical septal wall motion. Additionally, the degree of RV dysfunction documented on TTE with Doppler correlates with mortality, allowing for risk stratification and informing decisions regarding the aggressiveness of treatment interventions.[100]

V/Q Scan

The PIOPED study prospectively analyzed the diagnostic performance of V/Q scans in comparison with pulmonary angiography among hospitalized patients. Although almost all patients with PE had abnormal V/Q scans (sensitivity 98%), so did a large number of patients without PE, resulting in a specificity of only 10%.[101] Given the prevalence of both chronic and acute respiratory issues within an ICU population, the vast majority of patients will have preexisting defects in both ventilation and perfusion.[81] Attempting to identify superimposed abnormalities related to the PE would be a wasted effort. These challenges severely limit the utility of V/Q scans within an ICU setting.

Pulmonary Angiography and CT Angiogram

Although pulmonary angiography has historically been the gold standard for diagnosing PE, computed tomography pulmonary angiography (CTPA) has largely taken its place as the preferred diagnostic tool in clinical practice, with a sensitivity of 83% and specificity of 96% (Fig. 127.2).[102,103] CTPA is noninvasive, is faster, and has the

additional benefit of allowing assessment and quantification of RV dysfunction through evaluation of the LV:RV diameter ratio, interventricular septal bowing, contrast reflux into the superior and inferior vena cava, and pulmonary artery diameter.[102,104] Additionally, CTPA can detect other etiologies for the development of acute hypoxia such as pneumonia, lobar collapse, and pulmonary edema.

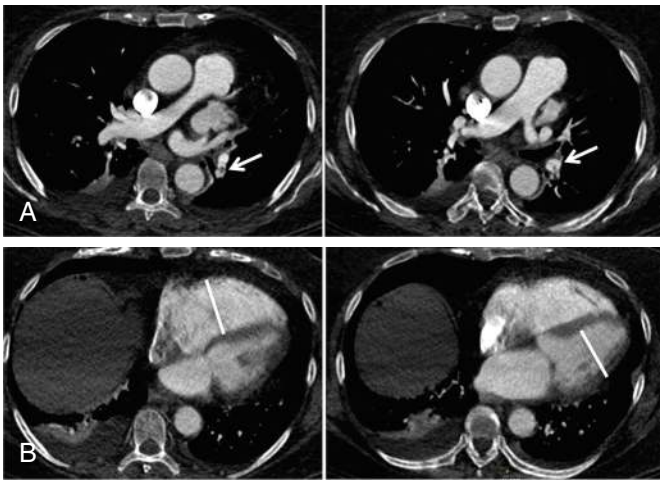

Fig. 127.2 A, Segmental pulmonary embolus (*arrows*) on computed tomography pulmonary angiogram (CTPA). **B,** Right ventricle to left ventricle ratio >1.0, suggestive of heart strain.

Treatment

The balance between the likelihood of an adverse outcome from PE and the anticoagulation/thrombolysis risk largely drives management decisions when treating ICU patients with PE. The degree of cardiovascular impact represents the best predictor of a poor outcome and is used to differentiate and treat the three main types of PE: massive PE, submassive PE with RV strain, and submassive PE without RV strain (also termed *low-risk PE*)[105] (Fig. 127.3).

Massive PE

The American Heart Association (AHA) defines massive PE as an acute PE with sustained hypotension, pulselessness, or persistent profound bradycardia (heart rate <40 beats per minute with evidence of shock). Sustained hypotension is defined as a systolic blood pressure <90 mm Hg or the need for inotropic support and cannot be the result of a cause other than PE, such as an arrhythmia, hypovolemia, sepsis, or LV dysfunction.[106]

Based on the ICOPER study, the mortality rate for patients with massive PE was 58.3% compared with 15.3% in those with PE without cardiovascular collapse.[107] In patients requiring cardiopulmonary resuscitation, the mortality rate may be as high as 65%.[108] As hemodynamic instability portends such a poor prognosis, more aggressive interventions must be considered in this patient population.

Submassive Pulmonary Embolism with Right Ventricular Strain

Submassive PE with RV strain describes patients with acute PE who are normotensive but have some evidence of RV dysfunction or myocardial

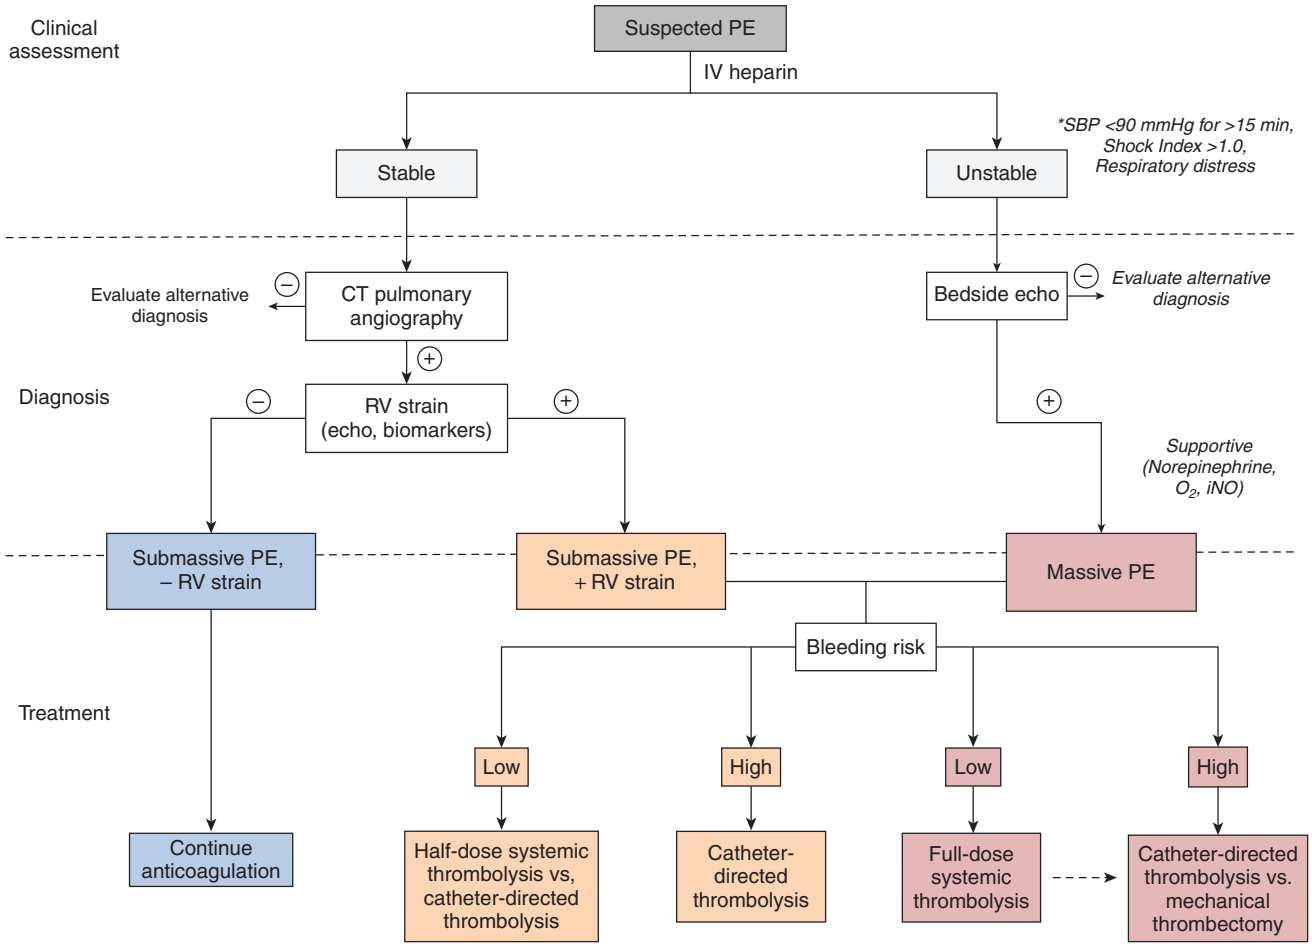

Fig. 127.3 Treatment Algorithm for Suspected Pulmonary Embolism (PE) in Critically Ill Patients.

ischemia on ECG, echocardiogram, CTPA, or laboratory work such as elevated troponin or brain natriuretic peptide.[106] This heterogeneous group spans the entire spectrum with respect to risk associated with their PE. Some patients with mild evidence of RV strain are likely to recover well with anticoagulation alone. However, others within this group behave more like patients with massive PE and thus might benefit from more aggressive and higher-risk interventions.

Submassive PE without RV Strain (Low-Risk PE)

Patients with acute PE who are hemodynamically stable and have no evidence of RV dysfunction or myocardial injury fall within the submassive PE without RV strain category and have the lowest risk of adverse outcome. In-hospital mortality for these patients is estimated at 8.1%.[108]

Anticoagulation

All patients diagnosed with PE, regardless of the severity, should receive prompt anticoagulation with UFH, LMWH, or fondaparinaux.[106] For patients with absolute contraindications to anticoagulation, an IVC filter should be placed without delay. Absolute contraindications to anticoagulation are rare but include (1) active intracranial hemorrhage and (2) uncontrolled bleeding related to conditions such as trauma, recent surgery, gastrointestinal or genitourinary pathology, or preexisting coagulopathy. Temporary contraindications should be regularly reassessed, and anticoagulation should be reconsidered as the initial contraindication abates.

Thrombolysis

Thrombolysis has been shown to more rapidly reverse RV dysfunction from PE than anticoagulation alone and confers a survival benefit in the setting of a massive PE.[88,109] For patients with submassive PE and documented RV dysfunction, a strong trend towards benefit exists based on meta-analysis, but results have varied among major studies. Thrombolysis is not recommended for patients with low-risk PE, as the risk of major bleeding outweighs the therapeutic benefit.[109]

Thrombolysis can be performed via systemic administration or using a catheter-based approach. Recent studies have found lower rates of bleeding complications with improved outcomes using catheter-based thrombolysis as opposed to systemic thrombolysis.[110,111] Despite the utility of thrombolysis in the treatment of severe PE, approximately one-third of patients with massive PE have significant contraindications to thrombolysis.[112] The prevalence of absolute contraindication is likely even higher in an ICU population. Mechanical thrombectomy and additional supportive interventions play an important role in patients who may benefit from thrombolysis but are not candidates for the therapy.

Supportive Care

Inhaled Nitric Oxide

Inhaled nitric oxide (iNO) acts as a selective pulmonary artery vasodilator, thus partially offloading RV pressure without negatively affecting systemic blood pressure.[113] Although it has been shown to be effective in reducing mean pulmonary artery pressure in the acute setting, few studies exist evaluating its use in patients with PE, and none of them are adequately powered to assess whether its use confers a mortality benefit.[113,114]

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) represents a potential supportive intervention for massive PE. ECMO has a number of beneficial characteristics that lend to its possibilities as an adjunctive treatment. ECMO allows for offloading of the RV and can provide a bridge to other therapeutic interventions (i.e., surgical embolectomy or catheter-directed therapy).[115,116] An additional advantage of ECMO is that cannulation can be performed at the bedside. Evidence for the utility of ECMO for massive PE is primarily composed of case series, and most guidelines consider ECMO as an adjunct to thrombolysis or embolectomy.[115–117]

Future Directions

Although there are few large, prospective studies in VTE disease in ICU patients, the Consortium of Leaders in the study Of Traumatic Thromboembolism (CLOTT) group is committed to doing just that. The CLOTT group consists of 17 trauma surgeons from Level I trauma centers across the country who are funded by the Combat Casualty Care Research Program (Department of Defense) to study two important areas related to VTE in seriously injured patients. The first area of investigation relates to some work initially published by Knudson and others suggesting that pulmonary clots visualized on CTPA may in fact be de novo clots and not embolic.[118] These clots were most prevalent in patients who had sustained pulmonary injury and were not associated with lower extremity VTE.[119,120] As many of these primary pulmonary clots are detected incidentally and are frequently subsegmental, the question arises as to whether or not they need to be treated at all. This would completely change practice in the care of critically injured patients and is the central hypothesis of the CLOTT Study Part 1.

CLOTT investigators are also examining thromboelastography data that suggest that certain critically injured patients are incapable of lysing clots after injury.[121] This syndrome is referred to as *fibrinolytic shutdown,* and the risk factors for and the incidence of this new diagnosis are the central goals of the CLOTT Study Part 2. Of particular importance is the association of fibrinolytic shutdown with the development of VTE events.[122] A better understanding of this pathology could change the focus of VTE prevention in at-risk trauma patients from preventing clots from forming to assisting in clot dissolution.

KEY POINTS

- VTE is common in the critically ill patient, and chemical prophylaxis must be provided as soon as possible for risk reduction.
- Compression US and CTPA are primary modes of diagnosing DVT and PE, respectively.
- Thrombolysis or mechanical thrombectomy should be considered for proximal DVT at risk for postthrombotic syndrome and for PE with evidence of right heart strain.

Anticoagulation in the Intensive Care Unit

Jerrold H. Levy

INTRODUCTION

Patients in an intensive care unit (ICU) often have received or require anticoagulation for multiple reasons that include acute thrombotic issues, mechanical valves, venous thromboembolic prophylaxis, atrial fibrillation, ischemic cardiovascular disease, and/or extracorporeal life support. The types of anticoagulation and need for therapy vary depending on whether patients have arterial or venous thromboembolic issues. These issues are important in critically ill patients and have critical perspectives for management. The concept of anticoagulation and the various therapeutic approaches have rapidly changed over recent years, with the advent of many oral anticoagulation agents that will be considered. In addition, there are important links between coagulation and other critical physiologic responses including inflammation, that are beyond the scope of this review.[1]

ICU patients are anticoagulated for both thrombosis treatment and thromboprophylaxis. As initially mentioned, this includes a broad spectrum of potential indications. Although multiple therapeutic agents prevent or treat thrombosis in pathologic states, it is crucial to consider that all anticoagulation agents can cause bleeding. Thus causes of bleeding in an ICU setting often are the result of an acquired hemostatic defect caused by alterations in the physiologic equilibrium of procoagulant and anticoagulation balances. Under normal physiologic states in healthy patients, anticoagulation is favored because of a multitude of mediators and vascular endothelial cells. After vascular injury resulting from metabolic causes, surgery, or trauma, patients also develop procoagulant changes that alter this complex balance. As a result, hemostasis and coagulation are far more complex than the simplified coagulation cascades that most clinicians have learned or considered because of the complex equilibrium among blood cells, platelets, coagulation factors, natural inhibitors of coagulation, and the fibrinolytic system.[2–5]

In ICU settings, patients may receive anticoagulants for multiple indications that include venous thromboembolism (VTE), deep vein thrombosis (DVT), and pulmonary embolism (PE) for either prevention or therapy. Patients may also have additional problems that include acute coronary syndromes, percutaneous coronary interventions (PCIs), or with an acute ischemic stroke that are arterial issues. Arterial thrombi are mediated by platelet responses, and important interactions exist in hemostasis and thrombus formation.[6] With an arterial injury, injury or rupture of an atherosclerotic arterial plaque serves as a procoagulant focus for clot formation caused by platelet adhesion, activation, and aggregation, with the clinical end result of myocardial infarction (MI) or stroke.[7] Platelets normally circulate in an inactivated state, but after activation as described, they express glycoprotein IIb/IIIa receptors that allow fibrinogen to bind, cross-link platelets, aggregate, and form a thrombus.[7] Vascular injury causes thrombin formation but also platelet activation and the formation of the platelet-fibrinogen plug. Because platelets have a pivotal role in the pathogenesis of thrombosis after plaque rupture, antiplatelet agents, including aspirin, thienopyridines (clopidogrel, prasugrel, ticagrelor, cangrelor), and the glycoprotein IIb/IIIa inhibitors, reduce adverse events that are associated with arterial thrombotic events, including plaque rupture.[7]

Patients therefore commonly present in the ICU with underlying hemostatic disorders because of preexisting preoperative anticoagulation or antiplatelet therapy. All therapies that prevent clots from forming in pathologic states also interfere with normal hemostasis, an important mechanism to protect patients from exsanguination. Multiple anticoagulation agents are also administered in the ICU setting that include low-molecular-weight heparins (LMWHs), oral anticoagulants (vitamin K antagonists [VKAs]/warfarin and the new direct non–vitamin K oral agents apixaban, dabigatran, edoxaban, or rivaroxaban), platelet inhibitors (the thienopyridines clopidogrel, prasugrel, or ticagrelor), or parenteral direct thrombin inhibitors (bivalirudin, argatroban).[8,9] This chapter focuses on current pharmacologic anticoagulation therapies ICU patients may receive and the therapeutic perioperative and prohemostatic pharmacologic approaches that are used to treat or prevent bleeding in this setting.

ANTICOAGULATION

The basis of anticoagulation is modulating clot formation by inhibiting both thrombin activation and platelet activation.[5] Thrombin is a critical component of hemostasis (stopping bleeding) and a critical procoagulant in coagulation. Thrombin catalyzes the formation of fibrin from soluble fibrinogen but also activates factors V and VIII and platelets. Activated platelets adhere to injured vascular endothelium through a von Willebrand factor bridge between the vasculature and the platelets. Platelets also, when activated, express IIb/IIIa receptors where fibrinogen binds, causing aggregation, but also facilitate the further generation of thrombin. There are also complex humoral amplification pathways that link both inflammatory and coagulation responses to generate thrombin and prothrombotic effects.[5] Thus anticoagulation is based on inhibiting thrombin activation, platelet activation, and/or both. Current anticoagulants used to prevent clot formation will be considered. An overview of the specific targets of the different anticoagulants is shown in Fig. 128.1.

HEPARIN

Heparin, the most commonly used anticoagulant, especially in an ICU setting, is isolated from porcine intestine, where it is stored in the mast cell granules. Unfractionated heparin (UFH) is a combination of 3000- to 30,000-dalton (Da) fragments.[10] Heparin binds to antithrombin III (also called antithrombin [AT]), increasing the rate of thrombin-AT complex formation, but also inhibits other steps in coagulation.[11]

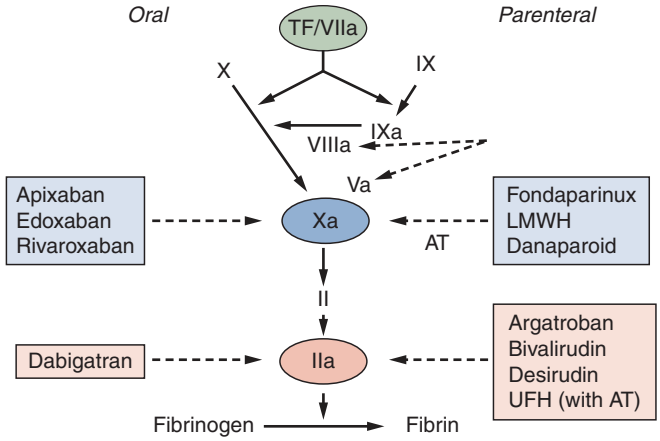

Fig. 128.1 The Sites of Action of Oral and Parenteral Anticoagulation Agents. The non–vitamin K oral anticoagulants, also called direct oral anticoagulants, include apixaban, edoxaban, and rivaroxaban. These drugs directly inhibit factor Xa, whereas dabigatran directly inhibits factor IIa (thrombin). The parenteral/intravenous anticoagulants that inhibit factor Xa include fondaparinux and low-molecular-weight heparin (*LMWH*) by antithrombin (*AT*)-cofactor dependent binding. Parenteral direct thrombin inhibitors include argatroban, bivalirudin, and desirudin that also directly inhibit thrombin, and unfractionated heparin (*UFH*) by antithrombin (AT)-cofactor dependent binding. Not shown in the figure is the mechanism of action of vitamin K antagonists (e.g., warfarin) that inhibit the posttranslational modification of coagulation factors II, VII, IX, and X to the active forms. Warfarin and its cogenders are anticoagulants because they decrease the circulating levels of critical hemostatic factors involved in coagulation.

Heparin anticoagulation has major advantages in an ICU setting, as it can be rapidly reversed with protamine, has a short half-life of ~1 hour, and is one of the few anticoagulants that can be readily administered in patients with renal dysfunction that may otherwise prolong the half-lives of most agents. One of the major side effects of UFH is heparin-induced thrombocytopenia (HIT) that can occur in ~1%–5% of ICU patients, especially postoperatively and after cardiac surgery with cardiopulmonary bypass.[12]

Low-Molecular-Weight Heparins

LMWHs are purified from UFH, with an average molecular weight of ~5000 Da. LMWHs have a longer half-life, are only partially reversible with protamine, and in patients with renal dysfunction, the effects can be greatly prolonged and should be avoided in this setting.[9] Commonly used LMWHs include enoxaparin and dalteparin.

Heparin-Induced Thrombocytopenia

HIT is a serious, prothrombotic effect of heparin that develops in 1%–3% of heparin-treated patients. HIT is an interesting paradigm where an anticoagulant produces an increased risk of thrombosis.[13] The pathophysiology of HIT is the result of a heparin–platelet factor 4 immunoglobulin G (IgG) antibody that binds and activates platelets and is associated with increased thrombotic morbidity and mortality.[13] HIT should be suspected whenever the platelet count drops >50% from baseline in 5–10 days after starting heparin (or sooner if there was prior heparin exposure) and/or new thrombosis occurring during, or soon after, heparin treatment, with other causes excluded. When HIT is strongly suspected, with or without complicating thrombosis, heparins should be discontinued, and a nonheparin alternative anticoagulant, such as a direct thrombin inhibitor (argatroban), should be initiated immediately.[13] Bivalirudin is also commonly used off-label, especially in this setting, and for HIT-positive patients requiring extracorporeal membrane oxygenation (ECMO).[14]

SYNTHETIC Xa INHIBITORS

Fondaparinux

Fondaparinux, a synthetic pentasaccharide with specific anti-Xa activity, has a long half-life and requires renal clearance and should be avoided in patients with renal dysfunction. Because of this, it is not commonly used in an ICU setting.[15]

Danaparoid

Danaparoid is one of the first anticoagulants evaluated in randomized trials in patients with HIT, was previously approved in the United States, and is currently being restudied in this setting in a randomized clinical trial with argatroban (https://clinicaltrials.gov/ct2/show/NCT03809481?term=danaparoid&draw=2&rank=1).[15]

DIRECT THROMBIN INHIBITORS: PARENTERAL AGENTS

An important major class of anticoagulants used primarily for HIT or for suspected HIT are the direct thrombin inhibitors that include bivalirudin, argatroban, and desirudin. Lepirudin is no longer available clinically. All of these parenteral direct thrombin inhibitors also vary in their binding affinities for thrombin and immunogenicity. All of the agents, except argatroban, are polypeptides, so there is a potential, but rare, risk for antibody formation and hypersensitivity responses.[15] Bivalirudin and argatroban are most often used in an ICU setting and will be considered separately.

Bivalirudin

Bivalirudin is a polypeptide with a molecular weight ~4000 Da and is approved as an anticoagulant for patients undergoing PCI with provisional use of glycoprotein IIb/IIIa inhibitor, with or at risk of HIT or HIT and thrombosis syndrome undergoing PCI, and with unstable angina undergoing percutaneous transluminal coronary angioplasty (PTCA).[15] It has also been used off-label as a replacement for heparin with ECMO. With normal renal function, the half-life is ~20 minutes but can be prolonged in patients with renal dysfunction.[15]

Argatroban

Argatroban is an injectable, synthetic, small-molecular-weight (~500 Da) direct thrombin inhibitor approved for prophylaxis or treatment of thrombosis in adult patients with HIT or as an anticoagulant in adult patients with or at risk for HIT undergoing PCI. However, for PCI, bivalirudin is currently used in this setting. The half-life is 40–50 minutes, and levels are not affected by renal dysfunction.[15] Patients with HIT often also present with acute renal failure, and all of the other agents used for acute HIT therapy are proteins that are renally eliminated. Argatroban is hepatically eliminated, so no dose adjustments are required in patients with renal dysfunction. Also, antigenicity is not an issue because of its low molecular weight.[15] We reported a study of 87 suspected HIT patients in the cardiothoracic ICU, of which 47 patients (54%) were treated with argatroban and 40 patients (46%) were not treated with argatroban. We concluded that clinical suspicion of HIT as detected by clinical probability score and thrombotic complications should prompt immediate cessation of heparin and initiation of an alternative anticoagulant such as argatroban.[16]

Desirudin

Desirudin (another recombinant hirudin) is approved in the United States for the prophylaxis of DVT, which may lead to PE in patients undergoing elective hip replacement surgery. Of note, desirudin has also been studied extensively in patients with stable angina undergoing PTCA. Because desirudin is primarily eliminated by the kidneys, patients with renal impairment require monitoring, and activated partial thromboplastin time (aPTT) can be used. However, this agent is seldom used, especially with the availability of the non–vitamin K oral anticoagulation agents.[17]

ORAL ANTICOAGULANTS

Vitamin K Antagonists: Warfarin

Warfarin is the only oral VKA agent available in the United States.[18] It is an effective anticoagulation agent by inhibiting vitamin K epoxide reductase that converts the vitamin K–dependent coagulation proteins (factors II [prothrombin], VII, IX, and X) to their active form as a posttranslational modification. One of the reasons that warfarin's onset is so slow is that it takes several days to decrease coagulation factors to the ~20%–40% level that is required for a therapeutic international normalized ratio (INR) of 2–3.[18]

Managing warfarin in the ICU setting is complicated and often bridged initially. However, in the bleeding patient, vitamin K will not immediately reverse the anticoagulant effect, and additional therapies are needed, as detailed in the guidelines for perioperative management by Douketis and colleagues in the American College of Chest Physicians (ACCP) guidelines and summarized in "ICU/Perioperative Management of Antithrombotic Therapy."[19] The ACCP guidelines also recommend the use of a four-component prothrombin complex concentrate (e.g., Kcentra/Beriplex, CSL Behring [King of Prussia, PA]; or Octaplex, Octapharma [Lachen, Switzerland]) for urgent warfarin reversal when required for bleeding or surgical interventions.[18] Additional considerations for warfarin reversal are reviewed next.

New Oral Agents: Apixaban, Dabigatran, Edoxaban, and Rivaroxaban

The non–vitamin K direct oral anticoagulation agents (DOACs) have a rapid onset, with therapeutic anticoagulation within hours of administration.[20] Dabigatran is an oral direct thrombin inhibitor, and apixaban, edoxaban, and rivaroxaban are direct factor Xa inhibitors similar to LMWH but independent of antithrombin.[17] Edoxaban has been recently approved and will not be further discussed. The new agents require dose adjustments for renal failure and will be considered separately.[17]

Apixaban

Apixaban is a factor Xa inhibitor anticoagulant approved for reducing the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation and for the prophylaxis of DVT, which may lead to PE in patients who have undergone hip or knee replacement surgery, for the treatment of DVT and PE, and for the reduction in the risk of recurrent DVT and PE after initial therapy.[20] If bleeding occurs and measurement of its effects is needed, then using a specific calibrated anti-Xa assay, similar to what is used for LMWH, is needed. However, measuring the effects of Xa inhibitors can be difficult.[17] The formulation can be crushed and given through a feeding tube if required in the ICU setting.

Dabigatran Etexilate

Dabigatran etexilate is an oral direct thrombin inhibitor currently approved to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation, for the treatment of DVT and PE in patients who have been treated with a parenteral anticoagulant for 5–10 days, and to reduce the risk of recurrence of DVT and PE in patients who have been previously treated.[20] Dabigatran has a rapid onset of action and no requirement for routine coagulation monitoring.

Dabigatran's effects can be measured best by tests similar to any direct thrombin inhibitor, including aPTT values, thrombin times, diluted thrombin times, or ecarin clotting times.[17,20] A specialized assay that uses a diluted thrombin time is helpful for the specific measurement of levels when needed and is sensitive to lower levels. However, the aPTT is still a good screening test and closely correlated with more sensitive assays in the larger clinical study. Dosing should also be adjusted for patients with renal dysfunction. The capsule is specially formulated and cannot be altered or crushed for administration in an ICU setting. A specific monoclonal antibody is in clinical trials for acute reversal of dabigatran and will be discussed later.

Rivaroxaban (Xarelto)

Rivaroxaban is a direct-acting factor Xa inhibitor, which, unlike heparins, does not require antithrombin.[20] Rivaroxaban has the broadest indications that include reduction of the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation; for the treatment of DVT and PE and for the reduction in the risk of recurrence of DVT and of PE; for the prophylaxis of DVT for knee or hip replacement surgery; and in combination with aspirin to reduce major cardiovascular events in patients with chronic coronary or peripheral artery disease. Rivaroxaban has also been recently approved for VTE prophylaxis in hospitalized acutely ill medical patients. If bleeding occurs and measurement of its effects are needed, then using a specific calibrated anti-Xa assay, similar to what is used for LMWH, is needed. The formulation can be crushed and given through a feeding tube, if required, in the ICU setting.

Edoxaban (Savaysa)

Edoxaban, a direct-acting factor Xa inhibitor, is approved to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation and for the treatment of DVT and PE in patients who have been treated with a parenteral anticoagulant for 5–10 days.[20]

Other Agents

Citrate for Regional Anticoagulation

In patients with acute renal failure, citrate is increasingly used as an anticoagulant for continuous renal replacement therapy (CRRT) in ICU patients to maintain circuit and filter patency. Although heparin is often used, ICU patients are routinely coagulopathic, may have either an increased risk of bleeding or hypercoagulability, and are often at high risk for developing HIT. As a result, regional citrate is effective by locally chelating ionized calcium. The goal citrate level to inhibit clotting is 4–6 mmol/L which corresponds to a prefilter ionized calcium of <0.35 mmol/L.[21] Most of the calcium–citrate complex is removed during CRRT, and calcium is infused to maintain normocalcemia.[21]

ICU Management of the Oral Anticoagulants

In the ICU, oral therapy often is not feasible, and parenteral agents need to be considered. In renal failure, heparin and argatroban are most often used, and bivalirudin offers an alternative, but all of these agents require monitoring. The direct thrombin inhibitors are routinely monitored using partial thromboplastin times. However, for urgent reversal or management of the bleeding patients, significant concerns have been expressed about the new agents, but despite the

extensive use of LMWH in the ICU, there is no antidote available, and LMWH accumulates in renal failure, requiring dose adjustments. The Xa inhibitor agents apixaban and rivaroxaban can be used in ICU settings and administered through a feeding tube, if needed, in patients who cannot take oral medications.

In the United States, warfarin is still a problem for clinicians because the balanced prothrombin complex concentrates (PCCs) that contain all four factors (II, VII, IX, and X), like KCENTRA for immediate INR reversal, are not readily used by clinicians but are recommended in recent ACCP guidelines.[18] Vitamin K takes days to work; ~4 units of fresh frozen plasma (FFP) are required, with transfusion risk issues and volume overload; and FFP never restores the INR to baseline but usually to ~1.4–1.6, which is the baseline INR for FFP.[18]

Managing Bleeding with the New Oral Anticoagulants

If patients are acutely bleeding, the new agents, as mentioned, can be evaluated with specialized tests that should be measured in such patients. For dabigatran, thrombin times (TTs) and a diluted TT and ecarin clotting times (used in Europe) are the most sensitive. The aPTT can measure its effects, although it is not as sensitive as a TT.[20] The aPTT potentially provides a qualitative assessment of anticoagulation. Although there currently is no specific antidote to antagonize the anticoagulant effect of all of the agents, with normal renal function, these agents have a relatively short duration of effect, are direct acting, and drugs should be discontinued when risks of bleeding exceed risks of thrombosis.

With bleeding, patients should be hemodynamically and hemostatically resuscitated, and therapy should be multimodal.[20] Dabigatran can be immediately reversed with the antidote idarucizumab (Praxbind), which is widely available in most institutions and has been studied in a variety of medically ill, critically ill, and surgical patients.[22,23] For reversal of factor Xa inhibitors, including apixaban and rivaroxaban, a specific antidote currently available is andexanet alfa.[24] However, this agent has been studied primarily in patients with intracranial hemorrhage and gastrointestinal (GI) bleeding, but is approved for reversal of Xa inhibitor anticoagulation when needed as a result of life-threatening or uncontrolled bleeding. In instances of life-threatening bleeding, the off-label use of other prohemostatic agents such as PCCs has been reported.[20,25,26] As noted, PCCs are increasingly considered in guidance documents as part of a multimodal approach for bleeding management. Guidance for the use of specific reversal agents has been reported.[27]

The major concerns in the ICU are emergency procedures or major bleeding. However, newer information is available to facilitate managing patients receiving DOACs. Important management of the DOACs is discontinuing use, but if reversal is required, specific therapeutic approaches should be considered and include the application of PCCs for reversal and/or bleeding. PCCs in the United States are available in four components (KCENTRA) or three components (Profilnine and Bebulin).[18] The three-component PCCs are deficient in factor VII. Multiple reports have noted the ability of PCCs to treat DOAC-associated bleeding, and there are increasing reports on their off-label use in bleeding after surgery or traumatic injury.[28,29]

Despite concerns about NOACs and bleeding, most studies suggest patients fare better on NOACs compared with warfarin.[30] In one study of 27,419 patients treated up to 3 years, 1034 patients had 1121 major bleeds. The 30-day mortality after the first major bleed was 9.1% in the dabigatran group compared with 13.0% in the warfarin group, and dabigatran-treated patients required a shorter ICU stay compared with warfarin.[30]

PLATELET INHIBITORS

Patients with ischemic cardiovascular and atherosclerotic vascular disease are often receiving platelet inhibitors as anticoagulants—agents that also increase the risk for bleeding.[31,32] Aspirin is an irreversible platelet cyclooxygenase and thromboxane A_2 inhibitor but is also a relatively weak antiplatelet agent, and resistance can occur.[31] More potent antiplatelet agents include the $P2Y_{12}$ receptor antagonists clopidogrel, prasugrel, and ticagrelor that selectively bind to the $P2Y_{12}$ receptor to inhibit the adenosine diphosphate–dependent mechanism of glycoprotein IIb/IIIa receptor expression and platelet activation.[31,33] Clopidogrel, now a generic drug, is the major agent used. Clopidogrel and prasugrel are both prodrugs, whereas ticagrelor is a direct-acting agent. One of the clinical issues regarding clopidogrel is the potential for altered responsiveness, often defined as resistance, compared with ticagrelor, which is a direct-acting agent.[34] Dual antiplatelet therapy with aspirin and clopidogrel is standard care after revascularization by PCI with stent insertion, during acute coronary syndromes, and for percutaneous intervention.[33] Intravenous agents include the IIb/IIIa receptor antagonists abciximab, tirofiban, and eptifibatide, but also a short-acting $P2Y_{12}$ inhibitor cangrelor that is increasingly used for bridging in short-term therapy, especially in ICU settings when the patient may need intermittent procedural interventions.[32]

Glycoprotein IIb/IIIa inhibitors that include abciximab (a monoclonal Fab fragment), eptifibatide (a polypeptide), and tirofiban (a synthetic molecule) are still used as intravenous antiplatelet therapies that prevent platelet aggregation by competitive inhibition with fibrinogen and von Willebrand factor. Tirofiban and eptifibatide have relatively short half-lives of approximately 2–3 hours, compared with abciximab, a monoclonal antibody with an approximately 12-hour half-life.

Cangrelor is the most recently approved intravenous agent that has a rapid onset with a 3- to 6-minute half-life and rapid recovery within 30–60 minutes after stopping the infusion, with clearance independent of renal function. Cangrelor is often used for short-term use in ICU settings when antiplatelet effects are needed and was approved by the Food and Drug Administration as an adjunct to PCI to reduce the risk of MI, repeat coronary revascularization, and stent thrombosis in patients who have not been treated with a $P2Y_{12}$ platelet inhibitor or a glycoprotein IIb/IIIa inhibitor. Beyond the PCI program, cangrelor has also been evaluated in the clinical bridging study in patients with acute coronary syndrome or coronary stent who had received a $P2Y_{12}$ platelet inhibitor and were awaiting surgical coronary revascularization. Patients were randomized to cangrelor or placebo and reported no differences in surgery-related bleeding, and there were no safety signals. In an ICU setting, cangrelor bridging using a 0.75 mcg/kg/min infusion can be started for 3–4 days after prasugrel discontinuation and 2–3 days after clopidogrel or ticagrelor discontinuation and provides an important method for management.[35]

ICU/PERIOPERATIVE MANAGEMENT OF ANTITHROMBOTIC THERAPY

The most recent guidelines from the ACCP in 2012 recommend stopping VKAs 5 days before surgery instead of a shorter time before surgery (Grade 1B).[19]

In patients with a mechanical heart valve, atrial fibrillation, or VTE at high risk for thromboembolism, they suggest bridging anticoagulation instead of no bridging during VKA interruption (Grade 2C); in patients at low risk, they suggest no bridging instead of bridging (Grade 2C). In patients who require a dental procedure, they suggest continuing VKAs with an oral prohemostatic agent or stopping VKAs 2–3 days before the procedure instead of alternative strategies (Grade 2C).[19]

In moderate- to high-risk patients who are receiving acetylsalicylic acid (ASA) and require noncardiac surgery, they suggest continuing ASA around the time of surgery instead of stopping ASA 7–10 days

before surgery (Grade 2C). In patients with a coronary stent who require surgery, they recommend deferring surgery >6 weeks after bare-metal stent placement and >6 months after drug-eluting stent placement instead of undertaking surgery within these periods (Grade 1C); in patients requiring surgery within 6 weeks of bare-metal stent placement or within 6 months of drug-eluting stent placement, they suggest continuing antiplatelet therapy perioperatively instead of stopping therapy 7–10 days before surgery (Grade 2C).[19] In all patients, relative risk versus benefit must be considered when managing patients.

For warfarin management, the BRIDGE study randomized warfarin anticoagulation with LMWH using 100 U dalteparin/kg or placebo from 3 days before a procedure until 24 hours before, then for 5–10 days after.[36] Warfarin was stopped 5 days before the procedure and was resumed within 24 hours after. Of the 1884 patients studied, arterial thromboembolism was 0.4% in the without bridging group compared with 0.3% with bridging, and major bleeding was 1.3% in the without bridging group compared with 3.2% with LMWH bridging.[36]

For DOAC management, the Perioperative Anticoagulation Use for Surgery Evaluation (PAUSE) cohort study was a multinational study of,Ãâ3007 atrial fibrillation patients who were receiving apixaban, dabigatran etexilate, or rivaroxaban and scheduled for an elective surgery or procedure.[37] The study was designed based on pharmacokinetics, procedure-associated bleeding risk, and renal function. In low-bleeding-risk patients, DOACs were discontinued for 1 day before, and for high-risk bleeding 2 days before, and restarted 1 day or 2–3 days post procedure, respectively. Major bleeding and arterial thromboembolic events and the number of undetectable or minimal residual anticoagulant level (<50 ng/mL) at the time of the procedure were determined. There was no difference in major bleeding that occurred in 1.35% of the apixaban group, 0.90% in the dabigatran group, and 1.85% of the rivaroxaban group. The rate of arterial thromboembolism was 0.16%, 0.60%, and 0.37%, respectively, and major bleeding occurred in approximately 3% of patients.[37]

KEY POINTS

- Anticoagulation is a critical aspect of cardiovascular disease management, and patients are increasingly presenting or requiring anticoagulation in an ICU setting.
- Heparin continues to be the mainstay of therapy because of its short half-life, the ability to use with renal dysfunction, and reversibility.
- Critically ill patients receiving heparin infusion should be monitored for thrombocytopenia and the potential risk for HIT.
- Patients may require other types of anticoagulants in ICU settings, including intravenous bivalirudin and argatroban or alternative therapies.
- LMWH, although extensively used, is renally eliminated, with prolongations of the half-life in patients with renal dysfunction.
- Patients may be receiving the new non–vitamin K oral anticoagulants; currently, reversal strategies are available for emergent and urgent reversal.
- For emergent and urgent reversal of warfarin anticoagulation, PCC should be used based on guidelines and other supporting data.
- Bridging for procedural interventions in patients receiving warfarin and non–vitamin K oral anticoagulants may not be necessary based on new data and guidelines.
- New shorter-acting intravenous antiplatelet agents are available, including cangrelor, that can be used in ICU settings when patients may require frequent procedural interventions.

Monitoring of Coagulation Status

Ashley Thompson

OVERVIEW OF EFFECTIVE COAGULATION

Components of Hemostasis

Fig. 129.1 depicts an overview of hemostasis. In a normal physiologic state, the body maintains a fine balance between hemorrhage and thrombosis through the regulation of various anticoagulant and prothrombotic systems. Four primary factors contribute to normal hemostasis. These factors are the vascular endothelium, platelets, coagulation factors, and fibrinolytic system.

The vascular endothelium is capable of evoking both antithrombotic and prothrombotic events. Under normal conditions, endothelial cells release prostacyclin and nitric oxide to inhibit platelet activation and promote vasodilation. After a tissue injury, vessel walls vasoconstrict to slow blood flow. Collagen and tissue factor (TF) are exposed and come in contact with blood. The exposed collagen initiates the accumulation and activation of platelets at the site of injury, while the TF triggers activation of coagulation factors. Once hemostasis has been obtained, the endothelium releases tissue plasminogen activator (tPA), activating fibrinolysis.[1,2]

Platelets contribute their hemostatic capacity via adhesion, activation, and aggregation.[3] Following the breach in the vessel wall, multiple signaling pathways are initiated that ultimately result in platelet activation. Once a platelet has been activated, additional platelets are recruited from the circulating blood to form a platelet plug via platelet–platelet cohesion. Thromboxane A_2, an eicosanoid produced by activated platelets, functions in an autocrine or paracrine manner to stimulate for further platelet aggregation.[4] The formation of the platelet plug is known as *primary hemostasis.*

After the nascent platelet plug is formed, it is stabilized by the formation of a fibrin mesh. The process by which this occurs is known as the *coagulation cascade* and is initiated by the exposure of tissue factor on the endothelial surface. The coagulation cascade consists of multiple factors that undergo a series of reactions that ultimately result in thrombin converting fibrinogen to fibrin.[5] The fibrin meshwork stabilizes the platelet plug, forming a clot. This stabilization phase is also known as *secondary hemostasis.*

The fourth factor in normal hemostasis is the fibrinolytic system. Once the vasculature has been repaired, plasmin breaks down the fibrin strands, resulting in clot degradation. Of note, there are antithrombotic control mechanisms that prevent spontaneous intravascular coagulation and excessive clotting. These include thrombomodulin, tPA, antithrombin, proteins C and S, and prostaglandins.[6]

Cell-Based Model of Hemostasis

The pathway by which hemostasis is obtained has traditionally been described by the extrinsic, intrinsic, and common pathways of the coagulation cascade. This classical model has been largely replaced with a "cell-based" model that incorporates the central role that cell surfaces play in coagulation. The cell-based model suggests that the process of coagulation occurs on different cell surfaces and occurs in three overlapping stages, which are initiation, amplification, and propagation.[7,8]

The initiation phase of the cell-based model occurs on the surface of TF-bearing cells (including immunostimulated endothelial cells, fibroblasts, and monocytes). The TF interacts with and activates factor VII (FVII), forming the TF–FVIIa complex. This complex activates factor IX and factor X, which leads to the generation of a small amount of thrombin. This initial thrombin is essential for the activation of platelets and factors V and VIII.

The amplification and propagation phases occur on the surface of platelets. During amplification, the procoagulant signal is shifted from the TF-bearing cells to the activated platelets. This allows for diffusion of factor IXa, which activates the intrinsic pathway and subsequently leads to large-scale thrombin generation. In the propagation phase, factor VIIIa interacts with factor IXa forming the FVIIIa/FIXa complex, which is a powerful activator of factor X. Factor Xa forms a complex with factor Va, which catalyzes prothrombin to thrombin. This FXa/Va complex is 300,000-fold more active than factor Xa alone in catalyzing prothrombin activation.[9]

BASIC NECESSARY CONDITIONS FOR PROPER HEMOSTASIS

Maintaining physiologic homeostasis between prothrombotic and excessive bleeding states requires a number of regulatory processes. Each component of the process of hemostasis can be disturbed, resulting in coagulopathy. Conditions that have been shown to cause coagulopathy include hypothermia, acidosis, and hypocalcemia.

Hypothermia may be a deliberately induced therapeutic maneuver or a consequence associated with trauma, surgery, or exposure. This can be exacerbated in patients who have sustained blood loss and are undergoing physiologic compensation with vasoconstriction. At a core temperature of less than 33°C, the coagulation cascade is impaired, platelet physiology is altered, and microvascular hypoperfusion is exacerbated.[10] In turn, this worsens the degree of acidosis. Hypothermia decreases coagulation factor activity by 10% for each degree decrease in core temperature.[11,12] Platelet adhesion is reduced by 33% at 33°C compared with 37°C and further reduced by 47% at 23°C.[13] In the nontrauma population, isolated hypothermia of 32.2°C leads to a 23% mortality rate, whereas in the trauma population, mortality approaches 100% when the core temperature reaches 32°C.[14,15]

Acidosis has been shown to be one of the most important predictors in coagulopathy.[16] The optimal pH for proteolytic activity of coagulation enzymes is well above physiologic pH.[17] When the pH drops

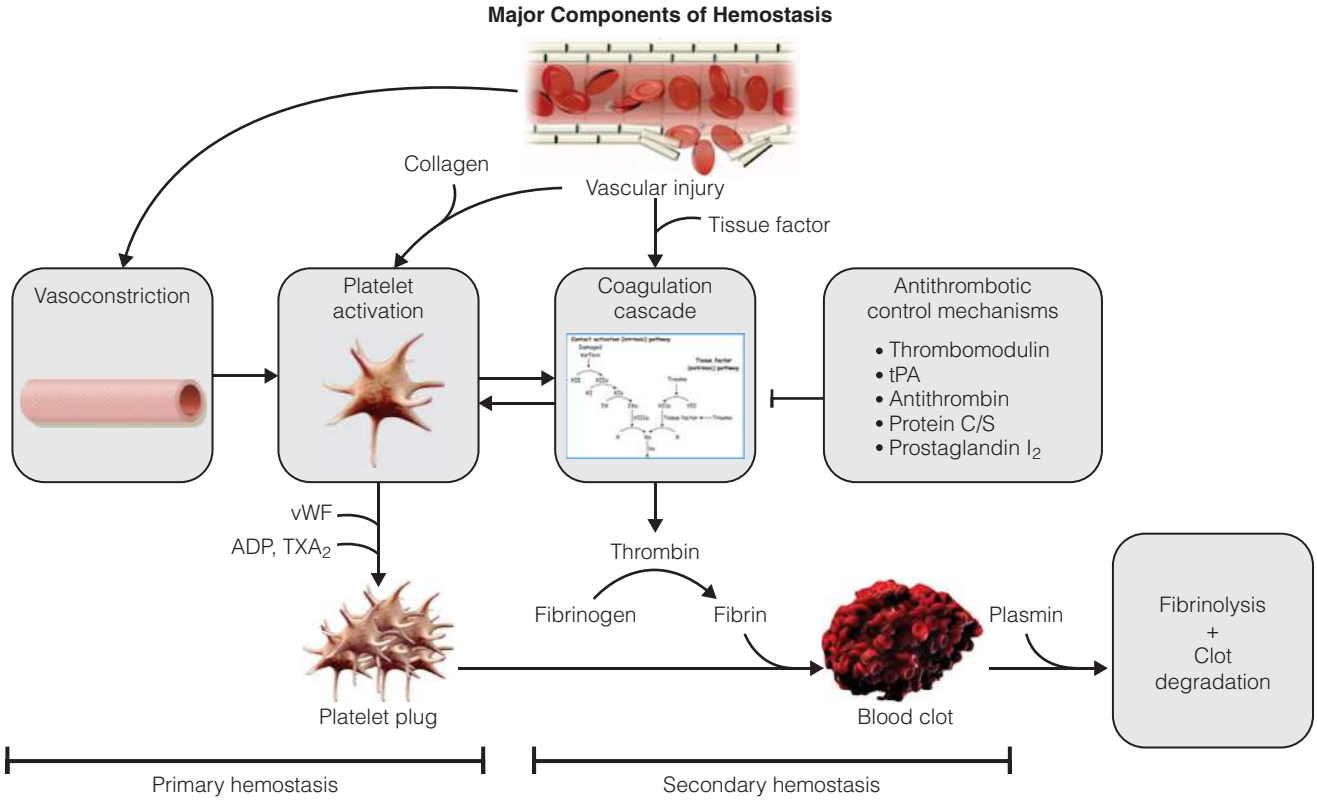

Fig. 129.1 Overview of the components of hemostasis. Immediately after vascular injury, the endothelium vasoconstricts, collagen exposure leads to platelet activation, and exposed tissue factor initiates the coagulation cascade. Activated platelets release factors, which ultimately result in the formation of a platelet plug, a process known as primary hemostasis. The coagulation cascade leads to the activation of thrombin, which promotes fibrin cross-linking. The fibrin stabilizes the platelet plug, resulting in the formation of a blood clot. This series of enzymatic reactions is known as secondary hemostasis. The clot will eventually undergo degradation via plasmin and fibrinolysis. *ADP,* Adenosine diphosphate; *tPA,* tissue plasminogen activator; *TXA_2,* thromboxane A_2; *vWF,* von Willebrand factor.

below 7.1, the ability of thrombin and fibrinogen to propagate a clot is severely diminished.[18] The activity of FVII is reduced by 90%, which leads to more blood loss and furthers the cycle. Platelets lose their ability to change shape when a patient becomes acidotic, which in turn hinders their ability to form a clot.

Ionized calcium is a necessary cofactor in the coagulation cascade. Citrate anion is capable of binding (chelating) ionized calcium, and this is how the citrate component of acid citrate dextrose (ACD) buffer used in blood storage leads to anticoagulation. Patients who have received massive resuscitation with citrated blood products should receive appropriate calcium replacement. Additionally, it has been hypothesized that hypocalcemia is associated with poor clot strength in critically ill patients, particularly for ionized calcium levels of <1.0 mmol/L.[19–21]

LABORATORY ANALYSIS FOR COAGULATION

Measures of Coagulation

Traditionally, the most commonly used clotting assays include prothrombin time (PT) or international normalized ratio (INR), activated partial thromboplastin time (aPTT), thrombin time (TT), and fibrinogen level. Each of these tests has limitations in that they are performed in plasma and do not reflect in vivo hemostasis. Therefore it is important to consider the patient's drug history, family history of coagulation disorders, and personal history of coagulopathies.

PT and aPTT are measures taken from the acellular, platelet-depleted plasma component of a citrated blood sample that has been centrifuged. The PT measures the time taken for clot formation after thromboplastin and calcium have been added to the sample. Several different thromboplastin reagents are commercially available with varying sensitivities. Therefore to standardize the PT assay, individual reagents are compared with a World Health Organization standard reference and assigned an international standardized index (ISI) value.[22] The ISI is then used to calculate the INR. The PT measures the extrinsic and common pathways and will be affected by the plasma concentrations of factors II, V, VII, and X and fibrinogen.

The aPTT measures the time taken for clot formation after the addition of calcium, phospholipid (partial thromboplastin), and a contact activator to the acellular plasma sample. aPTT evaluates the intrinsic pathway and will be prolonged with deficiencies of factors II, V, VIII, IX, X, XI, and XII or fibrinogen. Of note, the PT and aPTT are helpful in identifying factor deficiencies but cannot assess overall risk of hemorrhage.[23]

TT is measured by adding thrombin to platelet-depleted plasma and evaluating the conversion of fibrinogen to fibrin. TT may be used as a screening test for the detection of qualitative and quantitative fibrinogen abnormalities or fibrin formation disorders and is very sensitive to the presence of heparin or direct thrombin inhibitors in the sample.[24] Of the multitude of available coagulation assays, this is one of the most procedurally simple.

Fibrinogen levels can be helpful in the investigation of a prolonged PT or aPTT. Many methods have been used to measure plasma fibrinogen concentration, including gravimetric, immunologic (antigen-based),

optical, and functional assays. The most commonly used are the Clauss and prothrombin time–derived methods. The Clauss assay is a quantitative, clot-based, functional assay that measures the ability of fibrinogen to form a fibrin clot after being exposed to a high concentration of purified thrombin. This method does not measure fibrinogen directly, but determines the time until detectable clot formation.[25] Similarly, the PT-derived method is not a direct determination of plasma fibrinogen, but rather estimates fibrinogen based on absorbance changes during a prothrombin time assay. Thromboelastogram (TEG) and rotational thromboelastometry (ROTEM) are newer technologies that can be used to provide a qualitative indication of the fibrinogen concentration. These are discussed in further detail later in the chapter.

Measures of Platelet Disorders

Platelet count does not provide a functional assessment of platelets, but a low platelet count is associated with increased risk of bleeding and mortality.[26] Thrombocytopenia is defined as a platelet count below the lower limit of normal (150,000/μL). Spontaneous bleeding can occur with a platelet count less than 10,000/μL, and it is recommended that patients with counts below this level should receive a prophylactic platelet transfusion.[27] Guidelines often recommend a transfusion threshold of 50,000/μL before major surgery or if actively bleeding and 100,000/μL before surgery involving the brain or eyes.[28] Of note, a normal platelet count does not preclude platelet dysfunction.

The differential diagnosis for platelet dysfunction is broad and includes inherited syndromes in addition to acquired causes such as uremia, myelodysplasia, and drug-induced. These patients may present with ongoing bleeding in the setting of a normal platelet count. Numerous methodologies for assessment of platelet function are available. These include bleeding time, light transmission platelet aggregation (LTA), lumiaggregometry, impedance aggregometry on whole blood, platelet analysis based on flow cytometry, and platelet function methods combined with viscoelastic testing (TEG/ROTEM). The most commonly used tests rely on a platelet agonist (e.g., adenosine diphosphate [ADP], epinephrine, ristocetin, thrombin receptor agonist peptide [TRAP]), exposure to shear stress, or both to activate platelets. These tests monitor the rate of platelet aggregation through changes in light transmission, light scattering, electrical impedance, platelet aggregation on a plate, or occlusion of a tube.[29,30]

The platelet function analyzer (PFA-100) is a tool that analyzes primary hemostasis. A sample (<1 mL) of citrated blood is exposed to high shear stress within a capillary tube coated with collagen and either ADP or epinephrine. The shear stress and agonists in the membrane activate the platelets, leading to platelet aggregation. The flow rate is monitored and the time at which blood flow stops because of aperture occlusion of aggregated platelets, known as *closure time,* is reported.[31] The closure time will be abnormal in patients with congenital platelet dysfunction, von Willebrand disease, or recent aspirin ingestion. Anemia and thrombocytopenia may prolong closure time and, in general, the test is not useful in patients with a platelet count less than 80,000/μL or hematocrit <30%.[32]

The Multiplate multiple electrode aggregometry (MEA) analyzer (Roche Diagnostics, Mannheim, Germany) is a point-of-care test of platelet function that exposes platelets to platelet activators and monitors aggregation using the principle of impedance. A 300-μL sample of whole blood is obtained and diluted with saline. After incubation for 3 minutes, a platelet agonist is added and subsequent aggregation is recorded at 0.5-second intervals for 6 minutes. This test is commonly used to monitor treatment with antiplatelet agents such as aspirin and P2Y12 antagonists and has been evaluated as a potential predictor of bleeding risk in cardiac surgery and trauma patients.[33,34] Of note, unlike whole-blood clotting assays, the benefit of dedicated PFAs is their ability to reliably detect the effect of platelet antagonists.[35]

Viscoelastic Hemostatic Assays

Viscoelastic hemostatic assays (VHAs) are whole-blood tests that dynamically assess clotting time, clot strength, and clot lysis by continuously measuring the kinetics of all stages of clot formation. Two commercially available systems are available in the United States: TEG (Haemonetics, Braintree, MA) and ROTEM (Penthapharm, Basel, Switzerland). To perform these tests, a pin suspended by a torsion wire is lowered into a heated cup filled with whole blood. Either the cup (TEG) or the pin (ROTEM) is alternately rotated clockwise or counterclockwise. As the blood clots, strands of fibrin form between the cup and the pin, transmitting the torque of the cup to the torsion wire. The torque is continuously recorded and displayed as a graph.[36–38]

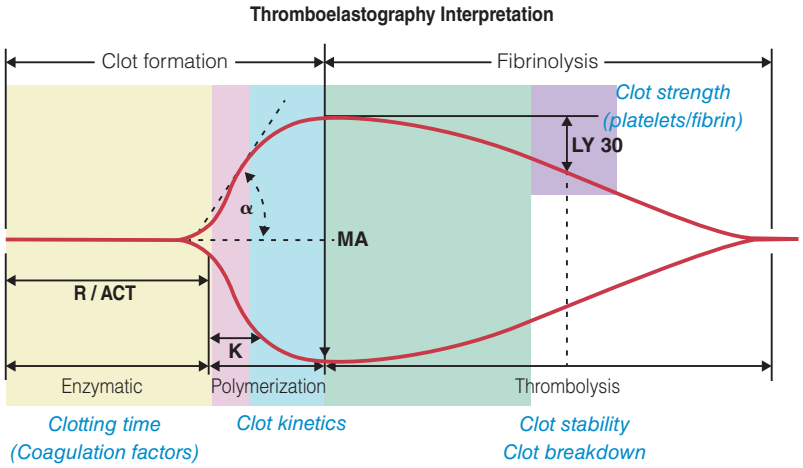
Fig. 129.2 depicts a TEG waveform and its interpretation. The data obtained from TEG and ROTEM are similar, but not interchangeable, because of differences in the methods and nomenclature. The time it takes to start forming a clot (reaction [R] time in TEG, clotting time [CT] in ROTEM) is the time from sample placement until the tracing amplitude reaches 2 mm. The kinetic time (K-time) in TEG, or clot formation time (CFT) in ROTEM, represent the time it takes for the clot to reach a fixed strength. Graphically, this is the time elapsed between the R-time and the point where the tracing amplitude reaches 20 mm. The angle is the speed of fibrin accumulation and is created from the developing curve from the point of clot initiation. Maximal amplitude (MA) in TEG or maximal clot firmness (MCF) in ROTEM is a function of the fibrin and platelet bonding. This represents the strongest point in the clot formation and correlates with platelet function. Lastly, clot dissolution is measured to evaluate for fibrinolysis. In TEG, lysis is measured at 30 and 60 minutes after the MA is recorded. In ROTEM, the lysis index 30 represents the percent reduction from MCF 30 minutes after CT.[39]

An individual's TEG/ROTEM results are compared with reference values. Deviation of these results from the reference values suggests specific disturbances of hemostasis. A prolonged R or clotting time represents a qualitative or quantitative deficiency in clotting factors, which may be corrected with the administration of fresh frozen plasma (FFP). A decreased alpha-angle or prolonged K-time/CFT indicates a fibrinogen deficiency that may be corrected with cryoprecipitate or lyophilized fibrinogen. A low MA/MCF suggests a functional or quantitative deficiency of platelets, which may be corrected with administration of desmopressin or a platelet transfusion. Increased lysis values indicate active fibrinolysis, which may be treated with fibrinolysis inhibitors such as tranexamic acid.

The primary advantage to TEG/ROTEM is the ability to deliver immediate, point-of care data for a bleeding patient using less than half of a milliliter of blood. VHAs provide a global assessment of coagulation, including coagulation factors, platelet function, and fibrinolysis. This information can be used to guide transfusion therapy and potentially decrease the use of blood products.[40,41] A 2016 Cochrane review determined that there is growing evidence that the use of TEG- or ROTEM-guided transfusion strategies may not only reduce the need for blood products but also may improve the morbidity in bleeding patients.[42]

Disseminated Intravascular Coagulation Score

Disseminated intravascular coagulation (DIC) is characterized by systemic overactivation of coagulation. Some inciting factor causes an overwhelming inflammatory response, which results in upregulation of tissue factor while simultaneously impairing physiologic anticoagulation and fibrinolysis. As a result, there is widespread fibrin deposition and microvascular thromboses. The formation of all of these clots results in consumption of coagulation factors, platelets, and anticoagulants. In laboratory studies, low platelet counts, prolonged PT/PTT, low fibrinogen levels, and elevated D-dimer can be seen.



TEG value	Normal	Description	Problem	Treatment
R-time	5–10 min	"Reaction time" = time to start forming clot	Coagulation factors	FFP
K-time	1–3 min	"Kinetic time" = time until clot reaches a fixed strength	Fibrinogen	Cryoprecipitate
α-angle	53–72 degrees	Speed of fibrin accumulation	Fibrinogen	Cryoprecipitate +/– platelets
MA	50–70 mm	"Maximum amplitude" = highest vertical amplitude of the TEG; corresponds to platelet function	Platelets	Platelets and/or DDAVP
LY 30	0–3%	Percentage of amplitude reduction 30 minutes after maximum amplitude	Excess fibrinolysis	TXA and/or aminocaproic acid

Fig. 129.2 Interpretation of thromboelastography waveform. Thromboelastography (*TEG*) is reported as a graph of the formation of a clot in a sample of whole blood. The tracing demonstrates the rate of clot formation, clot strength, fibrin cross-linking, platelet function, and the speed of clot degradation. Based on these data, the problematic components of the coagulation pathway can be identified and appropriately treated. *DDAVP,* Desmopressin; *FFP,* fresh frozen plasma; *LY 30,* lysis index 30; *TXA,* tranexamic acid.

DIC is always secondary to an underlying condition such as severe infection, solid or hematologic malignancies, trauma, or obstetric issues. Up to 35% of cases of severe sepsis may be complicated by DIC, and the severity of DIC has been shown to correlate with mortality in these patients.[43–45] In major trauma, DIC has been shown to approximately double the mortality rate.[46] A reliable diagnosis can be made using the International Society of Thrombosis and Hemostasis DIC Scoring Algorithm depicted in Table 129.1. Based on the platelet count, fibrinogen level, PT, and D-dimer, a DIC score can be calculated. A score of 5 or more has a sensitivity of 93% and specificity of 98% for diagnosing DIC.[47] The cornerstone treatment for DIC is supportive care and management of the underlying condition.

TABLE 129.1 International Society of Thrombosis and Hemostasis DIC Scoring Algorithm

DIC SCORE		
Parameter	**Value**	**Score**
PT	≤3 s	0
	3–6 s	1
	>6 s	2
Fibrinogen	>100 mg/dL	0
	<100 mg/dL	1
D-dimer	<400 ng/dL	0
	400–4000 ng/mL	2
	>4000 ng/mL	3
Platelets	>100,000/μL	0
	50,000–100,000/μL	1
	<50,000/μL	2
Score Interpretation:		
<5: Not suggestive of overt DIC, may be nonovert DIC; repeat within next 1–2 days and manage clinically as appropriate		
≥5: Compatible with overt DIC; treat for DIC as appropriate and repeat scoring daily

MONITORING ANTICOAGULATION

Unfractionated Heparin, Low-Molecular-Weight Heparin, and Fondaparinux

Unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), and fondaparinux all require antithrombin (AT) activation to express their anticoagulant effect. UFH binds to and potentiates the action of AT to inactivate factor Xa, preventing the conversion of prothrombin to thrombin and of fibrinogen to fibrin. LMWH similarly binds to and accelerates the activity of AT, but with a preferential and longer-lasting effect on factor Xa. Fondaparinux is essentially a synthetic derivative of LMWH that enhances the anti-Xa activity of AT by greater than 300-fold and has no direct effect on thrombin.[48] UFH can be monitored with aPTT until higher plasma concentrations are achieved, at which time an activated clotting time (ACT) is needed to accurately assess anticoagulation.

LMWH and fondaparinux do not uniformly affect the aPTT and anti-Xa assays calibrated to the particular agent are necessary for monitoring.[49]

Vitamin K Antagonists

Vitamin K is a fat-soluble vitamin that is an essential cofactor in the conversion of clotting factors II, VII, IX, and X into their active form. Vitamin K antagonists (VKAs) have been the mainstay of long-term anticoagulation therapy for more than 50 years. The most commonly used VKA is warfarin, sold under the brand name Coumadin. VKAs have a narrow therapeutic range and therefore require regular monitoring. The degree of anticoagulation is reliably measured with the INR of the PT.

Direct Oral Anticoagulants: Dabigatran, Apixaban, and Rivaroxaban

Direct oral anticoagulants (DOACs), also collectively known as *non–vitamin K oral anticoagulants* (NOACs), are a relatively newer class of drugs shown to have equal, if not superior, efficacy while maintaining a better safety profile and requiring less monitoring than VKAs.[50] Apixaban and rivaroxaban are direct factor Xa inhibitors. Both of these drugs can alter the PT and PTT, though this effect is not reliable, and normal values do not preclude clinically relevant drug concentrations. Anticoagulation can be measured with anti-Xa assays that are calibrated for the specific drug, though routine monitoring is not indicated. Dabigatran is a direct thrombin inhibitor (DTI) and is the only oral DTI available. Similar to the factor Xa inhibitors, dabigatran is generally given at a fixed dose without monitoring. If coagulation testing is needed, dilute thrombin time and ecarin clotting time can be used to quantify plasma drug levels.[49,51]

Parenteral Direct Thrombin Inhibitors: Argatroban and Bivalirudin

Argatroban and bivalirudin are synthetic peptide-based parenteral DTIs that are most commonly used in patients undergoing percutaneous coronary interventions (PCIs) and in those with heparin-induced thrombocytopenia (HIT). DTIs prolong the aPTT, PT/INR, and ACT. Monitoring is performed using ACT or aPTT.[52] Of note, as argatroban prolongs the INR, it should be discontinued while transitioning to warfarin if the INR is greater than 4 with an aPTT within goal range.[52]

Antiplatelet Agents

Antiplatelet medications can be classified based on their mechanism of action. The most common are the platelet aggregation inhibitors, which include cyclooxygenase enzyme (COX) inhibitors (aspirin) and oral thienopyridines (clopidogrel, ticagrelor, prasugrel). Monitoring is generally not required for antiplatelet medications. If bleeding is present, bleeding time may be used to determine if a platelet transfusion is needed or if the medication requires discontinuation. Studies previously discussed regarding platelet dysfunction may also be useful in the evaluation and management of a bleeding patient on antiplatelet therapy.[26–28]

KEY POINTS

- The cell-based model of hemostasis has largely replaced the classic cascade model as the current theory of how coagulation occurs in vivo. This model suggests that the process of coagulation occurs on different cell surfaces and occurs in three overlapping stages of initiation, amplification, and propagation.
- Hypothermia, acidosis, and hypocalcemia have been associated with coagulopathy and should be corrected in bleeding patients.
- PT/INR, PTT, fibrinogen, and platelet count are routinely used in the work-up of coagulation but do not necessarily reflect in vivo hemostasis. When measuring coagulation, it is important to consider a patient's drug history, family history of coagulation disorders, and personal history of coagulopathies.
- Thrombocytopenia is associated with increased risk of bleeding and mortality. Platelets should be prophylactically transfused for platelet count <10,000/μL because of the risk of spontaneous hemorrhage. Platelet count does not provide a functional assessment of platelets.
- TEG/ROTEM provides a point-of-care assessment of coagulation, which can be used to guide transfusion therapy. The use of TEG/ROTEM may reduce the need for blood products and improve morbidity in bleeding patients.
- DIC is a condition associated with a high mortality and can be reliably diagnosed by calculating a DIC score.
- UFH, argatroban, and bivalirudin can be monitored using aPTT and ACT. Warfarin is monitored with PT/INR. LMWH, fondaparinux, apixaban, and rivaroxaban can be monitored using anti-Xa assays with normalized curves for the specific agent. TT and ecarin clotting time can evaluate dabigatran activity.

Critical Care of the Hematopoietic Stem Cell Transplant Recipient

Robert M. Kotloff and Steve G. Peters

Hematopoietic stem cell transplantation (HSCT) is used to treat an ever-increasing array of disorders, including hematologic and lymphoid cancers; selected solid tumors; and nonneoplastic diseases, including autoimmune disorders, amyloidosis, and aplastic anemia. The main indications for autologous transplantation include multiple myeloma and lymphomas. Allogeneic transplants are most commonly performed for acute and chronic leukemia, lymphoma, and myelodysplastic syndrome. The most common graft source is peripheral blood; other graft sources include bone marrow and cord blood. A conditioning regimen is employed before transplantation to eradicate malignant cells and, in allogeneic transplantation, to induce immunosuppression that permits engraftment. The conditioning regimen can be myeloablative, reduced-intensity, or nonmyeloablative. Some patients are also given total-body irradiation for myeloablation and immunosuppression.

After HSCT, the immune system recovers along predictable patterns depending on the underlying disorder, stem cell source, and complications such as graft-versus-host disease (GVHD). Recovery occurs faster in autologous recipients, in those who receive peripheral blood stem cell grafts, and after nonmyeloablative conditioning. The posttransplant period is divided into three phases: preengraftment, early posttransplant, and late posttransplant. The preengraftment phase (0–30 days) is characterized by neutropenia and breaks in the mucocutaneous barriers. The early postengraftment phase (30–100 days) is dominated by impaired cell-mediated immunity. The impact of this cell-mediated defect is determined by the development of GVHD and the corresponding immunosuppressive medications. The late posttransplant phase (>100 days) is characterized by defects in cell-mediated and humoral immunity, in addition to function of the reticuloendothelial system in allogeneic transplant recipients.

INDICATIONS FOR ICU ADMISSION

Reflecting the multitude of potentially life-threatening complications that can punctuate the posttransplant course, the intensive care unit (ICU) is a common setting for the care of HSCT recipients. Reported rates of admission to the ICU vary widely in the published literature and are considerably higher for allogeneic compared with autologous recipients, for whom admission rates of 20%–35% have been reported in contemporary series.[1,2] Pulmonary complications represent the most common reason for ICU admission, accounting for approximately one-third of cases.[2,3] Pneumonia and sepsis-induced acute respiratory distress syndrome (ARDS) are common causes of hypoxemic respiratory failure in HSCT recipients. Noninfectious pulmonary complications also can lead to respiratory failure and ICU admission. Other common reasons for ICU admission include sepsis, cardiac events (arrhythmias, infarction, congestive heart failure), and neurologic complications (intracranial bleed, seizures, altered mental status).

COMMON INFECTIOUS COMPLICATIONS REQUIRING ICU CARE

Infectious complications are more common in patients who have undergone allogeneic transplantation because these recipients require the administration of immunosuppressive agents after transplantation to prevent or treat GVHD. In addition, GVHD itself causes an immunodeficient state by involving mucosal surfaces, the reticuloendothelial system, and bone marrow. The use of alternative hematopoietic precursor sources, such as mobilized peripheral blood stem cells, and cytokines, such as hematopoietic cell colony-stimulating factors, have shortened the period of neutropenia and decreased the frequency of infectious pulmonary complications. Additionally, effective prophylactic strategies have evolved that have further reduced the incidence of infections, in particular *Pneumocystis jiroveci* and cytomegalovirus (CMV). Nonetheless, pneumonia remains a leading cause of death after HSCT.

Bacterial Pneumonia

Bacterial pneumonia may occur at any time in the posttransplantation period but is particularly prevalent during the preengraftment period of profound neutropenia. Gram-negative pathogens, including *Pseudomonas aeruginosa,* predominate during this time.[4] *Legionella* species are an important cause of nosocomial pneumonia in some centers.

Bacterial pneumonia is commonly heralded by fever, but respiratory symptoms and signs may be absent in the neutropenic host. Presumably because of the paucity of neutrophils, chest x-ray abnormalities may be subtle or absent as well. In one series, the use of high-resolution computed tomography (CT) imaging revealed evidence of pneumonia in more than 50% of febrile neutropenic patients with normal chest radiographs.[5] Broad-spectrum antibiotics (with anti-*Pseudomonas* activity) should be initiated expeditiously in all suspected cases of bacterial pneumonia and in febrile, neutropenic patients without an identified site of infection. In choosing an antibiotic regimen, clinicians must be cognizant of the particular epidemiologic and susceptibility patterns in their hospital- and patient-associated risk factors that might increase the risk of highly resistant pathogens such as methicillin-resistant *Staphylococcus aureus,* extended-spectrum beta-lactamase-producing Enterobacteriaceae, and carbapenemase-producing organisms.

Aspergillus

Although the incidence of invasive aspergillosis has declined significantly with widespread implementation of azole prophylaxis, it remains one of the most devastating complications of HSCT and one of the leading causes of infectious death in this group. Allogeneic transplant recipients in particular are at increased risk for invasive

aspergillosis caused by neutropenia during the preengraftment phase and the administration of immunosuppressive agents to both prevent and treat GVHD. The reported frequency of invasive aspergillosis in the allogeneic population varies between 5% and 15% compared with 0%–8% among autologous HSCT recipients.[6]

Invasive aspergillosis is confined to the lungs in the majority of cases, but sinusitis and central nervous system involvement also occur with some frequency. Cough and dyspnea are the most common presenting symptoms. Pleuritic chest pain and hemoptysis are important, albeit nonspecific, clues to the presence of invasive aspergillosis, reflecting the tendency of the organism to invade blood vessels and cause pulmonary infarction. Fever may be absent in up to two-thirds of patients.

Initial radiographic findings include single or multiple nodules, cavities, and subsegmental or segmental consolidation. CT imaging is more sensitive in detecting abnormalities and can do so at an earlier stage of infection. A highly characteristic CT finding is the halo sign, a rim of low attenuation representing edema or hemorrhage that surrounds a pulmonary nodule. In one study, the halo sign was present in over 90% of neutropenic patients with invasive pulmonary aspergillosis when CT scans were performed at the onset of fever.[7]

Establishing a definitive diagnosis of invasive pulmonary aspergillosis remains difficult, and up to 30% of cases are unrecognized antemortem.[8] The recovery of *Aspergillus* species on cultures of bronchoalveolar lavage fluid is highly suggestive of invasive infection in the HSCT population, but sensitivity is only 27%–57%, with the lowest yields reported for peripheral nodular lesions.[9,10] Transthoracic fine-needle aspiration of accessible focal lesions has a yield of 50%–67%, but performance of this procedure is often precluded by the presence of severe thrombocytopenia.[11,12] An enzyme-linked immunosorbent assay that detects galactomannan, a fungal cell wall component released during invasive disease, has been introduced into clinical practice as a diagnostic tool, albeit with its own limitations. Among HSCT patients with proven or probable cases of invasive aspergillosis included in a meta-analysis, the pooled sensitivity, specificity, and positive and negative predictive values of serum galactomannan testing were 82%, 86%, 65%, and 65%, respectively.[13] Galactomannan testing of bronchoalveolar lavage (BAL) fluid appears to offer greater sensitivity than the serum assay, without sacrificing specificity.[9,14,15] Current practice guidelines from the Infectious Disease Society of America endorse the use of both serum and BAL galactomannan assays in the diagnosis of invasive aspergillosis in the HSCT population (strong recommendation; moderate-quality evidence).[10]

Voriconazole is the treatment of choice for invasive aspergillosis, based on demonstration of superior efficacy and less toxicity compared with amphotericin B.[16] A multicenter registry of HSCT recipients documented partial or complete response at 12 weeks in 64% of patients with invasive aspergillosis, the majority of whom were treated with voriconazole either alone or in combination with an echinocandin.[17] The mortality rate at this time point was 36%, a dramatic reduction from rates in excess of 80% reported in the 1990s. Liposomal amphotericin B and isavuconazole are alternative options for patients in whom voriconazole is contraindicated or not tolerated. The echinocandins (caspofungin, micafungin), used either alone or in combination with another antifungal agent, are considered to be salvage therapy for severe or refractory cases. Surgical resection of localized disease is sometimes used as an adjunct to antifungal therapy in refractory cases or in the setting of massive hemoptysis.

Cytomegalovirus

The risk of CMV pneumonia is far greater after allogeneic compared with autologous HSCT, a consequence of the need to administer immunosuppressive drugs to the former recipient group. The vast majority of episodes of CMV disease result from reactivation of latent virus in seropositive recipients. Seronegative patients who receive stem cells from a seropositive donor have a lower risk of posttransplantation CMV disease than do seropositive recipients, a situation that contrasts with that seen after solid organ transplantation. In the preprophylaxis era, the onset of CMV pneumonia almost invariably occurred between engraftment and day 100. The use of prophylaxis has dramatically reduced the incidence of CMV pneumonia to approximately 5% among allogeneic HSCT recipients but has also shifted the onset of disease to later in the posttransplantation course.

The clinical presentation of CMV pneumonia is not distinctive. Nonproductive cough, fever, and hypoxemia are typical, with rapid progression to respiratory failure in some cases. The chest radiograph most often demonstrates bilateral interstitial opacities, but focal or diffuse consolidation and nodular opacities may also be seen. Ground-glass opacities are commonly demonstrated by high-resolution CT. The diagnosis of CMV pneumonia is most definitively established by demonstration of viral inclusion bodies in specimens obtained by either transbronchial lung biopsy or BAL, but the yield of both of these techniques is low. In association with compatible clinical and radiographic features, detection of virus in BAL fluid by rapid culture technique or polymerase chain reaction (PCR) is considered diagnostic in this patient population. However, in cases lacking the classic features, these results must be interpreted with caution because viral shedding into the respiratory tract can occur in the absence of invasive disease. Identification of a high viral load in peripheral blood provides additional supportive evidence in the appropriate setting.

The combination of ganciclovir and high-dose intravenous immunoglobulin (IVIg) or CMV-specific immunoglobulin is standard of care for treatment of CMV pneumonia in HSCT recipients, though the need for the immunoglobulin preparations has recently been questioned.[18] Foscarnet is reserved for patients unable to tolerate ganciclovir and those infected with ganciclovir-resistant strains.

Community Respiratory Viruses

As a group, the community respiratory viral pathogens—respiratory syncytial virus (RSV), influenza A and B, parainfluenza, and human metapneumovirus—account for the majority of non-CMV viral respiratory infections in both autologous and allogeneic HSCT recipients. With the exception of parainfluenza virus, which occurs year-round, the other viruses occur predominantly in the late fall, winter, and early spring. These viruses most commonly present as upper respiratory tract infections, but all have the propensity to progress to involve the lower respiratory tract (LRTI; i.e., bronchiolitis or pneumonia) and to lead to respiratory failure.

Among patients with RSV infection, the risk of progression to LRTI approaches 80% for those who are less than 1 month posttransplant or still in the preengraftment stage but falls to less than 40% for those beyond this critical period.[19] Once LRTI develops, mortality from untreated RSV infection approximates 80%. Published studies, chiefly retrospective or prospective but nonrandomized, suggest that ribavirin alone or in combination with IVIg or RSV-specific monoclonal antibody (palivizumab) decreases mortality among HSCT recipients with RSV LRTI.[20] Aerosolized ribavirin has been used in most studies, but favorable results have also been reported with intravenous and oral administration. There is currently no consensus on the approach to treating RSV LRTI, but published guidelines endorse the use of aerosolized ribavirin and IVIg for HSCT recipients with LRTI.[21,22]

Ribavirin has been used in the treatment of LRTI with parainfluenza and human metapneumovirus, but there is no compelling evidence of efficacy. Patients with LRTI from influenza are commonly treated with the neuraminidase inhibitor oseltamivir, but its efficacy in

HSCT recipients has not been established. Postinfluenza bacterial pneumonias, typically with *S. aureus* or *Pneumococcus,* should be considered in patients who develop a second wave of fever associated with evidence of consolidation on imaging.

COMMON NONINFECTIOUS COMPLICATIONS REQUIRING ICU CARE

Acute Pulmonary Edema

Acute pulmonary edema is a common but potentially overlooked cause of pulmonary dysfunction during the neutropenic phase after HSCT. Noncardiogenic pulmonary edema has many contributory factors, including total-body radiation, induction drugs, aspiration, transfusion-related acute lung injury, and sepsis. Patients who develop hydrostatic/cardiogenic pulmonary edema have often received large volumes of fluid for medications, total parenteral nutrition, and multiple blood product transfusions. Cardiac dysfunction resulting from chemotherapeutic agents used during induction can also contribute to volume overload, as can renal impairment.

Engraftment Syndrome and Periengraftment Respiratory Distress Syndrome

Engraftment syndrome is characterized in its full expression by a combination of fever, erythrodermatous rash, diarrhea, diffuse capillary leak, and noncardiogenic pulmonary edema occurring coincident with neutrophil recovery.[23] This syndrome has been described most frequently after autologous HSCT, with a reported incidence of 7%–53%.[24,25] A similar presentation after allogeneic transplantation has been described but must be distinguished from acute GVHD. The term *periengraftment respiratory distress syndrome* (PERDS) has been applied to the subset of patients with engraftment syndrome who manifest hypoxemia and pulmonary opacities on chest radiographs.

The etiology of engraftment syndrome is poorly understood; release of proinflammatory cytokines during engraftment is postulated to play a principal role. The use of granulocyte–macrophage colony-stimulating factor has been identified in some studies as a risk factor for engraftment syndrome.[26]

Signs and symptoms of PERDS begin within 5 days preceding or after neutrophil engraftment. Dyspnea is universally present, accompanied by hypoxemia of varying severity. Frank respiratory failure requiring mechanical ventilator support develops in approximately one-third of patients with PERDS. The majority of patients are febrile; other clinical features of engraftment syndrome may be present, including a maculopapular rash, hypoalbuminemia, ascites, and peripheral edema. Bilateral pulmonary infiltrates are seen on chest x-ray and CT scan but are nonspecific. The diagnosis of PERDS is based on the presence of compatible clinic-radiographic features; onset in the periengraftment period; and the exclusion of infection, volume overload, diffuse alveolar hemorrhage (DAH), and other entities that share similar features. Early recognition and treatment with high-dose corticosteroids has been associated with rapid clinical improvement, even among patients requiring mechanical ventilation.[23,27]

Diffuse Alveolar Hemorrhage

In the context of HSCT, DAH is considered to be a manifestation of widespread alveolar injury of noninfectious etiology. DAH occurs with a frequency of 1%–5% among autologous HSCT recipients and 3%–7% among allogeneic HSCT recipients and, because of the high rate of associated respiratory failure, is a common indication for ICU admission in these patient populations.[28,29] DAH is most commonly observed within the first month, often during the periengraftment phase, but later onset is encountered in up to 47% of cases.[28,29] Older age, allogeneic donor source, severe acute GVHD, total-body irradiation, myeloablative conditioning regimen, and renal insufficiency have been identified as risk factors.[29] Although thrombocytopenia is common, platelet counts are not lower than those found in patients without DAH, and aggressive platelet transfusion does not result in improvement in respiratory status.[30]

The pathogenesis of DAH in HSCT recipients remains obscure. Postmortem investigations have shown that the majority of patients with DAH have evidence of diffuse alveolar damage.[30,31] It is likely that DAH, like idiopathic pneumonia syndrome (IPS) and PERDS, is part of a spectrum of acute lung injury induced by conditioning chemotherapy, radiation, and occult infection. The fact that many cases occur at the time of engraftment suggests that neutrophil influx into the lung may accentuate the injury and in some way precipitate hemorrhage.

Patients present with dyspnea, nonproductive cough, fever, and diffuse pulmonary infiltrates, but hemoptysis is notably rare. An otherwise unexplained drop in hemoglobin provides an important clue to the presence of DAH. The majority of patients require ICU admission and mechanical ventilation. Diagnosis centers on the bronchoscopic demonstration of progressively bloodier BAL fluid from at least three lobes or greater than 20% hemosiderin-laden macrophages in the BAL fluid and the exclusion of underlying infection. However, these criteria have been demonstrated to lack both sensitivity and specificity when using postmortem examination as the gold standard.[31]

Early descriptions using supportive therapy alone documented mortality rates of 80%–100%.[30,32] Retrospective case series subsequently suggested that administration of high-dose corticosteroids improved the survival rate,[32,33] but more recent single-center case series continue to document 60-day mortality rates in the range of 75%–80% even with this intervention.[29,34] Successful outcomes have been reported with the addition of recombinant factor VIIa[35,36] or aminocaproic acid[37] to high-dose steroids, but evidence to date is conflicting,[34] and use of these adjuvant therapies cannot be endorsed. Onset of DAH within the first 30 days of transplantation and autologous HSCT are associated with the most favorable outcomes.[29] Death is usually a result of superimposed multisystem organ failure or sepsis rather than respiratory failure from refractory hemorrhage.[28]

Idiopathic Pneumonia Syndrome

The term *idiopathic pneumonia syndrome (IPS)* applies to HSCT patients presenting with widespread alveolar injury in the absence of an identifiable infectious etiology. More recently, the definition was updated to additionally require exclusion of cardiac dysfunction, renal failure, and iatrogenic volume overload as the etiology for pulmonary dysfunction.[38] The updated diagnostic criteria, which continue to rely chiefly on BAL studies to exclude infection, are listed in Box 130.1. Adding to the ambiguity of the definition, some authorities include PERDS and DAH in the spectrum of IPS, whereas others treat them as distinct entities.

The incidence of IPS in the first 120 days after allogeneic HSCT with myeloablative conditioning historically has been reported in the range of 3%–15%.[39] With advances in transplant practices and better detection of underlying infectious etiologies, its incidence appears to be declining.[40] A recent report detected potential infectious pathogens, predominantly viral, in the BAL fluid of almost 60% of patients labeled as having IPS, challenging the fundamental definition of the entity as a noninfectious form of lung injury.[41] However, BAL alone does not distinguish between viral shedding, colonization, and true infection, so the implications of this study remain uncertain. Among allogeneic recipients, the incidence appears to be lower after nonmyeloablative versus conventional high-dose conditioning

BOX 130.1 Criteria for Diagnosing Idiopathic Pneumonia Syndrome

I. Evidence of widespread alveolar injury
- Multilobar infiltrates on routine chest radiographs or computed tomography
- Symptoms and signs of pneumonia (cough, dyspnea, tachypnea, rales)
- Evidence of abnormal pulmonary physiology
  - Increased alveolar to arterial oxygen difference
  - New or increased restrictive pulmonary function test abnormality

II. Absence of active lower respiratory tract infection based upon:
- Bronchoalveolar lavage cultures, cytology, polymerase chain reaction, and other studies negative for significant bacterial, viral, and fungal pathogens
- Transbronchial biopsy if condition of the patient permits

III. Absence of cardiac dysfunction, acute renal failure, or iatrogenic fluid overload as etiology for pulmonary dysfunction

Modified from Panoskaltsis-Mortari A, Griese M, Madtes DK, et al. An official American Thoracic Society research statement: noninfectious lung injury after hematopoietic stem cell transplantation: idiopathic pneumonia syndrome. *Am J Respir Crit Care Med.* 2011;183:1262–1279.

regimens, lending support to the belief that toxicity from intensive chemotherapy and radiation contributes significantly to pathogenesis. Acute GVHD has been identified as a risk factor for IPS, suggesting that alloimmune mechanisms may also come into play. IPS also occurs after autologous HSCT, but the frequency appears to be lower than that among recipients of allogeneic HSCT. It remains unclear whether the source of stem cells (bone marrow vs. peripheral blood vs. umbilical cord blood) affects the frequency of this complication.

The median time to onset of IPS has been reported to be 19 days, with the majority of cases occurring within the initial 120 days.[39] Patients with IPS present with dyspnea, fever, nonproductive cough, increasing oxygen requirements, and diffuse radiographic infiltrates. When obtained, lung biopsy specimens reveal two main patterns: diffuse alveolar damage and interstitial pneumonitis. The course is typically rapid, with up to two-thirds of patients progressing within several days to respiratory failure requiring mechanical ventilation.[39] Combined mortality in six of the larger published case series was 74%,[42] and the mortality rate among those requiring mechanical ventilation may exceed 95%.[39] Mortality at 120 days in a large contemporary study was 46%, suggesting that survival may be improving, possibly the result of advances in the care of critically ill patients.[40]

Beyond supportive care, there is no proven treatment for IPS. High-dose corticosteroid therapy is commonly administered, but substantiation of benefit is lacking. Based on evidence that anti–tumor necrosis factor therapy mitigates acute lung injury in murine models of IPS,[43] etanercept, a soluble tumor necrosis factor-alpha–binding protein, has been administered to patients with IPS. Two case series, encompassing a total of 37 patients treated with a combination of corticosteroids and etanercept, demonstrated high clinical response rates and improved short-term survival.[44,45] A subsequent prospective trial randomizing adults to either corticosteroids plus etanercept or corticosteroids alone aimed to enroll 120 patients but succeeded in accruing only 34 patients.[46] Acknowledging that it was underpowered to draw a definitive conclusion, the study nonetheless failed to demonstrate any difference in response rates or survival between the two groups. A more recent nonrandomized phase II trial involving 28 pediatric patients demonstrated a response rate (defined as survival to day 28 of the study plus complete discontinuation of supplemental oxygen support for >72 consecutive hours) of 71%.[47]

OUTCOMES AFTER ICU ADMISSION

Most of the published experience with HSCT requiring ICU admission has focused on allogeneic recipients, who have a significantly higher incidence of complications leading to critical illness. Historically, the prognosis of HSCT patients admitted to the ICU has been poor.[48–50] In particular, HSCT patients requiring mechanical ventilation for respiratory failure have experienced the poorest outcomes, leading some authorities in the past to consider this as a futile intervention.[51] In one of the largest studies involving 348 mechanically ventilated HSCT recipients at the Fred Hutchinson Cancer Research Center between 1986 and 1990, survival at 6 months was only 3%.[52] In another study from the same center, investigators found no survivors among ventilated patients with acute lung injury and either hepatic and renal insufficiency or hemodynamic instability necessitating vasopressors.[53]

More recent studies have reported improved outcomes for allogeneic HSCT recipients requiring ICU admission.[1,2] In particular, short-term survival rates in the subgroup who received mechanical ventilation approximate 15% in a contemporary series.[1] One likely reason for these favorable trends is the greater use of reduced-intensity conditioning regimens. These reports are encouraging, and despite the fact that survival rates remain disappointingly low, it can be argued that a trial of mechanical ventilation in select groups of HSCT recipients is reasonable.

There is limited experience with venovenous extracorporeal membrane oxygenation (VV-ECMO) in the allogeneic HSCT population. The largest experience of 37 patients comes from a consortium of 12 European centers.[54] The etiology of respiratory failure was pneumonia in 80%. Overall survival to hospital discharge was 19%; time from transplant was a discriminating factor, with a survival rate of only 4% among patients within 240 days of transplant compared with 46% for those further out. Pending further studies, VV-ECMO should be applied in a highly selective fashion and only with the understanding by the patient and/or family that this life-sustaining measure will be withdrawn if continuation is deemed to be futile.

To inform the appropriate use of the ICU and mechanical ventilation, a number of studies have attempted to identify factors predictive of outcome. Specific pre-ICU characteristics, including age, sex, primary disease, type of transplant, and conditioning regimen, have not proven to be reliable predictors.[50,55,56] Admission to the ICU within the engraftment period has been associated with a more favorable prognosis compared with later admission, particularly for recipients requiring mechanical ventilation.[56] Factors during the ICU course that have been associated with unfavorable outcomes are the need for mechanical ventilation, need for renal replacement therapy, presence of multiple organ failure, hyperbilirubinemia, use of vasopressors, and grade 3–4 acute GVHD.[1,2,56–58] Notably, the combination of mechanical ventilation with hepatic and renal dysfunction continues to portent nearly universal mortality.[59,60]

Well-known instruments used to prognostically stratify patients at the time of admission to the ICU, such as Acute Physiology and Chronic Health Evaluation (APACHE) II and APACHE III, and the Sequential Organ Failure Assessment have limited prognostic value in the HSCT patient population. As a result, indices specific to allogeneic HSCT have been developed. One such index, based on factors present at the time of initiation of mechanical ventilation, classifies patients with a creatinine <2 mg/dL and platelet count >20 × 10^9/L in a favorable category, with an overall survival at 100 days post mechanical ventilation of 29%, compared with only 5% for those not meeting both of these criteria.[61] The Hematopoietic Cell Transplantation–specific Comorbidity Index (HCT-CI) appears to be useful as a predictive instrument for in-hospital mortality among patients admitted to

the ICU within 100 days of their transplant. In one study, mortality was 46% for those with an HCT-CI score of 0–1 compared with 69% for those with a score ≥4.[62]

These predictive factors and indices allow for some stratification of risk but fall short of defining patients for whom ICU care and mechanical ventilation would be inappropriate. This is best accomplished through daily assessment of the critically ill patient's status and response to therapy, close communication between the ICU and transplant teams, and awareness of the patient's preferences and goals of care.

KEY POINTS

- ICU admission in the post-HSCT period is common; pulmonary complications, both infectious and noninfectious, represent the leading cause of ICU admission.
- Bacterial pneumonia is particularly common during the neutropenic preengraftment phase after both allogeneic and autologous HSCT.
- Because of the requirement for administration of immunosuppressive agents, allogeneic HSCT recipients are particularly predisposed to opportunistic infections, including CMV and invasive aspergillosis.
- Noninfectious pulmonary complications leading to respiratory failure include PERDS, DAH, and IPS.
- Outcomes after ICU admission are improving. However, the status of the underlying disease; presence of multiple organ failure; a need for mechanical ventilation, pressors, or renal replacement therapy; and absence of improvement after initial supportive measures may all contribute to poor prognosis and should be taken in context with the wishes and advance directives of the patient and proxy.

Cardiovascular and Endocrinologic Changes Associated With Pregnancy

Marie R. Baldisseri

Fundamental to the management of a critically ill pregnant woman is a detailed knowledge of the normal physiologic changes that occur during gestation and immediately after delivery. Some of these physiologic adaptations are from the hormonal changes associated with pregnancy, and others are to support the mother and the growing fetus.[1] Clinicians must have a good understanding of the extent of these changes, which occur in all pregnant women, to appropriately diagnose and treat critically ill patients whose additional pathology complicates the distinct metabolic homeostasis and hemodynamics of the normal pregnant state. It is important to recognize that these physiologic changes add a level of complexity to diagnosis and management in the critically ill pregnant woman. The normal baseline physiologic changes of pregnancy often alter the presentation of a disease process or illness that presents during pregnancy, and they can unmask a previously silent disease process of the woman. The normal physiologic maternal adaptations will change the interpretation of clinical and diagnostic examination findings in the pregnant woman. Subsequently, the endpoints of treatment can be significantly different from those for nonpregnant patients. To detect early signs of deterioration in a critically ill pregnant patient, modified early obstetric warning score (MEOWS) charts have been introduced in some obstetric centers.[2,3]

Some of the physiologic changes associated with pregnancy occur early in the normal course of gestation, whereas others occur during the middle or later stages. To render the most effective care of critically ill pregnant patients, the clinician must be aware of the timing of important physiologic changes. They affect almost all organ systems to varying degrees, depending in part on the gestational age of the fetus. Hemodynamic, metabolic, hormonal, and structural changes all occur during pregnancy and allow for the natural growth and development of the fetus. The healthy pregnant woman adapts remarkably well to these changes, as does the fetus, allowing the two to coexist symbiotically without harm to the other. However, if the pregnant woman is ill, either from a preexisting underlying disease process or from a new pathologic process that occurs during the pregnancy, the normal physiologic adaptive mechanisms of pregnancy are often insufficient to maintain the normal healthy union between mother and fetus. Depending on the severity of the underlying process or new illness, the hemodynamic ramifications to the pregnant woman and her fetus can be devastating and life threatening.

CARDIOVASCULAR CHANGES IN PREGNANCY

Cardiovascular and blood volume changes are among some of the more significant changes that occur in pregnancy (Table 131.1). These changes are primarily adaptive mechanisms, allowing the pregnant woman to accommodate her additional metabolic needs in addition to those of the fetus during gestation and immediately after delivery. Cardiac output is significantly increased during pregnancy by as much as 50% compared with nonpregnant values. Cardiac output is increased by 15% in twin pregnancies and in multiple gestations.[4] An increase in cardiac output is seen as early as the first 6–8 weeks of pregnancy. A series of meta-analyses of singleton pregnancies found that cardiac output peaks during the early third trimester: 1.5 L/min (31%) above nonpregnant values.[5] Cardiac output can increase by 75% by the end of the third trimester. The early increase in cardiac output is primarily the result of a significant increase in stroke volume. However, stroke volume decreases as the pregnancy advances because of aortocaval compression by the uterus and the pressure of the fetal presenting part on the common iliac vein. Caval compression occurs because the large, gravid uterus rests on the vena cava, decreasing venous return to the heart and therefore effectively decreasing ventricular preload. In the latter half of pregnancy, a progressive increase in the maternal heart rate by 15–20 beats/min is primarily responsible for maintaining the elevated cardiac output. The additional increase in cardiac output before labor and delivery is caused by a further increase in heart rate. Resting cardiac output either is maintained or decreases slightly as term approaches.[6,7]

Influence of Body Position

Venous return is further compromised with changes in body position, particularly if the pregnant patient is supine. As a result, cardiac output can be diminished by as much as 25%–30%. The effects of changes in body position are most obvious in the latter half of pregnancy when the fetal size and gravid uterus can effectively tamponade the vena cava, the abdominal aorta, and the iliac arteries. This phenomenon is exaggerated in women with poorly developed venous collaterals. With compression of the vena cava in the supine position, these women exhibit signs of severe hypoperfusion (hypotension and bradycardia), a phenomenon described as the *supine hypotensive syndrome of pregnancy*. Symptoms quickly resolve after the patient is repositioned to the left lateral recumbent position.[8] Cardiac output can decrease by

TABLE 131.1 Normal Hemodynamic Changes During Pregnancy

Physiologic Parameter	Term Pregnancy	Labor and Delivery	Postpartum
Cardiac output	Increases 30%–50%	Increases 50%	Increases 60%–80% within 15–20 min
Blood volume	Increases 30%–50%	Additional 300–500 mL with each contraction	Decreases to baseline
Heart rate	Increases by 15–20 beats/min	Increase depends on stress and pain relief	Decreases to baseline
Blood pressure	Decreases by 5–10 mm Hg in midpregnancy	Increase depends on stress and pain relief	Decreases to baseline
Systemic vascular resistance	Decreases	Increases	Decreases to baseline
Oxygen consumption	Increases by 20%	Increases with stress of labor and delivery	Decreases to baseline
Red blood cell mass	Increases by 15%–20%	—	—

30%–40% in patients with this syndrome. This vasovagal phenomenon underscores the influence of maternal body position on the hemodynamic alterations occurring in pregnancy.

Hemodynamic changes associated with decreases in preload and cardiac output are less pronounced when the gravid uterus is minimally compressing the vena cava, which is optimally achieved by maintaining the pregnant woman at greater than 20 weeks' gestation in the left lateral position when recumbent. Alternatives to this position, less optimal than the left lateral position but preferable to the supine position, are a left lateral tilt to 15 degrees or manual displacement of the gravid uterus. The latter maneuver of left uterine displacement can be performed by manually moving the uterus away from the midline to the left side when the patient is supine. This maneuver is particularly useful when performing cardiac compressions in a pregnant patient. In the supine position, the gravid uterus, which accounts for as much as 10% of the cardiac output, hinders successful resuscitation because of its adverse effects on intrathoracic pressure and venous return. Although hemodynamics are best in the left lateral position, it is difficult to achieve optimal chest compressions with the patient in this position. Acceptable alternatives are to perform cardiac compressions with the patient supine but with concurrent manual displacement of the uterus to the other side; it is also satisfactory to place a firm wedge under the right hip of the patient.[9,10]

Oxygen Consumption and Ventricular Performance

As cardiac output progressively increases, maternal oxygen consumption also increases. However, the increase in cardiac output is seen earlier than the rise in maternal oxygen consumption. Accordingly, the arteriovenous oxygen difference actually narrows early in pregnancy. The arteriovenous oxygen difference widens at the end of gestation. By term, there is a 20% increase in maternal oxygen consumption, mostly as a result of the increase in metabolic needs of the fetus. The increase in oxygen consumption is also a result of maternal increased work of ventilation during pregnancy, maternal increase in myocardial oxygen demand, and maternal increase in renal oxygen consumption. Oxygen extraction also gradually increases throughout gestation. The increase in cardiac output is probably the result of a combination of factors, including increased uterine blood flow, increased maternal circulating blood volume (and hence ventricular preload), and possibly estrogen- and prolactin-induced augmentation of myocardial contractility. Ventricular dynamics are improved during pregnancy as a direct result of the action of steroid hormones on the pregnant myocardium. In animal models, estrogens have been shown to increase cardiac output and decrease peripheral vascular resistance.[11] Echocardiographic studies performed in healthy pregnant women have demonstrated a decrease in the preejection period of left ventricular systole but an increase in the left ventricular end-diastolic dimension.[12–14] It may be that a combination of improved myocardial contractility and increased ventricular diastolic area may be responsible for increases in cardiac output during normal pregnancy.[15]

Hemodynamic Changes During Labor and Delivery

Although cardiac output remains relatively constant in the third trimester, there is a significant increase during active labor and immediately after delivery. With each uterine contraction, cardiac output dramatically increases as an additional 300–500 mL of maternal blood volume from the uterus is returned to the heart. Cardiac output can rise to 50% greater than normal when the pregnant woman is pushing in the second stage of labor. The amount of blood returned to the heart is accentuated in the supine position. When the pregnant patient is supine, uterine contractions can cause a 25% increase in cardiac output, a 15% decrease in maternal heart rate, and a 30%–35% increase in stroke volume. In the lateral recumbent position, the hemodynamic changes associated with uterine contractions are less pronounced; cardiac output and stroke volume may rise by only 6%–7%, and there may be only a small change in maternal heart rate. Cardiac output may be preferentially diverted to the heart if there is partial obstruction of the abdominal aorta by the uterus during contraction.

The hemodynamic changes seen during labor and delivery are influenced by anesthetic and analgesic techniques. The increase in cardiac output is less if caudal anesthesia is used.[16,17] Within the immediate 20–30 minutes after delivery of the fetus and placenta, there is an even greater increase in cardiac output, because blood is no longer diverted to the uteroplacental vascular bed. Approximately 500 mL is redirected to the maternal circulation in the so-called *autotransfusion effect of pregnancy.* This effect can increase cardiac output by 60%–80% after aortocaval compression is removed and blood volume is increased. Many of the physiologic changes of pregnancy resolve and revert to normal within several days after delivery. Cardiac output returns to normal within 2 weeks to 3 months after delivery as sodium and water balances normalize.

Blood Volume Changes

The changes in maternal blood volume during pregnancy are significant. Plasma volume increases by 30%–50% by the end of gestation. This value is increased in the multigravida patient compared with primigravidas, but the exact mechanism responsible for this effect is unclear. The increase in blood volume can be as high as 70% with twin pregnancies. An increase of 10%–15% in blood volume is seen as early as the sixth week of gestation. Blood volume is maximal at 30–34 weeks, after which the value plateaus until term.[18] Others have suggested that blood volume continues to increase until term.[19] Ventricular filling pressures do not increase despite the large increases in plasma volume.[20] This is most likely the result of vasodilatation with

concurrent decreases in systemic and pulmonary vascular resistance in addition to a normal heart adapting to chronic volume overload.

The increase in blood volume is a striking adaptive mechanism that permits additional blood flow to the uterus and other maternal organs, in particular the kidneys. Uterine blood flow increases to 100 mL/min by the end of the first trimester and reaches 1200 mL/min at term. Both sodium and water retention contribute to the increase in plasma volume. Total body water increases by approximately 6.5–8 L. Most of this increase is seen in the extracellular space and is preferentially distributed in the lower extremities. The total increase in body water includes approximately 3.5 L of amniotic fluid, placental fluid, and water in the fetus. The relative hypervolemia leads to a mild reduction in the serum sodium concentration (135–138 mEq/L) and in serum osmolality (approximately 280 mOsm/L). The maternal blood volume increases by 1–2 L. Red blood cell (RBC) mass accounts for only 300–400 mL of the increase in total blood volume.

Plasma renin and aldosterone levels are elevated during pregnancy despite expansion of the maternal blood volume. Activation of the renin–angiotensin–aldosterone system may result from the concomitant decrease in peripheral vascular resistance and the increase in vascular capacitance seen as early as the first 6 weeks of pregnancy.[6] Both estrogens and progesterone increase aldosterone levels, increasing sodium and water retention.[21] At 12 weeks of gestation, atrial natriuretic peptide levels also increase, most likely in response to the increase in plasma volume.

The increase in blood volume is an adaptive mechanism that provides some level of protection for the inevitable blood loss that accompanies delivery of the fetus and placenta.[22,23] Average blood loss during vaginal delivery is 500 mL; average blood loss during cesarean delivery is approximately 1000 mL. Although providing some degree of protection from peripartum blood loss, the increased plasma volume associated with pregnancy also can lull the clinician into a false sense of security. A pregnant woman can lose up to 35% of her blood volume before the usual signs of hypovolemia and acute hemorrhage are obvious. Although the pregnant woman may appear to have stable vital signs up to this point, the fetus may be severely compromised and deprived of adequate maternal blood flow. Tachycardia, hypotension, and other signs of hemodynamic instability are late manifestations of a significant deficit in maternal blood volume.

Physiologic Anemia of Pregnancy

Accompanying the increase in blood volume is an increase in RBC mass stimulated by increased circulating levels of erythropoietin. The RBC mass increases during the second trimester and continues to increase progressively throughout the pregnancy. However, the increase of 15%–20% in RBC mass is disproportionate to the 30%–50% increase in blood volume. As a result, the hematocrit decreases, resulting in the "physiologic hemodilutional anemia" of pregnancy. Hemodilution is most notable during the 30th to 34th gestational weeks. The hemoglobin concentration can decrease by as much as 9%. In the second trimester, the hemoglobin level can decrease to 11–12 g/100 mL, compared with the normal nonpregnant value of 13–14 g/100 mL. The decrease in blood viscosity associated with the anemia of pregnancy allows for a decrease in resistance to blood flow that improves placental perfusion. The hematocrit decreases until the end of the second trimester but increases later in the pregnancy, when the increase in RBC mass is proportionate to the increase in plasma volume. The hematocrit stabilizes at that point or even increases slightly as term approaches.

The degree of change in RBC mass during pregnancy depends in part on whether iron is supplemented. With the increase in RBC mass, there is a need for additional iron to prevent the development of iron-deficiency anemia. Maternal requirements for iron can increase to 5–6 mg/day. The fetus uses iron from maternal stores to prevent fetal anemia, but the presence of significant maternal iron-deficiency anemia has been shown to result in a higher incidence of fetal complications, including preterm labor and late spontaneous abortions.[24]

Renal Blood Flow During Pregnancy

Under the influence of circulating hormones, there is a preferential redistribution of blood flow to the uterus, breast, and kidneys during pregnancy. Each kidney increases in length and weight, and the renal pelvis and ureters dilate, leading to urinary stasis that predisposes pregnant women to frequent urinary tract infections.[25] The glomerular filtration rate (GFR) increases by 50%, and renal blood flow increases by 60%–80% above pre-pregnancy levels.[26] Changes in GFR and renal blood flow occur by the sixth week of gestation. The increase in renal blood flow plateaus early in pregnancy and remains unchanged or decreases slightly as term is approached. Urine flow and sodium excretion are increased and are influenced by position, especially in late pregnancy. Flow rates and the sodium excretion rate are significantly higher in the lateral recumbent position compared with the supine position. Concentrations of serum creatinine and blood urea nitrogen are reduced proportionately to the increase in GFR. Glycosuria may also occur during pregnancy as a result of the increase in GFR and impaired tubular reabsorption of glucose.

Changes in Blood Pressure and the Vascular System

Systolic and diastolic blood pressures usually decrease by 5–10 mm Hg below the patient's baseline blood pressures in the second trimester and may normalize to nonpregnant values by term.[27] Arterial blood pressure decreases as early as the sixth week of pregnancy; the lowest diastolic pressures are recorded during the second trimester. By the eighth week of gestation, diastolic blood pressure decreases by approximately 10%. Diastolic pressure reaches a nadir at 16–24 weeks and is typically 5–10 mm Hg less than normal. After the 16th to 24th gestational weeks, blood pressure progressively increases and is back to baseline by term. With the increase in venous return associated with uterine contractions and the additional factors of pain, anxiety, and stress during labor and delivery, an increase in blood pressure usually occurs during this time. Although earlier studies showed that blood pressure decreases during pregnancy, recent studies have demonstrated progressive increases in blood pressure during pregnancy, particularly in obese and overweight women.[28,29] The decrease in blood pressure during pregnancy is associated with a significant decrease in peripheral vascular resistance. Decreased systemic vascular resistance begins as early as the 5th week of gestation and plateaus between the 20th and 32nd weeks, after which it slowly increases to pre-pregnancy values by term.[30] The decrease in arteriolar tone is influenced by several factors, including hormonal changes that induce vasodilatation and lack of responsiveness to the pressor effect of angiotensin II.[31] There is evidence for blood vessel remodeling in pregnancy, leading to increased venous compliance.[32,33] During pregnancy, circulating levels of numerous endogenous procoagulant and anticoagulant proteins change, leading to a hypercoagulable state. As a consequence, the risk of venous thrombosis increases during pregnancy. The reported incidence is 0.7 cases per 1000 women, and this rate increases threefold to fourfold in the postpartum period.[34]

The treatment of choice for severe hypotension resulting from acute hemorrhage, sepsis, or other critical illness during pregnancy is aggressive fluid resuscitation. When hypotension is refractory and unresponsive to fluids, vasopressors should be used to prevent the detrimental consequences of hypotension to both the mother and fetus as a result of inadequate uterine blood flow. Most vasopressors increase maternal blood pressure at the expense of fetal blood flow, inducing vasoconstriction of the uterine vessels. There are few human

studies of these agents in pregnant women. However, animal studies have indicated that ephedrine and dopamine increase uterine blood flow to the uteroplacental circulation while at the same time increasing maternal blood pressure.[35]

Structural Remodeling of the Heart

The heart is dramatically remodeled during the first few weeks of pregnancy. There is enlargement of all four chambers. The valvular annular diameters increase, as do the thickness and volume of the left ventricular wall. End-diastolic volume increases, although end-diastolic pressure remains unchanged.[14] Transthoracic echocardiography and cardiovascular magnetic resonance have demonstrated an increase in left ventricular end-diastolic volume from 95 to 115 mL and 98 to 125 mL, respectively.[36] There is also increased left ventricular mass from 111 to 163 g and 121 to 179 g, respectively.[36] Chamber enlargement, particularly of the left atrium, may be a predisposing factor for supraventricular and atrial arrhythmias. Nonspecific ST-T–wave changes may also be found in the asymptomatic pregnant woman.

As the uterus enlarges and the diaphragm elevates, the heart is rotated upward and to the left. The apical impulse on physical examination is heard best over the fourth intercostal space, lateral to the midclavicular line. Left axis deviation is seen on the electrocardiogram as a result of the rotation of the heart. Because of the displacement of the heart, pregnant women may appear to have cardiomegaly on the chest radiograph. In addition, lung markings may be more prominent, suggesting vascular congestion. These changes can be similar to those seen in patients with heart disease. Even in women with no underlying cardiac pathology, the normal physiologic changes of pregnancy can result in signs and symptoms that are difficult to differentiate from those associated with cardiac disease. Symptoms such as fatigue, decreased exercise tolerance, peripheral edema, palpitations, chest pain, dyspnea, and orthopnea are common complaints as pregnancy advances.

New murmurs often appear during pregnancy. Systolic flow murmurs and a third heart sound are common but are soft. Mild pulmonic and tricuspid regurgitation occurs in more than 90% of healthy pregnant women.[37,38] One-third of pregnant women have evidence of clinically insignificant mitral regurgitation. Diastolic, pansystolic, and late systolic murmurs are rare in normal pregnancy and may indicate underlying heart disease. As a result of the mild four-chamber dilatation, clinically insignificant mitral, tricuspid, and mitral regurgitation is seen. Bruits originating from the internal mammary artery and venous hums with diastolic components are common during pregnancy. These findings can initially confuse the diagnosis of a more serious underlying cardiac illness.

Cardiac Disease and Pregnancy

In women with significant cardiac pathology, the hemodynamic aberrations associated with pregnancy can be life threatening. The incidence of significant cardiac disease in pregnancy is less than 2% but is increasing.[39,40] Cardiovascular disease in pregnancy has been reported as the leading cause of maternal mortality in North America.[36] Advances in medical therapy and in cardiac surgery, including transplantation, have allowed female cardiac patients to survive to childbearing age and to have successful term pregnancies.[41] For women with severe cardiac problems such as pulmonary hypertension, Eisenmenger syndrome, severe mitral stenosis, or Marfan syndrome (in which the risk of aortic dissection is high during pregnancy), the physiologic changes of pregnancy can increase both maternal and fetal morbidity and mortality by transiently or permanently worsening the underlying heart disease.[42] Increases in blood volume, stroke volume, cardiac output, and heart rate and the decrease in systemic vascular resistance are poorly tolerated by pregnant women with severe underlying cardiac disease. Maternal mortality is less than 1% for patients with less severe cardiac problems, but it increases to 50% if pregnancy is associated with the presence of underlying primary pulmonary hypertension or cyanotic disorders such as Eisenmenger syndrome.[43,44]

Approximately 90% of pregnant women with cardiac disease are rated as New York Heart Association (NYHA) functional class I or class II. These patients tolerate the hemodynamic changes of pregnancy and can be managed well with medical therapy, although the incidence of heart failure and arrhythmias tends to be higher in this group of patients.[45] The 10% of pregnant patients with NYHA functional class III or IV heart disease accounts for 85% of cardiac deaths.[46] Fetal morbidity and mortality are increased in these patients, and there is a higher incidence of prematurity, miscarriage, and intrauterine growth retardation.[47] Cardiac telemetry, fetal monitoring, and hemodynamic monitoring are usually necessary for these high-risk patients during labor and delivery and, because of the large changes in intravascular volume after delivery, during the first few postpartum days.

ENDOCRINE AND METABOLIC CHANGES IN PREGNANCY

There are numerous endocrine and metabolic alterations during pregnancy, many of which are directly attributable to hormonal signals originating from the fetoplacental unit. Maternal adaptations to hormonal changes that occur during pregnancy directly influence the growth and development of the fetus and placenta. In pregnancy, there is also a change in the normal hormonal feedback mechanisms that control the synthesis and release of hormones. As with cardiac disease, the presentation of endocrine and metabolic disorders may be difficult to differentiate from the normal hypermetabolic state of pregnancy.

Hypothalamic and Pituitary Alterations

As in the nonpregnant state, the hypothalamic–pituitary axis is responsible for regulating many aspects of metabolism. Circulating levels of most of the releasing hormones of the hypothalamus increase during pregnancy because of increased production by the placenta rather than increased production and release by the hypothalamus. The target organ of the hypothalamus, the pituitary gland, undergoes remarkable structural and metabolic changes in pregnancy. Its size increases almost threefold secondary to estrogen stimulation. Gonadotropin and growth hormone production decrease during pregnancy. However, synthesis of adrenocorticotropic hormone (ACTH), prolactin, and thyroid-stimulating hormone (TSH) increases.

Free and bound cortisol levels are increased in pregnancy, even though circulating ACTH concentrations are elevated. These changes suggest that the normal negative feedback loop between ACTH and cortisol concentrations is altered in the pregnant state.[48] Free plasma cortisol concentrations may be two to three times higher than normal at term. Diurnal variation of cortisol is blunted but maintained throughout pregnancy. The clinical signs of weakness, peripheral edema, glucose intolerance, and weight gain associated with Cushing disease are sometimes difficult to differentiate from the clinical features of normal gestation. The symptoms of Cushing disease are exacerbated by pregnancy but often resolve after delivery. Improved outcomes are seen with surgical therapy intrapartum if pituitary or adrenal tumors are discovered during the course of the pregnancy.[42,49] In normal pregnancy, cortisol release may not be suppressed with a low intravenous dose (1 mg) of dexamethasone. An 8-mg dose of dexamethasone is usually needed to suppress cortisol secretion if a tumor is present. In patients with occult adrenal insufficiency, a life-threatening adrenal crisis may be precipitated by the stress of labor and delivery. The signs and symptoms of adrenal insufficiency during pregnancy may be nonspecific and difficult to recognize, but with the stress

of labor, these symptoms are exaggerated. The clinical diagnosis is made in conjunction with laboratory evidence of a low cortisol level or even a low-normal level and no increase in the plasma cortisol concentration with an ACTH stimulation test. Immediate treatment with stress doses of hydrocortisone is indicated in these patients.

In preparation for lactation, circulating prolactin levels progressively increase to about 10 times normal during the course of pregnancy, secondary to stimulation of the anterior pituitary by placental estrogens and progesterone. The dramatic increase in plasma prolactin concentration may lead to an increase in the size of preexisting pituitary adenomas larger than 1 cm.[50] Symptoms resulting from an increase in prolactin secretion usually subside within 6 weeks after delivery if the patient is not breastfeeding.

The thyroid gland increases the production of thyroid hormones during pregnancy. TSH secretion is transiently decreased in the first trimester, but circulating TSH concentrations are usually increased by term. Circulating levels of thyroxine (T_4) and triiodothyronine (T_3) increase as a result of a twofold estrogen-stimulated increase in the synthesis of thyroxine-binding globulin. Levels of free (dialyzable) T_4 and free T_3 are unchanged. In 15% of women, the thyroid gland increases in size and volume. Pregnant women who obtain sufficient dietary iodine (more than 200 μg daily) have no untoward complications from the changes in thyroid function.[51,52] Patients with preexisting hypothyroidism should increase their levothyroxine daily dose by 30% early in pregnancy.[53]

Posterior pituitary hormones are altered in pregnancy. Circulating oxytocin levels increase, but the vasopressin concentration remains essentially unchanged. Plasma osmolality decreases by 5–10 mOsm/kg, suggesting that the threshold for secretion of vasopressin decreases during gestation. Although vasopressin levels remain unchanged, some women develop transient diabetes insipidus during pregnancy.[54]

Changes in Glucose Metabolism

Early in pregnancy, increased levels of estrogens and progesterone influence glucose metabolism primarily by inducing pancreatic beta-cell hyperplasia and increased insulin secretion. Placental hormones control glucose metabolism later in the pregnancy in response to the increased nutritional and metabolic demands of the fetus. Circulating glucose and insulin levels fluctuate widely depending on the nutritional state of the mother. Morning fasting levels of glucose can decrease to less than 55 mg/dL. Fasting blood glucose levels decrease by 10%–20% because of increased peripheral glucose use, decreased hepatic glucose production, and increased consumption of glucose by the fetus.

Pregnant women with diabetes mellitus experience more hypoglycemic episodes in the first trimester because hepatic gluconeogenesis is decreased during this period. Insulin secretion increases during pregnancy. There is a relative state of insulin resistance, as evidenced by postprandial maternal hyperglycemia.[55] Normally, women adapt to the state of relative insulin resistance during pregnancy. However, those women with marginal pancreatic reserve or preexisting insulin resistance caused by obesity may not produce sufficient insulin, leading to the development of gestational diabetes mellitus. Pregnant women with preexisting diabetes mellitus require as much as 30% more insulin than before pregnancy. There is a close correlation between maternal blood glucose levels and glucose uptake and use by the fetus because glucose crosses the placental barrier. Poor maternal glucose control worsens fetal morbidity. For patients with preexisting insulin-dependent diabetes mellitus, fetal and neonatal mortality rates have decreased significantly, from 65% to between 2% and 5%, as a result of implementing strict metabolic glucose control with insulin.[56]

Lipid metabolism is accelerated in pregnancy, and the circulating concentrations of triglycerides and cholesterol increase. Increased production of triglycerides allows for maternal consumption while sparing glucose for use by the fetus.[57] Lipolysis is stimulated in adipose tissue, and there is a release of glycerol and fatty acids that decreases maternal glucose use, additionally sparing glucose for the fetus.

KEY POINTS

- Normal pregnancy is associated with many physiologic changes that occur at different stages throughout pregnancy and affect almost all maternal organ systems. These changes may alter the presentation of a maternal disease process, confound the diagnosis, or alter the endpoints of treatment.
- Cardiac output, primarily as a result of augmented blood volume and, to a lesser extent, by the heart rate, is increased significantly up to the early third trimester. During labor and delivery, cardiac output is further increased with uterine contractions and the "autotransfusion" effect of increased preload after delivery of the fetus and placenta. This increase in preload can be particularly dangerous to those women with fixed or low cardiac output states, resulting in acute and precipitous respiratory insufficiency with pulmonary edema.
- Maternal body position directly affects cardiac output and stroke volume. In the supine position, the gravid uterus causes aortocaval compression and decreased preload. After the 20th week of gestation, pregnant women should not be placed supine, but rather in the left lateral recumbent position, which maximizes maternal hemodynamics. During cardiac resuscitation, the pregnant patient should be placed in this position, or manually displace the uterus to the left, to improve the efficacy of cardiac compressions.
- Blood volume increases by 30%–50% by the end of gestation. However, RBC mass increases by only 15%–20%, creating the "physiologic anemia" of pregnancy.
- A pregnant woman can lose up to 35% of her blood volume before tachycardia and hypotension occur as a result of acute hemorrhage or severe hypovolemia.
- A decrease in the diastolic blood pressure by 10% is seen in the second trimester, secondary to the decrease in systemic vascular resistance. By the end of pregnancy, blood pressure levels should increase to prepartum values.
- Blood vessel remodeling and changes in the coagulation system during pregnancy, including an increase in most clotting factors, makes the pregnant woman hypercoagulable and more susceptible to venous thromboembolism throughout pregnancy and in the postpartum period.
- Remodeling of the heart causes enlargement of all four chambers. The pregnant woman may be more susceptible to supraventricular and atrial arrhythmias because of left atrial enlargement.
- Pregnant patients with mild to moderate cardiac disease usually tolerate the hemodynamic changes of pregnancy. Those patients with pulmonary hypertension and right-to-left shunts have mortality rates as high as 50%.
- There are numerous endocrine and metabolic alterations during pregnancy that primarily affect the hypothalamus, pituitary, and adrenal glands. As with cardiac disease, the presentation of a patient with endocrine and metabolic disorders may be difficult to differentiate from the normal hypermetabolic state of pregnancy.
- Cushing syndrome can be exacerbated by pregnancy, and acute adrenal crisis may be precipitated by the stress of labor and delivery.
- Large fluctuations in glucose and insulin levels are seen in pregnancy, depending on the nutritional state of the mother. Fasting glucose levels can decrease by 10%–20%.
- During pregnancy, there is increased insulin secretion, with a relative state of insulin resistance.
- Obese women with insulin resistance and women with marginal pancreatic reserve can develop gestational diabetes mellitus.

ANNOTATED REFERENCES

Burt CC, Durbridge J. Management of cardiac disease in pregnancy. *CEACCP*, 2009;9:44.
This article is an excellent review of cardiac disease in pregnancy, focusing on the different causes of cardiac disease and their management in pregnancy. Cardiac disease is the most common cause of mortality in pregnancy and may present with cardiovascular decompensation during pregnancy, at the time of delivery, or immediately postpartum. The goals of therapy are early risk assessment, optimization, regular monitoring for deterioration, planning of delivery, and surveillance for deterioration in the immediate postpartum period. Vaginal delivery with low-dose regional analgesia and careful fluid management is the preferred method of delivery, and cesarean section deliveries should be reserved for obstetric indications.

Clark SL, Cotton DB, Lee W, et al. Central hemodynamic assessment of normal term pregnancy. *Am J Obstet Gynecol*. 1989;161:1439.
This landmark paper presents central hemodynamic data obtained with the use of a pulmonary artery catheter during pregnancy and after delivery. Ten primigravida patients in late pregnancy (between the 36th and 38th weeks of gestation) underwent pulmonary artery catheter and arterial catheter placement. These same patients were restudied with a pulmonary artery catheter at 11–13 weeks after delivery. All measurements were performed with the patient in the left lateral recumbent position. The authors found significant decreases in systemic vascular resistance, pulmonary vascular resistance, colloid oncotic pressure, and colloid oncotic pressure–pulmonary capillary wedge pressure gradient in the third-trimester measurements ($P < .05$*). A significant rise in cardiac output and heart rate was seen in all patients before delivery (*$P < .05$*). No significant changes in pulmonary capillary wedge pressure, central venous pressure, left ventricular stroke work index, or mean arterial pressure were found. Although blood volume and preload are elevated in pregnancy and end-diastolic volume increases, there were no substantial increases in the filling pressures of the heart as measured by the pulmonary artery catheter, suggesting a decrease in afterload with the decrease in the systemic and pulmonary vascular resistance.*

Panchal AR, Bartos JA, Cabanas JG, et al. Part 3: Adult basic and advanced life support: 2020 American Heart Association guidelines for cardiopulmonary and cardiovascular care. *Circulation*. 2020;142:S366–S468.
Recommendations and guidelines for cardiopulmonary resuscitation (CPR) and advanced cardiac life support (ACLS) drug administration in pregnancy are presented by the American Heart Association (AHA). Although cardiac arrest in women is a relatively rare event, the incidence has been increasing. The most common causes are hemorrhage, trauma, pulmonary embolism, amniotic fluid embolism, sepsis, complications of anesthesia, and severe preeclampsia. Relief of aortocaval compression is critical to improve the quality of cardiac compressions. Standard ACLS measures and drugs should be used during a cardiac arrest in a pregnant woman. Perimortem cesarean delivery has been shown to improve both maternal and neonatal outcomes when ROSC is not quickly achieved. Case reports using extracorporeal membrane oxygenation (ECMO) and TTM have shown favorable outcomes.

Snow V, Qaseem A, Barry P, et al. Management of venous thromboembolism: A clinical practice guideline from the American College of Physicians and the American Academy of Family Physicians. *Ann Intern Med.* 2007;146:204.
Recommendation 4: There is insufficient evidence to make specific recommendations for types of anticoagulation management of venous thromboembolism (VTE) in pregnant women. During pregnancy, women have a fivefold increased risk for VTE compared with nonpregnant women. Clinicians should avoid vitamin K antagonists in pregnant women, because these drugs cross the placenta and are associated with embryopathy between 6 and 12 weeks' gestation, in addition to fetal bleeding (including intracranial hemorrhage) at delivery. Neither low-molecular-weight heparin (LMWH) nor unfractionated heparin crosses the placenta, and neither is associated with embryopathy or fetal bleeding.

Van De Velde M, De Buck F. Anesthesia for non-obstetric surgery in the pregnant patient. *Minerva Anestesiologica.* 2007;73:235–240.
Surgery during pregnancy is relatively common. This review of the literature focuses on relevant issues such as maternal safety during nonobstetric surgery in pregnancy, teratogenicity of anesthetic drugs, avoidance of fetal asphyxia, prevention of preterm labor, the safety of laparoscopy, and the need to monitor the fetal heart rate, and will finally give a practical approach to manage these patients.

Hypertensive Disorders in Pregnancy

Marie R. Baldisseri

Hypertensive disorders associated with pregnancy are the most common medical diagnoses in pregnancy, occurring in approximately 6%–8% of pregnancies.[1,2] Guidelines from the Society of Obstetricians and Gynecologists have classified hypertension of pregnancy into two categories: (1) preexisting chronic hypertension or (2) preeclampsia superimposed on either gestational hypertension or preexisting chronic hypertension.[3] The National High Blood Pressure Education Working Group on High Blood Pressure in Pregnancy classified hypertension as (1) chronic hypertension; (2) preeclampsia-eclampsia; (3) preeclampsia superimposed on chronic hypertension; and (4) gestational hypertension, which is transient during pregnancy, or chronic hypertension identified in the latter half of pregnancy.[1] In 2015 the American College of Obstetricians and Gynecologists Committee on Obstetrics defined a hypertensive obstetric emergency as acute-onset, severe hypertension persistent for 15 minutes or longer.[4]

Gestational hypertension, including preeclampsia, occurs de novo after 20 weeks of gestation. Chronic hypertension is defined as blood pressure >140/90 mm Hg either occurring before the pregnancy or manifesting before the 20th week of gestation.[5,6] Chronic hypertension is present in up to 22% of women of childbearing age and occurs more commonly in women older than 35 years of age. Approximately 1% of pregnancies are complicated by chronic hypertension, 5%–6% by gestational hypertension, and 1%–2% of all pregnancies are associated with preeclampsia. Preeclampsia occurs in 20%–25% of women with preexisting chronic hypertension.

Preeclampsia, which is usually seen after 20 weeks' gestation, is seen more frequently, although not exclusively, in the older parturient. Preeclampsia is most often observed in younger women (<18 years) and in the older parturient (>35 years). Predisposing factors for the development of hypertension and/or preeclampsia during pregnancy include a family history of hypertension or preeclampsia, preexisting diabetes mellitus, black race, obesity (body mass index [BMI] ≥30), vascular or renal disorders, primigravid state, preeclampsia with a previous pregnancy, migraine history, and multiple gestational pregnancies.[7] Smoking during pregnancy may actually decrease the incidence of hypertension and preeclampsia during pregnancy, although this is controversial.[8] Hypertensive disorders in pregnancy are a significant leading cause of maternal mortality and morbidity, particularly when preeclampsia is superimposed on preexisting chronic hypertension. A pregnancy-related mortality of 7.4% was reported as a result of hypertensive disorders in the United States from 2011 to 2013.[9] The risk of recurrent preeclampsia during subsequent pregnancies is approximately 18%. Those who develop preeclampsia earlier during pregnancy have been shown to be at risk for cardiovascular disease later in life.[10] Women with hypertensive pregnancy disorders are at both immediate and long-term risk for cardiovascular complications.[11]

BLOOD PRESSURE MEASUREMENTS IN PREGNANCY

The definition of hypertension during pregnancy has been controversial in the past. *Hypertension* is now most commonly defined as a blood pressure (BP) greater than 140/90 mm Hg. Recently, there has been a consensus that the degree of increase in systolic blood pressures (SBPs) and diastolic blood pressures (DBPs) may actually be more important than the baseline values. Many authors now agree that significant hypertension in pregnancy is defined by an increase of at least 30 mm Hg in the SBP and an increase in the DBP of at least 15 mm Hg. Treatment of a DBP greater than 110 mm Hg or an SBP greater than 160 mm Hg is advocated because of the increase in maternal complications with this degree of hypertension.[12]

Sustained (rather than transient) increases in BP are the key risk factors; accordingly, BP should be measured on at least two separate occasions at least 4–6 hours apart. BP measurements should be made in a standardized fashion (e.g., with the patient sitting in the same position) at each evaluation. Measurements in the upper arm in the recumbent position may yield false-low values because of aortal and caval compression by the gravid uterus. BP is best recorded with the patient in the sitting position or in the inferior arm in the lateral recumbent position. Many automated BP cuffs are accurate during pregnancy but may underestimate BP measurements in preeclamptic women. Manual BP readings are best suited for this group.

PHYSIOLOGIC CHANGES IN PREGNANCY

Essential to the management of hypertension in pregnancy is an understanding of the normal physiologic changes in cardiac output, vasomotor tone, and systemic BP that occur. During pregnancy, cardiac output can increase by 50% up to the early third trimester. The increase in cardiac output during this time is primarily caused by increased maternal blood volume, with a small increase in maternal heart rate. Cardiac output plateaus for the remainder of the pregnancy until labor. An increase in cardiac output is seen with each uterine contraction. Cardiac output increases again during the immediate postpartum period after delivery of the fetus and the placenta. It is during this period that cardiac output is highest because of the *autotransfusion effect* (see Chapter 154).

Systemic vascular resistance, and consequently BP, decreases during the second trimester. Increased synthesis of vasodilating prostaglandins may play a role in the regulation of BP and uterine blood flow in pregnancy. In a normal pregnancy, vascular resistance is determined by a proper balance of the effects of vasoconstricting and vasodilating factors, including prostaglandins. This balance may be disturbed in hypertensive states, owing to inadequate prostaglandin synthesis. In pregnancy-related hypertensive states, there is a paradoxical increase in

the systemic vascular resistance compared with pregnancy without hypertension. It is noteworthy that all patients with newly acquired or preexisting hypertension in pregnancy have a relative decrease in DBP during the second trimester, reflecting a relative decrease in systemic vascular resistance. Indeed, BP normalizes during the second trimester in some patients with preexisting hypertension.

CAUSES OF HYPERTENSION IN PREGNANCY

There are multiple causes of hypertension during pregnancy (Box 132.1). The most common hypertensive states are gestational hypertension without the presence of proteinuria, essential chronic hypertension, and preeclampsia (i.e., gestational hypertension with significant proteinuria). This classification is clinically useful to the practitioner, but the risk from systemic hypertension is significant for all three conditions, regardless of the specific cause of high BP. Hypertension during pregnancy is associated with an increased risk of death for both the mother and fetus. Severe maternal hypertension during pregnancy is associated with placental abruption and intrauterine growth retardation.[13]

Preeclampsia is defined as primarily diastolic hypertension that occurs transiently during the pregnancy, usually manifesting after the 20th gestational week, and resolves within 1–2 months after delivery. Women who develop preeclampsia have a high rate of recurrence of hypertension with subsequent pregnancies and often develop chronic hypertension at a later time.

Essential chronic hypertension (i.e., hypertension that was present before the pregnancy, whether diagnosed or undiagnosed) persists in the postpartum period and accounts for approximately one-third of all cases of hypertension during pregnancy. Essential chronic hypertension may manifest during the first 20 weeks of pregnancy. Women who develop hypertension without proteinuria in the last trimester of pregnancy may have essential hypertension, either unmasked or precipitated by the pregnancy. In these cases of de novo presentation of hypertension, care must be exercised to rule out other nonpregnancy-related causes of hypertension, such as renal artery stenosis, polycystic kidneys, glomerular or interstitial renal disease, pheochromocytoma, coarctation of the aorta, primary aldosteronism, Cushing syndrome, hyperthyroidism, and hyperparathyroidism. Previously undiagnosed essential chronic hypertension is a consideration, particularly in older multiparous women. As the age of parturients has increased, the incidence of essential hypertension in pregnant women has also increased. For some patients, the initial diagnosis of hypertension may be made during a routine prenatal visit with an obstetrician. For some patients, this prenatal visit is their first encounter with a physician as an adult. Essential hypertension should be suspected if there is a family history of hypertension, diabetes, or obesity. If there is a suspicion of preexisting essential hypertension, cardiac echocardiography should be performed to evaluate for left ventricular hypertrophy, which would suggest that hypertension has been a problem for an extended period. If BP extremes are avoided with treatment, there is no significant worsening of maternal and perinatal outcomes for pregnant patients with essential hypertension. Complications related to intrapartum hypertension (e.g., placenta previa, placental abruption, and preeclampsia) are less likely with judicious treatment of elevated BP. Patients with essential hypertension have not been shown to have a higher incidence of preeclampsia, particularly if the BP is well controlled. In general, mortality and morbidity are not increased in patients with uncomplicated mild chronic hypertension. However, morbidity and mortality are both increased in those patients with severe uncontrolled hypertension, and this is further complicated by superimposed preeclampsia.[14]

BOX 132.1 Causes of Hypertension in Pregnancy

1. Pregnancy-induced hypertension (gestational hypertension without proteinuria)
2. Essential hypertension
   - Preeclampsia (gestational hypertension with proteinuria)
   - Primary aldosteronism (Conn syndrome)
   - Renal artery stenosis
   - Coarctation of the aorta
   - Pheochromocytoma
   - Cushing syndrome
   - Cocaine use
   - Methamphetamine use

PATHOLOGY OF PREECLAMPSIA

Preeclampsia is a pregnancy-related multisystem disease process that usually occurs after the 32nd week of gestation. Systemic hypertension and significant proteinuria (i.e., 0.3 g or greater in a 24-hour urine collection) are invariably present. Clinical onset is usually characterized by rapid weight gain associated with generalized edema, followed by onset of hypertension or proteinuria or both. The incidence of preeclampsia in the United States ranges from 5% to 7%. The highest frequency occurs in young primigravidas, and the second highest incidence is in older multiparous women, a group that has a higher maternal mortality rate than the young primigravidas. The incidence is higher in patients with preexisting hypertension or renal vascular disease, and the symptoms may present earlier than the 32nd gestational week in these patients. Diastolic hypertension is most often seen in association with preeclampsia. It is less common to record SBP values greater than 160 mm Hg. If the SBP is greater than 200 mm Hg, the clinician should consider the possibility of underlying essential hypertension, which may be superimposed on the preeclamptic state. Because preeclampsia is a multisystem disease process, it may imitate or mask other pathologic conditions, and a thorough investigation to rule out other coexisting pathologies should be carried out. Familial prevalence of preeclampsia has been reported.[15,16] In some cases, preeclampsia manifests 1–7 days after delivery.[17,18] Most commonly, if preeclampsia is present during the postpartum period, it manifests as the HELLP syndrome, a severe variant of the preeclamptic spectrum of diseases.[19] This syndrome always includes some, if not all, of the following features: microangiopathic hemolytic anemia (H), elevated liver enzymes (EL), and low platelets (LP). The syndrome can develop without substantial BP changes or with no significant changes compared with BP readings taken during the pregnancy.

A significant elevation of BP in the second trimester is associated with an increased risk of preeclampsia later in the pregnancy.[20] One-third of pregnant women with mean arterial pressures greater than 90 mm Hg in the second trimester develop preeclampsia later during pregnancy. Only 2% of women with mean arterial pressures less than 90 mm Hg develop preeclampsia. Relatively mild hypertension early in pregnancy, which might be ignored in nonpregnant patients, should not be overlooked or dismissed in the parturient. As many as 25% of all pregnant women have slightly elevated BPs in the last month of pregnancy, but the incidence of preeclampsia is also highest during this period. Accordingly, clinicians must remain vigilant when faced with new-onset hypertension and look for other signs and symptoms that might suggest the presence of the preeclamptic syndrome.

The exact pathogenesis of preeclampsia is still unknown, although it is believed to be related to endothelial cell injury and dysfunction

that occurs in most maternal organs as a result of toxic substances released from a poorly perfused placenta. Genetic and immunologic factors also have been implicated in the pathogenesis of preeclampsia.[21] The generalized vasospasm that occurs in preeclampsia is responsible for many of the organ-specific signs and symptoms apparent in this multisystem disease. Widespread vasospasm is associated with increased circulating levels of vasoconstrictors, increased sensitivity to angiotensin II, and decreased levels of vasodilators. An imbalance in circulating angiogenic factors is emerging as a prominent mechanism that mediates endothelial dysfunction and the clinical signs and symptoms of preeclampsia.[22] There is an imbalance in the ratio of prostacyclin to thromboxane production that contributes to the pathogenesis of preeclampsia, although preeclampsia is not simply a state of prostacyclin deficiency. This idea has prompted studies of low-dose aspirin to prevent development of preeclampsia. Duley and colleagues reviewed 59 trials involving 37,560 women that examined the use of antiplatelet agents in preeclampsia. Antiplatelet agents, including low-dose aspirin, showed moderate benefits when used for the prevention of preeclampsia and its consequences, decreasing preterm births, fetal and neonatal deaths, and small-for-gestational-age babies. However, they recommended that further information would be required to assess which women are most likely to benefit, when treatment is best started, and at what dose.[23] The US Preventive Services Task Force (USPSTF) conducted a systematic evidence review that showed lower risks with the use of aspirin at a dose of 60–150 mg daily.[24] In a randomized, double-blind, placebo-controlled trial of low-dose aspirin vs. placebo in patients at high risk for developing preeclampsia, preterm preeclampsia occurred in only 1.6% of the patients as compared with the placebo group (4.3%).[25] The maternal organs most affected in preeclampsia are the kidneys, brain, liver, and hematologic system. Despite a lack of understanding of the exact pathogenesis of preeclampsia, significant improvements in the identification of the disease, monitoring, and management of these complex cases has improved perinatal and maternal morbidity and mortality. If vasospasm affects the uteroplacental bed, the incidence of intrauterine growth retardation, stillbirths, and neonatal deaths increases.[26]

Peripheral edema is a common symptom and complaint of pregnant women that cannot be ignored, because it may herald the onset of preeclampsia. The majority of women with preeclampsia present with generalized edema, and significant weight gain is the first symptom. However, because peripheral edema is a ubiquitous symptom during pregnancy, it is no longer considered a hallmark trait of preeclampsia. Preeclampsia is often manifested initially by peripheral edema that is usually accompanied by a gradual increase in BP. Sodium retention is partly responsible for edema formation and hypertension. In normal pregnancy, the glomerular filtration rate increases by as much as 50%. There is a concomitant increase in sodium reabsorption by the renal tubules and a 60%–80% increase in renal blood flow. Renal blood flow increases because of the increase in cardiac output and a decrease in renal vascular resistance. In preeclampsia, sodium retention is caused by a decrease in the glomerular filtration rate, possibly resulting from a vasospasm of the renal vasculature, commonly seen in preeclampsia. Renin and aldosterone secretion decrease in patients with preeclampsia, probably as a result of extracellular volume expansion and associated edema. The exact cause of the decreased activity of these factors is unknown, but it may be related to decreased renal prostaglandin synthesis, increased systemic BP, or the expansion of extracellular volume. In spite of the decreased levels of renin and aldosterone, sensitivity to angiotensin II is increased, a factor that may play a role in the pathogenesis of hypertension in preeclampsia.[27] Vascular maladaptation with increased vasomotor tone, endothelial dysfunction, and increased sensitivity to angiotensin II and norepinephrine in preeclampsia may be explained on the basis of angiotensin II–mediated mechanisms. Although sodium retention occurs in preeclampsia, blood volume actually can be diminished compared with that in normotensive pregnant patients.[28] Plasma volume contracts as extracellular fluid is preferentially shifted from the vascular space to the interstitium. However, the decrease in plasma volume does not indicate volume depletion in patients with preeclampsia. In contrast to hypovolemic patients, cardiac output is increased and central venous and pulmonary capillary wedge pressures are normal to high in patients with preeclampsia.[29] These data can guide the management of preeclampsia, because efforts should be directed to control BP rather than injudicious volume resuscitation.

Hyperuricemia in preeclampsia occurs at least in part because of decreased renal excretion of uric acid. However, the development of hyperuricemia frequently predates increases in serum blood urea nitrogen and creatinine, suggesting that other mechanisms are involved as well. Hyperuricemia has been used as a marker of severity of preeclampsia, and it is a risk factor for fetal mortality.[30]

CLINICAL PRESENTATION OF PREECLAMPSIA

The severity of illness is defined as mild, moderate, or severe depending on the presenting signs and symptoms and associated comorbidities. Because the nature of the process is multisystemic, preeclampsia may manifest with a wide spectrum of organ-specific abnormalities in addition to the general findings of edema, hypertension, and proteinuria. The pathologic abnormalities associated with preeclampsia are not necessarily secondary to hypertension, and thus the severity of preeclampsia does not always correlate with the degree of BP elevation.[20] BP elevations are classified as mild, moderate, or severe. Hypertension in preeclampsia may result from increases in systemic vascular resistance and cardiac output.

In mild preeclampsia, SBP is 130–140 mm Hg and DBP is 80–95 mm Hg. Peripheral edema is minimal, and there is a lack of associated visual or cerebral symptoms. In moderately severe preeclampsia, the SBP may increase to as high as 150–160 mm Hg, and the DBP can be as high as 110 mm Hg. An increase in SBP of 25 mm Hg or more and an increase in DBP of 15 mm Hg or more suggests the presence of moderate to severe preeclampsia. Peripheral edema, hyperreflexia, and visual symptoms are often present with moderately severe preeclampsia. In severe forms of preeclampsia, the SBP is greater than 160 mm Hg and the DBP is 110 mm Hg or greater. In severe preeclampsia, there are signs of multiple organ system involvement. Pulmonary, cardiac, renal, and neurologic disturbances may be present. Severe renal involvement in preeclampsia leads to glomeruloendotheliosis, which manifests as marked proteinuria (excretion of greater than 5 g protein daily). Oliguria (urine output less than 500 mL/day) is also common, and the serum creatinine concentration is usually greater than 1.6 mg/dL. Acute renal failure is relatively rare, although clinical evidence of renal involvement in preeclampsia significantly increases perinatal mortality.[31] Hepatic involvement is manifested by epigastric or right upper quadrant pain with elevated circulating levels of bilirubin and transaminases. Severe preeclampsia itself is the most common cause of hepatic tenderness and liver dysfunction in pregnancy.[32] Severe hepatic pathology can result in subcapsular hematomas and lacerations that may require surgical intervention. Neurologic changes may include persistent headaches, visual disturbances, focal neurologic deficits, and severe hyperreflexia with or without clonus. Computed tomography of the brain may exhibit cerebral edema, especially in the occipital region.

Severe preeclampsia associated with central nervous system irritability, manifesting as generalized tonic-clonic seizures not caused by other cerebral pathology, is defined as *eclampsia*.[33] Eclampsia can

occur without significant hypertension or proteinuria. Cardiovascular and respiratory changes can manifest as pulmonary edema, resulting from iatrogenic fluid overload; acute systolic left ventricular failure; or diastolic left ventricular dysfunction secondary to chronic essential hypertension. Pulmonary edema may also result from increased capillary permeability or from a decrease in colloid osmotic pressure that occurs to some extent during normal pregnancy but can be accentuated by preeclampsia.[34] Hematologic disturbances consist of thrombocytopenia, disseminated intravascular coagulation, and hemolysis.

It is unknown whether preeclampsia leads to persistent chronic hypertension after delivery, although it seems that this is unlikely. Nevertheless, an episode of preeclampsia may identify a subgroup of women with an increased risk of the eventual development of essential hypertension at a later time. Women with preeclampsia have been shown to have an increased risk of death resulting from cardiovascular disease later in life, independent of other measured risk factors.[35] These findings reinforced previously reported recommendations that a history of preeclampsia be used to target women at risk for cardiovascular disease. Debate continues as to whether the presence of preeclampsia or the duration of the disease process may be responsible for influencing factors that later lead to the development of essential hypertension. Women who develop preeclampsia superimposed on previously undiagnosed essential hypertension or underlying renal disease are predisposed to the later development of essential hypertension.

OTHER CAUSES OF HYPERTENSION IN PREGNANCY

Some of the less common causes of hypertension are listed in Box 132.1.

Primary aldosteronism in pregnant women has been reported, but is uncommon. The treatment of hypertension in these patients is directed toward medical management during the pregnancy and postpartum operative intervention if an adenoma is present.

Renal artery stenosis can be associated with preeclampsia. Medical therapy with antihypertensive agents is recommended. Although ideal therapy for these patients would include angiotensin-converting enzyme (ACE) inhibitors, these agents are contraindicated during pregnancy, and other alternatives must be employed.[36]

Coarctation of the aorta is a rare cause of hypertension. It may be previously undiagnosed and then initially diagnosed during a patient's first pregnancy. It can be associated with preeclampsia. The greatest risk to these patients is aortic rupture caused by cystic medial necrosis of the aortic wall. This risk is amplified because the normal physiologic changes of pregnancy place further stress on the abnormal aorta. Increases in BP, cardiac output, and the strain of labor with contractions can increase this risk. Aggressive medical management with antihypertensive medications, including beta-adrenergic blockers, improves the outcome of these high-risk patients.

Pheochromocytoma is a rare cause of hypertension, but patients have a poor outcome if the tumor is not diagnosed and treated. These patients can present with nausea, vomiting, profuse diaphoresis, severe headache, generalized weakness, palpitations, and seizures. The immediate causes of sudden death are secondary to pulmonary edema, cerebral hemorrhage, and cardiovascular collapse. Because there is a risk of significant morbidity and mortality to both mother and fetus, it was previously recommended that immediate surgical intervention be carried out during pregnancy. Currently, most experts advocate medical therapy with alpha- and beta-adrenergic blockade during pregnancy and tumor removal after delivery.

Illicit drug use, particularly from cocaine and methamphetamine, during pregnancy has been shown to result in worse maternal and fetal outcomes. The use of cocaine during pregnancy is associated with maternal migraines, epileptiform seizures, premature rupture of membranes, spontaneous miscarriages, and aggravating and worsening preexisting maternal chronic hypertension leading to hypertensive crises.[37,38] Methamphetamine use during pregnancy can worsen preexisting chronic hypertension and gestational hypertension with preeclampsia.[39] Continued use of methamphetamines during pregnancy results in shorter gestational ages and lower birth weights.[40]

GENERAL TREATMENT PRINCIPLES

Many of the treatments of pregnancy-related hypertension states are based on expert opinion and observational studies and not randomized controlled trials, However, the goal of treatment, using general and specific pharmacologic therapies, is to prevent severe maternal cardiovascular and cerebrovascular complications and to prevent perinatal morbidity and mortality.[41] The benefits of a well-balanced, low-salt diet and exercise have been shown to decrease the incidence and severity of hypertension. Bennett and colleagues conducted a retrospective analysis of women who had prior bariatric surgery before becoming pregnant. These patients had lower rates of hypertensive disorders in subsequent pregnancies.[42] Previously, some experts were concerned that aggressive management of hypertension in pregnancy might be detrimental, perhaps because hypertension improved uterine blood flow. These concerns appear to be unfounded, because later studies showed that uterine blood flow either increases or shows no change after hypertension is controlled. Nevertheless, caution must be exercised to ensure that the treatment of hypertension during pregnancy does not induce hypotension, which adversely affects maternal hemodynamics and compromises fetal well-being. There is a significant correlation between maternal BP control and fetal morbidity, and evidence now suggests that antihypertensive treatment for severe hypertension results in an improved perinatal outcome. The development of mild hypertension or preeclampsia at or near term is associated with minimal maternal and neonatal complications. However, the onset of severe gestational hypertension and/or severe preeclampsia early in gestation is associated with significant maternal and perinatal complications.[43] General recommendations for management and monitoring of hypertension in pregnant patients include the stabilization and treatment of acute changes in BP. Specific goal-directed therapy is indicated for various organ system abnormalities that may be present, particularly in those patients with moderate to severe preeclampsia. If proteinuria is not present and there is no suspicion of preeclampsia, conservative management on an outpatient basis is usually adequate. Immediate hospitalization with bedrest is recommended for patients presenting with proteinuria if there is a high index of suspicion for the diagnosis of preeclampsia.

ANTIHYPERTENSIVE DRUG THERAPY

There is now an extensive pharmaceutical armamentarium available for the treatment of both acute hypertensive episodes and chronic hypertension in pregnancy. In 1979 the US Food and Drug Administration (FDA) established categories for all drugs with potential and actual adverse effects on the fetus.[44] Although helpful to the clinician, these categories most often did not reflect current scientific knowledge regarding specific teratogenic effects of the drugs. In 2015 the FDA removed the pregnancy letter categories (A, B, C, D, and X) and now requires that the Pregnancy and Lactation Labeling Rule (PLLR) format be used to assist healthcare providers in assessing the benefits and the risks of specific medications. The PLLR includes a comprehensive summary and discussion of the risks of a medication and relevant information to guide clinicians about the use of specific medications during pregnancy and lactation.[45] However, many clinicians continue

to use the preexisting pregnancy letter category system because the PLLR is somewhat confusing and cumbersome and is not widely used in the United States to make prescribing decisions.

Most newer antihypertensive drugs used during pregnancy have not been extensively studied in animals and women. The decision to use them during pregnancy should be based on the potential benefit of using them versus the potential risks to the fetus. Prazosin, alpha-methyldopa, hydralazine, nifedipine, and labetalol have been safely used for many years in pregnant patients without significant fetal risk. Because most antihypertensive drugs are used later in pregnancy, the potential teratogenic effects of these drugs are not usually a major concern. However, if treatment is initiated for patients with preexisting essential hypertension or early-onset gestational hypertension, teratogenic effects must be considered when choosing antihypertensive drugs. It may be necessary to change the antihypertensive therapy early in pregnancy if the patient is taking drugs that could increase the risk of fetal abnormalities.

The goal of hypertensive therapy in pregnancy is the prevention of maternal complications such as intracerebral hemorrhage, stroke, and decompensated heart failure. There are no convincing data to determine the optimal BP goal with drug therapy. There is also disagreement concerning the proper normal values for BP during pregnancy, but most agree that acute treatment is mandated if (1) the SBP is greater than 160 mm Hg or the DBP is 105 mm Hg or greater or (2) if the SBP is more than 30 mm Hg greater than the baseline value or the DBP is more than 15 mm Hg greater than the baseline. For women with preexisting chronic hypertension, a BP of more than 160/100 should be targeted. If acute and urgent drug therapy management is required, some patients may need to be hospitalized, depending on their compliance with drug therapy and the urgency of lowering the BP based on concomitant organ system involvement. For patients presenting with SBP 140 mm Hg or higher and DBP 90 mm Hg or higher, urgent drug therapy should be implemented if there is concurrent evidence of symptoms, underlying essential hypertension, or end-organ involvement. If the patient presents after the 24th gestational week and fetal viability is ascertained, both cardiac and fetal telemetry may be required. For patients presenting with SBP less than 140 mm Hg and DBP less than 90 mm Hg and no evidence of significant proteinuria, management and treatment can be provided on an outpatient basis, with frequent office visits and close maternal and fetal assessments. If the hypertension is refractory to standard therapy, hypertension worsens despite adequate drug therapy, or the suspicion of preeclampsia arises, immediate hospitalization is recommended.

Conservative drug therapy is advocated for moderately severe preeclampsia, but the ideal treatment of choice for severe preeclampsia and associated end-organ involvement is immediate delivery of the fetus. Delay in delivery for patients with severe preeclampsia and end-organ involvement before 34 weeks' gestation results in serious maternal and fetal complications, and perinatal outcomes have been shown to be worse.[46,47] Conservative management with vigilant monitoring and assessment of these patients should be performed in a hospital setting. If the fetus is of mature gestational age, factors influencing the decision to deliver are dependent on the progression of the disease process, assessment of fetal lung maturity, and the status of the cervix. The conservative management of preeclamptic patients at a gestational age less than 24 weeks is associated with serious maternal complications, and termination of the pregnancy should be considered.[48,49]

Updated guidelines in 2015 from the American College of Obstetricians and Gynecologists Committee on Obstetric Practice[4] recommend the following:

- In addition to parenteral hydralazine and labetalol, oral nifedipine and/or oral labetalol (200 mg) may be considered as a first-line therapy, particularly if there is no intravenous (IV) access.
- Parenteral labetalol should be avoided in women with asthma, heart disease, or congestive heart failure.
- Magnesium sulfate is not recommended as an antihypertensive agent but is the drug of choice for seizure prophylaxis in severe preeclampsia and for controlling seizures in eclampsia.
- Although sodium nitroprusside can be used for treatment in emergent situations, there is a risk of cyanide and thiocyanate toxicity in the mother and fetus and increased intracranial pressure with potential worsening of cerebral edema in the mother.

During pregnancy, the clinician must decide when to use antihypertensive medications and what level of BP to target. The choice of antihypertensive agents is more limited in pregnancy, because not all available antihypertensive drugs have been adequately evaluated in pregnant women, and some agents are contraindicated.[50] A first-line drug still used today in pregnant patients, although less commonly in the general populace, is oral alpha-methyldopa, a central alpha-2-adrenergic agonist. Historically this has been a first-line drug of choice for many obstetricians in the past, and there has been little evidence to convince them otherwise. The starting dose is 250 mg orally two to three times a day for the first 48 hours of treatment. Dosing can be increased every 2 days until the desired BP level is achieved. The maximum daily dose is 4 g. Beta-adrenergic blocker therapy with oral labetalol, a combined alpha- and beta-adrenergic antagonist, has become popular as a single-agent antihypertensive. The recommended initial dose is 100 mg orally twice daily. The dose can be increased as indicated, either semiweekly or weekly, and the maintenance dose is usually 200–400 mg administered twice daily. The benefits of the beta-adrenergic blockade make this an attractive drug for parturients with underlying chronic essential hypertension and possible cardiac and vascular involvement. Diuretics also may be used, although care must be exercised to prevent excessive fluid loss, which can exacerbate the decrease in blood volume associated with preeclampsia. As mentioned previously, ACE inhibitors and angiotensin II receptor antagonists should be avoided intrapartum because these agents can increase perinatal morbidity and mortality.

For acute and emergent drug therapy for severe hypertension, IV antihypertensive drugs should be used; IV infusions are particularly attractive because they provide rapid control of BP and can be titrated easily. IV hydralazine, a direct arteriolar vasodilator, remains the standard for many obstetricians, although other drugs may be preferable because hydralazine may decrease BP precipitously.[51] Excessive lowering of BP is a particular problem when hydralazine is administered to preeclamptic patients with contracted blood volume. If hydralazine is used, it should be given as 5- to 10-mg IV boluses every 15–30 minutes until BP is controlled. Onset of the hypotensive effect is 10–20 minutes, and the duration of action is about 8 hours. Infusions of hydralazine are difficult to titrate and may be associated with increased incidence of fetal distress.

IV labetalol, a nonselective beta- and alpha-adrenergic receptor blocker, is also commonly used for the acute management of hypertension.[52] Labetalol rapidly decreases the BP but not at the expense of uteroplacental blood flow. Labetalol crosses the placenta but rarely causes significant neonatal bradycardia. An initial IV bolus of 10 or 20 mg should be given, followed by boluses of 40–80 mg at 10- to 15-minute intervals as needed to control hypertension. Labetalol also can be given by continuous IV infusion; the usual dose is 1–4 mg/min. Contraindications to the use of labetalol are the same as those for other beta-adrenergic antagonists, notably heart block and acute asthma.

Sodium nitroprusside is a potent arterial and venous vasodilator that quickly decreases BP. Rapid titration with a continuous IV infusion can be instituted starting at a dose of 0.25–0.5 μg/kg/min and adjusted every few minutes and titrated to effect. Invasive arterial

monitoring is often recommended in conjunction with its use. As with all potent vasodilators, care must be taken when using sodium nitroprusside, because patients with volume depletion may be particularly sensitive to its effects. Despite a paucity of data, concern regarding the risks of fetal cyanide toxicity prompts some practitioners to avoid using this drug in pregnant patients. Careful attention to dosing and duration of use should minimize the risk of toxicity.

Other less frequently used agents include IV nitroglycerin, oral clonidine, and beta-adrenergic blockers other than labetalol. IV nitroglycerin is easily titrated and is especially attractive for the management of patients with pulmonary edema. However, its antihypertensive potency is somewhat limited. IV infusions of nicardipine and clevidipine (calcium channel blockers) have been used in pregnancy, although there are limited data to support this usage.[53] Oral clonidine, a centrally acting alpha-2-adrenergic agonist, is an effective antihypertensive drug, but concerns about the risk of rebound hypertension after cessation limit its use.

There remains considerable debate concerning the use of beta-adrenergic blockers in pregnancy because of the potential risks of fetal bradycardia and a decrease in perfusion to the uteroplacental bed. Beta-blockers have been used during pregnancy without evidence of teratogenic effects. Although there is limited experience, they are considered as indicated in pregnant women with hypertension, mitral stenosis with pulmonary hypertension, coarctation of the aorta, ischemic heart disease, and supraventricular and ventricular arrhythmias and can be continued during delivery.[1,54] Esmolol has been used widely for heart rate control in pregnancy, but its efficacy is limited as an antihypertensive agent.

MANAGEMENT OF HYPERTENSION DURING LABOR AND DELIVERY

Management of hypertension during labor and delivery is directed toward avoiding acute and maternal complications. Antihypertensive drug therapy with a judicious use of IV fluids is of paramount importance to avoid unnecessary complications. Postpartum monitoring is advocated for high-risk, chronically hypertensive patients. Hypertension associated with preeclampsia usually resolves spontaneously within a few weeks after delivery. These patients are at risk for the development of acute complications, such as hypertensive encephalopathy, pulmonary edema, and acute renal failure. The choice of antihypertensive medications or the doses used may have to be adjusted after delivery, and minute amounts of all antihypertensive agents are found in breast milk. Although limited data are available, adverse perinatal effects have not been observed with the more commonly used drugs, such as alpha-methyldopa, hydralazine, and the various alpha-adrenergic blockers.[54]

KEY POINTS

- Hypertensive disorders associated with pregnancy are not uncommon and can either predate the pregnancy or be precipitated or unmasked by the pregnancy.
- BP measurements should be consistently taken in either the sitting position or in the inferior arm in the lateral recumbent position with each evaluation and should be repeated in 4–6 hours.
- Treatment is recommended if the SBPs are 160 mm Hg or higher or the DBPs are 110 mm Hg or higher, or with lower BPs if the patient is symptomatic.Elevated BPs caused by essential hypertension may transiently improve during the second trimester of pregnancy.
- Consistently elevated SBPs greater than 200 mm Hg should prompt the practitioner to consider undiagnosed chronic hypertension or some of the less common causes of hypertension such as primary aldosteronism, renal artery stenosis, pheochromocytoma, or illicit drug use.
- Preeclampsia most often appears after the 32nd week of gestation and resolves with delivery of the fetus.
- Preeclampsia can be superimposed on chronic hypertension.
- Preeclampsia may initially present during pregnancy or after delivery as the HELLP syndrome.
- Hypertension with BP elevation of 140/90 mm Hg or higher and proteinuria are the principal characteristics of preeclampsia. Edema is no longer a criterion for preeclampsia.
- Preeclampsia is a multisystem disease. Severe preeclampsia manifests with signs and symptoms of end-organ involvement.
- The antihypertensive drugs most frequently used in pregnancy have not been associated with significant fetal abnormalities.
- First-line oral antihypertensive drugs for moderate hypertension are alpha-methyldopa and labetalol.
- Parenteral antihypertensive agents are used for more severe elevations of BP. The agents most commonly employed are labetalol, hydralazine, and sodium nitroprusside in addition to IV nicardipine and clevidipine infusions.
- Caution should be exercised with the administration of hydralazine, particularly in patients with decreased plasma volume.

ANNOTATED REFERENCES

AACE Hypertension Task Force. American Association of Clinical Endocrinologists medical guidelines for clinical practice for the diagnosis and treatment of hypertension. *Endocr Pract.* 2006;12:193.
In 2006 the American Association of Clinical Endocrinologists (AACE) proposed guidelines for the diagnosis and treatment of hypertension, focusing on identifying and managing hypertension relating to or coinciding with endocrinopathies. These guidelines are based on positive data from randomized clinical trials. They recommended diuretics, beta-blockers, angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), and calcium channel blockers (CCBs) for treating hypertension in patients, particularly those with diabetes mellitus.

Magee L, Chan C, Waterman EJ, et al. Hydralazine for treatment of severe hypertension in pregnancy: meta-analysis. *BMJ.* 2003;327:955.
A meta-analysis was performed to review the outcomes in randomized controlled trials published between 1966 and 2002 that compared hydralazine with other antihypertensive agents for severe hypertension in pregnancy. In 13 trials comparing hydralazine with either nifedipine or labetalol, hydralazine was an effective antihypertensive drug for severe hypertension but was associated with an increased incidence of maternal hypotension, cesarean section, placental abruption, oliguria, adverse effects on fetal heart rate, and lower Apgar scores.

Magee LA, Helewa M, Moutquin JM, et al. Diagnosis, evaluation, and management of the hypertensive disorders of pregnancy. *J Obstet Gynaecol Can.* 2008;30:S1.
These guidelines from the Society of Obstetricians and Gynecologists are a comprehensive review of the different manifestations of hypertension during pregnancy. The guidelines focus on the classification, pathophysiologic features, and management of the hypertensive disorders of pregnancy. The

authors classified hypertension of pregnancy into two categories, preexisting or gestational, with preeclampsia superimposed on either gestational or preexisting chronic hypertension. Through a combination of evidence-based medicine and consensus, this report updates contemporary approaches to hypertension control during pregnancy.

Seely EW, Maxwell C. Chronic hypertension in pregnancy. *Circulation*. 2007;115:e188–e190.

This review describes chronic hypertension during pregnancy. It further describes the complications of chronic hypertension during pregnancy and how chronic hypertension affects both maternal and fetal outcomes.

Sibai B, Dekker G, Kupferminc M. Pre-eclampsia. *Lancet.* 2005;359:785.

This is a comprehensive review of preeclampsia with information on epidemiology, pathogenesis, and different treatment modalities. Maternal and perinatal outcomes are also discussed. The authors reviewed findings on the diagnosis and risk factors of preeclampsia and the present status of its prediction, prevention, and management.

Acute Pulmonary Complications During Pregnancy

Cornelia R. Graves

During pregnancy, the respiratory system undergoes a number of changes and is subject to functional and anatomic stresses. The critical care provider must remember these changes to appropriately care for the maternal-fetal unit. Although the need for ventilatory support is rare in pregnancy, respiratory insufficiency, which may complicate up to 1 in 500 pregnancies, is still the most common indication in pregnancy for admission to a critical care unit.[1]

In this chapter, the unique physiologic changes that occur during pregnancy are addressed and guidance is provided to critical care specialists who may encounter pregnancies that are complicated by acute pulmonary complications.

PULMONARY PHYSIOLOGY IN PREGNANCY

A number of physiologic changes affect respiration during pregnancy. Normal pregnancy is associated with a 20% increase in oxygen consumption and a 15% increase in metabolic rate. During the first trimester, minute ventilation is increased, whereas the respiratory rate remains the same. Although one might assume that the lung volume during pregnancy would decrease owing to a rise in the maternal diaphragm, the tidal volume (VT) is actually increased by 40% over baseline values. The increase in VT is thought to be caused by the increase in circulating progesterone that affects the respiratory center.[2] Arterial blood gas measurements reflect respiratory alkalosis compensated for by metabolic acidosis that results in a relatively normal pH. $PaCO_2$ usually ranges from 28 to 32 mm Hg. Functional residual capacity (FRC), residual volume, and total lung volume are decreased near term. Because of this decrease, respiratory distress occurs more rapidly in the gravid than in the nongravid state. The function of the large airways, as measured by forced expiratory volume in 1 second (FEV_1) and peak expiratory flow rate (PEFR), is essentially unchanged throughout pregnancy.[3] Oxygen consumption reaches 20%–33% above baseline by the third trimester. Airway hyperemia and edema occur during pregnancy as a result for human placental growth hormone, resulting in the possibility of a difficult or failed intubation.[4]

Colloid osmotic pressure is decreased by 20%. This change in hydrostatic pressure results in a propensity for pregnant patients to develop cardiogenic and noncardiogenic pulmonary edema.

Dyspnea on exertion is common, especially in the third trimester of pregnancy, making the diagnosis of respiratory problems more difficult than that in the nongravid state.

Fig. 133.1 illustrates the graphic relationship of pulmonary changes.

ASTHMA

Epidemiology

Asthma is one of the most common pulmonary problems in pregnant women; recent studies have reported that approximately 8% are affected.[5] The disease is characterized by hyperactive airways, leading to episodic bronchoconstriction. The role of inflammatory mediators in the pathogenesis of asthma has become apparent in recent years, leading to the early use of antiinflammatory medications in the treatment of exacerbations.

Effects of Asthma on Pregnancy

Asthma may be triggered by environmental allergens, medications—especially aspirin or nonsteroidal antiinflammatory drugs (NSAIDs)—or stress. Most exacerbations are marked by cough, wheezing, and dyspnea. Rapid therapeutic intervention at the time of an exacerbation is imperative to prevent impaired maternal and fetal oxygenation because uncontrolled asthma can increase maternal morbidity. In several studies, even after controlling for confounding variables, adverse pregnancy outcomes are more pronounced in patients with asthma. These include low birth weight, preeclampsia, preterm birth, and stillbirth.[6,7] Although historical data have shown an increase in death and low birth weight, Fitzsimmons and colleagues observed low birth weight in only those patients treated for status asthmaticus.[8] In addition, Schatz and colleagues noted that intrauterine growth restriction was directedly related to lung function as measured by FEV_1.[9]

However, a recent meta-analysis of 40 studies demonstrated that maternal asthma is associated with an increase in low-birth-weight infants, intrauterine growth restriction, preterm delivery, and preeclampsia when controlled for all variables.[10]

Effect of Pregnancy on Asthma

Numerous studies have observed that the course of asthma may be affected by pregnancy. Gluck and colleagues found that, on average, asthma improved in 36% of women during pregnancy, remained unchanged in 41%, and worsened in 23%.[11] Schatz and colleagues, in an analysis of 366 pregnancies in which patient status was followed by objective criteria, found that asthma improved in 28% of women, remained unchanged in 33%, and worsened in 35%. Fifty-nine percent of the patients had similar asthma control in successive pregnancies.[9] Asthma exacerbations are not uniformly distributed in pregnancy. Observational studies have found that exacerbations were most frequent before 24 weeks' gestation.[11]

Fetal sex may influence asthma in pregnancy. In one study, mothers who gave birth to boys were more likely to report improved asthma symptoms.[12] Dodds and colleagues found that the use of medications to treat asthma was less common in mothers of boys.[13] Although a number of hypotheses have been proposed, including alterations in progesterone levels and the role of leukotrienes, changes in not one of these mediators can explain the varied course of pregnant asthmatics.[14]

Management

The National Asthma Education and Prevention Program issued specific guidelines regarding asthma treatment. In 1993 the Working

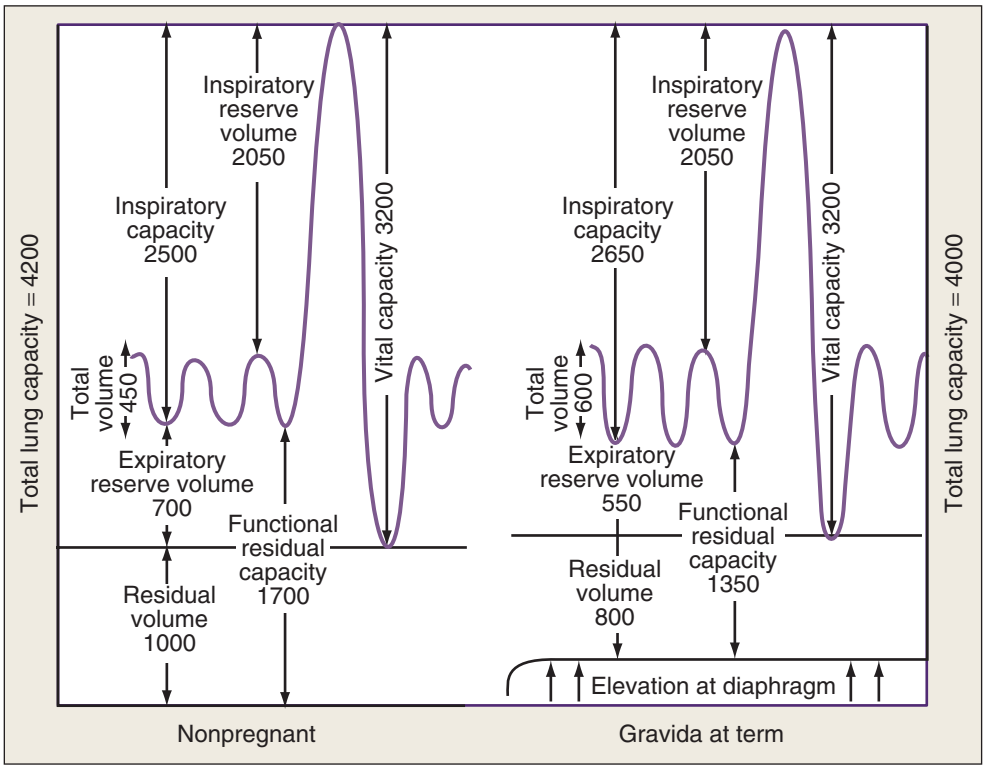

Fig. 133.1 Respiratory changes in pregnancy.

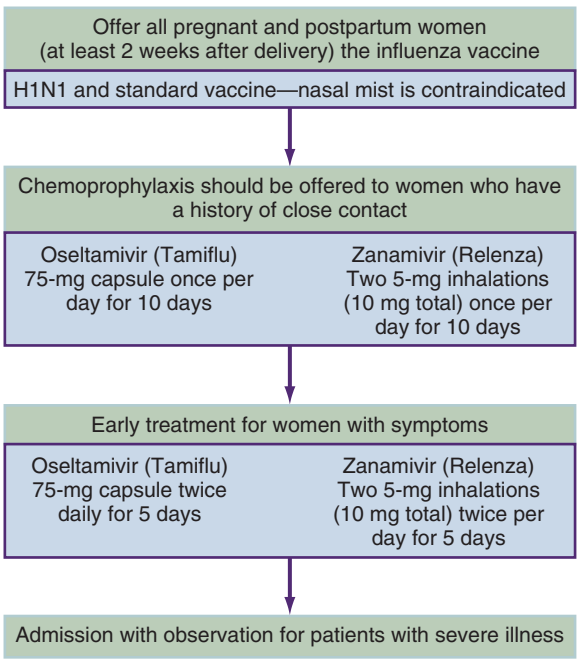

Fig. 133.2 Treatment during pregnancy.

Group on Asthma and Pregnancy established criteria for diagnosis and treatment among the gravid population (Fig. 133.2).[15]

The goals of treatment during pregnancy are to control exacerbation and prevent status asthmaticus, thereby reducing maternal and fetal hypoxemia. The initial step in treatment involves monitoring pulmonary function, and FEV_1 is the single best measure. A physical examination and chest radiography are poor measures of disease severity. A portable handheld peak flow meter gives a quick, accurate assessment by measuring PEFR. Most authorities believe that airways remain essentially unchanged throughout pregnancy; therefore every patient with asthma should be given a peak flow meter and be educated in its use. The patient should obtain a baseline PEFR during a quiescent period. The severity of disease is determined by the occurrences of exacerbations and changes in FEV_1 and PEFR. The PEFR can be used as a guide to refer the patient for emergency care.

Pharmacologic therapy is the mainstay of asthma treatment. Most drugs used in the treatment of asthma are thought to be safe in pregnancy. Inhaled beta-agonists are the most frequently used in asthma treatment. A prospective study of inhaled beta-agonists in 259 pregnancies showed no change in the rate of congenital malformation, perinatal mortality, low birth weight, or complications of pregnancy.[16] There is little role for the use of oral beta-agonists, which may cause more adverse systemic symptoms and are not more effective than inhaled drugs.

Inhaled corticosteroid therapy remains the mainstay of antiinflammatory treatment of asthma. Corticosteroids have also been advocated as first-line therapy in patients with mild asthma.[17] Studies have demonstrated that with asthma, those taking an inhaled corticosteroid were four times less likely than their nontreated counterparts to suffer an exacerbation.[18] Another randomized study noted that there was a 55% reduction in readmission rates because of acute asthma in patients using inhaled beclomethasone.[19] Inhaled corticosteroids can increase the effectiveness of beta-adrenergic agents by inducing the formation of new beta receptors. Because beclomethasone is the most studied of the inhaled corticosteroids in pregnancy, it is recommended as first-line therapy.[19] However, if patients are well controlled on other corticosteroid preparations, it is suggested they be continued on their current medication because all inhaled corticosteroids are labeled by the US Food and Drug Administration (FDA) as pregnancy class C. Other

BOX 133.1 Treatment of Asthma in Pregnancy

Mild Asthma
Characterized by FEV_1 or PEFR ≥80%
Brief (<1 hour) exacerbations
Treatment: inhaled beta-2-agonist

Moderate Asthma
Characterized by FEV_1 or PEFR range from 60% to 80%
Exacerbations more than twice per week; exacerbations may last for several days, and occasional emergency care needed
Treatment: inhaled corticosteroids and inhaled beta-2-agonist

Severe Asthma
Characterized by FEV_1 or PEFR <60% of baseline
Continuous symptoms, limited activity, frequent exacerbations and nocturnal symptoms, occasional hospitalization and emergency treatment needed
Treatment: inhaled corticosteroids, inhaled beta-2-agonist, sustained-release theophylline; oral corticosteroid taper for active symptoms

FEV_1, Forced expiratory volume in 1 second; *PEFR,* peak expiratory flow rate.

antiinflammatory medications used in the treatment of asthma (e.g., cromolyn sodium and nedocromil sodium) appear to be less effective than inhaled corticosteroids in reducing symptoms.

Systemic corticosteroids should be reserved for the periodic treatment of acute asthma exacerbations. Chronic oral corticosteroid therapy may increase the risks of gestational diabetes mellitus, preterm labor, low-birth-weight infants, and preeclampsia; however, it is evident that the benefits of controlled severe asthma outweigh the potential risks to the mother and fetus.

Intravenous corticosteroids have no increased benefits over oral corticosteroids in the treatment of acute exacerbations.[20] Methylprednisolone, hydrocortisone, and prednisone are safe for use in pregnancy, unlike betamethasone or dexamethasone, because very little active drug crosses the placenta.

Leukotriene pathway moderators have been shown to improve pulmonary function, as measured by FEV_1.[21] Zafirlukast and montelukast are rated as FDA category B; however, these drugs have not been frequently used in pregnancy, and their role is undetermined.

The treatment of asthma requires providing patient education in the preconceptional period and during the pregnancy for optimum outcome. Box 133.1 shows a suggested schematic for the treatment of asthma in pregnancy.

STATUS ASTHMATICUS

Status asthmaticus is a rare complication in pregnancy. Diagnosis is established by a PaO_2 of less than 70 mm Hg, a $PaCO_2$ of greater than or equal to 35 mm Hg, or a measured expiratory flow of less than 25% of expected. Because of impending respiratory failure, these patients should be managed in a critical care unit. Aggressive treatment of status asthmaticus is mandatory to protect the mother and fetus. Maternal mortality may be as high as 7% and fetal mortality as high as 11% despite adequate treatment. Epinephrine is not contraindicated in pregnancy during a respiratory emergency. Criteria for intubation in gravida with status asthmaticus include (1) inability to maintain a PaO_2 of greater than 60 mm Hg despite supplemental oxygen; (2) inability to maintain a PCO_2 of less than 40 mm Hg; (3) evidence of maternal exhaustion, with worsening acidosis (pH <7.2) despite intensive bronchodilator therapy; and (4) altered maternal consciousness.[15]

When traditional treatment proves to be ineffective, a number of therapies have been reported to be beneficial. The use of a helium–oxygen mixture that has been reported to be effective in studies in nonpregnant women has been used safely in pregnancy.[22]

Some drugs used in labor and delivery may increase the risk of inducing asthma in susceptible patients. 15-Methylprostaglandin $F_{2\alpha}$, ergonovine, and methylergonovine should be avoided. Prostaglandins E_1 and E_2 and oxytocin have very little effect on bronchospasm.

PULMONARY EDEMA

Pulmonary edema can be divided into two categories during pregnancy. *Cardiogenic pulmonary edema* is the result of high intravascular pressures creating a hydrostatic pressure gradient that results in extravasation of fluid into lung tissues despite the integrity of normal lung microcirculation. *Noncardiogenic pulmonary edema* is the result of a leaky pulmonary capillary bed despite normal intravascular pressures. During pregnancy, the distinction between these two types of edema may be blurred owing to disease states that exacerbate the hypo-oncotic state of pregnancy.

Etiology

There are a number of causes of pulmonary edema in pregnancy. Some are pathologic in their process; others are the result of idiopathic causes. One of the most common associations with pulmonary edema during pregnancy is hypertensive disease. In patients with hypertensive disease, pulmonary edema may be cardiogenic because of fluid overload or left ventricular dysfunction or noncardiogenic because of decreased oncotic pressure.

Another common cause of pulmonary edema in pregnancy is tocolytic therapy. Most cases described have resulted from the intravenous use of beta sympathomimetics. The use of magnesium sulfate therapy and the use of corticosteroids in association with tocolysis for preterm labor have been shown to exacerbate the condition. The incidence of edema is increased in multiple gestations and in patients with subclinical infection.

Underlying cardiovascular disease is also another cause of pulmonary edema during pregnancy. The increased cardiac output and heart rate that occur in pregnancy increase the gradient across a stenotic mitral value, which may lead to acute pulmonary edema.

Peripartum cardiomyopathy may also present as pulmonary edema in pregnancy; therefore cardiac imaging is recommended in all patients who present with acute refractory pulmonary edema in pregnancy.

Other causes of acute pulmonary edema in pregnancy include amniotic fluid embolism, aspiration, and the need for massive transfusion after hemorrhage.[23]

Treatment

The treatment of pulmonary edema during pregnancy depends on its etiology. The cause is best determined by the use of pulmonary artery catheterization and measurement of pulmonary capillary wedge pressure. Although all patients may not require this intervention, it is recommended in patients in whom the clinical picture may be unclear (e.g., those with hypertensive disease) and in those who do not respond to standard diuretic therapy.

For patients who do not improve rapidly with diuretic therapy, intubation and ventilation with positive pressure is recommended. In addition to the use of diuretic therapy, reduction of preload and afterload may be achieved by the use of vasodilators such as nitrates, hydralazine, or calcium channel blockers. All are safe for use in pregnancy.

Box 133.2 shows a guide for the treatment of patients with pulmonary edema.

BOX 133.2 Treatment in Patients With Pulmonary Edema

1. Determine the etiology, stop fluids, tocolysis, etc.
2. Treat with a diuretic (the author prefers furosemide in increments of 10- to 20-mg intravenous [IV] push).
3. Consider the use of morphine sulfate for patient comfort, 1- to 2-mg IV push q2–3h.
4. Proceed with hemodynamic monitoring if the patient does not rapidly respond to the earlier measures.
5. Consider intubation and mechanical ventilation with positive pressure for those patients with noncardiogenic pulmonary edema and those patients with cardiogenic pulmonary edema who need further support.

ACUTE RESPIRATORY DISTRESS SYNDROME

Etiology

The causes of acute respiratory distress syndrome (ARDS)[24–27] in pregnancy include preeclampsia, sepsis, aspiration, pyelonephritis, intrauterine infections, acute fatty liver of pregnancy, and amniotic fluid embolism.[28] In a review of 83 cases of ARDS associated with pregnancy, it was noted that among the causes of ARDS, 35 cases were attributed to uniquely obstetric conditions.[29] In addition, it was noted that varicella pneumonia and pyelonephritis were associated with ARDS. These conditions rarely trigger ARDS in immunocompetent adults. De Vaciana and colleagues pointed out that the development of lung injury in pregnancy correlates with known physiologic changes, including increased blood volume, decreased colloid osmotic pressure, and an unchanged critical lung closing volume despite a diminished FRC.[30]

Management

Management of ARDS includes diagnosis, maternal stabilization, fetal monitoring, investigation and treatment of underlying causes, and in many cases, evaluation for delivery. ARDS is a rare occurrence in the pregnant patient, with an estimated incidence of 16–70 per 100,000 pregnancies.[29]

Maternal stabilization includes intubation for mechanical ventilation if necessary. The clinician should consider intubation sooner rather than later in the presence of respiratory deterioration, keeping in mind that a decreased FRC exacerbates respiratory distress.

Contemporary thinking regarding the treatment of ARDS has found that a lung-protective ventilator strategy is the first therapy that has been found to improve outcomes. It has been noted in numerous studies that decreasing the VT from the standard of 12 mL/kg to 6 mL/kg or less and peak inspiratory pressures to less than 30 cm H_2O from 50 cm H_2O have resulted in decreased morbidity and mortality in patients with ARDS.[31] There has been considerable discussion in the literature concerning permissive hypercapnia and its use in preventing lung injury. However, there have been no controlled studies in pregnancy, and it is the opinion of the author that increasing $PaCO_2$ in pregnant patients should be undertaken with caution.

Judicious use of fluids is important in the management of ARDS. Although some authors have advocated the use of fluid restriction, clinicians must consider the volume-dependent status in pregnancy. It is recommended that fluid management be carefully guided by the use of hemodynamic monitoring.

Although oxygenation is important, it should be noted that oxygen should be used at the lowest concentration possible because it is toxic to the lung tissue in high doses. The goal of therapy is to keep the SaO_2 higher than or equal to 95%.

BOX 133.3 Management of the Patient With ARDS

1. Evaluate the patient in respiratory distress; calculate PaO_2/FiO_2 ratio; consider intubation if ≤200 mm Hg. The PEEP or CPAP mask is not recommended in pregnancy, owing to the high risk of aspiration.
2. Set tidal volume at 8–9 mL/kg to prevent increased peak pressures. Given recent evidence, aim to keep peak pressures less than 40 cm H_2O.
3. Use PEEP, starting at 5–8 cm H_2O to assist in recruiting alveoli.
4. Aim to keep FiO_2 less than 60%; keep SaO_2 greater than or equal to 95%.
5. Use a pulmonary artery catheter to assist in fluid management and to guide hemodynamic parameters.
6. Consider the use of tocolysis only after the patient has been adequately hydrated and oxygenated.
7. Consider delivery if indicated for obstetric conditions or if continuing the pregnancy has no clear benefit.

ARDS, Acute respiratory distress syndrome; *CPAP,* continuous positive airway pressure; *FiO_2,* fraction of inspired oxygen; *PaO_2,* partial pressure of oxygen; *PEEP,* positive end-expiratory pressure; *SaO_2,* oxygen saturation.

A number of other methods have been discussed in the treatment of ARDS, including inhaled nitric oxide, prostacyclin, surfactant, and inverse ratio ventilation. Currently, these modalities cannot be recommended because they have not been shown to decrease morbidity and mortality. The indications for prone positioning in pregnancy should be the same as for any other patient with severe ARDS.[32]

Fetal surveillance during ARDS may be more difficult because drugs used to sedate the mother can affect fetal heart rate and variability. Sedatives, anxiolytics, hypnotics, and nondepolarizing agents are not contraindicated in pregnancy. In addition, preterm contractions and labor may present a problem because of maternal hypoxemia. Clinicians are cautioned against starting tocolytic therapy before achieving adequate maternal oxygenation. If tocolysis is needed, beta-agonists such as terbutaline should be avoided because of the risk of increased pulmonary capillary permeability and increased demands on cardiac load. Magnesium sulfate is not strictly contraindicated, but it may also increase pulmonary capillary permeability. The use of NSAIDs may be the best choice for tocolysis because they have been proven to improve ARDS in animal models.[33] Consultation with a maternal-fetal specialist is recommended to assist intensivists in caring for these complex patients.

The timing of delivery of the patient with ARDS is a question that must be addressed by clinicians. Some authors advocate delivery after maternal stabilization, citing the possible "therapeutic effect" of delivery. Tomlinson and colleagues failed to demonstrate any significant benefit to delivery.[33] It is this author's opinion that delivery should be considered on a case-by-case basis, carefully weighing the risk/benefit ratio to the mother and fetus.

Extracorporeal membrane oxygenation (ECMO) support has been used successfully in pregnancy. One case series in pregnancy demonstrated an 88.9% chance of maternal survival and a 77% chance of fetal survival for patients who required support. In this series, four people delivered on ECMO, and if the fetus was viable, survival was 100%.[34]

Box 133.3 shows a reasonable management scheme for a patient with ARDS.

EMBOLISM

Because of the hypercoagulable changes in the coagulation cascade associated with pregnancy, there is an increased risk of venous

thromboembolism. It has been estimated that clinically symptomatic pregnancy-related venous thromboembolism occurs in 1–2 per 1000 pregnancies. Maternal age (>40 years) and ethnic and genetic factors may increase this risk. Postpartum thromboembolism is 3–5 times more common than antepartum thromboembolic events. A cesarean section confers a risk of 3–16 times that of a vaginal delivery.

Clinical signs of a pulmonary embolism include unexplained tachycardia, dyspnea, diaphoresis, and a nonproductive cough. The work-up for a suspected pulmonary embolism should include normal laboratory studies (arterial blood gases) and an electrocardiogram in conjunction with radiographic testing.[35] Pregnancy should not prevent obtaining appropriate radiographic studies. In patients with a high clinical index of suspicion for thromboembolic phenomena, a definitive diagnosis is imperative (Box 133.4). Ventilation-perfusion scans are recommended as the first diagnostic test. Spiral computed tomography has replaced ventilation-perfusion scanning in almost all centers as an initial test. Pulmonary angiography is still the gold standard for offering a definitive diagnosis. All of the aforementioned tests use less than the 5 rad of radiation exposure that has been associated with fetal teratogenesis. The use of an abdominal shield further decreases fetal exposure.

D-dimer levels have not been shown to be useful for the diagnosis of a thromboembolism during pregnancy because they may be elevated in the absence of a thrombus.[35] However, in a prospective study involving pregnant women with suspected pulmonary embolism, pulmonary embolism was ruled out if none of the three adapted YEARS criteria were met and the D-dimer level was less than 1000 ng/mL or if one or more of the three criteria were met and the D-dimer level was less than 500 ng/mL.[36]

Low-molecular-weight heparin (weight-based dosing BID) is the anticoagulant of choice in antepartum patients. Warfarin should be avoided during pregnancy, if possible. Unfractionated heparin can also be used. Neither of these drugs crosses the placenta, owing to the size of the drug molecule. Patients on low-molecular-weight heparin should be monitored with factor Xa levels to ensure a therapeutic level.

Warfarin may be used in the second and third trimesters in patients in whom heparin therapy may be contraindicated. Coumarins may be difficult to reverse and are not routinely recommended during pregnancy. All anticoagulants can be used in the postpartum period and are compatible with breastfeeding.[37]

The goals for therapy during the antepartum and postpartum periods (6–8 weeks postdelivery) should be an activated partial thromboplastin time of 2.0–2.5, a factor Xa level of 0.6–1.1, or an international normalized ratio (INR) of 2.5–3.0.

An amniotic fluid embolism is a rare phenomenon that may initially present as severe respiratory distress. Risk factors include rapid labor, multiple gestation, polyhydramnios, and uterine rupture. Patients with an amniotic fluid embolism usually have symptoms of acute respiratory distress, cardiovascular collapse, and profound disseminated intravascular coagulation. Treatment is supportive; however, maternal mortality may be as high as 80%.

BOX 133.4 Treatment of Pulmonary Embolism in Pregnancy

1. Begin therapy immediately based on strong clinical suspicion while awaiting complete diagnostic work-up.
2. Establish the diagnosis with appropriate diagnostic imaging test.
3. Maintain maternal and fetal oxygenation.
4. Administer intravenous heparin and maintain full anticoagulation for 7–10 days before changing to subcutaneous injections (antepartum) or warfarin (postpartum). Oral anticoagulation should be continued 6–8 weeks after delivery.
5. Keep the international normalized ratio, activated partial thromboplastin time, or factor Xa level in the therapeutic range.

PNEUMONIA

Concern over the H1N1 virus has reinforced the seriousness of influenza infection in pregnant patients. Historical data have shown that during an influenza pandemic, mortality rates among pregnant women are unusually high. Neuzil and colleagues noted that even during a normal season, compared with their postpartum counterparts, pregnant women were more likely to be hospitalized.[38] The risk of hospitalization was highest in the third trimester, with women nearly five times more likely to be hospitalized than the postpartum control group. Influenza-related morbidity occurs in 10.5 of 10,000 pregnant women, compared with 1.91 of 10,000 in nonpregnant controls. Influenza pneumonia mortality in pregnancy has been noted to range from 12.5% to 42.1%.[39]

Contemporary management of influenza infection in pregnancy includes the use of antiviral medications for preventing and treating the disease. Amantadine and rimantadine have been shown to be effective in shortening the course and duration of disease in influenza A and influenza B. Recently, oseltamivir (Tamiflu) and zanamivir (Relenza) have been recommended for the prevention of influenza infection. Current Centers for Disease Control and Prevention (CDC) guidelines recommend that treatment be initiated for pregnant women (including patients until 2 weeks postpartum) with documented exposure to influenza virus and those patients who present with symptoms in the first 48 hours of illness, regardless of their gestational age. Medication should be started at the first sign of symptoms; awaiting confirmation of the diagnosis and delaying therapy could result in rapid progression of the disease. In the 2009 flu season, 6% of deaths were in pregnant women, even though only 1% of the population is pregnant at any given time. Data suggest that the use of antiviral medications significantly reduces perinatal morbidity and mortality. Since 1995 the CDC has recommended that all pregnant women receive influenza immunizations. There has been some discussion regarding the use of thimerosal, which is used in the standard influenza vaccine; most authorities feel that the thimerosal-free vaccine, when available, is preferable.

It is the opinion of the author that all pregnant patients who present with respiratory symptoms after exposure to viral illness should be hospitalized for observation.[39–41] Changes in maternal respiratory physiology during pregnancy can make progression from mild respiratory distress to severe respiratory distress rapid and unpredictable[38] (see Fig. 133.1).

Since first being identified in December 2019, the novel coronavirus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), has rapidly spread around the globe. Data from 8207 pregnant women in the United States suggest that the symptoms of COVID-19 are similar to the nonpregnant population, with most presenting with cough (>50%) and shortness of breath (30%). Chronic lung disease, diabetes mellitus, and cardiovascular disease were more commonly reported among pregnant women than among nonpregnant women. Among women with COVID-19, hospitalization was approximately six times higher. After adjusting for age, presence of underlying medical conditions, and race/ethnicity, pregnant women were significantly more likely to be admitted to the intensive care unit and receive mechanical ventilation. The risk of death in pregnancy was noted to be significantly higher that in the non pregnant population.[42] We are still learning about this virus in pregnancy—the use of

steroids and remdesivir in pregnancy has been associated with improved outcomes.[43]

CONCLUSION

Because of the rare need for mechanical ventilation, there are no randomized controlled trials to determine the treatment modalities that are most effective in pregnancy. A retrospective study noted a maternal mortality rate of 14% and a fetal mortality rate of 11% in patients who required mechanical ventilation during pregnancy. The critical care specialist, maternal-fetal medicine specialist, anesthesiologist, and other members of the healthcare team should work closely to provide coordinated care.[44] Understanding the physiologic changes during pregnancy, combined with aggressive treatment of early pathologic changes, will assist in providing improved management in gravid patients with potentially lethal pulmonary complications.

KEY POINTS

- Physiologic changes in pregnancy affect the management of respiratory disease, making the pregnant patient more susceptible to respiratory compromise.
- Caution should be used when considering treatment for preterm labor in patients requiring respiratory support. Correction of oxygenation is usually more effective than pharmacologic therapy.
- The need for mechanical ventilatory support does not mandate delivery of the fetus. Most studies do not report significant maternal improvement after delivery.
- Pregnancy is a hypercoagulable state that increases the risk of thromboembolic phenomena.
- Care should be taken to carefully evaluate pregnant patients with viral pneumonia for acute respiratory symptoms.
- Amniotic fluid embolism is a rare cause of respiratory complications in pregnancy.
- ECMO support has been used successfully in pregnancy with excellent maternal and fetal survival.
- The identification of pulmonary embolism in pregnancy may be enhanced by using the adjusted YEARS algorithm, which re-evaluates the use of D-dimer in pregnancy.
- Asthma is the most common respiratory complication in pregnancy and should be controlled in pregnancy in order to avoid perinatal complications.
- As respiratory complications in pregnancy are rare, assembly of a multidisciplinary team is essential to improve maternal and fetal outcomes.

Postpartum Hemorrhage

Cornelia R. Graves

Obstetric hemorrhage remains a leading cause of maternal mortality and morbidity worldwide, with most deaths occurring in the postpartum period. Recognition of blood loss in obstetric hemorrhage can be challenging. Therefore interventions focused at the patient level, provider and unit level, and system level are imperative in order to provide optimal patient care. In smaller centers, guidelines to establish which patients should be triaged to a higher level of care should be considered. In all centers, a plan for evaluating and managing obstetric hemorrhage, which may include assessing additional resources, should be in place in order to reduce maternal morbidity and mortality.

DEFINITION

The commonly accepted definition of *postpartum hemorrhage* (PPH) is excessive and life-threatening bleeding after 20 weeks of gestation, which occurs at the time of delivery of the fetus or placenta. Primary PPH is excessive blood loss within 24 hours of delivery. Secondary PPH is any abnormal or excessive bleeding that occurs between 24 hours and 12 weeks after delivery. Most commonly, bleeding occurs in the third stage of labor, which refers to the time between delivery of the fetus and delivery of the placenta after its separation and expulsion from the uterus. Defining excessive bleeding is somewhat problematic because it can be difficult to determine the exact amount of blood loss, and clinicians tend to underestimate blood loss. With a normal vaginal delivery, blood loss is typically 500 mL or less; after a normal cesarean section, it is usually 800–1000 mL. Blood loss greater than these amounts has been used to define PPH. However, uncomplicated vaginal and cesarean deliveries can occasionally occur with greater amounts of blood loss but without hemodynamic compromise. Therefore a more comprehensive definition of PPH is bleeding (regardless of the volume of shed blood) that is severe enough to cause hemodynamic compromise.

A decrease in hematocrit greater than 10% as a diagnostic criterion has also been widely accepted as a definition of PPH. The hematocrit level initially may be in the low-normal to normal range despite excessive bleeding, because hematocrit does not change quickly in response to rapid hemorrhage. The hematocrit is also determined in part by the volume of infused resuscitation fluid. Because the parturient's blood volume is increased by 30%–50%, the signs of tachycardia and hypotension may not manifest until blood loss exceeds 1500 mL. If the patient is hemodynamically unstable but the amount of blood visualized externally is relatively insignificant, occult sites of internal bleeding should be suspected immediately.

INCIDENCE AND MORTALITY

Maternal mortality has significantly decreased over the past 50 years in developed countries, in part because of improvements in obstetric care. However, in the United States maternal mortality rose to a high of 17.4 per 100,000 in 2018. Much of this increase was associated with rising rates of hemorrhage. This increase was the highest among developed countries. Racial and ethnic gaps exist between non-Hispanic black (37.1 deaths per 100,000 live births), non-Hispanic white (14.7), and Hispanic (11.8) women.[1]

In the United States, the rate of PPH increased 26% between 1994 and 2006 primarily because of increased rates of atony. In contrast, maternal mortality from postpartum obstetric hemorrhage has decreased since the late 1980s and accounted for slightly more than 11% of maternal mortalities (approximately 1.7 deaths per 100,000 live births) in 2009. This observed decrease in mortality is associated with increasing rates of transfusion and peripartum hysterectomy.[2–4] Worldwide, obstetric hemorrhage is the leading cause of maternal mortality, causing 24% of maternal deaths, or an estimated 127,000 maternal deaths annually. PPH is the most common type of obstetric hemorrhage and accounts for the majority of the 14 million cases that occur each year. In developing countries, PPH may cause up to 40% of all maternal deaths.

PATHOPHYSIOLOGY

At term, blood flow to the uterus and placenta increases to 600–1200 mL/min, accounting for 10% of the maternal cardiac output. To stem the flow of blood and provide immediate hemostasis after delivery of the fetus, the uterus begins to contract. Myometrial contraction is the primary mechanism for both placental separation and hemostasis. The myometrial muscle fibers of the uterus simultaneously contract and retract, causing compression and occlusion of the blood vessels. Uterine atony results when this adaptive mechanism fails and the myometrial fibers are unable to contract and retract normally. Excessive bleeding from the uterus and lower genital tract from many causes, including lacerations, placental anomalies, and trauma, is directly related to the increase in blood flow to the uterus and placenta. At term, there is a physiologic increase in the circulating concentrations of various clotting factors. This adaptive response also helps control the bleeding that is a normal consequence of delivery. However, these factors are overwhelmed by the excessive bleeding of PPH.

PRESENTATION

PPH often manifests as brisk and excessive flow of blood from the uterus. Maternal hemodynamics may be unaltered initially. If the bleeding is left untreated, typical presenting signs of hypovolemic shock (i.e., tachycardia, tachypnea, and hypotension) become apparent. Bonnar described the symptoms related to PPH in relation to the amount of blood loss (Table 134.1).[5] However, the signs and symptoms of

TABLE 134.1 Presentation of Symptoms in Postpartum Hemorrhage

Percent Blood Loss (mL)	Systolic Blood Pressure (mm Hg)	Signs and Symptoms
Stage I: 10–15 (500–1000)	Normal	Tachycardia, palpitations, dizziness
Stage II: 15–25 (1000–1500)	Low to normal	Tachycardia, weakness, diaphoresis
Stage III: 25–35 (1500–2000)	70–80	Restlessness, pallor, oliguria
Stage IV: 35–45 (2000–3000)	50–70	Collapse, air hunger, anuria

hemorrhagic shock may not occur immediately and may extend over a longer period if shed blood is sequestered in the uterus. Occult bleeding occurs most frequently with retained placental fragments; uterine atony; and concealed hematomas in the pelvis, perineum, or retroperitoneal space. Occult hemorrhage in the uterus or hematomas should be suspected in patients who are in the third stage of labor with hemodynamic instability but little or no evidence of external bleeding. Signs and symptoms of excessive bleeding also may be delayed because of the relative hypervolemic state of the patient and by the position of the patient after delivery with the legs elevated in stirrups.

CAUSES

Obtaining a detailed antenatal history is important in helping to determine a possible cause of PPH. Because obstetric hemorrhage is difficult to predict, it is important for all institutions that deliver obsterical care to have protocols in place to manage and treat obstetrical hemorrhage. Risk assessment tools are readily available and have been shown to identify 65%–80% of patients who may experience PPH. However, it should be remembered that risk factors may change during the labor process, so constant assessment is essential in order to attempt to identify patients at risk.[6]

A history of prior bleeding episodes associated with heavy menses or with dental or surgical procedures should raise the possibility of an underlying coagulation or bleeding disorder. Significant predisposing risk factors for the development of PPH include previous episodes of PPH, multiparity, and multiple fetuses. Women with a prior history of PPH can have up to a 15% risk of recurrence with subsequent pregnancies.[6] Risk factors associated with the development of PPH are listed in Box 134.1. Early recognition of these risk factors may aid in the diagnosis and subsequently in the management of PPH. A randomized controlled trial (RCT) comparing oxytocin administration before and after delivery of the placenta found that birth weight, labor induction with augmentation, chorioamnionitis, use of magnesium sulfate infusions, and previous episodes of PPH increased the risk of developing PPH.[7] However, a significant number of patients with PPH have no obvious predisposing factors.[8]

Potential causes of PPH are listed in Box 134.2. Risk factors for obstetric causes at the time of admission should be identified and reassessed during the intrapartum and postpartum process. The most frequent cause of PPH is uterine atony after delivery of either the fetus or placenta. Bleeding is from the uterine vessels or from the placental site of implantation if the placenta has been delivered. The incidence of uterine atony is approximately 1 in 20 deliveries. Uterine atony can lead to rapid and severe PPH. Overdistention of the uterus secondary to multiple gestation, fetal macrosomia, or polyhydramnios is a major predisposing risk factor for the development of uterine atony. Other predisposing factors are retained placenta, chorioamnionitis, uterine structural abnormalities, and muscle fatigue after prolonged or stimulated labor. General anesthesia, particularly with halogenated anesthetics, and magnesium sulfate infusions can inhibit effective uterine contractions and lead to uterine atony. The diagnosis of uterine atony is a clinical diagnosis made by assessing the tone of the uterus and its size by manually palpating the uterus externally. Bimanual examination of the uterus also can be performed to diagnose uterine atony. A boggy uterus associated with heavy vaginal bleeding or with an appreciable increase in the size of the uterus is diagnostic of uterine atony. The size of the uterus may be larger than normal because of accumulated blood within it.

Lacerations of the lower genital tract are the second most frequent cause of PPH. Lacerations of the vagina and cervix can result from a number of causes. These lesions occur most commonly as a result of prolonged or tumultuous labor, particularly with uterine hyperstimulation with oxytocic agents. Nevertheless, lacerations can occur spontaneously as well. They are seen in deliveries associated with

BOX 134.1 Predisposing Risk Factors for Obstetric Hemorrhage

Low Risk
No previous uterine incision
Singleton pregnancy
<4 previous vaginal births
No known bleeding disorder
No history of PPH

Moderate Risk
Prior cesarean section or uterine surgery
Multiple gestation
>4 previous vaginal births
Chorioamnionitis
History of previous PPH
Polyhydramnios
Large uterine fibroids

High Risk
Placenta previa or low lying
Suspected accreta or percreta
HCT <30 *and* other risk factors
Platelets <100,000
Active bleeding on admission
Known coagulopathy

HCT, Hematocrit; *PPH,* postpartum hemorrhage.

BOX 134.2 Causes of Postpartum Hemorrhage

Uterine atony
Cervical or vaginal lacerations
Retention of placental fragments
Placental anomalies
Traumatic hematomas of the perineum or pelvis
Coagulation disorders
Uterine rupture
Uterine inversion

instrumentation, such as forceps deliveries, or with extrauterine or intrauterine manipulations of the fetus. Attempts to remove the placenta or placental fragments manually or with instrumentation can lead to traumatic lesions or hematomas. Excessive vaginal bleeding or traumatic hematomas can result from these lacerations. Careful examination with palpation of the vagina and cervix may reveal the presence of lacerations.

Retention of placental fragments or the entire placenta can lead to severe and life-threatening hemorrhage, which may be immediate or delayed depending on the extent of accumulated blood in the uterus. The most common definition of retention of the placenta in utero is when part or all of the placenta is retained in the uterus for more than 30–60 minutes after delivery of the fetus. Retained placenta is more likely to occur with a preterm gestation of less than 24 weeks.

Placental abnormalities (i.e., placenta accreta, placenta increta, and placenta percreta) have been associated with retained placenta and failure of complete separation of the placenta from the uterus. If the placenta has been delivered, it is imperative to closely examine the placenta to look for missing fragments, a finding that suggests retained placental tissue.

Another less frequent cause of PPH is uterine rupture. Rupture is more common in patients with prior cesarean incisions and in those with any prior operative procedures of the uterus (e.g., intrauterine device placement, laparoscopy, hysteroscopy). Uterine rupture may manifest with severe and acute abdominal pain and hemodynamic instability, but there may not be significant bleeding initially. Uterine inversion is relatively uncommon but may be associated with blood losses of up to 2 L.

A defect in hemostasis resulting from an underlying coagulopathy should be considered if the uterus is contracting normally and manual exploration has excluded either placental retention or uterine rupture. Disseminated intravascular coagulation (DIC) associated with placental abruption (premature separation of a normally implanted placenta), the HELLP syndrome (*h*emolysis, *e*levated *l*iver enzymes, and *low p*latelets), intrauterine fetal death, acute fatty liver of pregnancy, sepsis, or amniotic fluid embolism may precipitate PPH. The incidence of severe DIC associated with PPH is estimated at 0.1% of pregnancies.[9]

Amniotic fluid embolism syndrome (AFES) is a catastrophic condition that can occur either during the pregnancy or after the delivery. AFES manifests with acute respiratory failure, cardiogenic shock, and/or DIC.[10] As much as 80% of these patients develop DIC, and in some, DIC is the major clinical abnormality. Oozing from intravenous (IV) or skin puncture sites, mucosal surfaces, or surgical sites should raise the suspicion of DIC; confirmation of the diagnosis is made by laboratory coagulation studies. Although the coagulation profile is unlikely to be abnormal with acute postpartum bleeding in the absence of DIC, coagulation parameters are clearly abnormal in the presence of DIC, regardless of the cause. In late pregnancy, the circulating fibrinogen level usually is two to three times the normal prenatal value, but fibrinogen concentration is dramatically decreased if DIC is present. Preexisting or pregnancy-acquired disorders of coagulation are relatively infrequent causes of significant PPH.

DIAGNOSTIC STUDIES

Although the diagnosis is obvious with significant and excessive bleeding after delivery, not all patients present with immediate bleeding because of hematoma formation or accumulations in the interior of the uterus. Bedside ultrasonography can be used for the detection of clots, hematomas, and retained placental products. For patients who are at high risk for development of PPH, periodic ultrasound examinations during pregnancy can offer invaluable information concerning the extent and progression of placental disease. Angiography with selective arterial embolization can be used both diagnostically and therapeutically. Bleeding sites can be visualized and embolized simultaneously. For evaluation of a proven or suspected case of PPH, the following laboratory studies are almost always indicated: complete blood count with platelet count, coagulation studies with prothrombin and activated partial thromboplastin times, fibrinogen, and fibrin split products. D-dimer may be of limited use, as it may be elevated in normal pregnancies. With acute hemorrhage, the measurements of hemoglobin concentration and hematocrit may also be of limited use.

PREVENTION

There has been much controversy concerning the preferred methods of managing the third stage of labor in terms of decreasing bleeding complications. The debate concerns active versus expectant management. Expectant management consists of waiting for separation and expulsion of the placenta, with minimal intervention except for gentle fundal massage. Active management of the third stage of labor involves three components. The first consists of administering a uterotonic drug, usually oxytocin, immediately after delivery of the fetus to promote contraction of the uterus and subsequent expulsion of the placenta. The second maneuver consists of gentle traction on the umbilical cord after the uterus is well contracted and then using countertraction against the uterine fundus.[11] The third maneuver is uterine massage after delivery of the placenta.

Manual external uterine massage should be performed immediately to stimulate uterine contractions and express clots if uterine atony is suspected or confirmed. If the uterus does not respond to vigorous manual external massage and the rapid administration of oxytocin, bimanual massage with one hand on the uterus and the other hand placed anterior to the cervix in the vagina should be performed. Aggressive uterine manipulation can result in uterine inversion. Direct pressure should be maintained over visible perineal, vaginal, or cervical lacerations. These general treatment measures can control excessive bleeding and even stop the hemorrhage in a significant proportion of patients.

The two modalities were compared in five RCTs in a Cochrane meta-analysis of studies enrolling more than 6000 women. A 60% decrease in PPH was associated with active management of the third stage of labor.[12]

GENERAL TREATMENT MEASURES

Many deaths associated with PPH may have resulted because clinicians underestimated the extent of blood loss and failed to provide rapid and aggressive resuscitation with fluids and blood products. Several authors have suggested the use of specific management protocols for the care of patients with PPH.[5,13,14] These guidelines can expedite rapid diagnosis and management of obstetric hemorrhage. Quantification of blood loss during delivery has been recommended, as it gives a better assessment of blood loss. Several current toolkits are available to assist medical personnel in managing the weighing of pads and laps in order to give an accurate assessment.[15] Simulation may also be used to assist the team in responding more quickly to this emergency.[36]

A general assessment of the patient, evaluation of vital signs, a detailed physical examination, and a review of the obstetric delivery details are all necessary for the clinician to formulate a comprehensive evaluation and critique of the situation. The general treatment measures for PPH are the same as those for any patient with acute hemorrhage (Box 134.3). Oxygen should be administered routinely. At least two large-caliber IV lines should be placed immediately. Central venous access is usually unnecessary unless peripheral access cannot be

BOX 134.3 General Treatment Measures for Postpartum Hemorrhage

Oxygen administration
Gentle massage of the uterine fundus
Placement of large-caliber intravenous catheters for rapid and aggressive fluid resuscitation with isotonic solutions using the "3:1 rule"
Blood product administration depending on the extent of bleeding and coagulation abnormalities

TABLE 134.2 Therapeutic Response to Initial Fluid Resuscitation

Response	Description	Follow-Up Treatment
Rapid response	<20% of blood volume lost	No additional fluids or blood are needed.
Transient response	20%–40% of blood volume lost; responds to initial fluid bolus but later has worsening vital signs	Continue fluids and consider blood transfusions.
Minimal or no response	Ongoing severe hemorrhage with >40% blood volume lost	Continue aggressive fluid and blood product replacements.

obtained quickly. Aggressive volume resuscitation should be instituted immediately, because this intervention can be lifesaving in patients with ongoing bleeding and hemodynamic instability. Either normal saline or lactated Ringer's solution is the preferred fluid for aggressive resuscitation. Isotonic electrolyte solutions provide transient intravascular volume expansion. Monitoring of changes in blood pressure, heart rate, and pulse pressure can help the clinician to determine the amount of blood loss, particularly in cases in which bleeding is internal (Table 134.2).

Initiation of transfusion therapy should be undertaken in the setting of ongoing blood loss. In the setting of PPH, hemoglobin and hematocrit will not reflect blood loss. Vital signs may also be difficult to follow, as maternal vital signs may lag behind actual loss. In patients with ongoing blood loss of 1500 mL or more, preparation should be made for transfusion. The use of tranexamic acid (TXA) should be considered. In a large, randomized trial (WOMAN) 1 gram of TXA was noted to reduce the risk of maternal mortality rates. The data suggest that for every 15-minute delay in treatment, there was a decrease in survival by 10%.[37] When given after 3 hours, there was no change in maternal mortality. The dose may be repeated in 30 minutes or if hemorrhage recurs within 24 hours. The use of TXA did not increase the risk of thrombosis. It is the opinion of the author that TXA should be started when the need for transfusion is being considered. The use of prophylactic TXA has not been well established. Preliminary studies suggest that prophylactic application during cesarean section may reduce blood loss; however, RCTs are pending.[16]

Delay in replacing blood loss in pregnancy may lead to an increased risk of coagulopathy and multisystem organ failure. Most of the literature governing blood product replacement in pregnancy has been taken from the trauma literature. The current recommendation is for packed red blood cells and fresh frozen plasma in a 1:1 ratio.[17] In women with a consumptive coagulopathy, early administration of cryoprecipitate and fresh frozen plasma should be considered. A normal fibrinogen level in pregnancy is higher than in the nonpregnant patient; therefore coagulopathy should be suspected in patients with a fibrinogen less than 200 mg/dL.

BOX 134.4 Blood Product Replacement

Crossmatched blood.
Type-specific or "saline crossmatched" blood.
Compatible ABO and Rh blood types.
Administration of tranexamic acid (1 g) when there is a need for massive transfusion. May repeat in 30 minutes if needed.
Rh-negative blood is preferable if typed blood is not available.
Warm the blood, if possible, especially if the rate of infusion is >100 mL/min or if the total volume transfused is high; cold blood is associated with an increased incidence of arrhythmias and paradoxical hypotension.
Administer calcium if blood is transfused rapidly at >100 mL/min because of the binding of calcium by anticoagulants in banked blood.
Give fresh frozen plasma (FFP) and 10 units of packed red blood cell (PRBC) transfusions in a 1:1 ratio when possible.
Give 10–12 units of platelets if the platelet count decreases to $<50 \times 10^9$/L.
Cryoprecipitate can be given to replace fibrinogen in addition to the FFP.
Consider 60–120 μg/kg intravenous bolus injection of recombinant activated factor VII (rFVIIa).

As in trauma, emergent use of O Rh–negative blood should be available for use. Each hospital and unit should establish protocols based on the resources available.

Although cell salvage or autologous blood transfusion may be used in patients with anticipated hemorrhage (i.e., placenta accreta), the emergent nature of PPH often limits its use.[18] The previous concerns for amniotic fluid contamination are no longer an issue with new filtration techniques.

Recombinant activated factor VII (rFVIIa) has been recommended in cases of refractory PPH that has not responded to medical measures, including blood product administration.[19] Although supported by few and uncontrolled studies, the available data suggest a potential role of rFVIIa in the management of severe PPH before performing a definitive hysterectomy. A management protocol has been provided (Box 134.4).

SPECIFIC TREATMENT MEASURES

Oxytocic (uterotonic) drugs administered IV, intramuscularly, or intramyometrially are used to stimulate the uterus by producing rhythmic contractions and controlling the degree of hemorrhage. Dosing regimens for oxytocic drugs are listed in Table 134.3.

Oxytocin (Pitocin) remains first-line therapy for most obstetricians. Prophylactic oxytocin, given either before or after placental delivery, decreases the incidence of PPH up to 40%.[20] It is also used prophylactically after delivery of the fetus but before delivery of the placenta to decrease the duration of the third stage of labor and the amount of blood loss. In an RCT, the incidence of PPH was similar, regardless of whether oxytocin was given before or after placental delivery.[7] Additionally, the incidence of retained placenta was similar for patients treated with oxytocin before or after delivery of the placenta. Oxytocin should be used with caution in patients with hyperactive uterine contractions or hypertension, because the pressor effect of sympathomimetic drugs can increase if they are used with oxytocin.

Methylergonovine (Methergine) is now considered second-line therapy. It is a direct uterotonic agent that reduces uterine bleeding and shortens the third stage of labor. Hypertension is a relative contraindication for the use of Methergine. Carboprost tromethamine (Hemabate), a synthetic prostaglandin similar to prostaglandin $F_{2\alpha}$ but

TABLE 134.3 Dosing Regimens for Oxytocic Drugs

Drugs	Regimens
Oxytocin (Pitocin)	5-unit IV bolus
	Add 20–40 units oxytocin to 1 L of fluids
	10 units intramyometrially
Methylergonovine (Methergine)	0.2 mg IM every 2–4 h
Ergonovine maleate (Ergotrate)	100–125 μg IM or intramyometrially every 2–4 h
	200–250 μg IM
	Total dose 1.25 mg
Carboprost (Hemabate)	250 μg IM or intramyometrially every 15–90 min
	Total dose 2 mg
Misoprostol	800 μg PR or 800 μg of sublingual misoprostol

IM, Intramuscular; *IV,* intravenous; *PR,* per rectum.

with a longer duration, produces myometrial contractions that induce hemostasis at the placentation site, reducing postpartum bleeding. It is used in some centers as a second-line uterotonic agent. Asthma is a relative contraindication to the use of carboprost. Carboprost has been shown to be effective in decreasing PPH refractory to oxytocin and ergonovine. Misoprostol, prostaglandin E_1, causes uterine contractions, and rectal administration of this drug has been shown to be useful in refractory PPH. Although oxytocin is considered the standard of care for treating PPH, it is not always viable or available, particularly in resource-poor clinical settings, because of refrigeration requirements and the need for IV administration. In a large randomized prospective trial, the efficacy and acceptability of 800 μg of sublingual misoprostol were compared with 40 IU of IV oxytocin to control postpartum bleeding.[21] The primary endpoints were cessation of active bleeding within 20 minutes and additional blood loss of 300 mL or more after treatment. The findings suggested that sublingual misoprostol is a viable alternative to 40 IU of IV oxytocin for treatment of primary PPH after oxytocin prophylaxis during the third stage of labor. Misoprostol stopped bleeding as rapidly as oxytocin and with a similar quantity of additional blood loss.

The practice of uterine packing to control bleeding remains somewhat controversial. Although this practice had been abandoned for many years, it has recently resurged as an effective method for tamponade of bleeding from the uterus. Balloon occlusion catheters have been used in the treatment of PPH.[22] Recent data suggest that balloon tamponade is an effective method for controlling hemorrhage, and in 80% of cases, hysterectomy was averted. When a specific uterine balloon catheter is not available, placement of a Sengstaken-Blakemore tube or a large Foley catheter can also be used to control bleeding.[23]

If there is a suspicion of retained placenta, examination of the uterus is both diagnostic and therapeutic. The uterus must be explored digitally and retained placental fragments removed either manually or with instruments. Because this procedure can be difficult and quite painful, it may be necessary to use regional or general anesthesia to obtain optimal visualization and manipulation of the uterus. Administration of oxytocic drugs should continue during manual extraction of placental fragments. Administration of broad-spectrum antibiotics has been recommended whenever there is manipulation or instrumentation of the uterus.

Compression of the abdominal aorta against the vertebral column, which can be achieved by pressing a fist on the abdomen cephalad to the umbilicus, can be a lifesaving temporizing maneuver to control hemorrhage before surgery in the presence of fulminant bleeding with severe hemodynamic compromise. If there is persistent and significant bleeding despite the therapeutic measures described, consideration should be given to arteriography with selective arterial embolization. This procedure requires the expertise of an interventional radiologist and may not be readily available in many hospitals. Successful embolization of the bleeding sites can be accomplished, obviating the need for surgical intervention.[24] In addition, fertility can be preserved with this procedure.[25] Prophylactic placement of embolectomy catheters in patients at high risk for PPH to minimize the procedural delay in the presence of active bleeding has also been used in some centers. If embolization is unsuccessful, balloon catheter occlusion of the hypogastric and iliac arteries has been successfully performed as a temporizing measure before surgery.[26–28] Complications are minimal, and postprocedural fever appears to be the most common complication of the procedure.

SURGICAL THERAPY

Surgical therapy is reserved for cases not amenable to medical therapy. Patients with ongoing hemorrhage despite aggressive medical therapy are candidates for operation. Surgery is the treatment of choice for uterine rupture. Lacerations, if visible, are directly repaired and oversewn. Lacerations high in the vaginal vault or in the cervix may require operative repair, primarily for improved visualization of the lesions. Hematomas of the lower genital tract are incised and drained. Arterial embolization of vaginal and vulvar lesions has been used. Hematomas of the broad ligament and in the retroperitoneal space are often managed conservatively if there is only minimal further expansion of the hematoma, but surgical exploration or embolization is mandated if additional significant bleeding occurs. Radiographic imaging with computed tomography, magnetic resonance imaging, and/or ultrasonography is a useful adjunct to monitor the expansion of these hematomas.

Ligation of the uterine, ovarian, or internal iliac (hypogastric) arteries can be performed. The uterine arteries provide 90% of uterine blood flow. Ligation of these arteries can often control bleeding with success rates of up to 92% and a complication rate of 1%.[29] If hemostasis is not achieved with uterine artery ligation, the ovarian and internal iliac arteries can be ligated as well. Ligation of the internal iliac arteries is technically more difficult, and success rates range from 40% to 100%.[29,30] Ligation of the internal iliac arteries usually is done only if ligation of the uterine and ovarian arteries has proved unsuccessful in halting bleeding.

Uterine compression sutures running through the full thickness of both uterine walls (posterior and anterior) have recently been described for the surgical management of atonic PPH.[31–33] The different uterine suture techniques have proved to be valuable and safe alternatives to hysterectomy in the control of massive PPH. In contrast, hysterectomy remains the definitive surgical therapy to control bleeding. Hysterectomy is required if bleeding continues despite ligation of the internal iliac arteries. Subtotal or total hysterectomy is curative in PPH. In cases of uterine rupture, it is the only surgical option, and nonsurgical modalities are only temporizing measures until the patient can be brought to the operating room. In developed countries, the incidence of postpartum emergent hysterectomy is approximately 1 in 2000 deliveries. Rossi and colleagues reviewed 24 articles that included 981 cases of emergency postpartum hysterectomy. They found women at highest risk of emergency hysterectomy are those who are multiparous, who had a cesarean delivery in either a previous or the present pregnancy, or who had abnormal placentation.[34]

COMPLICATIONS

Serious morbidity may follow PPH. Complications from postpartum bleeding include hematologic abnormalities such as DIC and dilutional coagulopathy from massive fluid resuscitation and/or massive transfusion (more than 10 units of packed red blood cells). Dilutional coagulopathy occurs when more than 80% of the original blood volume has been replaced. Life-threatening complications of hemorrhagic shock, including renal failure and liver failure, acute respiratory distress syndrome (ARDS), and pituitary necrosis (Sheehan syndrome), can occur. Sheehan syndrome can result from severe PPH that causes permanent hypopituitarism from avascular necrosis of the pituitary gland.[35]

PROGNOSIS

The prognosis of PPH depends on many factors, some of which are directly related to prompt diagnosis and treatment. The cause of bleeding, the duration of bleeding, and the extent of bleeding all affect the likelihood of a good outcome.

KEY POINTS

- PPH is defined as excessive bleeding after a vaginal or cesarean delivery that can be associated with hemodynamic instability if the bleeding is severe.
- Every center that performs obstetric care should have a protocol in place to manage patients with obstetric hemorrhage.
- The usual signs of tachycardia and hypotension associated with severe bleeding may not manifest early because of the relative hypervolemic state of pregnancy.
- Occult bleeding occurs most frequently with retained placental fragments; uterine atony; and concealed hematomas in the pelvis, perineum, or retroperitoneal space.
- Many women have predisposing factors leading to the development of PPH. Ongoing evaluation of the patient in the antepartum, intrapartum, and postpartum period is essential for risk identification.
- The most frequent cause of PPH is uterine atony, which occurs in 1 of every 20 deliveries. Risk factors for uterine atony include overdistention of the uterus, retained placenta, uterine muscle fatigue, and use of halogenated anesthetic agents.
- DIC is associated with placental abruption, the HELLP syndrome, acute fatty liver of pregnancy, intrauterine fetal death, sepsis, and amniotic fluid embolism.
- The early use of TXA has been shown to reduce maternal morbidity and mortality.
- Aggressive resuscitation leads to improved outcomes. Transfusion should be considered early. Current recommendations suggest 1:1 placement of red blood cells to plasma to prevent consumptive coagulopathy.
- Placenta accreta spectrum, defined as abnormal invasion of the placenta into the uterine wall, is associated with significant maternal morbidity and mortality. Optimal management involves a standardized approach with a comprehensive multidisciplinary care team accustomed to managing this condition.

Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State

Jan Gunst and Greet Van den Berghe

Diabetic ketoacidosis (DKA) and hyperosmolar hyperglycemic state (HHS) are endocrine emergencies occurring in diabetes patients. Both conditions require prompt, adequate treatment to avoid mortality. In patients with known diabetes mellitus, both conditions are most commonly triggered by noncompliance with diabetes treatment or infection. Nevertheless, any condition that induces severe insulin resistance and elevated counterregulatory hormones may trigger DKA or HHS, including severe trauma, myocardial infarction, and stroke. DKA and HHS may be the presenting syndrome of previously unknown or new-onset diabetes.[1,2]

PATHOPHYSIOLOGY

DKA and HHS are caused by an absolute or relative, respectively, insulin deficiency in the presence of elevated counterregulatory hormones (glucagon, cortisol, growth hormone, and catecholamines) (Fig. 135.1).[2] This constellation leads to increased hepatic gluconeogenesis and glycogenolysis and reduced peripheral glucose utilization in insulin-dependent tissues. The resultant hyperglycemia induces glycosuria once above the renal threshold, leading to osmotic diuresis and significant losses of water and electrolytes, in particular potassium and phosphate. In cases of (nearly) absolute insulin deficiency or very severe insulin resistance with substantially elevated counterregulatory hormones, lipolysis is activated, and free fatty acids are oxidized to ketone bodies in the liver. Ketones by themselves may aggravate osmotic diuresis, and accumulation of ketone bodies induces ketoacidosis. In patients with residual insulin effect, hepatic ketogenesis is suppressed. As a result, hyperglycemia and associated fluid and electrolyte losses further aggravate, eventually leading to a hyperosmolar hyperglycemic state, characterized by severe dehydration and alterations in mental state. As DKA can only develop in cases of minimal insulin effect, it mainly occurs in patients with type 1 diabetes, whereas HHS develops in patients with type 2 diabetes. DKA usually develops rapidly (within 24 hours), whereas HHS develops more insidiously over days.[2]

In the vast majority of cases, DKA patients present with severe hyperglycemia (>200–250 mg/dL [11.1–13.9 mmol/L]).[2] However, some diabetes patients at risk—taking sodium-glucose co-transporter 2 (SGLT2) inhibitors, pregnancy, excessive alcohol intake, prolonged fasting, chronic liver disease—may develop ketoacidosis in the absence of elevated blood glucose concentrations.[3] Several pathophysiologic mechanisms may contribute to the so-called "euglycemic DKA" or "DKA with lower-than-anticipated glucose levels," including increased urinary glucose losses, glucose uptake by the fetus, and insufficient gluconeogenesis because of lack of substrate or liver disease.[3]

DIAGNOSIS

In most cases, the diagnosis of a hyperglycemic emergency is obvious after taking a history and performing a clinical examination and is confirmed by laboratory examination (Table 135.1). Apart from diagnosing DKA/HHS, the precipitating event also should be sought, which often needs additional diagnostic tests.[2]

Clinical Features

Patients with DKA/HHS present with polyuria and clinical signs of volume depletion and weight loss, which are accompanied by polydipsia in alert patients.[2] Nausea, vomiting, and abdominal pain frequently occur in DKA patients but not in HHS patients.[2,4] DKA patients usually present with Kussmaul respiration because of metabolic acidosis, with a fruity breath scent resulting from exhaled acetone.[5] Patients with HHS and severe DKA typically have decreased consciousness secondary to the pronounced metabolic alterations and volume depletion. Focal neurologic deficits and seizures may also occur in HHS.[5]

Key Diagnostic Criteria

DKA patients usually present with the classic triad of severe hyperglycemia (the "D" in DKA), ketosis ("K"), and metabolic acidosis ("A"). The key diagnostic criterion in DKA is a significant elevation in circulating ketone concentrations.[6]

Three ketones are produced in DKA: acetoacetate, a ketoacid produced by the liver; beta-hydroxybutyrate, a hydroxyacid formed by reduction of acetoacetate; and acetone, a true ketone that is formed by decarboxylation of acetoacetate and that is exhaled.[6] Increased ketogenesis can be confirmed by measuring increased circulating ketone concentrations or by detecting ketonuria. The preferred diagnostic test is the direct measurement of blood beta-hydroxybutyrate, however, for several reasons.[6] First, beta-hydroxybutyrate is the most abundant circulating ketone in DKA, exceeding values of 3 mmol/L (31 mg/dL). Second, the alternative test, the nitroprusside test, which semiquantitatively detects acetoacetate in blood or urine, may yield false-positive and false-negative results. Finally, acetoacetate testing may not be reliable to monitor therapy during DKA. Indeed, because beta-hydroxybutyrate is converted into acetoacetate during treatment to be excreted in the urine, rise in acetoacetate concentrations may falsely give the impression of insufficient treatment response.[6]

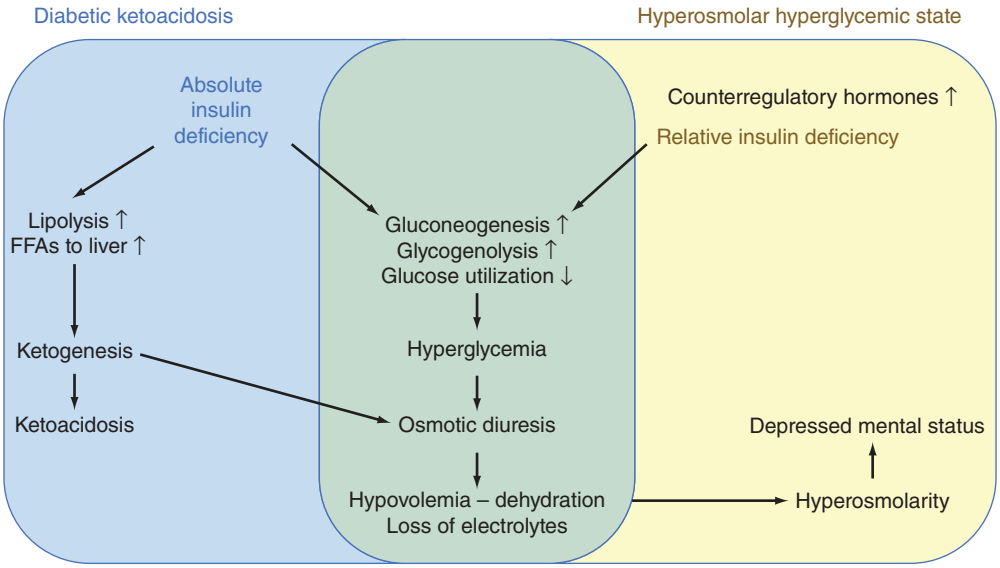

Fig. 135.1 Pathophysiology of Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State. Insulin deficiency, either absolute or relative, and a concomitant increase in counterregulatory hormones (glucagon, growth hormone, cortisol, and catecholamines) stimulate gluconeogenesis and glycogenolysis and attenuate glucose utilization. The ensuing hyperglycemia induces osmotic diuresis, leading to large fluid and electrolyte losses. When insulin deficiency is absolute, lipolysis is activated and free fatty acids (*FFAs*) are used for hepatic ketogenesis, which aggravates osmotic diuresis. The resultant clinical picture is diabetic ketoacidosis, with the classic triad of hyperglycemia, ketonemia, and metabolic acidosis. When residual insulin effect is present, ketogenesis is inhibited, allowing a further increase in blood glucose concentrations and associated fluid and electrolyte losses. The resultant hyperosmolarity is accompanied by profound alterations in mental status, characteristic of hyperosmolar hyperglycemic state.

The traditional blood glucose cutoff of DKA is 200–250 mg/dL (11.1–13.9 mmol/L), and in most cases, admission blood glucose is even considerably higher.[5,7] However, in patients with additional risk factors—SGLT2 inhibitors, pregnancy, excessive alcohol intake, prolonged fasting, chronic liver disease—DKA may develop without severe hyperglycemia.[3] Moreover, pseudonormoglycemia may develop in cases of severe hyperlipidemia.[5]

The third diagnostic criterion of DKA is metabolic acidosis (pH <7.3 and HCO_3^- <18 mmol/L) with elevated anion gap, explained by the accumulation of ketones. Metabolic acidosis can be classified as mild (pH 7.25–7.3 and HCO_3^- 15–18 mmol/L), moderate (pH 7.0–7.24 and HCO_3^- 10–14.9 mmol/L), or severe (pH <7.0 and HCO_3^- <10 mmol/L).[5]

HHS is characterized by more severe hyperglycemia (>540–600 mg/dL [30–33.3 mmol/L] and often >1000 mg/dL [55.6 mmol/L]) and hyperosmolarity (serum osmolality >320 mmol/kg) in the absence of significantly elevated ketone concentrations and metabolic acidosis.[5,8] However, mild ketonemia may develop. The laboratory alterations in HHS are typically accompanied by severely impaired mental status (stupor, coma).[2]

Other Laboratory Abnormalities

DKA and HHS patients may have secondary organ damage because of volume depletion, including acute kidney injury. Acute kidney injury is usually more pronounced in HHS patients, because of a more protracted time course before admission and more severe volume depletion.[5] Although patients have a potassium and phosphate deficit, admission serum potassium and phosphate are often normal or elevated as a result of insulin deficiency, hypertonicity, and acidemia. Severe hyperlipidemia caused by lipolysis may lead to pseudohyponatremia and pseudonormoglycemia in DKA. Because infection is a common trigger for DKA and HHS, patients often have increased inflammatory parameters upon admission. C-peptide is low in DKA patients because of absolute insulin deficiency, whereas C-peptide is usually in the normal range in HHS patients.[5]

TREATMENT

Initial treatment consists of fluid resuscitation, insulin therapy, potassium supplementation, and treatment of the precipitating cause (Box 135.1). Other treatments, including bicarbonate and phosphate substitution, are controversial. After resolution of ketoacidosis and HHS, insulin therapy should be switched to maintenance therapy.[5,7,8]

Fluid Resuscitation

DKA and HHS patients have profound volume depletion, with an approximate water deficit of 100 mL/kg and 100–200 mL/kg body weight, respectively.[1] Fluid resuscitation is essential to restore volume homeostasis and tissue perfusion. Moreover, it will directly reduce blood glucose by dilution and reducing counterregulatory hormones.[1] Restoration of peripheral perfusion is also a prerequisite to obtain sufficient perfusion of tissues with insulin-dependent glucose uptake (skeletal muscle and adipose tissue).

Isotonic saline has been recommended as initial resuscitation fluid, although infusion of large volumes may induce hyperchloremic metabolic acidosis.[5,7,8] No large randomized controlled trial has investigated whether balanced crystalloids are clinically superior in this patient population, however.[9] Guidelines recommend to administer 1000–1500 mL normal saline during the first hour, after which the fluid infusion rate is titrated according to hemodynamics and readouts of peripheral perfusion (urinary output, skin perfusion, etc.).[5,7,8] In general, fluid rates of 250–500 mL are recommended after the first

TABLE 135.1 Clinical and Diagnostic Features in Patients With Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State

Diabetic Ketoacidosis	Hyperosmolar Hyperglycemic State
Precipitant Factors	
Noncompliance with insulin treatment	Noncompliance with treatment
Infection	Infection
New-onset (type 1) diabetes	New-onset (type 2) diabetes
Other	Other (corticosteroids, excess diuretics, etc.)
Course of Illness	
Rapid (in general <24 hours)	Insidious (days)
Clinical Findings	
Polyuria, polydipsia, dehydration, hypovolemia	Polyuria, dehydration, hypovolemia
Nausea, vomiting, abdominal pain	Depressed mental status up to coma
Fruity odor of breath, Kussmaul respiration	
Diagnostic Laboratory Criteria	
Blood glucose >200–250 mg/dL*	Blood glucose >540–600 mg/dL*
AND elevated ketones in blood or urine	AND serum osmolality >320 mmol/kg
AND metabolic acidosis	NO significant ketosis
(pH<7.3 and HCO_3^- <18 mmol/L)	NO metabolic acidosis
Concomitant Laboratory Abnormalities	
Elevated anion gap	Variable anion gap
Low C-peptide	Normal C-peptide
	Acute kidney injury

*For conversion of blood glucose concentrations in mg/dL to mmol/L, divide by 18. American Diabetes Association guidelines recommend the highest reported blood glucose cutoff for both diabetic ketoacidosis and hyperosmolar hyperglycemic state, UK guidelines the lowest.[5,7,8] In patients at risk—taking sodium-glucose co-transporter 2 (SGLT2) inhibitors, pregnancy, excessive alcohol use, decreased caloric intake, chronic liver disease—ketoacidosis may develop in the absence of elevated blood glucose concentrations (euglycemic diabetic ketoacidosis).[3]

BOX 135.1 Protocol for Initial Management of Patients Admitted With Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State

Fluids
- Administer 1000–1500 mL 0.9% NaCl during the first hour
- After first hour: titrate infusion rate according to hemodynamics and adjust the type of fluid depending on electrolyte status and blood glucose concentration:
  - In general 250–500 mL/h
  - Normal or high corrected serum Na concentration[1]: 0.45% NaCl
  - Low corrected serum Na concentration: 0.9% NaCl
  - Add dextrose 5% to IV fluid when blood glucose <200–250 mg/dL[2] (DKA) or 250–300 mg/dL (HHS)

Insulin
- Initiate 0.1 U/kg/h through continuous IV infusion (hold in case of hypokalemia)
- Measure blood glucose every 1–2 hours
- Increase insulin by 1 U/h if blood glucose does not decrease by at least 50 mg/dL/h
- When blood glucose <200–250 mg/dL (DKA) or 250–300 mg/dL (HHS): reduce insulin to 0.02–0.05 U/kg/h IV and add dextrose to IV fluid
- Maintain blood glucose between 150 and 200 mg/dL until resolution of ketoacidosis (DKA) or between 200 and 300 mg/dL until HHS has resolved

Potassium
- Measure potassium and other electrolytes every 2–4 hours: universal potassium deficit – target K^+ = 4–5 mmol/L
- If K^+ <3.3 mmol/L: hold insulin and administer 20–40 mEq/h until K^+ >3.3 mmol/L
- If 3.3 mmol/L < K^+ <5.2 mmol/L: administer 20–40 mEq in each liter of IV fluid
- If K^+ >5.2 mmol/L: no supplementation, check after 2 hours

Identify and Treat Precipitating Cause

DKA, Diabetic ketoacidosis; *HHS,* hyperosmolar hyperglycemic state; *IV,* intravenous.
[1]For each 100 mg/dL glucose above 100 mg/dL, add 1.6 mmol/L Na to obtain a corrected serum Na value.
[2]For conversion of blood glucose concentrations in mg/dL to mmol/L, divide by 18.

hour. At the same time, the fluid type may need to be adapted according to the electrolyte status and the blood glucose concentration.[5,7,8] When the corrected serum sodium concentration is normal or high, it is recommended to switch to 0.45% sodium chloride. In addition, when blood glucose falls below 200–250 mg/dL (11.1–13.9 mmol/L) in DKA or 250–300 mg/dL (13.9–16.7 mmol/L) in HHS, dextrose 5% should be added to the intravenous fluid to allow continued insulin treatment to suppress ketogenesis while avoiding hypoglycemia.[5,7,8]

Insulin Therapy

A second mainstay of treatment is insulin therapy.[2] Insulin is administered through continuous intravenous infusion at a rate of 0.1 U/kg/h after eventual correction of hypokalemia. An initial bolus of insulin is not needed, because fluid resuscitation by itself will reduce blood glucose, as described earlier.[1] Blood glucose should be measured every 1–2 hours, and insulin is adjusted if needed. The goal is to lower blood glucose by 50–100 mg/dL per hour (2.8–5.6 mmol/L/h).[2] The insulin dose is decreased to 0.02–0.05 U/kg/h and dextrose 5% is added to the intravenous fluid when blood glucose falls below 200–250 mg/dL (11.1–13.9 mmol/L) in DKA or 250–300 mg/dL (13.9–16.7 mmol/L) in HHS to further suppress ketogenesis with insulin while preventing hypoglycemia.[5,7,8] Blood glucose concentrations are kept between 150 and 200 mg/dL (8.3 and 11.1 mmol/L) until resolution of ketoacidosis or between 200 and 300 mg/dL (11.1 and 16.7 mmol/L) until HHS has resolved.[5,7,8]

Most cases of DKA are treated with intravenous insulin. In mild cases, subcutaneous insulin may be considered as an alternative.[6] Because these patients are generally not admitted to an intensive care unit, this option falls beyond the scope of this chapter.

Potassium Supplementation

Although serum potassium upon admission is often normal or elevated, DKA and HHS patients have a potassium deficit, usually in the range of 3–5 mEq/kg.[1] Because treatment of DKA/HHS will lower

potassium levels by an intracellular shift induced by insulin, correcting acidosis and restoring volume homeostasis, monitoring of serum potassium concentrations and adequate supplementation are crucial. Guidelines recommend adding 20–40 mEq per liter of intravenous fluid unless the patient has hyperkalemia.[5,7,8] When the patient has hypokalemia, it is recommended to hold insulin therapy until serum potassium levels are above 3.3 mmol/L.

Treatment of the Precipitating Cause

Besides supportive measures, treatment of the precipitating cause of DKA/HHS is crucial. A variety of conditions may precipitate DKA or HHS. In patients with previously known diabetes, nonadherence to antidiabetic therapy and infection are predominant causes.[2] Hence, treatment of the DKA/HHS patient often involves treatment of a precipitating infection.

Other Initial Treatments

Bicarbonate treatment in DKA is controversial. A systematic review including three randomized controlled trials did not identify clinical benefit.[10] Moreover, bicarbonate treatment increases the risk of hypokalemia and may paradoxically worsen intracellular acidosis.[1,5] Guidelines recommend to only consider bicarbonate in patients with severe acidosis (pH <7.0).[5,7]

Likewise, phosphate supplementation in DKA and HHS patients is controversial, despite the universal phosphate depletion (on average, 1.0 mmol/kg body weight).[5] Randomized controlled trials have not shown benefit of routine phosphate supplementation on clinical outcome, although these trials may have been underpowered to detect a clinical benefit.[11–13] Phosphate concentrations generally recover after resuming oral intake, and intravenous phosphate supplementation may precipitate hypocalcemia, especially when administered at high doses.[9] Therefore routine supplementation to DKA patients has been discouraged.[5] Nevertheless, when patients have profound and/or potentially symptomatic hypophosphatemia, as expressed by severe muscle weakness, supplementation may be indicated.[5]

As DKA and HHS are procoagulant states, patients are at risk for venous thrombosis. Therefore prophylactic administration of low-molecular-weight heparin is indicated.[8]

Switch to Maintenance Therapy

Intravenous insulin should be continued until DKA and HHS have resolved. Resolution of DKA has been defined as blood glucose concentrations below 200 mg/dL (11.1 mmol/L), plus two of the following: pH >7.3, bicarbonate ≥ 15 mmol/L, and/or anion gap ≤ 12 mmol/L. Resolution of HHS has been defined as normal serum osmolality and regained mental status.[2]

After resolution of DKA/HHS, maintenance antidiabetic therapy should be initiated in consultation with an endocrinologist. In view of the short half-life of intravenous insulin, the intravenous insulin infusion should be continued for at least 2 hours to prevent rebound hyperglycemia or ketoacidosis. In patients with previously unknown diabetes, insulin can be initiated at a total dose of 0.5–0.7 U/kg/day.[1]

COMPLICATIONS AND OUTCOME

Before the discovery of insulin, DKA was a lethal condition. In current intensive care, mortality has declined to less than 1%, however.[14] In contrast, mortality of HHS is estimated at 10%–20%.[15,16] The higher mortality of HHS may be related to the higher risk profile of these patients, who are generally older and have more comorbidities.[2] Nevertheless, the insidious time course of HHS, with more severe dehydration and secondary organ damage, may also contribute to the higher mortality risk.

Common complications of DKA/HHS treatment include hypokalemia, hypoglycemia, and hyperchloremic metabolic acidosis.[2] Indeed, insulin treatment induces an intracellular shift of potassium in a condition in which total potassium stores are already low. Therefore, insulin treatment should be temporarily withheld if hypokalemia develops. A considerable number of patients may develop transient hyperchloremic metabolic acidosis after the infusion of large amounts of normal saline. Although this condition can potentially be prevented by infusion of balanced crystalloids,[9] no large randomized controlled trial has compared normal saline with balanced crystalloids in DKA/HHS, and current guidelines still recommend normal saline.[5,7,8]

The most feared complication of DKA is cerebral edema. This condition most often occurs in DKA episodes in children, with a prevalence of 0.3%–1%.[17,18] In adults and patients with HHS, the condition is very rare. Once cerebral edema develops, mortality rates are high (20%–40%), and survivors are at risk for long-term sequelae. Clinical symptoms include new or worsening headache, gradually decreased consciousness, irritability, and seizures.[5] When cerebral edema is suspected, prompt treatment with mannitol (0.5–1.0 g/kg) has been recommended before computed tomography is obtained.[2] Traditionally, development of cerebral edema has been attributed to rapid normalization of hyperosmolarity by fluid therapy and blood glucose lowering.[5] Therefore, gradual correction of hyperglycemia and fluid deficits has been recommended, especially in critically ill children. Nevertheless, more recent evidence has questioned the role of fluid therapy in mediating the risk of cerebral edema. Indeed, a large randomized controlled trial with 2-by-2 factorial design found no impact of fluid administration rate or the sodium chloride content on the neurologic outcome of children admitted with DKA ($n = 1389$).[19] This may suggest that the risk of cerebral edema is possibly related to the initial severity of DKA, rather than to DKA treatment. Potential mediators are hypocapnia-induced cerebral vasoconstriction, hypovolemic shock–induced neurologic damage, inflammatory damage to the brain, and damage caused by intracellular acidosis.[18,20–22]

PREVENTION OF RECURRENT EPISODES

After initial treatment, patients should be instructed on how to prevent recurrent DKA/HHS.[1] This includes instructions on appropriate antidiabetic therapy and on adaptations of treatment in conditions of metabolic stress.

Concern has arisen regarding the potentially increased incidence of euglycemic DKA with the introduction of SGLT2 inhibitors.[23,24] However, the overall incidence of DKA in patients taking such drugs remains low, and both professional societies and regulatory authorities have concluded a favorable risk-benefit profile.[25] Nevertheless, to attenuate the risk of DKA, patients taking SGLT2 inhibitors should avoid periods of prolonged starvation, ketogenic diets, and excessive alcohol intake, and SGLT2 inhibitors should be withheld in hospitalized patients who are fasted.[25]

CONCLUSION

DKA and HHS are hyperglycemic emergencies that require prompt treatment by intravenous fluids, insulin infusion, and potassium supplementation. In addition, the precipitating event should be sought and treated. In contemporary intensive care, DKA mortality is relatively low, whereas mortality of HHS remains elevated, which may partially be related to the higher intrinsic risk profile of these patients.

KEY POINTS

- DKA and HHS are endocrine emergencies that are caused by an absolute (DKA) or relative (HHS) insulin deficiency in the presence of elevated counterregulatory hormones.
- In patients with known diabetes, the most common precipitants of DKA and HHS are noncompliance with diabetic treatment and infection.
- Key diagnostic criteria for DKA are the classic triad of severe hyperglycemia (D), elevated blood ketone concentrations (K), and metabolic acidosis (A).
- In patients at risk—taking SGLT2 inhibitors, pregnancy, excessive alcohol intake, prolonged fasting, chronic liver disease—ketoacidosis may develop in the absence of elevated blood glucose concentrations (euglycemic diabetic ketoacidosis).
- Key diagnostic criteria for HHS are severe hyperglycemia and hyperosmolarity and changes in mental state.
- Both DKA and HHS are characterized by large fluid and potassium deficits, although serum potassium concentrations may be normal or high upon admission.
- The initial treatment consists of fluid resuscitation, insulin therapy, potassium supplementation, and treatment of the precipitating cause.
- After initial glucose lowering with insulin therapy and fluid resuscitation, blood glucose should be maintained at 150–200 mg/dL (DKA) or 200–300 mg/dL (HHS) with insulin treatment until ketoacidosis or HHS has resolved.
- The most severe complication of DKA is cerebral edema, which is most prevalent in children and which requires prompt treatment with mannitol.
- In contemporary intensive care, mortality of DKA is <1%, whereas mortality of HHS remains at approximately 10%–20%, which is at least partially related to a higher risk profile of HHS patients (older age, more comorbidities).

Adrenal Insufficiency

Herwig Gerlach

During stress response, the central nervous system (CNS) induces activation of both the sympathoadrenergic system (by release of catecholamines) and the hypothalamic-pituitary-adrenal (HPA) axis (by release of steroid hormones, glucocorticoids [GCs], and mineralocorticoids), with the target of maintaining homeostasis by influencing metabolic, cardiovascular, immunologic, and endocrine functions. In this context, the adrenal gland plays a key role, combining the location for synthesis and expression of catecholamines, GCs, androgenic hormones, and factors of the renin-angiotensin-aldosterone (RAA) system. Acute and chronic inflammatory diseases include stimulation of the HPA axis by the immune system, thereby leading to morphologic and functional changes, especially of the adrenal cortex. This phenomenon has been described for acute infectious diseases and for sepsis and septic shock.

Over 60 years ago, the seminal observation was made that administering an adrenal cortical steroid extract to a patient with progressive, active rheumatoid arthritis slowed progression of the disease. This soon led to the development of synthetic adrenal cortical steroids, which gained a remarkable reputation in the treatment of a wide range of inflammatory and autoimmune disorders. However, it soon became apparent that this efficacy did not come without a cost in terms of potentially serious adverse effects. In patients with sepsis and septic shock, negative results of trials with high doses of GCs evoked skepticism over the years. Meanwhile, several randomized trials revealed contradictory results with low doses of corticosteroids in patients with septic shock. Hence, there is still controversy about which patients profit best from this therapy and how to define and evaluate adrenal gland disorders.[1–4]

ANATOMY OF THE ADRENAL GLAND

The two paired adrenal glands are located in the retroperitoneal soft tissue near the top of each kidney. In neonates, the adrenal glands are relatively large (approximately one-third of the kidney's size) compared with other organs. In the postnatal period, the cortex portion shrinks, leading not only to a relatively but also an absolutely smaller size of the organ. In adults, each adrenal gland weighs 4–5 g, has a flat form with a sagittal diameter of less than 1 cm, a transverse diameter of 3 cm, and a craniocaudal diameter of 4–5 cm. The right gland has a triangle/pyramid-like shape, whereas the left gland has a half-moon shape.

Circulatory supply to the adrenals, with a flow rate of about 5 mL per minute, is maintained by up to 50 arterial branches from the aorta, renal arteries, and inferior phrenic arteries for each gland. Blood flow is directed from the capsule into the subcapsular arteriolar plexus through the cortex toward the medulla, where a single vein drains the blood entering the vena cava or the renal vein. Direct blood supply to the medulla is maintained by medullary arteries.

The adrenal cortex receives afferent and efferent innervation. Direct contact of nerve terminals with adrenocortical cells has been suggested, and chemoreceptors and baroreceptors present in the adrenal cortex infer efferent innervation. Diurnal variation in cortisol secretion and compensatory adrenal hypertrophy are influenced by adrenal innervation. Splanchnic nerve innervation has an effect in regulating adrenal steroid release. The adrenal medulla secretes the catecholamines epinephrine and norepinephrine, both of which affect blood pressure, heart rate, sweating, and other activities regulated by the sympathetic nervous system. The adrenal cortex is divided into three layers: (1) the zona glomerulosa, just under the capsule; (2) the zona fasciculata, the middle layer; and (3) the zona reticularis, the innermost, netlike patterned area with reticular veins draining into medullary capillaries. The zona glomerulosa exclusively produces the mineralocorticoid aldosterone; the zonae fasciculata and reticularis produce GCs and androgens.[5]

PHYSIOLOGY OF THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

The adrenal glands are part of a complex system that produces interacting hormones to maintain physiologic integrity, especially during the stress response.[6,7] This system, the *HPA axis,* includes the hypothalamic region that produces corticotropin-releasing hormone (CRH), which stimulates the pituitary gland. The pituitary gland is composed of two major structures: the adenohypophysis (anterior pituitary) and neurohypophysis (posterior pituitary). The anterior pituitary is responsible for the secretion of corticotropin (adrenocorticotropic hormone [ACTH]), thyroid-stimulating hormone (TSH), growth hormone (GH), beta-lipotropin, endorphins, prolactin, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). The posterior pituitary secretes vasopressin (antidiuretic hormone [ADH]) and oxytocin. Corticotropin regulates the production of corticosteroids by the adrenal glands. Hypothalamic neurons receive input from many areas within the CNS; they integrate these inputs and initiate an output to the anterior pituitary via the median eminence. The median eminence secretes releasing hormones into a hypophyseal portal network of capillaries that connect the median eminence with the pituitary hormones.

The anterior pituitary gland secretes adrenocorticotropin (ACTH) under stimulation from hypothalamic CRH. ACTH, in turn, stimulates the synthesis and release of GCs, mineralocorticoids, and androgenic steroids from the adrenal gland. In terms of a feedback loop, ACTH release is inhibited by GCs, which act on both the pituitary corticotropic cells and hypothalamic neurons. ACTH is also released during stress, independent of the circulating serum cortisol level. CRH, vasopressin, and norepinephrine act synergistically to increase ACTH release during

stress. Endorphinergic pathways also play a role in ACTH regulation. Acute administration of morphine stimulates release of ACTH, whereas chronic administration blocks secretion of ACTH. ACTH and cortisol are secreted normally in a diurnal pattern, with the lowest concentrations between 10:00 PM and 2:00 AM and highest levels around 8:00 am. Samples obtained at different times can provide useful dynamic information regarding HPA function. Loss of diurnal rhythm may indicate hypothalamic dysfunction.

The HPA axis is stimulated not only by physical or psychic stress but also by peptides such as ADH and cytokines. Thus the HPA axis plays an important role during infections and immunologic disorders.[8,9] Via interaction with the RAA system regulating fluid and salt balance, synthesis of androgens (e.g., dehydroepiandrosterone) with a possible impact on immunomodulation, and the sympathoadrenergic system, the HPA axis is probably the most important organ of the stress response. Stimulation of the immune system by infections induces the release of proinflammatory cytokines such as tumor necrosis factor-alpha (TNF-α), interleukin (IL)-1β, or IL-6. After a cascade, these cytokines stimulate both the hypothalamus and the anterior pituitary gland, which ultimately leads to the release of GCs. IL-6 is also able to induce a steroid release directly from the adrenal gland. The adequate increase of GC levels during inflammation is a crucial factor for an appropriate stress response. In acute infections, this release maintains metabolic and energy integrity. If the process is chronic, the HPA axis develops an adaptation, which induces typical clinical manifestations such as hypercatabolic states; hyperglycemia; and suppression of androgens, growth, and thyroid hormones. These changes, however, may increase the risk of secondary infections. Increased cortisol levels suppress higher regulatory levels of the HPA axis in terms of a negative feedback loop. Hence, after major surgery or during sepsis and septic shock, high cortisol and low ACTH levels are detectable.[10,11] Even the infusion of dexamethasone or CRH is not able to suppress increased cortisol levels in these patients.[12,13] Several investigations have demonstrated that adrenal cortisol synthesis in critically ill patients is not regulated by ACTH, but by paracrine pathways via endothelin, atrial natriuretic peptide, or cytokines such as IL-6.[14–16] IL-6 directly induces the adrenal cortex to release cortisol, which, in chronic courses, can worsen the prognosis.[17]

CELLULAR RESPONSE TO ADRENOCORTICAL HORMONES AND RELATED DRUGS

Cortisol, the major free circulating adrenocortical hormone, is a hydrophobic hormone and circulates in the bloodstream bound to protein. Cortisol-binding globulin (or transcortin)–protein complexes account for about 95% of circulating cortisol, but only the free form is biologically active with a plasma half-life of 60–120 minutes. Cortisol is metabolized by hydroxylation in the liver, and metabolites are excreted in the urine. Steroid hormones enter the cytoplasm of cells, where they combine with a receptor protein. Metabolic, immunologic, and hemodynamic responses to adrenocortical steroid hormones are regulated in a highly complex manner that includes transactivation, transcription, posttranscriptional/translational regulation, and nongenomic effects. The immediate nongenomic effects of steroid hormones are primarily attributed to mineralocorticoids (aldosterone), with rapid activation of the sodium-proton exchanger, increase in intracellular Ca^{++} levels, and activation of second messenger pathways.[18,19] A randomized trial in patients during cardiac catheterization revealed that within minutes after aldosterone injection, cardiac index and arterial pressure increased significantly for 10 minutes and returned to baseline thereafter.[20] Interestingly, the genomic effects of aldosterone seemed to be mediated by binding to GC receptors (GRs) and not to mineralocorticoid receptors.[21] There is evidence that GC, like cortisol, also modulates immune functions by rapid, nongenomic effects via nonspecific interactions with cellular membranes and specifically binding to membrane-bound GRs.[22] Nonspecific membrane effects have been demonstrated for inhibition of sodium and calcium cycling across plasma membranes by impairing Na^+/K^+-ATPase and Ca^{++}-ATPase. Moreover, the rapid activation of lipocortin-1 and inhibition of arachidonic acid release after GC were independent of GR translocation. Finally, high-sensitivity immunofluorescence staining revealed membrane-bound GRs on circulating B lymphocytes and monocytes.[22]

The multiple mechanisms by which GCs modulate cellular responses include mainly genomic pathways.[23–25] Nongenomic effects are thought to account for immediate immune effects of high doses of GC, whereas membrane-bound receptors probably mediate low-dose GC effects. The classic model is that GCs bind to the cytoplasmic ligand-regulated GC receptor alpha (GRα), which is an inactive multiprotein complex consisting of two heat shock proteins (hsp90) acting as molecular chaperones, in addition to other proteins (Fig. 136.1). Upon GC binding to GRα, a conformational change causes dissociation of hsp90, with subsequent nuclear translocation of GRα homodimers, binding of GRα to GC response elements (GREs) of DNA, and transcription of responsive genes (transactivation) such as lipocortin-1 and beta-2-adrenoreceptors. Alternatively, GRα may bind to negative GRE (nGRE) and repress transcription of genes (transrepression) such as pro-opiomelanocortin (POMC). More important, transrepression without direct binding of GRα to GRE by protein-protein interactions of GRα with transcription factors, nuclear factor kappa B (NF-κB), and AP-1 has been recognized as a key step by which GC suppresses inflammation.[26] In turn, synthesis of TNF-α, IL-1β, IL-2, IL-6, IL-8, inducible nitric oxide synthase (iNOS), cyclooxygenase (COX)-2, cell adhesion molecules, and growth factors is inhibited and apoptosis promoted.[27] In addition, NF-κB repression may be mediated by GC-induced up-regulation of the cytoplasmatic NF-κB inhibitor, IκBα (see Fig. 136.1), which prevents translocation of NF-κB.[28] Clinical investigations provide support for the presence of endogenous GC inadequacy in the control of inflammation and peripheral GC resistance.[29] With GC treatment, the intracellular relations between the NF-κB and GRα signaling pathways change from an initial NF-κB–driven and GRα-resistant state to a GRα-sensitive one. However, data are conflicting and probably do not explain the early (<2 hours) suppressive effects of GC, but may account for the longer-term dampening effect of GC on inflammatory processes.[23]

Besides transcriptional regulation, posttranscriptional, translational, or posttranslational processes have been described for GC-induced modulation of COX-2, TNF-α, GM-CSF, IL-1β, IL-6, IL-8, and interferon gamma (IFN-γ).[23] Furthermore, GCs act at multiple levels to regulate iNOS expression via (1) decreased iNOS gene transcription and messenger RNA (mRNA) stability; (2) reduced translation and increased degradation of the iNOS protein by the cysteine protease, calpain[30]; (3) limitation of the availability of the NOS cofactor, tetrahydrobiopterin; (4) reduced transmembranous transport and de novo synthesis of the NOS substrate, L-arginine; and (5) lipocortin-1–induced inhibition of iNOS.[31,32] Together, these complex mechanisms result in the ability of GC to inhibit inflammation and to stabilize hemodynamics. Finally, GRs have been found in nearly every nucleated cell in the body, and because each cell type has specific responses to GC, it follows that GCs have many effects in the body, equally true of endogenously produced GC hormones or exogenously administered GC medications. Both increase hepatic production of glucose and glycogen and decrease peripheral use of glucose. Steroids also affect fat and protein metabolism. They increase lipolysis both directly and

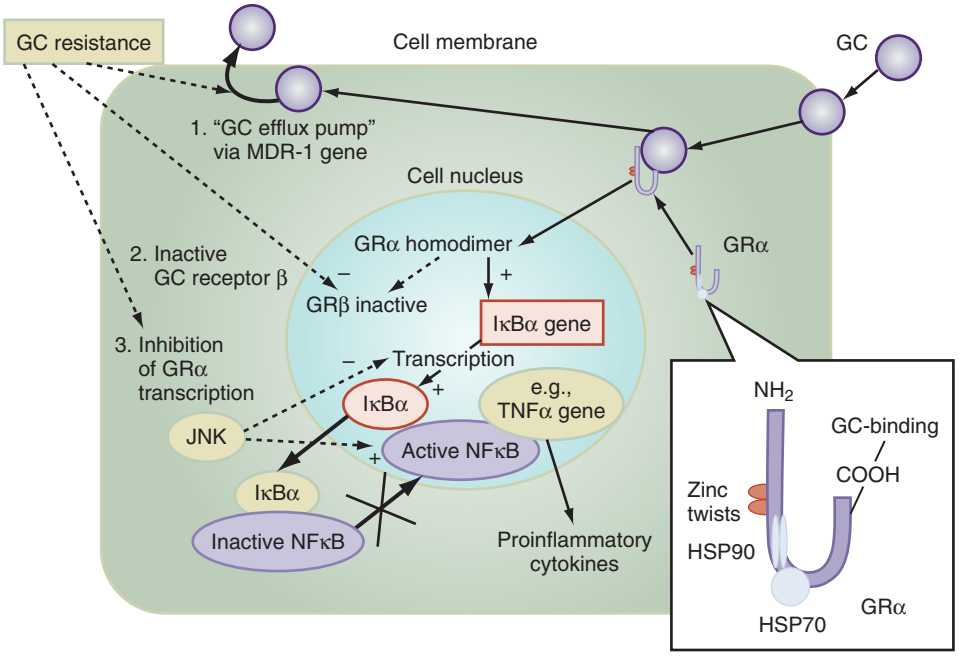

Fig. 136.1 Cellular mechanisms of glucocorticoid effects *(right)* and glucocorticoid resistance *(left).* After passive transport through the cell membrane, GCs bind to the intracellular GC receptor alpha (GRα), which is sequestered in the cytoplasm and bound to the HSP complex that comprises chaperone molecules HSP70 and HSP90. Binding of GC to GRα allows formation of a homodimer that is transported into the nucleus. GR-mediated transcription induces inhibitor kappa B alpha (IκBα), which binds to and inhibits nuclear factor kappa B (NF-κB). Thus GC inhibits the NF-κB–mediated synthesis of proinflammatory cytokines like tumor necrosis factor alpha (TNF-α). Impaired GC sensitivity (GC resistance) includes three major pathways *(dotted arrows)*: (1) decreased cytoplasmatic GC concentrations secondary to increased P-glycoprotein–mediated efflux of GC caused by overexpression of the MDR-1 gene; (2) increased expression of a truncated splice variant of the GR that is unable to transactivate GC-sensitive genes (GRβ); and (3) activation of proinflammatory mediators via upstream kinases (JNK), which can directly inhibit GR transcription activity. *GC,* Glucocorticoids; *GR,* glucocorticoid receptor; *HSP,* heat shock protein; *JNK,* c-Jun N-terminal kinase; *MDR-1,* multidrug resistance gene 1.

indirectly by elevating free fatty acid levels in the plasma and enhancing any tendency toward ketosis. GCs further stimulate peripheral protein metabolism, using the amino acid products as gluconeogenic precursors.

DEFINITIONS OF ADRENAL INSUFFICIENCY

The adrenal glands may stop functioning when the HPA axis fails to produce sufficient amounts of the appropriate hormones. *Primary adrenal insufficiency* is defined by the inability of the adrenal gland to produce steroid hormones even when the stimulus by the pituitary gland via corticotropin is adequate or increased. Primary adrenal insufficiency affects 4–6 out of 100,000 people. The disease can strike at any age, with a peak between 30 and 50 years, and affects males and females about equally. In 70% of cases, the cause is a primary destruction of the adrenal glands by an autoimmune reaction ("classical" Addison disease or autoimmune adrenalitis), with about 40% of patients having a history of associated endocrinopathies. Most adult patients have antibodies against the steroidogenic enzyme, 21-hydroxylase,[33] but their role in the pathogenesis of autoimmune adrenalitis is uncertain. In the other 30%, the adrenal glands are destroyed by cancer, amyloidosis, antiphospholipid syndrome, adrenomyeloneuropathy, acquired immunodeficiency syndrome (AIDS), infections (e.g., tuberculosis, cytomegaly, fungi), or other identifiable diseases (Box 136.1). In these cases, the typical morphologic changes of the adrenal cortex are atrophy, inflammation, and/or necrosis. In primary adrenal insufficiency, the whole adrenal cortex is involved, resulting in a deficiency of GCs, mineralocorticoids, and adrenal androgens.[34,35]

Secondary adrenal insufficiency is characterized by adrenal hypofunction caused by the lack of pituitary ACTH or hypothalamic CRH. Diseases of the anterior pituitary that can cause secondary adrenal insufficiency include neoplasms (e.g., craniopharyngiomas, adenomas), infarction (e.g., Sheehan syndrome, trauma), granulomatous disease (e.g., tuberculosis, sarcoidosis), hypophysectomy, and infection.[36] Causes also include hypothalamic dysfunction, such as after irradiation or surgical intervention (see Box 136.1). Because aldosterone secretion is more dependent on angiotensin II than on ACTH, aldosterone deficiency is not a problem in secondary adrenal insufficiency. Selective aldosterone deficiency can occur as a result of depressed renin secretion and angiotensin II formation.[34] Rarely, patients have an isolated deficiency of CRH,[37] and lymphocytic hypophysitis with subsequent adrenal insufficiency has been described in women.[38] These disorders may lead to an isolated ACTH deficiency.[34]

The so-called *tertiary adrenal insufficiency,* which is often summarized together with secondary forms, commonly occurs after withdrawal of exogenous GCs. Many of these patients do well during normal activities but are unable to mount an appropriate GC response to stress. This effect depends on the dose and duration of treatment and varies greatly from person to person. It should be anticipated in any patient who has been receiving more than 30 mg of hydrocortisone per day (or 7.5 mg of prednisolone, or 0.75 mg of dexamethasone per day)

BOX 136.1 Etiology of Adrenal Insufficiency

Primary Adrenal Insufficiency

- Autoimmune adrenalitis (Morbus Addison), often with concomitant endocrinopathies
- Hemorrhage (trauma, anticoagulants)
- Infarction, thrombosis
- Tumors
- Infections (tuberculosis, cytomegaly, fungi, AIDS)

for more than 3 weeks.[35] If supraphysiologic doses of GCs have been administered to a patient for more than 1–2 weeks, the drug should be tapered to allow for adrenal gland recovery. It may take 6–12 months for the adrenal glands to recover fully after prolonged use of exogenous GCs.[39] Because ACTH is not a major determinant of mineralocorticoid production, the basic deficit in adrenal insufficiency is that of deficient GC production. It is important that neither the dose of applied GCs, nor the time of treatment, nor the basal plasma level of cortisol allows sufficient assessment of the function of the HPA axis. Several drugs have also been described to induce adrenal insufficiency, either by directly affecting adrenocortical steroid release (e.g., fluconazole, etomidate)[40,41] or by enhanced hepatic metabolism of cortisol (e.g., rifampicin, phenytoin).[35]

Isolated hypoaldosteronism is quite rare and should be suspected in cases of hyperkalemia in the absence of renal insufficiency. The main causes for isolated deficiency of aldosterone secretion are congenital deficiency of aldosterone synthetase, hyporeninemia caused by defects in the juxtaglomerular apparatus, or treatment with angiotensin-converting enzyme inhibitors that lead to loss of angiotensin stimulation. Other forms of hypoaldosteronism usually occur in patients with chronic renal disease and/or diabetes mellitus.

RELATIVE ADRENAL INSUFFICIENCY

The aforementioned forms of adrenal insufficiency, which lead to an absolute deficiency of steroid production, are rare in critically ill patients (0%–3%).[42] To reflect the notion that subnormal adrenal corticosteroid production during acute severe illness can also occur without obvious structural defects in the HPA axis, deficiency syndromes caused by a dysregulation have been termed *functional adrenal insufficiency*.[43] Functional adrenal insufficiency can develop during the course of critical illness and is usually transient.[35] Decreased levels of GCs occur much more often; these levels might be sufficient in normal subjects but are too low for stress situations, owing to higher need, and

BOX 136.2 Values Indicating Normal Adrenocortical Function

- Plasma cortisol (7:00–8:00 AM): 5–25 μg/dL (135–700 nmol/L)
- Plasma adrenocorticotropin (ACTH) (7:00–8:00 AM): <70 pg/mL
- Urine excretion rate of free cortisol: 20–90 μg/d
- Urine excretion rate of 17-hydroxycorticosteroid (17-OHCS): 4–10 mg/d

are associated with a worse outcome.[44] This led to the concept of *relative adrenal insufficiency* (RAI). The major cause of RAI is inadequate synthesis of cortisol caused by cellular dysfunction. Hence, in contrast to absolute adrenal insufficiency, the morphologic changes in the adrenal glands associated with RAI may be minor, sometimes characterized by cellular hyperplasia within the adrenal cortex. This is often combined with peripheral GC resistance of the target cells, which is caused by inflammatory events and aggravates the clinical course, although the absolute cortisol serum levels might be normal.[45] In septic shock, RAI may be the result of impaired pituitary corticotropin release, attenuated adrenal response to corticotropin, and reduced cortisol synthesis (Fig. 136.2).[35,46,47] In addition, cortisol transport capacity may be reduced, and response to cortisol may be impaired at the tissue level by cytokines modulating GC receptor affinity to cortisol and/or GREs.[48,49] In clinical trials, it was demonstrated that prolonged treatment of systemic inflammation in patients with severe acute respiratory distress syndrome (ARDS) with methylprednisolone can improve the decreased GC response by increasing the GC receptor affinity and reducing the NF-κB–mediated DNA binding and transcription of proinflammatory cytokines.[29] Thus if RAI can be identified, treatment with supplemental corticosteroids may be of benefit.[35] Prevalence of RAI in the critically ill varies from 0% to 77% with different definitions, cutoff values, study populations, and adrenal function tests[34,35,46,50,51] and may be as high as 50%–75% in septic shock.[52]

EVALUATION OF ADRENAL INSUFFICIENCY

In clinical practice, assessment of adrenal function is difficult, especially in critically ill patients, because the diurnal rhythm is disrupted. Values indicating normal adrenocortical function are listed in Box 136.2. Normally, serum cortisol concentrations in the morning (8:00 AM) of less than 3 μg/dL (80 nmol/L) are strongly suggestive of absolute adrenal insufficiency,[53] and values below 10 μg/dL (275 nmol/L) make the diagnosis likely. Basal urinary cortisol and 17-hydroxycorticosteroid excretion is low in patients with severe adrenal insufficiency but may be low-normal in patients with partial adrenal insufficiency. Generally, baseline urinary measurements are not recommended for the diagnosis of adrenal insufficiency. To differentiate among primary, secondary, and tertiary adrenal insufficiency in cases of low cortisol, it is recommended to measure plasma ACTH concentrations simultaneously. Inappropriately low serum cortisol concentrations in association with increased ACTH concentrations are suggestive of primary adrenal insufficiency, whereas the combination of low cortisol and ACTH concentrations indicates secondary or tertiary disease. This diagnosis, however, should be confirmed by stimulation of the adrenal gland with exogenous ACTH. In secondary or tertiary adrenal insufficiency, the adrenal glands release cortisol, whereas in primary adrenal insufficiency, the adrenal glands are partially or completely destroyed and do not respond to ACTH.

ACTH stimulation tests usually consist of administering 250 μg (40 international units) of ACTH (so-called *high-dose ACTH stimulation test*). For long-term stimulation tests, which are preferred for differentiating between secondary and tertiary adrenal insufficiency,

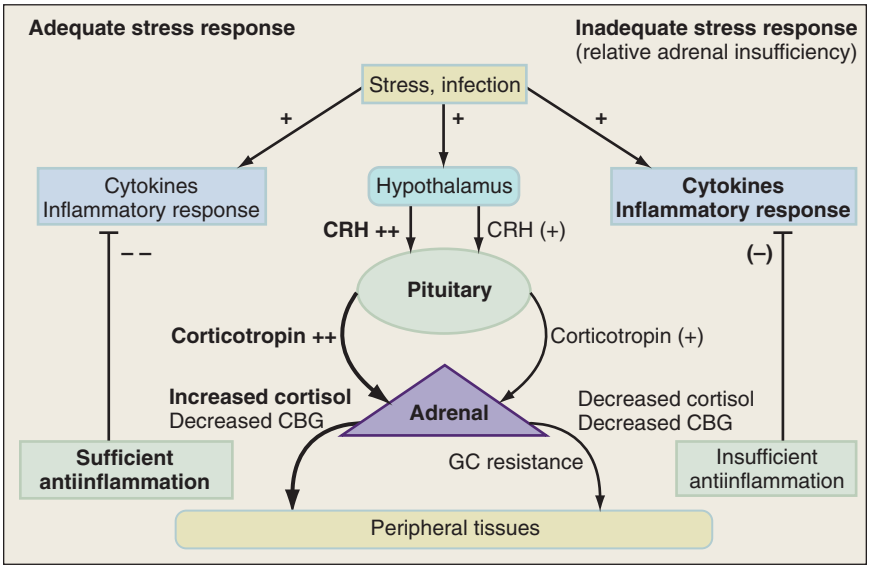

Fig. 136.2 Concept of relative adrenal insufficiency (RAI). Unlike in an adequate stress response *(left)*, RAI may occur when causal or additional factors impair the function of the hypothalamic-pituitary-adrenal (HPA) axis. This may be the result of microcirculatory failure, additional drugs like antibiotics, anesthetic drugs, infections, long-term use of steroids, or hemorrhages. Impaired HPA axis function results in an insufficient antiinflammatory response and an increased inflammatory response. Plus (+) denotes activation; minus (−), inhibition. *CBG,* Cortisol-binding globulin; *CRH,* corticotropin-releasing hormone; *GC,* glucocorticoids.

250 μg of ACTH are infused either over 8 hours or over 2 days.[54] Serum cortisol and 24-hour urinary cortisol and 17-hydroxycorticosteroid (17-OHCS) concentrations are determined before and after the infusion. This test may be helpful in distinguishing primary from secondary/tertiary adrenal insufficiency. In primary adrenal insufficiency, there is a minimal to no response of plasma or urinary cortisol and urinary 17-OHCS. Increases of these values over the 2–3 days of the test are indicative of a secondary/tertiary cause of adrenal insufficiency. In normal subjects, the 24-hour urinary 17-OHCS excretion increases threefold to fivefold above baseline. Serum cortisol concentrations reach 20 μg/dL (550 nmol/L) at 30–60 minutes and exceed 25 μg/dL (690 nmol/L) at 6–8 hours post initiation of the infusion. At present, this approach is used frequently because clinical manifestations of adrenal insufficiency combined with basal cortisol levels, short-term ACTH stimulation tests, and CRH tests (see later discussion) usually provide sufficient information.

A short-term stimulation test with 250 μg ACTH, mostly used for patients who are not critically ill, determines basal serum cortisol levels and the induced-response concentration 30 and 60 minutes after intravenous (IV) administration of ACTH. The advantage of the high-dose test is that pharmacologic plasma ACTH concentrations can be achieved by either IV or intramuscular injection.[55] This dose of ACTH, however, may be too high to identify mild cases of secondary adrenal insufficiency or chronic deficiencies.[56] Furthermore, it should not be used when acute secondary adrenal insufficiency (e.g., Sheehan syndrome) is presumed, because it takes several days for the adrenal cortex to atrophy, and it will still be capable of responding to ACTH stimulation normally. In these cases, a low-dose ACTH test or an insulin-induced hypoglycemia may be required to confirm the diagnosis of adrenal insufficiency.[57,58] A rise in serum cortisol concentration after 30–60 minutes to a peak of 18–20 μg/dL (500–550 nmol/L) or more is considered a normal response to a high-dose ACTH stimulation test and excludes the diagnosis of primary adrenal insufficiency and almost all cases of secondary adrenal insufficiency except those of recent onset.[59–61]

To further differentiate between secondary and tertiary adrenal insufficiency, laboratory investigations may be augmented by a CRH stimulation test. In both conditions, cortisol levels are low at baseline and remain low after CRH. In patients with secondary adrenal insufficiency, there is little or no ACTH response, whereas in patients with tertiary disease, there is an exaggerated and prolonged response of ACTH to CRH stimulation that is not followed by an appropriate cortisol response.[62,63] In the past, the HPA axis was also tested by a stimulated hypoglycemia test. After administering 0.1 units of insulin per kilogram body weight, inducing a hypoglycemic state of less than 40 mg/dL serum glucose, an intact HPA axis is associated with a serum cortisol concentration of more than 20 μg/dL. Nowadays, this procedure is considered obsolete because of the high risk of symptomatic hypoglycemia.

In critically ill patients, primary causes of absolute or RAI are multiple and often undetectable if no specific hypothesis exists. Volume-resistant septic shock or any other form of life-threatening hypotension with an increased need for catecholamines indicates the need to evaluate adrenal function. Previously, a serum cortisol value less than 20 μg/dL was suggestive of the diagnosis of adrenal insufficiency.

Several factors complicate investigations of the HPA axis in patients with critical illness. A short-term ACTH stimulation test may be performed in critically ill patients suspected of having adrenal insufficiency. However, in most patients, RAI will be present, especially in patients with sepsis and septic shock. A clear definition of RAI is still missing, and the pathophysiology is rather complex, which makes it difficult to define clear cutoffs for both basal serum cortisol concentrations and incremental increases after short-term ACTH stimulation tests. Proposed cutoff points may depend on different methods used to measure cortisol, with variations when compared with high-performance liquid chromatography (HPLC) as the reference method.[64] In addition, considering free cortisol or an increase in free cortisol in response to ACTH could increase the accuracy of adrenocortical function tests.[48] Furthermore, extrapolating the diagnosis from reference values obtained from healthy people or patients with HPA disorders

may be misleading, because normal or high-normal cortisol concentrations in septic shock may indicate inadequate adrenal response to stress. In a large series of patients, receiver operating characteristic curve (ROC) analysis reached the highest sensitivity (68%) and specificity (65%) for a reference value of less than 9 μg/dL (incremental increase) to detect nonresponders.[52] Basal cortisol of 34 μg/dL and an incremental increase of 9 μg/dL after stimulation were the best cutoff points to discriminate between survivors and nonsurvivors. The higher the basal plasma cortisol and the weaker the cortisol response to corticotropin, the higher the risk of death. Some investigators have questioned the discriminative power of the incremental increase of cortisol after stimulation in patients with high basal cortisol values, as increases may reflect adrenal reserve more than adrenal function. Hence, RAI was defined based on the hemodynamic response when a randomly measured cortisol was less than 25 μg/dL.[46]

Routine use of the low ACTH stimulation test in critically ill patients cannot be recommended at present, although the low-dose test is preferred in patients with secondary or tertiary adrenal insufficiency.[65] After stimulation with 250 μg ACTH, circulating corticotropin concentrations are 40–200 pg/mL during stress but may be as high as 60,000 pg/mL.[35] Stimulation of the adrenal gland with low doses of ACTH (1 μg) was shown to increase sensitivity and specificity to detect adrenal insufficiency in patients with HPA disorders who respond normally to traditional high-dose stimulation.[35,66–69] The test is performed by measuring serum cortisol concentrations immediately before and 30 minutes after IV injection of ACTH at a dose of 1 μg (160 mIU) per 1.73 m^2 body surface.[34] This dose stimulates maximal adrenocortical secretion up to 30 minutes post injection and in normal subjects results in a peak plasma ACTH concentration about twice that of insulin-induced hypoglycemia.[70] A value of 18 μg/dL (500 nmol/L) or more at any time during the test is indicative of normal adrenal function. The advantage of this test is that it can detect partial adrenal insufficiency that may be missed by the standard high-dose test.[57,58]

Using the 1-μg ACTH stimulation test to identify patients with RAI in septic shock has been proposed, but the 1-μg stimulation test has not been well validated in critically ill patients or patients with septic shock.[34,35] In addition, studies evaluating low-dose and high-dose ACTH stimulation tests in septic shock may have been flawed by methodologic problems. At present, using the 1-μg ACTH stimulation test cannot be recommended routinely until further data from well-designed randomized studies in septic shock patients are available.

The current recommendation is to use a three-level therapeutic guide for evaluating RAI in critically ill patients, especially those with septic shock. Patients with a random basal cortisol below 15 μg/dL will likely benefit from low-dose corticosteroid therapy, whereas corticosteroid replacement is unlikely to be helpful when basal cortisol is above 34 μg/dL. When a random basal cortisol value is between 15 and 34 μg/dL, adrenocortical stimulation with 250 μg ACTH should discriminate responders (incremental increase ≥9 μg/dL) from nonresponders (<9 μg/dL). However, it has been pointed out that no cutoff values are entirely reliable.[35]

CLINICAL SYMPTOMS

About 25% of patients with adrenal insufficiency present with adrenocortical crisis.[34] The symptoms are nonspecific and include sudden dizziness, weakness, dehydration, hypotension, and shock (Box 136.3). In many cases, the clinical picture may be indistinguishable from shock because of loss of intravascular fluid volume. Other features such as anorexia, nausea, vomiting, diarrhea, abdominal pain, and delirium may be present, but they are also common in patients with other acute illness. Hence, these symptoms may not be helpful in establishing the diagnosis of adrenal insufficiency and are often misleading. Hypoglycemia is rare in acute adrenal insufficiency but more common in secondary adrenal insufficiency; it is a common manifestation in children and women with the disorder. For patients in the intensive care unit (ICU), it remains extremely difficult to recognize acute, absolute adrenal insufficiency based on clinical symptoms. However, if the diagnosis is missed, the patient will probably die, so the threshold for laboratory investigations in cases of unexplained catecholamine-resistant hypotension should be low. It is important to be mindful that the onset of an acute adrenocortical crisis is not necessarily the acute beginning of the underlying disease itself. The preceding course is often gradual and may go undetected until an acute illness, stress, trauma, pregnancy, or other conditions precipitate adrenal crisis.[34,71]

BOX 136.3 Clinical Manifestations of Adrenal Insufficiency

Acute Adrenal Insufficiency

- Acute apathy
- Nausea, vomiting
- Fever
- Acute dehydration, tachycardia
- Craving for salt
- Hypotension, shock

Chronic Adrenal Insufficiency

- Weakness, fatigue
- Lack of appetite
- Orthostatic hypotension
- Weight loss, anorexia
- Hyperpigmentation (only in primary Addison disease caused by increased ACTH)
- Vitiligo
- Nonspecific gastrointestinal symptoms (diarrhea, nausea, abdominal pain)
- Nonspecific pain (myalgia, arthralgia, headaches)
- Nonspecific psychological symptoms (depression, lack of concentration, confusion, psychosis)
- Hypoglycemia
- Hyponatremia
- Hyperkalemia
- Acidosis, prerenal azotemia
- Lymphocytosis, eosinophilia

ACTH, Adrenocorticotropin.

Typical symptoms of primary adrenal insufficiency, such as hyperpigmentation, scanty axillary and pubic hair, hyponatremia, or hyperkalemia, may be diagnosed in the acutely ill patient. Adrenal crisis can occur in patients receiving appropriate doses of GCs if their mineralocorticoid requirements are not met.[72] After spontaneous events leading to primary adrenal insufficiency (e.g., hemorrhage, myocardial infarction, adrenal vein thrombosis), these signs are absent. If an acute adrenal crisis is suspected, a blood sample should be obtained to confirm the diagnosis. The main clinical problem is hypotension and shock caused by acute mineralocorticoid deficiency. However, GC deficiency may also contribute to hypotension by decreasing vascular responsiveness to angiotensin II, norepinephrine, and other vasoconstrictive hormones, reducing the synthesis of renin substrate and increasing production and effects of prostacyclin and other vasodilatory hormones.[73,74] Finally, panhypopituitarism may be associated with symptoms, owing not only to a lack of corticotropin but also TSH, gonadotropin, and GH.

In chronic adrenal insufficiency, the major clinical features (see Box 136.3) may be detected but may also be absent if adrenal gland

insufficiency develops over a prolonged period. There is a stage characterized by normal basal steroid secretion but an inability to respond to stress; hence, the patient may be asymptomatic. In other cases, there may also be signs and symptoms suggestive of other hormone deficiency, such as decreased thyroid and gonadal function. Independent of the underlying cause, the most common clinical manifestations are general malaise, fatigue, weakness, anorexia, weight loss, nausea, vomiting, abdominal pain, arthralgia, postural syncope, diarrhea that may alternate with constipation, hypotension, electrolyte abnormalities (hyponatremia, hyperkalemia, metabolic acidosis), decreased axillary and pubic hair, and loss of libido and amenorrhea in women.[34,71]

In primary adrenal insufficiency, hyperpigmentation and autoimmune manifestations (vitiligo) are typically the result of increased ACTH concentrations, whereas these findings are not seen in secondary or tertiary adrenal insufficiency. Another specific symptom of primary adrenal insufficiency is a craving for salt.[35] Typical laboratory abnormalities are hyponatremia, hyperkalemia, acidosis, slightly elevated creatinine concentrations, mild normocytic anemia, and, rarely, hypercalcemia.[35]

In secondary adrenal insufficiency, because production of mineralocorticoids by the zona glomerulosa is generally preserved, dehydration and hyperkalemia are not present, and hypotension is less prominent than in primary disease. Especially in the early stages, the onset of chronic adrenal insufficiency is often insidious, and the diagnosis may be difficult. Some patients initially present with gastrointestinal symptoms such as nausea, vomiting, diarrhea, and abdominal cramps.[35,75] In other patients, the disease may be misdiagnosed as depression or anorexia nervosa.[76,77] Hyponatremia and increased intravascular volume may be the result of an "inappropriate" increase in vasopressin secretion. Decreased libido and potency and amenorrhea may occur. Hypoglycemia is more common in secondary adrenal insufficiency, possibly the result of concomitant GH insufficiency, and in isolated ACTH deficiency. Clinical manifestations of a pituitary or hypothalamic tumor, such as signs and symptoms of deficiency of other anterior pituitary hormones, headache, or visual field defects, may also be present.[34,71] Finally, in young patients suspected of having adrenal insufficiency, delayed growth and puberty point to the presence of hypothalamic-pituitary disease, as would headaches, visual disturbances, or diabetes insipidus in patients of any age.[35,36] Laboratory screening in patients with chronic adrenal insufficiency usually reveals hyponatremia, hypoglycemia, lymphocytosis, and eosinophilia.[35]

THERAPEUTIC APPROACHES

Treatment of adrenal insufficiency involves addressing the precipitating cause (e.g., tumor, infection) and hormone replacement. In acutely ill patients, if the diagnosis of adrenal crisis is suspected but not known, blood should be obtained for measurement of cortisol concentrations, followed by the administration of 250 μg of ACTH in patients with an unknown history. Replacement therapy should be started immediately while awaiting the results of testing.[78] Dexamethasone (1 mg every 6 hours) may be given as the initial GC replacement, because it does not cross-react with cortisol in the plasma while adrenal testing is being performed. Patients are usually treated with IV fluids in the form of isotonic saline to restore intravascular volume and replace urinary salt losses. Dextrose infusion may be added to prevent hypoglycemia. Hydrocortisone (100-mg IV bolus or over 30 minutes, followed by continuous infusion of 10 mg/hr, or 50 mg every 4 hours, or 75–100 mg every 6 hours, resulting in a total daily dose of 240–300 mg hydrocortisone) is frequently given for hormonal replacement.[34,78] However, equivalent GC doses of methylprednisolone or dexamethasone may also be used. Typically, mineralocorticoid replacement therapy is not required in adrenal crisis as long as the patient is receiving isotonic saline. Prophylactic use of antibiotics is not beneficial, but specific infections should be treated aggressively with appropriate antibiotic therapy.

Once the patient is stable, GCs can be tapered to maintenance doses. Long-term replacement doses consist of hydrocortisone, usually 30 mg/d, with two-thirds (20 mg) given in the morning and one-third (10 mg) given at night, or prednisone 7.5 mg in a similar regimen (5 and 2.5 mg, respectively). The daily dose may be decreased to 20 or 15 mg of hydrocortisone as long as the patient's well-being and physical strength are not reduced.[34] The goal should be to use the lowest dose that relieves the patient's symptoms in order to prevent weight gain and osteoporosis.[34,78,79] If the patient continues to experience weakness or other symptoms of GC deficiency, the dose can be increased. Excessive GC therapy should be avoided so as to minimize complications. In addition, mineralocorticoid effect is provided with fludrocortisone (50–100 μg orally daily) to prevent sodium loss, intravascular volume depletion, and hyperkalemia, especially when the dose of hydrocortisone decreases below 100 mg/d. Therapy can be guided by monitoring blood pressure, serum potassium, and plasma renin activity, which should be in the upper normal range.[34,61] Clinical response, however, is the best indicator of the adequacy of replacement. Excessive mineralocorticoid replacement may cause congestive heart failure, alkalosis, hypokalemia, or hypertension. Patients receiving prednisone or dexamethasone may require higher doses of fludrocortisone to lower their plasma renin activity to the upper normal range, whereas patients receiving hydrocortisone, which has some mineralocorticoid activity, may require lower doses. The mineralocorticoid dose may have to be increased in the summer, particularly if patients are exposed to temperatures above 29°C (85°F). In cases of isolated hypoaldosteronism, treatment includes liberal sodium intake and daily administration of fludrocortisone. In patients with secondary adrenal insufficiency caused by panhypopituitarism, replacement with other hormones may also be necessary. In women, the adrenal cortex is the primary source of androgen in the form of dehydroepiandrosterone and dehydroepiandrosterone sulfate. Although the physiologic role of these androgens in women has not been fully elucidated, their replacement is being increasingly considered in the treatment of adrenal insufficiency.[80,81]

Once the patient is stable and on maintenance doses of steroids, ACTH testing can be repeated to document adrenal recovery. Patients with primary adrenal insufficiency require lifelong GC and mineralocorticoid replacement therapy and should carry a card containing information on current therapy, in addition to some type of bracelet or necklace with recommendations for treatment in emergency situations. One of the important aspects of the management of chronic primary adrenal insufficiency is patient and family education. Patients should understand the reason for lifelong replacement therapy; the need to increase the dose of GCs during minor or major stress; and how to inject hydrocortisone, methylprednisolone, or dexamethasone in emergencies. Patients should also have supplies of dexamethasone sodium phosphate and be educated about how and when to administer it. The survival rate for patients with chronic primary adrenal insufficiency has gone from 2 years or less before the availability of steroid replacement to that of the normal population now that GCs are readily available. In acute adrenal insufficiency, prompt recognition and treatment usually result in a favorable outcome, provided the underlying disease process can be treated.

GLUCOCORTICOID REPLACEMENT IN PATIENTS WITH SEPTIC SHOCK

In patients with sepsis and septic shock, the clinical course is extremely varied. The impact of the primary disease, in addition to immunologic factors (including cytokines) associated with sepsis, affect the HPA

axis. In contrast to the early phase of septic shock, adrenal cortisol release may recover, thus leading to RAI with absolute steroid levels around or even above normal range.[82] In refractory septic shock, the prevalence of RAI may be as high as 50%–75%.[52] Furthermore, dynamic testing is not always available in ICUs, making it difficult for the physician considering hormone replacement therapy, because decisions have to be made within hours in severe forms of septic shock to improve prognosis.

Proposed mechanisms of protection from high-dose GCs include improvement of hemodynamic, metabolic, endocrine, and phagocytic functions, resulting in the maintenance of normal morphologic-functional status of tissues including brain, liver, heart, kidneys, and adrenals.[83] In addition, GCs are recognized to inhibit key features of inflammation: endothelial cell activation and damage; capillary leakage; granulocyte activation; adhesion and aggregation; complement activation; and formation and release of eicosanoid metabolites, oxygen radicals, and lysosomal enzymes.[84–89]

However, in only one long-term prospective study in humans receiving high doses of methylprednisolone (30–60 mg/kg) or dexamethasone (2– 4 mg/kg), including 179 bacteremic septic shock patients over a period of 8 years, were experimental results confirmed and mortality reduced from 38% to 10%.[90] Evidence from another study suggested that prolongation of treatment might have been beneficial, because shock reversal and improved survival occurred after a bolus GC application in an early time window but vanished after several days.[91] Two meta-analyses included 9 and 10 randomized trials, respectively, of patients with severe sepsis and septic shock who received up to 42 g of hydrocortisone equivalent or more; both concluded that high doses of corticosteroids were ineffective[92] or harmful.[93] This was confirmed by a large randomized trial in 1987.[94] High-dose GCs were associated with increased risk of secondary infections, mortality,[93] and incidence of renal and hepatic dysfunction.[95] Taken together, these results suggest that high-dose GCs are not effective in septic shock.

Similar to studies of high-dose GC treatment, numerous randomized controlled trials with low-dose corticosteroids in patients with septic shock also confirmed shock reversal and reduction of vasopressor support within a few days after initiation of therapy in most patients.[96–101] In a crossover study, mean arterial pressure and systemic vascular resistance increased during low-dose hydrocortisone treatment and heart rate, cardiac index, and norepinephrine requirement decreased significantly.[102] All effects were reversible with cessation of hydrocortisone. Some studies indicated that corticosteroid-induced increase of sensitivity to norepinephrine was more pronounced in patients with RAI than in patients without RAI.[46,101] There are multiple potential mechanisms by which corticosteroids may modulate vascular tone. Considerable evidence confirms that cytokine-induced formation of nitric oxide (NO) plays a central role in vasodilation, catecholamine resistance, maldistribution of blood flow, and mitochondrial and organ dysfunction and that the amount of NO production correlates with shock severity and outcome.[103,104] In a crossover trial, norepinephrine requirement could be reduced by administering low-dose hydrocortisone in nearly all patients within 1–2 days. Hydrocortisone treatment also induced a significant and prolonged decline of nitrite/nitrate levels, which significantly correlated with reduction of norepinephrine requirements during hydrocortisone infusion.[102] Considering the complex genomic and nongenomic actions of corticosteroids described earlier, it is probable that NO is not the only target.

GCs modulate the stress response in a very complex manner that includes not only antiinflammatory and immunosuppressive actions to protect the host from overwhelming inflammation but also immune-enhancing effects.[27] Markers of the inflammatory response, antiinflammatory response, granulocyte, monocyte, endothelial activation, antigen-presenting capacity, and innate immune response were investigated in septic shock patients.[102] Hydrocortisone significantly attenuated inflammatory and antiinflammatory responses and granulocyte, monocyte, and endothelial activation. Monocyte HLA-DR expression was depressed, but receptor down-regulation was limited and was followed by a rebound increase after drug withdrawal.[102] The immune effects of low-dose hydrocortisone treatment in septic shock may thus be characterized as immunomodulatory rather than immunosuppressive.

Although data on outcomes in septic shock patients after low-dose corticosteroid treatment are limited, up to 300 mg hydrocortisone per day may improve survival. In some trials with low-dose corticosteroids,[96–100] 28-day all-cause mortality was reduced, whereas in high-dose trials, there was no significant effect. In a multicenter trial in 300 patients with severe volume and catecholamine-refractory septic shock, survival time was significantly increased in patients with RAI but not in responders to ACTH.[97] Similar results were obtained for ICU and hospital mortality but not for 1-year follow-up. Significant increases of serious adverse events during treatment with low-dose hydrocortisone have not been reported. The incidence of gastrointestinal bleeding, superinfections, or hyperglycemia has not been different in patients treated with corticosteroids or placebo, and wound infections were even less frequent in patients treated with low-dose hydrocortisone.[97] However, these findings were not confirmed by another large randomized trial, the Corticosteroid Therapy of Septic Shock (CORTICUS) trial,[105] which used different inclusion criteria. Only patients who were successfully resuscitated by volume therapy plus vasopressors were included.[105] These contradictory results led the Surviving Sepsis Campaign in the recent 2016 guidelines to recommend against the use of low-dose GCs for patients who are responding adequately to volume plus vasopressor therapy—that is, those who are no longer hypotensive.[106] Only in the minority of patients, when a stabilization of blood pressure cannot be obtained by using volume plus vasopressors, continuous low-dose hydrocortisone might be considered.[106] These recommendations were confirmed by the two largest randomized controlled trials on low-dose corticoids in septic shock, both published in 2018: The first one (APROCCHSS trial), which was comparable to the first low-dose steroid trial from 2002,[97] used combined glucocorticoid and mineralocorticoid therapy in vasopressor-resistant septic shock, and an improved survival could be demonstrated.[107] The second one (ADRENAL trial) was similar to the CORTICUS trial,[105] used only glucocorticoids in patients with septic shock (vasopressor resistance was not required), and failed to show any outcome benefit.[108] Based on these results, the aforementioned recommendations by the Surviving Sepsis Campaign were not adapted.[106]

Treatment with low-dose hydrocortisone may induce an increase of sodium levels within a few days, and hypernatremia with values over 155 mmol/L have been reported during prolonged treatment.[100] Nevertheless, the indication for low-dose corticosteroids should be weighed against possible risks, and treatment should be limited to the duration of volume- and vasopressor-restrictive hypotension.

Dosing of hydrocortisone in septic shock is similar to that in adrenal crisis (100 mg initial bolus, followed by 200–300 mg per day), and the dose should be tapered once the patient stabilizes. Hydrocortisone is the synthetic equivalent to the physiologic final active compound, cortisol, so treatment with hydrocortisone directly replaces cortisol independently from metabolic transformation. In contrast to dexamethasone, hydrocortisone has intrinsic mineralocorticoid activity. A recent randomized trial demonstrated that the addition of oral fludrocortisone to low-dose hydrocortisone has no benefit in septic shock patients.[109] It has not been established whether a weight-adjusted regimen (e.g.,

0.18 mg/kg/hr)[56] of continuous hydrocortisone infusion is superior to a fixed regimen; moreover, a comparative study of bolus versus infusion regimens has not been performed so far. Patients should be weaned from low-dose hydrocortisone over several days to avoid hemodynamic and immunologic rebound effects. In patients with septic shock, abrupt cessation of low-dose hydrocortisone was followed by significant reversal of many hemodynamic and immunologic effects observed during corticosteroid therapy, even after a short treatment period of 3 days.[102] Adrenal function tests with 250 μg ACTH can be performed in patients with septic shock; however, at present this approach cannot be recommended to exclude responders or patients with high random cortisol values from low-dose corticosteroid therapy.[35] When basal serum cortisol concentrations are less than 15 μg/dL in septic shock, low-dose hydrocortisone replacement is recommended; levels of over 34 μg/dL are considered sufficient. Between 15 and 34 μg/dL, an incremental increase of less than 9 μg/dL serum cortisol makes RAI likely, and therapy may be considered according to the clinical state.[35] Other recommendations use a randomly assigned cutoff level of below 25 μg/dL serum cortisol.[46] The routine use of the low ACTH stimulation test (1 μg ACTH) cannot be recommended at present until further data from well-designed randomized studies in septic shock patients are available. Most importantly, it has to be realized that all the aforementioned studies were performed in patients with catecholamine-resistant septic shock. To date, there are no data justifying the use of low-dose steroids in patients with sepsis. Significant effects on outcome have been observed only in patients with systolic blood pressure below 90 mm Hg despite vasopressor therapy.[97] It is not yet known whether low-dose corticosteroids are also effective in patients with less severe shock. Sufficient data on the dose-response characteristics of GCs in septic patients are still lacking, and the current recommended strategy using 200–300 mg hydrocortisone per day is based on empiric recommendations; further investigations are needed.

FURTHER IMPLICATIONS FOR ANESTHESIA AND CRITICAL CARE

Surgical stress increases serum cortisol levels fivefold to sixfold postoperatively, with return to normal at 24 hours unless stress continues. Patients who have received GCs equivalent to 30 mg/d cortisol for longer than 3 weeks may have impairment in this stress response, and steroid supplementation should be considered. However, short-term treatment of heterogeneous groups of patients with critical illness is controversial, and supraphysiologic doses of GCs are not beneficial and may even be harmful.[110] Hence, outside the situations in which benefit has been proved, supraphysiologic doses of GCs (e.g., 30 mg methylprednisolone per kilogram of body weight per day) in patients with critical illness are not indicated. Whereas early treatment with dexamethasone was suggested to decrease morbidity in bacterial meningitis,[111,112] a recent meta-analysis was less enthusiastic.[113] The positive effects of steroid treatment on tissue-specific resistance to GCs have already been described. However, despite the frequent suggestion that unexplained intraoperative hypotension and even death reflect unrecognized hypocortisolism, there is no evidence that primary adrenal insufficiency is a likely explanation for this response.

Patients with known chronic adrenal insufficiency must be advised to double or triple the dose of hydrocortisone temporarily whenever they have any febrile illness or injury.[34] In stressful situations or during major surgery, trauma, burns, or medical illness, high doses of GCs up to 10 times the daily production are required to avoid an adrenal crisis, although no data from randomized trials are available. A continuous infusion of 10 mg of hydrocortisone per hour or the equivalent amount of dexamethasone or prednisolone eliminates the possibility of GC deficiency. This dose can be halved on the second postoperative day, and the maintenance dosage can be resumed on the third postoperative day. However, it is important with regard to possible detrimental effects and the possibility of decreased resistance to infections that this treatment not be used for prolonged periods in the absence of evidence of corticosteroid insufficiency. General perioperative management should include avoidance of etomidate as an anesthetic drug (selection of other drugs and muscle relaxants is not influenced by the presence of treated hypocortisolism); infusion of sodium-containing fluids; minimal doses of any anesthetic drugs to avoid increased sensitivity to drug-induced myocardial depression; invasive monitoring of hemodynamics, glucose, and electrolytes; and decreased initial doses of muscle relaxant while monitoring the effect using a peripheral nerve stimulator. Especially when acute adrenal insufficiency has been detected in a critically ill patient with a previously unknown disorder, thorough diagnostic evaluation is required, even after improvement.

The control of cortisol secretion in response to stress is more complex than originally thought. Interactions between corticotropin-releasing factor (CRF), vasoactive intestinal polypeptide, arginine vasopressin, catecholamines, and other hormones involved in the control of cortisol secretion have been described.[114] Alpha-2-adrenergic receptor antagonists (e.g., clonidine), which are widely used in ICUs, may suppress the cortisol response to surgical stress. On the other hand, increases in intracranial pressure stimulate cortisol release without increasing ACTH levels, and adrenalectomy, but not adrenal demedullation, increases the permeability of brain tissue to macromolecules.[115] Evidence also suggests that white blood cells may release ACTH-like peptides that can stimulate adrenal gland secretion of cortisol and that primary adrenal insufficiency is associated with increases in serum levels of angiotensin-converting enzyme.[116]

Multiple interactions between drugs and the HPA axis have to be considered if absolute or RAI is suspected. Moreover, in patients with hepatic dysfunction, GC doses should be tapered, especially when using prednisone, because hydroxylation to the active component needs considerable metabolic capacity. Special attention is required in the concomitant use of GCs with other drugs, because of potential interactions and because some drugs may affect the metabolism of steroids, which may lead to a decreased or increased GC effect on their target tissues.[117,118] GCs decrease blood levels of aspirin, coumarin anticoagulants, isoniazid, insulin, and oral hypoglycemic agents, whereas cyclophosphamide and cyclosporine levels may be increased. Conversely, antacids, carbamazepine, cholestyramine, colestipol, ephedrine, mitotane, phenobarbitone, phenytoin, and rifampicin decrease GC blood concentrations, whereas concentrations are increased by cyclosporine, erythromycin, oral contraceptives, and troleandomycin. Furthermore, the combination of exogenous GC administration and amphotericin B, digitalis glycosides, and potassium-depleting diuretics may induce or worsen hypokalemia, warranting frequent monitoring of potassium levels. Finally, the general risk of immunosuppression by GCs precludes any use of vaccines from live attenuated viruses to avoid severe generalized infections.[117,118]

CONCLUSION

Underproduction of adrenal hormones can lead to serious illness. GCs play a critical permissive role in intermediary metabolism, are counterregulatory in relation to insulin, modulate inflammatory and immune responses, and optimize cardiovascular and CNS function. Therefore diseases with a primary adrenocortical dysfunction or those leading to secondary adrenal insufficiency may have severe sequelae, which often are life threatening. The concept of RAI in critically ill patients with functional disorders of the HPA axis has gained attention. Especially in patients with sepsis and septic shock, this phenomenon is suspected of

having a major impact on the severity of illness and prognosis. Both absolute adrenal insufficiency and RAI should be diagnosed by using adequate laboratory investigations. In most cases, testing the basal level of cortisol, combined with a short-term stimulation test with 250 μg ACTH, can identify the disease. In patients with critical illnesses, however, it continues to be difficult to diagnose RAI.

In cases of suspected adrenal crisis with severe volume- and catecholamine-resistant shock, immediate replacement therapy is indicated. If the diagnosis is questionable, dexamethasone should be administered to allow an appropriate diagnostic evaluation. Once the diagnosis of adrenal insufficiency is made, hydrocortisone is the preferred therapy, because it provides both glucocorticoid and mineralocorticoid effects. After stabilization, the dose of GCs should be tapered down to a total of 20–35 mg hydrocortisone per day or equivalent. Randomized controlled trials of high-dose GCs failed to improve outcome from sepsis and septic shock. However, prolonged treatment of refractory septic shock with low doses of corticosteroids is only considered a therapeutic option if the patient does not respond to volume replacement and vasopressor therapy.

KEY POINTS

- The definition of adrenal insufficiency is based on the inability of the adrenal gland to produce adrenocortical steroid hormones.
- The main cause of *primary adrenal insufficiency* (70%–80%) is an autoimmune disorder that induces morphologic destruction of more than 90% of the adrenal cortex. The result is a critically decreased synthesis of steroids, with typical clinical manifestations.
- *Secondary adrenal insufficiency* is characterized by reduced stimulation of the intact adrenal gland caused by low ACTH levels (hypothalamic-pituitary insufficiency), which also results in reduced cortisol levels.
- *Tertiary adrenal insufficiency* is caused by long-term treatment with steroid hormones, which induces feedback inhibition of the HPA axis.
- The definition of *relative adrenal insufficiency* (RAI) in critically ill patients is based on plasma cortisol levels. The critical threshold is a basal cortisol level of 18–25 μg/mL without preceding stimulation.
- Clinical manifestations of adrenal insufficiency are usually nonspecific and include weakness, anorexia, orthostatic hypotension, and general gastrointestinal symptoms. Typical signs of primary forms are hyperpigmentation caused by increased ACTH levels, vitiligo in cases of autoimmune disorders, and hyperkalemia. Secondary forms cause milder symptoms as a result of maintained mineralocorticoid effects.
- Evaluation of adrenal insufficiency generally includes measurement of basal serum cortisol concentrations and the incremental increase after stimulation with ACTH. A high-dose test (250 μg ACTH) is preferred, which uses 30- and 60-minute cortisol levels after stimulation. Long-term tests or low doses (1 μg ACTH) are only used for special indications. Basal values for serum cortisol of less than 3 μg/dL indicate severe, absolute hypocortisolism warranting immediate intervention. In critically ill patients, basal cortisol levels of less than 18–25 μg/mL have been recommended as an indication for low-dose replacement therapy.
- Acute adrenal insufficiency (Addisonian crisis) requires immediate intervention. Establishing IV access, infusion of saline, monitoring serum glucose, and administering dexamethasone after drawing a blood sample may be lifesaving. ACTH stimulation tests should be used for diagnosis. Once the results after stimulation are known, hydrocortisone therapy is preferred for its mineralocorticoid effects.
- Chronic adrenal insufficiency may require long-term replacement therapy with glucocorticoids and mineralocorticoids (for primary forms). Any physical or emotional stress must be considered as possibly harmful, with the need for 3–10 times increased doses of glucocorticoids.
- In patients with septic shock who are not adequately responding to volume and vasopressor therapy, replacement with low-dose hydrocortisone (200–300 mg/d) may be considered, although optimal dosing and timing have yet to be established. A preliminary ACTH test in these patients is no longer recommended.

This is a recent multicenter clinical trial that was able to demonstrate that low-dose hydrocortisone combined with fludrocortisone reduces mortality in patients with severe volume- and vasopressor-restrictive septic shock.

Keh D, Boehnke T, Weber-Carstens S, et al. Immunologic and hemodynamic effects of "low-dose" hydrocortisone in septic shock: A double-blind, randomized, placebo-controlled, crossover study. *Am J Respir Crit Care Med.* 2003;167:512-520.
The authors performed a randomized trial in patients with septic shock, using a crossover design that demonstrated that (1) hemodynamic stabilization by low-dose steroids is paralleled by reduced synthesis of endogenous nitric oxide, (2) low-dose hydrocortisone modulates rather than suppresses immunologic functions, and (3) rapid withdrawal of steroids induces rebound phenomena with impairment of the clinical course.

Liberman AC, Druker J, Garcia FA, et al. Intracellular molecular signaling. Basis for specificity to glucocorticoid anti-inflammatory actions. *Ann N Y Acad Sci.* 2009;1153:6-13.
This paper is an important publication on the cellular pathways of glucocorticoid response. It demonstrates how steroids inhibit NF-κB, which represents a key pathway of inflammatory diseases.

Loriaux DL, Fleseriu M. Relative adrenal insufficiency. *Curr Opin Endocrinol Diabetes Obes.* 2009;16:392-400.
This review demonstrates that the phenomenon of relative adrenal insufficiency has a crucial impact on outcome in critically ill patients.

Venkatesh B, Finfer S, Cohen J, et al. Adjunctive glucocorticoid therapy in patients with septic shock. *New Engl J Med.* 2018;378(9):797-808.
In contrast to the aforementioned study, this randomized trial did not show any benefit of low-dose hydrocortisone therapy in septic shock; however, these patients were responsive to vasopressor therapy, which underlines the relevance of thorough patient selection.

Thyroid Disorders

Angela M. Leung and Alan P. Farwell

NORMAL THYROID HORMONE ECONOMY

Regulation

Synthesis and secretion of thyroid hormone is under the control of the anterior pituitary hormone thyrotropin (or thyroid-stimulating hormone [TSH]). Consistent with a classic negative feedback system, TSH secretion increases when serum thyroid hormone levels fall and decreases when they rise (Fig. 137.1). TSH secretion is also under the regulation of the hypothalamic hormone thyrotropin-releasing hormone (TRH). The negative feedback of thyroid hormone is targeted mainly at the pituitary level, but also likely affects TRH release from the hypothalamus. In addition, input from higher cortical centers can affect hypothalamic TRH secretion.

Under the influence of TSH, the thyroid gland synthesizes and releases thyroid hormone. Thyroxine (3,5,3′,5′-tetraiodothyronine, or T_4, which is 65% iodine by weight) is the principal secretory product of the thyroid gland, comprising about 90% of secreted thyroid hormone under normal conditions.[1] Although T_4 may have direct actions in some tissues, it primarily functions as a hormone precursor that is metabolized in peripheral tissues to the transcriptionally active 3,5,3′-triiodothyronine (T_3, which is 59% iodine by weight).

Metabolic Pathways

The major pathway of metabolism of T_4 is by sequential monodeiodination.[2] At least three deiodinases, each with its unique expression in different organs, catalyze deiodination reactions involved in the metabolism of T_4. Removal of the 5′-, or outer ring, iodine by type I iodothyronine 5′-deiodinase (D1) or type II iodothyronine 5′-deiodinase (D2) is the "activating" metabolic pathway leading to the formation of T_3. Removal of the 5′-, or inner ring, iodine by type III iodothyronine deiodinase (D3) is the "inactivating" pathway that produces the metabolically inactive thyroid hormone 3,3′,5′-triiodothyronine (reverse T_3 or rT_3). D1 is found most abundantly in the liver, kidneys, and thyroid. It is up-regulated in hyperthyroidism and down-regulated in hypothyroidism. D2 is found primarily in the brain, pituitary, and skeletal muscle and is down-regulated in hyperthyroidism and up-regulated in hypothyroidism. D3 is expressed primarily in the brain, skin, and placental and chorionic membranes. The actions of D3 also include inactivation of T_3 to form T_2, another inactive metabolite. Under normal conditions, about 41% of T_4 is converted to T_3, about 38% is converted to rT_3, and about 21% is metabolized via other pathways, such as conjugation in the liver and excretion in the bile.[3,4]

T_3 is the metabolically active thyroid hormone and exerts its actions via binding to chromatin-bound nuclear receptors and regulating gene transcription in responsive tissues.[5] It is important to note that only around 10% of circulating T_3 is secreted directly by the thyroid gland, whereas more than 80% of T_3 is derived from the conversion of T_4 in peripheral tissues.[1,2] Thus factors that affect peripheral T_4-to-T_3 conversion will have significant effects on circulating T_3 levels. Serum levels of T_3 are approximately 100-fold less than those of T_4, and like T_4, T_3 is metabolized by deiodination to form diiodothyronine (T_2) and by conjugation in the liver. The half-lives of circulating T_4 and T_3 are 5–8 days and 1.3–3 days, respectively.[3]

Serum Binding Proteins

Both T_4 and T_3 circulate in the serum as hormones bound to several proteins synthesized by the liver.[4] Thyroid-binding globulin (TBG) is the predominant transport protein and binds to approximately 80% of the circulating serum thyroid hormones. The affinity of T_4 for TBG is about 10-fold greater than that of T_3, which accounts in part for the higher circulating T_4 levels as compared with T_3 levels. Other serum binding proteins include transthyretin, which binds about 15% of T_4 but little, if any, T_3; and albumin, which has a low affinity but a very large binding capacity for T_4 and T_3.[6] Overall, 99.97% of circulating T_4 and 99.7% of circulating T_3 are bound to plasma proteins.

Role of the Free Thyroid Hormones

Essential to an understanding of the regulation of thyroid function and the alterations of circulating thyroid hormones seen in critical illness is the "free hormone" concept, which is that only the unbound hormone has metabolic activity. Although overall thyroid hormone production is regulated by the pituitary, serum thyroid function is affected by changes in the free thyroid hormone concentrations. Alterations in either the concentrations of binding proteins or the binding affinity of thyroid hormones to their serum binding proteins have significant effects on total serum hormone levels, owing to the high degree of binding of T_4 and T_3 to these proteins. However, despite these changes, binding effects do not necessarily translate into clinically significant thyroid dysfunction.

THYROID HORMONE ECONOMY IN CRITICAL ILLNESS

Widespread changes in thyroid hormone economy in critically ill patients[7,8] occurs as a result of (1) alterations in peripheral metabolism of thyroid hormones, (2) alterations in TSH regulation, and (3) alterations in the binding of thyroid hormone to TBG.

Peripheral Metabolic Pathways

There is considerable variation in the transcriptional and translational activities of genes important for thyroid hormone metabolism during acute illness.[9] One of the initial alterations in thyroid hormone metabolism in acute illness is the acute inhibition of D1, which results in the impairment of T_4-to-T_3 conversion in peripheral tissues.[10] D1 is

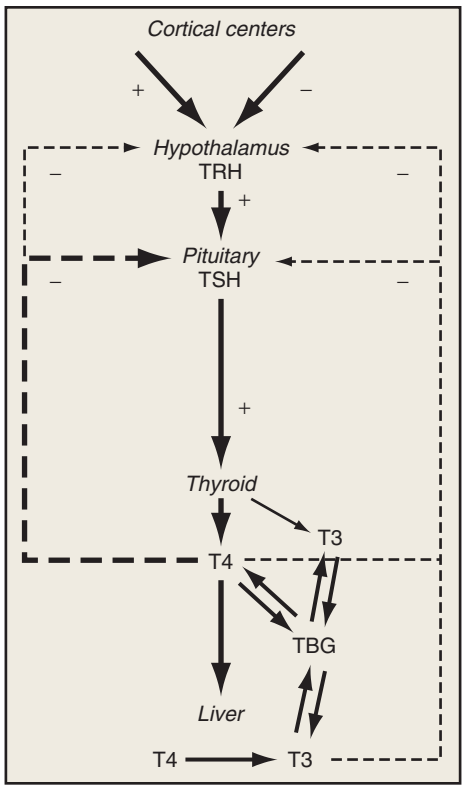

Fig. 137.1 Diagram of the hypothalamic-pituitary-thyroid axis. Inhibitory effect of T_4 and T_3 on TSH secretion is shown by dashed line and minus sign, and stimulatory effects of TRH on TSH secretion and TSH on thyroid secretion are shown by solid lines and plus signs. T_4 and T_3 may also have an inhibitory effect on TRH secretion.

inhibited by a wide variety of factors, including acute illness (Box 137.1),[2] resulting in the acute decrease in T_3 production in critically ill patients. In contrast, inner ring deiodination by D3 may be increased by acute illness, resulting in increased levels of rT_3.[11] Additionally, because rT_3 is subsequently deiodinated by D1, degradation of rT_3 decreases, and levels of this inactive hormone rise in proportion to the fall in T_3 levels. There may also be potential roles of other T_4 metabolites like 3,5-diiodothyronine (3,5-T2) and 3-iodothyronamine (3-T1AM) in critical illness, but this remains unclear.[12]

Nondeiodinative pathways may play an important role in critical illness, as sulfoconjugation and alanine side chain deamination/decarboxylation are increased, resulting in increased levels of T_3-sulfate and Triac, respectively, although thyroid hormone hypermetabolism may not entirely be the result of these processes in critical illness.[13] Triac, which binds to the thyroid hormone receptor and has weak thyromimetic activity, increases locally during illness and fasting. An increase in Triac production in the pituitary may be a factor in decreasing TSH levels during illness.

Finally, in critical illness, there is impaired transport of T_4 to peripheral tissues, such as the liver and kidney, where much of the circulating T_3 is produced. This further contributes to the decrease in the production of T_3.[14,15] Interestingly, increased expression of the thyroid hormone transporters OATP1C1 and MCT8 in animal models[16] and increased expression of MCT8 and MCT1 in the liver and muscle in human studies involving critical illness have been observed.[17] The mechanisms underlying the decrease in tissue transport during critical illness has yet to be more fully elucidated.

BOX 137.1 Factors That Inhibit Type 1 5′-Deiodinase Activity (D1)

Acute and chronic illness
Caloric deprivation
Malnutrition
Glucocorticoids
Beta-adrenergic blocking drugs (e.g., propranolol)
Oral cholecystographic agents (e.g., iopanoic acid, sodium ipodate)
Amiodarone
Propylthiouracil
Fatty acids
Fetal/neonatal period
Selenium deficiency
Hepatic disease

BOX 137.2 Factors That Decrease Pituitary Secretion of TSH

Acute and chronic illness
Adrenergic agonists
Caloric restriction
Carbamazepine
Clofibrate
Cyproheptadine
Dopamine and dopamine agonists
Endogenous depression
Glucocorticoids
Insulin-like growth factor (IGF)-1
Metergoline
Methysergide
Opiates
Phenytoin
Phentolamine
Pimozide
Rexinoids
Somatostatin and its analogs
Serotonin
Surgical stress
Thyroid hormone metabolites

Thyrotropin Regulation

It has long been recognized that serum TSH levels are usually normal in the early phases of acute illness.[18,19] Decreased TRH secretion caused by inhibitory signals from higher cortical centers, impaired TRH metabolism,[20] alteration of pulsatile TSH,[21] and the decrease or absence of a nocturnal TSH surge[21,22] may all further lower TSH levels. Serum levels of leptin, the *ob* gene product that has been shown to vary directly with thyroid hormone levels, also falls as illness progresses[23] and hypothalamic TRH secretion falls, which in turn lead to lowered TSH levels. The decrease of hypothalamic TRH gene expression in animal models, however, is not associated with increased serum T_4 and T_3 levels.[16] Finally, certain thyroid hormone metabolites that are increased during acute nonthyroidal illness may play a role in the inhibition of TSH and TRH secretion.[7]

Common medications used in the treatment of critically ill patients may also have inhibitory effects on serum TSH levels (Box 137.2). Van den Berghe and colleagues reported that intravenous (IV) administration of dopamine for 15–21 hours can acutely decrease TSH, whereas

TABLE 137.1 Factors That Alter Binding of T_4 to Thyroid-Binding Globulin

	Increase Binding	Decrease Binding
Drugs	Estrogens	Glucocorticoids
	Methadone	Androgens
	Clofibrate	L-Asparaginase
	5-Fluorouracil	Salicylates
	Heroin	Mefenamic acid
	Tamoxifen	Phenytoin
	Raloxifene	Furosemide
		Heparin
		Anabolic steroids
Systemic Factors	Liver disease	Inherited
	Porphyria	Acute illness
	HIV infection	NEFAs
	Inherited	

HIV, Human immunodeficiency virus; *NEFA,* Nonesterified free fatty acid.

its withdrawal results in a 10-fold increase in serum TSH levels.[24] Other medications that can inhibit TSH secretion include glucocorticoids, rexinoids, and somatostatin.[25]

Serum Binding Proteins

The affinity of thyroid hormones binding to transport proteins and the concentration of serum binding proteins are altered with acute illness (Table 137.1). Serum levels of transthyretin and albumin decrease, especially during prolonged illness, malnutrition, and in high catabolic states. TBG levels may be increased, as seen with liver dysfunction, or decreased, as seen with severe or prolonged illness.[26]

An acquired binding defect of T_4 to TBG is commonly seen in patients with critical illness. This is thought to result from the release of some as yet unidentified factor from injured tissues that has the characteristics of unsaturated nonesterified fatty acids (NEFAs),[27] which also inhibit T_4-to-T_3 conversion.[28] In systemically ill patients, NEFA levels rise in parallel with the severity of the illness,[29] and drugs such as heparin stimulate the generation of NEFA.[30] Many drugs, including high-dose furosemide, antiseizure medications, and salicylates, also alter the binding of T_4 to TBG.[25] The alteration in serum binding proteins in critical illness makes estimating free hormone concentrations challenging.

EVALUATION OF THYROID FUNCTION IN CRITICALLY ILL PATIENTS

Diagnostic Tests

Thyrotropin Assays

Abnormal thyroid function tests caused by nonthyroidal illness have been reported in up to approximately 70% of acutely ill patients.[31,32] In a study of 1580 hospitalized patients, only 24% of patients with suppressed TSH values (i.e., TSH levels below the limit of detection) and 50% of patients with TSH values over 20 mU/L were found to have thyroid disease.[33,34] More importantly, none of the patients with subnormal but detectable TSH values and only 14% of patients with elevated TSH values less than 20 mU/L were subsequently diagnosed with intrinsic thyroid dysfunction. A review by Kaptein and colleagues suggested that patients with isolated increased TSH concentrations in the setting of chronic cardiac, hepatic, or renal disease usually do not persist or progress to overt hypothyroidism.[35]

The development of sensitive third-generation TSH assays has led to small improvements in discerning between overt hyperthyroidism and nonthyroidal illness.[33] Overall, however, although a normal TSH level has a high predictive value of normal thyroid function, an abnormal TSH value alone is not helpful in evaluating thyroid function in critically ill patients.

Serum T_4 and T_3 Concentrations

Measurement of free thyroid hormone concentrations in patients with nonthyroidal illness is similarly fraught with difficulty.[36] The gold standard for determination of free hormone levels is equilibrium dialysis. However, this technique is labor intensive, time consuming, and rarely used. The most commonly available laboratory tests for thyroid hormone concentrations are free T_4 index, free T_4, and free T_3 that are measured by analog methods; however, these methods are estimates of free hormone concentrations and thus subject to inaccuracies.[37,38]

The free T_4 index (FT4I) is determined by multiplying the total T_4 concentration by the T_3 or T_4 resin uptake, which is an inverse estimate of serum TBG concentrations.[38] Free T_4 levels can also be measured by the analog method, a less expensive alternative to the FT4I[39]; the two tests are likely comparably,[40] and in a healthy population, there is a close correlation between the FT4I and free T_4 levels. However, in critically ill patients, this association is no longer seen, mainly because of difficulties in estimating TBG binding with resin uptake tests. Despite this, the sensitivity of the FT4I in a large study of hospitalized patients was 92.3%, compared with 90.7% for the sensitive TSH test.[33]

Of the serum thyroid function tests, serum T_3 concentrations are affected to the greatest degree by alterations in thyroid hormone economy during acute illness. Therefore there is no indication for routine measurement of serum T_3 levels in the initial evaluation of thyroid function among critically ill patients. This test should be obtained only if thyrotoxicosis is clinically suspected in this setting (i.e., in the presence of a suppressed sensitive TSH and elevated [or high normal] FT4I or free T_4 values). The total T_3 assay is preferable to the free T_3 (analog) assay, owing to the variability among laboratories with the latter test,[41] although there are limited data reporting the utility of free T_3 levels in predicting mortality in the ICU.[42] Similarly, although there is some evidence that ICU patients with lower serum rT_3 levels have higher risks of mortality,[15,43,44] rT_3 levels are generally unreliable and are difficult to distinguish between intrinsic thyroid dysfunction and nonthyroidal illness.[45]

Serum Thyroid Autoantibodies

Autoantibodies to thyroglobulin and thyroid peroxidase (TPO), two intrinsic thyroid proteins, are commonly ordered serum tests.[46] Increased serum titers of either or both of these antibodies indicate the presence of autoimmune thyroid disease, but the presence of thyroid autoantibodies alone does not necessarily indicate thyroid dysfunction, as they are present in up to 26% of the general population.[47,48] Thyroid autoantibodies do, however, add to the sensitivity of abnormal TSH and FT4I values in diagnosing known intrinsic thyroid disease.[33,34]

Imaging Studies

Imaging studies are rarely essential for the diagnosis of thyroid disorders in critically ill patients. Occasionally, functional analysis of thyroid glands using the radioisotope ^{123}I may be useful in patients with suspected thyrotoxicosis and equivocal laboratory tests. However, these studies are labor intensive, and managing the underlying acute illness often overshadows the benefits of obtaining these studies. Anatomic studies such as ultrasound, isotopic imaging, computed tomography

(CT), and magnetic resonance imaging (MRI) are useful in the evaluation of thyroid nodules and goiter, but these conditions are rarely the cause of acute illness; as such, these radiologic studies are not usually helpful in critically ill patients.

Diagnosis

Routine serum thyroid function screening of an ICU population is not recommended because of the high prevalence of abnormal thyroid function tests and low prevalence of true thyroid dysfunction. When thyroid function tests are ordered in hospitalized patients, they should only be done if there is a high clinical index of suspicion for thyroid dysfunction. Whenever possible, it is best to defer evaluation of the thyroid-pituitary axis until patients have recovered from the acute illness. Because every test of thyroid hormone function can be altered in critically ill patients, no single test can definitively rule in or rule out the presence of intrinsic thyroid dysfunction.

If there is a high clinical suspicion for intrinsic thyroid dysfunction in critically ill patients, reasonable initial tests should include either serum free T_4 index or free T_4 and TSH measurements. Assessment of these values in the context of the duration, severity, and stage of illness will allow the correct diagnosis in most patients. For example, a mildly elevated TSH coupled with a low FT4I or free T_4 is more likely to indicate primary hypothyroidism early in an acute illness, as opposed to the same values obtained during the recovery phase of the illness. Similarly, the combination of an elevated TSH and low-normal FT4I or free T_4 is more likely to indicate thyroid dysfunction in hypothermic, bradycardic patients than the tachycardic, normothermic individuals. If both the FT4I or free T_4 and TSH are normal, thyroid dysfunction is effectively eliminated as a significant contributing factor. If the diagnosis is still unclear, measurement of thyroid antibodies is helpful as a marker of intrinsic thyroid disease and increases the sensitivity of both the FT4I or free T_4 and the TSH. Only in the case of a suppressed TSH and a mid- to high-normal FT4I or free T_4 are measurements of serum T_3 levels indicated.

NONTHYROIDAL ILLNESS

In patients without underlying thyroid dysfunction, critical illness causes multiple nonspecific alterations in thyroid hormone concentrations that relate to the severity of the illness.[8,49] Proposed mechanisms of nonthyroidal illness include the induction of a central hypothyroidism arising from decreased TSH production, an acute phase response leading to thyroid binding alterations within the circulation, and impaired function of thyroid hormone transporters across cell membranes.[50]

The alterations in thyroid hormone parameters represent a continuum of changes that depends on the severity of the illness and can be categorized into several distinct stages (Fig. 137.2).[51] The wide spectrum of changes observed often results from the differing points in the course when serum thyroid function tests are obtained. Importantly, these changes are rarely isolated and are often associated with alterations of other endocrine systems, such as the hypothalamic-pituitary-gonadal and -adrenal axes.[17] Thus sick euthyroid syndrome should not be viewed as an isolated pathologic event, but as part of a coordinated systemic reaction to illness involving both the immune and endocrine systems.

The effect of nonthyroidal illness has been studied in several acute and chronic diseases. Some investigators have postulated an association between hypothyroidism and chronic kidney disease, although the thyroid function abnormalities in this patient population with a chronic illness may represent a component of nonthyroidal illness.[52] Others have reported that the presence of nonthyroidal illness portends worsened overall prognosis in patients with coexisting end-stage renal disease,[53] cardiorenal syndrome,[54] and enterocutaneous fistulas[55] and in burn patients.[43] There is limited literature regarding the optimal treatment of nonthyroidal illness in children who are hospitalized in the ICU.[56–58]

Low T_3 State

Common to all of the abnormalities in thyroid hormone concentrations seen in critically ill patients is a substantial depression of serum T_3 levels, which can occur as early as 24 hours after the onset of illness. Over half of patients admitted to the medical service will demonstrate depressed serum T_3 concentrations.[33,34] As noted earlier, multiple pathways contribute to the development of the low T_3 state in critical illness, including decrease in peripheral T_4-to-T_3 conversion through inhibition of type 1 deiodinase, increase in T3-to-T2 conversion through increased type 3 deiodinase expression, increase in T3 sulfation, and increase in Triac formation. This results in marked reduction of T_3 production and rT_3 degradation,[59] thereby leading to reciprocal changes in serum T_3 and serum rT_3 concentrations. The low T_3 state has been

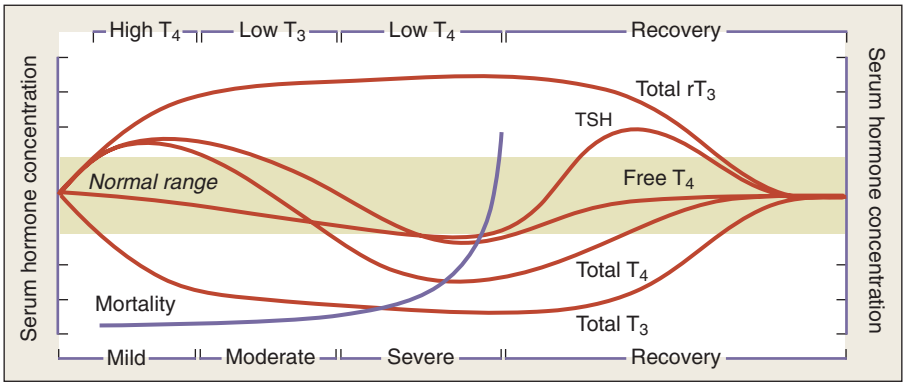

Fig. 137.2 Alterations of serum thyroid hormone concentrations in critical illness. Schematic representation of the continuum of changes in serum thyroid hormone concentrations in patients with nonthyroidal illness. Alterations become more pronounced with increasing severity of illness and return to normal range as illness subsides and the patient recovers. A rapidly rising mortality accompanies the fall in total and free T_4 concentrations. *rT_3,* reverse triiodothyronine (3,3′5′-triiodothyronine); *T_3,* 3,5,3′-triiodothyronine; *TSH,* thyroid-stimulating hormone (thyrotropin). (From Farwell AP. Sick euthyroid syndrome in the intensive care unit. In Irwin RS, Rippe JM, eds. *Intensive Care Medicine,* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

described as a predictor of both all-cause and cardiac mortalities in critical care patients with acute decompensated heart failure.[60] During critical illness, T_3 levels are also abnormally low in peripheral tissues.[44] Moreover, thyroid hormone receptor expression is decreased in acute nonthyroidal illness,[61] possibly in response to the decrease in tissue T_3 levels.

High T_4 State

Serum T_4 levels may be elevated early in acute illness because of either the acute inhibition of type 1 deiodinase or increased TBG levels. This is seen most often in the elderly and in patients with psychiatric disorders. As the duration of illness increases, nondeiodinative pathways of T_4 degradation increase serum T_4 levels to the normal range.[34]

Low T_4 State

As the severity and duration of the illness increase, serum total T_4 levels decrease into the subnormal range. Contributors to this decrease in serum T_4 levels are (1) a decrease in the binding of T_4 to serum carrier proteins; (2) a decrease in serum TSH levels, leading to decreased thyroidal production of T_4; and (3) an increase in nondeiodinative pathways of T_4 metabolism. The decline in serum T_4 levels correlates with prognosis in the ICU, with mortality increasing as serum T_4 levels drop below 4 μg/dL and approaching 80% in patients with serum T_4 levels below 2 μg/dL.[62–64] Despite marked decreases in serum total T_4 and T_3 levels in critically ill patients, free hormone levels have been reported to be normal or even elevated,[50] providing a possible explanation for why most patients appear eumetabolic despite thyroid hormone levels in the hypothyroid range. Thus the low T_4 state is unlikely to be a result of a hormone-deficient state and is probably more of a marker of multisystem failure in critically ill patients.

Recovery State

As acute illness resolves, so do the alterations in thyroid hormone concentrations.[65] This stage may be prolonged and is characterized by modest increases in serum TSH levels. Full recovery with restoration of thyroid hormone levels to the normal range may require several weeks or months after hospital discharge. One study reported that 35 of 40 patients with nonthyroidal illness after coronary artery bypass grafting were able to regain normal thyroid function 6 months after surgery.[66]

Treatment of Nonthyroidal Illness

The question of whether nonthyroidal illness in critically ill patients represents pathologic alterations in thyroid function that negatively affect these patients or simply reflects multisystem failure (i.e., respiratory, cardiac, renal, hepatic failure) is still debatable in both adults[67–70] and children.[49] However, in most studies, thyroid hormone replacement therapy has been shown to not be beneficial,[69,71] including in pediatric patients.[72]

Initial evidence suggested a beneficial effect of liothyronine (L-T_3) on increasing organs available for harvest from brain-dead patients,[73] such that L-T_3 was included in hormonal preservation of organs before transplant.[74] However, a subsequent meta-analysis, including prospective studies, failed to confirm any beneficial effect.[75] Although L-T_3 normalizes serum T_3 levels[76] and improves hemodynamic and neurohumoral parameters in patients with dilated cardiomyopathy[77] and impaired myocardial function[78] slightly, these benefits may represent a pharmacologic effect of T_3 rather than a physiologic replacement hormonal effect. Most recently, T_3 has been used in the setting of a myocardial infarction in a small series of patients with borderline low/low T_3 levels with no adverse effects and a suggestion of a decrease in regional wall motion abnormalities.[79] These studies involving patients with congestive heart failure and myocardial infarction are more remarkable for a lack of deleterious effect of L-T_3 treatment than for any sustained clinical benefit. In any event, future studies are warranted in this patient population.

Therapies other than thyroid hormone replacement have been shown to be beneficial options in the management of nonthyroidal illness. One randomized multicenter clinical trial reported that the use of *N*-acetylcysteine (NAC) was able to prevent serum thyroid function derangements, consistent with nonthyroidal illness among patients after an acute myocardial infarction.[80] The findings suggest that NAC, a potent intracellular antioxidant, is able to reduce oxidative stress, presumed as a causative factor of nonthyroidal illness.[81] Changes in thyroid hormone parameters occurring postoperatively have been prevented by early institution of nutritional support.[82] Finally, some investigators have suggested that patients with prolonged critical illness may represent a different disease entity than those with acute disease,[9,49] and treatment with hypothalamic-releasing factors should be tested in future trials.[49] In summary, in the absence of any clinical evidence of hypothyroidism, there does not appear to be any compelling evidence for the use of thyroid hormone therapy in patients with decreased thyroid hormone parameters related to sick euthyroid syndrome.

THYROID STORM

Thyroid storm is an acute, life-threatening complication of hyperthyroidism and represents the extreme manifestation of the disease.[83,84] Historically, thyroid storm was associated with surgery for hyperthyroidism.[85] Currently, because of better recognition of the disease and improved perioperative management, thyroid storm is rare, accounting for an incidence of 0.20–0.76 per 100,000 hospitalized patients.[86–88] Most often, thyroid storm is precipitated by an intercurrent medical problem in untreated or partially treated hyperthyroid patients.[89] The diagnosis of thyroid storm is a clinical one; there are no distinctive laboratory features, and thyroid hormone concentrations are similar to those observed in uncomplicated thyrotoxicosis. Although the cause of rapid clinical decompensation is unknown, a sudden inhibition of thyroid hormone binding to plasma proteins by the precipitating factor, causing a rise in free hormone concentrations in the already elevated free hormone pool, may play a role in the pathogenesis of thyroid storm.[90]

Clinical Manifestations

Thyroid storm is primarily a clinical diagnosis; as such, the varying incidence of this disorder in patient series likely results from the strictness of the diagnostic criteria. Clinical features are similar to those of thyrotoxicosis but more exaggerated (Box 137.3). Cardinal features of thyroid storm include fever (temperature usually >38.5°C), tachycardia out of proportion to the fever, and mental status changes.[91] Tachyarrhythmias, especially atrial fibrillation in the elderly, are common. Nausea, vomiting, diarrhea, agitation, and delirium are frequent presentations. Vascular collapse and shock caused by dehydration and cardiac decompensation are poor prognostic signs, as is the presence of jaundice.[92] Multiorgan failure has been reported.[93] Coma and death may ensue in up to 20% of patients, frequently the result of cardiac arrhythmias, congestive heart failure, hyperthermia, or the precipitating illness.[94] Involvement of the central nervous system may portend a worsened prognosis.[95,96]

Most patients display the classic signs of Graves disease, the most common cause of thyrotoxicosis, with ophthalmopathy and a diffusely enlarged goiter as the usual manifestations. In the elderly, atypical signs and symptoms may include severe myopathy, profound weight loss, apathy, and a minimally enlarged goiter.[97]

BOX 137.3 Clinical Features of Thyroid Storm

- Fever (as high as 105.8°F)
- Tachycardia/tachyarrhythmias
- Mental status changes
- Delirium/agitation
- Congestive heart failure
- Tremor
- Nausea and vomiting
- Diarrhea
- Sweating
- Vasodilatation
- Dehydration
- Hepatomegaly
- Splenomegaly
- Jaundice

BOX 137.4 Precipitating Factors for Thyroid Storm

- Surgery
  - Thyroidal
  - Nonthyroidal
- Infections
  - Pneumonia
  - Upper respiratory
  - Enteric
  - Other
- Stress
- Trauma
- Diabetic ketoacidosis
- Labor
- Cardiac disease
- Iodinated intravenous contrast agents
- Radioactive iodine (^{131}I) therapy

Precipitating Factors

In the past, thyroid storm was frequently associated with surgery for hyperthyroidism (Box 137.4), with symptoms beginning a few hours after thyroidectomy in patients prepared for surgery with potassium iodide alone. Most of these cases occurred in patients who were not appropriately prepared for surgery by current standards. Certain clinical and socioeconomic factors have also been suggested to be associated with complicated hyperthyroidism, including lack of insurance, age younger than 30 or older than 50, and serum T_4 concentrations greater than twice the upper limit of normal.[98] Because of better recognition of the disease, preoperative treatment with thionamides to deplete the gland of thyroid hormone before surgery, and improved perioperative management with beta-blockade, thyroid storm now is rarely a postoperative complication of thyroid surgery.

Currently, thyroid storm appears most commonly after infection, causing the thyrotoxic state to decompensate.[89] Pneumonia, upper respiratory tract infections, and enteric infections are common precipitating infections. Other precipitating factors include stress, trauma, nonthyroidal surgery, diabetic ketoacidosis, labor, heart disease, and iodinated contrast studies in unrecognized or partially treated hyperthyroid patients.[99–102] Iatrogenic thyroid storm has also been reported as a result of thyroid hormone overdose.[103,104] Thyroid storm associated with gestational trophoblastic disease and TSH-secreting pituitary adenoma are uncommon.[105,106] Thyroid storm occurring after ^{131}I therapy is extremely rare.[107] When reported, radioiodine-induced thyroid storm usually occurs if there was no pretreatment with antithyroid drugs. Tyrosine kinase inhibitors, used for the treatment of various cancers, has also been described to precipitate thyroid storm.[108]

Diagnosis

The diagnosis of thyroid storm is based primarily on clinical judgment. The Burch-Wartofsky[109] and Akamizu[86] scoring systems may be helpful in distinguishing the likelihood of thyroid storm in patients presenting with hyperthyroid symptoms. These scoring systems use criteria that include temperature, central nervous system effects, gastrointestinal effects, cardiovascular effects, and precipitant history to assist in the diagnosis.

There are no distinct laboratory abnormalities apart from elevated thyroid hormone concentrations, which are similar to those found in uncomplicated thyrotoxicosis. Serum T_3 concentrations are often elevated to a greater degree than serum T_4 concentrations, owing to the preferential secretion of T_3 by the hyperthyroid gland.[89] There is little correlation between the degree of elevation of thyroid hormones and the presentation of thyroid storm. Serum TSH concentrations are typically undetectable; however, because of the influence of nonthyroidal illness on TSH secretion (see earlier), a low TSH by itself is insufficient to make a diagnosis of thyroid storm. Serum T_4 and T_3 concentrations in the normal range, regardless of the TSH concentration, effectively eliminate thyroid storm as a tenable diagnosis.

In thyroid storm, abnormal serum liver function tests are common. Hypocalcemia may be observed secondary to increased osteoclast-mediated bone resorption in the hyperthyroid patient. Hematocrit concentrations may be elevated because of volume contraction, and leukocytosis is common even in the absence of infection.

The differential diagnosis of thyroid storm includes sepsis, neuroleptic malignant syndrome, malignant hyperthermia, and acute mania with lethal catatonia, all of which can precipitate thyroid storm in the appropriate setting. Clues to the diagnosis of thyroid storm are a history of thyroid disease, history of iodine ingestion, and the presence of a goiter or stigmata of Graves disease. The physician must have a high clinical index of suspicion for thyroid storm, as therapy must be instituted before the availability of thyroid function test results in most cases.

Treatment

It should be emphasized that a thyroid storm is an important medical emergency that must be treated in an ICU.[89] Therapy can be divided into two major categories (Box 137.5): (1) *thyroid-directed treatment* aimed at decreasing thyroid hormone production, conversion, and secretion and blocking the peripheral manifestations of thyroid hormone and (2) *supportive treatment* aimed at controlling the fever, stabilizing the cardiovascular system, and managing the precipitating cause.

Thyroid-Directed Treatment

Prompt inhibition of thyroid hormone synthesis and secretion is essential. Antithyroid drugs are given in large doses to both inhibit synthesis of thyroid hormones and block the uptake of iodine. Propylthiouracil (PTU) is preferred over methimazole, given its greater efficacy when used in large doses, in reducing T_3 levels during severe hyperthyroidism (by inhibition of type 1 deiodinase) and impairing peripheral conversion of T_4 to T_3.[110] However, because other, more powerful inhibitors of type 1 deiodinase are usually part of the therapeutic

BOX 137.5 Treatment of Thyroid Storm

Thyroid-Directed Therapy

Direct Inhibition of Thyroid Hormone Synthesis

Propylthiouracil: 800 mg PO/PR first dose, then 200–300 mg PO/PR q8h, *or*
Methimazole: 80 mg PO/PR first dose, then 40–80 mg PO/PR q12h

Block Release of Thyroid Hormones From the Gland

Telepaque (iopanoic acid): 1 g PO once daily (if available), *or*
SSKI: 5 drops PO q8h, *or*
Lugol solution: 10 drops PO q8h, *or*
Lithium: 800–1200 mg PO once daily; achieve serum lithium levels 0.5–1.5 mEq/L

Adjunctive

Block T_4-to-T_3 Conversion

Telepaque (iopanoic acid)
Corticosteroids: dexamethasone 1–2 mg PO/IV q6h
Propylthiouracil
Most beta-blockers: propranolol 40–80 mg PO q6h

Remove Thyroid Hormones From Circulation

Cholestyramine: 4 g PO q6h, *or*
Colestipol: 20–30 mg PO once daily, *or*
Plasmapheresis, *or*
Peritoneal dialysis

Supportive Therapy

Hyperthermia

IV fluids
Antipyretics
Cooling blanket

Hemodynamic

Beta-adrenergic blocking drugs:
- Propranolol: 1 mg IV/min to a total dose of 10 mg, then 40–80 mg PO q6h, *or*
- Esmolol: 500 mg/kg/min IV, then 50–100 mg/kg/min, *or*
- Metoprolol: 100–400 mg PO q12h, *or*
- Atenolol: 50–100 mg PO daily

Other

Vasopressors
Digoxin

Etiologic

Treatment of underlying illness(es)

Other

Anxiolytics (once mental status clears)

IV, Intravenous; *PO,* orally; *PR,* rectally.

regimen in thyroid storm, the main beneficial effects of PTU are its inhibition of iodide uptake and hormone synthesis. PTU and methimazole can be administered by nasogastric tube or rectally, if necessary.[111] Neither of these preparations is available for parenteral administration, although a protocol has been reported for the reconstitution of methimazole to be given IV.[112]

Iodides, the most effective drugs to block release of thyroid hormone from the thyroid gland, should be used only after antithyroid drugs have been administered. Monotherapy with iodides will actually increase the synthesis of new thyroid hormones and markedly worsen the hyperthyroidism when the gland escapes from the initial iodide-induced blockade of hormone secretion (the acute Wolff-Chaikoff effect).[113] Previously, the iodide preparation of choice was the radiographic contrast dye, iopanoic acid, because of its high iodine content (0.6 mg iodine/g dose) and the ability for the drug to directly inhibit type 1 deiodinase and thus block T_4-to-T_3 conversion; however, this drug is largely unavailable worldwide. Thus Lugol solution and saturated solution of potassium iodide (SSKI) are currently the main sources of therapeutic iodides.[114] It is important to realize that use of iodides precludes the use of radioactive iodine as a definitive therapy for hyperthyroidism for several months. Lithium has also been reported to be effective in inhibiting thyroid hormone release to a similar degree as iodides.[115]

High-dose dexamethasone is recommended as supportive therapy, both as an inhibitor of T_4-to-T_3 conversion and as management of possible coexistent adrenal insufficiency. Beta-adrenergic blockers, specifically propranolol, are also weak inhibitors of T_4-to-T_3 conversion, although their main beneficial effect is on heart rate control.[116] Orally administered ion-exchange resin (colestipol or cholestyramine) can trap hormone in the intestine and prevent recirculation.[117] Plasmapheresis, peritoneal dialysis, and charcoal hemoperfusion have also been used in severe cases.[118]

Supportive Treatment

Simultaneously with antithyroid-directed therapy, treatments aimed at cooling the patient down to a reasonable temperature and providing hemodynamic support should be instituted. IV fluids, antipyretics, and cooling blankets are all effective. Beta-adrenergic blockers such as propranolol (oral or IV) and esmolol (IV) are given for heart rate control. Calcium channel blockers may be used to control tachyarrhythmias. Anxiolytics are frequently helpful once the patient's mental status improves. Finally, treatment of the underlying precipitating illness is essential to survival in thyroid storm.

Long-Term Therapy

Once the acute phase of thyroid storm is controlled, antithyroid drug therapy should be continued until euthyroidism is achieved, and the adjunctive therapy can be discontinued. Definitive therapeutic options for hyperthyroidism include radioactive iodine (after a few months to allow excretion of the excess iodides used during acute management of thyroid storm) and surgery.[119] Treatment with antithyroid drugs for 18–24 months in the hopes of achieving a remission is recommended for patients with Graves disease,[119] and there are emerging data that even a much longer period of antithyroid drugs may be an option.[120]

MYXEDEMA COMA

Myxedema coma is a rare syndrome that represents the extreme expression of severe long-standing hypothyroidism.[121–123] It is a medical emergency, and even with early diagnosis and treatment, the mortality can be as high as 60%.[124] The name is somewhat of a misnomer, as actual coma is rare. The syndrome includes decompensated hypothyroidism, central nervous system impairment, and cardiovascular compromise. Myxedema coma occurs most often in the elderly and during the cold months; in one series in India, 15 of 23 cases of myxedema coma were admitted in the winter.[125] As with thyroid storm, myxedema coma is usually caused by a precipitating event in untreated or partially treated hypothyroid patients.

Clinical Manifestations

The cardinal features of myxedema coma are (1) hypothermia, which can be profound; (2) altered mental status; (3) cardiovascular depression; and (4) a precipitating cause (Box 137.6). Severely hypothyroid patients essentially become poikilothermic because of disordered thermoregulation.

BOX 137.6 Clinical Features of Myxedema Coma

- Mental obtundation
- Hypothermia
- Bradycardia
- Hypotension
- Coarse, dry skin
- Myxedema facies
- Hypoglycemia
- Atonic gastrointestinal tract
- Atonic bladder
- Pleural, pericardial, and peritoneal effusions

BOX 137.7 Precipitating Factors of Myxedema Coma

- Cold stress
- Infection
  - Pneumonia
  - Urinary tract
  - Other
- Stroke
- Congestive heart failure
- Trauma
- Burns
- Surgery
- Intravascular volume contraction
  - Gastrointestinal blood loss
  - Diuretic use
- CNS-active drugs

  - Sedatives/hypnotics
  - Tranquilizers
  - Anesthetic agents

CNS, Central nervous system.

This is the reason many cases occur in the winter months. Body temperatures as low as 23.3°C have been reported; thus rectal temperatures are essential in making the diagnosis. Excessive lethargy and sleepiness may have been present for weeks to months, often interfering with meals, and patients may even present obtunded.[125] Decreased consciousness has been found to be an important adverse prognostic indicator for mortality.[126] Rarely, psychosis and delirium have been reported. Bradycardia and hypotension may be profound, and the respiratory rate is often depressed. Because intrinsic hypothyroidism by itself is insufficient to produce the clinical syndrome of myxedema coma, a precipitating cause must be assumed to be present.

Most patients have the physical features of severe hypothyroidism, including macroglossia; delayed reflexes; dry, rough skin; and myxedematous facies, which results from periorbital edema, pallor, hypercarotenemia, and patchy hair loss. Hypotonia of the gastrointestinal tract is common and often so severe as to suggest an obstructive lesion.[127] Urinary retention caused by a hypotonic bladder is related but less frequent. Cardiac manifestations such as pleural, pericardial, and peritoneal effusions; cardiac tamponade; and heart failure may be present.[128] Severe airway obstruction has been reported.[129]

Precipitating Factors

The stress of severely cold temperatures is a common precipitant to myxedema coma (Box 137.7). Other common precipitating factors include pulmonary and urinary tract infections, cerebrovascular accidents, trauma, surgery, congestive heart failure, and intravascular volume loss from acute or chronic gastrointestinal bleeding or overuse of diuretics.[121–123] The clinical course of lethargy proceeding to stupor and then coma is often hastened by drugs, especially sedatives, narcotics, antidepressants, and tranquilizers.[130] Amiodarone, because of its high iodine content,[113] has been reported to induce both thyroid storm[131] and myxedema coma.[132] Similar to the association of tyrosine kinase inhibitors and thyroid storm, agents such as sunitinib have also been reported to induce severe hypothyroidism.[133] Many cases of myxedema coma have occurred in undiagnosed hypothyroid patients who present for other medical problems.[134]

Diagnosis

Like the diagnosis of thyroid storm, myxedema coma is a clinical diagnosis, and similar to thyroid storm, a scoring system by Wartofsky and colleagues has been proposed.[135] Elderly patients may present with particularly subtle findings. Even though it is rare, the diagnosis of myxedema coma should be considered in hypothermic, obtunded patients. Medical histories of these patients, including a prior history of hypothyroidism, may only be able to be confirmed from other sources. Friends, relatives, and acquaintances might have noted increasing lethargy, complaints of cold intolerance, sluggishness, and despondency. Clues to the diagnosis include an outdated container of L-T_4 (levothyroxine) discovered with the patient's belongings, which suggests that the patient has been noncompliant in taking thyroid hormone replacement medication. The medical record may also indicate prescribed thyroid hormone use, previous referral to treatment with radioactive iodine, or a history of thyroidectomy. Finally, the physical examination finding of a thyroidectomy scar should raise suspicion as to the diagnosis.

Because the vast majority of myxedema coma cases are a result of primary hypothyroidism,[129] the laboratory findings include an elevated serum TSH and low or undetectable total and free serum T_4 concentrations. These thyroid hormone abnormalities are similar to those in uncomplicated overt hypothyroidism. In patients with central hypothyroidism, the diagnosis of myxedema coma may be very difficult, as serum TSH concentrations will be normal or low. However, other symptoms of pituitary dysfunction are usually present in these rare patients.

Dilutional hyponatremia is common and may be severe. Elevated creatine kinase concentrations, sometimes markedly so, are encountered frequently and may misdirect the clinical picture toward cardiac ischemia.[136] However, the MB fraction in most of these cases is normal, and an electrocardiogram (ECG) often demonstrates low voltage and loss of T waves that are characteristic of severe hypothyroidism. Elevated lactate dehydrogenase (LDH) concentrations, acidosis, and anemia are common findings. Lumbar puncture reveals increased opening pressure and high protein content in the cerebrospinal fluid.

Few of the signs and symptoms discussed are unique to myxedema coma. Protein-calorie malnutrition, sepsis, hypoglycemia, and exposure to certain drugs and toxins, in addition to cold exposure, can cause severe hypothermia. Hypotension and hypoventilation, other cardinal features of myxedema coma, occur in other disease states. Furthermore, low thyroid hormone concentrations may be seen in critically ill patients with nonthyroidal illness (see earlier). As with thyroid storm, the physician must have a high clinical index of suspicion for myxedema coma, as therapy must be instituted before the availability of thyroid function test results in most cases.

Treatment

Treatment of myxedema coma is a medical emergency and should be managed in an ICU setting.[129] The mainstays of therapy are supportive care with ventilatory and hemodynamic support, rewarming, correction of hyponatremia and hypoglycemia, treatment of the precipitating incident, and administration of thyroid hormone (Box 137.8).[121,129] Sedatives, hypnotics, narcotics, and anesthetics must be minimized or avoided altogether because of their extended duration of action and exacerbation of obtundation in hypothyroid patients.

Hypothermia is one of the hallmarks of myxedema coma, and its severity may be underestimated if the thermometer used does not register below 30°C. At core temperatures below 28°C, ventricular fibrillation is a significant life-threatening risk. Despite its gravity, the management of the hypothermia of myxedema coma differs from the treatment of exposure-induced hypothermia in euthyroid subjects. In myxedema coma, patients should be kept in a warm room and covered with blankets. Active heating should be avoided, because it increases oxygen consumption and promotes peripheral vasodilation and circulatory collapse. Active heating is recommended only for situations of severe hypothermia where ventricular fibrillation is an immediate threat. In these cases, the rate of rewarming should not exceed 0.5°C per hour, and the core temperature should be raised to approximately 31°C.

Because of the possibility of coexisting adrenal insufficiency in patients with myxedema coma, IV steroids (i.e., hydrocortisone 100 mg IV every 8 hours) are indicated before initiating L-T_4 therapy. Parenteral administration of thyroid hormone is necessary because of uncertain absorption through the gut.[137] A reasonable approach is an initial IV loading dose of 200–300 μg of L-T_4. If there is inadequate improvement in the state of consciousness, blood pressure, or core temperature during the first 6–12 hours after administration, another dose of L-T_4 should be given to bring the total dose during the first 24 hours to 0.5 mg. This should be followed by 50–100 μg IV every 24 hours until the patient is stabilized. Alternatively, in the most severe cases, some clinicians recommend using L-T_3 at a dosage of 12.5–25 μg IV every 6 hours until the patient is stable and conscious. Caution must be used to avoid overstimulation of the cardiovascular system. Once stable, the patient should be switched to L-T_4. The dose of thyroid hormone should be adjusted on the basis of hemodynamic stability, the presence of coexisting cardiac disease, and the degree of electrolyte imbalance.

Although myxedema coma is associated with a high mortality, survival can be maximized by correcting the secondary metabolic disturbances and reversing the hypothyroid state in a sustained but gradual fashion. Efforts to correct hypothyroidism too rapidly may completely negate the beneficial effects of the initial treatment.

BOX 137.8 Treatment of Myxedema Coma

Supportive

Assisted ventilation
Hemodynamic support
Passive rewarming for hypothermia
Intravenous glucose for hypoglycemia
Water restriction or hypertonic saline for severe hyponatremia
Hydrocortisone IV (100 mg q8h)
Treatment of precipitating factor(s)
Avoidance of all CNS-acting medications

Thyroid Hormone Replacement

L-T_4: 200- to 300-μg loading dose IV, up to 500 μg IV in the first 24 h *and/or*
L-T_3: 12.5 μg IV q6h

CNS, Central nervous system; *IV,* intravenous.

Long-Term Therapy

Once the patient with myxedema coma is clinically stable, thyroid hormone replacement can be switched to oral L-T_4. The dose of L-T_4 should be adjusted over the ensuing weeks and months to achieve serum T_4 and TSH concentrations in the normal range.

KEY POINTS

- Critical illness can result in multiple nonspecific alterations in serum thyroid function tests that relate to the severity of the illness.
- The interpretation of thyroid function tests in the ICU patient can be challenging.
- In the ICU, identifying those patients with intrinsic thyroid dysfunction must take into consideration both the clinical assessment of the patient and the duration and severity of the illness. Whenever possible, it is best to defer evaluation of thyroid function until the patient has fully recovered from the critical illness.
- The benefits of treating nonthyroidal illness, including use of thyroid hormone, in various populations remain controversial and incompletely understood.
- Thyroid storm and myxedema coma are medical emergencies that are associated with high mortality rates. Recognition of their clinical presentation and rapid initiation of treatment are critical.

Diabetes Insipidus

Serge Brimioulle

Diabetes insipidus is a disorder of water metabolism associated with polyuria, urine hypotonicity, and hypernatremia.[1,2] The quantitative criteria include urine output greater than 200 mL/hr or 3 mL/kg/hr, urine osmolality less than 150 mOsm/kg, and plasma sodium greater than 145 mEq/L. If urine osmolality measurement is not available, hypotonicity can be assessed from a urine specific gravity less than 1.005.

CENTRAL DIABETES INSIPIDUS

Neurogenic or central diabetes insipidus is characterized by a lack of antidiuretic hormone (ADH) that may result from any injury to the anterior hypothalamus, pituitary stalk, or posterior pituitary gland.[3] In acute critically ill patients, the most common causes of diabetes insipidus are surgery for pituitary tumors, cerebral trauma, intracranial hypertension, and brain death (Table 138.1). Diabetes insipidus also may occur as a complication of bacterial meningitis or encephalitis, vascular aneurysm or thrombosis, drug administration, or alcohol intoxication. Injuries to the hypothalamus most often yield permanent diabetes insipidus because ADH is synthesized in the hypothalamus itself. Injuries to the pituitary stalk and neurohypophysis more commonly cause transient diabetes insipidus because hypothalamic ADH secretion can be effective even in the absence of anatomic pathways to the normal site of release. Chronic diabetes insipidus in critically ill patients generally results from tumors of the pituitary region and from the sequelae of cerebral trauma.

CLINICAL PICTURE

In complete hypothalamic or pituitary injuries, diabetes insipidus generally develops 6–24 hours after the injury because previously released ADH remains circulating this long. Patients with untreated diabetes insipidus usually develop urine outputs of 10–15 L/day. When the thirst mechanism is preserved, it is activated as soon as osmolality or volemia decreases. If the patient remains conscious and is given free access to water, he or she may be able to drink large amounts and compensate for the urine losses. In other cases, the large amounts of dilute urine rapidly result in dehydration, with hypovolemia and hypotension, and in hypernatremia, with neurologic deterioration. It is important that diabetes insipidus be recognized and treated rapidly, especially in comatose or noncommunicative patients. In patients with partial diabetes insipidus, the onset of polyuria may be delayed and the volume of urine may be lower. Nevertheless, if urine is hypo-osmolar and the diabetes insipidus is not treated, dehydration and hypernatremia finally occur and cause symptoms.

Clinical signs of hypernatremia usually appear only when the plasma sodium concentration increases to greater than 155–160 mEq/L or plasma osmolality increases to greater than 330 mOsm/kg.[1–3] Signs may appear sooner if hypernatremia is associated with other metabolic disorders, particularly with disorders that also increase plasma osmolality. Symptoms mainly include confusion and lethargy. Severe hypernatremia results in coma and sometimes seizures. Acute and severe dehydration and hypernatremia may lead to cerebral shrinkage, sometimes associated with subdural or intraparenchymal hemorrhages.

Clinical signs of dehydration include blood volume depletion and hypotension in the most severe cases. Biologic markers of dehydration are usually absent in ICU patients with central diabetes insipidus because the urine loss begins abruptly and commonly reaches more than 1 L/hr. The free water deficit can be estimated by the following formula:

$$\text{Deficit (L)} = \text{body weight (kg)} \times 0.6 \times (Na^+ - 140)/Na^+$$

The formula assumes that only free water has been lost and that sodium stores are normal. Most often, some sodium has been lost together with additional water, and the total water deficit is even higher than that estimated from the formula. A moderate level of hypernatremia (e.g., 155 mEq) already is associated with a free water deficit of more than 4 L and a total water deficit that may be much higher if sodium has been lost.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of polyuria includes the intake of diuretic drugs, hyperglycemia, fluid overload, and fluid mobilization. The search for diuretic administration should include not only conventional diuretics but also mannitol and iodinated contrast agents. The administration of diuretics may not be evident when these substances have been given before admission to the intensive care unit (ICU) (e.g., in another hospital before patient transfer; in an ambulance during transfer; or in the operating room during neurosurgery, trauma surgery, or vascular surgery). Preventive administration of furosemide and mannitol is given routinely in some neurosurgical procedures and may result in marked polyuria during and after the operation. Hyperglycemia-induced osmotic diuresis is common, can be suspected from polyuria or from hyperglycemia, and is confirmed or ruled out by the presence or absence of glucosuria. Hypervolemia, resulting from fluid overload or unmasked by discontinuation of sustained positive-pressure ventilation, may increase urine output to greater than 5 L/day for several days in patients with normal renal function. Mobilization of edema, at the time of recovery from disease or from surgery, also can result in sustained polyuria. In all these conditions, however, the urine remains close to isotonic (osmolality about 300 mOsm/kg). Abundant intake of hypotonic fluid can cause polyuria and urine hypotonicity but does not result in hypernatremia if renal function is normal. The observation of decreased urine output after ADH administration is

TABLE 138.1 Causes of Diabetes Insipidus

Central
Congenital anomalies: corpus callosum agenesis, cleft palate
Granulomatous disease: sarcoidosis, tuberculosis, Wegener disease
Histiocytosis
Sickle cell disease
Idiopathic: autoimmune
Tumors: suprasellar, infrasellar, aneurysms
Infection: meningitis, encephalitis
Head trauma, neurosurgery, brain death
Nephrogenic
Congenital disease
Renal disease: obstructive uropathy, reflux nephropathy, cystic disease, electrolyte disorders
Renal involvement in systemic disease: sarcoidosis, amyloidosis, sickle cell disease
Drugs: phenytoin, aminoglycosides, amphotericin, antivirals, demeclocycline, lithium

Monitor and replace urine losses hourly
Monitor plasma electrolytes and adapt therapy every 4 hours

DDAVP, 1-deamino-8-D-arginine vasopressin.

not diagnostic of diabetes insipidus because ADH is able to reduce urine output and to increase urine osmolality in all conditions except nephrogenic diabetes insipidus.

Copeptin has been recently reported useful in the diagnosis of diabetes insipidus.[4,5] ADH and copeptin are released together and in a 1:1 proportion during the breakdown of the VP-NPII precursor. Whereas ADH levels are difficult to measure because of technical reasons, copeptin has been reported as a sensitive and simple marker of ADH release.[4,5] Copeptin is therefore interesting to differentiate primary polydipsia and the two forms of diabetes insipidus. It has been reported useful in chronic states of hypotonic polyuria and during diagnostic tests.[6,7] Copeptin is less contributive in critically ill patients, in whom the symptom clarity and the recent history are often sufficient to yield the diagnosis.

TREATMENT

The management of diabetes insipidus includes two components (Table 138.2): (1) reduction of excessive urine output and (2) correction of water deficit. The polyuria of central diabetes insipidus is treated effectively by vasopressin (ADH) or by its synthetic analog desmopressin acetate (DDAVP [1-deamino-8-D-arginine vasopressin]).[8,9] As indicated by its multiple names, vasopressin not only has antidiuretic but also vasoconstrictive and oxytocic effects, whereas desmopressin essentially retains the antidiuretic action. The effects of aqueous vasopressin (4–10 U subcutaneously or intramuscularly) on diuresis begin rapidly but last for only a few hours. Vasopressin must be repeated every 4–6 hours, and it has been recommended only for diagnostic purposes or in acute conditions (e.g., trauma) in which the diabetes insipidus might be transient. The effects of vasopressin tannate in oil emulsion (2–5 U intramuscularly) last 48–96 hours, but the preparation requires close attention to warming and mixing the suspension before injection. Vasopressin tannate previously used to be the standard therapy in patients with central diabetes insipidus, but it has now been abandoned in favor of desmopressin. Vasopressin tannate, where available, still may be used in patients who are refractory to desmopressin or who experience significant side effects. Desmopressin has prolonged effects (8–20 hours) and is appropriate for intravenous, subcutaneous, and intranasal routes. Lypressin is another ADH analog that is appropriate for intranasal use, but its effectiveness is limited by its duration of action of only 4–6 hours. Desmopressin is known to increase factor VIII and von Willebrand factor levels and is sometimes used for this purpose in patients with coagulation disorders and in surgical procedures associated with significant bleeding. In the ICU and acute central diabetes insipidus, desmopressin is initially given as 10–20 μg intranasally and repeated every 30–60 minutes until urine output is reduced to less than 100 mL/hr. The initial dose required to maintain a normal urine volume ranges from 10 to 60 μg in most patients. The total appropriate dose is given again when the urine output increases again to greater than 200 mL/hr (i.e., after 8–24 hours). The dosage must be reduced if urine output is excessively decreased. Systematic administration is not recommended because most cases of diabetes insipidus seen in ICUs are associated with acute events and may be incomplete or intermittent or both. The subcutaneous route is seldom used because absorption may be erratic in vasoconstricted patients and because an intravenous line is virtually always available in ICU patients. Desmopressin is injected intravenously when the intranasal route is not available (i.e., in cases of rhinorrhea and facial trauma). The required initial dose ranges from 2 to 20 μg and is given as repeated 2- to 4-μg boluses.

Vasopressin therapy can be associated with arterial hypertension, myocardial infarction, mesenteric infarction, peripheral ischemia, and uterine cramps. Vasopressin tannate may cause allergic reactions, ranging from urticaria to anaphylaxis, and sterile abscesses at sites of injection. Desmopressin may interfere with anticoagulant drugs and cause hypercoagulability. When given in excess, all these antidiuretic agents can result in oliguria, hyponatremia, and water intoxication. The severity of diabetes insipidus may vary over time, even in patients with chronic diabetes insipidus, and some patients with chronic diabetes insipidus who are used to drinking large amounts of water may continue to do so even if urine output is limited by a diuretic drug.

Patients with acute diabetes insipidus should receive a sufficient amount of water to match urine output until the polyuria is controlled and to correct the deficit of free water that already exists at the time of diagnosis. If the gastrointestinal system is functional, water can be infused at rates of 1–2 L/hr through a gastric tube. Otherwise, isotonic dextrose should be infused intravenously in appropriate amounts (hypotonic dextrose administration can be obtained by infusing equal amounts of water and isotonic dextrose in a central vein, but this procedure has been associated with vascular injuries). Practically, the dedicated gastric or intravenous infusion rate is adjusted at least hourly to match the urine output of the last equivalent period. Additional water is provided to correct the initial water deficit over a few hours. Plasma electrolytes should be monitored every 4 hours until a normal natremia is restored and stabilized. Blood glucose must be monitored closely and hyperglycemia treated aggressively using intravenous insulin. Failure to control hyperglycemia may be associated with osmotic diuresis caused by glucosuria and superimpose an equivalent of diabetes mellitus on the already present diabetes insipidus.

NEPHROGENIC DIABETES INSIPIDUS

Nephrogenic diabetes insipidus is characterized by the inability of the renal parenchyma to concentrate urine in response to ADH.[10] The disorder is seldom diagnosed in the ICU and is usually more severe

when it is congenital. Hereditary forms generally result from mutations to the AVP-2 receptors or AQP-2 water channels. Acquired forms are the result of vasopressin resistance of the distal tubule and collecting duct or of markedly reduced renal concentrating capacity. Most of them are attributed to electrolyte disturbances and to lithium therapy, but many other drugs have been implicated. Nephrogenic diabetes insipidus may be treated with a low-sodium, low-protein regimen that reduces the solute load, with thiazide diuretics that induce a mild volume depletion and help reduce the urine volume to acceptable values, and with nonsteroidal antiinflammatory drugs such as indomethacin that inhibit prostaglandin synthesis.

KEY POINTS

- Diabetes insipidus is characterized by polyuria, urine hypotonicity, and hypernatremia.
- Central diabetes insipidus results from a lack of ADH; nephrogenic diabetes insipidus results from renal insensitivity to ADH.
- In the ICU, diabetes insipidus is caused mainly by pituitary surgery, trauma, and brain death.
- Clinical signs are related to dehydration and hypernatremia.
- ICU patients generally are unable to compensate for excessive urine losses by drinking.
- Differential diagnosis includes administration of diuretics, mannitol, and iodinated agents.
- Polyuria is controlled with desmopressin 10–20 μg intranasally or 2–4 μg intravenously.
- Water deficit is corrected with enteral water or intravenous 5% dextrose in water.
- Diuresis should be monitored hourly, and ongoing urinary losses should be compensated for.

General Principles of Pharmacokinetics and Pharmacodynamics

Mitch A. Phelps and Henry J. Mann

Critically ill patients suffer from a variety of physiologic insults that result in a rapidly changing physiologic status, thus making appropriate drug dosing a challenging problem. Understanding how these changes affect pharmacokinetics and pharmacodynamics can result in improved dosing decisions. This chapter reviews the basic principles of pharmacokinetics and pharmacodynamics and how they may be affected by critical illness.

The terms *pharmacokinetics* and *pharmacodynamics* describe the amount of drug in the body at a given time and the pharmacologic effects caused by the drug.[1] Pharmacokinetics describes the movement of a drug into, within, and out of the body over time, whereas pharmacodynamics explains the effects the drug has on the body. How a patient responds to therapy is a function of both the physiologic processes that dictate drug exposure (the changes in drug concentration over time) and the processes that govern how that exposure translates into pharmacodynamic effects. Understanding the pharmacokinetic parameters of clearance, volume of distribution, half-life, steady state, and absorption, along with pharmacodynamic principles such as receptor theory, potency, affinity, tolerance, and minimum effective concentration can enhance the treatment of critically ill patients.

GENERAL PRINCIPLES OF PHARMACOKINETICS

Clearance, volume of distribution, half-life, and bioavailability are four pharmacokinetic parameters that allow the clinician to better estimate dosing requirements. If the concentration of a drug in a sampled fluid (e.g., plasma, urine, saliva) correlates well with its pharmacologic response (therapeutic or toxic), then the application of pharmacokinetics is likely to be beneficial (Fig. 139.1). This is especially true for drugs where lack of efficacy because of low exposure or toxicity because of high exposure pose significant risks to the patient.

Measurement of the relationship between drug concentration and therapeutic or toxic response in a large number of patients enables the development of a therapeutic range or target concentration for that drug (Fig. 139.2).[2,3] A multitude of host factors (e.g., hemodynamic status, decreased organ function, nutritional status, concurrent disease states) increase the likelihood that drug dosing based on individualized pharmacokinetic assessment will be beneficial.[4,5] Gender-related differences can occur in both pharmacokinetic and pharmacodynamic responses.[6] Individual chapters in this text are devoted to many of these agents and their adjustments for dosage in patients with renal or hepatic failure.

PHARMACOKINETIC MODELS

The pharmacokinetic concepts of clearance, volume of distribution, half-life, and bioavailability are based on enormously complex physiologic principles and use mathematical models that make many assumptions. Most clinically useful pharmacokinetic equations assume one- or two-compartment models (see Fig. 139.2).

When the drug enters the one-compartment model, it is assumed to be instantaneously and completely mixed in a given volume of distribution, resulting in a uniform concentration throughout the compartment. The rate constant *K* reflects the usual situation of elimination by a first-order, linear process. The drug is assumed to enter the compartment instantaneously in the case of an intravenous bolus dose. If the dosage is administered through oral or intramuscular routes, entry into the compartment is assumed to occur at a rate defined by a first-order absorption rate constant (Ka), whereas entry into the compartment is assumed to occur at a constant rate described by a zero-order rate constant (Ro) if the drug is administered by intravenous infusion. *Bioavailability* (F) is defined as the fraction of the administered dose that reaches the systemic circulation.

Clearance (CL) is a primary parameter that can be physiologically associated with a particular organ in the body such as the liver or kidney. Clearance is often expressed by the equation $CL = K \times V$, leading to the impression that CL is a function of the parameters K and V. However, this arrangement of the equation is not correct from a physiologic point of view. CL and V are both primary parameters, and K is a secondary parameter. The first-order rate is determined by changes in either CL or V, and the equation is correctly written as $K = CL/V$.

Half-life ($t_{1/2}$) is a useful measure of how quickly a drug is eliminated from the body and is related to the first-order elimination rate constant:

$$t_{1/2} = \frac{\ln(2)}{K} = \frac{0.693}{K} \qquad \text{(Equation 1)}$$

Specifically, $t_{1/2}$ defines the time taken for the drug concentration to decrease by one-half. In a linear pharmacokinetic system with first-order elimination, $t_{1/2}$ is constant, and it takes the same amount of time for the concentration to fall from 100 to 50 (arbitrary units) as it does to decline from 50 to 25 (Fig. 139.3).

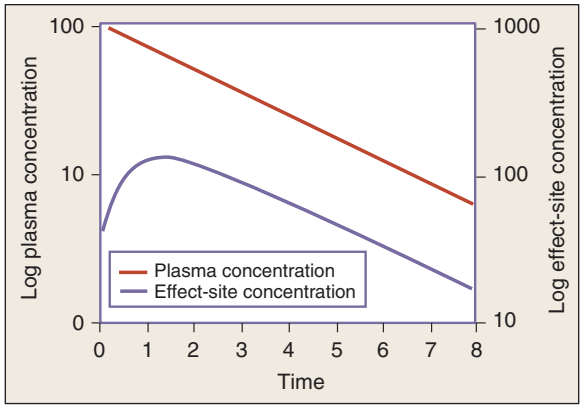

Fig. 139.1 For concentration monitoring to be useful, there must be a strong relationship between concentration of the drug measured in an easily accessible fluid and concentration at the effect site.

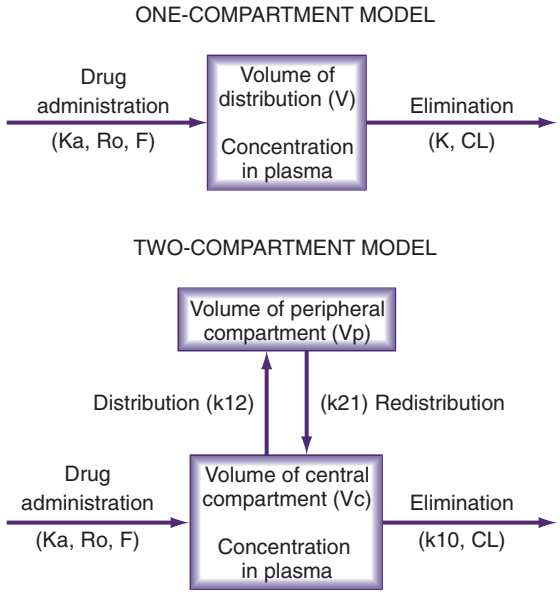

Fig. 139.2 Pharmacokinetic models simplify complex physiologic process. Concentrations may behave as if the body were a single rapidly equilibrating compartment or follow a more complicated two-compartment model in which a slower distribution phase into tissues is observed. See text for explanation of terms.

The one-compartment model allows concentrations at any point in time to be calculated:

$$C2 = C1 \times \exp^{-K \times \Delta t} \qquad \text{(Equation 2)}$$

where Δt is the time between measurements C1 and C2. The monoexponentially decreasing concentration-time curve appears linear when plotted on semi-log coordinates.

Sometimes a drug does not instantly equilibrate with all tissues in the body. This can often be adequately described by a two-compartment model, which is characterized by a rapidly distributing central compartment and a more slowly equilibrating peripheral compartment (Fig. 139.4). The equation describing the concentration-time profile for the two-compartment model is:

$$C = A \times \exp^{-\alpha \times t} + B \times \exp^{-\beta \times t} \qquad \text{(Equation 3)}$$

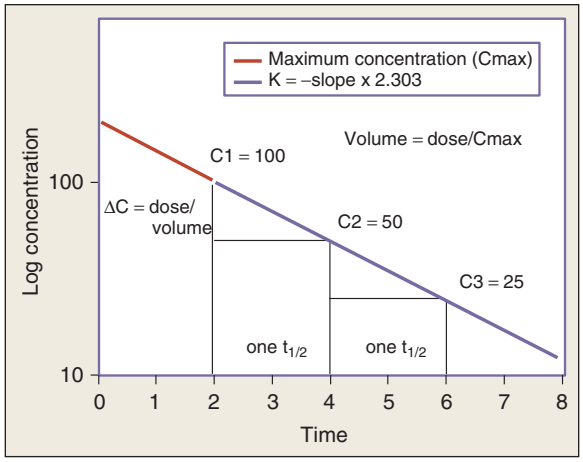

Fig. 139.3 Log concentration-time curve for a one-compartment model after intravenous administration, illustrating volume of distribution, elimination rate constant, and half-life.

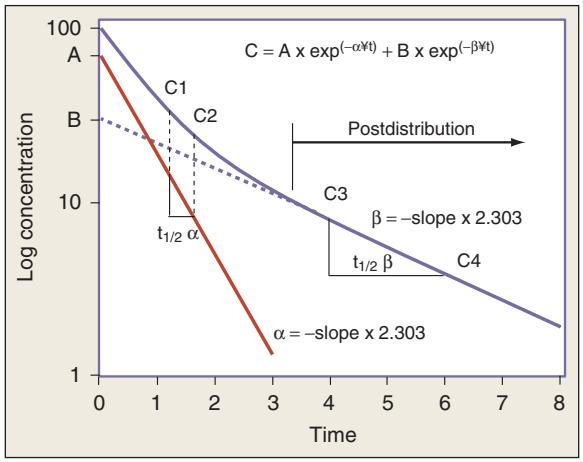

Fig. 139.4 Log concentration-time curve for a two-compartment model after intravenous administration, illustrating a distribution period (α) and postdistribution period (β). Concentrations C1 and C2 reflect both distribution and elimination processes, whereas concentrations C3 and C4 reflect postdistribution elimination processes.

The distinguishing feature of this biexponential equation is that when plotted on semi-log coordinates, the concentrations are the sum of two distinct straight lines representing two half-lives. One is the *terminal* or β half-life, and the other is the *rapid distribution* or α half-life. As the rapid distribution exponential becomes negligible in the equation, the slower exponential term dominates, and the concentration-time profile resembles that of a single-compartment drug. Consequently, the equation:

$$C2 = C1 \times \exp^{-\beta \times \Delta t} \qquad \text{(Equation 4)}$$

in which β replaces K, can still be used to predict concentrations, as long as both C1 and C2 are in the postdistributive phase. This sum-of-exponentials approach can be extended to three-compartment or even more complex models, but it is difficult to obtain all the concentrations needed to characterize each exponent.

Clearance

CL is a primary pharmacokinetic parameter that measures the ability of the body to eliminate a drug. It is often stated that clearance is the

volume of blood (plasma) that is completely cleared of drug per unit time. Although this is one way to define clearance, it does not capture the relationship between drug clearance (mL/min) and the rate of drug elimination (mg/hr). In pharmacokinetics, the general concept of clearance is also the rate of elimination relative to the concentration. In a first-order pharmacokinetic system, the rate of elimination is proportional to the drug concentration; clearance is this proportionality constant:

$$\text{Rate of elimination} = CL \times \text{concentration} \qquad \text{(Equation 5)}$$

Clearance is clinically useful because it can be directly related to the organ of elimination. We can talk about renal clearance, hepatic clearance, or biliary clearance, and the sum of each of the individual clearances is the total body clearance. This allows us to adjust doses in response to changes in organ function. A patient with developing renal failure is likely to require a reduction of the dose of a drug that is eliminated by the kidney but not necessarily a dose reduction of a drug that is eliminated by the liver. For example, if the clearance of a drug is known to be 50% renal and 50% hepatic and renal function is decreased by 50%, it is necessary to reduce the dose by only 25% to maintain the same concentration.

The area under the curve (AUC) is a useful measure of drug exposure and results from dose and CL:

$$AUC = \frac{Dose}{CL} \qquad \text{(Equation 6)}$$

This concept is similar to a steady-state concentration (Css) being considered as the measure of drug exposure during a continuous intravenous infusion. The Css is solely a function of the infusion rate (Ro) and CL:

$$Css = \frac{Ro}{CL} \qquad \text{(Equation 7)}$$

Notice that Css is not a function of the volume of distribution. Though counterintuitive, doubling the volume of distribution will not result in a halving of Css. The important point is that the equation is predicting the concentration at a steady state. During a constant infusion, rapidly doubling the volume of distribution will only transiently halve the concentration. If clearance remains unchanged, the concentration will return to the same Css.

With intermittent dosing, drug concentrations go up and come down during each dosing interval. The average Css (Css,avg) is a time-averaged concentration (i.e., the mean of all concentrations during the dosing interval); it is also a function of clearance and the dosing rate. In the case of oral administration, the dosing rate is a function of the dose administered (D), dosing interval (τ), and F:

$$Css,avg = \frac{F \times D/\tau}{CL} \qquad \text{(Equation 8)}$$

As before, the overall drug exposure is not influenced by the volume of distribution, but it does change in proportion to changes in clearance or the dosing rate through changes in F, D, or τ.

Volume of Distribution

The volume of distribution (V) is another primary pharmacokinetic parameter and is useful for determining the change in drug concentration for a given dose. After an intravenous bolus dose in a one-compartment pharmacokinetic model, the change in concentration (ΔC) between the maximum concentration (Cmax) and the concentration immediately before the dose is administered is a function of the dose (D) and the V:

$$\Delta C = \frac{D}{V} \qquad \text{(Equation 9)}$$

This equation is useful for predicting both the concentration after a first bolus dose and the increase in concentration at any point in time after a bolus dose. If a concentration before a bolus dose is known, the equation can be used to predict the increase in concentration after the dose is administered (see Fig. 139.3). This equation is also useful for estimating the dose needed to reach a given concentration. If it is known that the volume of distribution is 0.45 L/kg and a Cmax of 10 mg/L is desired after the loading dose, the dose is estimated to be 10 mg/L $\times$ 0.45 L/kg = 4.5 mg/kg. This equation only predicts loading doses and not maintenance doses. A steady-state condition is not necessary, which is common in critical care.

The value for the volume of distribution does not necessarily coincide with any particular physiologic space. The veracity of this statement becomes readily apparent when one considers a drug such as digoxin, which has a volume of distribution of approximately 440 L. Clearly, a volume of distribution of that magnitude cannot have a relationship to any physiologic space in an average-sized human. Therefore the term *apparent volume of distribution* is often used.

The concept of the volume of distribution gets more complex when more than one compartment is needed to describe the pharmacokinetics of a drug. Mathematically, the volume of distribution is a hypothetical volume that is needed to relate the amount of drug in the body to a measured concentration in a fluid (plasma). Unlike the one-compartment model, wherein the entire drug in the body is regarded as being in a single compartment until it is eliminated, drug also circulates through additional compartments in a multicompartment model. In this situation, the volume of distribution must increase as drug distributes to other compartments until distribution equilibrium among all compartments is reached. Technically, an infinite number of volumes of distribution are observed as this equilibration process occurs, but only three are commonly defined. The *volume of distribution of the central compartment* (Vc) is the volume of the usual sampling compartment; it is always the smallest volume term. Immediately after the administration of an intravenous bolus, all added drug is in the central compartment, and Vc can be used to calculate a change in concentration.

The volume of distribution increases over time until a *distribution equilibrium* is reached among all compartments. This is the largest value for the volume of distribution. The fact that the distribution equilibrium has occurred can be discerned from a log concentration versus time plot (see Fig. 139.4). The curve becomes log linear when the rate of drug entry into each peripheral compartment equals the rate of return from each compartment. Because it is often calculated using the clearance and β or terminal elimination half-life, this volume is often called V_β:

$$V_\beta = \frac{CL}{\beta} \qquad \text{(Equation 10)}$$

The *steady-state volume of distribution* (Vss) is the sum of the volumes of all the compartments in the model. If a drug were infused to steady state, Vss would be the proportionality constant relating Css to the total amount of drug in the body.

Half-Life

Half-life ($t_{1/2}$) is defined as the time taken to reduce the drug concentration by half (see Fig. 139.3). Half-life is referred to as a *secondary parameter* because it is a function of two primary parameters, clearance and volume of distribution:

$$t_{1/2} = \frac{\ln(2) \times V}{CL} = \frac{0.693 \times V}{CL} \qquad \text{(Equation 11)}$$

A change in either clearance or volume of distribution results in a proportional change in half-life.

Because the half-life characterizes how rapidly concentrations decrease over time, it is used to determine how frequently a drug needs to be dosed. Drugs with rapid half-lives need to be dosed more frequently than drugs with longer half-lives. For example, the half-life for an aminoglycoside is relatively short in patients with good renal function, and the drug may require dosing every 6 hours. In patients with poor renal function, the half-life is longer, and dosing may be prolonged to 24-hour intervals to maintain appropriate peak and trough concentrations. In the critical care patient, the development of renal failure can significantly change aminoglycoside clearance, and the accompanying change in drug half-life will necessitate a change in dosing interval.

In a one-compartment system with constant clearance and volume of distribution, drug half-life is also constant. However, in a multicompartment model, the volume of distribution increases over time as drug equilibrates into tissue compartments until V_β is reached. According to the previous equation, the half-life also increases over time and eventually reaches a maximum at $t_{1/2\beta}$ (see Fig. 139.4).

In multicompartment models, there is usually one half-life of interest for each compartment. These half-lives are derived from the hybrid time constants associated with each compartment. In a two-compartment model, these two exponentials are typically called α and β and are arbitrarily termed the *rapid* and *slow exponents,* respectively. These time constants give rise to the distribution $t_{1/2}\alpha$ and the slower or terminal $t_{1/2}\beta$. One useful way to think about distribution half-lives is analogous to the standard way of thinking about any half-life. In the one-compartment model, it takes five half-lives for 97% of the drug to be eliminated from the body. The situation is similar for each exponent, but the interpretation is that it takes five distribution half-lives for that exponent to become negligible in the sum of exponentials equation—that is, for the rapid distribution phase to reach equilibrium.

Most drugs have a rapid distribution phase that could be detected if concentrations were measured frequently enough. Aminoglycosides are again an illustrative example of this concept because they have a rapid, although not instantaneous, distribution phase (Fig. 139.5).

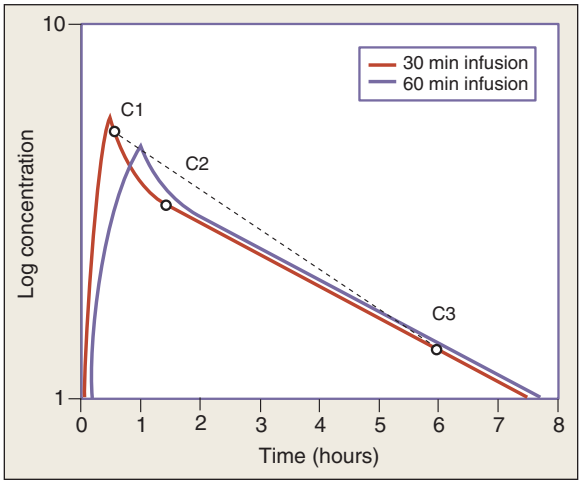

Fig. 139.5 If an aminoglycoside (tobramycin) is administered by intravenous infusion over 30 minutes, the peak concentration will be higher than with infusion over 60 minutes, but the total area under the curve will be the same. In therapeutic drug monitoring, if sample C1 is obtained during the distribution phase and paired with C3, the calculated half-life will be shorter than if two postdistribution concentrations (C2 and C3) are paired together.

With a distribution phase half-life of 5–10 minutes, it would take approximately 25–50 minutes before the log-linear elimination phase could be observed. This results in the recommendation to wait approximately 1 hour after the end of an infusion before sampling blood to measure an aminoglycoside concentration. If a blood sample is obtained before this time, the drug will still be in the distribution phase, and the concentration measured will lead to underestimation of the drug half-life. In addition, slowly equilibrating compartments have been demonstrated when aminoglycoside concentrations are measured during washout.[7] Aminoglycosides are usually dosed frequently enough so that the slowly equilibrating compartment is not detected.

Bioavailability

The extent of drug absorption, termed *bioavailability* (F), is generally a reference to the exposure when the drug is intravenously administered. This parameter is determined by comparing the AUC of the drug intravenously administered to that of the same drug administered via another route. The bioavailability of a drug intravenously administered is regarded as being 100% (i.e., F = 1.0), and other routes of administration (e.g., oral dosing, intramuscular injection) often have a reduced bioavailability (e.g., F = 0.8, or 80% bioavailability). Bioavailability is a function of the extent of absorption and the amount of drug metabolized before entering the systemic circulation (first-pass effect). Drugs with low bioavailability either cannot be administered by any route other than the intravenous one (e.g., sodium nitroprusside, dobutamine) or require higher doses when administered via the oral route compared with the intravenous route (e.g., furosemide, morphine, propranolol). Alternative routes of administration (e.g., rectal, topical, subcutaneous injection, intramuscular injection) are occasionally used in critically ill patients, owing to poor oral bioavailability. These routes all suffer from problems with delayed or poorly predictable serum concentrations. Vasoconstriction, hypoperfusion, edema, gastric suctioning, ileus, diarrhea, and enhanced gastrointestinal motility are all common problems in critically ill patients that can adversely affect bioavailability.

The *first-pass effect* limits drug absorption in three ways. As some drugs enter the gut wall, they are susceptible to transport proteins (primarily P-glycoprotein) that actively pump the molecules back into the lumen of the gastrointestinal tract.[8] Molecules that escape this process are then subjected to metabolism by enzymes in the gut wall. Those that escape gut metabolism enter the hepatic circulation and are subjected to metabolism in the liver before their first opportunity to be presented to the systemic circulation.[9] Drugs that have a high hepatic extraction ratio (i.e., are very efficiently removed by the liver) are most likely to show decreased bioavailability because of this first-pass effect; conversely, the bioavailability of these drugs increases if liver dysfunction decreases the hepatic extraction ratio.

Steady State

After an infusion is started, drug concentrations increase and eventually reach a concentration that does not change over time. At this point, the rate of drug entering the body is equal to the rate leaving it, and steady-state conditions apply. During intermittent dosing, drug concentrations accumulate over time, and eventually a steady state is attained when the concentration profile over each interval resembles all other steady-state profiles (Fig. 139.6). In the clinical setting, the measurement of drug concentration is often delayed for a period equal to five half-lives because at that point the concentration will reflect 97% of the final Css.

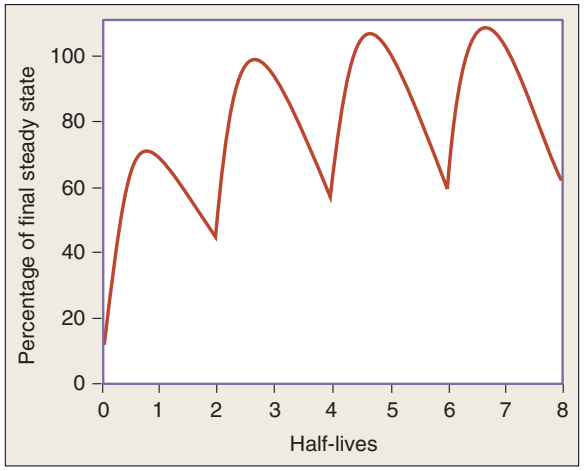

Fig. 139.6 With intermittent dosing, concentration profiles also approach steady state wherein peak and trough concentrations during one cycle are reproducible in the next cycle.

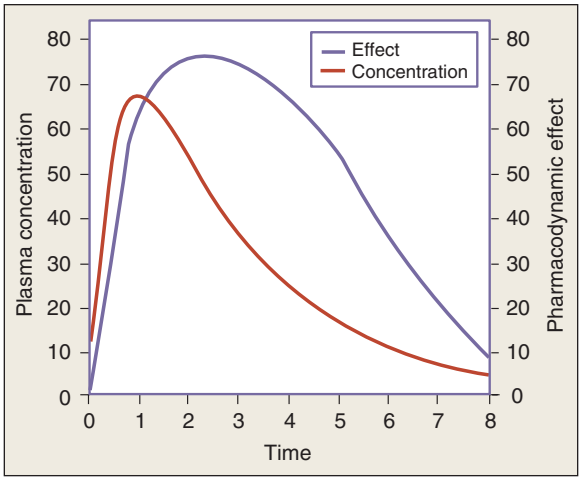

Fig. 139.8 Pharmacodynamic effects often lag behind the matching pharmacokinetic model. In this instance, maximum concentration in blood occurs at 1 hour, whereas maximal drug effect occurs between 2 and 3 hours.

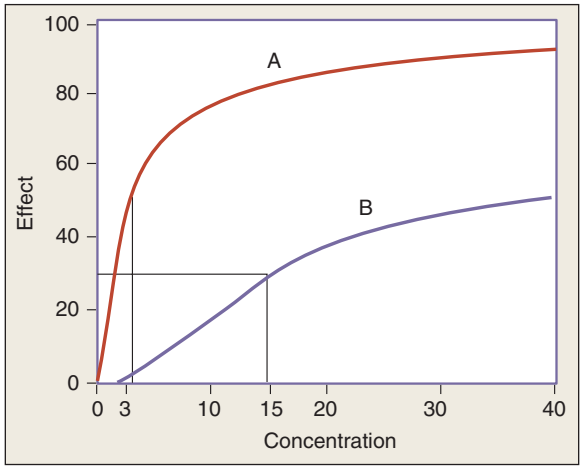

Fig. 139.7 The Emax pharmacodynamic model illustrates that as drug concentrations continue to increase, the increases in drug effect become progressively smaller. Drug A has a lower EC50 (3) than drug B (15) and is said to be more potent than drug B.

PHARMACODYNAMICS

Pharmacodynamics is the study of the relationship between the concentration or exposure of a drug and its pharmacologic effect. Complex pharmacodynamic models with many linked submodels are routinely employed during drug development to determine drug-dosing regimens. In clinical practice, the relatively simple Emax model is often adequate[10]:

$$\text{Effect} = \frac{\text{Emax} \times \text{concentration}}{\text{EC50} + \text{concentration}} \qquad \text{(Equation 12)}$$

Graphically, this equation has a hyperbolic shape (Fig. 139.7) with parameters Emax and EC50. Emax represents the maximal effect attainable because of the drug. The EC50 is the concentration at which half the maximal effect is observed; it is thus a measure of drug potency. The model dictates that increasing doses of the drug do not proportionately increase its effect; eventually, the effect of the drug begins to reach a plateau. If the drug concentration is expected to be less than EC50, increasing the dose will produce a nearly proportional increase in effect. However, as concentrations exceed the EC50, an increase in dose may not be warranted. The increased concentrations will produce a lesser increase in desired effect and may place the patient at risk for development of adverse drug-related effects.

Time does not appear in the Emax model, and concentrations are explicitly defined as Css so that the effect resulting from a given concentration is considered to be a steady-state effect. This model applies when drug in the plasma rapidly equilibrates with drug at the site of action, and there is no indirect mechanism between the concentration at the site of effect and the effect itself. The more common situation is that the effect lags somewhat behind the concentration (Fig. 139.8). If concentrations are going up and coming down over time, as would be expected with an intermittent intravenous or oral dosing schedule, the effect is also expected to go up and down over time, but the time frames may not coincide exactly. For example, the plasma concentration might peak at 1 hour and the effect might peak several hours later. There is a mismatch or disequilibrium between concentration and effect, and a plot of effect versus concentration—with the points connected in time order—yields a hysteresis loop. For any given concentration, there are two effects: one on the upswing of the concentration-time curve and another on the downswing.

The pharmacodynamic effects noted with a given drug result from the drug's interaction with receptors and the resultant activation or inhibition of effects mediated by that receptor. These effects may be either the desired therapeutic action or an unwanted toxic effect. Generally, it is assumed that the intensity of effect produced by the drug is a function of the quantity of drug at the receptor site, whereas relative potency results from varying degrees of selectivity for the receptor and the receptor's affinity for binding the drug. More potent drugs elicit a given effect at lower concentrations than less potent drugs.

Drugs that stimulate a response from the receptor are *agonists,* and those that inhibit a response from the receptor are *antagonists*. Because antagonists have no effect of their own at the receptor, the net effect depends on both the concentration of the antagonist and the agonist being blocked. The relative concentration of the agonist compared with the antagonist primarily determines the effect observed when an antagonist is competing for the same binding site as the molecule or drug that stimulates the receptor. Irreversible antagonists, however, either bind with very strong affinity to the receptor so they cannot be displaced or bind to another site on the substrate that interferes with

binding at the receptor. The effect of irreversible antagonists is independent of the agonist's concentration and results in a decrease in the maximal effect of the agonist. The duration of effect for irreversible antagonists is determined by the rate of turnover for the receptor.

Tolerance to a drug is seen when the response at a given dose decreases. This may be a result of receptor down-regulation (decreased number or sensitivity of receptors) or enzyme induction (increased metabolism). Cross-tolerance, as is commonly seen with opioids, occurs when similar drugs act on the same receptor.

PROTEIN BINDING

Many drugs are bound to plasma proteins, most commonly albumin and alpha-1 acid glycoprotein (AAG), which are highly abundant at concentrations in the ranges of ~3.5–5 g/dL and ~0.04–0.1 g/dL, respectively, in healthy individuals.[11] In general, drug bound to plasma proteins neither can be cleared through metabolism or excretion, nor can it bind to its target to impart its therapeutic (or toxic) effect. Therefore clearance processes act only on unbound drug, which dictates the pharmacodynamic effects. The terms *bound drug concentration* (Cb), *unbound* (or free) *drug concentration* (Cu), *total* (bound plus unbound) *drug concentration* (Ctot), and *unbound* (or free) *fraction* (fu) are frequently used:

$$\text{Ctot} = \text{Cu} + \text{Cb}$$

$$\text{Fu} = \frac{\text{Cu}}{\text{Ctot}} \qquad \text{(Equation 13)}$$

Similarly,

$$\text{AUCu} = \text{fu} \times \text{AUCtot} = \text{fu} \times \text{F} \times \frac{\text{Dose}}{\text{CL}} \qquad \text{(Equation 14)}$$

where AUCu is the unbound drug exposure, fu is the fraction unbound, AUCtot is the total exposure (total AUC), F is the bioavailability, and CL is the clearance.

The clinical relevance of protein binding and of changes in protein binding during therapy have been previously debated. Based on a review in 2002 by Benet and Hoener, changes in plasma protein may be clinically relevant and result in significant changes to steady-state unbound concentration only for drugs with low fu (<30%), high extraction ratio, and either administered intravenously or when administered orally but where nonhepatic clearance is the primary route of elimination.[12]

Benet and Hoener reviewed pharmacokinetic data on 456 drugs from the literature. No orally administered drug with a high extraction ratio and nonhepatic clearance met the criterion for low fu (<30%). Only 25 (5%) of the 456 drugs had high extraction ratios, were not administered by the oral route, and met the criterion for which protein binding may influence drug exposure. However, many of these 25 agents are routinely used in critical care (Table 139.1).

Other analyses have been presented more recently, and these highlight additional complexities that may not have been considered fully in previous reports. Schmidt and colleagues suggest generalized recommendations may be incomplete, and clinical relevance of protein binding depends on each drug's distinct properties, such as mechanism of action, affinity for plasma proteins and the drug target, biodistribution and local concentrations at the site of action, or incorrect assumptions such as the reliance on estimated instead of measured fu.[11]

In critically ill patients, protein concentrations can change quickly. This is particularly true of the acute-phase reactant, AAG. Given the relatively low blood levels of AAG compared with albumin, fu could increase dramatically as a result of rapidly declining AAG levels.[11] In addition, some patients (e.g., those undergoing dialysis or those with cachexia) have altered protein binding.[13] The extent of protein binding, route of administration, route of elimination, and extraction ratio of the drug all should be considered when determining whether a change in binding is likely to result in a change in effect.

TABLE 139.1 Drugs for Which Changes in Protein Binding May Influence Clinical Drug Exposure After Intravenous or Intramuscular Administration*

Alfentanil	Itraconazole
Amitriptyline	Lidocaine
Buprenorphine	Methylprednisolone
Chlorpromazine	Midazolam
Cocaine	Milrinone
Diltiazem	Nicardipine
Diphenhydramine	Pentamidine
Doxorubicin	Propofol
Erythromycin	Propranolol
Fentanyl	Remifentanil
Gold sodium thiomalate	Sufentanil
Haloperidol	Verapamil
Idarubicin	

*Criteria for selection included >70% protein binding and hepatic clearance >6.0 mL/min/kg or nonhepatic extraction ratio clearance ≥0.28 × renal blood flow (>4.8 mL/min/kg).
Modified from Benet LZ, Hoener BA. Changes in plasma protein binding have little clinical relevance. Clin Pharmacol Ther. 2002;71:115–121.

As a final note on protein binding, care must be taken when evaluating total drug concentrations in patients with altered protein binding. Consider the case of phenytoin. The percentage of unbound drug is typically 10% but is approximately doubled in patients receiving hemodialysis (Table 139.2). If phenytoin were administered as a standard dose to all patients, there would be no problem; phenytoin is a low-clearance drug, and protein binding should not influence overall unbound exposure whether the drug is administered orally or intravenously. However, phenytoin concentrations are often obtained for the purposes of therapeutic drug monitoring, and efforts are made to achieve circulating levels within the commonly accepted therapeutic range of 10–20 mg/L. In patients with normal protein binding, this exposure equates to an unbound therapeutic range of 1–2 mg/L. In patients with 20% unbound drug, the desired unbound range is still 1–2 mg/L, but the range based on total concentration is approximately halved. In cases of higher fu, if phenytoin dosing is increased to achieve 10–20 mg/L, toxicities may be observed because the unbound concentration will be twice the desired value.

NONLINEAR PHARMACOKINETICS

The application of pharmacokinetics to therapeutic drug monitoring becomes considerably more difficult with drugs that exhibit nonlinearities. With linear pharmacokinetics, parameters are stable over time and across concentrations and dose levels. Doubling of the dose results in doubling of the concentration, and a given dose provides the same AUC regardless of the dosing history. *Nonlinear pharmacokinetics* is a term used when these principles of superposition no longer hold. An increase in dose may result in an increase in concentration that is more than or less than proportional, or it may result in clearance changes

TABLE 139.2 Effect of Decreased Protein Binding on Bound and Unbound Concentrations of Phenytoin

	CONCENTRATIONS OF PHENYTOIN AT THERAPEUTIC RANGE (MG/L)		
Concentration	Typical Patient	Patient With Protein Binding Decreased By 50%	Result of Erroneous Increase in Phenytoin Dose in Patient With Decreased Protein Binding*
Total (Ctot)	20	10	20
Unbound (Cu)	2 (10%)	2 (20%)	4 (20%)
Bound (Cb)	18	8	16

*Because of the altered protein binding, Ctot is less when Cu is in the therapeutic range (i.e., 2 mg/L). During therapeutic drug monitoring, it is the Ctot that is measured. If the decreased protein binding is not taken into account and the phenytoin dose is increased to achieve a Ctot of 20 mg/L, the actual Cu will double and toxic effects could ensue.

over time. Several common types of nonlinearities occur in the clinical setting.

Phenytoin is the classic example for nonlinear elimination. Increases in a phenytoin dose can result in greater-than-proportional increases in concentration. In any pharmacokinetic system, clearance is defined as the rate of elimination relative to the concentration. Hence, an instantaneous rate of elimination can be defined as follows:

$$\text{Rate of elemination} = CL \times C \qquad \text{(Equation 15)}$$

In a linear elimination process, clearance is constant, and doubling the concentration doubles the rate of elimination. In the case of phenytoin with nonlinear elimination, clearance is not constant. Nonlinear elimination occurs because the metabolic pathway responsible for the elimination of the drug is saturable. The enzyme system has a maximum rate of metabolism that can be approached at therapeutic concentrations of phenytoin. These principles can be better understood by considering the rate of elimination described by the Michaelis-Menten equation (Fig. 139.9). It has two parameters, the *maximum rate of elimination* (Vmax) and the *concentration that results in one-half the maximum rate* (Km):

$$\text{Rate of elemination} = \frac{V\text{max} \times C}{Km + C} \qquad \text{(Equation 16)}$$

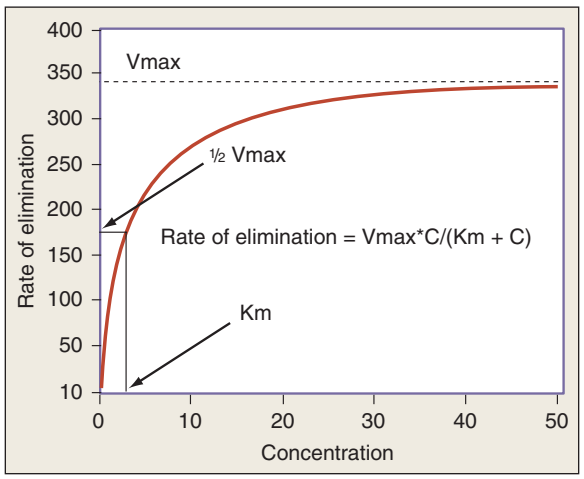

Fig. 139.9 The Michaelis-Menten model demonstrates elimination as a nonlinear function of concentration, with characteristics including a maximum rate of elimination (Vmax) and a concentration at which one-half of the maximum rate of elimination occurs (Km).

Although the parameters Vmax and Km are constant, it can be seen that clearance is a function of concentration (C). The clearance of a drug decreases as the concentration increases:

$$CL = \frac{\text{Rate of elemination}}{C} = \frac{V\text{max}}{Km + C} \qquad \text{(Equation 17)}$$

Although enzyme systems do have maximal rates, the usual drug concentrations attained in the clinical setting are considerably lower than Km, the quantity Vmax/(Km + C) is minimally influenced by concentration, and clearance becomes constant. Therefore even though many drugs are metabolized by hepatic enzymes, few drugs of clinical interest display detectable nonlinear elimination.

At steady state, the amount of drug eliminated every day must equal the dose taken, and the elimination rate equals the dosing rate. After rearranging the equation for the Css:

$$Css = \frac{\text{Dosing rate} \times Km}{V\text{max} - \text{Dosing rate}} \qquad \text{(Equation 18)}$$

This equation shows that an increase in dosing rate produces a greater-than-proportional increase in the Css. Furthermore, if the dosing rate exceeds Vmax, a Css will never be attained.

Another type of nonlinearity is time-dependent pharmacokinetics, as demonstrated by carbamazepine inducing its own metabolism.[14] This autoinduction causes the clearance of carbamazepine to increase over time. It is important to gradually increase the dose of carbamazepine during the first few weeks of therapy up to the expected maintenance dose to avoid toxicities related to elevated concentrations.

Protein binding also can become saturable with some drugs. Intuitively, one might think that saturation of protein binding would result in higher unbound drug concentrations available to exert desirable effects and toxicities, but it must be kept in mind that the organs responsible for drug clearance are eliminating unbound drug. Therefore unless the clearance of a drug also changes, the steady-state unbound concentration will remain constant in the face of saturable protein binding. The total concentration is a function of the unbound concentration and the fraction unbound:

$$Ctot = \frac{Cu}{fu} \qquad \text{(Equation 19)}$$

If the fraction unbound increases at higher unbound concentrations, total concentrations do not increase in proportion to unbound concentrations. This can be perplexing in therapeutic drug monitoring situations. Increases in dose produce less-than-expected increases in

total concentration. As the dose is pushed higher to reach desired total concentrations, toxicities may be observed because saturable binding causes the unbound concentration to be greater than expected.

LARGE-MOLECULE THERAPEUTICS

Historically, large-molecule drugs have not been a major concern in the critical care setting. However, given the successes of protein therapies, namely monoclonal antibody (mAb) drugs, there has been a dramatic increase in the clinical use of these protein therapies as standard of care for a variety of immune disorders, cancers, and other diseases.[15] Recent studies are also evaluating mAb immunotherapies for sepsis and drug-resistant infections.[16,17] Although the principles discussed earlier apply to both small-molecule and large-molecule therapies, there are a few aspects of large-molecule and mAb drug pharmacology that are distinctly different from small molecules and are worth noting here.

Because of their large size and inability to diffuse across biologic membranes, and despite decades of ongoing research to develop delivery strategies via other routes, intravenous infusion remains the primary route of administration for mAb therapies, though some can achieve therapeutic systemic concentrations via subcutaneous or intramuscular injection as well.[18,19] As mAbs do not diffuse across membranes, central volumes of distribution for mAbs tend to be small and on the order of ~2–3 L equating to plasma water volume, and tissue distribution may add another ~5–15 L.[20] Also because of their large size, mAbs are not cleared through renal filtration. Instead, the primary pathway for clearance of mAb therapies is lysosomal degradation via pinocytosis and endocytic uptake in epithelial cells. This tends to be a slow process, and mAb therapies often have half-lives of days or weeks. The long half-life is enhanced by the neonatal Fc receptor, FcRn, which binds to the Fc region of the mAb structure in a pH-dependent manner and recycles the endocytosed mAb away from the lysosomal pathway back to the cell surface, where it is released back into circulation.[20] Though this process is generally linear, mAb therapies may have nonlinear pharmacokinetics because of concentration-dependent and time-dependent clearance mechanisms. For example, mAb therapies are sometimes immunogenic and induce the production of antidrug antibodies (ADAs).[21] In other words, the patient receiving the mAb therapy may develop antibodies to the mAb therapy. This typically results in immune-mediated clearance that increases over time.

Similar to the time-dependent changes in mAb clearance from ADA, the high specificity and high affinity binding of mAbs to their therapeutic targets can also contribute to nonlinear disposition of mAb therapies through target-mediated drug disposition (TMDD).[20] Because mAb binding is with high specificity and high affinity to the target, the law of mass action drives the equilibrium toward the drug-target complex:

$$[D] + [T] \rightleftharpoons [D \cdot T] \longrightarrow Effect \qquad \text{(Equation 20)}$$

where *[D]* is drug concentration, *[T]* is target concentration, and *[D·T]* is drug-target complex concentration. For high-affinity drugs, such as mAbs, when the quantity of target receptors expressed is similar to the quantity of mAb drug molecules in the body, a significant portion of the mAb may be effectively removed from circulation through the high-affinity binding to the target. In some cases, this binding leads to target-mediated clearance of the mAb through internalization and degradation of the mAb-target complex. In other cases, the mAb may slowly release from the target over time, which does not result in clearance, but rather contributes to a higher apparent volume of distribution because the bound mAb is effectively removed from circulation temporarily as if it had distributed to a separate extravascular compartment. In either case, the pharmacokinetics would be nonlinear because they would depend on the concentration of mAb relative to target. Furthermore, as the expression of the target changes over time, either as a direct result of the mAb therapy or as a result of changing disease status, the impact of TMDD will also change over time. This can be overcome by administering the mAb therapy at high enough doses or at short enough intervals to ensure mAb concentrations far exceed the target concentrations. In this scenario, the target is continuously saturated with excess mAb, and the contribution of TMDD is minimal relative to total other processes governing mAb distribution and clearance. Based on the law of mass action, we can determine the target engagement, or fraction of total target that is bound by the mAb drug:

$$\frac{[D \cdot T]}{[T_t]} = \frac{[D]}{[D] + K_d} \qquad \text{(Equation 21)}$$

where *[D]* is the drug concentration, $[T_t]$ is the total target concentration, and K_d is the dissociation constant of the drug-target complex, *[D·T]*. This fraction is often expressed as a percentage of receptor occupancy (RO%). Therapeutically, we generally aim to ensure a minimum RO% is maintained (e.g., >95% or >99%) throughout the dosing interval. This ensures maximal and prolonged pharmacodynamic drug effect, and it has the added benefit of ensuring TMDD will have a minimal impact on overall drug disposition.

KEY POINTS

- Modification of a drug dosing regimen, or even modification in the choice of therapy, may be necessary in the critically ill patient because of changes in physiologic processes that alter drug pharmacokinetics; this is especially true for drugs where clear dose-response or exposure-response relationships have been established and where lack of efficacy because of low exposure or toxicity because of high exposure pose significant risks to the patient.
- Clearance (CL) is a primary or fundamental pharmacokinetic parameter that describes the efficiency of the body in eliminating a drug and is defined by the volume of a particular compartment (blood or tissue) completely cleared of drug per unit time; volume of distribution (V), another fundamental pharmacokinetic parameter, reflects the theoretical volume into which a drug distributes and is not necessarily associated with an actual, physiologic space.
- Secondary pharmacokinetic parameters include drug half-life ($t_{1/2}$), the measure of how quickly a drug is eliminated from the body and described as $t_{1/2} = 0.693/Kel$ or $0.693 \times V/CL$; the area under the concentration- time curve (AUC), which is a measure of drug exposure and is defined by AUC = Dose/CL; and the extent of drug absorption or bioavailability (F), which is the ratio of dose-normalized AUCs for extravascular to intravascular routes of administration, where $F = (AUCEV/Dose_{EV})/(AUCIV/Dose_{IV})$.
- After five half-lives of either α (the distribution $t_{1/2}$) or β (the elimination $t_{1/2}$), a drug will be 97% distributed throughout the body or eliminated from the body, respectively.
- The first-pass effect refers to the elimination of drug that is absorbed orally but then metabolized and/or secreted in either the liver or the gut wall before reaching the systemic circulation.
- The typically observed hyperbolic relationship between effect and dose that results in less-than-proportional increases in response as concentrations increase is often described by the Emax pharmacodynamic model; observed pharmacologic effects often lag behind the serum concentration eliciting the effect and can be observed as a hysteresis loop when effect-concentration pairs are connected in time order.

- Antagonists may inhibit an effect at a receptor through concentration-dependent competitive blocking or by binding irreversibly to the receptor.
- Most small-molecule drugs are bound to some extent by plasma proteins, and it is the unbound concentration of drug that determines the pharmacodynamic effect; changes in protein binding that may occur in the critically ill patient may affect drug exposure or pharmacodynamic effects depending on several factors, although these changes do not affect clinical outcomes from therapy for a majority of drugs.
- Nonlinear pharmacokinetics occurs when clearance or volume changes as a function of dose, drug concentration, or time; the Michaelis-Menten equation, $CL = Vmax/(Km + C)$, where Vmax is the maximum rate of elimination, Km is the concentration of drug that results in one-half the maximum rate, and C is the concentration of drug, is often used to describe nonlinear clearance processes.
- Because of their large size and relatively slow rates of clearance through catabolic or nonlinear, target-mediated pathways, mAb therapies have low volumes of distribution and typical half-lives of days or weeks; just as with small-molecule drugs, changes in physiologic processes in the critically ill patient can alter the pharmacokinetics of mAb therapies.

Poisoning: Overview of Approaches for Evaluation and Treatment

Brenna Farmer

Patients presenting to the hospital with overdoses and poisonings should undergo an initial evaluation to determine whether a specific poisoning can be detected that would lead to specific management options. History and physical examination are key to determine what poisoning, such as a toxidrome—a syndrome related to a toxic exposure (cholinergic, anticholinergic, sympathomimetic, opioid, sedative-hypnotic, or withdrawal syndromes)—could be causing a patient's presentation. Once a poisoning or overdose has been identified, management can be determined. Management options can include gastrointestinal decontamination, enhancing elimination, and/or use of antidotes. Additionally, some poisonings and overdoses only require supportive care.

HISTORY

A thorough poison history should be obtained. Route of exposure should be obtained. Necessary elements for a suspected ingestion include suspected substance, amount ingested, time of ingestion, and any possible coingestants. Other important elements include past medical history, medication history, social history, and family history. Access to other medications in the home, including dietary and herbal supplements and over-the-counter medications, must be determined. Review of symptoms, including if vomiting was present, will also be important when determining if gastrointestinal decontamination would be useful.

PHYSICAL EXAMINATION

Poisoned patients should undergo a thorough physical examination to determine if a toxidrome is present. Specific elements of the examination that allow for this determination include mental status; pupil size and reactivity; mucous membrane evaluation; cardiac and pulmonary examinations; abdominal examination for bowel sounds and presence of palpable bladder; skin examination for temperature, flushing, and perspiration; muscle tone; and neurologic examination for the presence of tremors, clonus, and reflexes. See Table 140.1 for toxidrome physical examination findings.

LABORATORY ANALYSIS

While determining whether a poisoning has occurred or trying to determine the cause of an undifferentiated poisoning, some laboratory values can be helpful. Common laboratory studies to obtain include basic metabolic panel for electrolytes and to determine anion gap; ethanol, acetaminophen (paracetamol), and salicylate concentrations; liver function tests for transaminases; serum osmolarity if toxic alcohol is suspected; and blood gas for pH. These laboratories can aid in narrowing the differential diagnosis when a patient has overdosed or make the diagnosis in acetaminophen or salicylate poisoning.

TOXICOLOGY LABORATORY

Urine drug screens are usually obtained in poisoned patients; however, there is no standardized screen. The interpretation of these tests depends on the clinician's knowledge of which toxins have been screened and whether confirmatory testing (ideally performed by a different analytic method) will follow.[1] The length of time required to receive results varies among hospitals. Quantitative serum drug testing is done when quantitation of a toxin is clinically relevant, as is the case for acetaminophen, anticonvulsant agents, salicylates, digoxin, ethanol, ethylene glycol, methanol, iron, lithium, and theophylline. The clinician caring for the poisoned patient should discuss drug testing with the analytic toxicologist so that the results of testing can be appropriately interpreted. The clinical value of analytic toxicology testing depends on the clinician's ability to understand and interpret the results because of limitations of the screening and other tests.[1]

Once a poisoning has been identified, specific management options may be necessary, from gastrointestinal decontamination and enhancing elimination, to use of specific antidotes.

GASTROINTESTINAL DECONTAMINATION

The theory of gastric decontamination is that removal of toxins is done first from the stomach (where absorption is poor) before moving to the small intestine (where absorption is more rapid) so as to decrease the toxicity of the poisoning. Because of controversies regarding the role of gastrointestinal decontamination (GID), senior toxicologists from the American Academy of Clinical Toxicology and the European Association of Poison Centres and Clinical Toxicologists (EAPCCT) agreed to collaborate on the production of position statements on GID treatments. These statements, published in 1997, are systematically developed guidelines founded on a criteria-based critical review of all relevant scientific literature.[2] All position statements were updated in 2004, with some getting new updates in 2014 (Table 140.2). GID included ipecac, gastric lavage, single-dose activated charcoal, cathartics, and whole-bowel irrigation.

Ipecac

Ipecac, a prepared form of the *Cephaelis acuminata* or *Cephaelis ipecacuanha* plant, is no longer recommended for routine use in the management of poisoned patients, as there is no evidence that it improves outcomes.[3] Vomiting within 30 minutes after administration is caused

TABLE 140.1 Toxidrome Physical Examination Findings

Toxidrome Physical Examination	Cholinergic	Anticholinergic	Sympathomimetic	Opioid	Opioid Withdrawal	Sedative-Hypnotic	Sedative-Hypnotic Withdrawal
Mental status	Awake	Obtunded or delirious	Awake	Depressed	Awake	Depressed	Agitated, awake, delirious
Pupils	Pinpoint Reactive	Dilated Unreactive	Dilated Reactive	Pinpoint Reactive	Dilated Reactive	Normal	Dilated Reactive
Mucous membranes	Wet	Dry	Normal	Normal	Normal	Normal	Normal
Cardiovascular	↓ Heart rate	↑ Heart rate	↑ Heart rate	Normal	Normal	Normal	↑ Heart rate
Pulmonary	Wheeze, rhonchi ↑ Respiratory rate	Normal	Normal	↓ Respiratory rate ↓ Depth of breathing	Normal	Normal	Normal
Bowel sounds	↑	↓	Normal	↓	↑	Normal	Normal
Bladder	Not palpable	Palpable	Normal	May be palpable	Normal	Normal	Normal
Skin temperature	↓	↑	↑	Normal	Normal	Normal	↑
Skin color	Normal	Flushed	Flushed	Normal or cyanotic	Normal	Normal	Normal
Perspiration	Present	Absent	Present				Present
Antidote	Atropine						
Pralidoxime	Physostigmine	Benzo-diazepines	Naloxone			Benzodiazepines	

TABLE 140.2 Position Statement Summaries on Gastrointestinal Decontamination Treatments

Management	Recommendation
Gastric Decontamination	
Ipecac	Syrup of ipecac should not be administered routinely for the management of poisoned patients.[3]
Gastric lavage	Gastric lavage should not be employed routinely in the management of poisoned patients.[4]
Single-dose activated charcoal	Single-dose activated charcoal should not be administered routinely in the management of poisoned patients.[5]
Cathartic	Administration of a cathartic alone has no role in the management of poisoned patients. Routine use of a cathartic in combination with activated charcoal is not endorsed.[6]
Whole-bowel irrigation	Whole-bowel irrigation should not be used routinely in the poisoned patient.[7]
Enhance Elimination	
Multiple-dose activated charcoal	Multiple-dose activated charcoal should be considered if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline.[8]
Urinary alkalinization	Urinary alkalinization should be considered as first-line treatment in patients with moderately severe salicylate poisoning who do not meet the criteria for hemodialysis. Urinary alkalinization also should be considered for patients with severe poisoning caused by 2,4-dichlorophenoxyacetic acid or mecoprop (MCPP) poisoning. Urinary alkalinization is not recommended as first-line treatment for cases of phenobarbital poisoning, because multiple-dose activated charcoal is superior.[9]

by local irritation of the gastric mucosa, and after 30 minutes vomiting is centrally induced.[10] In experimental studies, the amount of marker removed by ipecac treatment was highly variable and diminished with time.[3]

Gastric Lavage

Gastric lavage should not be employed routinely in the management of poisoned patients, as there is little clinical evidence of benefit and no controlled trials showing benefit.[4] If performed because of a potentially life-threatening poison ingestion, an experienced provider should perform the lavage based on the complications that can occur.[4] Gastric lavage involves a large-bore (36F–40F) orogastric tube passed into the stomach, after which small volumes (200–300 mL) of liquid are alternately administered and aspirated. Comatose patients and those with loss of their protective airway reflexes should have an endotracheal tube placed before this procedure. An oral airway prevents biting of the tube. The amount of stomach contents removed via this procedure is highly variable and decreases with time.[11–13] The procedure can actually push stomach contents into the intestine.[14] Contraindications include loss of protective airway reflexes (unless the patient is endotracheally intubated),

ingestion of a corrosive substance or a hydrocarbon, gastrointestinal pathology, and other medical conditions that could be worsened by the use of lavage. Complications of the procedure include aspiration, laryngospasm, hypoxia, hypercapnia, mechanical injury, and fluid and electrolyte imbalances in children.[15]

Single-Dose Activated Charcoal

Activated charcoal is made when coconut shells, peat, wood, or other materials undergo controlled pyrolysis and are subsequently activated by heating in steam or air at high temperatures. Activation creates multiple internal pores and the small particle size necessary for adsorption. The particles have a large surface area and are capable of adsorbing poisons with varying affinities. Although in vitro studies demonstrate adsorption of many drugs to activated charcoal, animal studies reveal variable reductions in the systemic uptake of marker substances.[16] Volunteer and clinical studies have not demonstrated that single-dose administration of activated charcoal improves outcome. Therefore single-dose activated charcoal should not be administered routinely in the management of poisoned patients. Administration of activated charcoal may be considered if a patient has ingested a potentially toxic amount of poison that is known to be adsorbed to charcoal not longer than 1 hour before treatment, as its effectiveness decreases over time. There is no evidence that the administration of activated charcoal improves outcome.[5,17]

Contraindications to the administration of activated charcoal include decreased level of consciousness and unprotected airway, ingestion of caustic substances or hydrocarbons, gastrointestinal pathology, and medical conditions that could be further compromised by the administration of activated charcoal. Complications include aspiration and direct administration of charcoal into the lung.[5]

Because activated charcoal is an inert substance, it is thought that lung injury after aspiration of activated charcoal is caused by gastric contents. Aspiration of gastric contents causes neutrophils to release neutrophil elastase, which increases pulmonary vascular permeability.[18] In comparison, intratracheal administration of activated charcoal does not increase elastase in the bronchoalveolar fluid.[19] Activated charcoal can activate alveolar macrophages, which are a potent source of oxygen radicals, proteases, and other inflammatory mediators. Charcoal also causes obstruction of small distal airways. Overdistention of alveolar segments in areas not occluded by charcoal leads to volutrauma in those areas, which increases microvascular permeability.[20] Although case reports reveal long-term pulmonary pathology after aspiration or instillation of activated charcoal,[21,22] the true incidence of chronic problems after charcoal aspiration is unknown.

Cathartics

Administration of a cathartic alone has no role in the management of poisoned patients. Routine use of a cathartic in combination with activated charcoal is not endorsed.[6]

Whole-Bowel Irrigation

Whole-bowel irrigation consists of administration through a nasogastric tube of an osmotically balanced, polyethylene glycol–based electrolyte solution to decontaminate the entire gastrointestinal tract by physically expelling intraluminal contents. As much as 1500–2000 mL/hr can be administered to an "awake" adult patient. Negotiation to let the patient attempt to drink the solution only causes delay, because patients are unable to drink at a constant rate. Whole-bowel irrigation should not be used routinely in the poisoned patient. However, it can be considered for potentially toxic ingestions of sustained-release or enteric-coated drugs and for drugs not likely to be adsorbed to activated charcoal (iron, lithium, potassium) and for the removal of illicit drug packets.[7] Contraindications include bowel pathology, unprotected or compromised airway, hemodynamic instability, and intractable vomiting. Complications are nausea, vomiting, and abdominal cramps.[7]

Clinical Implications of Gastrointestinal Decontamination

There is no role for syrup of ipecac in the hospital setting. Gastric lavage may be considered for obtunded patients if it can be instituted within 1 hour after the ingestion. Single-dose activated charcoal should not be routinely administered to patients with mild to moderate degrees of poisoning. Whole-bowel irrigation should be considered for awake patients within the first hours after ingestion of a sustained-release preparation, ionic compounds (e.g., lithium), or packets of illicit drugs.

These guidelines refer to the routine management of poisoned patients. Cellular toxins require special consideration. The physician should always call the Poison Center (1-800-222-1222 in the United States) to discuss a patient with an ingestion and to seek further guidance on management.

ENHANCED ELIMINATION

Multiple-Dose Activated Charcoal

Multiple-dose activated charcoal is the repeated oral administration of activated charcoal, without sorbitol, to enhance drug elimination. If the drug concentration in the gut is lower than that in the blood, the drug will passively diffuse back into the gut. The concentration gradient, intestinal surface area, permeability, and blood flow determine the degree of passive diffusion. As the drug passes continuously into the gut, it is adsorbed onto the charcoal particles, a process called *gastrointestinal dialysis*. Multiple-dose activated charcoal also interrupts the enterohepatic and enterogastric circulation of drugs. Drugs with a prolonged elimination half-life, a small volume of distribution (less than 1 L/kg), and little protein binding are the most amenable to this sort of management.[8] Multiple-dose activated charcoal should be considered if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline. With all of these drugs, data confirm enhanced elimination, although no controlled studies have demonstrated clinical benefit.[8] Other ingestions may benefit from multiple-dose activated charcoal, but there are insufficient clinical data to routinely recommend its use.

The initial dose of charcoal is 50–100 g, and this treatment is followed every 1, 2, or 4 hours by a dose equivalent to 12.5 g/hr. More frequent, smaller doses may prevent vomiting. Multiple-dose activated charcoal can be continued until the patient improves clinically. Contraindications include an unprotected airway, intestinal obstruction, and an anatomically abnormal gastrointestinal tract. Complications include bowel obstruction and vomiting with subsequent aspiration.[8]

Urinary Alkalinization

Urinary alkalinization is the administration of intravenous (IV) sodium bicarbonate to produce urine with a pH $\geq$7.5. The objective of treatment is pH manipulation, not forced diuresis. Hypokalemia is the most common complication. Alkalemia also can occur.[9] Urinary alkalinization should be considered as first-line treatment in patients with moderately severe salicylate poisoning who do not meet the criteria for hemodialysis. Urinary alkalinization also should be considered for patients with severe poisoning caused by 2,4-dichlorophenoxyacetic acid or mecoprop (MCPP) poisoning. Urinary alkalinization is not recommended as first-line treatment for cases of phenobarbital poisoning, because multiple-dose activated charcoal is superior.[9]

SELECTED ANTIDOTES

Stabilization of the patient always should precede administration of antidotes. The effects of the toxin can outlast the effects of the administered antidote. Patients receiving antidotes should be observed in a critical care setting.

Dextrose

Up to 8% of patients with altered mental status are hypoglycemic.[23] Hypoglycemia can be a result of drug or toxin exposure, nutritional deprivation, or a medical complication (e.g., sepsis, hyperthermia). Glucose should be checked at the bedside for all patients with altered mental status.

Naloxone

Endogenous and exogenous opiates produce their effects by binding at one or more opiate receptors. Naloxone, nalmefene, and naltrexone are competitive opioid antagonists that bind at the mu, kappa, and delta receptors and competitively prevent the binding of endogenous and exogenous opiates at these receptors. The duration of action of naloxone is 15–90 minutes. Its clinical effects depend on the dose and route of naloxone administration and the dose and rate of elimination of the opiate agonist. Naloxone can be administered by IV, intramuscular, intratracheal, or sublingual routes. After IV administration, naloxone rapidly enters the central nervous system (CNS). In patients with opioid poisoning, respiration improves within 1–2 minutes, and consciousness may be restored. The goal of naloxone administration is to restore respiratory function. Miosis, inhibition of baroreceptor reflexes, laryngospasm, and decreased gastrointestinal motility are also reversed.[24,25]

Naloxone should be administered to all patients presenting with respiratory depression (slowed respiratory rate and/or decreased depth of breathing) or respiratory failure and altered mental status or coma of unknown cause. Opioid-dependent patients should receive only small doses in an effort to restore respiratory function and prevent rapid withdrawal. If a patient is not opioid dependent, a reasonable starting dose is 0.4 mg, increasing to 10 mg (in increments) if there is no response. Large doses of naloxone may be necessary to reverse the effects of drugs with high affinity for the delta and kappa opiate receptors.[24,25]

If respiratory depression returns, the initial dose of naloxone may have to be repeated or a constant infusion of naloxone initiated. The starting dose for a constant infusion of naloxone is hourly administration of about one-half to two-thirds of the bolus dose that reversed the opioid effects. If withdrawal is precipitated, it is short lived and not life-threatening. Complications of naloxone administration are very rare.[24,25] Naloxone is not indicated for patients once they are intubated and receiving mechanical ventilation, as these procedures reverse respiratory depression.

Flumazenil

Flumazenil competitively antagonizes the pharmacologic effects of drugs that act on the benzodiazepine receptor of the gamma-aminobutyric acid A ($GABA_A$) receptor (e.g., all drugs in the benzodiazepine class).[26] Receptor occupancy follows the law of mass action, and antagonism is dose dependent. The duration of action of flumazenil is variable and depends on the type of benzodiazepine ingested, relative doses of agonist and antagonist, presence of ongoing benzodiazepine absorption, and relative receptor binding affinities. Flumazenil also antagonizes the sedative effects of drugs other than benzodiazepines, such as zolpidem (Ambien), cannabis, ethanol, promethazine, chlorzoxazone, and carisoprodol. These drugs may have differing affinities for the $GABA_A$ receptor, implying that the dose of flumazenil required to reverse the effects depends on the affinity of the specific drug for the receptor.[27]

Flumazenil is safe and effective for reversing conscious sedation after short procedures such as endoscopy. This safety has been generalized to imply that flumazenil also is safe for patients with a multidrug overdose and that reversal of benzodiazepine-induced sedation prevents morbidity from procedures such as endotracheal intubation or computed tomography. However, many patients have experienced single or multiple seizures after flumazenil administration. Status epilepticus has been precipitated, leading to death. The data are insufficient to determine whether morbidity or mortality is increased as a result of flumazenil-precipitated seizures.[28,29]

Flumazenil administration can precipitate seizures in patients with an overdose who have ingested both a benzodiazepine and a proconvulsant drug or just a proconvulsant drug. Flumazenil also can precipitate seizures in patients who have a history of seizures, chronic benzodiazepine ingestion, or head injury. Identification of patients at risk for seizures is difficult.[30] Before administering flumazenil to a patient with a benzodiazepine ingestion, it is reasonable to first obtain an electrocardiogram to rule out exposure to proconvulsant tricyclic antidepressants. Resedation occurs after 18–120 minutes in approximately half of patients awakened by flumazenil. Therefore either continuous IV infusion or observation for a number of hours is required.[31]

Administration of flumazenil to patients with an overdose should not be routine. It should be limited to the following situations: iatrogenic overdose with known patient history, obtundation in a toddler secondary to ingestion of benzodiazepine, and reversal of a paradoxical response to benzodiazepine.

Physostigmine

Physostigmine inhibits acetylcholinesterase, the enzyme responsible for the metabolism of acetylcholine (ACH). ACH is an endogenous neurotransmitter that mediates action by binding to muscarinic and nicotinic receptors. Accumulation of ACH stimulates cholinergic nerve endings. In the poisoned patient, physostigmine is most frequently administered to treat anticholinergic toxicity. Clinical signs of anticholinergic toxicity are recognized by the mnemonic, "Blind as a bat, Red as a beet, Hot as a hare, Dry as a bone, Mad as a hatter" (see Table 140.1). Physostigmine administration should be considered if life-threatening clinical signs of anticholinergic peripheral effects (hypertension, tachycardia, and seizures) or central effects (painful psychosis, delirium) are present. Physostigmine is superior for delirium control from anticholinergics compared with other treatments for anticholinergic toxicity.[32] Complications of cholinergic crises caused by excessive doses of physostigmine include hypertension, dysrhythmia, asystole, bronchorrhea, bronchoconstriction, seizures, and status epilepticus. Contraindications to physostigmine administration include bradycardia and conduction delays, reactive airway disease, peripheral vascular disease, intestinal or bladder obstruction, and treatment with a depolarizing neuromuscular blocking agent (e.g., succinylcholine). An acceptable dose of physostigmine is 1–2 mg IV over 10 minutes. This drug should be administered in the presence of a physician because of the potential for precipitation of life-threatening cholinergic effects.[33]

HYPOTENSION IN THE POISONED PATIENT

Hypotension in the poisoned patient is most frequently caused by receptor blockade, drug-induced myocardial depression, or drug-induced vasodilatation. Clinicians reflexively initially treat hypotension by infusing IV fluids; however, unless the poisoned patient is hypovolemic, large volumes of fluid can predispose patients to the development of acute respiratory failure.

Catecholamines are the pressors of choice for treatment of hypotension in most intensive care unit (ICU) patients who are older, chronically ill, or acutely ill from an infectious process. The causative factors in sepsis-induced vasodilation and myocardial depression/ischemia are different from the factors that cause drug-induced vasodilation, myocardial depression, or ischemia. Treatment approaches must address the cause of the hypotension and not assume that all hypotensive patients should be treated in a similar manner.

Poisoned patients who are young and healthy respond to hypotension with an outpouring of endogenous catecholamines. Adrenergic receptors are sensitive in young patients. Administration of exogenous catecholamines is unlikely to be of much benefit because catecholamine receptors are already maximally stimulated by endogenous catecholamines. Agents that must be considered for the treatment of hypotension in the poisoned patient are sodium bicarbonate (for a sodium channel–blocking agent), glucagon, and insulin/glucose.

Glucagon

The cardiovascular effects of glucagon are mediated by myocardial glucagon receptors that are catecholamine independent. Stimulation activates adenylate cyclase, leading to increased intracellular levels of the second messenger, cyclic adenosine monophosphate (cAMP). This cyclic nucleotide increases myocardial calcium uptake. Both the slope of phase zero of the action potential and the conduction velocity through the atrioventricular node are increased. Glucagon increases heart rate and stroke volume, thereby increasing cardiac output. After IV administration, augmented inotropy is seen within 1–3 minutes, with a peak effect in 5–7 minutes.[34]

Glucagon should be considered early in the treatment of hypotensive poisoned patients, especially those patients with beta-adrenergic antagonist toxicity. Treatment regimens vary. An acceptable regimen is 10 mg of glucagon given over 10 minutes (rapid administration causes vomiting), followed by 1–3 mg/hr. If the patient wretches, the hourly dose of glucagon should be decreased. Elderly patients may be more sensitive to the emetic effects of the drug. Tachyphylaxis can occur with glucagon. Therefore additional therapies may be needed.

Insulin and Glucose

Insulin improves contractility in anoxic rat hearts and improves cardiac index after cardiopulmonary bypass surgery. During drug-induced shock, insulin shifts myocardial fatty acid oxidation to carbohydrate oxidation, which increases contractility, left ventricular pressure, and rate of change of developed pressure. Enhanced fatty acid oxidation, such as occurs after epinephrine administration, transiently increases contractility at the expense of increased myocardial oxygen consumption.[35]

Insulin and glucose treatment in poisoned patients is commonly referred to as *high-dose insulin-euglycemia therapy* (HIET). Insulin can be bolused at 0.5–1 U/kg, followed by an infusion at 0.5–1 U/kg/hr.[36] The infusion can be titrated up to improve inotropy and contractility and to increase blood pressure. Case reports have had safe outcomes with large bolus and infusion doses.[36] Concurrent administration of glucose is used to maintain euglycemia. Hourly serum glucose checks are mandatory because hypoglycemia occurs frequently. Potassium should also be monitored because of intracellular shift.

CARDIAC ARRHYTHMIAS

ICU treatment regimens assume that a diseased heart is the cause of most cardiac arrhythmias. This assumption is invalid in poisoned patients. Treatment of the arrhythmia must take into consideration the pharmacology of the toxin causing the arrhythmia.

ACUTE RENAL FAILURE

In poisoned patients, acute renal failure (ARF) is most frequently the result of a decrease in extracellular fluid volume and renal hypoperfusion caused by drug- or chemical-induced vasodilation, drug-induced myocardial depression, or rhabdomyolysis. Attempts to prevent ARF are important because there is no specific therapy once ARF is established. Studies evaluating the efficacy of low-dose dopamine (0.5–3.0 mg/kg/min) in preventing ARF have not demonstrated any benefit, but the patient populations in these studies consisted of critically ill patients with established ARF or at high risk for developing ARF.[37] The efficacy of administration of low-dose dopamine after periods of hypotension in poisoned patients who typically are younger and without chronic disease has not been evaluated. When dopamine is administered to normal human subjects, there is a dose-dependent increase in renal blood flow, sodium excretion, and glomerular filtration rate.[38] Low-dose dopamine also limits adenosine triphosphate (ATP) use and oxygen requirements in nephron segments at risk for ischemia.[39] Although there are no studies regarding the efficacy of low-dose dopamine in cases of drug-induced hypotension, one may consider administration in previously healthy poisoned patients who have adequate vascular volume and remain oliguric or anuric despite maximal diuretic therapy.

SEIZURES

Blood pH can be as low as 7.17 at 30 minutes and 7.20 at 60 minutes after resolution of a 30- to 60-second seizure.[40] Acidosis decreases cardiac output, oxygen extraction, and left ventricular end-diastolic pressure and impairs myocardial contractility. If a patient has ingested a cardiotoxic drug (e.g., a tricyclic antidepressant) that causes significant myocardial depression, the consequences of acidosis can increase the toxicity of the drug. Ictal increases in plasma epinephrine levels can add to the potential risk for cardiac arrhythmias. Additionally, airway reflexes are inhibited postictally, which adds to the potential for aspiration.[41]

Whether seizures increase morbidity and mortality in poisoned patients is difficult to ascertain. Deaths of poisoned patients who sustain seizures are usually attributed to the toxicity of the drug. Because of the number of variables, it is impossible to know whether the risk for mortality is influenced by the presence of convulsions. Accordingly, the physician should take an aggressive approach toward terminating seizures in poisoned patients. Benzodiazepines are the drugs of choice to quickly terminate seizures because they are lipophilic and rapidly enter the CNS.

MECHANICAL VENTILATION AND EXTUBATION

Endotracheal intubation is commonly indicated for the management of poisoned patients on the basis of respiratory depression or impaired protective airway reflexes or both. As the drug is metabolized, its effects abate, and the patient's sensorium improves, the patient may become alert slowly or very suddenly. The patient should be extubated if ability to protect the airway is evident and ventilation is adequate for 15–60 minutes with minimal respiratory support (e.g., 5 cm H_2O positive end-expiratory pressure and 5 cm H_2O pressure support). Unnecessary or excessive administration of sedatives or anxiolytics in an attempt to make the patient more comfortable can delay weaning from mechanical ventilation and extubation and increase the risk for complications.

KEY POINTS

- The theory of gastric decontamination is that removal of toxins from the stomach (where absorption is poor) before they move into the small intestine (where absorption is more rapid) decreases the toxicity of the poisoning.
- Stabilization of the patient should always precede administration of antidotes. The effects of the toxin can outlast the effects of the administered antidote. Patients receiving antidotes should be observed in a critical care setting.
- Treating hypotensive, poisoned patients with large volumes of IV fluids can increase the risk for acute respiratory failure.
- Efforts to prevent development of ARF in the poisoned patient are important because there is no specific therapy once ARF is established.
- An aggressive approach should be taken toward terminating seizures in the poisoned patient. Benzodiazepines are the drugs of choice to quickly terminate seizures, because they are lipophilic and rapidly enter the CNS.
- The clinical value of analytic toxicology testing depends on the clinician's ability to understand and interpret the results.

Resuscitation of Hypovolemic Shock

S. Ariane Christie and Juan Carlos Puyana

Alfred Blalock demonstrated that injury precipitates local and regional fluid loss, the effects of which can be ameliorated by vigorous restoration of intravascular volume. This concept is foundational to understanding the pathophysiology of shock and provides the rationale underlying intravenous (IV) therapy for hemorrhage and hypovolemia.[1]

Severe hypovolemia consists of loss of intravascular or total body fluid volume necessary to cause insufficient tissue perfusion at the local and cellular level. If not rapidly corrected, hypovolemic shock leads to refractory end-organ damage, multisystem organ failure, and death. Broadly, hypovolemic shock can be divided into two etiologies with concomitant differences in treatment (Fig. 141.1). Nonhemorrhagic hypovolemic shock consists of body fluid loss and is treated primarily with fluid replacement to restore intravascular volume. Hemorrhagic shock results from blood loss and is treated with hemorrhage control, replacement of whole blood or its components, and avoidance or correction of coagulopathy.

NONHEMORRHAGIC HYPOVOLEMIC SHOCK

Management of nonhemorrhagic hypovolemic shock centers around rapid replacement of intravascular volume and subsequent restoration of tissue perfusion. Additional priorities include management of concomitant electrolyte and acid/base abnormalities and diagnosis and treatment of the etiology of the patient's underlying fluid loss.

Fluid Resuscitation Principles

For the majority of patients with hypovolemia, resuscitation should consist of rapid bolus infusion of isotonic crystalloid solution with ongoing monitoring of physiologic and laboratory data to evaluate response and dictate termination of therapy. Potential resuscitation products to treat hypovolemia include crystalloid solutions (0.9% normal saline and buffered solutions), colloid solutions (albumin, dextran, hyperoncotic starch) and blood products (fresh frozen plasma [FFP], packed red blood cells [PRBCs], platelets). Multiple large, randomized control trials (SAFE,[2] CRISTAL[3]) and subsequent meta-analyses comparing outcomes with crystalloid versus colloid solutions have demonstrated no significant advantage to colloid resuscitation in terms of 28-day mortality. Data on secondary outcomes, including renal replacement and intensive care unit (ICU) and hospital length of stay have been mixed, but no clear benefit to colloid resuscitation has been demonstrated. Notably, in subgroup analysis of the SAFE trial, resuscitation with albumin was associated with higher mortality among patients with head injuries. Because of a lack of demonstrable benefit and higher cost of colloid, crystalloid resuscitation should be used as the first-line resuscitation fluid for severe hypovolemia in critically ill patients. Despite a paucity of data favoring colloid use, albumin may be an appropriate resuscitation adjunct in cases of refractory hypovolemia thought to be secondary to low oncotic pressure. Other colloid solutions, including hyperoncotic starch, have been associated in large, randomized trials with increased risk of renal failure and death and should not be used to treat hypovolemia.[4,5]

There is ongoing debate regarding the most appropriate crystalloid product for resuscitation for hypovolemia. Normal saline contains high levels of sodium and chloride compared with plasma (154 mEq/L each of Na and Cl), raising concerns that particularly large volume resuscitations of 0.9% normal saline may precipitate hyperchloremic metabolic acidosis. Buffered isotonic solutions, including PlasmaLyte-A and lactated Ringer's, have been suggested as potential first-line alternatives in resuscitation. The 2018 Balanced Crystalloids versus Saline in Critically Ill Adults (SMART) trial randomized over 15,000 critically ill patients to either 0.9% normal saline or buffered crystalloids. The authors reported a lower composite rate of 30- day all-cause mortality, new need for renal replacement therapy, or renal dysfunction among patients resuscitated with buffered solutions compared with 0.9% normal saline (odds ratio [OR] 0.91, $P = .04$).[6] However, a 2019 Cochrane database meta-analysis of 21 randomized controlled trials and 20,000 patients failed to find an advantage of buffered solutions over 0.9% normal saline with regard to hospital mortality or renal failure.[7] Overall, data suggest that infusion of buffered isotonic crystalloids is likely a reasonable first-line approach for resuscitation of hypovolemic shock among critically ill patients, although specific fluid choice should continue to be tailored to each patient's specific metabolic and physiologic parameters.

Electrolyte and Acid/Base Disturbances

Nonhemorrhagic hypovolemic shock often occurs concomitantly with or results in metabolic disturbances, including critical excesses or deficiencies of electrolytes such as sodium, potassium, magnesium, chloride, bicarbonate, and disordered acid/base balance. Although the detailed discussion of the management of electrolyte abnormalities is addressed elsewhere in this text, it is important to rapidly identify and correct these disturbances to restore physiologic homeostasis to the patient in hypovolemic shock.

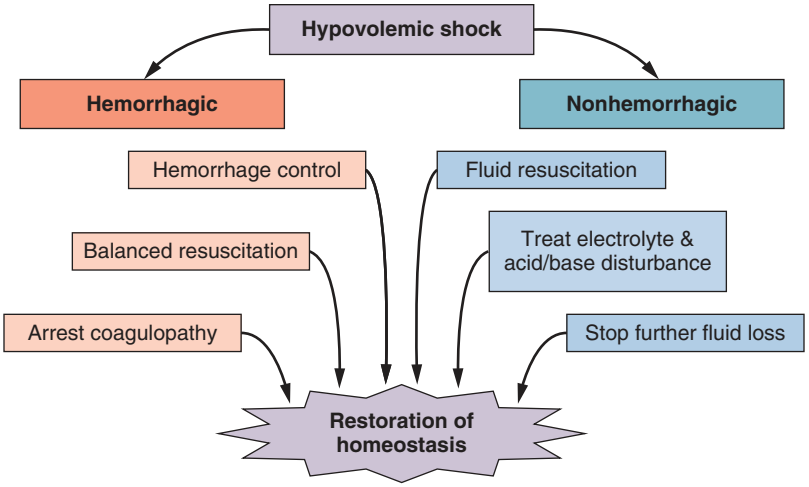

Fig. 141.1 Etiology and Treatment of Hypovolemic Shock.

Etiologies of Nonhemorrhagic Hypovolemic Shock

Although the cornerstone of managing nonhemorrhagic hypovolemic shock is rapid fluid replacement, identification and treatment of the underlying cause of fluid loss is necessary to avoid further hypovolemia and tailor resuscitation strategy. Etiologies of hypovolemic shock include inadequate fluid intake (often in hospitalized, elderly, debilitated, or restrained patients) or losses of fluid from the skin or soft tissue (exertional and insensible losses during strenuous activity, burns and desquamating conditions, open wound and abdomens), the gastrointestinal tract (vomiting, diarrhea, nasoenteric tube, biliary drain, or ostomy losses), third-spacing conditions (sepsis, small bowel obstruction, cirrhosis, heart failure, pancreatitis), and renal conditions in which resorption of electrolytes or water is impaired (diabetes insipidus, cerebral salt wasting, diuretic overuse). Clinical work-up, laboratory, and imaging studies should focus on diagnosis of these conditions.

HEMORRHAGIC SHOCK

Hemorrhagic shock is the most common cause of preventable trauma death,[8] but also can occur as a result of surgical bleeding, aneurysm rupture, massive gastrointestinal hemorrhage, or refractory coagulopathy. Prompt and definitive control of hemorrhage, replacement of whole blood or its components to restore tissue perfusion and prevention, and treatment of coagulopathy are the cornerstones of treatment (Fig. 141.2).[9,10] To facilitate these goals a systematic approach to resuscitation must include rapid scene-to-hospital transport; expedient

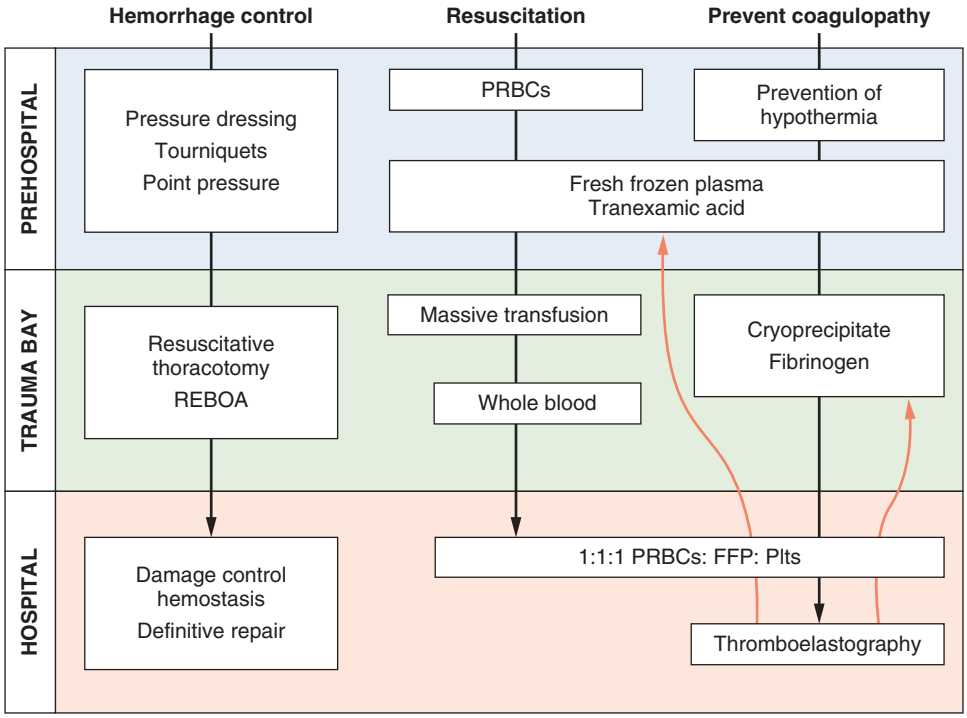

Fig. 141.2 Management Diagram of Hemorrhagic Shock Resuscitation. *FFP,* Fresh frozen plasma; *Plts,* platelets; *PRBCs,* packed red blood cells; *REBOA,* resuscitative endovascular balloon occlusion of the aorta.

surgical intervention; interventional radiology (IR)-guided angioembolization; and balloon occlusive techniques such as resuscitative endovascular balloon occlusion of the aorta (REBOA[11]), early management with balanced blood product transfusions, and avoidance of excessive crystalloid resuscitation. Trauma centers of all levels benefit from standardizing protocols for resuscitation and the diagnosis and treatment of trauma-induced coagulopathy.

Vascular Access for Patients With Severe Hemorrhage

In the trauma patient presenting with multiple serious injuries and hemorrhagic shock, obtaining prompt vascular access is essential to facilitate resuscitation. Advanced trauma life support (ATLS) guidelines recommend placement of two large-bore (16 gauge or larger) IV catheters to allow rapid infusion though a short-length, large-diameter canula. The most suitable veins are at the wrist, dorsum of the hand, antecubital fossa in the arm, and the saphenous vein in the leg.

If peripheral IV catheters cannot be placed, two additional options for rapid access include central venous and intraosseous access. The femoral vein is the most frequent central vein cannulated in trauma resuscitations. Femoral venous access can be placed using anatomic landmarks or ultrasound guidance, and the site is readily compressible against the femur. Femoral vein cutdown under direct vision may be used to obtain rapid access in pulseless patients. Subclavian venous access is another central venous alternative and can be placed safely in experienced hands. The internal jugular vein is rarely used in trauma patients because of the possibility of cervical spine injuries and the concomitant need for cervical collar immobilization.

Intraosseous (IO) needles are increasingly used in the emergency department and prehospital settings to obtain rapid access for medication administration or, if necessary, product resuscitation.[12,13] The technique is particularly useful in challenging or dynamic environments such as in a moving vehicle or in unstable patients where hypovolemia makes venous cannulation difficult. IO needle placement is easy to learn, and prehospital responders are trained in application in many trauma systems.

Importantly, regardless of access type, access should never be initiated on an injured limb. When thoracoabdominal injury is suspected, it is prudent to obtain infradiaphragmatic and supradiaphragmatic access.

Resuscitative Strategies in Hemorrhagic Shock: Red Cells, Platelets, and Plasma—the Ideal Ratio and Whole-Blood Resuscitation

The worldwide experience in severe traumatic injury during military conflicts provided the background and much of the data underlying product resuscitation. The introduction of whole-blood transfusion during World Wars I and II dramatically changed patient outcomes in cases of severe hemorrhage. However, because of lack of knowledge about how infusates disperse and are eliminated after trauma, fluid overload was a common and lethal side effect of resuscitation through the Korean War. Between the Korean and Vietnam Wars, Shires and colleagues described how fluid and electrolytes shift into cells after severe hemorrhagic shock.[14] Subsequent changes in resuscitation practice resulted in better outcomes and lower incidence of acute renal failure during the Vietnam War. The 1970s brought about the separation of blood components.[15] It has taken nearly three decades and the two Middle Eastern conflicts of the 2000s for clinical practice to return to the basic concept that hemorrhagic losses should ideally be replaced with whole blood or, at least, a physiologic ratio of whole blood's main components: plasma, platelets, and red cells,[16,17] an approach referred to as balanced or *whole blood–like* resuscitation.[18,19]

Use of whole blood continues to increase across trauma centers in the United States, and whole blood is now readily available directly in many trauma bays for immediate resuscitation. Whole blood innately provides the bleeding patient the correct ratios of lost components while maximizing the resuscitative and hemostatic effects of product transfusion.[20,21] Additional benefits include minimization of donor exposures, as the lower shelf-life capacity of whole-blood storage results in "fresher" transfusions compared with transfusion of balanced components, which can be stored longer.

Blood options include type O negative, type specific, typed and screened, or typed and crossmatched whole blood or PRBCs. The initial choice depends on the degree of hemodynamic instability. A type and screen identify the patient's blood group and evaluate the serum for major blood group antibodies. Obtaining type-specific red cells requires 5–10 minutes in most institutions. A full crossmatch involves mixing donor cells with recipient serum to rule out antigen/antibody reactions and generally requires about 45 minutes.

Type O negative red cells have no major antigens and can be used safely for patients with any blood type. Unfortunately, only 8% of the population has O-negative blood, and stored O-negative blood availability is chronically limited. O-positive blood can be used empirically in male patients but should be avoided in female patients of childbearing age. Importantly, if 50%–75% of the patient's blood volume has already been replaced with type O blood, type O should continue to be used throughout the resuscitation, as the patient may have received enough anti-A or anti-B antibodies to precipitate hemolysis if A, B, or AB units are subsequently given.

Massive transfusion protocols are a critical part of hemorrhage control in major trauma centers. Activating the massive transfusion protocol hastens the preparation, allocation, and delivery of a fixed ratio of red cells to plasma to platelets.

If component products are to be used, clinicians should employ a balanced 1 PRBCs:1 FFP:1 platelets resuscitation strategy. Multiple military and civilian retrospective studies demonstrated increased survival when PRBC transfusions were accompanied by high plasma- and platelet-to–red cell ratios.[22,23] The Prospective Observational Multicenter Major Trauma Transfusion (PROMMTT) trial found early product administration in a 1:1:1 or 1:1:2 ratio was associated with improved 6-hour survival after admission.[24,25] In 2015 a multicenter, randomized clinical trial was completed in order to address the effectiveness and safety of a 1:1:1 transfusion ratio compared with a 1:1:2 transfusion ratio in patients with trauma who were predicted to receive a massive transfusion. The Pragmatic, Randomized Optimal Platelet and Plasma Ratios (PROPPR) trial showed that in patients with severe trauma and major bleeding, early administration of plasma, platelets, and RBCs in a 1:1:1 ratio compared with a 1:1:2 ratio did not result in significant differences in mortality at 24 hours or at 30 days. However, more patients in the 1:1:1 group achieved hemostasis and fewer experienced death resulting from exsanguination by 24 hours. As expected, though, there was an increased use of plasma and platelets transfused in the 1:1:1 group, but no other safety differences were identified between the two groups.[26]

Trauma-Induced Coagulopathy and Viscoelastic-Directed Component Resuscitation

In addition to prompt hemorrhage control and balanced product resuscitation, treatment of hemorrhagic shock requires prevention and rapid reversal of coagulopathy. Coagulopathy develops in approximately one-third of all injured patients and is associated with increased transfusion-related multiorgan system failure and death.

Until recently, trauma-induced coagulopathy (TIC) was thought to be a secondary phenomenon resulting from dilutional loss of coagulation factors during hemorrhage and fluid resuscitation. In 2003 two independent investigators identified early prothrombin time (PT) and

TABLE 141.1 Cutoffs for Conventional Coagulation Assays in Trauma-Induced Coagulopathy

Assay	Reported Cutoff		
Partial thromboplastin time (PTT)	>34–60 seconds	or	>1.5× institutional reference range
Prothrombin time (PT)	>18 seconds		
International normalized ratio (INR)	>1.2–1.5		

partial thromboplastin time (PTT) abnormalities in severely injured patients before resuscitation, identifying an independent pathology now referred to as TIC.[27,28] Several highly integrated coagulation and inflammatory pathways have since been implicated in the pathophysiology of TIC and are the subject of ongoing research. Known mediators include activated protein C, disordered fibrinolysis, and posttraumatic platelet and endothelial dysfunction.[29–37]

To adequately attenuate and prevent TIC, clinicians should be aggressive with providing up-front balanced product resuscitation to critically injured patients according to the principles outlined earlier and without waiting for serum coagulation tests. As resuscitation proceeds, we advocate routine use of thromboelastography (TEG) to help tailor product management. Although TIC was initially defined by prolongation of the standard coagulation assays (PTT and international normalized ratio [INR]) different cutoffs have been described in the trauma literature (Table 141.1), and there has been increased interest and use of point-of-care functional viscoelastic tests such as TEG and rotational thromboelastometry (ROTEM) for the diagnosis and management of patients with TIC.[38] TEG is a well-validated point-of-care assay of clot generation, integrity, and breakdown providing rapid assessment of TIC in the acute setting.[39,40] It allows providers to target specific resuscitation products (cryoprecipitate, FFP, platelets, fibrinogen) to the patient's individual needs and has become standard of care in trauma resuscitations in high-volume trauma centers. Prospective randomized data have demonstrated a mortality benefit for patients undergoing TEG-guided massive transfusion compared with conventional coagulation assays, and viscoelastic assays should be used routinely as part of trauma resuscitation and massive transfusion algorithms.[41]

Fibrinogen deficit and hyperfibrinolysis are known to contribute to the pathophysiology of TIC. FFP does not contain sufficient amounts of fibrinogen for adequate replacement, and in the United States cryoprecipitate is often used to replace fibrinogen stores.[42] In Europe, retrospective studies have reported good efficacy of fibrinogen concentrate in correcting functional deficits after trauma, and emerging data suggest that this approach may demonstrate promise in reducing blood requirements after injury.[43,44]

Platelet Dysfunction After Injury

Platelet dysfunction likely plays a particularly important role in disordered clotting after injury. Endothelial cell injury (leading to extensive adenosine diphosphate [ADP] metabolism) and overwhelming immediate platelet activation (leading to "platelet exhaustion") may both contribute to platelet dysfunction in early trauma. A prolonged refractory state after initial injury could explain why platelets may be qualitatively dysfunctional even without thrombocytopenia.

Disturbances in platelet function are common after injury and portend poor outcomes. Multicenter observational data suggest that platelets are inhibited in 86.1% of trauma patients compared with 4.2% in healthy volunteers with worse base deficit (a marker of injury severity) correlating to greater platelet dysfunction.[45] Another prospective observational study found nearly half of critically injured patients had evidence of platelet hypofunction upon admission. Platelet hypofunction was associated with up to a 10-fold increase in 24-hour mortality (20.0% vs. 2.1%, $P = .009$).[46]

Hyperfibrinolysis and Tranexamic Acid for Trauma Patients

Evidence of hyperfibrinolysis as underlying TIC has led to interest in antifibrinolytic agents as potential adjuncts for the resuscitation of injured patients. The CRASH-2 (Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage 2) trial was a placebo-controlled trial performed in 274 hospitals in 40 countries. Adult trauma patients were included if they presented within 8 hours of blunt or penetrating injury, were at risk of significant hemorrhage, or presented with systolic blood pressure <90 mm Hg or heart rate >110 beats per minute. The authors found that patients randomized to 1 g tranexamic acid (TXA) had a lower relative risk (RR) of mortality compared with placebo (RR 0.91, $P = .0035$), and the risk of bleeding (RR 0.85, $P = .0077$) and vascular occlusion (RR 0.69, $P = .096$) were also decreased. This study was performed in a rigorous manner that reflected real-world clinical practice across a variety of settings ranging from austere environments to tertiary medical centers. The CRASH-2 trial provides level I evidence supporting TXA, and TXA is now widely administered in trauma centers to improve outcomes in patients at risk of hemorrhagic shock. Notably, outcomes are best when TXA is administered early, ideally within the first 3 hours of injury.[47]

Prehospital Resuscitation

Ideal resuscitation starts as early as possible after injury. Recent research efforts have evaluated strategies and effectiveness of prehospital transfusion of plasma, PRBCs, and whole blood. Prehospital PRBC administration has been independently associated with a lower risk of 24-hour mortality, 30-day mortality, and TIC in patients with severe blunt traumatic injury.[48] Additionally, initiating PRBC transfusion during patient transport to the trauma center was independently associated with improved outcomes. Similarly, the Prehospital Air Medical Plasma (PAMPer) trial was a multicenter cluster-randomized clinical trial that compared the administration of thawed plasma with standard-care resuscitation during air medical transport among 501 injured patients at risk for hemorrhagic shock. Patients randomized to receive prehospital plasma had significantly lower 30-day mortality compared with the standard-care group (23.2% vs. 33.0%, $P = .03$). Mean PT ratios were lower in the plasma group vs. standard-care group (1.2 vs. 1.3, $P < .001$).[49]

The Control of Major Bleeding after Trauma (COMBAT) trial sought to assess the effect of ground ambulance plasma administration but found no difference in overall mortality among patients receiving plasma compared with their standard-care counterparts.[50] Post hoc pooled analysis of PAMPer and COMBAT participants indicated prehospital plasma was associated with a survival benefit in patients with hemorrhagic shock among patients with transit times exceeding 20 minutes.[51]

The safety and efficacy of prehospital TXA administration has also been the subject of considerable interest and study. A recent multicenter, randomized controlled trial failed to find significant differences in 30-day mortality between patients receiving prehospital TXA versus placebo.[52] However, among a severely hypotensive subgroup of patients (systolic blood pressure [SBP] ≤70 mm Hg), TXA was associated with significantly increased survival (18.5% vs. 35.5%; difference, $P < .003$), suggesting that TXA is likely a useful and safe prehospital adjunct particularly in critically ill patients. Notably,

survival benefit was seen when TXA was administered within the first hour of injury.

Prediction of Coagulopathy

Multiple algorithms have been developed to attempt to predict patients at risk for TIC. Notable prediction tools include the Assessment of Blood Consumption (ABC) score and the Clinical Coagulopathy Score (created by the Trans-Agency Consortium for Trauma-Induced Coagulopathy [TACTIC]). The ABC score includes four dichotomous variables: penetrating mechanism, SBP ≤90 mm Hg, emergency department heart rate ≥120 beats/minute, and positive fluid on abdominal ultrasonography. In a multicenter study the ABC score yielded a negative predictive value of 97%, and less than 5% of patients who require massive transfusion will be missed using the ABC score.[22] The TACTIC clinical coagulopathy score for TIC helps define postinjury mortality caused by coagulopathy, offering standardized clinical scoring and mortality criteria in patients with TIC. However, none of these scoring systems have become widely accepted in the diagnosis of TIC. Retrospective data comparing various scoring systems failed to demonstrate a difference between their capacity to predict massive transfusion.[23]

Putting It All Together: A Comprehensive Approach for Management of Shock and Severe Bleeding

Resuscitation management should start at the scene. Emergency medical technician (EMT) personnel should be trained in hemostasis, and tourniquets should be liberally applied. Prehospital product, plasma, and TXA should be used in severely injured patients as part of early resuscitation.

Trauma centers should have systems in place for whole blood or (if not yet available) balanced product resuscitation.

Once the patient arrives to the trauma center, TEG, hemoglobin, and a venous blood gas should be immediately obtained and used to tailor resuscitation. Massive transfusion and TXA protocols should be activated early for patients presenting with critical injury or hemorrhagic shock.

Emergency department, interventional radiology, and surgical interventions for hemorrhage control should be implemented rapidly. Damage control and staged procedures must be carefully planned, and multidisciplinary communication with the ICU team and other consultants is key to maintain the proper order of priorities and to implement ancillary care. Throughout resuscitation, serial TEG should be used to guide resuscitation.

KEY POINTS

- Hypovolemic shock can be divided into two etiologies with concomitant differences in treatment. Nonhemorrhagic hypovolemic shock consists of body fluid loss and is treated primarily with fluid replacement to restore intravascular volume. Hemorrhagic shock results from blood loss and is treated with hemorrhage control, replacement of whole blood or its components, and avoidance or correction of coagulopathy.
- Nonhemorrhagic hypovolemia should be treated with rapid bolus infusion of isotonic crystalloid with ongoing monitoring of physiologic and laboratory data to evaluate response and dictate termination of therapy. We prefer use of buffered isotonic solutions for critically ill patients, particularly in large-volume resuscitations.
- Hemorrhagic shock is the most common cause of preventable trauma death.
- Trauma resuscitation should be systematic and include rapid scene-to-hospital transport and expedient prehospital, emergency department, surgical, and IR-guided techniques for hemorrhage control.
- Patients with severe injuries should receive early management with whole blood or balanced blood product transfusions in a 1:1:1 ratio of PRBCs:FFP:platelets. Excessive crystalloid resuscitation should be avoided.
- TEG should be promptly obtained and used to further tailor resuscitation.
- Trauma centers of all levels benefit from standardizing protocols for resuscitation and the diagnosis and treatment of TIC.

Annane D, Siami S, Jaber S, et al. Effects of fluid resuscitation with colloids vs crystalloids on mortality in critically ill patients presenting with hypovolemic shock: The CRISTAL randomized trial. *JAMA.* 2013;310(17):1809–1817. doi:10.1001/jama.2013.280502.
In this trial 2757 patients with hypovolemia were randomized to crystalloid versus colloid resuscitation. There was no difference in 28-day mortality between patients undergoing crystalloid versus colloid resuscitation, and the study was terminated early for futility. Study generalizability was limited by the heterogeneity of fluids used in both the crystalloid and colloid arms.

Single-center randomized trial comparing 111 patients receiving massive transfusion guided by either TEG or conventional coagulation assay. The authors found 28-day survival was significantly higher in patients receiving TEG-guided resuscitation (19.6% vs, 36.4%, P = .049).

Holcomb JB, Tilley BC, Baraniuk S, et al. Transfusion of plasma, platelets, and red blood cells in a 1:1:1 vs a 1:1:2 ratio and mortality in patients with severe trauma: The PROPPR randomized clinical trial. *JAMA.* 2015;313(5):471–482. doi:10.1001/jama.2015.12.
Multicenter, randomized clinical trial comparing effectiveness and safety of a 1:1:1 transfusion ratio compared with a 1:1:2 transfusion ratio in patients with trauma who were predicted to receive a massive transfusion. The authors found no significant differences in mortality at 24 hours or at 30 days. However, more patients in the 1:1:1 group achieved hemostasis and fewer experienced death caused by exsanguination by 24 hours.

Study randomizing 15,802 critically ill patients to either 0.9% normal saline versus buffered solutions. The authors reported a lower composite rate of 30-day all-cause mortality, new need for renal replacement therapy, or renal dysfunction among patients resuscitated with buffered solutions compared with 0.9% normal saline (OR 0.91, P = .04).

Shakur H, Roberts I, Bautista R, et al. Effects of tranexamic acid on death, vascular occlusive events, and blood transfusion in trauma patients with significant haemorrhage (CRASH-2): A randomised, placebo-controlled trial. *Lancet.* 2010;376:23–32.
Multinational placebo-controlled trial performed randomizing patients at risk of hemorrhagic shock to 1 g tranexamic acid (TXA) versus placebo. The authors found that patients who received TXA had lower relative risk of mortality (RR 0.91, P = .0035), risk of bleeding (RR 0.85, P = .0077), and vascular occlusion (RR 0.69, P = .096). Notably, outcomes were best when TXA was administered within the first 3 hours of injury.

Mediastinitis

Eric I. Jeng, Giovanni Piovesana, and Thomas M. Beaver

The mediastinum is the thoracic space confined by the sternum anteriorly, the spine posteriorly, the pleural laterally, the diaphragm inferiorly, and the thoracic outlet superiorly. It can be divided anatomically into superior and inferior compartments by the sternal angle. The inferior compartment is further divided into the anterior (between the posterior sternum and the anterior pericardium), middle (the intrapericardial contents), and posterior (bounded anteriorly by the posterior pericardium and posteriorly by the spine) mediastinum (Fig. 142.1).

Mediastinitis is defined as inflammation of the mediastinum, and the diagnosis, treatment, and prognosis are determined by location and etiology. Primary mediastinitis arises without prior intervention, whereas secondary mediastinitis occurs postintervention. Clinically, mediastinitis of the anterior and middle mediastinum occurs most frequently as a postoperative complication of a cardiothoracic procedure. Esophageal pathology accounts for the overwhelming majority of the mediastinal infections of the posterior compartment.

Other more unusual forms of mediastinal infections or inflammation include those that migrate into the mediastinum from adjacent contiguous spaces and those that are more indolent than acute and are characterized by chronic inflammation and fibrosis.

Accordingly, this presentation follows these anatomic and etiologic distinctions: acute anterior mediastinitis, acute posterior mediastinitis, and migratory and chronic mediastinal inflammation.

ACUTE ANTERIOR MEDIASTINITIS

The most common form of acute anterior mediastinitis occurs after sternotomy for a cardiothoracic operation. It may also occur after traumatic sternal fracture[1]; descending cervical infections; and/or teratomatous, thymic, and thyroid infections/inflammation.

The term *mediastinitis* after cardiothoracic surgery refers to an infection involving the space deep to the sternum. Other forms of postoperative infection can be identified as superficial sternal wound infection (SWI; above the fascia without sternal involvement) and sternal osteomyelitis (without deeper infection).

Clinically, it is sometimes unclear as to whether one is dealing with a superficial problem above the level of the fascia, a sterile dehiscence, or a deeper infection. As no impervious anatomic barrier exists between the posterior cortex of the sternum and the space behind it, any infection posterior to the sternum is considered an infection of the anterior mediastinum. More than a small amount of drainage, any sternal instability, or evidence of separation suggest at least a sterile dehiscence and the need for re-exploration, deep cultures, and appropriate reclosure.

Incidence, Pathology, and Prevention

The reported incidence of mediastinitis ranges from 0.24% to 4% postcardiotomy.[2–4] Comorbidities that increase the risk of postoperative mediastinitis include diabetes, elevated body mass index, older age, renal failure, prolonged preoperative hospitalization, immunosuppression, chronic obstructive pulmonary disease, cigarette smoking, reoperation, and preoperative atrial fibrillation.[3,5–7]

Intraoperative factors have also been shown to play a role in postcardiotomy infection. Bilateral internal mammary use for coronary bypass grafting has about a 5% risk of sternal dehiscence as compared with 1% in single internal mammary usage. In addition, off-midline sternotomy, prolonged operative time, and the use of an intraaortic balloon pump[7] have also been shown to increase risks of mediastinitis.

Multiple studies have cited bone healing is significantly impaired by using bone wax for sternal hemostasis as compared with water-soluble polymer wax, suggesting the use of the latter as a useful alternative, because bone healing immediately postoperatively is the most critical time frame for the prevention of sternal nonunion and infection.[8]

In high-risk patients, sternal closure with rigid plate fixation may decrease the incidence of postoperative mediastinitis[9] as compared with a similar population of patients whose sterna were closed with traditional wire alone. Some have shown that the use of cyanoacrylate glue can decrease the infection rates of superficial and deep surgical sites in patients who have sternal detachment and/or are at high risk for developing infection.[10] For those advocating minimally invasive and alternative approaches to cardiac procedures, all together avoiding the sternotomy appears to also reduce the risk of mediastinal infection after cardiac operations.[7]

Postoperatively, increased glucose levels (>200 mg/dL),[11,12] re-exploration, and prolonged ventilator use are associated with a higher incidence of deep sternal infection.[7] As such, many quality metrics postcardiotomy are related to glucose control and time to extubation. In patients requiring complex cardiac repair, postoperative tracheostomy is frequently required. Despite the close proximity to the sternal incision, early tracheostomy for patients with ventilator dependence has not been shown to be associated with an increased incidence of mediastinitis.[13] Tracheostomy per se is not a risk factor for sternal breakdown, but rather serves as a surrogate for respiratory failure.[14,15] As many ICUs have moved toward percutaneous tracheostomy, Hubner and colleagues evaluated the technique of percutaneous tracheostomy specifically and found that it has not been associated with a subsequent increase in mediastinal infection.[16]

Staphylococcal species are the most common organisms seen in patients with poststernotomy deep wound infection, and these are increasingly methicillin resistant.[17] Coagulase-negative resistant organisms are more common in patients who have prolonged hospitalizations.[18] Gram-negative organisms may be cultured, particularly from patients with diabetes, in patients with gram-negative pneumonia before operation, or in those who require re-exploration.[1] Given the most common organisms causing these infections, a second-generation cephalosporin is still the most accepted preoperative prophylaxis. Vancomycin is substituted in patients with penicillin allergy, and the

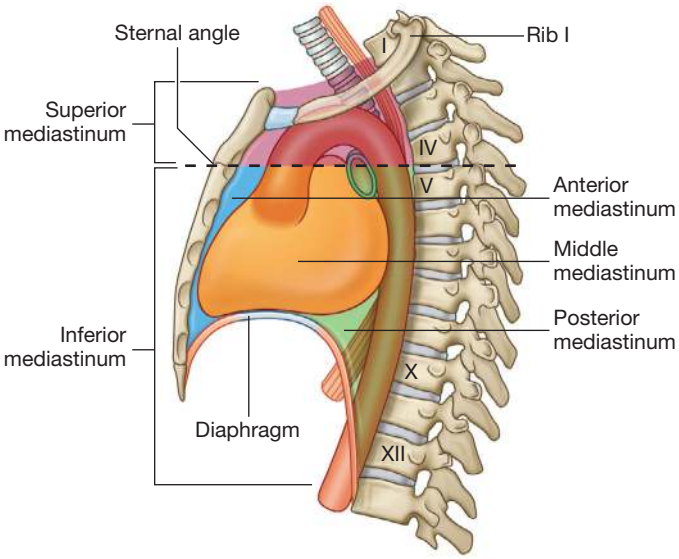

Fig. 142.1 With respect to etiology, mediastinitis may be either primary, arising without prior intervention, or secondary, occurring postintervention. Clinically, the anatomic anterior and middle compartments can be considered together, as mediastinitis occurs most commonly in these combined spaces secondarily as a postoperative complication of cardiac operations. Esophageal pathology accounts for the overwhelming majority of mediastinal infections of the posterior compartment. (From Drake RL, Vogl AW, Mitchell AW. *Gray's Anatomy for Students*, 2nd ed. Philadelphia, PA: Churchill Livingstone; 2009: Fig 3-5.)

addition of preoperative gram-negative coverage is appropriate in such cases, given vancomycin's poor coverage of such organisms.[19] Topical vancomycin has been shown to be effective in decreasing the incidence of sternal infections, and it is used routinely in some practices.[20] Evidence-based guidelines from the Society of Thoracic Surgeons recommends gram-positive prophylaxis for no more than 48 hours in addition to preoperative nasal mupirocin.[17,19]

Diagnosis

Patients with mediastinitis after sternotomy generally have clinical signs of wound drainage and sternal instability, but neither may be initially present. Fever and leukocytosis are common symptoms. Some patients manifest signs of sepsis, with mental status changes and hemodynamic compromise. Mediastinitis can appear as early as 1 day after the index operation or as remotely as months after an operation. The variable diagnostic accuracy of imaging techniques for the diagnosis of mediastinitis permits them to be supportive,[21] but rarely, if ever, definitive. This is especially true during the early time frame (<30 days), when the vast majority of patients present. During this time, fluid collections and mediastinal soft tissue changes are common, if not universal, with both being nonspecific for infection.[22]

Computed tomography (CT), magnetic resonance imaging (MRI), and technetium-99m leukocyte imaging can identify patients who have deep sternal wound infection (DSWI) and require surgical débridement.[23] Cooper and colleagues showed that the patterns of intense uptake at 4 and 20 hours or increasing uptake between 4 and 20 hours were 100% sensitive and 89% specific for the detection of DSWI. It is useful in patients with suspected DSWI when clinical examination fails to confirm a diagnosis or when deep sternal aspirates of the superficial SWIs are equivocal. Leukocyte imaging is not useful for detecting superficial SWIs.[24] Given the speed and efficiency, CT scan is favored in localizing the site of pathology and can give a better picture of the overall patient condition.

A profile of abnormal cytokine levels has been characterized,[25] with the terminal SC5b-9 complement complex concentration being substantially higher in patients with mediastinitis and having no overlap with the values in non-mediastinitis, post–cardiac surgery controls. In difficult-to-diagnose cases, blind retrosternal, subxiphoid needle aspiration and culture have been variably employed, and aspiration with ultrasound guidance has been reported after cardiac transplantation.[26] A recent small series suggested diagnostic success in patients without classic signs of infection by anteriorly inserting a 22-gauge needle percutaneously and aspirating between the recently closed sternal edges. Cultures and Gram stains were used to establish the presence of infection, with a high degree of specificity and sensitivity.[27]

Treatment

The different technical approaches to treat anterior mediastinitis are related to the temporal interval from the antecedent operation, the depth and extent of the infection, and the acuity of the patient.[28] The classification by Pairolero and Arnold[29] is based on clinical features and can be used to practically approach the various types of clinical entities.

There are three major types of sternomediastinitis in this system.

Type I sternomediastinitis manifests with serosanguineous drainage within a few days after sternotomy. Purulence, osteomyelitis, and chondritis are notably absent. Mediastinal tissues are still soft and pliable. Bacterial cultures are initially negative or yield staphylococci. In such cases, the sternotomy is reopened, all blind pockets are eliminated, and the mediastinum is irrigated. This type of infection is best managed by the reinsertion of drainage tubes and reclosure of the sternum with either a variation of the Robicsek[30] weave or a commercially available plate fixation device. Aggressive intravenous and topical antibiotic treatment should be used in these cases.

Type II sternomediastinitis is a fulminant process that occurs 1–3 weeks after surgery. In addition to reopening, drainage, and irrigation, these patients require débridement of the necrotic soft tissue, bone, and cartilage. This may be performed initially, when the wound is reopened, but may be delayed if the patient is septic or if their general condition is too critical to allow a major intervention. An effort should be made to remove all foreign materials such as felt pledgets and pacing wires. Exposed suture lines can be reinforced with autologous tissue, such as fascia lata, omentum, and/or covered with muscle flaps. The wound is then kept open and treated with daily dressing.

Type III sternomediastinitis occurs 1 month to 1 year after surgery. The patient typically presents with chronic draining sinus tracts that lead to the infected sternum, cartilages, or retained foreign bodies. Repair requires wide exposure, extensive débridement, often total sternectomy, and/or muscle/omental flap coverage using autologous tissues.

Diluted antibiotic, povidone-iodine, and aqueous acid solutions have been reported as irrigation protocols.[28,31] The duration of irrigation has varied from 3 days to 1 week, while systemic antibiotics are continued, as would be the case for other adult bone infections.[32] The cultures obtained at operation dictate the systemic antibiotics that will ultimately be used, but initial coverage may include a second-generation cephalosporin and gram-negative coverage until a Gram stain or the culture results are definitive.

If a multiple-stage approach is indicated, the approach involves an interval during which the sternum and skin are left open and a negative-pressure wound vacuum device is used.[33,34] It should be cautioned that the management of open sternal wounds can be associated with a risk of sudden cardiac hemorrhage from the exposed grafts, the aorta, and/or the right ventricle. The risk of death in such patients is >50%,[35–37] but this may be the result of the underlying etiology requiring open

chest management. Given the added risks of an unapproximated sternum, most recommend close attention be paid to the proximity of the sternal edges and the right ventricle. A custom fashioned plastic 60-cc syringe to mechanically prop open the sternum, in theory, can be used to prevent both tamponade in an already edematous heart and mechanical shearing of the right ventricle against the sternal edge. Postoperative management includes sedation, possible muscle paralysis, and mechanical ventilation until complete coverage can be achieved.

Whether used as an initial single-stage procedure or as a secondary procedure, tissue transposition into the anterior mediastinum has dramatically changed the prognosis of this once often fatal complication.[38]

The use of omentum versus any specific muscle flap is dictated by availability, but when the option exists, the use of omentum has been touted as advantageous over muscle flaps.[39] Omentum has also been successfully employed in infections after ascending aortic replacement for its properties of improving oxygen supply, enhancing antibiotic delivery, and enhancing the immunologic response while absorbing secretions that can lead to bacterial proliferation.[40] Skin coverage over a transposed flap may be accomplished by primary presternal skin reapproximation or split-thickness skin grafting, or, with the rectus muscle, a skin paddle may be transposed as well.

Prognosis

Although the mortality of mediastinitis has improved dramatically over the past three decades, the likelihood of death remains high (13%–47%) and most often from associated comorbidities or complications.[41] Early detection with expeditious operative débridement and tissue coverage are the major advances that have enabled improvement of short-term mortality. It should be noted that despite these improvements, there are still long-term consequences of mediastinitis past the acute phase. The Northern New England Cardiovascular Disease Study Group found that the 4-year mortality for patients with a postoperative deep sternal infection was three times greater than that for patients without this complication, and this increased all-cause mortality rate persisted with up to 10 years of follow-up. For patients surviving for longer than 6 months after a cardiac operation, the incidence of death was 70% higher than the rate among patients who did not have a mediastinal infection.[42]

POSTERIOR MEDIASTINITIS

Acute infections that arise in the posterior mediastinum generally result from primary disease of the esophagus or, more frequently, iatrogenic complications from esophageal intervention.[43]

In general, esophagitis (eosinophilic, fungal, or other pathogenic organisms) that extends through the esophagus results in mediastinitis. This can lead to periesophageal abscess formation caused by micro/macro perforations. Other common causes of esophageal perforation include Boerhaave syndrome and corrosive or foreign body ingestion. Periesophageal pathology may additionally be secondary to esophageal operations. The source of an infection may be anastomotic disruption, with esophageal leaks occurring in 4.3%–8.7% of patients who underwent an intrathoracic esophagogastric anastomosis.[44] Traumatic injuries to the trachea, proximal bronchi, or esophagus obviously may also result in the contamination of this space. More rarely, the erosion of a broncholith from a partially or completely obstructed bronchus can also cause posterior mediastinistis.[45]

Diagnosis

With a relevant history, the presence of cervical pain and/or chest pain with a high fever would strongly suggest the diagnosis. Supraclavicular crepitus may be identified in patients with upper mediastinal pathology, but is generally absent initially in those with middle or lower esophageal disease. Leukocytosis may be the singular early laboratory abnormality. Furthermore, sepsis with altered mental status and hypotension may occur. Certainly, in some of these patients, plain chest film may reveal a pleural effusion, and more rarely, air may be seen in the retropharyngeal space or other abnormal locations along the length of the mediastinum posterior to the pericardium. Fluoroscopic esophagogram and CT scan with oral contrast are the mainstays for diagnosis and localization. CT can demonstrate abnormal air or fluid collections along the esophagus or esophagogastric junction in the thoracic, abdominal, and pelvic spaces. Direct visualization via endoscopy can aid in diagnosis and repair strategy. In addition, transesophageal ultrasonography and fine-needle aspiration have been jointly used to diagnose a variety of periesophageal infections.[46]

Treatment

A contained esophageal disruption (extravasation of contrast that drains rather promptly back into the lumen) may be managed successfully in stable patients by serial clinical evaluation, limited oral intake, antibiotic therapy, and repeat imaging.[47] This may be particularly true in young children.[48]

In patients with more frank mediastinal contamination not confined to the local perforation but identified within the first 24 hours, operation with primary repair and drainage is often indicated.[49,50] If the length of time since the perforation is sufficiently short and the injury is sufficiently small so that local inflammation is limited, primary repair of a disruption—preferably with viable vascularized tissue buttressing—has been successfully employed,[50] even after 24 hours.[51] Success has also been recently reported with the use of covered self-expanding esophageal stents.[52] Image-guided nonoperative drainage with antibiotics has been successfully employed in selected cases where a defined collection or abscess could be identified.

In a case series reported by Ben-David and colleagues, uncontained acute (less than 24 hours) esophageal perforations in the chest greater than 2 cm in size were successfully treated with a combination of endoscopically placed stent, minimally invasive laparoscopic/thoracoscopic mediastinal drainage, and a laparoscopically placed gastrostomy or jejunostomy tube. By adopting this treatment algorithm, control of the esophageal leak was confirmed in all patients within 24 hours of the esophageal stent placement, and 73% of the patients were able to begin a diet 48 hours after their esophagogram confirmed no further extravasation of contrast.[53,54]

In patients with more extensive local inflammation, such as those diagnosed more than 24 hours after perforation and those who are more systemically ill, drainage with or without some esophageal diversion may be employed. Continued sepsis and multiple organ failure are the most common causes of death among these patients, and multiple operations to excise necrotic tissue and drain the space are sometimes required before definitive reconstruction.

MIGRATORY AND CHRONIC MEDIASTINAL INFLAMMATION

The mediastinum may be infected secondarily from contiguous acute infections involving adjacent anatomic spaces such as the pleurae, lungs, spine, intraabdominal processes, and retroperitoneum.[55]

Perhaps the most dramatic and well described of the migratory mediastinal infections are those that descend from the neck, which is known as *descending necrotizing mediastinitis*. These include those infections that arise as classic Ludwig angina (odontogenic or nonodontogenic) or from cervical puncture wounds. Gravity and the negative

pressure of the thoracic cavity have been cited as reasons for this descent through the pretracheal space into the upper posterior mediastinum. These patients are often young and may have a history of a dental infection. Cervical pain, cellulitis, necrosis, and abscess formation may occur, and a high index of suspicion leading to CT imaging can be diagnostic. Broad-spectrum antibiotics are essential and must be accompanied by cervical and mediastinal drainage directed by the clinical and radiologic findings.[56,57] Drainage may be accomplished in a variety of ways, including right thoracotomy, left-sided video-assisted thoracoscopy, or an anterior clamshell incision. The mortality of this condition has historically ranged from 20% to 40% and increases directly with the interval between the onset of symptoms and diagnosis.

Oropharyngeal cervical infections descending into the mediastinum have been successfully managed with antibiotics and a combination of percutaneous drains and/or videoscopic débridement.[55,58] In any case, aggressive imaging surveillance and a commitment to achieving and maintaining adequate drainage (multiple varied procedures) are necessary to successfully manage this relatively rare life-threatening disorder.[59]

Mediastinal fibrosis is a chronic condition that may present precipitously when the process constricts a mediastinal structure, compromising its lumen. Pulmonary vein, pulmonary artery,[60] vena cava,[61] and tracheal stenoses are the most commonly seen. The diagnosis is generally established by CT or MRI, which reveals a diffusely infiltrating, sometimes calcified, mass. Bronchoscopy may contribute to the diagnosis.[62] The fibrosis is a benign, acellular proliferation of fibrous collagenous tissue that is idiopathic or may be an immunologic sequela of an intervention (e.g., radiofrequency ablation) or infection (mycotic, specifically, and most commonly, *Histoplasma*).[63,64] Treatment may include steroid therapy[65] and local dilation of the stenotic lumen with stents or operation.[66]

ACKNOWLEDGMENT

The authors are grateful to Dr. Robert G. Johnson, whose treatment of this topic in previous editions of this textbook forms the basis of much of the current chapter.

KEY POINTS

- The mediastinum can be separated into the superior, anterior, middle, and posterior mediastinal spaces.
- Diagnosis and early treatment of acute anterior mediastinitis can improve short-term mortality.
- Etiology of mediastinitis defines treatment and diagnostic options.
- Preoperative, intraoperative, and postoperative factors can contribute to mediastinitis.
- CT, MRI, and technetium-99m leukocyte imaging can aid in the diagnosis and treatment of mediastinitis.
- Mediastinitis worsens short- and long-term morbidity and mortality.

Epistaxis

Rohit Pravin Patel

Epistaxis is an acute hemorrhage from within the nasal cavity, including the nasopharynx, and accounts for 0.5% of all U.S. emergency department visits. Approximately 60% of individuals experience epistaxis at least once in their lifetime, although only 6% of cases require medical treatment.[1,2] The peak incidence of epistaxis in adults is in the 45- to 65-year-old age group, and the incidence of severe posterior bleeding is greater.[3] Special aspects regarding the care of critically ill patients with epistaxis, including prevention, diagnosis, and management options, will be discussed in this chapter. An algorithm for the management of epistaxis by the American Academy of Otolaryngology Head and Neck Surgery is included to assist in clinical decision support (Fig. 143.1).

ANATOMY

The vascular supply of the nasal cavity forms from the terminal branches of the internal and external carotid arteries. The majority of epistaxis (90%–95%) occurs on the anterior nasal septum at a region called *Little area*. This area is supplied by Kiesselbach plexus, a network of vessels from three large thin-walled arteries (sphenopalatine artery, anterior ethmoidal artery, and superior labial artery).[4] Epistaxis is classified as anterior or posterior, although no clear landmarks separate the two.[1,5] Melia and McGarry proposed that anterior bleeding is from a source anterior to the plane of the pyriform aperture (the anterior bony nasal aperture), which includes bleeding from the anterior septum and from the vestibular skin and mucocutaneous junction. Posterior bleeding is from a vessel situated posterior to the piriform aperture and allows for further division into the lateral wall, septal, and nasal floor bleeding.[6] The two primary sites of posterior epistaxis include the posterior lateral nasal wall and the posterior nasal septum, with the most common artery involved being the sphenopalatine artery. Epistaxis from the anterior ethmoidal artery is less common and is typically associated with midface trauma or iatrogenic injury during endoscopic sinus surgery.[7,8]

DIAGNOSIS

It is important that the clinician wear appropriate safety clothing and equipment (disposable apron, gloves, surgical face mask, suction, and headlight). It is also important to gather details of the initial presentation, previous bleeding episodes, comorbid conditions, and current medications. Coagulation screening is only indicated when the clinical history suggests coagulopathy of a known use of anticoagulants.[9] Warfarin is a commonly prescribed anticoagulant, and patients with epistaxis on warfarin are older, have longer mean hospital stays, and show trends that they require more aggressive treatment to control. In a review of patients taking warfarin with epistaxis, it was found that more than 75% of the patients were over-anticoagulated at the time of admission.[10] Critically ill patients are frequently supine, with decreased alertness, and blood may drain into the nasopharynx and, subsequently, the stomach, making it difficult to differentiate from gastrointestinal bleeding. An anterior speculum examination with a good light source usually allows the identification of focal anterior bleeding. Generalized mucosal ooze in a patient with systemic coagulopathy and large amounts of bleeding that obscures visualization can make identification of the source difficult. In addition to the anterior/posterior classification system discussed earlier, bleeding can be classified as venous/arterial or high/low flow based on the rate of bleeding. Venous bleeding can involve low flow, such as mucosal oozing, or it can be high flow from structures such as the cavernous sinus. Arterial bleeding can be low flow from oozing from small perforating vessels, or it can be high flow in carotid artery injuries.[11] Epistaxis can also be classified as primary or secondary when there is an underlying coagulopathy associated with anticoagulant/antiplatelet medications.[6] For patients in which anterior bleeding is not easily identifiable, nasal endoscopy has been shown to identify over 80% of bleeding sites not otherwise seen and reduce the duration of hospital admission. Chiu and McGarry reported positive identification of 94% of posterior bleeding sites in 50 consecutive patients, while Supriya and colleagues identified 38 of 47 posterior bleeding sites in a series of 100 patients, with an overall positive identification rate of 91%.[8,12]

TREATMENT

General management includes protection of the airway, addressing hemodynamic compromise, and controlling active hemorrhage. Patients with a reduced level of consciousness or head injury are at risk of aspiration and should require consideration of airway protection with endotracheal intubation. Intravenous access and fluid resuscitation should be addressed quickly, as patients can become unstable. The first priority is to control or slow the active hemorrhage with some form of temporizing packing. Commercially available anterior or posterior balloon combination packs can be used with the goal of slowing the rate of blood loss while the setup of anticipated equipment is established. Before insertion of these packing materials, an attempt can be made by simply applying pressure to the nose while the patient is positioned upright and leaning forward for 20 minutes. The goal here is to slow the blood loss rate by collapsing the bleeding vessels and forming a clot.

Treatment: Anterior Bleeding

Cautery of an identified bleeding point is the optimal method of management in adult epistaxis and can successfully control anterior bleeding, with silver nitrate and electrocautery as options. Silver nitrate is applied by rolling the applicator stick between your thumb and first finger while gently applying the tip to the area you wish to cauterize for

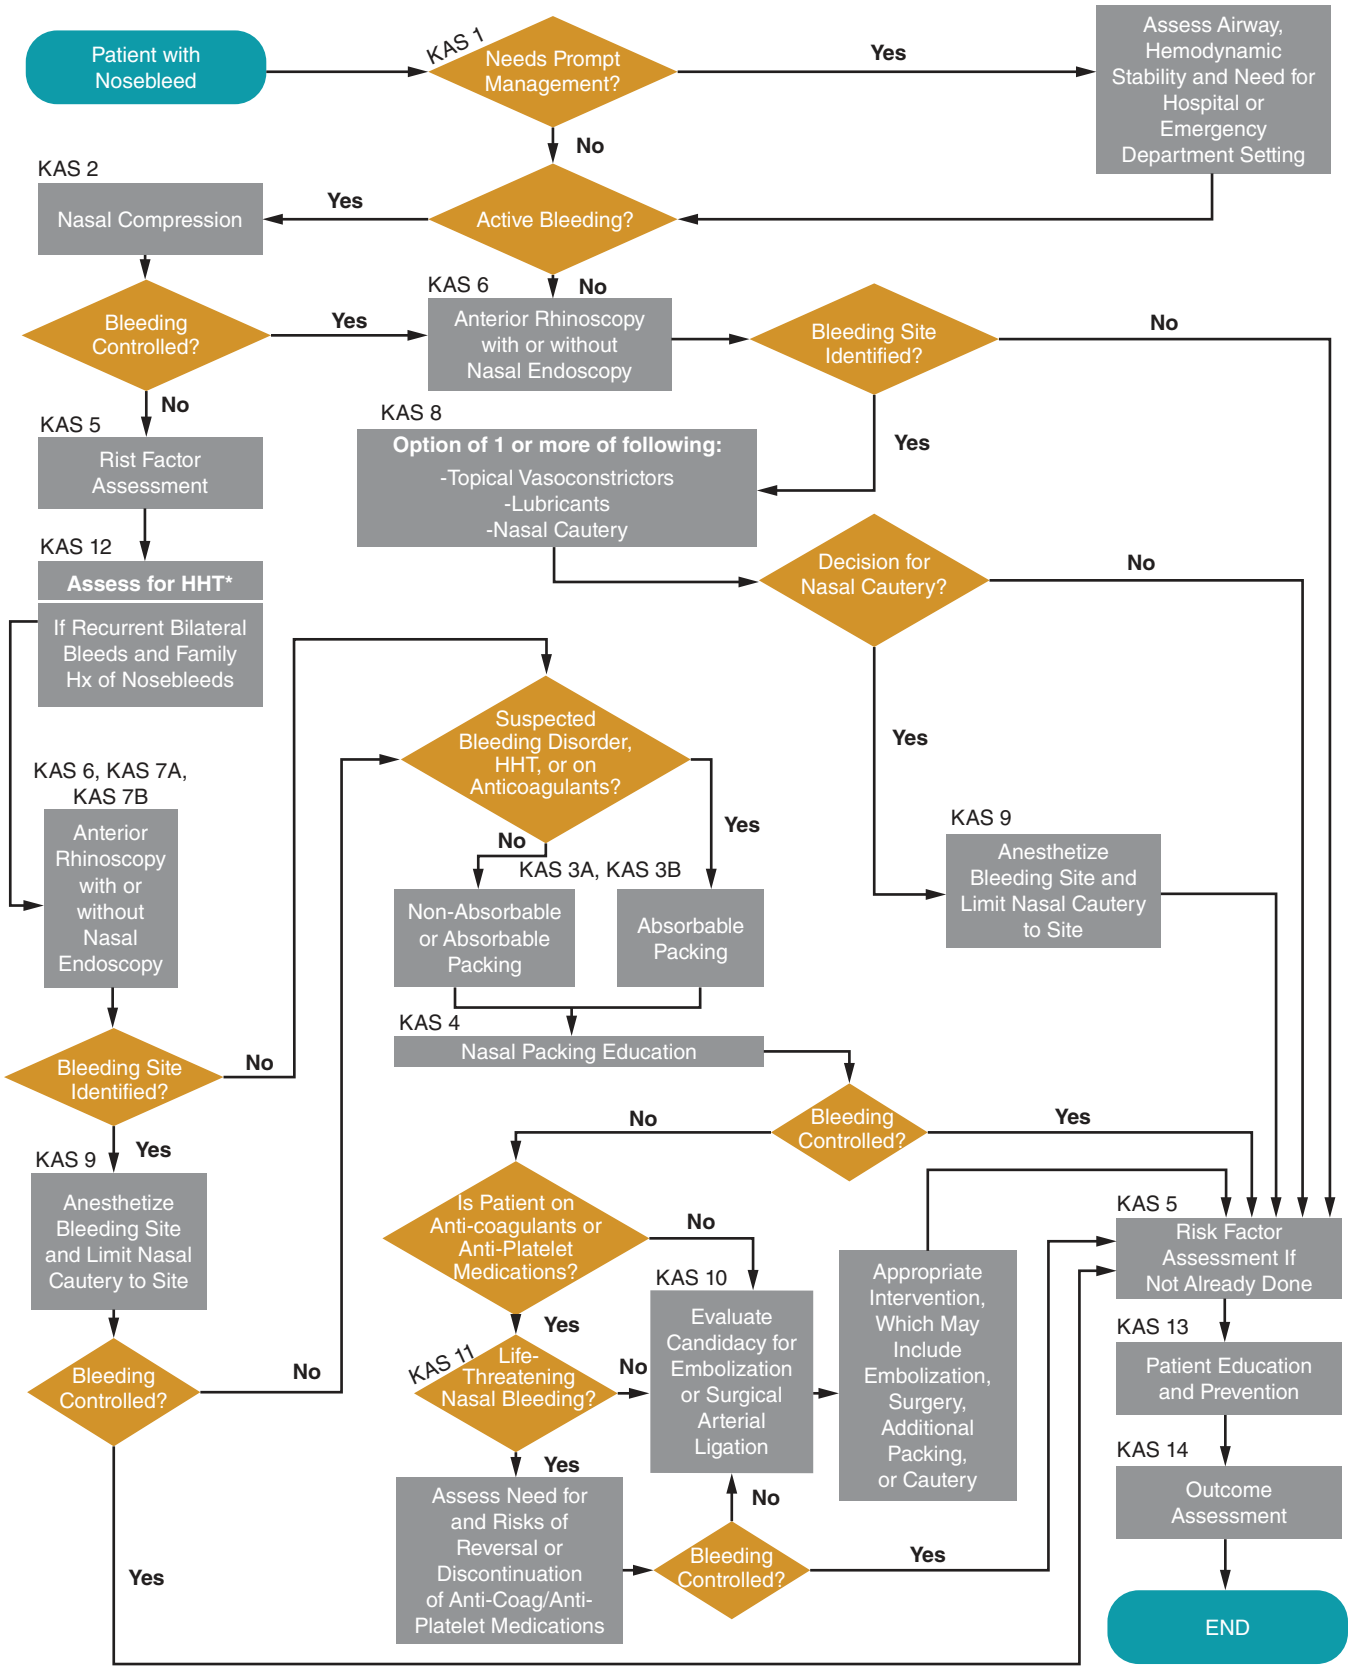

Fig. 143.1 Epistaxis guideline key action statements: Diagnostic and treatment algorithm. *HHT,* Hereditary hemorrhagic telangiectasia; *Hx,* history; *KAS,* key action statement. (From Tunkel DE, Anne S, Payne SC, et al. Clinical practice guideline: Nosebleed (epistaxis). *Otolaryngol Head Neck Surg.* 2020;162[Suppl. 1]: S1–S38, Figure 6.)

about 5–10 seconds. Care should be taken not to burn the nasal skin as you enter the nose or aggressively use it on the septum. Start adjacent to the vessel, making an orbit around the vessel before rolling the tip in to the center, as rebleeding is common when going straight for the site. Shargorodsky and colleagues found that cautery had a significantly lower treatment failure rate (defined as a rebleed requiring intervention by a physician within 7 days) and a lower mean number of interventions required to achieve lasting hemostasis with nondissolvable packing. Among the patients who required admission, those who underwent directed vascular control had fewer inpatient days.[13] If cautery does not control the bleeding, a nasal pack will be required. Nasal packs should be introduced into the nose directly front-to-back following the floor of the nose. Never place it upward, as this does not work, is painful, and increases the risk of complications. Commercially available packs are available and consist of balloon/hydrocolloid fabrics that expand after placement into the nasopharynx. Most of these have a string or tubing that should be taped to the patient's cheek to secure it.

Treatment: Posterior Bleeding

Severe idiopathic nontraumatic posterior bleeding typically occurs in the elderly, who often have underlying cardiac and respiratory comorbidities. It should be suspected after appropriate anterior control measures have been taken and bleeding continues. Typically, a 12 French Foley catheter or similar item is used in conjunction with a ½-inch ribbon gauze or commercially available anterior packing supplies. The catheter balloon should be tested with saline before use. A nasal decongestant and topical local anesthetic solution should be administered to the nasal cavity and on the ribbon gauze. The catheter is lubricated and advanced into the nose until the tip can just be seen passing the soft palate in the mouth. At this point, the catheter needs to be pulled back 1 cm as the balloon inflates in the nasopharynx. Between 5 and 10 mL of saline is used to inflate the balloon, and once inflated, the catheter is pulled taut so that the balloon is effectively occluding the posterior nasopharynx at the back of the nasal cavity. Anterior packing is then performed by folding layers of the ribbon. These patients are at risk for adverse events such as rebleeding and hypoxia, likely the result of comorbidities such as cardiovascular disease, pulmonary disease, renal disease, obesity, and obstructive sleep apnea.[14,15] For continued bleeding, surgery or embolization is an option. Moshaver and colleagues showed that compared with surgical intervention, posterior nasal packing resulted in a significantly shorter mean hospital stay and reduced healthcare costs. The overall success rate was 89%, and no difference was found in the complication rates between the two treatment options.[16] Arterial embolization appears similar to surgery in terms of its success in controlling intractable epistaxis, with several recent studies showing success rates of 80%–90%.[17–21] The advantage of surgery is a lower risk for major complications such as stroke, blindness, and soft tissue ischemia. The advantage of embolization is the ability to perform the procedure under local anesthesia, thus avoiding general anesthesia in patients with comorbidities, in addition to the improved diagnosis of vascular abnormalities such as malformations and pseudoaneurysms. Marin and colleagues showed that 90.6% of episodes requiring vascular intervention had a posterior source. The most performed surgical technique was endoscopic sphenopalatine artery ligation (ESPAL) (69.4%), followed by cautery of mucosal bleeding (24.2%), cautery of the ethmoidal artery (24.2%), argon plasma coagulation (8.1%), and endoscopic clipping/ligation of maxillary artery (3.2%).[22] There is a growing body of support for early intervention in epistaxis with ESPAL, with the increased use of endoscopic sinus surgery and greater understanding of local regional anatomy, with improved patient satisfaction and cost reduction compared with traditional packing techniques.

Treatment: After Packing the Nose

The packing is usually kept in for 5 days, but this is usually physician and institution dependent. Patients do not tolerate nasal packing well. Shargorodsky and colleagues examined whether the duration of packing was associated with the recurrence of epistaxis after removal and did not demonstrate a significant difference between the recurrence rate and the number of pack days, showing no evidence that removing the packing after fewer than 5 days was associated with increased recurrence of epistaxis.[13] Furthermore, good results have been shown in packing durations of 1–3 days, with the control of bleeding as high as 85% for anterior epistaxis.[23] Nasal packing of all types requires gram-positive coverage for prophylaxis against toxic shock syndrome. *Staphylococcus aureus* can be isolated from the nasal cavity in one-third of these patients, of whom 30% produce the exotoxin responsible for toxic shock syndrome.[24] Other complications include pressure necrosis of the palate, alar, or skin and displacement with airway obstruction.

MEDICOLEGAL THOUGHTS

The absence of a defined management algorithm, wide therapeutic options, and the potential for severe complications all contribute to epistaxis as a target for medicolegal cases. Understanding the variables will assist in advancing strategies and enhancing patient care. The most common reason has been the alleged failure of the treating physician to recognize complications in a timely manner and delays in the subsequent diagnosis, such as cancer and retained foreign bodies.[25–27] It is important to realize that epistaxis is a sign, not a diagnosis. Other cases have been related to a failure in recognizing anatomic variations, which led to blindness and stroke caused by inadvertent embolization.[5,28] This shows the importance of preinterventional imaging. Last, malposition or inadequate nasal packing with complications such as aspiration and dislodgment have been found throughout the hospital stay.[29]

SPECIFIC INTENSIVE CARE UNIT SITUATIONS: NASAL INTUBATION

Nasotracheal intubation commonly causes epistaxis from injury to the nasal mucosa or turbinate. Good mucosal preparation for nasotracheal intubation should include adequate lubrication, topical local anesthetics, and vasoconstrictors. Moreover, if resistance is met, the tube should be slightly rotated to allow better passage, or the other nare should be attempted.[30,31] The inferior turbinate and the adjacent septum are the most common sites of nasal damage.[32,33] Placement into intracranial compartments has occurred in the setting of skull base trauma. Blind placement in these situations may be associated with severe complications. Although posterior nasal packing should not be performed in the presence of nasal bone fractures, severe epistaxis may necessitate nasal packing with the use of balloon systems or arterial embolization ligation.[34,35] Cribriform plate fractures are the most common site for intracranial catheter placement and can occur with even small amounts of pressure.

SPECIFIC INTENSIVE CARE UNIT SITUATIONS: POSTOPERATIVE EPISTAXIS

Sellar and parasellar lesions are typically approached through transsphenoidal surgery, and postoperative bleeding originates from the external carotid system. Redundant mucosa, highly vascular and friable mucosa, large septal deviations, septal spurs, and complex sphenoid septations can make endoscopic transsphenoidal surgery difficult and

increase the risk for epistaxis.[36] Management of bleeding immediately postoperatively involves nasal packing and re-exploration in the operating room if the packing is not successful. In delayed bleeding, otorhinolaryngologic services typically perform endoscopic packing, balloon tamponade, silver nitrate application, and/or electrocautery. If these measures do not stop the bleeding, angiography followed by embolization can be performed.[37] Postoperative hypertension is generally viewed as a risk factor for epistaxis and is also an independent risk factor for persistent spontaneous epistaxis.[38]

SPECIFIC INTENSIVE CARE UNIT SITUATIONS: MASSIVE FACIAL TRAUMA

Traumatic pseudoaneurysms of the internal carotid artery are rare but can be a fatal cause of epistaxis, with a mortality rate as high as 50%.[39,40] Pseudoaneurysms or localized arterial disruptions are caused by blunt or penetrating trauma. Shearing forces and hemorrhages in the arterial wall weaken the artery and allow formation, and the continued pulsatile forces cause erosion on the thin bone layer.[41,42] The Maurer triad, which consists of unilateral blindness, orbital fracture, and massive epistaxis, is considered pathognomonic for internal carotid artery pseudoaneurysms.[43] The diagnosis is often delayed because of a latency period between the trauma and the bleeding, which averages 3 weeks in 88% of cases.[44,45] Angiographic imaging is the gold standard, with endovascular techniques being the preferred therapeutic approach.

NOVEL AND ADJUNCTIVE THERAPIES

Vasoconstrictors, hot water irrigation, and topical hemostatic compounds have all been used as adjunctive therapies to the previously mentioned procedures for the control of bleeding. Hot water irrigation via a balloon placed in the nasopharynx for approximately 3 minutes at 50°C to induce mucosal edema (and occlude the bleeding vessel) has been shown to control posterior epistaxis.[46,47] Topical hemostatic compounds are now available, consisting of gelatin granules and human thrombin. Studies show higher effectiveness, ease of application, and lower discomfort scores for their insertion and removal.[48]

MORTALITY

A number of risk factors are associated with increased mortality after admission with epistaxis, and this information could help with risk stratification. Factors include increased age and comorbidity scores, low admission albumin, low admission hemoglobin, an abnormal clotting screen, and an admission time of more than 2 days. Use of anticoagulation medications did not affect the mortality rate. Pneumonia and malignancy were the two most common causes of death.[49]

ALGORITHM[50]

Consistent with previous discussion, the American Academy of Otolaryngology Head and Neck Surgery have provided clinicians with an algorithm based on action statements produced from its clinical practice guideline supplement (see Fig. 143.1).[50]

KEY POINTS

- In the critically ill patient, diagnosis of epistaxis may be more difficult because of supine positioning and decreased alertness and is often confused with upper gastrointestinal bleeding.
- Epistaxis is a sign and not a diagnosis; once bleeding is controlled, the search for the etiology should be conducted. Coagulation studies should be performed in those on anticoagulant/antiplatelet medications, with consideration of correction.
- For intractable epistaxis, options should include surgery or embolization. Surgery has the advantages of decreased complication rates of stroke and blindness, and embolization has the advantage of avoiding general anesthesia in patients with nasopharyngeal bleeding.
- Aspiration, hypoxia, and dislodgment complications with nasal packing must be continuously evaluated for, especially in patients with severe comorbidities.
- In the absence of life-threatening bleeding, the clinician should initiate first-line treatments (nasal compression, vasoconstrictors, moisturizing or lubricating agents, nasal cautery/packing) before transfusion, reversal of anticoagulants, or withdrawal of anticoagulation/antiplatelet agents.
- Factors that increase the risk of mortality should be considered when making a treatment plan.
- Use of an algorithm for management of epistaxis may improve patient outcomes, decrease length of stay, and decrease costs.

Management of the Postoperative Cardiac Surgical Patient

Shailesh Bihari

Intensive care may account for more than one-third of the total hospital costs for cardiac surgery patients, and much of the short-term morbidity and mortality are based on perioperative events. The overall mortality after cardiac surgery is low. However, this ranges from less than 1% for elective coronary artery bypass grafting to more than 30% for more complex surgery in patients with significant myocardial dysfunction and significant comorbidities. Hence a comprehensive understanding of cardiovascular physiology and surgery is essential for a modern-day intensivist.

The initial days of care for a cardiac surgery patient present multiple challenges for an intensivist. The intensive care unit (ICU) stay for most patients lasts for 24–48 hours, but during this critical period, life-threatening problems such as low cardiac output (CO), arrhythmias, and coagulopathy may occur. After 48 hours, the problems encountered tend to become more like those experienced by other groups of critically ill patients.

CARDIAC SURGERY PATIENTS IN THE INTENSIVE CARE UNIT

History of Cardiac Surgery Linked to the History of Intensive Care

The development of modern cardiac surgery is intimately related to the development of the ICU. Until the 1950s, cardiac surgery was limited to the control of traumatic injuries and the closed repair of valves. The development of the extracorporeal pump oxygenator in 1953 ushered in the era of open heart surgery.[1] Heart valve replacement then became possible, and subsequently in the 1960s, coronary artery bypass grafting (CABG) for ischemic heart disease was developed and rapidly popularized.[2]

Several studies have demonstrated that risk-adjusted mortality rates after CABG vary significantly among surgeons and hospitals and that mortality is related both to the number of surgeries performed by each surgeon and the total volume of procedures performed at the hospital.[3–6] For high-risk surgical patients, survival is also related to the characteristics of the ICU care.[7]

Changing Epidemiology of Cardiac Surgery

Over the past decade, the population of patients treated with cardiac surgery has changed dramatically. Advances in cardiology, including reperfusion therapy, angioplasty, stenting, and drug-eluting stents, have obviated the need for surgical approaches to treatment except for particularly complex problems or after failure of other, less invasive modalities. In the year 2000, 561,000 patients in the United States underwent percutaneous transluminal coronary angioplasty (PTCA), an increase of 262% relative to 1987. In the same year, 314,000 patients underwent CABG. Multiyear trends, represented in Fig. 144.1, show a leveling off and subsequent decrease in the overall number of patients undergoing CABG.[8] Studies comparing the use of stents versus CABG for left main disease have found no significant difference in rates of death, Q-wave infarction, or stroke; however, stenting was associated with higher rates of target vessel revascularization than was CABG.[9]

Even as younger patients are being treated with interventional techniques, the elderly are increasingly referred for operation. As the population ages and care becomes more sophisticated, cardiac surgery is being performed on older, sicker, and more complicated patients. Although these operations are successful even in most octogenarians, they are associated with increased hospital mortality and longer ICU and hospital stays. It is clear, however, that good results in terms of long-term survival and quality of life are achievable.

There has been significant research into organizational factors in general ICU; however, there is less supporting information around issues such as open versus closed ICU and surgeon-led care versus intensivist-led care in the cardiac arena.

Alternative Techniques for Cardiac Surgery

The increasing age of patients undergoing cardiac surgery and the relatively high incidence of adverse effects related to cardiopulmonary bypass (CPB) have led to the development of less invasive cardiac surgical techniques. These techniques are intended to decrease postoperative morbidity, reduce length of hospital stay, reduce costs, and hasten recovery of lifestyle (Table 144.1). Three major techniques have been proposed.

Minimally invasive direct coronary artery bypass (MIDCAB) differs from conventional CABG mainly in the type of surgical incision. Instead of a median sternotomy, access is obtained via a left or right thoracotomy, a parasternal incision, or a partial sternotomy. Although the proposed benefit of such an approach is the reduction in morbidity related to median sternotomy, this advantage has not been demonstrated. MIDCAB grafting is a challenging technique and should be performed only in selected patients with favorable coronary anatomy. Both bare-metal and drug-eluting stenting have been shown to be inferior to MIDCAB for proximal left anterior descending coronary artery lesions, owing to higher reintervention rates and similar results in mortality and morbidity.[4,10]

Off-pump coronary artery bypass (OPCAB) is performed on a beating heart without the benefit of CPB. The proposed advantage of this procedure is the reduction of morbidity related to hypothermia and CPB. The procedure is undertaken using partial to full heparinization. Extubation may be achieved earlier in these patients because

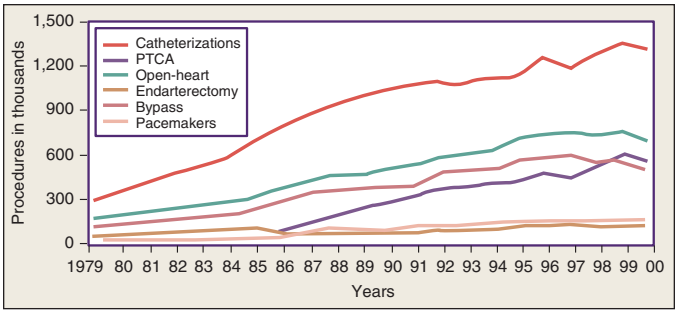

Fig. 144.1 Trends in cardiovascular operations and procedures in the United States, 1979–2000. *PTCA,* Percutaneous transluminal coronary angioplasty. (From American Heart Association. *Heart Disease and Stroke Statistics—2003 Update*. Dallas, TX: AHA; 2003.)

they do not require rewarming and are less coagulopathic. A subset of patients cannot tolerate the extent of retraction of the heart required for the surgery and need to be urgently placed on CPB. These patients may suffer ischemic myocardial injury and require support with inotropes or intraaortic balloon pumping (IABP) during the postoperative period.

A third method of minimally invasive cardiac surgery is the port access technique. This operation entails obtaining access for CPB with the use of endovascular catheters. It allows surgery to be performed using CPB via either a left or right thoracotomy. The technique is particularly useful for mitral valve replacement through a right thoracotomy and for redo CABG (avoiding the complications associated with repeat sternotomy). The port access technique has been shown to be safe and is associated with shorter lengths of stay, reduced transfusion requirements, fewer infections, decreased incidence of renal failure, and less atrial fibrillation (Afib) compared with conventional techniques.[11] Widespread adoption of this technique has been limited by the technical complexity of placing the required catheters, which requires both extra time and a specially trained, skilled operative team. As the techniques of minimally invasive cardiac surgery continue to evolve, the intensivist caring for cardiac surgical patients must continue to keep abreast of these new methods.

Organization of the Postoperative Cardiac Surgery Unit

Optimal results from cardiac surgery require a skilled, dedicated, and multidisciplinary ICU team. Patients undergoing cardiac surgery are usually admitted to the hospital on the day of surgery and arrive in the ICU directly from the operating room (OR). A typical patient is transferred to a step-down unit on the morning after surgery. This unit allows continued monitoring with telemetry for an additional 24–48 hours. Patients remaining in the ICU beyond 48 hours tend to become similar to a standard ICU population, as they develop secondary complications such as sepsis, pneumonia, and acute respiratory distress syndrome (ARDS).

Guidelines developed by the American Heart Association and the American College of Cardiology outline the requirements for cardiac surgical ICUs.[12–14] These include the development of protocol-driven care, a minimum number of cardiac surgical ICU beds that is half the number of surgeries performed per week, and one-to-one nursing care during the first night in the unit. The ICU coverage by a dedicated intensivist has been shown to improve outcomes in other types of major surgeries and should be recommended after cardiac surgery as well.[7]

Surgeon-Intensivist Relationship

Cardiac surgery involves a continuum of care from presentation to postdischarge management and rehabilitation. The intensive care specialist must be involved in this continuum, rather than functioning in isolation from surgeons, anesthetists, and cardiologists.

SEPARATION FROM CARDIOPULMONARY BYPASS AND THE END OF SURGERY

Successful management of a postoperative cardiac surgery patient begins by understanding what occurs in the OR because operative problems often persist after transfer to the ICU. An understanding of the

TABLE 144.1 Comparison of Minimally Invasive Cardiac Surgery Techniques

Technique	Incision Site	Cannulation Site	Advantages	Disadvantages
Conventional	Median sternotomy	Ascending aorta	Excellent exposure	Mediastinitis
CABG	Median sternotomy	Right atrium and Ascending aorta	Stable closure and extensive experience	Postoperative respiratory function limited by pain
MIDCAB	Left or paramedian or right thoracotomy or partial sternotomy	Ascending aorta and right atrium	Avoids median sternotomy	Limited exposure. May require multiple incisions
Port access	Right anterior thoracotomy, *or*	Ascending aorta via right paramedian port	Avoids median sternotomy Avoids atriotomy	Increased cost of equipment Contraindicated in patients with ascending aortic pathology
	Paramedian or left thoracotomy	Femoral vessels	Access to mitral valve Smaller skin incision	Limited operative exposure Significant learning curve.
OPCAB	Median sternotomy, *or* Right or left thoracotomy, Partial sternotomy	None	Avoids aortic manipulation Avoids atriotomy and CPB	Cost of equipment Learning curve Worse graft longevity

technical and pathophysiologic aspects of CPB may help an intensivist better manage the postoperative cardiac surgical patient.

Cardiopulmonary Bypass

The goal of CPB is to separate the heart and lungs from the systemic circulation so that the heart may be arrested while the surgical repair is performed. Blood is drained from the right side of the heart via a cannula in the right atrium or via the femoral vein advanced into the right atrium. The blood is collected in a reservoir and then pumped through an oxygenator that contains a membrane where the blood is oxygenated and carbon dioxide is removed (Fig. 144.2). A perfusionist controls both the fraction of inspired oxygen and the rate of oxygen flow through the circuit, thereby controlling the patient's arterial oxygen and carbon dioxide levels, respectively. The treated blood then passes through an air filter and is returned to the patient via an arterial cannula placed in either the ascending aorta or the femoral artery. The perfusionist controls the amount of systemic flow provided to the patient (i.e., CO). Mild to moderate systemic hypothermia (28°C–34°C) is used during bypass to minimize oxygen consumption by both the body and the brain. After adequate CPB is established, an aortic cross-clamp is applied to the ascending aorta, between the aortic cannula and the heart. The interval when the cross-clamp is applied is referred to as *ischemic* time, because no blood is circulated through the heart during this period. The heart is arrested by infusing a high-concentration potassium solution into the native coronary arteries (antegrade cardioplegia) via a cannula placed between the aortic cross-clamp and the heart. Cardioplegia may also be given "backward," through the venous system of the myocardium (retrograde cardioplegia) via a catheter placed in the coronary sinus. Potassium is used as the arresting agent because it stops the heart from beating and minimizes myocardial oxygen consumption.

Myocardial Protection

Several measures are taken to protect the heart during ischemic time, because irreversible myocardial damage may otherwise occur. Electromechanical arrest is the most important protective measure, because the beating action of the heart accounts for about 85% of the heart's total oxygen consumption. The heart is usually cooled to about 10°C with a cold cardioplegia solution (4°C) supplemented with topical ice slush. Additionally, the left ventricle is "vented" to prevent distention, which could lead to subendocardial ischemia. Finally, various additives are included in the cardioplegia solution to minimize myocardial edema, maintain normal intramyocardial pH, and provide substrates for anaerobic metabolism. The adequacy of intraoperative myocardial protection is critical for determining the subsequent course and final outcome for a patient.

Separation from Cardiopulmonary Bypass

Weaning from CPB is the process whereby cardiopulmonary function is transferred from the bypass system back to the patient's own heart and lungs. Successful separation from CPB requires that the metabolic, cardiac, and respiratory parameters are as close to normal as possible. Separation from CPB implies that the native circulation will be required to support the body's metabolic demands. The surgical team manipulates the heart rate and rhythm, preload, afterload, and myocardial contractility to achieve this goal.

In most cases, normal sinus rhythm is restored after discontinuation of cardioplegia and rewarming of the heart. Occasionally, discontinuation of

cardioplegia and rewarming lead to the onset of ventricular fibrillation; in such cases, electrical defibrillation is required. Other dysrhythmias commonly encountered are atrioventricular dissociation and Afib. An attempt should be made to convert these to sinus rhythm by pharmacologic means. Bradyarrhythmias are treated by pacing, using temporary epicardial wires placed by the surgeon after completion of the repair. A heart rate of 70–90 beats/min usually is optimal. Pharmacologic support of the circulation may be needed to provide appropriate afterload or systemic vascular resistance (SVR) during separation from CPB. Most patients are vasodilated to some extent, possibly as a result of a systemic inflammatory response to CPB or the effects of rewarming, or both. As a consequence, the infusion of a vasoconstrictor is often required. Care must be taken to strike a proper balance so that increased SVR maintains adequate arterial blood pressure without excessively increasing left ventricular afterload and compromising CO.

Most often, myocardial function is adequate, and the infusion of an inotrope is not necessary. However, inotropic support is often needed for patients with a poor preoperative ventricular function or inadequate myocardial protection or revascularization during CPB. The optimal inotrope in this situation is a matter of considerable debate, and data are lacking to support a strong recommendation for a specific agent. Epinephrine, norepinephrine, dopamine, dobutamine, amrinone, and milrinone have all been used successfully. Intraoperative monitoring using transesophageal echocardiography (TEE) is particularly useful for titration of inotropic therapy.

Once all preparations for separation from CPB have been made, the perfusionist begins to wean the patient from bypass. This is done by slowly decreasing the amount of blood drained from the right atrium while simultaneously reducing flow into the aorta. Once the patient is off CPB (i.e., no blood is being drained from the right atrium into the circuit), the perfusionist, at the direction of the anesthesiologist or surgeon, may continue to infuse through the aortic cannula. This maneuver allows optimization of ventricular filling or preload. However, care must be taken not to overdistend the heart; also, during this period, TEE is extremely useful.

Reversal of Anticoagulation

After weaning from CPB, protamine is given to neutralize any residual heparin. Dosing may be based on the patient's weight, the total amount of heparin given, or an assay of residual heparin activity. Institutional preference governs the technique employed, but all have been proven effective. Several adverse responses to protamine administration are possible, including histamine-induced systemic hypotension, immunoglobulin E–mediated allergic reactions, and complement-mediated catastrophic pulmonary hypertension. The clinical sequelae of cardiopulmonary bypass are summarized in Table 144.2.[15]

TABLE 144.2 Clinical Sequelae of Cardiopulmonary Bypass

Intraoperative Event	Sequelae	Postoperative Manifestation
Aortic cannulation and clamping	Atheroembolism Aortic dissection	Stroke Splanchnic embolization Organ ischemia
Right atrial cannulation	Atrial wall injury	Bleeding and arrhythmias
Femoral artery cannulation	Distal leg ischemia Vascular trauma Retrograde aortic perfusion	Muscle injury and necrosis Compartment syndrome Hematoma Need for vascular repair Lymphocele Retrograde embolism Cerebral hypoxemia Left ventricular distension
Femoral vein cannulation	Vascular trauma	Hematoma Deep venous thrombosis Lymphocele
Graft twisting	Mechanical obstruction to blood flow	Myocardial injury and dysfunction
High-dose heparin	Systemic anticoagulation	Coagulopathy Heparin-induced thrombocytopenia
Crystalloid priming of CPB circuit	Hemodilution	Volume overload Dilutional anemia Dilutional coagulopathy
Extracorporeal circulation	Complement activation Fibrinolysis Systemic inflammatory response Microvascular hypoperfusion Microemboli	Coagulopathy Vasoplegia, hypotension, inflammatory end-organ damage (e.g., lung injury) Impairment of renal and mesenteric blood flow Stroke (small vessel)
Cardioplegic arrest	Inadequate cardioprotection	Myocardial injury and dysfunction Heart failure Conduction disturbance Arrhythmias

TABLE 144.2 Clinical Sequelae of Cardiopulmonary Bypass—cont'd

Intraoperative Event	Sequelae	Postoperative Manifestation
Hypotension on CPB	Sympathetic hyperactivity Renin-angiotensin activation Cerebral and visceral hypoperfusion	Arrhythmias Blood pressure lability End-organ damage
Hypothermia	Splanchnic vasoconstriction Impairment of coagulation cascade Shivering Sympathetic hyperactivity	Mesenteric and renal ischemia Coagulopathy, hemorrhage Increased O_2 consumption, increased CO_2 production Arrhythmias Blood pressure lability
Hypothermic circulatory arrest	Cerebral ischemia Somatic and spinal ischemia	Stroke Encephalopathy Paralysis Kidney injury Mesenteric ischemia Myonecrosis
Reaction to protamine	Anaphylactoid generalized reaction Noncardiogenic pulmonary edema	Hypotension Bronchoconstriction Hyperinflation of the lungs Pulmonary hypertension
Coronary air embolism	Coronary ischemia	Myocardial injury and dysfunction

CPB, Cardiopulmonary bypass.
Modified from Stephens RS, Whitman GJ. Postoperative critical care of the adult cardiac surgical patient. Part I: Routine postoperative care. *Crit Care Med.* 2015;43(7):1477–1479.

Transport and Admission to the Intensive Care Unit

After chest closure, confirmation of hemodynamic stability, and adequate medical and surgical hemostasis, the patient is transferred to the ICU. Transport of a critically ill patient is a potentially dangerous process and requires extreme vigilance. Transport between the OR and the ICU should be done with the same degree of monitoring as would be available at either end. This usually includes continuous monitoring of arterial blood pressure, pulmonary artery pressure and/or central venous pressure (CVP), electrocardiogram (ECG), and pulse oximetry. The transport bed should be equipped with a full oxygen tank, a bag valve mask, intubation equipment, resuscitation drugs, and defibrillator. Care must be taken to ensure that infusions of vasoactive drugs are not interrupted.

On arrival in the ICU, the intensivist-led team assumes patient care. A detailed sign-out from the operative team ensures continuity of care. The sign-out should include a detailed history, including an assessment of preoperative cardiac functional status, a list of preoperative medications, and a detailed description of the surgery. Key facts are the type of repair performed, target vessels (if the patient has undergone CABG), duration of CPB and cross-clamping, difficulties encountered in separation from CPB, presence of abnormal bleeding, and postoperative assessment of cardiac function. All treatments administered in the OR should be detailed, in particular, fluids, blood products, and vasoactive drugs.

Structured Handover

Handover should be structured to minimize disruption and maximize communication. The priorities are to confirm surgical procedure and any complications, confirm integrity and position of the endotracheal tube, re-establish mechanical ventilation of both lungs, re-establish all patient monitoring, access details of premorbid conditions, confirm venous, arterial and central access, heart rhythm and presence and mode of any pacing devices. The handover should also include details of the chest drains, establishing a blood pressure target, document results of any intraoperative echocardiography regarding ventricular function, provide details of intraoperative transfusion of blood or factors together with the results of any benchtop or laboratory tests of hemostasis and getting an early 12-lead electrocardiograph to exclude or identify acute ischemia.

Once care has been handed over to the ICU team, a thorough examination of the patient should immediately follow. This examination should include verification of endotracheal tube placement, type and position of arterial or central venous lines, chest tube position and patency, and presence and location of any epicardial pacing wires.

MONITORING THE POSTOPERATIVE CARDIAC SURGERY PATIENT

Hemodynamic Monitoring

All patients admitted to the ICU after cardiac surgery will have their blood pressure continuously monitored using an intraarterial line, which is usually placed in either a radial or a femoral artery. Accuracy of the measurements depends on strict attention to calibration, leveling, and removal of air from the tubing. After CPB, femoral arterial pressure may more accurately reflect central aortic pressures,[16] but this problem is usually resolved by the time the patient arrives in the ICU. If the radial artery is cannulated, the hand should be examined for signs of ischemia.[17] Vascular complications of femoral arterial lines are extremely rare, but femoral catheters may be associated with an increased incidence of infection.[18]

Central venous access is required in all patients for drug administration and hemodynamic monitoring. In low-risk patients, a CVP catheter may be all that is needed, particularly if echocardiography is available as a backup. Pulmonary artery catheters have the advantage of allowing measurement of pulmonary artery occlusion pressure (PAOP), thermodilution, and CO, in addition to sampling of the mixed venous blood saturation (SvO_2). Use of the pulmonary artery catheter remains controversial. Improved outcome resulting from the

use of a pulmonary artery catheter for monitoring cardiac surgical patients has not been demonstrated.[19] Some studies showed an increased risk of death or adverse outcome when treatment was guided by the use of a pulmonary artery catheter.[20,21] However, many of these studies have been criticized on methodologic grounds, and the use of a catheter in cardiac surgery remains widespread.[22] Current guidelines recommend the use of a pulmonary artery catheter in high-risk patients undergoing surgery (severely decreased left ventricular [LV] function [ejection fraction <30%], right ventricular [RV] failure, pulmonary hypertension, severe renal insufficiency, or thoracic transplantation) in an appropriate practice setting.[23] Such a setting is the one in which the physician and nursing staff are familiar with the catheter and trained to properly interpret the information obtained. If echocardiography is readily available, it is possible to manage even high-risk patients using a CVP catheter.

Electrocardiography

On admission to the ICU, the patient is connected to a continuous ECG monitor, and a formal 12-lead ECG is obtained. The cardiogram is examined for rate, rhythm, QRS complex morphology, and signs of myocardial ischemia. For patients who are being paced postoperatively, the type of pacing and the degree of capture should be assessed.

Continuous ECG monitoring allows detection of arrhythmias. If an arrhythmia is detected, a 12-lead ECG should be obtained and serum electrolyte concentrations should be measured. Treatment of arrhythmias should be carried out using established protocols.[24] If a malignant arrhythmia occurs, myocardial ischemia should be considered as a possible precipitating cause.

Monitoring of trends in ST-segment elevation or depression allows early detection of postoperative myocardial ischemia. Although transient ST-segment changes are relatively common and of unclear significance, persistent changes should be investigated by obtaining a 12-lead ECG and measuring circulating levels of creatine kinase myocardial band (CK-MB), troponin-T, or troponin-I.[25,26] If ischemia is strongly suspected, echocardiography followed by coronary angiography should be considered. Findings from these studies may indicate the need for further coronary revascularization.

Chest Radiography

The postoperative chest radiograph should be systematically evaluated. Proper placement of the endotracheal tube and any central lines inserted should be confirmed. If a pulmonary artery catheter is placed, the location of its tip should be noted and adjusted as needed. The lung fields should be examined for the presence of pneumothorax (PTX) or consolidation. Additional air may be noted as subcutaneous emphysema or pneumopericardium, although these findings are of little clinical significance. Further examination of the lung fields commonly shows small areas of atelectasis and pleural effusion. The cardiac silhouette is often enlarged after surgery as a result of myocardial edema and accumulation of fluid in the open pericardial sac. Increasing size of the cardiac silhouette or pleural effusions on serial chest radiographs may be evidence of ongoing mediastinal bleeding. The admission radiograph detects abnormalities in up to 35% of patients, although few of these result in a change in therapy.[27]

Echocardiography in the Intensive Care Unit

Echocardiography is an excellent tool for evaluating chamber size and function and the adequacy of valve repair or replacement. Indications include postoperative assessment of LV function, assessment of unexplained sudden hemodynamic deterioration, evaluation to rule out pericardial tamponade, and workup of new cardiac ischemia. Limitations to transthoracic echocardiography include inadequate windows early after operation because of air and edema in the soft tissues and wound dressings.

TEE is increasingly being used as a tool to facilitate decision making in managing critically ill patients, including cardiac surgical patients. In the cardiac surgical ICU, this modality may have a particularly high yield when used to establish the cause of postoperative hypotension.[28] In one large series, a new diagnosis was established or an important pathology was excluded in 45% of TEE examinations performed in the ICU. Pericardial tamponade was diagnosed in 34 cases (11%) and excluded in 36 cases (12%). Other diagnoses included severe LV failure and the presence of large pleural effusions. The results of TEE had an impact on therapy in 220 cases (73%) by leading to a change of pharmacologic treatment and/or fluid administration, reoperation, or a decision that reoperation was unnecessary.[29]

However, the early postoperative period after cardiac surgery presents unique challenges to image optimization because of mechanical ventilation and surgical dressings and drains and to image interpretation because of diagnostic findings unusual in other clinical settings.

Pericardial hematoma can cause focal cardiac chamber compression; thus every cardiac chamber must be clearly visualized. Rarely, massive hemothorax can cause tamponade. Dynamic left ventricular outflow tract (LVOT) obstruction should be suspected in the patient with mitral valve repair, hypertrophic left ventricle, or aortic valve replacement for aortic stenosis who develops shock that fails to respond to catecholamines or intraaortic balloon counterpulsation.

Echocardiography in these patients demonstrates a high LVOT flow velocity and mitral regurgitation. RV dysfunction may occur in isolation because of inadequate intraoperative cardioplegia. Increased intrathoracic pressure may present with hemodynamic features similar to pericardial tamponade, but should be recognized from assessment of ventilation. On echocardiography there are features of acute cor pulmonale. Patient prosthesis mismatch results in a high transvalvular pressure gradient and difficultly weaning from mechanical ventilation. Other causes of prosthetic valve dysfunction (e.g., leaflet entrapment or paravalvular leak) warrant expert and TEE evaluation.

CLINICAL MANIFESTATIONS IN THE POSTBYPASS PERIOD

The Normal Course

Patients are typically admitted to the ICU intubated and ventilated. Sedation with a short-acting agent, typically propofol, is continued until the patient is ready for extubation.[30,31]

Hypothermia (<36°C) is used intraoperatively to preserve cardiac and neurologic function postoperatively. Unfortunately, hypothermia carries the risk of adverse effects, including increased SVR, increased risk of arrhythmias, shivering, and coagulopathy. Shivering is of particular concern, as it increases oxygen (O_2) consumption while also increasing carbon dioxide (CO_2) production, sometimes precipitating acidosis. Pethidine and dexmedetomidine have been shown to treat shivering.[32,33] The increase in SVR can mask hypovolemia and increase afterload, which increases myocardial demand. The dangerous combination of increased SVR and coagulopathy can also lead to mediastinal bleeding. Without active rewarming with forced air, hypothermia and its complications, particularly the prolongation of anesthetic time half-life, can also prolong intubation times. There is evidence that the risk of wound infection also increases with hypothermia as well, likely owing to the immunosuppressive effects of hypothermia. Therefore upon arrival to the ICU, steps should be taken to increase core body temperature to normal using forced air, as that has been shown to be

more effective at expeditiously increasing core body temperature than radiant heaters or warming blankets.

Once hemodynamic stability is ascertained and chest tube drainage is judged to be under control, the patient is allowed to awaken. There is no need for prolonged weaning from mechanical ventilation. A short trial of spontaneous ventilation is sufficient to determine whether respiration will be adequate without mechanical support. Chest tubes are commonly removed on the first postoperative day. The pulmonary artery catheter, if present, is discontinued, and the patient may be transferred to a step-down unit.

The current trend in cardiothoracic surgery is toward early extubation, variably described as extubation within 6 hours or up to 12 hours. Extubation criteria may differ among cardiothoracic groups, but, at a minimum, patients should be awake with stimulation and following commands, moving all extremities (i.e., without neuromuscular blockade), minimal chest tube drainage (<50 or 100 mL/hr), core temperature above 35.5°C, hemodynamically stable with a CO >2.2 L/min per meter squared, free of arrhythmias, with ventilator stability with respiratory rate between 12 and 30 breaths/min, and reassuring arterial blood gas (ABG) levels.

Fast-tracking of cardiac surgical patients refers to a comprehensive program designed to reduce both length of stay and hospital costs.[34,35] As a part of this program, multiple anesthetic techniques designed to allow earlier postoperative extubation have been proposed, studied, and shown to be safe. The key to proper use of this technique is patient selection. Patients who are at risk of prolonged intubation are those with increasing age, chronic obstructive pulmonary disease, tobacco use, chronic kidney disease, peripheral vascular disease, depressed LV fraction (ejection fraction <30%), myocardial infarction within the past 90 days, preoperative ventilation, prior cardiac surgery, or urgent or emergent surgery. Intraoperative risk factors also exist, such as deep hypothermic circulatory arrest, coagulopathy, and long pump runs (>4 hours). Postoperatively, mediastinal bleeding, hemodynamic instability, respiratory failure, and stroke are the major risk factors for prolonged intubation. It is estimated that about 5%–10% of patients are unable to be extubated early and remain intubated for 48 hours or longer.[36] The fast-track group has been shown to have shorter extubation times, shorter ICU or postanesthesia care unit stays, and a lower incidence of low CO syndrome.[31]

Low Cardiac Output Syndrome

Low CO is the most common problem encountered in the postoperative cardiac surgical patient. A hallmark of low CO is low blood pressure. However, a patient may have a low CO with tissue hypoperfusion and still maintain what appears to be an adequate blood pressure. In the postoperative state, the physician must continuously examine and monitor the patient for signs of hypoperfusion. Physical signs of inadequate tissue perfusion include altered mental status; cool, pale, or even cyanotic extremities; diaphoresis; and low urine output. Global measures of hypoperfusion include increased base deficit, elevated blood lactate concentration, and decreased SvO_2. Although the clinician must consider CO in terms of adequacy of perfusion, blood pressure per se is still important. Both the brain and kidneys depend on adequate blood pressure to maintain tissue perfusion. Additionally, coronary artery blood flow is dependent on the diastolic blood pressure.

When assessing a patient with hypotension or signs of hypoperfusion, it is useful to consider the problem in relation to the components of CO—namely, preload, contractility, afterload, and rate and rhythm.

Preload

Preload refers to the stretch of the left ventricle at the end of diastole and is determined by the extent of diastolic ventricular filling. Adequate filling is required to ensure ejection in the subsequent systole. The most common cause of inadequate preload in postoperative patients is hypovolemia. Intravascular volume status should be continually monitored by assessing changes over time with respect to physical examination, chest tube output, and filling pressures (CVP, PAOP, or pulmonary artery diastolic pressure). Because none of the clinically measured filling pressures correlates perfectly with actual ventricular preload (i.e., end-diastolic volume) and correlation is particularly poor when the heart is diseased, it is often useful to obtain a snapshot of ventricular filling using echocardiography. By this means, it is possible to assess the relationship between measured filling pressures and actual preload in a specific patient. Preoperative catheterization data may also be helpful for determining this relationship. Hypovolemia should be treated with fluid replacement. Crystalloids are generally used. Surprisingly, there is no generally accepted hemoglobin concentration or hematocrit that should be used as a trigger for ordering transfusion of packed red blood cells (PRBCs).[37]

Dynamic approaches to assessing preload, such as respiratory arterial pulse pressure variation (PPV) and stroke volume variation (SVV, based on pulse contour analysis), using an approximate threshold value of more than 11% to indicate a volume deficit, may be more accurate in predicting fluid responsiveness.[38] However, these techniques require controlled mechanical ventilation, the absence of spontaneous breathing, and normal cardiac rhythm; they are inaccurate in patients with open chests.[39] The use of lower tidal volumes (<8 mL/kg) may limit the accuracy of PPV and SVV.[40] Ultrasound measurement of inferior vena cava diameter does not appear to be useful after cardiac surgery.[41]

Fluids and Fluid Therapy

Despite generous intraoperative fluid administration, effective hypovolemia is common in the early postoperative period, especially as warming with associated vasodilatation occurs. Hence administration of intravenous fluid is common. However, no benefit for any specific resuscitation fluid has been established, and an excessively positive fluid balance may increase perioperative complications. More recently, use of small-volume resuscitation with hyperoncotic albumin, when compared with crystalloid fluid, has resulted in less positive fluid balance and provides several hemodynamic and potential ICU treatment advantages in post–cardiac surgery patients.[42] In some cases, low preload is not caused by absolute hypovolemia, but by relative or distributional hypovolemia. CPB and subsequent rewarming may lead to vasodilatation and subsequent hypotension. Intravascular volume expansion may be required to maintain perfusion. An acceptable alternative is administration of a low dose of vasopressor such as phenylephrine or norepinephrine to maintain an adequate perfusion pressure. Vasopressin in doses between 0.01 and 0.1 units/min has been demonstrated to be effective in this situation.[43,44] Vasodilatation is usually a transient problem that resolves during the first several hours after separation from CPB. Continued vasodilatation after this period should prompt a search for another cause, particularly infection.

Pump Failure

Either or both ventricles may fail postoperatively (Box 144.1). Decreased myocardial contractility may be caused by impaired preoperative function, inadequate revascularization at surgery, post-CPB reperfusion injury, or perioperative myocardial ischemia or myocardial infarction (MI). The incidence of infarction is approximately 5% in a large series.[45] Preoperative myocardial function and the adequacy of revascularization at surgery should be clear from the history. Determination of circulating levels of CK-MB or troponin postoperatively may provide evidence of perioperative ischemia or infarction.[25,26] Often, diminished contractility

LIMA, Left internal mammary artery.

after operation is caused by inadequate myocardial protection during surgery. Decreased myocardial contractility secondary to inadequate myocardial protection usually resolves within the first 24 hours postoperatively.

Persistent new myocardial dysfunction associated with ECG changes and echocardiographic evidence of new wall-motion abnormalities should raise suspicion that the problem is an occluded graft and MI. Measurements of CK-MB in serum are of limited usefulness because levels of this enzyme are commonly elevated after surgery as a result of manipulation of the heart and incision of the atria. If CK-MB levels are very high (>80 mg/dL), perioperative MI is likely.[46] Cardiac troponins are more specific for diagnosing perioperative infarction. A comparison of CK-MB, troponin-T, and troponin-I showed that a troponin-I level of greater than 5 μg/L was the most accurate indicator of MI.[47] Elevated serum concentrations of troponin-I are associated with a cardiac cause of death and major postoperative complications.[48] In addition, troponin-T concentrations measured after surgery are an independent predictor of in-hospital death after cardiac surgery.[26] If ischemia or MI is diagnosed, the patient may be taken urgently for angiography or re-exploration and revascularization.

Postoperative valvular insufficiency may occur not only in patients with preexisting valvular lesions but also as a result of injury during surgery. The mitral valve is most commonly affected. Ischemia of the papillary muscles because of inadequate myocardial protection or perioperative MI may lead to acute mitral regurgitation in the postoperative period. Diagnosis is often made by TEE in the OR, but inadequate CO and a new systolic murmur should prompt echocardiographic evaluation.

Myocardial Dysfunction After Cardiopulmonary Bypass

A temporary impairment in contractility is seen after CPB. There are multiple theories to explain this, but the concept of myocardial stunning seems to be the prevailing thought at this time. The inflammatory state induced during heart surgery may also play a role in this impairment in contractility seen after the myocardium is reperfused. This is a transient phenomenon and resolves within 24–48 hours. Management of these patients includes inotropic support and management of the volume overload that was related to the vasodilatation and capillary leak seen and addressed intraoperatively.

Right Ventricular Dysfunction

RV failure after cardiac surgery is reasonably common. Common etiologic factors include direct RV ischemia or infarction, poor myocardial protection, an anteriorly placed right ventricle, and preexisting pulmonary hypertension. Management of RV dysfunction is challenging, and management involves careful volume resuscitation, maintenance of RV perfusion pressure with vasoconstrictors, intraaortic balloon counterpulsation, and inotrope administration. RV afterload reduction is an integral part of this, and useful afterload-reducing agents include nitric oxide, prostaglandins, and sildenafil. Delayed sternal closure has an established role.

Postoperative diastolic dysfunction must also be taken into consideration. Impaired relaxation of the left ventricle is particularly common in the elderly and in patients with significant LV hypertrophy. Postischemic injury and myocardial stunning related to CPB may exacerbate the problem. These patients will require a higher left ventricular end-diastolic pressure (LVEDP) to maintain an adequate postoperative preload. Progressive impairment in diastolic function is a hallmark of aging, even in patients with apparently normal systolic function and without hypertrophy of the left ventricle. On a structural level, aging results in a decreased number of ventricular myocytes and an increase in the amount of connective tissue matrix. The result is a stiffer, less compliant ventricle. The degree of diastolic dysfunction in a given patient may be demonstrated through the use of various echocardiographic techniques. Patients with diastolic dysfunction may demonstrate increased sensitivity to changes in loading conditions, making them less able to tolerate rapid volume shifts. Nevertheless, their ventricle will be intensely dependent on preload to maintain filling. Positive lusitropic agents such as milrinone may be of benefit in the immediate postbypass period.[49]

Rate and Rhythm

CO is the product of heart rate and stroke volume. Many dysrhythmias may adversely affect CO. If the heart rate is too low, CO may be compromised. If the heart rate is too fast, ventricular diastolic filling may be impaired, thus decreasing CO. Rhythm disturbances are common after cardiac surgery and may be divided into bradyarrhythmias and tachyarrhythmias; these categories are further divided into atrial and ventricular arrhythmias.

Bradycardia may lead to ventricular distention, increasing wall tension and decreasing coronary perfusion pressure, factors that may promote the development of ischemia and heart failure. A heart rate of 80–90 appears to be optimal, allowing adequate filling and preventing overdistention but not causing rate-related ischemia. Bradycardia may be corrected by pacing. In general, epicardial pacing wires are left in place after chest closure and are attached to an external pacemaker in the immediate postoperative period. If the dysrhythmia is sinus bradycardia, atrial pacing is usually optimal. The second most common cause of bradyarrhythmia after cardiac surgery is atrioventricular dissociation. The combination of atrial and ventricular leads allows atrioventricular pacing for managing dissociation.

Synchronization of the atrioventricular interval between 0.1 and 0.225 seconds optimizes CO.[50]

Afib is the most common tachyarrhythmia. It occurs in 10%–35% of patients after cardiac surgery, usually on the second or third postoperative day. Postoperative Afib is associated with increased morbidity and mortality and with longer, more expensive hospital stays.[51] Independent predictors of postoperative Afib include advanced age, male sex, history of Afib, history of congestive heart failure (CHF), and pre-CPB heart rate greater than 100 beats/min.[52] Surgical practices such as pulmonary vein venting, bicaval venous cannulation, postoperative atrial pacing, and longer cross-clamp times also were identified as independent predictors of postoperative Afib. Patients who developed postoperative Afib had longer lengths of stay, both in the ICU and in the ward, compared with patients who did not develop the complication.

Although premature ventricular contractions are common, sustained ventricular arrhythmias are far less frequent. Severe ventricular arrhythmias occurring after cardiac surgery are related to ischemia, hypoxemia, hypovolemia, electrolyte abnormalities, effects of vasoactive drugs, or underlying preexisting cardiomyopathy.[53] In a series of 2100 cardiac operations, only 16 patients (0.8%) developed ventricular fibrillation or sustained ventricular tachycardia during an interval from 3 days to 3 weeks after surgery. Ten of these patients had undergone valve surgery.[54] Prognosis in these patients is dependent on the preoperative ventricular prognosis. In those with an LV ejection fraction of less than 40%, the mortality rate may be as high as 75%.[55] Hypomagnesaemia and hypokalemia are frequent in the early postoperative stage and are exacerbated by polyuria. It is generally considered that levels should be maintained in the high-normal range.

Clinical and laboratory assessment of perfusion is still the cornerstone of managing these patients. A physical examination demonstrating warm extremities with strong pulses and good urine output is reassuring for adequate perfusion but should be supplemented by objective data. Lactate is an extremely sensitive marker of impaired perfusion, and even minimally elevated levels can identify patients with occult hypoperfusion. Higher lactate levels (>3–4 mmol/L) and slow lactate clearance accurately predict major complications after cardiac surgery.[56]

Afterload

Ventricular afterload is the impedance to ventricular ejection during systole. Hypertension develops in as many as 60% of patients after surgery. Increased arterial blood pressure occurs even among patients without a preoperative history of hypertension. Predisposing factors include hypoxemia, hypercapnia, inadequate rewarming, pain, fluid overload, and increased sympathetic tone. Perioperative discontinuation of beta-adrenergic blockers also may contribute to the development of postoperative hypertension. Hypertension and increased afterload may lead to myocardial ischemia by augmenting ventricular stroke work. Additionally, hypertension may lead to bleeding from surgical sites, aortic dissection, and increased risk of stroke.

Tamponade

Tamponade refers to the hemodynamic consequences of a collection of blood or other fluid in the pericardial sac. In postsurgical patients, the presentation of tamponade may be subtle and differ significantly from classic descriptions. Equilibration of filling pressures typically is not seen. More commonly, patients present with isolated elevation of right atrial pressure caused by compression of the right atrium and superior vena cava. After cardiac surgery, as many as 66% of pericardial fluid collections are loculated posterior effusions.[57]

Bleeding from the atrial cannulation site is a common cause of tamponade. As the pressure on the right atrium increases, ventricular filling is impaired and CO decreases. The diagnosis of tamponade is made difficult by the high overall frequency of pericardial effusions after surgery. Echocardiographic studies have shown that moderate effusions are present in 30% of patients on the eighth postoperative day, with 2% of patients having large effusions.[58]

Diagnosing tamponade in the postoperative patient requires a high index of suspicion and prompt intervention. Any hemodynamic instability should be assessed for tamponade. Low CO, hypotension, and tachycardia accompanied by an elevation of the left, right, or both atrial pressures should lead to a prompt echocardiogram. Other signs that may be present include a widened mediastinum on chest radiography, dysrhythmias, and decreased ECG voltage. Because of the influence of positive-pressure ventilation, the classic sign of pulsus paradoxus may not be present.

If time permits, the diagnosis of tamponade may be confirmed with the use of echocardiography. Although effusions are common, signs of compression or collapse of either atrium or the right ventricle are diagnostic.[59–61] It is important to remember that the diagnosis may be made on clinical suspicion alone and that treatment should not be withheld to await confirmation. Once tamponade is diagnosed, volume transfusion may temporize the situation. Pericardiocentesis is not effective in this situation, and prompt re-exploration for hemostasis and evacuation of a clot is indicated.

Respiratory Complications

Patients undergoing cardiac surgery are at risk for multiple pulmonary complications. These include PTX and pleural effusion in the immediate postoperative period. After the first 24 hours, patients sometimes develop acute lung injury (ALI), ARDS, or pneumonia. Diaphragmatic dysfunction secondary to phrenic nerve injury may occur.

Residual PTX is often seen on the initial postoperative chest radiograph and is commonly on the left side as a result of opening the left parietal pleura during dissection of the left internal mammary artery (LIMA). The PTX usually resolves spontaneously as the chest tubes are placed on suction. Occasionally, a PTX is seen on the right side as a result of accidental incision of the right parietal pleura. Right PTX may progress to tension PTX and significant hemodynamic deterioration. This diagnosis should be considered in any unstable patient. Treatment consists of insertion of an additional chest tube.

Pleural effusion in the first 24 hours after cardiac surgery should raise the suspicion of hemothorax. Effusions should be watched carefully for expansion and correlated with other signs and symptoms of continued bleeding. Massive, expanding hemothorax is an indication for immediate re-exploration and hemostasis. Pleural effusion after the first 24 hours is generally a benign process. Most pleural effusions resolve spontaneously. Thoracocentesis should be performed only if the effusion occupies more than 50% of the lung field on radiography or if the patient has significant impairment of respiratory function.

Atelectasis, especially of the left lower lobe, remains an important problem in the management of cardiac surgery patients. There have been many improvements in surgical techniques, but entering the thoracic cavity and pleura irritation from chest tubes can be painful. Adequate analgesia and incentive spirometry are mainstays in the management in the first 24–48 hours. Volume overload can lead to hypoexpansion, especially in the lung bases. Earlier mobilization helps, but it also leads to increased blood flow in the bases, which may increase hypoxemia by shunting. Patients can develop fever, impaired gas exchange, and if not addressed, postoperative pneumonia in the areas of atelectasis. Treatment is best begun proactively. Correction of volume overload, pain management, early mobilization, incentive spirometry, and aggressive pulmonary toilet with noninvasive positive pressure may also be beneficial. Continuous positive airway pressure

and high-flow nasal oxygen are some of the modalities that may be used by respiratory therapy to help avoid reintubation.

Cardiac surgery is associated with surfactant dysfunction[62]; however, ALI and ARDS are rare (<0.5%) complications after cardiac surgery, CPB, and blood transfusion. The mortality rate associated with this complication ranges between 15% and 70%.[63] During the postoperative period, patients with ARDS were more likely to have had prior cardiac surgery or received more blood products and developed shock more frequently than patients without ARDS.[64] Transfusion-related lung injury (TRALI) is a common cause of morbidity or mortality related to the administration of blood products.[65] The current hypothesis is that there is a "two-hit phenomenon." The first insult is that the patient is in a heightened inflammatory state. This sensitizes the individual for the second "hit," which is the transfusion with blood products that further activates or enhances the proinflammatory state.[66] CPB provides the first hit with overall activation of the immune system. The intraoperative or postoperative need for transfusion is the second insult. Treatment of TRALI is supportive. The principles that apply to ALI are used in this disorder. Volume restriction and low tidal volume ventilation are mainstays of therapy.

Nosocomial pneumonia may complicate any ICU stay. Patients who require mechanical ventilation for longer than 48 hours are at particular risk. These pneumonias are usually caused by aspiration of oral or gastric secretions into the lungs. The incidence of nosocomial pneumonia may be reduced by diligent mouth care to prevent pooling of secretions and elevation of the head of the bed to greater than 30 degrees. Nosocomial pneumonia carries a mortality rate of 24%–50% and warrants appropriate broad-spectrum antimicrobial therapy.[67] Early broad-spectrum antibiotics (based on the cardiac ICU–specific antibiogram) should be initiated and then deescalated once the results of quantitative cultures are available.

Diaphragmatic dysfunction is usually caused by a cold-induced injury of the phrenic nerve as a result of the application of ice slush to the heart as part of the cardioplegia regimen. This complication occurs in up to 2% of patients undergoing cardiac surgery with topical hypothermia.[68,69] While the patient is being ventilated with positive pressure, this injury will not be apparent. If preoperative pulmonary function was normal, unilateral diaphragmatic paralysis usually is well tolerated. Pulmonary function may be severely compromised if pulmonary problems were present preoperatively or if bilateral diaphragmatic injury occurs.[70] Such patients are at an increased risk of developing nosocomial pneumonia, failing to wean from the ventilator, and succumbing to death. Bedside ultrasound has been used as a diagnostic tool for both unilateral and bilateral dysfunction and can also be used to monitor recovery of the paralyzed diaphragm. Diaphragmatic dysfunction usually resolves spontaneously within 3–4 months.

The risk of deep vein thrombosis (DVT) and pulmonary embolism (PE) is increased in individuals with immobility, delayed recovery, or CHF. The risk may be accentuated in this group by prior history of DVT/PE, recent MI, obesity, hyperlipidemia, and heparin-induced thrombocytopenia (HIT). Given the high risk of DVT in patients undergoing cardiac surgery, the actual incidence of PE is low, and fatal PE is negligible. Even though these rates are lower than other major surgical specialties, this should not be an argument against DVT prophylaxis. Strong consideration should be given to prophylaxis in the first 48 hours postoperatively. Sequential decompression devices have been used in patients who remain intubated in the ICU, but are not recommended as routine primary prophylaxis after cardiac surgery. There has been no evidence that prophylactic dosing of anticoagulants leads to increased bleeding in routine postoperative cardiac surgical patients if initiated after 48 hours.

Continued Bleeding

Continued bleeding is a common problem and requires immediate and aggressive management before the onset of further complications. The reasons for continued bleeding are often multifactorial and include inadequate surgical hemostasis, platelet dysfunction, coagulopathy, and inadequate heparin reversal. Often these factors occur in combination, and patients undergoing valve replacement are at an increased risk.[71]

Multiple clotting abnormalities are possible, most of which result either directly or indirectly from the use of CPB.[72] The tubing, blood reservoir, and oxygenator membrane are all foreign surfaces that may activate the clotting cascade. Because the pump must be primed with either normal saline or lactated Ringer's solution, the priming process leads to substantial dilution of all blood components, including red blood cells, platelets, and clotting factors. After CPB, the platelet count is decreased and the remaining platelets are functionally deranged.[73,74] There is sequestration of platelets in the liver, spleen, and CPB circuit itself. Systemic fibrinolysis caused by activation of this system by the CPB circuit occurs.

Inadequate reversal of heparin should be diagnosed at the bedside by the activated coagulation test (ACT) or by measuring the activated partial thromboplastin time (APTT). Because the half-life of heparin is longer than that of protamine, heparin-induced anticoagulation may rebound in the immediate postoperative period. The treatment is administration of additional protamine.

Currently the most accurate and effective measure of bleeding is obtained using a thromboelastogram (TEG). The drawback of even the rapid TEG is that the results take some time. However, it remains the most specific test to identify coagulopathies so that they can be identified and treated in a more targeted manner.[75] In the absence of a TEG, complete blood cell count, calcium levels, full metabolic panel (to evaluate uremia and hepatic function), prothrombin time, international normalized ratio, and fibrinogen levels can all be useful in identifying sources of bleeding requiring correction.

Renal Dysfunction

Mild renal dysfunction is a common postoperative event (7%),[76] with approximately 1% of patients diagnosed with acute renal failure (ARF) requiring renal replacement therapy. These patients have increased morbidity and mortality with prolonged ICU length of stay as much as fivefold.[76]

A multicenter study of 2222 patients undergoing CABG identified five independent preoperative predictors of renal dysfunction: age 70–79 years or 80–95 years, CHF, previous myocardial revascularization, type 1 diabetes mellitus (DM) or preoperative serum glucose levels exceeding 300 mg/dL, and preoperative serum creatinine levels of 1.4–2.0 mg/dL. Independent perioperative factors that exacerbated risk were CPB lasting 3 hours or longer and various measures of ventricular dysfunction.[76]

Renal dysfunction tends to follow one of the three main patterns.[77] *Abbreviated ARF* (creatinine peaks on postoperative day 4) is a transient event, most probably related to intraoperative renal ischemia. *Overt ARF* (creatinine peaks at a higher level than abbreviated ARF and then decreases over weeks) occurs when the duration of the predisposing insult, usually low CO, is longer. *Protracted ARF* (frequently irreversible renal failure) occurs when a second insult, commonly sepsis or hypotension, is superimposed on the resolving renal function.

Neurologic Complications

Neurologic sequelae of CPB range from subtle neurocognitive deficits (appearing in up to 80% of patients) to stroke. To estimate the relative risks of neurologic sequelae associated with various clinical factors, a logistic regression model was applied to prospectively collected data

from 273 patients enrolled at 24 American medical centers.[78] Adverse cerebral outcomes occurred in 16% of patients and were almost equally divided between type I (8.4%; 5 cerebral deaths, 16 nonfatal strokes, and 2 new transient ischemic attacks) and type II outcomes (7.3%; 17 new cases of intellectual deterioration persisting at hospital discharge and 3 cases of newly diagnosed seizure disorder). Resource use for these patients was significantly increased: median ICU stay was prolonged from 3 days to 6–8 days, and total duration of hospitalization was increased by 50% (type II outcomes) to 100% (type I outcomes). After discharge from the acute care setting, specialized care was required for 69% of the patients with adverse neurologic sequelae. Risk factors for type I outcomes related primarily to embolic phenomena include proximal aortic atherosclerosis, intracardiac thrombus, and intermittent clamping of the aorta during surgery. Risk factors for type II outcomes included, in addition to these factors, a preoperative history of endocarditis, alcohol abuse, perioperative dysrhythmia, poorly controlled hypertension, and low CO after CPB.

Injury to the brachial plexus during cardiac surgery is not infrequent but is underdiagnosed and underreported because it is often transient.[79] The mechanisms proposed for this injury are multiple. Hyperabduction of the arms, traction, and compression during sternal retraction and direct trauma owing to insertion of internal jugular lines have been postulated as possible mechanisms of injury. Harvesting of the internal mammary artery with asymmetric sternal retraction has been reported to have a higher rate of plexopathy.

Postoperative delirium is a prevalent issue across all ICUs.[80] Multiple factors contribute to this disorder. The aging population, disruption of sleep patterns, central nervous system (CNS) active medications, and loss of visual cues in unfamiliar surroundings are a few considerations that should be taken into account. Frequent reorientation, allowing for a more normal sleep-wake environment, and engaging familiar people or family may be useful nonpharmacologic maneuvers. Patients may need sedation if they are a threat to themselves or others, but these agents should be avoided because they may be of transient benefit in the short term and worsen or prolonged the delirium. The hyperadrenergic state that accompanies this delirium may be detrimental in the postoperative patient and should be treated with beta-blockers and other antihypertensives. Short-acting agents are preferred because as the delirium lifts, the adrenergic activation may resolve with resultant hypotension. Drug and alcohol withdrawal are important considerations and a frequently missed diagnosis in the ICU population with delirium. Finally, seizures are rare in the immediate postoperative period.[81] Seizures in the postoperative population either herald an underlying, unrecognized neurologic defect or are related to drug withdrawal (therapeutic drugs, illicit drugs, or alcohol). On rare occasions, a global tonic-clonic seizure may develop in patients who are hypoglycemic or hypoperfused. After seizures are controlled, a computed tomography (CT) scan of the brain should be performed to rule out CNS pathology. The next step would be an electroencephalogram, as some anticonvulsants may be proconvulsants at elevated levels. Some cardiac medications, like lidocaine at toxic levels, may lower the seizure threshold. This can be seen in individuals with renal failure at normal dosing of lidocaine. Tranexamic acid has proconvulsant activity.[82] This antifibrinolytic agent should be avoided in any individuals with a seizure disorder or in those who have exhibited seizures in the perioperative or postoperative period.

Gastrointestinal Complications

Acute abdominal complications are relatively rare after cardiac surgery. If they do occur, they are associated with extremely high rates of morbidity and mortality. One prospective study of 1116 patients undergoing CPB found that abdominal complications occurred in 23 (2.1%). Ten of these patients underwent subsequent abdominal surgery, and 20 died. Early complications occurred on postoperative days 6 and 7 and consisted of bowel ischemia or hepatic failure. These complications are probably related to perioperative hypotension and low CO.[83] Late complications consisted of pseudomembranous colitis, cholecystitis, pancreatitis, and rupture of a septic spleen.[84]

Mild transient increases in circulating levels of hepatocellular enzymes are common after surgery. These changes are generally of no consequence; however, increased serum transaminase levels, if sustained or very high (e.g., serum alanine aminotransferase concentration >500 IU/L), may represent evidence of severe ischemic injury of the liver and carry a high risk of mortality. This complication is strongly associated with low CO and increased filling pressures, suggesting that liver ischemia is induced by a combination of decreased perfusion and venous congestion.[85]

Infections

Sternal wound infections can be a late complication after surgery associated with significant morbidity. The risk factors associated with these infections are obesity, DM or perioperative hyperglycemia, mobilization of bilateral internal mammary artery for grafting, prolonged duration of surgery (>5 hours), staple use for skin closure, obstructive airway disease, prior cardiac surgery, blood transfusion, and end-stage renal failure on dialysis.

MANAGEMENT OF COMMON POSTOPERATIVE PROBLEMS

Optimization of Cardiac Output

Treatment of hypotension and low CO must be tailored to the cause (Box 144.2). Again, it is useful to consider treatment in terms of

BOX 144.2 Causes of Postoperative Hypotension

Hypovolemia
- Hemorrhage

TABLE 144.3 Comparison of Relative Activity of Available Vasoactive Agents

Agent	α_1	β_1	β_2	Phosphodiesterase Inhibition	Dose (mcg/kg/min)
Epinephrine	++	+++	+	−	0.01–0.15
Norepinephrine	++++	+++	+	−	0.01–3
Dopamine	++	++	+	−	2–20
Dobutamine	+	+++	+	−	2–20
Phenylephrine	+++	−	−	−	0.4–9.1
Milrinone	−	−	−	+++	0.375–0.75

−, no activity; +, mild activity; ++, moderate activity; +++, strong activity.

preload, contractility, afterload, and rate and rhythm. Inadequate filling pressures are treated with volume infusion. The intravascular volume expander may be a crystalloid solution, a colloid solution, or packed red blood cells if hematocrit is low or there is evidence of ongoing bleeding. It is important to remember that inotropic therapy is ineffective and possibly detrimental if adequate blood volume is not restored.

If CO or blood pressure remains low despite intravascular volume resuscitation, then it is necessary to institute an inotropic or vasopressor support. No single agent is optimal in all cases. Rather, selection of the agent should be based on the suspected cause of low CO or hypotension and knowledge of pharmacologic effects of the various inotropic and vasopressor drugs that are available (Table 144.3). If the primary cause of hypotension appears to be vasodilatation, administration of a vasoconstrictor (e.g., phenylephrine, norepinephrine, or vasopressin) is indicated. If hypotension is related to inadequate ventricular ejection, then inotropic therapy (e.g., epinephrine, norepinephrine, dopamine, or dobutamine) with a beta-adrenergic agent should be instituted. In patients with chronic systolic dysfunction, response to these agents may be impaired. Chronically elevated levels of circulating catecholamines deplete myocardial norepinephrine stores and down-regulate the expression of myocardial beta-adrenergic receptors. In these patients, tachyphylaxis to beta-adrenergic agonists may develop rapidly. Adding a phosphodiesterase inhibitor (e.g., amrinone or milrinone) is often effective in these patients.[86,87] In all cases, agents should be titrated to achieve adequate end-organ perfusion.

Three recent large randomized controlled trials (RCTs)[88–90] did not demonstrate any benefit of perioperative levosimendan, and a meta-analysis of five low-risk-of-bias trials including 1910 patients showed no association between levosimendan use and mortality, acute kidney injury (AKI), need for renal replacement therapy, MI, or ventricular arrhythmias, but did show an association with a higher incidence of supraventricular arrhythmias.[91]

Mechanical Support of the Circulation

Failure to respond to appropriate vasopressor or inotropic therapy may necessitate mechanical support of the circulation. IABP is the most commonly used method. The balloon is positioned in the aorta just distal to the take-off of the left common carotid artery. Inflation of the balloon during diastole increases the diastolic pressure above the balloon, thereby increasing the coronary perfusion pressure. Conversely, deflation during systole decreases the LV afterload. This combination of hemodynamic effects ameliorates myocardial ischemia and improves CO. The common reasons for intraaortic balloon counterpulsation use in cardiac surgery are left main disease >70%, LV ejection fraction <0.4, unstable angina, reoperation, and failure to wean from CPB.

Ventricular assist devices (VADs) are more effective than IABP for maintaining CO. Either the left ventricle or the right ventricle or both may be supported with VADs. Currently, VADs may be used either as a bridge to transplantation or as a bridge to recovery. Either situation assumes that the VAD is a time-limited intervention. There are some data to support the view that resting the heart through the use of a VAD may allow some recovery of acutely injured myocytes, permitting eventual withdrawal of mechanical support. If the heart is chronically diseased, there is little hope of recovery, and the VAD serves to support the patient until transplantation becomes possible.[92–94]

Ongoing clinical trials are investigating the use of VADs as definitive therapy rather than as a bridge to transplantation. Implantation of these devices may increase the long-term survival of patients with end-stage heart failure.[95]

Emergency Reoperation

Emergency re-sternotomy is indicated as part of resuscitation when hemodynamic stability cannot be rapidly re-established with conventional means. Advantages compared with closed-chest resuscitation include establishment of the cause of instability, correction of the cause (e.g., tamponade, kinked graft), more effective cardiac massage, and direct establishment of atrial and ventricular pacing. Re-sternotomy also enables the re-establishment of CPB and regrafting or correction of mechanical abnormalities as required. Infectious complications of emergency re-sternotomy are probably increased, but the incidence is not prohibitive.

Cardiac arrest can occur as progression from refractory postoperative shock or as an unheralded event. Resuscitation protocols should be immediately initiated; however, the applicability of advanced cardiac life support protocols is limited in postoperative cardiac patients. Specific guidelines for the ICU resuscitation of postoperative cardiac arrest, known as *cardiac advanced life support,* have been published.[96] These include up to three immediate attempts at defibrillation of either ventricular fibrillation or ventricular tachycardia. Timely defibrillation is critical. Similarly, epicardial pacing can be attempted for asystole or severe bradycardia if epicardial leads are in place. Attempts at defibrillation or pacing should take precedence over chest compressions.

Management and Correction of Arrhythmias

Afib is the most commonly encountered arrhythmia after cardiac surgery. Prophylactic use of beta-adrenergic blockers reduces the incidence of postoperative Afib, and they should be administered after cardiac surgery to all patients unless specific contraindications are present.[97] Prophylactic treatment with amiodarone and atrial overdrive pacing should be considered for patients who are at high risk for postoperative Afib (e.g., those with a history of previous Afib or mitral valve surgery).[98]

If Afib develops after cardiac surgery, the intensivist needs to determine whether the primary strategy should be to control the ventricular rate or to restore normal sinus rhythm. If Afib is associated with hemodynamic instability or anticoagulation is contraindicated, rhythm management using electrical cardioversion or amiodarone is preferred.[99,100] Overdrive pacing using atrial pacing wires also may be effective. The appropriate strategy for most stable patients may be control of ventricular rate, because most will spontaneously revert to sinus rhythm within 8 weeks after discharge.[101,102] Appropriate agents to achieve ventricular rate control include intravenous or oral beta-adrenergic blockers or calcium channel blockers. All patients with Afib

persisting for longer than 24–48 hours should be anticoagulated unless there is a specific contraindication. Long-term outcomes are similar regardless of whether the rate-control strategy or the rhythm-control strategy is selected.[103,104]

Postoperative ventricular arrhythmias should be treated immediately according to the current advanced cardiac life support protocols.[24] Any postoperative ventricular arrhythmia should prompt a search for an underlying cause. Importantly, ischemia should be ruled out. Patients with sustained ventricular arrhythmias should undergo electrophysiologic testing before long-term antiarrhythmic therapy is instituted. The implantable cardioverter-defibrillator device has been shown to be superior to drug therapy for patients with hemodynamically significant arrhythmias.[105]

Hypertension in the Postoperative Period

Hypertension leading to an increase in ventricular afterload is a common cause of decreased CO. Hypertension may be controlled by an intravenous infusion of sodium nitroprusside, nitroglycerin, beta-adrenergic antagonists, or calcium channel blockers. These agents should augment CO by reducing blood pressure and afterload in the hypertensive patient. Frequently, acute hypertension resolves within 24–48 hours postoperatively. If hypertension persists beyond this initial period of recovery, intravenous agents should be weaned and oral therapy initiated. Both beta-adrenergic blockers and angiotensin-converting enzyme inhibitors have been shown to confer a long-term mortality benefit and should be started. If hypertension was not a problem preoperatively, prolonged antihypertensive therapy postoperatively usually will not be necessary.

Correction of Coagulopathy

Postoperative coagulopathy may promote bleeding and accumulation of blood in the chest or pericardial cavity. Aggressive measures must be used to correct the coagulopathy. A systemic approach to the evaluation and treatment of continued bleeding is needed; one such approach is outlined in Table 144.4. Hypothermia may contribute to coagulopathy. Therefore profoundly hypothermic ICU patients must be actively rewarmed with the use of transcutaneous warming. Laboratory evaluation of suspected coagulopathy should include measurements of platelet count, prothrombin time (PT), APTT, ACT, and bleeding time. The use of TEG may be useful to guide component transfusion requirements.

TABLE 144.4 Evaluation and Treatment of Postoperative Coagulopathy

Coagulation Test	Normal Range	Suggested Treatment
Body temperature	–	If less than 35.5°C, the patient should be actively rewarmed.
PT	11–13.3 seconds	Consider fresh frozen plasma or cryoprecipitate or prothrombin complex concentrate.
PTT	21–32 seconds	Consider additional protamine.*
Platelets	140,000–440,000/μL	If <100,000, transfuse platelets.
Fibrinogen	150–360 mg/dL	If <100, transfuse cryoprecipitate.
Bleeding time	2.5–9.5 min	If prolonged and platelet count is normal, consider platelet dysfunction and treat with DDAVP and/or cryoprecipitate.
ACT	90–120 seconds	Consider additional protamine.*

ACT, Activated coagulation test; *DDAVP,* desmopressin acetate; *PT,* prothrombin time; *PTT,* partial thromboplastin time.
*Excessive protamine may itself cause bleeding.[106]

Two RCTs have examined transfusion goals after cardiac surgery. In the Transfusion Requirements After Cardiac Surgery trial,[107] 502 patients were randomized to either a restrictive (maintain hematocrit ≥24%) or liberal (hematocrit ≥30%) transfusion strategy. There was no difference in mortality or major morbidity, and PRBC use was decreased by 60% by the restrictive strategy. The second trial is the Transfusion Indication Threshold Reduction trial, which randomized 2003 elective cardiac surgical patients to a restrictive (maintain hemoglobin ≥7.5 g/dL) or liberal (hemoglobin ≥9 g/dL) transfusion strategy.[108] In this study, blood use was significantly decreased by nearly 40% in the restrictive group (53% of patients received a transfusion vs. 92% in the liberal group), and there was no difference between the groups in the study's primary composite outcome of serious infection (sepsis or wound infection) or an ischemic event (permanent stroke [confirmation on brain imaging and deficit in motor, sensory, or coordination functions], MI, infarction of the gut, or AKI) within 3 months after randomization.

Management of Postoperative Bleeding

Bleeding that continues after correcting coagulopathy needs to be treated aggressively. Venous bleeding in the chest may be partially controlled by applying positive end-expiratory pressure (PEEP).[109,110]

Continuing mediastinal hemorrhage, or the suspicion of cardiac tamponade, is an indication for immediate re-exploration. Exsanguinating hemorrhage or impending arrest from tamponade may require that re-exploration be carried out at the bedside in an ICU. Bleeding that is unresponsive to medical therapy and requires re-exploration is usually associated with a surgical source. Accepted guidelines for reoperation include bleeding rates of 400 mL/hr for 1 hour, 300 mL/hr for 2 hours, or 200 mL/hr for 3 hours. A sudden decrease or total cessation of drainage from mediastinal tubes may be equally ominous. Cessation of drainage from a mediastinal or chest tube may be caused by clotted blood occluding the tube. If bleeding persists but drainage ceases, the result may be tamponade.

Re-exploration is associated with increased morbidity and mortality. However, this increased mortality and morbidity may be partially explained by delays in the decision to re-explore that lead to avoidable open-chest resuscitations in the ICU.[111,112]

Management of Postoperative Renal Failure

The cornerstone of prevention and treatment of renal failure in the cardiac surgical patient is the maintenance of adequate renal perfusion. This goal is best achieved by optimizing circulating blood volume and CO. Multiple pharmacologic regimens for renal protection have been described. Dopamine at low "renal" doses (1–3 μg/kg per minute) has been used. The rationale for this strategy is that dopamine activates type 1 dopaminergic (DA1) receptors, leading to renal artery dilation, natriuresis, and diuresis. However, numerous human studies have failed to show that low-dose dopamine prevents renal failure or improves survival.[113] Even low doses of dopamine increase CO, and this may be the basis for any increase in urine output observed.[114] Fenoldopam[115] and dopexamine[116] are DA1 receptor antagonists that have also been proposed as renal protective agents and used with mixed success.[117]

Loop diuretics such as furosemide have been proposed as renal protective agents, not only because of their ability to produce diuresis and natriuresis but also because these drugs may reduce medullary tubular oxygen consumption. Mannitol, an osmotic diuretic, has been

used to prevent the development of ARF. Neither mannitol nor furosemide has been shown to improve outcomes in patients with ARF.[76] Indeed, these drugs may be deleterious because of their ability to promote diuresis and thus exacerbate hypovolemia and inadequate renal perfusion.

The failure of pharmacologic means of preventing and treating renal failure has led to interest in other methods. Early and intensive use of continuous venovenous hemofiltration achieved a better-than-predicted outcome in patients with severe ARF who underwent cardiac operations.[118]

Glucose Control

Studies have shown that tight control of blood glucose level in the ICU is associated with an increase in morbidity and mortality. Hyperglycemia and insulin resistance are common in critically ill patients, even those who have not previously had DM. Results of a prospective randomized controlled study[119] in which 6104 critically ill adult patients were randomly assigned to receive either intensive insulin therapy (maintaining blood glucose concentration between 80 and 108 mg/dL) or conventional treatment (infusing insulin to keep blood glucose level 180 mg/dL or less) showed that, at 3 months, the intensive insulin therapy group had an increase in hypoglycemic episodes and ICU mortality.

OUTCOMES OF CARDIAC SURGERY

Increasingly, healthcare is being driven by outcome data. Cardiac surgery has been one of the leading specialties in this field. It is difficult to assess results from crude mortality data, because these do not take into account case complexity and differing preoperative risks among patients. Crude comparisons of death rates may be misleading and may encourage surgeons to practice risk-averse behavior. Death rates should be stratified by risk. It is, however, possible to make some generalizations. Among low-risk patients undergoing CABG, mortality rates lower than 2% are achievable.[120] Higher mortality rates are to be expected in selected subgroups of patients with major preoperative risk factors (e.g., poor ventricular function, advanced age, and comorbid conditions) or major operative risk factors (e.g., reoperative surgery and complex operations). Euro SCORE II is the predominant preoperative cardiac surgical risk score, but this performs less well as an ICU score. The majority of ICU scoring systems are also not designed with cardiac surgery patients in mind.

A prospective cohort of 27,239 consecutive patients undergoing isolated CABG was examined to determine the risk factors for hospital mortality. After adjustment for patient and disease characteristics, the following comorbid conditions were found to be related to postoperative mortality: DM, vascular disease, chronic obstructive pulmonary disease, peptic ulcer disease, and dialysis-dependent renal failure.[121]

Cardiac surgery is being performed more frequently in patients aged 80 years and older. In one study, the 30-day mortality rate for patients aged 65–75 years was 3.4% and for those older than 80 years was 13.5%. Older patients had longer ICU and postoperative lengths of stay. Although emergency operations and complex procedures carry high risks for octogenarians and increasing costs for society, most of these patients may be offered operation with short-term morbidity, mortality, and resource use that only modestly exceed those of younger patients.[122] Once discharged from the hospital, older patients report a high quality of life.[123]

Overall, fewer than 10% of cardiac surgical patients spend more than 48 hours in the ICU. Most survive and eventually report improved functional status and a reasonable quality of life.[124,125]

SPECIFIC PROCEDURES AND CONSIDERATIONS[126]

Coronary Artery Bypass Graft

Long-term graft patency has been dramatically improved by the use of arterial conduits; the LIMA is the conduit of choice for bypassing the left anterior descending coronary artery. Saphenous venous grafts are commonly used to bypass other vessels. Aspirin, at recommended doses of 100–325 mg daily, increases long-term graft patency and reduces mortality, MI, stroke, bowel infarction, and renal failure after CABG. Beta-blockers reduce the risk of postoperative Afib and may also reduce myocardial ischemia and mortality. It is reasonable to start with a low dose (e.g., metoprolol 12.5–25 mg twice daily) and increase as tolerated by heart rate and hemodynamics.

Off-Pump CABG

Compared with conventional CABG, off-pump CABG (OP-CABG) patients are less coagulopathic, have less bleeding, and require fewer transfusions; some studies have reported fewer immediate postoperative respiratory and renal complications than after on-pump CABG.[127] The rate of immediate perioperative strokes appears to be reduced, and OP-CABG may have a particular niche when aortic atherosclerosis precludes cross-clamping. However, there appears to be no difference between OP-CABG and conventional CABG in terms of risk of renal injury requiring dialysis, risk of stroke, or neurocognitive. dysfunction.

Endocarditis Vascular Surgery

These patients may have acute or subacute presentation. They should be managed by a multidisciplinary endocarditis team, including cardiac surgeons, cardiologists, and microbiologists. Early organism identification can aid antibiotic selection and duration. Prior undiagnosed end-organ damage may present postoperatively, and a high index of suspicion is required. If expedited surgery occurs, there may be a massive inflammatory response with bleeding and hypotension. If it persists, a secondary source of infection must be sought through clinical and radiologic examination.

Mitral and Tricuspid Valve Surgery

In the developed world, surgery for mitral incompetence is more common, whereas mitral stenosis predominates in nations with undeveloped economies. Pulmonary hypertension, RV pressure overload and impairment, and tricuspid valve regurgitation may develop with long-standing disease. These conditions significantly increase the risk of cardiac surgery; therefore expert management is demanded. Tricuspid valve repair with a de Vega suture or an annuloplasty ring is increasingly performed at the same time as left-sided surgery. The treatment of pulmonary hypertension with pulmonary vasodilators may be needed in addition to inotropic support of the right ventricle and appropriate ventilator settings. Monitoring with a pulmonary artery catheter and phosphodiesterase inhibitors have a role here, but dose titration to avoid refractory hypotension is important.

Long-standing mitral disease can cause pulmonary hypertension and RV compromise; the stress of surgery and CPB can incite acute postoperative RV failure. Inhaled pulmonary vasodilators may be useful if RV failure develops. A unique feature of mitral valve repair is the development of dynamic LVOT obstruction caused by systolic anterior motion (SAM) of the anterior leaflet of the mitral valve, which is typically the result of a mismatch between leaflet tissue and mitral annular size and occurs in approximately 5% of patients after mitral repair.[128,129] SAM occurs when the anterior leaflet or chordae of the mitral valve paradoxically moves toward the interventricular septum during systole, causing dynamic LVOT obstruction, reduced CO, and

potential hemodynamic collapse. SAM is exacerbated by an underfilled, hyperdynamic left ventricle; thus management consists of adequate volume resuscitation, avoidance of inotropes, minimizing tachycardia, and early beta-blockade.

Aortic Valve Surgery

Appropriate fluid management is essential, especially when surgery is performed for aortic stenosis (AS), as the hypertrophied left ventricle is exquisitely sensitive to preload. Blood pressure control after aortotomy is important to limit stress on the aortic suture line. Any sudden increase in bleeding should raise concern regarding the integrity of the aortotomy closure. The postoperative ECG must be evaluated for conduction disturbances and ischemia, as injury to the conduction system occurs not infrequently, often from placement of sutures through conduction tissue. Conduction disturbances typically manifest within the first 3 postoperative days.[130] Malpositioned aortic valve prostheses can occlude either coronary ostia; the right is particularly at risk. Finally, manipulation of the aorta is a risk factor for cerebral embolism, and a postoperative neurologic examination should be performed once feasible.

Surgery for Hypertrophy Obstructive Cardiomyopathy

Patients with symptomatic hypertrophic obstructive cardiomyopathy suffer from exertion dyspnea and fatigue. A dynamic outflow obstruction in the LVOT is often the underlying lesion. Surgery involves septal myectomy, which alleviates this obstruction and coexisting mitral regurgitation. Diastolic dysfunction is common in these patients, and they do not tolerate Atrial fibrillation (A-fib). In addition, inotropes should be avoided. There is an increased risk of heart block, and these patients may need permanent pacemakers.

Transcutaneous Aortic Valve Insertion

Transcutaneous aortic valve insertion (TAVI) allows treatment of AS in patients felt not to be medically fit for open surgery. This is often the result of advanced age, LV dysfunction, and multiple comorbidities. Compared with medical therapy for those patients unable to have open surgery, TAVI reduces mortality. However, there is an increase in stroke and vascular complications.[131] On the ICU, these patients have a high risk of delirium. Because of their premorbid state, the risks of other organ failure is raised, and they may benefit from prolonged postoperative monitoring.

Ascending Aorta and Aortic Arch Surgery

Ascending aortic procedures include aneurysm repair with interposition tube grafts, aortic root replacements, aortic arch replacements, and emergent repair of dissections.

Aortic surgery involves a period of deep hypothermic circulatory arrest, which can be up to 30 minutes at 18°C. These patients should be carefully rewarmed in theater, and the avoidance of pyrexia is a key postoperative precaution. Active cooling may be considered. High arterial pressures are avoided to minimize the risk of extending arterial intimal dissection; however, the maintenance of cerebral circulation must be considered. There is a high vascular complication rate in these patients, with a mortality rate of 8%–15% and stroke rates of 7%–11%.[132] Subtle long-term cognitive dysfunction is common.[133]

In aortic root replacement procedures (e.g., valve-sparing root replacement or replacement of the aortic root, valve, and ascending aorta with a composite prosthetic valve and graft [the Bentall procedure]), the coronary arteries are reimplanted into the graft, and coronary occlusion or kinking with resultant myocardial ischemia is possible. This typically involves the right coronary artery, and new RV failure should raise concern for right coronary artery occlusion.[134]

CONCLUSIONS

Most cardiac surgical patients may be discharged from the ICU to a step-down unit within 24–48 hours after operation, but an increasing number cannot. Patients who require longer and more intensive services in the ICU are typically older and sicker preoperatively. Adherence to best practices in the ICU optimizes the opportunity for even these high-risk patients to survive their operation and achieve a good quality of life after hospitalization.

The ongoing development of less invasive techniques in cardiology and cardiac surgery will paradoxically bring about a further increase in the complexity of cases treated in the cardiac surgical ICU, as patients who are less sick are treated elsewhere. This trend will lead to increasing challenges for intensivists working in these units and allow them to continue to be at the forefront of critical care medicine.

ACKNOWLEDGMENTS

We acknowledge the significant contribution to the previous edition chapter by Drs. Patrick J. O'Neill, Conrad F. Diven, and Daniel R. Meldrum. The chapter from the previous edition was used as a template for this updated version. Although multiple aspects were expanded or updated, significant aspects of it were incorporated without alteration.

KEY POINTS

- Developments in interventional cardiology have led to older and medically complex populations being referred for cardiac surgery.
- Much of the care of cardiac surgical patients should be protocol driven and conducted in specialized units.
- Most patients undergoing cardiac surgery require only a shorter ICU stay.
- Patients may be extubated once hemodynamic stability is achieved and mediastinal bleeding is deemed to be under control.
- Low CO after surgery should be treated based on the components of the CO: rate, rhythm, preload, afterload, and contractility.
- Afib continues to be a cause of significant morbidity.

Intensive Care Unit Management of Lung Transplant Patients

Satish Chandrashekaran, Amir M. Emtiazjoo, and Juan C. Salgado

OVERVIEW OF LUNG TRANSPLANT

Lung transplantation offers hope for improved survival and quality of life for selected patients with end-stage lung disease. The availability of suitable donor organs and preservation injury remain the initial limiting factors to successful transplantation. Novel techniques aiming to extend the donor pool have resulted in the ability to offer transplantations to more patients, both by allowing for better evaluation of questionable organs and by allowing potential treatment and repair of injured organs.[1,2] Like other solid organ transplants, rejection and infection, in addition to organ system dysfunction associated with the perioperative course, remain challenges.[3] However, over 40 years of experience have led to substantial improvements in early outcome. This experience has been reflected in changes in various aspects in the field, including a different allocation system wherein priority is given based on medical urgency and expected outcome,[4] donor and recipient assessments, innovative surgical techniques, better understanding of early complications, and the development of newer immunosuppressive medications.

Diagnoses for which adults undergo lung transplantation include chronic obstructive lung disease (COPD) from emphysema (32%); interstitial lung disease (24%); cystic fibrosis (16%); alpha-1 antitrypsin deficiency (5%); and other conditions, including sarcoidosis, congenital heart disease, and connective tissue disease complicated by advanced lung disease.[3] Over the past 2 decades, the number of single-lung transplant (SLT) procedures has remained stable, and the number of bilateral lung transplant (BLT) procedures has seen a steady increase. In recent years, most recipients who had the most common indications for lung transplantation underwent bilateral procedures, with COPD, either from emphysema or alpha-1 antitrypsin deficiency, being the most frequent diagnosis prompting transplantation. This has been the setting in which the trend toward bilateral transplantation has been more noticeable.[3]

Donor selection, procurement, and lung preservation protocols tend to be individualized on an institutional basis. The limited availability of donor lungs, however, has increased the scrutiny with which organs are judged in order to avoid rejecting them inappropriately. Significant lung contusion, smoking-related lung damage, pneumonia, pulmonary edema, and significant aspiration are prime concerns in evaluating the suitability of donor organs. Although already described as an independent association for primary graft dysfunction (PGD),[5] donor's older age is being challenged at some centers as a risk factor for worsened outcomes. More transplants are being performed when the donor does not meet overly stringent criteria.[6] Procurement and lung preservation protocols often include administration of antiinflammatory agents, pulmonary vasodilators, and antioxidants.

The surgical technique involves thoracotomy for SLT or transverse thoracosternotomy (clamshell incision) for BLT transplants. Minimally invasive techniques are being developed in some centers as well. The surgical procedure includes anastomoses of the pulmonary artery, atrium, and bronchus. Cardiopulmonary bypass (CPB) is avoided in the case of SLT and BLT, unless preexisting pulmonary hypertension precludes cross-clamping of the pulmonary artery or cardiorespiratory stability cannot otherwise be maintained. On completion of the operation, a double endotracheal tube (EBT) is exchanged for a standard endotracheal tube (ETT), unless allograft function appears tenuous or there is evidence of air trapping. Heart-lung transplants are performed using either a clamshell incision or sternotomy. CPB is obviously a requirement in these patients. The vascular anastomoses include the aorta and a cuff of the right atrium including both vena cavae. Bibronchial airway anastomoses, which are associated with less dehiscence than a single tracheal anastomosis, are performed.

MANAGEMENT OF CRITICALLY ILL LUNG TRANSPLANT CANDIDATES: BRIDGE TO LUNG TRANSPLANT

In recent years, the proportion of candidates requiring support beyond noninvasive measures, including mechanical ventilation and extracorporeal life support (ECLS), has increased, resulting in a larger proportion of patients requiring intensive care management and support before transplantation.[7]

The field has learned that, in large-volume centers,[8] outcomes are unaffected and that the technology around ECLS has evolved to become simpler.[9–12] Technologic advances include heparin-coated circuits, development of polymethylpentene oxygenator membranes, introduction of centrifugal pumps, dual-lumen cannulas, and miniaturized systems. Although these have translated into an increased interest toward the earlier implementation of ECLS, its use has been described as a risk factor for airway dehiscence, stroke, infection, and thromboembolic complications after transplantation.[11] Efforts toward ECLS without mechanical ventilator support—"awake ECLS"—aim to offset the risks of prolonged sedation and subsequent postoperative deconditioning.[13] Awake ECLS has resulted in improved early outcomes.[13]

Intraoperative Issues

The type of surgical incision (clamshell incision vs. anterolateral thoracotomies vs. median sternotomy) for lung transplantation depends on several factors, including single or bilateral lung transplantation, CPB use, history of prior thoracic surgery in the recipient, and surgeon's preference. Bilateral anterior thoracotomy (sternal sparing) performed for BLT has a lower rate of sternal infections and healing complications than the clamshell incision.[14] During surgery, three

anastomoses are made on each side. They include the bronchus, pulmonary artery, and cuff of the pulmonary veins to the left atrium from posterior to anterior. Bronchial artery anastomosis is usually not made. In addition, lymphatic and nerve-ending anastomoses are not made. About 30%–40% of patients require CPB support intraoperatively for hemodynamic instability, hypoxemia, and right ventricular failure after clamping the first or second pulmonary artery. CPB is also commonly needed in recipients with pulmonary hypertension or in situations where independent lung ventilation is impossible.[15] The tubing, cannulas, membrane oxygenators, and pumps used in the CPB machine often trigger a systemic inflammatory response, and patients tend to be hypotensive from the resulting vasoplegia. Intraoperative extracorporeal membrane oxygenator (ECMO) machines have several advantages over CPB. They decrease the length of the circuit, thus decreasing the blood–air interface. There are fewer blood products that are transfused and a lower incidence of PGD.[16] After the surgery, the double-lumen ETT used for independent lung ventilation is exchanged for a single-lumen ETT. The patient is transferred to the intensive care unit (ICU) after chest closure. The patient is then weaned off the ventilator and from EMCO in the ICU.

Lung transplant recipients who have pulmonary hypertension require special attention. During surgery, every effort is made to prevent a sudden rise in pulmonary pressure that may cause right ventricular failure. Intraoperative transesophageal echocardiography (TEE) helps monitor the right ventricular function very closely. Inhaled nitric oxide (iNO), inhaled prostacyclin, and intravenous milrinone are used to support right ventricular function intraoperatively and during the immediate postoperative period.[17]

Immediate Postoperative Intensive Care Unit Management

Weaning the patient off the mechanical ventilator and ECMO is performed by the ICU physician who collaborates with the thoracic surgeon.[18] Stabilization of respiratory function and ventilator weaning are the initial goals when the patient arrives in the ICU from the operating room. Either pressure- or volume-targeted ventilation is used. The goal is to keep the airway pressures low to avoid barotrauma and gas leakage through the fresh bronchial anastomoses, prevent atelectasis, and at the same time avoid volutrauma to the newly implanted grafts. Lung-protective ventilation strategy with tidal volumes (V_T) around 6 mL/kg of predicted body weight and low to moderate positive end-expiratory pressure (PEEP) should be used.[19] High PEEP should be avoided. In patients who undergo SLT, it might be challenging to ventilate the graft, as the compliance of the native lung will be different. Care should be taken to avoid overinflation of the native emphysematous lung, as this might lead to hemodynamic compromise from auto-PEEP (intrinsic PEEP). Patients typically present with hypoxemia, hypercapnia, and hemodynamic instability.

Decreasing the respiratory rate, increasing the expiratory time, and decreasing the PEEP can help. If these measures do not help, brief disconnection from the ventilator circuit should be considered. If the situation continues, double-lumen tube placement and independent lung ventilation should be considered.[20] Likewise, the compliance of the native fibrotic lung will be worse when compared with the new graft. This might risk the overinflation of the newly transplanted allograft. Mild pulmonary edema is a common finding in transplanted lungs because of the absence of lymphatic drainage. This usually clears up in the first few days. If end-organ perfusion is adequate, as indicated by adequate urine output and downtrending lactate, an increase in fluids to boost preload is avoided.[19,21] iNO is frequently used in patients with pulmonary hypertension and right ventricular failure in the operating room. However, the intraoperative use of iNO does not seem to decrease the incidence of PGD.[22,23] The patient is rapidly weaned from iNO in the ICU. As soon as clinical stability is achieved, weaning from the mechanical ventilator is started. The oxygen fraction is steadily decreased if tolerated.[19] The majority of the patients can be weaned and extubated within the first 24 hours.[20,23] Early extubation minimizes the chance of pulmonary infections and lowers stress on the bronchial anastomoses. Patients can be extubated to noninvasive positive-pressure ventilation (NIPPV). This helps in the unloading of the respiratory muscles, decreasing respiratory rate and dyspnea and improving ventilation/perfusion mismatch. NIPPV can also be used in recipients who demonstrate phrenic nerve dysfunction.[24] Patients requiring prolonged mechanical ventilation should be considered for early tracheostomy.[24] In these patients, early tracheostomy would minimize sedation and help with physical therapy while providing easier access for secretion clearance.[15] Patients who require reintubation can also be considered for tracheostomy. If patients cannot be extubated, the decision to perform a tracheostomy should be made by the end of the first week.[25] Although lung transplant recipients who end up with a tracheostomy tend to be sicker, have a longer ICU stay, and require prolonged ventilation, there is no difference in their short- and long-term survival rates compared with recipients who do not have a tracheostomy. Tracheostomy in this population is an important option that enables weaning from the mechanical ventilator and is associated with better patient tolerance.[26] Chest tube removal depends on the 24-hour drainage from each tube. Apical chest tubes are removed first, followed by the basilar tubes, provided their drainage is less than 150 mL/24-hour period.[15] Vigorous airway clearance techniques to mobilize secretions are an essential component of the recovery process after extubation. The cough reflex is blunted in these patients because of denervated lungs and splinting of the chest because of the pain resulting from the incision and the presence of chest tubes. Airway clearance techniques include bronchodilators, incentive spirometry, the flutter valve, chest physiotherapy, and nebulized hypertonic saline.

Pain control is an essential component of postoperative ICU care. Adequate analgesia is critical to prevent splinting of the chest that would cause atelectasis. Fentanyl infusion and patient-controlled analgesia pumps are used once patients are more awake in the immediate postoperative period. Morphine is avoided, as the creatinine clearance tends to fluctuate with the initiation of calcineurin inhibitors, and there is a risk of accumulating toxic metabolites of morphine. During surgery, patients undergo stretching of thoracic joints, ribs, vertebrae, and muscles; manipulation of pleura and lungs; and chest tube placement. All of these cause considerable pain upon waking from anesthesia. Inadequate pain control prevents patients from coughing and expanding the graft, thus increasing pulmonary complications. Moreover, the transplanted lungs are denervated and lack cough reflex. Patients tend to splint from pain, and as a result, diaphragmatic excursions are decreased, causing retention of mucus that leads to atelectasis. Thoracic epidural analgesia is used for unilateral or bilateral thoracotomy. Epidural analgesia also reduces opiate requirements, thus decreasing sedation from opiates and enabling patients to participate more in mobilization and physical therapy.[27] Oxycodone is started once patients are extubated and able to tolerate oral medications. Nonsteroidal antiinflammatory drugs are avoided for analgesia, as they tend to worsen renal function, especially in patients who are on tacrolimus or cyclosporine. More recently, thoracic paravertebral catheter and intercostal cryoanalgesia have been used for postoperative pain control from the clamshell incision and pain emanating from the chest tubes. In thoracic paravertebral catheter analgesia, four paravertebral catheters are placed, two at the T4 level for controlling pain from the clamshell incision and two at the T8 level for pain emanating from chest

tubes. Intercostal cryoanalgesia is performed intraoperatively on intercostal nerves 3–9 bilaterally. Both modalities decrease the amount of opiate required in the postoperative period and aid with pulmonary rehabilitation.[28,29]

Immunosuppression

Immunosuppression is initiated in the operating room. The first dose of an induction agent, basiliximab, is administered on the day of surgery, just before the graft's first perfusion. The second dose is repeated on the fourth postoperative day. The first dose of Solu-Medrol (methylprednisolone) (10 mg/kg) is also administered before the first graft's perfusion. This is followed by 1 g of intravenous mycophenolate mofetil. Tacrolimus is initiated after the arrival of the patient in the ICU. This practice might vary slightly from one center to another.

After transplantation, the main immunosuppressive drugs include a combination of calcineurin inhibitors (tacrolimus or cyclosporine), antimetabolites (mycophenolate mofetil or azathioprine), and steroids. Calcineurin inhibitors are the cornerstone of the regimen. We default all patients to tacrolimus, mycophenolate mofetil, and prednisone. The dose of tacrolimus is gradually titrated to a tacrolimus trough level of 10–14 ng/mL by the end of the first postoperative week while closely monitoring serum creatinine levels. Mycophenolate mofetil is administered at a dose of 1 g twice daily while cautiously monitoring for cytopenias.

Antimicrobials

Broad-spectrum antibiotics that would cover gram-positive and gram-negative organisms are initiated before making skin incisions on the recipient. Typical antibiotics include a combination of vancomycin and cefepime—donor bronchus culture and prior cultures from recipient sputum guide the types and duration of the antibiotics. Trimethoprim-sulfamethoxazole, prophylaxis against *Pneumocystis jiroveci,* is started and given three times a week. Antifungal prophylaxis depends on pretransplant risk factors for *Aspergillus*. Recipients with cystic fibrosis and cavitary disease are thought to have a high risk and are prophylaxed with oral voriconazole or posaconazole or isavuconazole and inhaled amphotericin. Patients who are at low risk for aspergillosis are prophylaxed with itraconazole. The oral prophylaxis is continued for 6 months. Cytomegalovirus (CMV) prophylaxis depends on the CMV serologic status (IgG) of the donor and recipient before the transplantation. If the donor is positive and the recipient is negative (D+/R−, CMV mismatch), the recipient is prophylaxed with daily valganciclovir for a year or longer. If the donor is CMV negative and the recipient is CMV positive (D−/R+) or if the donor and recipient are CMV positive (D+/R+) (intermediate-risk group), the recipient is prophylaxed with Valcyte for 9–12 months. If the donor and recipient are CMV negative (D−/R−, low-risk group), the recipient is prophylaxed with acyclovir, which is effective against all herpesviruses other than CMV.

General Measures

Patients tend to get constipated from immobilization and opiate analgesics used in the immediate postoperative period. This is prevented by instituting scheduled laxatives. Constipation and ileus also interfere with the absorption of immunosuppressive medications. Hence, great care is taken to avoid constipation and the slowing of gut motility. This is especially true in patients with cystic fibrosis who might require more aggressive measures that include osmotic laxatives in addition to stimulant laxatives.[18] On a similar note, electrolyte imbalance could make constipation and ileus worse. Magnesium, calcium, potassium, and creatinine levels need to be monitored closely. Hypomagnesemia results from tacrolimus, proton pump inhibitors, and diuretics in the initial postoperative period. Intracellular levels of magnesium might be lower despite normal serum levels. This should be aggressively corrected to minimize neurotoxicity and cardiac dysrhythmias. Magnesium is a vital cofactor in muscle function and gastrointestinal motility.[18] The incidence of venous thromboembolism in lung transplant recipients is much higher than in other populations. It is thought to be between 8% and 29%. As a result, deep vein thrombosis prophylaxis is enforced as soon as possible with low-molecular-weight heparin.[30]

Lung transplant recipients have a high risk of gastroesophageal reflux from underlying esophageal dysmotility and recent thoracic surgery. Measures to control acid reflux and aspiration include keeping the head of the bed elevated at a 30-degree angle or more and using a proton pump inhibitor. Early and aggressive physical therapy is crucial in the success of lung transplantation to avoid critical care illness neuromyopathy. Once patients are extubated, they are mobilized to sit in a chair twice a day. If patients can achieve adequate analgesia, walking with assistance is encouraged.

POSTOPERATIVE COMPLICATIONS

Infectious Complications

Infectious complications are higher in lung transplant recipients compared with other solid organ transplantations. This most likely relates to the fact that the allograft is exposed to the environment. Moreover, immunosuppression in lung transplantation recipients is much higher than other solid organ transplantations.[31] Bacterial infections of the lower respiratory tract are the most common infectious complications. The risk factors for these include immunosuppressed status, mechanical ventilation, and blunted cough because of pain.

Bleeding Issues

Increased bleeding is frequently seen in recipients who have had previous pleurodesis and use of intraoperative or preoperative extracorporeal circulation (ECMO/CPB). Coagulopathy should be rapidly corrected with the transfusion of blood products. If there is increased bloody chest tube drainage of more than 200 mL/30 min, exploratory surgery should be considered. Even if the source of bleeding is not identified, the evacuation of blood products from the pleural space prevents collapse of the graft and development of compartment syndrome.[19]

Acute Renal Failure

Acute renal failure is a common complication from calcineurin inhibitors. It results from intense afferent arteriole vasoconstriction caused by tacrolimus or cyclosporine, resulting in decreased renal blood flow and glomerular filtration rate. Hypotension or systemic hypertension further worsens renal function. Hypertension should be well controlled, preferably with calcium channel blocking agents.[15,31] Nonsteroidals should be avoided for analgesia. Diuretics should be used sparingly.

Atrial Tachyarrhythmias (Atrial Fibrillation, Atrial Flutter, and Supraventricular Tachycardia)

Atrial tachyarrhythmia is common in this population, occurring in 34%–47% of patients.[15] The incidence is higher in double-lung transplants than in SLTs and tends to appear 3–7 days after surgery. The incidence is also high in older patients, patients who had been on CPB, and patients who had atrial manipulations. Electrolyte imbalance, sympathetic stimulation from pain, and anxiety precipitate atrial fibrillation. Rate control with beta-blockers is preferred. Antiarrhythmic drugs are used if patients fail to respond to initial treatment. Different centers have used amiodarone, sotalol, and propafenone.[32–34]

Phrenic Nerve Injury and Diaphragmatic Paralysis

Phrenic nerve injury and diaphragmatic paralysis are underdiagnosed complications, with an incidence of around 1%–3%. Difficulty weaning from the ventilator or thoracoabdominal asynchrony during spontaneous breathing trials, the disproportionate elevation of one hemidiaphragm on postoperative chest x-rays, or postoperative hypercapnia otherwise unexplained should raise suspicion for this complication. The diagnosis can be confirmed on a chest ultrasound or fluoroscopy when the recipient is breathing spontaneously. Decreased, absent, or paradoxical movement of the hemidiaphragm further confirms the diagnosis. Diaphragmatic weakness causes prolonged mechanical ventilation and increased length of hospital stay.[19]

Gastroparesis and Gastroesophageal Reflux

Vagal nerve injury during surgery might result in gastroparesis and gastroesophageal reflux. Patients might experience delayed gastric emptying, early satiety, epigastric fullness, nausea, vomiting, and worsening acid reflux. Acid reflux increases the risk of microaspiration and injury to the new graft and can cause acute rejection. Hence, during the immediate postoperative recovery in the ICU, it is essential to remain vigilant for complications. The head end of the bed has to be kept elevated to prevent aspiration. Likewise, prokinetics like azithromycin and metoclopramide are administered for gastroparesis until there is spontaneous recovery.[19]

Thrombotic Microangiopathy

Microangiopathic hemolytic anemia (MAHA) refers to nonimmune intravascular red blood cell fragmentation that produces schistocytes in peripheral blood smear. Direct Coombs test is negative, lactate dehydrogenase and indirect bilirubin increase, and haptoglobin remains low or undetectable. Thrombotic microangiopathy (TMA) refers to MAHA with thrombocytopenia. TMA is a life-threatening complication caused by small-vessel microthrombi. It results from endothelial injury, microcirculatory thrombosis, fibrin deposition, and platelet consumption. MAHA, renal failure, and thrombocytopenia are present in TMA, whereas neurologic abnormalities are rare. TMA post–lung transplant could be drug-induced or complement-mediated.

Drug-induced TMA after lung transplantation results from dose-dependent nonimmune-mediated effects from drugs like tacrolimus, cyclosporine, and mammalian target of rapamycin (mTOR) inhibitors. The incidence of TMA from calcineurin inhibitors is thought to be between 3% and 4.5%.[35] It is more common in the first 3 months after transplantation.[15] Once drug-induced TMA is identified, the offending drug should be stopped. The majority of the care is supportive. Once the condition improves, another calcineurin inhibitor can be attempted under close monitoring.

Complement-mediated TMA is sudden in onset, preceded in some cases by a diarrheal illness. It is associated with general malaise and poor appetite, hypertension, and acute renal failure. The role of complement testing (C3, C4, CH50) is unclear. Decreased levels of complement might suggest complement-mediated TMA. However, normal levels do not exclude the possibility. The complement levels might take days to weeks to result. In complement-mediated TMA, eculizumab should be started as soon as possible, even while the results of complement levels are pending. As there is an increased risk of meningococcal infection, a meningococcal vaccine is required. In addition, empiric antibiotics should be considered for 2 or more weeks.

Hyperammonemia

Hyperammonemia after lung transplantation is a rare but often fatal complication. It manifests as an elevation of serum ammonia level that leads to encephalopathy, cerebral edema, seizures, coma, cerebral herniation, and death. Incidence of hyperammonemia ranges from 1% to 4%, with fatality rates exceeding 75%. The exact etiology is unclear, but it is thought to result from a deficiency in hepatic glutamine synthetase, a urea cycle enzyme that plays an essential role in processing nitrogenous waste.[31] More recently, infection with urea-splitting microorganisms has been reported.[36] Once hyperammonemia is recognized (serum ammonia levels >60 μmol/L), management includes discontinuing all protein intake for the first 24–48 hours, including tube feeds. After this pause, the protein intake is resumed at 0.25 g/kg and gradually increased to the goal. Antibiotics to cover *Mycoplasma* and *Ureaplasma* like azithromycin or levofloxacin or doxycycline are started. Nitrogen scavengers like sodium phenylbutyrate, sodium benzoate, arginine, and levocarnitine are initiated. In cases where the ammonia levels go above 250 μmol/L, intermittent hemodialysis and continuous renal replacement therapy in hemodynamically unstable patients should be initiated. Bowel decontamination with lactulose, metronidazole, and rifaximin should be performed.[37]

Bronchial Necrosis and Dehiscence

Bronchial circulation is not established during transplantation. Perfusion to airways and parenchyma depends solely on the pulmonary arterial circulation. Pulmonary artery blood supply may be insufficient during the perioperative period, especially when vasopressors are used for hypotension. This perfusion inadequacy might result in ischemic injury to the anastomosis or postanastomotic bronchus.[38] Relative ischemia, exacerbated by intraoperative or postoperative hypotension and hemodynamic fluctuations, makes anastomoses susceptible to necrosis, dehiscence, and infection. The severity of necrosis varies from commonly encountered mild focal necrotic sloughing to extensive necrosis, perforation, and bronchial dehiscence.[38] This usually occurs 1–5 weeks postoperatively with an incidence of 1%–10%.[39] Hence, anastomosis should be examined carefully during every bronchoscopy. Clinical features include dyspnea, pneumomediastinum, subcutaneous emphysema, pneumothorax, lung collapse, and persistent air leaks in the early posttransplant period.[40] Because chest x-rays are unreliable if bronchial dehiscence is suspected, computed tomography (CT) of the chest should be considered, as it will very clearly delineate the bronchial defects and extraluminal air around the anastomosis.[38] Placement of self-expanding metallic stents that promote granulation can be used to aid healing.[38,39]

Pulmonary Artery Stenosis

Patients with pulmonary artery stenosis present with hypotension and severe right heart failure. This condition, which mimics pulmonary embolism, can be treated with surgical correction or stent placement.

Pulmonary Vein Stenosis/Pulmonary Venous Obstruction

Pulmonary venous obstruction after lung transplantation is a very rare complication. It is associated with high morbidity and mortality unless recognized very early in the postoperative period. Patients present with progressive hypoxemia and infiltrate in the grafted lung on chest x-ray, mimicking acute pulmonary edema. Respiratory secretions in the endotracheal tube could be frothy pink or hemorrhagic. The pulmonary capillary wedge pressure may be high. This condition is diagnosed with TEE. The severity of the hypoxemia depends on the number of lungs transplanted, whether pulmonary venous obstruction is unilateral or bilateral, and whether the recipient had prior pulmonary hypertension. In patients who have undergone SLT and have prior pulmonary hypertension, pulmonary venous stenosis in the graft will cause severe hypoxemia and graft failure very early on. Bedside TEE is a beneficial tool to detect this condition. CT angiography is another option. Once diagnosed, patients need to be taken back to the operating room for the reconstruction of the venous anastomoses.[41]

Thoracic Compartment Syndrome

Thoracic compartment syndrome is seen in the immediate postoperative period, either immediately after chest closure or several hours later. Patients present with hemodynamic instability. This complication occurs most commonly in BLT, especially if there is a prolonged intraoperative course and transfusion of multiple blood products and/or use of CPB. Clinical features include high ventilator airway pressures, refractory hypotension, and progressive acidosis. Worsening lactic acidosis, tissue perfusion, renal function, and urine output are also noted. Immediate thoracotomy and delayed closure are recommended.[42]

PRIMARY GRAFT DYSFUNCTION AFTER LUNG TRANSPLANTATION

PGD is a form of acute lung injury that occurs within the first 72 hours after lung transplantation and is triggered by ischemia-reperfusion injury. PGD manifests as progressive hypoxemia and the presence of radiographic pulmonary infiltrates without other identifiable causes such as cardiogenic pulmonary edema, pneumonia, hyperacute rejection, or pulmonary venous anastomotic obstruction. It affects almost one-third of lung transplant recipients and is the major cause of early morbidity and mortality after lung transplantation.[43] In addition, PGD has been associated with an increased risk of chronic lung allograft dysfunction (CLAD), which is the major cause of late mortality after lung transplantation.[44]

In 2005 the International Society of Heart and Lung Transplantation (ISHLT) Working Group on PGD proposed a standardized definition and grading system based a ratio of PaO_2:FiO_2 (P:F or arterial oxygen partial pressure/fraction of inspired oxygen) and the radiographic presence of infiltrates in the transplanted lung(s) assessed within the 6 hours after lung transplantation (T0) and at 24 hours (T24), 48 hours (T48), and 72 hours (T72) posttransplantation (Table 145.1).[45,46] The definition was updated in 2017 to classify patients receiving posttransplant ECMO because of hypoxemia as severe PGD (PGD grade 3) and those on ECMO for reasons other than hypoxemia (i.e., cardiac support) as ungradable PGD. Furthermore, unlike in the 2005 definition, the 2017 definition recommended that the use of inhaled pulmonary vasodilator agents such as iNO and aerosolized epoprostenol that may improve oxygenation not be considered when grading severity of PGD. Additionally, the new update provided an alternative grading schema using a ratio of oxygen saturation/fraction of inspired oxygen SaO_2/FiO_2 in cases where a PaO_2 measurement was unobtainable with adjusted cutoffs of 235 and 315 (see Table 145.1).[46]

Subsequent validation studies using the standardized definition of PGD demonstrated better discrimination of grade 3 PGD to predict early mortality. Specifically, grade 3 PGD beyond 48 hours after transplantation demonstrated the most robust associations with early and overall mortality after lung transplantation compared with the other grades of PGD.[47–50]

Prior studies have proposed several risk factors for the development of PGD based on the donor, recipient, and surgical variables. Risk factors such as donor smoking, donor alcohol use, undersized donor:recipient lung matching based on the predicted total lung capacity (pTLC), recipient diagnosis of sarcoidosis, recipient elevated mean pulmonary artery pressure, and high fraction of inspired oxygen at allograft reperfusion are likely to be associated with development of PGD (Table 145.2). Some of these risk factors are potentially modifiable (e.g., avoiding undersized donor:recipient lung matching, FiO_2 at reperfusion, obesity) and thus may suggest preventive strategies.[47,51]

The pathogenesis of PGD is an area of intense investigation. The underlying etiology is thought to be the airway epithelial and vascular endothelial cell damage caused by the ischemia-reperfusion injury (IRI) after lung transplantation. This results in release of damage-associated molecular patterns (DAMPs) that are recognized by pattern recognition receptors (PRRs), which stimulate inflammatory cytokine gene expression, and ultimately leads to activation of the innate immune system, including the complement cascade, alveolar macrophages, and an influx of neutrophils into the lungs. This inflammatory cascade will cause alterations in the integrity of the endothelial barrier and alveolar epithelial capacity to resorb fluid, leading to development of PGD.[55–57]

During the past decade, several strategies targeting putative pathways in PGD have been studied, such as the use of iNO, modulation of the complement cascade, instillation of surfactant, and prevention of neutrophil extracellular trap (NETs) formation using an antiplatelet agent or intraalveolar disruption of NETs using DNase I.[58–60]

TABLE 145.1 2005 ISHLT Primary Graft Dysfunction Taxonomy

Grade	Pulmonary Edema on Chest x-ray	PaO_2:FiO_2	Specific Exceptions
0	−	Any	
1	+	>300	
2	+	200–300	
3	+	<200	Any patients on ECLS for hypoxia and pulmonary edema

If PaO_2 is not available for calculation of a arterial oxygen partial pressure/fraction of inspired oxygen (*PaO_2:FiO_2*) ratio, then oxygen saturation/fraction of inspired oxygen (SaO_2/FiO_2) ratio should be calculated and the 200 and 300 PGD grading cutoffs should be adjusted to 235 and 315. Use of nitric oxide, aerosolized epoprostenol, or other pharmacologic agents that may improve oxygenation should not change grading methods. Use of extracorporeal lung support (*ECLS*) with bilateral pulmonary edema on chest x-ray image should be graded as grade 3, and ECLS use should be explicitly recorded. The use of ECLS for nonhypoxic indications without pulmonary edema on chest x-ray imaging should be considered ungradable and explicitly recorded separately. Time window notes: PGD is graded at 4 time points: every 24 hours and over the first 72 hours after transplantation (T0, T24, T48, and T72 hours). Time starts at reperfusion of the second lung. T0, T24, T48, and T72 have time windows ±6 hours. If multiple blood gas values are available, the worst PaO_2/FiO_2 ratio on a given calendar day should be used. Adapted from Snell GI, Yusen RD, Weill D, et al. Report of the ISHLT Working Group on Primary Lung Graft Dysfunction, part I: Definition and grading—A 2016 Consensus Group statement of the International Society for Heart and Lung Transplantation. *J Heart Lung Transplant*. 2017;36:1097–1103.

TABLE 145.2 Risk Factors for Development of Primary Graft Dysfunction Based on Donor, Recipient, and Surgical Variables

Donor	Recipient	Operative
Smoking	Sarcoidosis	Undersized donor:recipient lung matching
Alcohol use	Pulmonary hypertension	High fraction of inspired oxygen at allograft reperfusion
Specific genetic factors	Elevated mean pulmonary artery pressure	Transfusions >1:2 FFP:PRBC transfusion
	Diastolic dysfunction	
	Abdominal subcutaneous adipose tissue (overweight/obese) phenotype	
	Specific biomarkers	
	Specific genetic factors

Currently, the therapy for PGD remains generally supportive and draws from therapies applied in patients with acute respiratory distress syndrome (ARDS), including lung-protective ventilation strategies. Additionally, pressure-controlled ventilation modes may be used to minimize barotrauma and airway anastomosis complications. Diuresis should be initiated, with blood pressure support, if needed, and excess fluid administration should be avoided.[61] Despite the encouraging results with iNO administration to prevent and treat severe PGD suggested by several animal studies and case series,[62–65] randomized controlled studies did not support efficacy for iNO use in the clinical setting.[22,66] However, despite the lack of an established role for iNO in prevention or treatment of PGD, its use may be justified as salvage therapy in selected cases for improving oxygenation, reducing mean pulmonary arterial pressure, and increasing mean systemic arterial pressure early after transplant.[67]

Institution of ECMO in patients with severe PGD has gained in popularity, with better outcomes reported in cases of early ECMO initiation, preferably within the first 24 hours after transplantation.[68–71] In cases with refractory respiratory failure, retransplantation has been performed. However, predicted survival is poor, and this practice is generally not recommended.[58,72]

Acute Rejection after Lung Transplantation

Acute rejection after lung transplantation is common and continues to affect approximately 40% of lung transplantation recipients in the first year posttransplantation.[73] The clinical manifestations are variable, nonspecific, and potentially confounded by coexisting diseases and processes. The presentations range from being asymptomatic with no radiographic changes, detected via routine posttransplantation surveillance biopsies, to a clinical picture resembling ARDS.[74] Acute rejection after lung transplantation encompasses acute cellular rejection (ACR) and antibody-mediated rejection (AMR).

Acute Cellular Rejection

ACR is the result of an immune reaction against donor antigens that are expressed on the surface of donor cells and recognized by recipient lymphocytes. Recipient lymphocytes can react to various donor antigens, such as blood group antigens and human leukocyte antigens (HLAs). HLAs are polymorphic cell-surface molecules and can lead to a robust immune response when mismatched between donor organ and recipient. The lung is a rich lymphoid organ and possesses all immune cell lines necessary for initiation and maintenance of an immune reaction. Shortly after transplantation, the donor HLA proteins are presented to recipient T cells by the donor's own antigen-presenting cells (APCs) ("direct pathway") or later by migrated recipient APCs to the transplanted lung ("indirect pathway"). APC stimulation induces naive T cells to become memory T cells capable of direct and rapid recognition of alloantigens and subsequent injury.[75,76]

ACR is defined as the presence of lung perivascular and/or peribronchiolar lymphocytes in the absence of infectious etiologies. To date, bronchoscopic transbronchial biopsy remains the gold standard for diagnosis of ACR.[77,78] However, multiple studies have been conducted in assessing less invasive tests such as bronchoscopy-guided airway brushings,[79] bronchoalveolar lavage (BAL),[80–82] or serum biomarkers for diagnosis of ACR.[83] Similarly, spirometry testing has utility but is not diagnostic.[84] Thus after several decades of attempts to find a less invasive, more precise surrogate marker of ACR in lung transplantation, bronchoscopic tissue analysis remains the most reliable diagnostic modality.

Acute rejection can be seen as early as a week after lung transplantation. Although ACR is more often present as a nonspecific decline in spirometry with no significant radiographic changes, it can manifest as a fatal hypoxic respiratory failure with diffuse pulmonary infiltrates in its severe form. This can make the diagnosis and treatment of other ICU complications difficult. ACR presentation can mimic symptoms of pneumonia, and sometimes ACR can be triggered by earlier pneumonia. Therefore development of new infiltrates after lung transplantation requires diagnostic evaluation using bronchoscopy with BAL and transbronchial biopsy. Importantly, ACR is directly responsible for only a small proportion of deaths in lung transplantation recipients. In fact, less than 4% of deaths are attributable to ACR in the first posttransplant month, and, at later time points, this incidence decreases to less than 2%.[73] Nevertheless, much attention has been paid to the early diagnosis and treatment of ACR, as it remains the most significant risk factor for the development of CLAD, which is the ultimate cause of mortality from lung transplantation.[85,86]

The most commonly administered first-line therapy for ACR is high-dose steroids with intravenous methylprednisolone; doses range from 10 to 15 mg/kg daily for 3 days, followed by a prednisone taper.[87–89] The therapeutic plans for persistent or recurrent acute rejection that warrants further augmentation of immunosuppression are variable among centers. This scaling up can be achieved by a repeat course of pulse steroids, optimization of maintenance immunosuppression,[87–91] anti–T-cell agents such as polyclonal antithymocyte globulins (ATGs), or an anti-CD52 monoclonal antibody (alemtuzumab) in the treatment of severe and refractory ACR.[89,92]

Antibody-Mediated Rejection

AMR is a widely accepted cause of graft dysfunction after lung transplantation.[89,93,94] It is mediated by donor-specific antibodies (DSAs), produced by B cells or plasma cells, and upon binding to their cognate antigen in the transplanted lung, they cause a deleterious effect via complement-dependent[95] and complement-independent pathways.[95,96] DSA may be present at the time of transplantation (sensitized recipient) or develop de novo after transplantation.[97]

The presence of DSA before transplantation can lead to hyperacute rejection, which is the most severe form of AMR and occurs within minutes to hours after lung transplantation. Clinical manifestations include the rapid development of diffuse pulmonary infiltrates and hypoxia followed by systemic inflammatory response syndrome, including coagulopathy, thrombocytopenia, oliguria, and hemodynamic instability.[94,98–100] Although hyperacute rejection is generally considered to be a fatal complication after lung transplantation, there are a few case reports of survival after enforcing aggressive immunotherapy strategies.[101–103] A therapeutic approach to hyperacute rejection includes various combinations of high-dose steroids, plasmapheresis, cyclophosphamide, high-dose intravenous immunoglobulin (IVIg), ATG, and rituximab, an anti-CD20 monoclonal antibody.[94,98–103]

Aside from the risk for development of hyperacute rejection, the presence of DSA before lung transplantation has been associated with ACR, AMR, and CLAD.[104–107] Therefore prevention through the avoidance of the donor with known DSA HLA targets has been common, but doing so can significantly limit access to a transplant in the sensitized recipients.[108–110] Alternatively, pretransplantation desensitization using a combination of plasmapheresis, ATG, IVIg, and mycophenolate has been reported with equivalent posttransplantation outcomes to unsensitized patients.[104,111–113] Overall, hyperacute rejection has become rare since the implementation of more sensitive methodologies for screening recipient HLA antibodies before transplantation.

Pretransplant DSA, in addition to the de novo development of DSA after lung transplantation, can be asymptomatic (silent) or result in clinical manifestations of antibody-mediated rejection.[104–106,112] The clinical presentations of ACR and AMR are indistinguishable.

Additionally, ACR and AMR can manifest together, or one can trigger the other form of rejection.[114,115] Unfortunately, AMR in lung transplantation has remained a diagnostic challenge.[97,116] The lung transplant recipient presenting with an otherwise unexplained drop in lung function, anti-HLA DSA, a neutrophilic capillaritis, and positive C4d staining on transbronchial biopsy is highly likely to have AMR as the cause for graft dysfunction. In such cases, a diagnosis of "definite AMR" is suggested.[97,99,116] However, this scenario is uncommon, and the more common clinical presentation is of a patient with an unexplained deterioration of pulmonary function and a new or increasing titer DSA. In these cases, lung biopsy does not suggest an alternative diagnosis or demonstrate confirmatory features of AMR. Therefore the absence of confirmatory histology should not automatically rule out the diagnosis of AMR.[99,116]

Because of the variability in diagnosis of AMR across transplant centers, a working group was created in 2016 by the ISHLT with the aim of determining criteria for pulmonary AMR and establishing a definition. Pulmonary AMR was defined as clinical when there is allograft dysfunction, as evaluated by pulmonary function test (which can be asymptomatic otherwise), or subclinical when there is normal allograft function. Both clinical and subclinical AMR were further subcategorized into three mutually exclusive possibilities (definite, probable, and possible). These categories were based on the degree of certainty related to the presence or absence of a number of pathologic, serologic, clinical, and immunologic criteria (Table 145.3).[117]

In general, there is no consensus agreement about the choice of agent or duration of therapy for AMR. Therapeutic options have been extrapolated from renal transplant and other areas of medicine without clinical trials. Treatment has generally consisted of multiple sequential interventions. It is very common to initiate therapy with pulse steroids (methylprednisolone 0.5–1 g daily for 3–5 days),[118] followed by plasmapheresis, high-dose IVIg, and B-cell depletion therapy with rituximab.[119–123] In recent years, a plasma cell-targeted therapy using proteasome inhibitors such as bortezomib and carfilzomib has been used in the management of AMR.[124,125]

Chronic Lung Allograft Dysfunction

CLAD is characterized by substantial and persistent decline in and loss of pulmonary function (≥20% measured FEV_1 value), which cannot be explained by other potentially reversible complications such as acute rejection, infection, or bronchial stenosis.[125] It affects up to 50% of lung transplant recipients after 5 years and is the major cause of overall morbidity and mortality after lung transplantation.[7,126,127] CLAD can present either as a predominantly obstructive ventilatory pattern, a restrictive pattern, or a mixed obstructive and restrictive pattern.[125,127,128] Obstructive CLAD includes bronchiolitis obliterans syndrome (BOS), which is caused by recurrent inflammation, destruction, and eventual fibrosis of small airways, forming obliterative bronchiolitis (OB) lesions in the lung allograft. It presents as a persistent, nonreversible obstructive ventilatory decline in spirometric measures of lung function with an essentially clear chest radiograph. High-resolution CT imaging of the chest often demonstrates air trapping, tree-in-bud opacities, or bronchiectasis. Because of the patchy distribution of OB lesions in the lungs, transbronchial biopsy is insufficiently sensitive to achieve diagnosis. Therefore the diagnosis of BOS is made by at least a 20% decline in FEV_1 from the best postoperative baseline, assessed by two measurements with a minimum interval of 3 weeks.[127,129,130] BOS is often irreversible; however, recently it became clear that 30%–40% of patients with a diagnosis of BOS may respond to treatment with azithromycin. A placebo-controlled trial in patients with BOS confirmed that azithromycin was superior to placebo for improvement in FEV_1 in established BOS.[131,132] Most patients who responded to azithromycin had elevated BAL neutrophilia during diagnosis. This observation led to a further subclassification of obstructive CLAD to BOS and a new phenotype known as *neutrophilic-reversible allograft dysfunction* or *azithromycin-responsive allograft dysfunction*.[127,129,130]

Approximately 70% of CLAD is attributable to obstructive CLAD and 30% to the restrictive phenotype of CLAD, also known as *restrictive allograft syndrome* (RAS).[128] RAS is characterized by a restrictive pulmonary function decline and persistent parenchymal infiltrates on chest radiography. CT of the chest can demonstrate subpleural thickening and nonspecific interstitial changes. Additionally, organizing pneumonia, pleuroparenchymal fibroelastosis, and OB may be seen in the histopathology.[133] Unfortunately, the median survival after development of RAS is limited to 6–18 months, as opposed to 3–5 years in BOS.[128]

In general, the diagnosis of CLAD is made after carefully ruling out other causes of declining lung function, which are not related to intrinsic graft dysfunction, as outlined in Box 145.1.[125] The medical management of CLAD centers around stabilizing rather than restoring graft

Data from Verleden GM, Glanville AR, Lease ED, et al. Chronic lung allograft dysfunction: Definition, diagnostic criteria, and approaches to treatment—a consensus report from the Pulmonary Council of the ISHLT. *J Heart Lung Transplant.* 2019;38(5):493–503.

BOX 145.1 Processes and Diseases That May Lead to Chronic Loss of Allograft Function and Are Not Included in the Current Definition of CLAD

A. Factors where recalculation/resetting of the FEV_1 reference value may be valid (if FEV_1 remains stable for at least 6 months):
   1. Decreasing lung function because of the normal aging process
   2. Surgical factors
      - Transplant lung resection, chest-wall surgery, phrenic nerve damage
   3. Mechanical factors
      - Persistent pleural effusion
      - Persistent lung edema because of significant kidney/heart/liver failure
      - Airway stenosis
      - Myopathy, neuropathy, and Parkinson disease
      - Weight gain
      - Native lung hyperinflation after single-lung transplant
   4. Localized infection with chronic scarring
      - Abscess/empyema/mycetoma

B. Factors that cannot be differentiated easily from CLAD and do not ever allow recalculation/resetting of the FEV_1 reference value:
   1. Any from (A) above where there is not a period of at least 6 months of stability
   2. Infiltration with tumor
   3. Infiltration of the allograft with proven disease recurrence from the underlying transplant indication (e.g., LAM, sarcoidosis)
   4. Drug or other induced pulmonary toxicity (e.g., sirolimus, methotrexate, amiodarone, radiotherapy)
   5. Pulmonary arterial strictures or emboli
   6. Acute/subacute generalized infection
   7. Acute/subacute cellular or antibody-mediated rejection
   8. Acute/subacute effects of aspiration

C. Failing to reach normal predicted lung function (i.e., low FEV_1 reference value such that FEV_1 is ≤80% of the recipient predicted value). This situation may include an age difference between donor and recipient, where older donor lungs are implanted, or when an intraoperative allograft reduction surgery/lobectomy is performed.

CLAD, Chronic lung allograft dysfunction; *FEV_1,* forced expiratory volume in 1 second; *LAM,* lymphangioleiomyomatosis.

function. Effective medical treatment for CLAD is an unmet need, and retransplantation remains the only effective therapeutic option for advanced CLAD.[125] For management of BOS, current guidelines recommend transitioning from cyclosporine to tacrolimus, antireflux surgery (e.g., Nissen fundoplication or Toupet fundoplication) in cases of documented gastroesophageal reflux, and a trial of azithromycin for more than 8 weeks.[125,129,130] Additionally, total lymphoid irradiation (TLI) or extracorporeal photopheresis (ECP) may reduce the rate of decline in certain patients with obstructive CLAD.[125,134,135] Currently there are no formal guidelines for management of patients with restrictive CLAD. Some beneficial effects have been reported using pirfenidone and alemtuzumab in RAS.[129] Although in selected cases clinicians may consider retransplantation for end-stage BOS, emerging data discourage this in RAS.[129,130,136] For the majority of patients with end-stage CLAD, palliation becomes the priority. Symptom control in advanced disease remains challenging. Noninvasive ventilation for hypercapnia is generally ineffective, and ventilatory support and subsequent weaning are usually unsuccessful.[134,137,138]

KEY POINTS

- Lung transplantation continues to offer hope for many advanced lung disease processes. Much has been learned about the natural history of these otherwise terminal lung diseases, which has influenced significant changes in the overall practice of lung transplantation, including the lung allocation system and the donor selection criteria.
- Primary graft failure (dysfunction) is a severe form of ischemia-reperfusion injury and carries enormous morbidity and mortality.
- Lung transplant recipients with postoperative respiratory compromise should be maintained "on the dry side."
- Growing evidence suggests that suboptimal early immunosuppression, in addition to recurrent aspiration from reflux disease, are the two most modifiable risk factors associated with chronic rejection. Patient selection, consideration of antireflux surgery before transplantation or early after, and appropriate immunosuppression schedules should be implemented in protocols at every center.
- Hyperammonemia continues to be a rare but feared complication after lung transplantation, given that its mechanism has yet to be understood. Aggressive management options, including gut decontamination, high levels of dialysis, and pharmacologic treatments targeted at urea-cycle enzyme deficiencies, are the only available tools but have yet to show promise in changing outcome.

ANNOTATED REFERENCES

Christie JD, Edwards LB, Aurora P, et al. The Registry of the International Society for Heart and Lung Transplantation: Twenty-sixth official adult lung and heart-lung transplantation report—2009. *J Heart Lung Transplant.* 2009;28:1031–1049.

This yearly document published by the International Society for Heart and Lung Transplantation summarizes and explicitly describes the statistical trends of lung and heart-lung transplantation. This registry allows the reader to put in perspective the indications for transplantation; the donor characteristics; their impact on transplantation outcomes, including rejection, complications, and survival; and the centers offering transplantation and their influence on these outcomes in terms of the case load they are challenged with. It allows an organized chronologic understanding of lung and heart-lung transplantation outcomes.

Christie JD, Sager JS, Kimmel SE, et al. Impact of primary graft failure on outcomes following lung transplantation. *Chest.* 2005;127:161–165.

This single-center retrospective study conducted by field experts looked into the overall incidence of grade III primary graft failure in 255 consecutive procedures done in a period of over 10 years. It demonstrated an incidence of 11.3% of PGD, an increased mortality, worsened hospital length of stay, and increased duration of mechanical ventilation. A reported 73.3% of patients who received the diagnosis of primary graft failure died during their hospitalization versus 14.2% of those who did not. A 1-year follow-up also demonstrated significantly affected physical function in those who had experienced primary graft failure.

Hachem RR, Trulock EP. The new lung allocation system and its impact on waitlist characteristics and post-transplant outcomes. *Semin Thorac Cardiovasc Surg.* 2008;20:139–142.

This review clearly explains the current lung allocation process, which basically is geared toward making organs available to those who need them more urgently because of their underlying disease process and its expected outcome. A thorough comparison of the prior allocation process to the current one in terms of waiting time, waiting mortality, and more importantly, the steady proportional increase of idiopathic pulmonary fibrosis as the underlying cause of transplantation is made. This increase is explained by the comparable uncertainty of the disease's natural history and the high mortality of its exacerbations.

Perioperative Management of the Liver Transplant Patient

Caleb Fisher and Stephen Warrillow

INTRODUCTION

The introduction of liver transplantation over 50 years ago has revolutionized outcomes for patients with both acute and chronic liver failure. Since experimental beginnings, liver transplantation has grown worldwide, with the number of transplants per year ranging from approximately 400 in Australia to over 1000 in the UK and over 8000 in the United States.[1–3] Concurrently, survival from transplantation continues to improve, with 5-year survival reported between 75% and 85%, depending on reporting jurisdiction.[1–3] This has been largely the result of improvements in surgical technique, anesthetic management, and postoperative critical care.

DONOR SELECTION

Liver transplantation is a treatment option for patients with both acute and chronic liver failure. Common causes include chronic liver disease as a result of alcohol use disorder; viral hepatitis; metabolic conditions such as Wilson disease and alpha-1-antitrypsin deficiency; and autoimmune conditions such as autoimmune hepatitis, primary sclerosing cholangitis, and primary biliary cirrhosis.[4–6] Selection for liver transplantation in chronic liver disease is largely based on disease severity and the likelihood of death on the transplant waiting list. The Model for End-Stage Liver Disease (MELD) score is the most commonly used criteria for transplantation listing, with the cutoff of 15 used as a trigger for commencement of the transplant assessment process in many jurisdictions.[6–8] A separate cohort are patients with hepatomas, who are listed on the basis of malignant disease burden.[9,10] Eligibility for transplantation has changed such that even critically ill patients are now often listed. These patients often exhibit acute-on-chronic liver failure (AoCLF) and require high-level critical care support for preoperative optimization followed by a frequently slow postoperative recovery.[11–14] In contrast, patients with acute liver failure (ALF) are almost always managed in the intensive care unit (ICU) at the time of transplant listing. Various predictive criteria have been developed to determine the likelihood of survival without liver transplantation in ALF, although their utility is increasingly questioned as improvements in both understanding of the pathophysiology of ALF and improved critical care management have led to improved outcomes.[15–17] Regardless of the indication for transplant, an essential requirement for effective care is a systematic and coordinated approach to management (Table 146.1 and Fig. 146.1).

A SYSTEMS-BASED APPROACH TO MANAGEMENT OF THE POST–LIVER TRANSPLANT PATIENT

Cardiovascular

Patients with end-stage liver disease (ESLD) have a characteristic cardiovascular profile. The classic pattern is a hyperdynamic circulation with low systemic vascular resistance and an increased cardiac output. The mean arterial pressure (MAP) tends to remain low/normal despite these changes.[18–21] Furthermore, ESLD patients have an abnormal distribution of total body blood volume because of complex alterations in the splanchnic, renal, and systemic circulations.[20,21] This involves the redistribution of blood into the splanchnic circulation secondary to the overproduction of nitric oxide (NO) and other proinflammatory mediators. The overproduction of inflammatory mediators is believed to be compounded by gut bacterial translocation in the setting of raised portal pressures.[22,23]

The postoperative hemodynamic course of these patients is influenced considerably by persistence of these preoperative hemodynamic disturbances. The hemodynamic changes of cirrhosis can take days to weeks to fully resolve after transplantation.[18,24] Because of the marked hemodynamic instability that can occur during the peritransplant period, invasive monitoring in the ICU is necessary to guide therapy and optimize graft function.[25] Traditionally, the pulmonary artery catheter has been the gold standard for intraoperative and postoperative monitoring; however, its utility has been questioned on the basis of its invasiveness, inability to predict fluid responsiveness, and lack of evidence for improving patient outcomes.[26,27] Less invasive techniques such as pulse contour analysis have gained popularity in other critical care populations, but their utility in the complex hemodynamic changes occurring during liver transplantation has recently been questioned.[27,28]

Hypotension is the most common hemodynamic abnormality encountered postoperatively. Causes include postoperative bleeding, persistence of the preexisting vasodilated state, postreperfusion vasoplegia, the effects of narcotics and sedatives, and fluid shifts causing hypovolemia.[20] Refractory vasoplegia postreperfusion can continue into the postoperative period; however, its incidence and impact upon outcomes are not known.[29] Common to other vasoplegic syndromes, hypotension that is refractory to standard vasoconstrictors may be amenable to treatment with methylene blue.[30,31]

Initial treatment aims to restore normovolemia by judicious use of fluid resuscitation. There is no consensus on the preferred fluid in this setting. Experience derived from the care of other critically ill patients suggests that balanced crystalloids may be preferred, as they avoid inducing hyperchloremia.[32,33] Albumin-containing solutions are an attractive alternative in patients who are hypoalbuminemic and offer potentially protective effects to the endothelial glycocalyx with improved postoperative outcomes.[34–36]

The optimal target for arterial blood pressure has not been established; however, a MAP of 65 mm Hg seems appropriate in these patients to ensure adequate end-organ perfusion, especially for the engrafted liver. A higher MAP may be required in the presence of poor hepatic arterial flow because of high resistive indices. A central venous pressure of 8–12 mm Hg appears to be safe; however, further resuscitation and increases in volume state may have deleterious effects on

TABLE 146.1 Management Challenges in Patients Undergoing Liver Transplantation

Body System	Management Challenge
Cardiovascular	Vasodilatation, hypotension, cirrhotic cardiomyopathy, redistributed blood volume
Respiratory	Fluid overload, hydrothorax, atelectasis, hepatopulmonary syndrome, portopulmonary hypertension
Renal	Acute kidney injury, end-stage kidney disease, hepatorenal syndrome
Gastrointestinal	Ascites, spontaneous bacterial peritonitis, bacterial translocation, ileus, poor nutrition, hypoalbuminemia
Neurologic	Encephalopathy, delirium, potential increased sensitivity to neuroleptic agents
Coagulation	Rebalanced hemostasis, thrombocytopenia, hypofibrinogenemia, potential hyperfibrinolysis

hepatic outflow, leading to graft congestion and poor function.[20,37] In the presence of hypotension not related to bleeding or resolving with judicious fluid resuscitation, the application of vasoconstrictor agents is required. There is little evidence on which to prefer one agent over another, although norepinephrine is often used. Terlipressin is commonly used in the preoperative setting for decompensated liver failure, and in the postoperative setting some evidence exists suggesting use may decrease ascitic drain output and the incidence of acute kidney injury; however, its routine use is not recommended.[38]

Although cardiac performance is generally preserved in patients undergoing liver transplantation, there are occasional instances where this may not hold true. Cirrhotic cardiomyopathy occurs to some extent in up to half of cirrhotic patients.[39,40] In contrast to traditional cardiomyopathies, patients with cirrhotic cardiomyopathy have normal cardiac function in terms of both output and contractility, but have evidence of blunted systolic contractile response to stressors and the presence of diastolic dysfunction at rest.[39] As liver transplantation is a major physiologic stressor, overt cardiac dysfunction may only become apparent during the perioperative period. The major implications for management in the postoperative period are to ensure normovolemia and prevent significant fluid shifts.[41] Additionally, prevention of electrolyte abnormalities and avoidance of other factors that may further depress cardiac function (e.g., hypothermia, severe acidosis) is required.[41] In the presence of an established low cardiac output state with a corresponding decrease in end-organ perfusion, the use of inotropic agents such as milrinone or dobutamine may be necessary.

As patients waitlisted for liver transplant are increasingly older and more comorbid, underlying cardiovascular disease has become more common.[42,43] Larger numbers of patients with nonalcoholic steatohepatitis cirrhosis and metabolic syndrome also make this scenario more common.[43,44] It is recognized that patients with established coronary artery disease undergoing liver transplant have poorer outcomes posttransplantation.[45,46] Correspondingly, an appropriate risk assessment and consideration for revascularization is required for those being evaluated for transplantation.[46] Recent studies have shown a higher rate of arrhythmic complications but a low rate of ischemic events.[47,48] The timing of recommencing antiplatelet agents is challenging and requires multidisciplinary review to ensure the maximal protection of existing stents is balanced against the risk of bleeding.

Patients undergoing transplantation for ALF often have additional cardiovascular challenges, with vasoplegic shock similar to that seen in severe sepsis being typical, especially for hyperacute presentations.[49] Massive hepatic necrosis releases inflammatory mediators, which persist in the circulation because of a lack of hepatic clearance.[16] This pattern may take days to resolve after successful liver transplant.

Respiratory

Respiratory complications are common after liver transplantation, with a reported incidence of over 50% depending on the definition and method of assessment.[50,51] The optimal timing of extubation remains unclear.[52–54] In the majority of liver transplants, prolonged mechanical

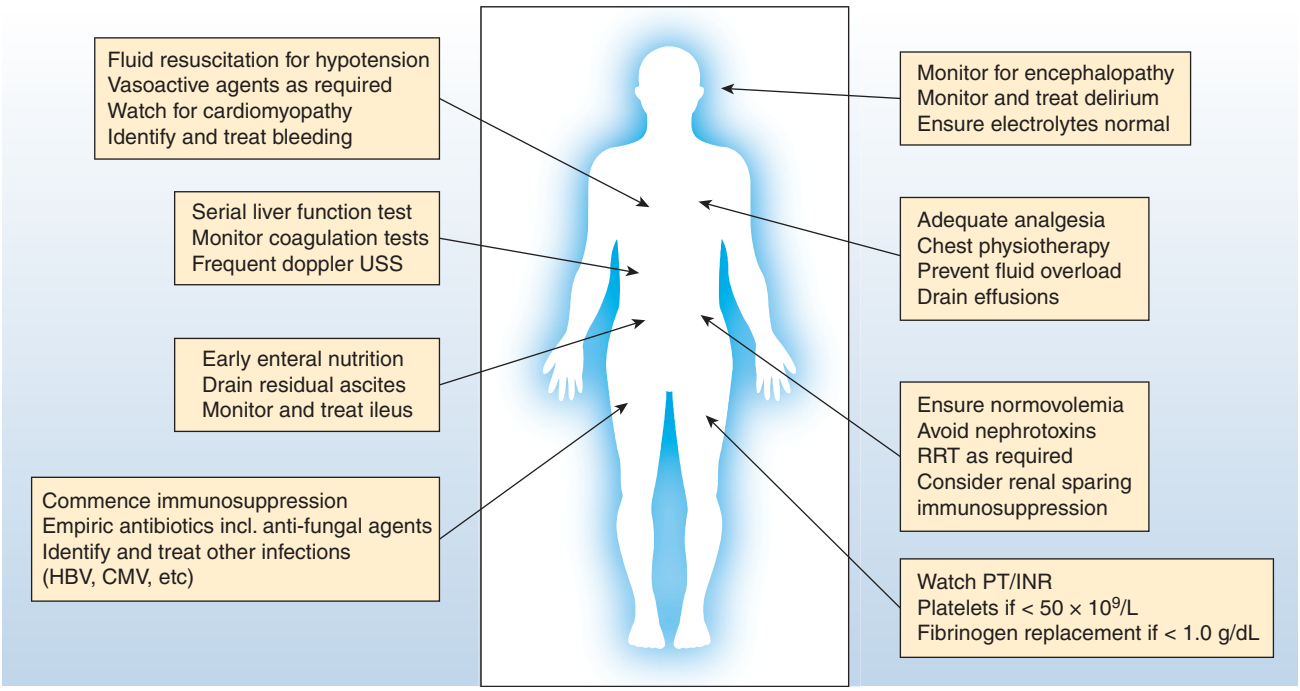

Fig. 146.1 Systematic approach to critical care after liver transplant. *CMV,* Cytomegalovirus; *HBV,* hepatitis B virus; *INR,* international normalized ratio; *PT,* prothrombin time; *RRT,* renal replacement therapy; *USS,* ultrasound.

ventilation is not required, and with the use of short-acting sedative and narcotic agents, immediate extubation in the operating room or postanesthetic recovery unit can sometimes occur. An early extubation approach is supported by evidence from the cardiac and thoracic surgical literature, suggesting no increased risk of complications and possible decreased ICU length of stay.[55] Conversely, the benefit of delayed extubation allows for ongoing hemodynamic stabilization, correction of hemostasis, assessment of early graft function, and optimization of analgesia before liberation from ventilation. Overall, the majority of liver transplant recipients can be extubated shortly after admission to the ICU.

In common with other major abdominal surgeries, the provision of appropriate analgesia, preemptive physiotherapy, and early mobilization may reduce the risk of pulmonary atelectasis and hospital-acquired pneumonia, thereby reducing ICU length of stay.[56] Common respiratory problems include preexisting cirrhotic complications such as pleural effusions/hydrothoraces and pulmonary edema/fluid overload caused by large volumes of intraoperative fluid administration. Hypoalbuminemia can exacerbate all the previously mentioned respiratory complications. Careful postoperative critical care management involves the achievement of gentle negative fluid balance, provision of noninvasive ventilation as required, and the consideration of the placement of intercostal catheters to drain symptomatic effusions.[57,58]

Overt postoperative respiratory failure, as defined as the requirement for reintubation or the need for mechanical ventilation for longer than 48 hours posttransplant, is associated with significant morbidity and mortality.[59] Risk factors include older age, elevated MELD score, operative bleeding, acute kidney injury, and preexisting respiratory compromise.[59] Acute lung injury/acute respiratory distress syndrome (ALI/ARDS) has a reported incidence of between 4% and 16% in posttransplantation and has been associated with increased morbidity and mortality.[60–62] Posttransplant ALI/ARDS is a multifactorial process occurring as a consequence of blood product administration, large-volume fluid shifts, hepatic ischemic/reperfusion injury, and preexisting hypoalbuminemia. The management of ALI/ARDS remains largely supportive, with a low tidal volume and open-lung–based ventilation strategy being the mainstays of therapy. The prevention of a positive fluid balance and treatment of any potential infective or mechanical contributions can also be beneficial. The optimal positive end-expiratory pressure (PEEP) in this setting is not known, as it is necessary to balance the need for adequate oxygenation for the new liver graft and the risk of higher levels of PEEP impeding hepatic outflow and compromising graft function. It is currently believed that hepatic venous outflow is not impaired by PEEP of up to 10 cm H_2O.[63]

Two unique cardiorespiratory complications of liver disease require special mention: hepatopulmonary syndrome (HPS) and portopulmonary hypertension (POPH).

HPS is diagnosed by the triad of hypoxemia, intrapulmonary vascular shunts as documented by echocardiography or lung contrast scans, and the presence of cirrhosis and/or portal hypertension.[64] The incidence has been reported to range between 4% and 47%, but may be affected by the choice of diagnostic technique and the high frequency of asymptomatic patients.[64] The disorder is believed to be related to intrapulmonary vasodilation and aberrant pulmonary angiogenesis secondary to increased NO production, resulting in arteriovenous shunting and systemic hypoxemia.[64] Liver transplant is the only definitive treatment for HPS. Postoperative management includes the avoidance of fluid overload in addition to usual postoperative pulmonary care.[57] Despite such measures posttransplant, some HPS patients may develop profound hypoxia. Management of patients in this setting revolves around strategies to address intrapulmonary shunting, such as the provision of 100% oxygen, or inhaled pulmonary vasodilators, such as epoprostenol or NO.[64] Intravenous methylene blue has been used successfully in a number of case reports.[65] In cases of refractory HPS, embolization of target pulmonary vessels can be considered along with venovenous extracorporeal membrane oxygenation support. However, given that it may take months for HPS to reverse, careful consideration with regard to duration of therapy is required. Even though many grafts tolerate moderate levels of hypoxia, there is the risk that in marginal or extended criteria grafts, refractory hypoxia may impair graft function, with refractory hypoxia in posttransplant HPS having a reported of mortality up to 50%.[66]

POPH is the presence of pulmonary hypertension in the setting of cirrhosis/portal hypertension and the absence of another contributing cause.[64] POPH is a rare condition with a reported incidence of less than 5% of all cirrhotic patients being worked up for transplantation.[67] The pathophysiology is believed to be pulmonary arterial vasoconstriction and endothelial proliferation caused by increased circulation of vasoactive mediators.[67] It is best diagnosed by echocardiography and confirmed with dedicated right heart catheter studies, with severity based on the mean pulmonary artery pressures (MPAPs).[67] Initial management of POPH involves confirming the diagnosis and excluding other causes of increased pulmonary pressures. Important exclusions include fluid overload and the presence of a hyperdynamic circulation, as they both increase the pulmonary vascular resistance in the absence of structural change. Subsequent management is based on reversing the structural changes that similarly occur with other forms pulmonary hypertension, with the use of endothelial antagonists, inhaled prostacyclin, and inhibitors of phosphodiesterase type 5.[64] The appropriateness of liver transplantation for patients with POPH is unclear, with previous studies suggesting near-universal mortality while undergoing liver transplant.[64] However, further understanding and treatment of POPH have demonstrated that select patients who are pulmonary vasodilator therapy responsive have acceptable outcomes provided MPAP remains lower than 45–50 mm Hg.[68] In patients undergoing liver transplant, pulmonary pressures should be monitored with a pulmonary artery catheter, and pulmonary hypertension therapy should be continued throughout the transplant period. Standard measures at optimizing the pulmonary vascular pressures and right heart function, such as maintaining optimal oxygen and carbon dioxide levels, and selective use of vasoactive agents such as noradrenaline, milrinone, and dobutamine should be applied.[69] It is less clear whether POPH resolves with successful liver transplant, with the results of a small series showing variable improvement in pulmonary hemodynamics and ability to be weaned off long-term POPH therapy.[70]

Renal System

Renal dysfunction is common throughout the perioperative period for liver transplant recipients. Acute kidney injury (AKI) occurs in up to 50% of patients before transplantation and is strongly associated with portal hypertension–mediated splanchnic vasodilation.[71] Management of AKI leading into transplantation predominately consists of treating underlying sepsis;, volume expansion with fluids such as concentrated albumin, a balanced crystalloid, or blood in the event of upper gastrointestinal bleeding; relief of large-volume ascites (with supplementation of concentrated albumin); and withdrawal of nephrotoxic agents such as furosemide and spironolactone. The early initiation of vasoconstrictor therapy—terlipressin or noradrenaline—has been shown to improve outcomes.[72] To date, there have been no randomized studies looking at the early (pretransplantation) initiation of renal replacement therapy (RRT) in liver transplant patients. Early initiation may be considered in those patients awaiting urgent transplant in order to allow early optimization of hyponatremia and prevention of further organ dysfunction secondary to fluid overload.

Renal dysfunction post–liver transplant has a reported incidence of 8%–64%[73,74] and is associated with increased graft failure, infectious complications, longer ICU length of stay, greater hospital costs, and higher mortality.[75,76] Posttransplant AKI is usually multifactorial, influenced by preoperative, intraoperative, and postoperative factors. Preoperative factors include prior renal function; severity of underlying liver disease; the presence of hepatorenal syndrome; and other medical risk factors such hypertension, diabetes, and hypercholesterolemia.[74] Intraoperative factors include duration of caval occlusion, postreperfusion syndrome, and blood loss.[74] Postoperatively, early allograft dysfunction, hypovolemia, sepsis, and direct toxic effects of calcineurin inhibitors (CNIs) are common factors.[74] Management of patients with AKI or at risk of posttransplant AKI consists of optimization of fluid balance with a preference for albumin solution, maintenance of organ perfusion, and avoidance of nephrotoxic agents, in particular CNIs.[77]

There is currently limited evidence to guide timing of initiating RRT in this population; however, it is likely that earlier institution will improve graft function and patient outcomes, particularly in the setting of cumulative positive fluid balance.[78] Given that renal impairment tends to improve as hepatic function is established in the early posttransplant period, the need for RRT is often brief.

Renal dysfunction in ALF is different than in those with chronic liver disease. Renal failure in ALF has an incidence of up to 70% and is almost never the result of hepatorenal syndrome.[79] Risk factors for AKI in ALF include paracetamol toxicity (direct toxic effect), older age, severity of multiorgan failure, and concurrent sepsis.[79] Management principles are similar to those applicable to AKI in the setting of severe septic shock. The role of RRT in ALF is evolving, with accumulating evidence for possible neuroprotective effects through the improved control of hyperammonemia from early initiation of continuous RRT (CRRT).[80,81] Most patients who undergo transplantation for ALF will continue to require CRRT in the immediate postoperative period, with the majority experiencing complete renal recovery in the long term.[79,82] For the small number who have delayed renal recovery, a transition to intermittent hemodialysis may be considered as they progress through the recovery phase of their illness.

Gastrointestinal System

A number of gastrointestinal issues affect management of the post–liver transplant patient. Despite improvements in surgical technique, surgical complications occasionally occur after liver transplantation. The most commonly encountered complications involve the biliary system, namely strictures, obstructions, and leaks; fluid collections such as bilomas or seromas; and bleeding or hematoma formation.[83,84] These complications are best detected by maintaining a high risk of suspicion in the setting of ongoing vasopressor requirement, anemia, new organ dysfunction (especially AKI), unexplained early allograft dysfunction, or new fever and sepsis. Imaging plays a key role in the diagnosis of these complications, and options include ultrasound, computed tomography, dedicated T-tube cholangiograms, or magnetic resonance cholangiopancreatography.[84,85] Management options need to be made in conjunction with the local expertise of the transplant surgical teams, with options including surgical revision, stenting, re-exploration, or radiologic drainage. Common to other forms of major abdominal surgery, ileus occurs frequently post–liver transplantation, with the identification and treatment of precipitating factors, provision of adequate analgesia, balanced fluid and electrolyte management, bowel rest, and decompression being the mainstay of management.[86] Prolonged ileus may necessitate changing to intravenous forms of CNIs or mycophenolate to achieve adequate immunosuppression. Early consultation with the transplant hepatologist and pharmacists is essential to guide management under such circumstances.

It is crucial that patients undergoing liver transplantation have an adequate nutritional assessment. Malnutrition and sarcopenia are frequent complications of cirrhosis, and adequate nutritional support is required to optimize recovery and prevent complications after transplantation.[87,88] Evidence from the wider critical care and surgical literature suggests that early enteral nutrition has significant benefits in preventing infective complications, postoperative ileus, and subsequently allowing optimal early graft function.[89] Recent consensus opinion suggests that the provision of energy of up 30–35 cal/kg/day, with protein 1.2–1.5 g/kg/day, is required.[90] Currently, there is no evidence to suggest that routine supplementation of enteral nutrition with parental nutrition confers additional benefit.[91] For patients who are unable to tolerate enteral nutrition because of prolonged ileus or surgical complications, it is appropriate to consider early parental nutrition; however, this decision needs to be balanced by the possible increase risk of infectious, cholestatic, and metabolic complications.[90] In the setting of ALF, ammonia levels should be monitored during commencement of enteral feeding to ensure that there is no associated rebound of ammonia to dangerously high levels.[90]

Coagulation System

Recent studies demonstrate that patients with both acute and chronic liver failure have evidence of rebalanced hemostasis.[92] In the postoperative period, careful monitoring of hemostatic parameters is required. Bleeding is a major complication, occurring in up to 20% of patients, and is associated with poor outcomes.[93] Risk factors for bleeding include severity of underlying liver disease, surgical technique, and AKI.[94] Hemostatic resuscitation of the bleeding liver transplant patient should be managed according to major guidelines and may be guided by point-of-care viscoelastic testing.[95] In the absence of major surgical bleeding, a restrictive transfusion approach may be beneficial, as the administration of blood products is associated with decreased graft and patient survival, with associated immune dysfunction a likely key factor.[95] The prothrombin time (PT)/international normalized ratio (INR) is a well-established parameter for assessing liver function, and serial monitoring can identify early graft dysfunction.[96] However, it has limited ability to accurately predict spontaneous bleeding risk, and in the absence of active hemorrhage, an abnormal INR should not usually be treated with coagulation factors.

Other aspects of the coagulation system can affect postoperative care. Multifactorial thrombocytopenia is common, and the transfusion of platelets may be required if there is evidence of ongoing blood loss or concerns regarding the safe removal of intravascular devices; a target aim of 30–50 $\times$ 10^9/L appears safe in this setting.[95,97] Hypofibrinogenemia can occur, particularly in the setting of early graft dysfunction, and replacement with cryoprecipitate or fibrinogen concentrate should occur and evidence of hyperfibrinolysis sought.[95,97] The decision on timing of commencement of venous thromboprophylaxis can be difficult, as many posttransplant patients may be hypercoagulable despite disordered hemostatic parameters.[98] The use of mechanical thromboprophylaxis is recommended until the patient is able to adequately mobilize. The ideal timing of pharmacologic thromboprophylaxis is unclear, and individualized decision making, depending on graft function and other organ failure, is required.[98]

Neurologic System

The incidence of neurologic complications after liver transplantation is up to 47%, with delirium, new-onset seizures, strokes, drug toxicity (in particular, CNI therapy), and prolonged hepatic encephalopathy all reported.[99] Consistent with other critically ill populations, delirium is

the most common neurologic complication and is associated with increased ICU length of stay and mortality.[100]

Management of delirium involves treating any precipitating factors such as sepsis, unnecessary medications, electrolyte disturbance, or organ dysfunction (in particular, renal, cardiac, or pulmonary). Nonpharmacologic methods such as reorientation, establishment of day-night cycles, early mobilization, and involvement of family members can be beneficial in select cases. However, in most cases pharmacologic therapy is required to ensure patient and staff safety—recent trials have shown that atypical antipsychotics may reduce the duration of delirium and should be first-line agents.[101] The centrally acting alpha-2 agonist dexmedetomidine decreases time to extubation but may be harmful in the setting of hemodynamic instability and prolonged use.[102]

Aside from delirium, liver transplant recipients have a much higher rate of neurologic complications than other solid organ transplants.[103] The reason may relate to overt or subtle neurotoxicity from chronic hyperammonemia.[103] Further research in this area is required. In ALF, cerebral edema and associated neurologic injury may occur during or after otherwise successful liver transplantation; therefore the provision of CRRT and other neuroprotective measures for a short period posttransplantation may be wise.

Immune System

The liver is a unique immunologic organ, playing key roles in immune surveillance and in the innate and adaptive immune responses.[104] In patients with ALF and ESLD, the loss of hepatic function results in the development of an immunocompromised state. Factors contributing to this include impaired immune surveillance caused by injury of the reticuloendothelial system, reduced activation and phagocytic ability of the innate immune system, and generalized systemic inflammation.[104] This combination of preexisting immune dysfunction coupled with the strong immune suppression required in the early posttransplant period places patients at high risk of infective complications. Most major centers use prophylactic broad-spectrum antibiotics and antifungal agents in this period, although the recommended duration is unclear.[105,106] Antimicrobial selection should be based on local resistance patterns and expert advice.

The provision of immunosuppression is crucial in the early transplant period; local regimens vary but commonly involve high-dose steroid therapy and CNI therapy (Table 146.2).[107] More recently, there is an increase in use of individualized regimens, including selective agents tailored to an individual patient's particular risk profile.[108] These regimens aim to minimize the risk of immunosuppression-related complications. Monitoring levels of immunosuppressive medications requires daily blood levels and close consultation with transplant hepatologists to ensure appropriate dose adjustment to avoid CNI toxicity in the early posttransplant period.

ASSESSMENT OF GRAFT FUNCTION

Monitoring and assessment of graft function are of fundamental importance in the early posttransplant period and are commonly undertaken through clinical assessment, measurement of biochemical and coagulation parameters, and results of imaging (Table 146.3). As the new graft is reperfused and begins to resume function, the patient's hemodynamics state usually stabilizes and postperfusion acidosis resolves. A persistent or increasing vasopressor requirement or worsening metabolic acidosis may be a sign of early graft dysfunction. Biochemical and coagulation values provide an excellent guide to early graft function. Hepatic transaminases (alanine transaminase [ALT] and aspartate transaminase [AST]) frequently rise early as the graft is reperfused and then trend downward over the following 24- to 48-hour period. A slowing of the transaminase downward trend or a sustained rise suggests new graft injury. Restoration of liver function leads to a reduction in the PT/INR as new coagulation factors are synthesized, and failure of this to occur warrants investigation. The use of Doppler ultrasound to assess hepatic vasculature can identify early complications in the hepatic artery and hepatic and portal veins and assist in the detection of bleeding complications and is now considered standard of care.[109,110] Hepatic artery thrombosis (HAT) is the most feared early vascular complication of liver transplantation and occurs in between 2% and 9% of patients.[111] Although many risk factors for HAT have been reported, both surgical and nonsurgical, the exact pathologic mechanism often remains unclear.[111,112] Treatment options include percutaneous thrombolysis, surgical re-exploration, and relisting for transplantation. Prophylactic aspirin therapy has been postulated to decrease the risk of HAT, but convincing evidence is lacking.[113]

The increased prevalence in the use of marginal or extended criteria grafts and patients with significant frailty has amplified the importance of vigilance for identifying poor graft function. *Early allograft dysfunction (EAD)* is a term used to describe an early poorly functioning graft; however, there is currently no consensus definition of

TABLE 146.2 List of Commonly Used Immunosuppressive Agents After Liver Transplantation

Class	Agents	Use	Common Side Effects
Corticosteroids	Methylprednisolone, prednisolone	Induction of immune suppression Acute rejection management	Short term: delirium, hyperglycemia Long term: metabolic syndrome, obesity, osteoporosis
Calcineurin inhibitors	Tacrolimus, cyclosporin	Maintenance of immunosuppression	Renal dysfunction, hypertension, neurotoxicity
Antiproliferative	Mycophenolate mofetil, azathioprine	Maintenance of immunosuppression, Acute rejection management	Nausea, vomiting, diarrhea, bone marrow suppression
mTORi	Sirolimus, everolimus	Maintenance of immunosuppression, Acute rejection management	Hyperlipidemia, oral ulcers, delayed surgical wound healing, early use associated with HAT
Interleukin-2 monoclonal antibody	Basiliximab	Induction of immunosuppression, Use in renal-sparing regimens	Infective complications
T-cell–depleting antibody (monoclonal, polyclonal)	Alemtuzumab, ATG	Induction of immunosuppression, Steroid-resistant rejection	Leucopenia, transfusion reactions, increased infective risk, especially HCV recurrence and CMV reactivation

ATG, Antithymocyte globulin; *CMV,* cytomegalovirus; *HAT,* hepatic artery thrombosis; *HCV,* hepatitis C virus; *mTORi,* mammalian target of rapamycin inhibitors.

TABLE 146.3 Common Postoperative Investigations and Significance

Investigation	Significance
Liver function tests	Declining transaminase indicates good graft health, delayed cholestatic pattern can be benign or sign of graft rejection
Coagulation studies	Normalization of PT/INR strong indicator of underlying graft function
Arterial blood gas	Declining lactate and resolution of acidosis indicate good early graft function
Doppler ultrasound	Assess patency of hepatic vessels, in particular hepatic artery; can also assess resistance across graft, suggesting poor graft function

INR, International normalized ratio; *PT,* prothrombin time.

BOX 146.1 Risk Factors for Ischemic Reperfusion Injury

Donor and recipient age
Illness severity at time of transplantation
Donor warm ischemic time
Donor cold ischemic time
Donor hepatic steatosis >30%
Altered coagulation profile

EAD.[114] Graft dysfunction may be identified by increasing transaminase levels, serum bilirubin concentration, PT/INR, and ammonia levels.[114] EAD may be viewed as an extreme endpoint of ischemic reperfusion injury (IRI), as many of the risk factors for EAD are influenced by the degree of IRI.[115] IRI occurs after successful implantation, when the liver graft is exposed to oxygenated blood, and results in free radical production, endothelial cell damage, and graft dysfunction. Currently, management of established EAD/IRI is largely supportive, with the identification of potential contributing factors such as concomitant sepsis, organ failure—in particular renal, and maintenance of electrolyte and fluid balance (Box 146.1). Recent research has explored the potential to decrease the risk of IRI and EAD by the use of liver perfusion devices to decrease the impact of risk factors.[116] Evidence thus far has demonstrated lower peak transaminase rises, decreased biliary complications, and lower incidences of EAD and primary nonfunction; however, these trials are small in number, and we await the outcomes in larger, more diverse populations.[116] Although widely used, there is no evidence that the use of prostacyclin or such agents improves patient or graft outcome.[117]

CONCLUSIONS

Liver transplantation has progressed over recent years with significant improvements in all aspects of care. Along with this progress, long-term survival has also continued to improve. However, patients undergoing transplantation continue to have multiorgan dysfunction both before and after liver transplantation. ICUs play a key role in the provision of life-sustaining therapies preoperatively—in particular the management of those with ALF. Postoperatively, critical care continues to provide specialized high-quality, multiorgan support that is required for optimal outcomes in this complex surgical population.

KEY POINTS

- Post–liver transplant outcomes continue to improve with high-quality ICU care.
- Nonhepatic organ failures influence postoperative outcomes, most commonly cardiac, respiratory, and renal issues.
- A systematic approach is required for optimizing care.
- Multimodal assessment of graft function is crucial to early detection of complications.
- Multidisciplinary decision making is essential throughout the period around transplantation.

Intestinal and Multivisceral Transplantation: The Ultimate Treatment for Intestinal Failure

Arpit Amin, Vikram K. Raghu, George V. Mazariegos, and Geoffrey J. Bond

INTRODUCTION

Intestinal and multivisceral transplantation remains a dynamic process, moved forward by advances in the multidisciplinary care of intestinal failure, surgical techniques, innovative immunosuppressive strategies, and an improved understanding of intestinal transplantation immunology. More recently, great strides have been made in the medical and surgical management of patients with intestinal failure, which has resulted in a decrease in the number of patients added to the intestinal transplant waiting list and subsequently undergoing intestinal transplantation (Figs. 147.1 and 147.2).[1,2] Multidisciplinary dedicated intestinal rehabilitation and transplantation units have become established at high-volume centers, where patients are managed with an available armamentarium of medical therapy, intestinal rehabilitation surgeries, and intestinal transplantation. The goal of these multidisciplinary dedicated intestinal rehabilitation and transplantation units is that patients likely to require transplantation will be listed, followed, and transplanted at the optimum time after weighing the risks and benefits and complications of each of these modalities (medical therapy, intestinal rehabilitation surgery, intestinal transplantation).

In the United States alone, 1204 patients were alive with a functioning intestinal allograft as of June 2018.[1] Immunosuppression for intestinal and multivisceral transplantation commonly involves some form of perioperative (antibody) induction protocol, although many centers now tailor induction and maintenance protocols to individualize strategies based on each patient's situation, often by employing immunologic testing (crossmatching and donor-specific antibody testing) to help determine optimum strategies.

The future of intestinal transplantation depends on the prevention and treatment of chronic rejection, which disproportionately affects isolated intestinal allografts. Chronic rejection continues to be a fundamental barrier to achieving successful long-term outcomes and is the ongoing subject of rigorous investigation. Long-term data on nutritional outcomes and transplantation morbidity help further determine the optimal timing and role of intestinal and multivisceral transplantation in patients with intestinal failure.

DEFINITION AND MANAGEMENT OF INTESTINAL FAILURE

As per the most recently updated guidelines published by the European Society of Clinical Nutrition and Metabolism (ESPEN) in 2018, intestinal failure is defined as "the reduction of gut function below the minimum necessary for the absorption of macronutrients and/or water and electrolytes, such that intravenous supplementation is required to maintain health and/or growth."[3,4] Patients with intestinal failure are initially managed by administration of parenteral nutrition (PN) through central venous access.

The duration of intestinal failure is variable and, in certain patients, unpredictable, from shortterm to lifelong, and depends largely on the adaptation capacity of the remaining viable intestine, which is dependent on variable factors such as patient age and underlying diagnosis. As such, intestinal failure can be functionally classified based on ESPEN guidelines published in 2015 into three categories:

1. Type 1—acute intestinal failure, short-term, self-limiting
2. Type 2—prolonged acute intestinal failure requiring PN over periods of weeks to months
3. Type 3—chronic intestinal failure requiring PN over months to years

Furthermore, 2015 ESPEN guidelines further help conceptualize intestinal failure by classifying it into five major pathophysiologic classifications: (1) short bowel syndrome (reduced absorptive mucosal surface), (2) intestinal fistula (bypass of large areas of absorptive mucosal surface), (3) intestinal dysmotility (intolerance to oral/enteral nutrition because of nonmechanical intestinal obstruction), (4) mechanical obstruction, and (5) extensive small bowel mucosal disease (inefficient absorptive and/or nutrient-losing mucosal surface).

Optimal management of patients with intestinal failure is achieved after a detailed multidisciplinary evaluation. Obtaining a comprehensive history is critical and must include birth details (such as prematurity) and disease history; complicating comorbid medical history; past surgical procedures; infections; number and location of previous central venous lines; presence of central venous thrombosis; a detailed nutrition history, including duration of PN, details of PN prescriptions, and maximal enteral feeding tolerance and its trajectory (still advancing or static); medication history; and frequency/volume of stools. A careful history and physical examination performed by the intestinal rehabilitation team is critical to the process of achieving a complete pretransplant work-up. Further investigations include blood tests, upper gastrointestinal (GI) contrast study with small bowel follow-through; contrast enema if indicated; abdominal sonogram to assess for hepatosplenomegaly; and an examination of central venous anatomy either by ultrasound, computed tomography (CT) or magnetic resonance (MR) venography, or traditional venography. Occasionally, endoscopy with small intestinal aspiration for quantitative microbial culture and mucosal biopsy is recommended. In equivocal cases, liver biopsy is recommended if there is evidence of liver dysfunction or portal hypertension to determine if concomitant liver-containing transplantation is required.

Management of patients with intestinal failure focuses on optimization of gut adaptation and recovery of intestinal function to achieve enteral autonomy. With improved management of PN and minimization of complications, longer durations of PN can be achieved to allow for gut adaptation.[5] Clinical trials have shown favorable outcomes with the use of the glucagon-like peptide analogue (GLP-2) teduglutide in increasing intestinal adaptation and increasing the likelihood

of weaning off PN in short bowel syndrome patients. As a result, the Food and Drug Administration (FDA) has approved the use of teduglutide for the management of patients with short bowel syndrome over the last decade.[6,7] A small portion of patients have shown excellent response with the ability to greatly reduce or even completely eliminate parenteral support. However, the high cost of the medication, estimated at >$400,000 per year per patient, limits its general use, especially without guidance on which patients will achieve enteral autonomy with therapy.

Simultaneously, progress has been made in intestinal rehabilitative surgical therapies, including autologous reconstructive surgeries (repairing enterocutaneous fistulae, restoring enteral continuity with primary reconstruction or use of alimentary conduits) and bowel-lengthening procedures such as the longitudinal lengthening procedure described by Bianchi and the serial transverse enteroplasty (STEP).[8–10] A recent study focusing on outcomes of the full spectrum of intestinal rehabilitative surgeries and bowel-lengthening procedures on 500 consecutive patients with intestinal failure has shown remarkable results, with restored nutritional autonomy in 82% of patients with a 5-year survival of 70%.[11]

Alternatively, if gut dysfunction is considered irreversible, management of these patients concentrates on maintaining optimal growth in children and nutritional repletion in adults to prepare them for likely intestinal transplantation. Recently, there has been a shift in timing of intestinal transplantation, focused more on the individualized risks and complications of PN versus intestinal transplantation. In other words, if patients, especially children where there still may be hope for further adaptation, are stable on PN with no significant complications, then deferring transplant is quite reasonable.

Small bowel bacterial overgrowth (SBBO) is a common clinical problem in patients with intestinal failure and is treated with a variety of antibiotic regimens. To date, no comparative studies are available to enable an evidence-based approach to treat SBBO. The use of metronidazole for anaerobic overgrowth, combined with trimethoprim and sulfamethoxazole or an oral aminoglycoside for gram-negative organisms, is a common theme. Metronidazole monotherapy is used if the dominant symptoms suggest predominantly anaerobic overgrowth (such as bloating, increasing diarrhea, and D-lactic acidemia). The extreme sensitivity of anaerobes to oxygen makes the use of small bowel aspirate cultures relatively unreliable as a means of microbial surveillance or indication to treat SBBO. Probiotics such as *Lactobacillus* and *Saccharomyces* have been used in an attempt to limit SBBO. Given the absence of randomized evidence to support the efficacy of probiotics, coupled with reasonable concerns about impurities and possible contamination with other bacteria (e.g., *Leuconostoc*), the use of probiotics is controversial and mostly discouraged in patients with central venous catheter access and intestinal failure and especially after transplantation because of increased immune suppression.

Parenteral nutrition–associated liver disease (PNALD), also referred to as *intestinal failure–associated liver disease* (IFALD), remains a critical problem in this patient population, affecting infants disproportionately. The 1-year mortality of patients with PNALD exceeds 20% in the absence of PN weaning or transplantation.[12] Although not always feasible, the best strategy to prevent and treat PNALD involves a commitment to the advancement of enteral nutrition. Despite a conscientious approach to PN therapy, many children and adults still develop cholestasis relatively early in their clinical course. Prevention and timely treatment of infection, minimizing SBBO, preventing overfeeding with dextrose, providing adequate amino acids, cycling PN, or providing PN-free days when possible are probably important measures to slow the progression of PNALD.[13] Stasis of bile in the nonstimulated biliary system and gallbladder can lead to sludge buildup and cholelithiasis. In the authors' experience, cholecystectomy may be beneficial to minimize the risks of developing biliary obstructive episodes and pancreatitis and should be considered early in any operative course as part of a combined procedure. Cholecystectomy on its own is rarely done, as it seldom improves liver function and is not indicated for PNALD alone. Bowel reconnection, even in patients with very short guts, may relieve some of the high pressure in the upper GI tract and issues of reflux cholangitis, which may allow for long-term improvements in liver function.

Rates of PNALD have significantly decreased with novel methods to reduce phytosterol exposure from parenteral lipid emulsions through lipid minimization protocols with the reduction of traditional soybased lipid solutions and even their eventual removal by substituting with Omegaven (a fish oil–based, intravenous [IV] lipid solution rich in omega-3 fatty acids). Omegaven has recently been FDA approved (as of July 2018) for use in neonatal and pediatric patients suffering from PNALD.[14] Another option in patients with PNALD is the use of a mixed oil lipid-based emulsion such as SMOF (soybean oil, medium-chain triglycerides, olive oil, fish oil) lipid, which is currently approved for use in adults in the United States with an ongoing pediatric trial. SMOF lipid may offer another alternative in pediatric patients with PNALD

who demonstrate poor weight gain or develop essential fatty acid deficiencies while on fish oil–based emulsions.[14,15] Although biochemical improvement in liver disease has been shown with these alternative lipid formulations, it is unclear whether they actually alter histologic progression of liver disease.

In addition to PNALD, patients on long-term PN are at risk of developing metabolic bone disease (MBD). Associated with an insidious onset of bone pain that can become quite severe, patients with MBD will present with normal serum calcium, phosphorus, vitamin D, and parathyroid hormone, but with hypercalciuria. Nontraumatic spinal and rib fractures have been reported in these patients. To optimize bone maintenance in patients on PN, it is important to include calcium in parenteral formulations, prevent metabolic acidosis, and minimize aluminum contamination. Symptoms of MBD tend to resolve only after stopping PN.

Many intestinal transplant recipients will require intensive care unit (ICU) management during the pretransplant period, although the number of patients being transplanted from home (outside of a hospital setting) has increased with improved medical management and resulted in improved outcomes in this subset of patients. Sepsis and GI hemorrhage are common reasons for ICU admission in patients with intestinal failure. Blood products, though necessary in the resuscitation of GI hemorrhage, should be used judiciously in the absence of acute bleeding. Pretransplant exposure to blood products, particularly platelets, can predispose intestinal transplant recipients to developing antibodies and can place them at a higher risk of developing antibody-mediated rejection after transplantation. Leukoreduced blood products may be preferable in patients awaiting transplant.

Central line–associated bloodstream infections (CLABSIs) unfortunately are common in PN-dependent patients. All attempts should be made to avoid this event, with fastidious central line care at the core of the matter. Centers have employed central line care bundles to aid in sterile central line care at home. Lock therapy has played an important role in further reducing the incidence of CLABSI with ethanol, taurolidine, and sodium EDTA locks all showing various degrees of effectiveness.[16] One of the determining factors to move forward with transplantation is loss of venous access. Hence, although infection (especially fungal and life-threatening gram-negative infections) may necessitate removal of a tunneled central venous catheter, all attempts at salvaging the line, or at least the venous site, should be considered. Smaller pediatric patients and patients with a history of thrombosis may have limited venous access, necessitating preservation and treatment through an infected line. Percutaneous lines should be placed with caution in these patients, as great vessels may no longer be patent, and the trauma to the remaining vessels may have serious consequences. Many surgeons, anesthesiologists, and intensivists now place central lines under ultrasound guidance, although the more difficult and chronic-issue lines are best served in interventional radiology, with their vast cadre of specialized techniques. Ultrasound evaluation of deep veins to assess for patency is notoriously variable and often unreliable, and in difficult or concerning cases venography remains the gold standard. Many centers now use cross-sectional imaging through MR or CT venography in place of traditional fluoroscopic venography. Mapping should be considered before excessive loss of venous access occurs.

Nutritionally deplete patients are relatively immune suppressed and prone to severe community-acquired infections. Pediatric patients with intestinal failure and IFALD are at increased risk of respiratory failure even with common viral infections. Because children have a compliant chest wall, increased abdominal girth creates a mechanical disadvantage even during normal tidal volume breathing. In the setting of pulmonary infection, volume overload, or decreased cardiac output, the work of breathing can lead to fatigue.

Neurodevelopmental outcomes of children with intestinal failure have been understudied. Conflicting evidence exists regarding neurodevelopmental outcomes, with some reports of gross motor and cognitive deficits identified within the first few years of life.[17]

INDICATIONS FOR TRANSPLANT

The goals of the transplant team are to determine whether the patient may benefit from transplantation, assess alternatives to transplant, evaluate any contraindications to transplantation, and provide education to the patient and caregivers about the complex process of undergoing transplantation. After evaluation by the multidisciplinary team and open and frank discussion among all the team members, the usual result is one of three choices: (1) the patient may be followed closely as an intestinal care patient and listing status deferred depending on progress; (2) the patient may be listed as a status 2 recipient to accrue time on the list while awaiting possible medical improvement or bowel adaptation but realizing that transplantation is still quite likely; or (3) the patient may be listed as a status 1 intestinal recipient if the patient has met criteria for complications of irreversible intestinal failure, or as a liver intestine recipient if the patient is deemed to have irreversible intestinal failure and associated irreversible significant liver dysfunction for immediate consideration where criteria make transplantation inevitable.

In October 2000, the Centers for Medicare and Medicaid Services approved intestinal, combined liver-intestine, and multivisceral transplantation as a standard of care for patients with irreversible intestinal failure who could no longer be maintained with PN. As experience with intestinal rehabilitation and transplantation has increased over the last two decades, there has been debate about updating the original guidelines published in 2001 about indications of intestinal transplants. As a result, a working group of worldwide experts on intestinal failure and transplantation was assembled at the XIV International Small Bowel Transplant Symposium in 2015. Based on this deliberation, a recent consensus statement about updated indications of intestinal transplantation was published in 2019.[18] Most notably, extreme short bowel and transplantation for quality of life are absent from the revised indications, largely because of the advances in intestinal rehabilitation and resultant improvements in quality of life on PN. Based on these updated 2019 guidelines, indications for intestinal transplantation in the current era can be summarized as follows:

1. Evidence of advanced or progressive IFALD defined as either (a) hyperbilirubinemia >4.5 mg/dL that persists for more than 2 months despite IV lipid modification strategies or (b) any combination of elevated serum bilirubin, reduced synthetic function (low albumin or elevated international normalized ratio [INR]), and laboratory indications of portal hypertension and hypersplenism (especially low platelets) persisting for more than 1 month in the absence of a confounding infectious event(s).
2. Progressive loss of central venous access, typically defined by loss of at least two upper body central venous sites (left subclavian, left internal jugular, right subclavian, or right internal jugular) or occlusion of a brachiocephalic vein in children. In adults, this criterion should be evaluated on a case-by-case basis.
3. Life-threatening morbidity in the setting of indefinite PN dependence of either anatomic or functional etiology, as suggested by (a) in children, two admissions to the ICU (after initial recovery from the event resulting in intestinal failure) because of cardiorespiratory failure (mechanical ventilation or inotrope support) resulting from sepsis or other complications related to intestinal failure and (b) in adults, on a case-by-case basis.
4. Invasive intraabdominal desmoids in adolescents and adults.

TABLE 147.1 Indications for Intestinal and Multivisceral Transplantation

Pediatric Patients	Adult Patients
Volvulus	Superior mesenteric artery thrombosis
Gastroschisis	Crohn disease/irritable bowel disease (IBD)
Necrotizing enterocolitis	Desmoid tumor
Pseudo-obstruction	Volvulus
Intestinal atresia	Trauma
Microvillous inclusion disease	Familial polyposis
Hirschsprung disease	Budd-Chiari disease
Trauma	Intestinal adhesions
	Pseudo-obstruction
	Radiation enteritis

5. Acute diffuse intestinal infarction with hepatic failure.
6. Failure of first intestinal transplant.

Owing to the particularly high morbidity and mortality of children with IFALD, increasing efforts have been made by the pediatric medical community to optimize timing of referral of these patients to specialized intestine failure rehabilitation centers and transplant centers to improve overall outcomes. In addition to the earlier criteria for intestinal transplantation, a recent expert consensus panel recommended the following patients be evaluated for intestinal transplant: (1) children with massive small bowel resection, (2) continuing prognostic or diagnostic uncertainty, (3) microvillous inclusion disease or intestinal epithelial dysplasia, and (4) the request of the patient or family.[19] This initiative, to a large extent, has been relatively successful in breaking down previously held prejudices and allowed for prompt and, at times, very early evaluation. This in turn has allowed for more coordinated expert multidisciplinary management of these patients. With fewer patients now heading into liver failure with improved preservation of the liver, it gives the medical and surgical teams more time to let the native bowel adapt, so that more patients, even after 5 or more years of PN therapy, are eventually able to wean off of PN who previously would never have been given this chance.

The initial underlying pathophysiologic disorders leading to intestinal failure and subsequently intestinal transplantation in children and adults are summarized in Table 147.1. Based on data from the Intestine Transplant Registry published in 2015, short gut syndrome is the most common pathophysiologic mechanism responsible for intestinal failure requiring intestinal transplantation in children and adults.[2] The relative distribution of various pathophysiologic indications leading to intestinal failure and subsequently to intestinal transplantation in children and adults is summarized in Fig. 147.3.

Transplantation is unlike any other surgical procedure in that it is rarely an isolated event, unlike general surgical procedures, and has significant short- and long-term medical and surgical issues that need to be considered. Nowadays, as the overall management of PN improves, the indication and timing of transplantation become a balancing act, trying to weigh the risks and complications of PN versus the potential short- and long-term risks of intestinal transplant.

EVALUATION FOR TRANSPLANT

For both children and adults, the evaluation of intestinal and multivisceral candidates usually begins as an inpatient process because of the complexity of the case and the need for many different services to see the patients and investigations that may be required. Most intestinal failure units use multidisciplinary teams that assess patients during evaluations. This comprises the GI team, other medical teams as indicated (cardiac, renal, genetic, immunology, pulmonology, etc.); general surgery (especially pediatric surgery); transplantation; and many allied services including psychology, social work, pharmacy, and others as indicated in each case. Transplant teaching is a vital component, as is determining fiscal ability and supportive structures for potential recipients. Each team provides recommendations, and, in particular, the GI team may make recommendations with the PN and IV fluids and medications that may be quite beneficial to the patient and the referring team. At times, especially in a multidisciplinary center with both good pediatric surgical and transplant skills, these patients may undergo surgical exploration and attempts at reconstruction and/or bowel-lengthening procedures before transplantation. These are done with an attempt to either avoid transplantation, or at least minimize the need for PN and concomitant liver disease and delay the need for transplantation, or to make the conditions at transplant better (i.e., obtain colonic growth and health in previously disconnected patients or resecting enteric fistulae/intraabdominal abscesses that may be contributing to sepsis). Having a surgeon well versed in medical management strategies, able to operate as a general surgeon to try to help restore enteral

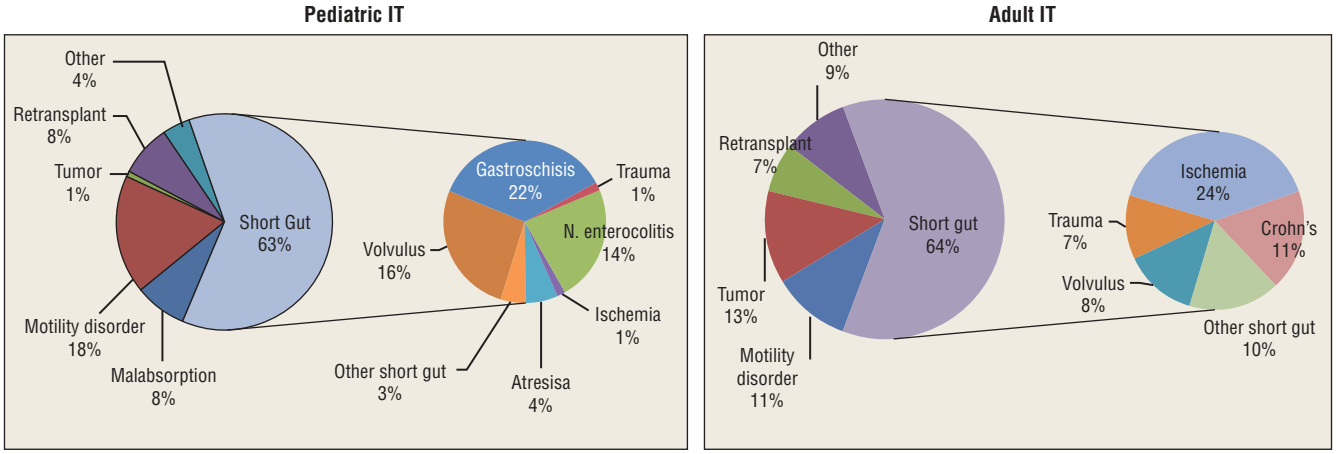

Fig. 147.3 Indications of intestinal transplantation in children and adults. (Adapted from Grant D, Abu-Elmagd K, Mazariegos G, et al. Intestinal Transplant Registry report: Global activity and trends. *Am J Transplant.* 2015;15[1]:210–219. doi: 10.1111/ajt.12979. Epub 2014 Dec 1.)

autonomy by surgical means, and be able to set the patient up for transplant is advantageous for both the patient and intestinal failure unit, allowing for more aggressive surgical interventions to try to avoid or delay transplantation.

Determining which type of allograft to use in patients with intestinal failure involves a comprehensive evaluation of the function and anatomy of the remaining bowel along with other abdominal organs. Intestinal failure patients are considered candidates for isolated intestinal transplant (with or without colon), combined liver and intestine transplant, multivisceral transplant (including liver, stomach, duodenum, pancreas, and small bowel with or without colon), or modified multivisceral transplant that excludes the liver. There has been ongoing debate in the transplant community regarding the previously mentioned nomenclature; however, from a practical and immunologic point of view, the major differentiation is the inclusion of the allograft liver as part of the transplant bloc. Whether to perform simultaneous hepatic replacement remains a challenging decision even to experienced transplant surgeons, particularly for patients with borderline liver dysfunction and a biopsy that shows fibrosis (Ishak level 3–4 and above) and some degree of synthetic dysfunction suggestive of portal hypertension. Nevertheless, it must be realized that the classic symptoms and signs of impending liver failure may not be the same in patients with limited or no intestine, and the use of Omegaven or SMOF may normalize the bilirubin but not affect fibrosis. This also affects the Model of End-Stage Liver Disease (MELD) and Pediatric End-Stage Liver Disease (PELD) score in these potential recipients; hence the essential need for "supplemental" points to be added to their total when the intestine is added to the United Network for Organ Sharing (UNOS) liver transplant listing. This has been allowed in the pediatric population for some time now but remains a vexed issue in the adult population.

The key factors in determining whether to perform liver transplant in patients with intestinal failure are the extent of portal hypertension and the severity of parenchymal liver disease. In general, patients with mild portal hypertension should be cautiously considered for isolated intestinal transplant. Under these circumstances, it is mostly recommended that venous outflow from the intestinal allograft bypass the portal circulation and be drained to the recipient systemic circulation through the inferior vena cava. This is especially relevant as there has been no documented proof that portal drainage is more beneficial or that relative portal and mesenteric hypertension may have deleterious effects on intestinal allograft function. The other predicament is the patient with marginal intestinal length who may, under ideal circumstances and more time, be able to adapt and come off of PN but the liver has undergone such considerable damage that it needs to be replaced. In this circumstance, liver transplantation alone in the face of short gut syndrome can and has been done but is fraught with potential dramatic consequences and the potential need for liver and intestine retransplantation if it is not successful.

TRANSPLANTATION PROCEDURES

Brief descriptions of recipient operations are provided here. The multivisceral donor procurement operation has previously been well described.[20] It is important to note that to a large extent, the future course after transplant is significantly determined by the quality of the donor and success of the donor recovery and back-table preparation. The intestine is perhaps the most sensitive donor organ and prone to ischemic events either by nature of the cause of death or because of pharmacologic agents (vasopressors) that are used to support the donor leading up to and after neurologic determination of death. It is thought that damage to the bowel sets up an inflammatory cascade that in turn makes the organ more immunogenic, or at least more susceptible to a rejection episode once it is reperfused in the recipient. Hence, the recipient surgeon is extremely judicious in the selection of a suitable donor and the number of acceptable donors is restricted. Other factors that play into this decision include blood group (generally identical), size-matching issues because of restricted abdominal domain (reduced grafts have been shown to have short- and long-term issues), and some potential crossmatch issues (especially in retransplant patients). Because of stringent donor selection criteria, the intestinal allograft is one of the more infrequently recovered allografts from available donor pool.[21]

Isolated Intestinal Transplant

For isolated intestinal transplants (Fig. 147.4), the donor intestinal graft (jejunum and ileum) is procured along with donor vascular conduits, including an artery (iliac and/or carotid) and a vein (iliac, occasionally jugular). The donor superior mesenteric vessels are occasionally anastomosed directly to the recipient superior mesenteric artery and vein if adequate length is achieved. More commonly, interposition vascular conduits are anastomosed to the recipient infrarenal aorta and recipient superior mesenteric vein (portal drainage) or inferior vena cava (systemic drainage) to provide sufficient length and proper orientation for the allograft.

The intestinal reconstruction involves a proximal duodenojejunostomy or jejunojejunostomy, depending on individual recipient considerations of remnant bowel viability and anatomy. The distal end of the intestinal allograft may be used as a permanent end ileostomy if the recipient has no remaining viable colon or may be anastomosed to the remnant colon, leaving a short portion of allograft distal to the enterocolic anastomosis to bring out as a temporary end ileostomy (Bishop-Koop ileostomy) that allows access to the bowel for endoscopic surveillance and mucosal biopsies.

Colonic transplantation with the small bowel has been used more frequently, especially in situations where the native colon is very short or nonfunctional (such as Hirschsprung disease or pseudo-obstruction). In this case, a loop ileostomy is formed so that the small bowel can be biopsied and the colon normally brought out as an end colostomy, or if anastomosed to the remaining colon, a loop allograft colostomy may be

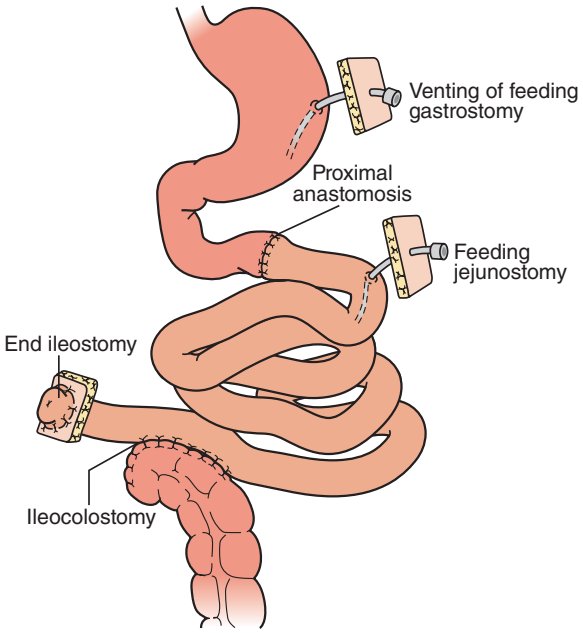

Fig. 147.4 Isolated intestinal transplant.

formed as well. Inclusion of colonic graft with small bowel graft has been shown in a recent study to provide improved postoperative renal protection along with increasing rate of interval ileostomy reversal in intestinal transplant recipients.[22]

In patients with gastric dysmotility, although a stomach-inclusive allograft may be ideal, because of donor availability (size and/or anatomic vascular aberrations), it may not be recoverable; hence a gastrojejunostomy may also need to be performed as an alternative to drain the stomach. Single or multiple feeding tubes (gastrostomy tube, jejunostomy tube, and combined gastrojejunostomy tube) may be placed based on multiple considerations, including recipient pretransplant oral intake capacity and dysmotility issues.

Combined Small Bowel and Liver Transplant

For combined small bowel and liver transplants (Fig. 147.5), the recipient hepatectomy is routinely performed with preservation of the native retrohepatic inferior vena cava. The recipient foregut, including stomach, native pancreas, and proximal duodenum, is also preserved and its venous outflow maintained with a permanent end-to-side portocaval shunt. The composite donor allograft includes the primary organs (liver and small bowel) and the donor duodenum and pancreas, allowing for maintenance of donor hepatobiliary continuity. Arterial inflow to the composite donor allograft is achieved using an arterial interposition conduit from the recipient infrarenal aorta to the reconstructed donor aorta placed onto the Carrel patch of donor celiac artery and superior mesenteric artery. Allograft venous outflow via the suprahepatic inferior vena cava commonly involves the well-described "piggyback" technique, anastomosing the donor suprahepatic inferior vena cava/hepatic veins cuff to the confluence of the recipient hepatic veins and cava. Occasionally, a "standard" bicaval anastomosis is performed. Intestinal reconstruction is performed in a similar fashion to an isolated intestinal transplant, mostly with the upper anastomosis being a jejunojejunostomy. Feeding tubes are placed as indicated.

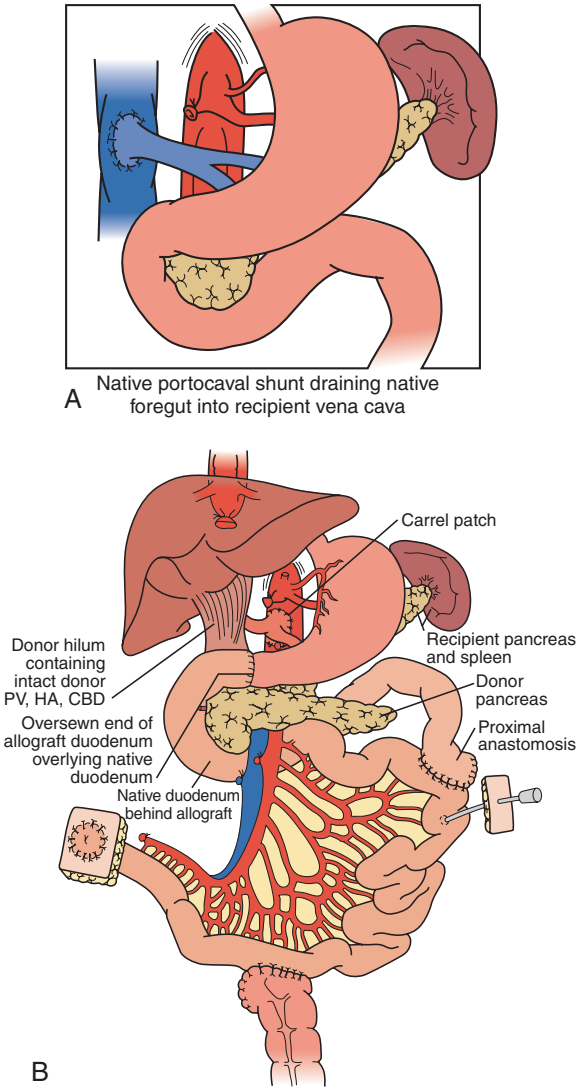

Fig. 147.5 Combined liver and intestinal transplant. **A,** Portocaval shunt draining native foregut. **B,** Combined liver and intestinal transplant with feeding jejunostomy. *CBD,* Common bile duct; *HA,* hepatic artery; *PV,* portal vein.

Full Multivisceral Transplant

In the majority of cases of full multivisceral transplant procedures (Fig. 147.6), before implantation, the recipient distal stomach, duodenum, pancreas, liver, and remaining small bowel are resected. The recipient inferior vena cava is routinely meticulously preserved. The absence of remaining foregut or midgut precludes the need for a portocaval shunt. Vascular inflow is similar to composite liver-bowel transplant but now includes celiac inflow to the stomach as well. Vascular outflow is identical to composite liver-bowel transplant. The donor spleen is removed from the composite allograft on the back table before reperfusion. Intestinal reconstruction is performed proximally with a gastrogastrostomy anastomosis, and the distal anastomosis is similar to previously described intestinal transplants. To avoid gastric outlet obstruction resulting from vagal denervation, a Heineke-Mikulicz pyloroplasty is routinely performed after reperfusion. Feeding tubes are placed as indicated.

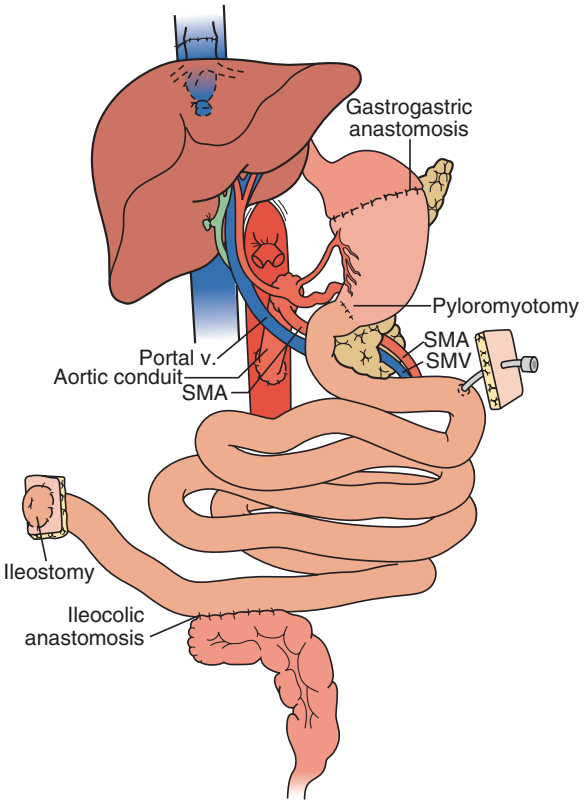

Fig. 147.6 Full multivisceral transplant. *SMA,* Superior mesenteric artery; *SMV,* superior mesenteric vein.

Modified Multivisceral Transplant

A "modified" multivisceral transplant (Fig. 147. 7) involves transplantation of a full composite allograft without a liver. The recipient liver is preserved along with its vasculature and the extrahepatic biliary system with duodenum, pancreas, and spleen. Vascular conduits are used routinely (Fig. 147.8). If the native enterohepatic biliary system is intact, the native duodenum or jejunum is drained into the allograft duodenum or jejunum. If, however, the procedure involves disruption of hepatobiliary continuity, the native bile duct can be drained via Roux-en-Y hepaticojejunostomy constructed from donor intestinal allograft (often the case in children where the donor bile duct is very small), or in adults and older children via a choledochoduodenostomy (duct-to-duct) anastomosis.

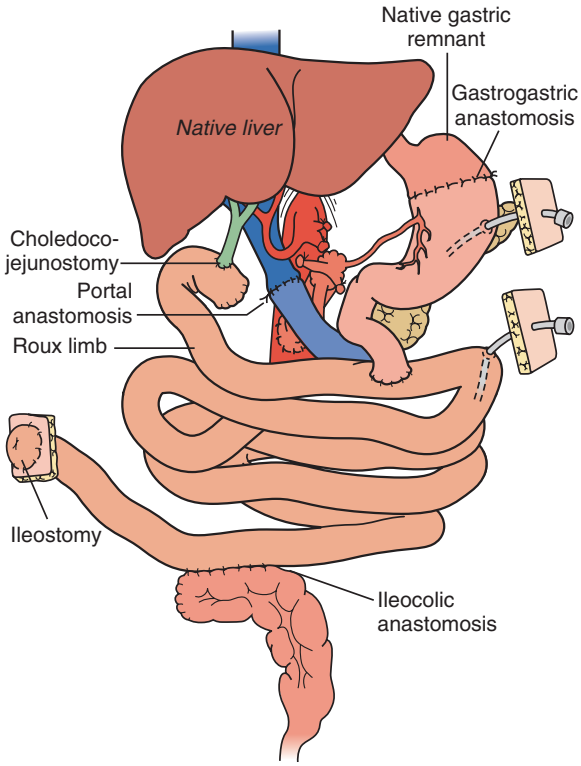

Fig. 147.7 Modified multivisceral transplant.

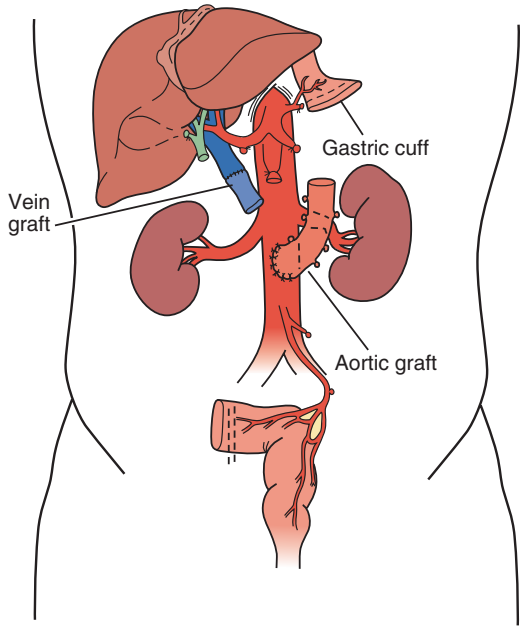

Fig. 147.8 Vascular conduit extensions for modified multivisceral transplant.

Abdominal Wall Closure After Intestinal Transplantation

Fascial closure after intestinal transplant can be difficult because of reduced abdominal domain, loss of fascial compliance from prior laparotomies, and possible concern for abdominal compartment syndrome. Previous studies have shown that abdominal fascia cannot be closed in about one-third of intestinal transplant cases. Low donor to recipient weight ratio (<0.8) has been shown to be an important predictive factor for allowing fascial closure after intestinal transplant.[23,24] A recent study identified high-risk recipient factors (preexisting enterocutaneous fistulas, male sex, and age over 4 years) contributing to an inability to achieve sustained abdominal wall closure after intestinal transplant.[25] Currently available options for abdominal closure in these cases include skin-only closure, advanced reconstructive surgical options including use of biologic mesh and delayed skin grafting, and consideration of abdominal wall transplant at the time of intestinal transplant.[25]

POSTOPERATIVE MANAGEMENT

Advances in the technical aspects of intestinal and multivisceral transplantation have occurred in parallel with improvements in intraoperative monitoring and postoperative critical care management of these challenging patients.

Ventilatory Management

Extubation is commonly achieved within 48 hours of the transplant operation in adult patients. Mitigating factors that might delay extubation include graft malfunction, delayed abdominal wall closure, volume overload, sepsis, organ failure, and surgical complications such as bleeding. In children, delayed abdominal wall closure is commonly necessary because of allograft size constraints and swelling postreperfusion and requires continued neuromuscular blockade and mechanical ventilation while diuresis is performed. Given that recipients tend to be nutritionally compromised preoperatively and that intestinal and multivisceral transplant operations are relatively long in duration (8–18 hours), a careful assessment of weaning parameters before extubation is essential. Changes in intraabdominal pressure and abdominal girth may adversely affect respiratory mechanics, leading to rapid, shallow breathing. These problems are most common in children, in small adults who receive large allografts, and in patients whose course is complicated by large-volume ascites. Pleural effusions are common because of nutritional depletion with hypoalbuminemia and intraoperative manipulation of the diaphragm. Although attempts to overcome them by diuretics may be attempted, thoracentesis and placement of pleural tubes often are necessary.

Renal Function

It is common for intestinal transplant recipients to demonstrate some degree of renal dysfunction pretransplant, owing to multiple episodes of sepsis with hypotension, the side effects of antibiotics, chronic dehydration, and hepatic dysfunction. Although patients receive significant volumes of fluid during the long course of the transplant operation, intravascular volume depletion can be a problem in the immediate posttransplant period. Significant fluid volume may accumulate in the intestinal allograft secondary to preservation injury (peaking at 48–72 hours), and large-volume ascites or chylous ascites

production because of mesenteric lymphatic leakage may occur. Either of these processes can lead to profound and sometimes underappreciated intravascular volume depletion and can worsen the nephrotoxicity of immunosuppressive agents and antibiotics.

Maintenance of ideal volume status is challenging in these patients, and interventions should be directed at optimizing cardiac output and organ perfusion. Extravascular volume overload is common and should be interpreted with caution, particularly in the immediate posttransplant period. In patients with impaired renal function or high tacrolimus drug levels, urine output may not be an accurate indicator of perfusion. Skin perfusion, mixed venous oxygen concentration, and serum lactate are useful surrogates. Because intestinal transplant recipients are commonly nutritionally deplete, use of 5% albumin as a volume expander may be preferable to larger volumes of crystalloid solution. In patients with large-volume stoma output or ascites drainage, standing orders for fluid replacement may be necessary. Balancing adequate volume resuscitation with the avoidance of volume overload in the setting of baseline renal dysfunction can be a significant challenge that requires considerable clinical experience and meticulous attention to detail.

Infection

Recipients of intestinal or multivisceral transplants will routinely receive prophylactic broad-spectrum antibiotics intratransplant and posttransplant. Any history of nosocomial infections before transplant should be addressed with administration of the appropriate specific antibiotics. Colonizing organisms growing from enterocutaneous fistula tracts should also be covered appropriately. Selective bowel decontamination with nonabsorbable oral antibiotics is performed routinely in the donor and in some intestinal transplant recipients.

Translocation of bacteria or bacterial toxins from the intestine into the bloodstream can cause sepsis or systemic inflammatory response syndrome (SIRS). In a recent study evaluating the incidence of bacterial bloodstream infections within 6 months after intestinal transplant, about 50% of intestinal transplant recipients developed bloodstream infection, typically within 3 months of intestinal transplant.[26] The most common sources of bacterial bloodstream infections were gut translocation concurrent with rejection episode (35%), central line infection (20%), and intraabdominal abscesses (14%).[26]

A history of repeated exposure to broad-spectrum antibiotics leads to colonization with multiple resistant organisms in many intestinal transplant recipients. In a recent study analyzing intraabdominal infections after intestinal and multivisceral transplant, about 43% of recipients developed intraabdominal infections within 2 years posttransplant, with the most common isolates being enterococci, *Escherichia coli,* and *Klebsiella* species. The majority of the enterococci infections (63%) were vancomycin-resistant enterococci, and about 22% of gram-negative infections were noted to be resistant to extended-spectrum penicillins.[27]

Some centers also perform surveillance stool cultures on a regular basis posttransplant. In the absence of positive blood cultures to direct antibiotic therapy, organisms growing from quantitative stool cultures in significant numbers ($>10^8$ colony-forming units [CFU]/mL) in patients with sepsis or acute cellular rejection may be considered potential causes of bacteremia and may be treated with IV antibiotics. The high incidence of renal dysfunction in intestinal transplant recipients should prompt use of nonnephrotoxic antibiotics when possible and careful monitoring of antibiotic levels when necessary.

One of the major complications posttransplantation requiring frequent readmissions is enteritis of the intestinal graft (viral or bacterial). In a recent study, the incidence of viral enteritis in intestinal transplant recipients was noted to be 43.9% within the first year posttransplant, and pediatric intestinal transplant recipients had a higher incidence of viral enteritis compared with adult intestinal transplant recipients. Viral enteritis episodes usually resolved within 1 week after supportive treatment with IV hydration and gradual reintroduction of enteral feedings once diarrhea resolves.[28] Similarly, there is a higher incidence (40%) of *Clostridium difficile* enteritis in intestinal transplant recipients within the first year posttransplant.[29] Standard antibiotic therapy with vancomycin or metronidazole therapy usually is enough to treat *C. difficile* enteritis.[29]

In addition, fungal infections must always be considered in recipients with persistent fevers and negative cultures, and often appropriate antifungal treatment is commenced empirically pending extended culture results and imaging studies.

Antiviral Prophylaxis

Opportunistic viral infections play a significant factor in postoperative complications. Antiviral prophylactic strategies have evolved with intestinal transplantation. Viral infections can cause significant morbidity, especially in pediatric recipients in the early postoperative period. Common pathogens include cytomegalovirus (CMV), Epstein-Barr virus (EBV), herpes simplex virus (HSV), adenovirus, and influenza viruses. Many pediatric recipients have no prior protective exposure to these viruses, so primary infection occurs in these patients while they are highly immunosuppressed. Recent advances in prophylaxis and preemptive therapy have significantly decreased early morbidity associated with EBV, CMV, and HSV, lowering the incidence of clinically significant infections to less than 5%.

Lack of definitive treatment for infections with respiratory viruses such as influenza and adenovirus in the early postoperative period can be catastrophic because of clinical sequelae, including disseminated viremia, necrotizing pneumonitis, and bacterial superinfection. At UPMC Children's Hospital of Pittsburgh, the current protocol for anti-CMV prophylaxis includes a 2-week course of IV ganciclovir (IV dose 5 mg/kg twice daily), except in the case of donor CMV negative to recipient CMV donor negative. CMV infection most commonly presents as intestinal graft enteritis. CMV graft enteritis and/or viremia posttransplant is frequently treated with a reduction in immunosuppression dosing, IV ganciclovir, and concomitant administration of cytomegalovirus-specific hyperimmune globulin (Cytogam). EBV infection can lead to posttransplant lymphoproliferative disorder (PTLD), and its management is further elaborated under the PTLD section later in this chapter. Close monitoring of CMV and EBV polymerase chain reaction (PCR) is performed frequently posttransplant and spaced out, moving away from the time of transplant and as indicated.

Nutritional Support

Immediate posttransplant nutritional support is administered using standard PN, which is tapered gradually as enteral feeding is advanced. Tube feedings with isotonic formula are started based on clinical determination of intestinal allograft function. In the authors' experience, most intestinal transplant patients, especially children, do not voluntarily ingest adequate amounts of nutrition in the early postoperative period. To achieve maximal nutritional repletion, tube feeding is usually required once the intestinal tract becomes functional. Resistance to oral feedings is a clinical challenge in younger pediatric recipients, many of whom demonstrate oral aversion. A recent study examining factors that affect eating behaviors in pediatric intestinal transplant recipients found that learning to eat at the recommended age along with positive pretransplant eating experiences in pediatric intestinal failure patients was associated with significantly less oral food aversion behavior postintestinal transplant.[30] Hence, oral aversion must be recognized pretransplant and efforts made to gradually encourage oral feedings pretransplant by the clinical teams.

Immunosuppression

Although a variety of combinations of immunosuppressive drugs have been used in intestinal transplant recipients, most patients are maintained on tacrolimus (Prograf [Astellas, Tokyo, Japan]) therapy along with other adjunctive medications. Organ Procurement and Transplantation Network (OPTN) data show that 99% of intestinal transplant recipients receive tacrolimus as part of their maintenance immunosuppression at the time of posttransplant discharge. Moreover, during the first posttransplant year, only a select number of patients are taken off of tacrolimus (mostly for complications perceived to be related to tacrolimus), with nearly 97% remaining on tacrolimus-based therapy. Recent international Intestinal Transplant Registry data suggest that rapamycin may have some improved outcomes and could be used as an alternative or in combination with tacrolimus. However, further research is needed to validate these data.[2] Currently, the most common regimen at 1-year posttransplant is tacrolimus in combination with steroids, with tacrolimus monotherapy being the second most common.[1] In some patients who have had significant rejection, a third agent may be employed in addition to tacrolimus and steroids, like mycophenolate mofetil (MMF) or azathioprine (Imuran).

Two classes of immunomodulatory drugs have been used for intestinal transplantation and have been associated with improvements in 1-year patient and graft survival. Depleting antilymphocyte antibody therapies include rabbit antithymocyte globulin (rATG, Thymoglobulin [Genzyme Corp., Cambridge, MA]), and rarely now, alemtuzumab (Campath-1H [Genzyme Corp.]). The individual use of these agents by high-volume single centers has demonstrated improved short-term survival and decreased rejection rates and severity of rejection, especially during the early posttransplant period.[31–34] Associated with similar improvements in survival and decreased incidence of acute rejection and severity, induction with the nondepleting interleukin (IL)-2 receptor antagonists daclizumab (Zenapax) and basiliximab (Simulect) has also gained increasing acceptance by many intestinal transplant programs. In select cases of suspected antibody-mediated rejection (class II donor-specific antibodies [DSA] and evidence of histologic injury), other agents such as rituximab or bortezomib may also be used (often in addition to pheresis and intravenous immunoglobulin [IVIg]). Immunosuppression for intestinal and multivisceral transplantation now involves perioperative antibody induction protocols in over 60% of cases.[1]

Immunologic Monitoring

The gold standard for monitoring and diagnosing rejection in intestinal and multivisceral transplant recipients to date remains routine ileoscopy and proximal enteroscopy with histopathologic examination of multiple random mucosal biopsies. Significant investigation is under way into the development of tools to guide and monitor the immunologic state of intestinal transplant recipients. Ideally, noninvasive markers such as serologic, proteomic, or genomic markers may identify those patients who are at increased risk of rejection and, conversely, those who might benefit from decreased levels of immunosuppression.[35,36] A recently developed Pleximmune test may be helpful, in conjunction with other studies, to determine both those who seem to be at risk for or are currently undergoing rejection and warrant augmented levels of immunosuppression or, conversely, maintain or lower immunosuppression in those who appear to be at lower risk of rejection.[37] Further validation in a larger cohort of patients is needed. Preformed antibody and de novo anti-DSA measurements may be of assistance in determining the risk of rejection.[38,39] When technically feasible, the presence of circulating donor cells in the recipient peripheral blood should be serially evaluated after transplantation by either flow cytometry or PCR. The presence of DSAs, especially class II, in intestinal transplant recipients may prompt aggressive therapy with augmentation of immunosuppression and addition of other agents and, in some circumstances, serial plasmapheresis and IVIg until clearance of antibodies has been confirmed. The use of fecal calprotectin or serum citrulline as noninvasive biochemical markers of allograft rejection has certain restrictions in timing of the test and sensitivity issues, especially in the initial posttransplant phase, and does not appear to be warranted based on currently available data.[40,41]

As mentioned, to date the gold standard for detection of rejection after intestinal transplant is histologic evaluation. At the majority of intestinal transplant programs, surveillance endoscopy and biopsy (esophagogastroduodenoscopy [EGD], ileoscopy, colonoscopy) are performed biweekly for the first 4–6 weeks posttransplant and then weekly for an additional 4–6 weeks to monitor for rejection. After the first 3 months posttransplant, the frequency of surveillance endoscopies performed in recipients is based on individual clinical assessments. More frequent endoscopes and biopsies are performed where clinically or histologically indicated. More recently, there have been a few reports in the literature suggesting that endoscopic surveillance and biopsy of intestinal grafts be performed "only for cause" (i.e., only in intestinal transplant recipients exhibiting signs and symptoms of rejection) as compared with routine protocol-driven surveillance endoscopy and biopsy.[42] However, additional studies on this topic are required to resolve this controversy about performing routine protocol-driven surveillance endoscopy versus "only for cause" endoscopy surveillance in intestinal transplant recipients.

Assessment of Intestinal Allograft

The process of examining the anatomic and functional integrity of the intestinal allograft begins in the operating room. The normal intestinal allograft after reperfusion appears pink and nonedematous, with occasional contractions. Altered appearance can be observed in the operating room, especially in the mucosa when the bowel is opened for the anastomosis, and in the proximal jejunal and distal ileal segments using endoscopy postoperatively.

Surveillance for intestinal allograft rejection in the early postoperative period focuses on clinical evaluation and gross morphologic examination of the stoma and distal ileum. Frequent routine endoscopic surveillance is the most reliable method for achieving an early diagnosis of intestinal rejection (Fig. 147.9). Endoscopic evaluations are performed initially twice a week through the allograft ileostomy. Upper endoscopy is reserved for occasions where clinical changes are not well explained by distal allograft evaluation and biopsy. Common physical changes to the normal appearance of an intestinal allograft include edema, cyanosis, congestion, and increased stomal output. These changes should prompt an immediate work-up, with a differential diagnosis that includes preservation injury (Fig. 147.10), sepsis, rejection, enteritis, and vascular compromise (such as thrombosis).

The allograft stomal output is assessed for volume and consistency. Normal stomal output during the early postoperative period is characteristically clear and thin. During the first week posttransplant, normal stomal output is 1–2 L/day and 40–60 mL/kg/day for adult and pediatric recipients, respectively. If these stomal volumes are exceeded in the absence of significant pathology, agents to control volume of output can be started, including loperamide, diphenoxylate-atropine, paregoric (tincture of opium), pectin, rarely somatostatin, or oral antibiotics. The presence of blood in the stomal output is an ominous sign and a concern for acute rejection, until proven otherwise. Other causes, however, include anastomotic bleeds in the early posttransplant period, perianastomotic ulcers in the later period, or postbiopsy bleeding, which is often seen initially or 5–7 days after the biopsy.

Intestinal allograft absorption of nutrients and medications develops gradually and commonly requires several weeks posttransplant to

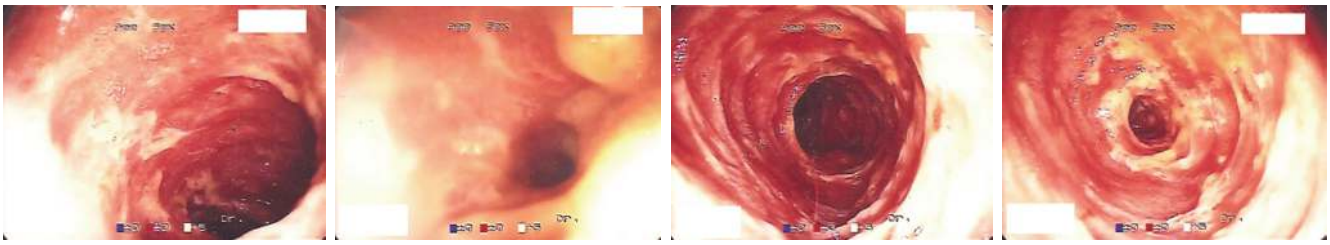

Fig. 147.9 Enteroscopic findings consistent with acute cellular rejection of intestinal allograft. (Courtesy Kareem Abu-Elmagd, MD.)

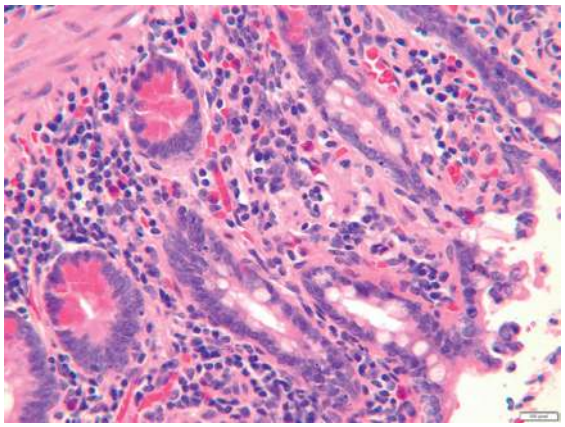

Fig. 147.10 Ischemia-reperfusion injury. Reperfusion injury is characterized by extensive loss of villi, followed by pronounced regenerative changes of crypt epithelium with conspicuous mitosis, capillary congestion, shortening of villi, and variable degrees of neutrophil-rich inflammatory infiltration.

improve. Abnormal absorption/stomal output after approximately 1 month should prompt an aggressive search for underlying pathology, especially rejection. The ability to maintain whole-blood tacrolimus trough levels above 15 ng/mL on oral therapy alone is a good indicator of adequate absorption. In the authors' experience, intestinal transplant recipients demonstrate evidence of sufficient absorptive function at a mean of 28 days after transplantation.

MANAGEMENT OF ALLOGRAFT REJECTION

Allograft rejection (Fig. 147.11) is strongly associated with graft loss and mortality and remains a significant obstacle to achieving successful long-term outcomes for intestinal and multivisceral transplant recipients. Historically, acute cellular rejection was reported in 70%–90% of intestinal allografts within 90 days posttransplant. In contrast, rejection rates of 30%–40% are currently reported by large centers because of advances in allograft histopathologic surveillance, immunosuppression, and immunologic monitoring. There does appear to be disparity between some centers where reported rejection rates may be

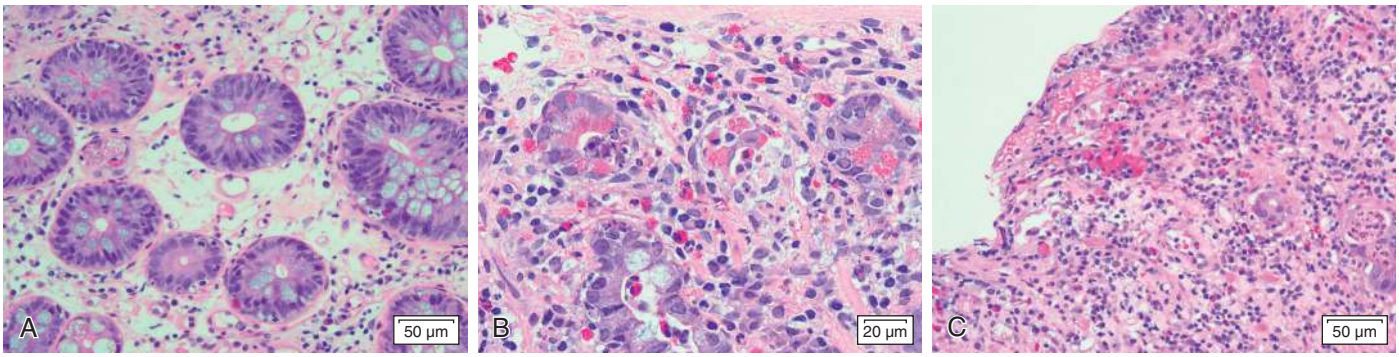

Fig. 147.11 Acute cellular rejection of intestinal allograft: mild (A), moderate (B), and severe (C). **A,** Mild acute rejection is characterized by a generally mild and localized inflammatory infiltrate, which tends to be concentrated around small venules in the lamina propria. Mucosa is intact, but crypt epithelium displays evidence of injury: mucin depletion, cytoplasmic basophilia, decreased cell height, nuclear enlargement with hyperchromasia, and inflammatory infiltration. Crypt epithelial apoptosis is increased, usually with more than six apoptotic bodies/10 crypts. If sampled by biopsy specimen, preexisting lymphoid aggregates (Peyer patches) demonstrate an intense accumulation of activated lymphocytes. Villi are variably shortened, and architecture may be slightly distorted owing to expansion of lamina propria by inflammatory infiltration. **B,** In moderate acute rejection, inflammatory infiltrate is widely dispersed within the lamina propria. Crypt injury and cryptitis are distributed more diffusely than in mild acute rejection, and villi tend to have a greater degree of flattening. Number of apoptotic bodies is greater than in mild acute rejection, usually with focal "confluent apoptosis." Mild to moderate intimal arteritis may be seen. Mucosa remains intact without ulceration, although focal superficial erosions can be present. **C,** Severe acute rejection is distinguished by a marked degree of crypt damage and mucosal ulceration, with lymphocytic infiltration extending deep into allograft wall and involving nerves and ganglia. As a consequence of mucosal destruction, luminal contents gain access to submucosa, prompting a neutrophil-rich infiltrate and an overlying fibropurulent (pseudomembranous) exudate with widespread mucosal sloughing as the final result. Adjacent viable epithelium usually shows rejection-associated changes such as crypt epithelial damage and abundant apoptosis. Severe intimal arteritis or transmural arteritis may be seen.

very low (less than 10%), whereas others still have higher rates (greater than 50%), possibly because of differing induction therapies or monitoring and reporting trends. Unlike liver allograft rejections, the natural history of rejection of intestinal allografts is unforgiving, making early diagnosis and treatment critical for successful reversal of the rejection process.

Until proven otherwise by culture and allograft biopsy, each episode of allograft dysfunction should prompt an expeditious evaluation for acute rejection. No reliable laboratory tests are currently available to warn of allograft dysfunction or rejection for intestinal transplantation, although preliminarily the Pleximmune assay has shown good sensitivity and specificity when used in certain criteria. Clinical features of intestinal allograft rejection include nonspecific signs and symptoms such as diarrhea (increased stomal output), nausea/vomiting, fever, and abdominal pain. Infectious enteritis and medication-related loose bowel movements are common etiologies of allograft dysfunction that present with a clinical picture similar to allograft rejection. The stoma may become edematous, erythematous, and friable. Endoscopy may demonstrate normal mucosa despite mild to moderate grades of ongoing acute cellular rejection. Moderate to severe rejection of the intestinal allograft usually leads to mucosal inflammation beginning with erythema and friability, progressing to mucosal slough and exudates overlying ulcers, with eventual loss of the mucosal layer. Histologically, there is variable presence of edema in the lamina propria and villous blunting. However, mononuclear cell infiltrates and intestinal crypt apoptosis with eventual crypt loss are the hallmark signs of intestinal allograft rejection that establish the diagnosis.

Treatment of intestinal acute cellular rejection initially involves steroids. At UPMC Children's Hospital of Pittsburgh, methylprednisolone is usually given, either by three boluses of 10 mg/kg/day over 3 days or, more routinely, by a single 10 mg/kg bolus and subsequent cycle of tapering doses over a more extended duration. Antilymphocyte antibodies for steroid-resistant rejection include antithymocyte globulin (rATG, Thymoglobulin) and, rarely nowadays, alemtuzumab (Campath-1H [Genzyme Corp.]). Unfortunately, the discontinuation of muromonab-CD3 (OKT3, a murine monoclonal anti-CD3 antibody) has been detrimental to the field. Adverse immune-mediated drug reactions to immunomodulatory antibodies can be life threatening. These agents are usually administered to patients with cardiopulmonary monitoring after premedication with steroids, antipyretics, and histamine blockers. In many cases, it is appropriate to initiate therapy in an ICU setting. During and after the treatment of acute rejection, tacrolimus whole-blood levels are maintained around 15–20 ng/mL in intestinal and multivisceral allograft recipients. Maintenance steroid therapy usually consists of 1–2 mg/kg/day of IV methylprednisolone converted to oral prednisone, tapered over several weeks to months based on individual clinical assessments. Addition of a third agent such as MMF (CellCept [Roche]) or sirolimus (Rapamune) or azathioprine (Imuran) may be indicated if rejection is refractory or recurrent.

A fundamental principle that guides treatment of allograft rejection is the preservation of as much intestinal function as possible. Each episode of rejection likely shortens the longevity of intestinal graft function, so the diagnosis of steroid-resistant rejection in intestinal allografts must be made in a timely fashion than in a more tolerant and recoverable organ such as the liver. Sequential biopsies separated by reasonable time intervals allow for objective confirmation of steroid treatment failure. Once confirmed, antilymphocyte therapy will rapidly reduce the overall number of immunocompetent cells and is usually a highly effective treatment. In those cases of intestine recipients with preexisting immune debilitation or a predisposition to a life-threatening illness such as PTLD, allograft enterectomy may be safer than escalation of immune suppression, and this can potentially be lifesaving.

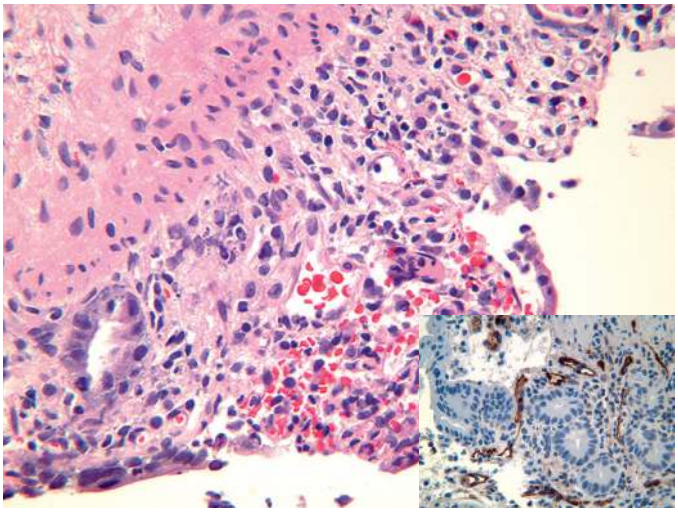

Fig. 147.12 Antibody-mediated rejection of intestinal allograft. Humoral rejection is characterized by a grossly cyanotic small-intestine allograft. Histologic findings include severe congestion, neutrophilic margination, and fibrin-platelet thrombi within the lamina propria microvasculature, along with focal hemorrhage. Immunohistochemical staining to C4d confirms the diagnosis of antibody-mediated rejection with heavy and diffuse staining of the lamina propria capillaries.

Antibody-mediated rejection (AMR) of the intestinal allograft (Fig. 147.12) is characterized by intestinal dysfunction, diffuse C4d staining on allograft biopsy, and usually identification of DSAs. Recent studies in the literature focusing on the concept of DSAs and graft rejection have shown that preformed DSA before transplant, persistence of DSAs posttransplant, and development of de novo DSAs posttransplant are factors associated with increased risk of rejection and graft loss.[43,44] In addition, these studies have shown that liver inclusive intestine allografts demonstrated greater clearance of DSAs posttransplant and had lower rate of de novo DSA formation post-transplant leading to better graft survival compared with intestine-only allografts.[43,44] Treatment of AMR remains challenging. A combination of IVIg, rituximab, plasmapheresis, and/or bortezomib needs to be considered in addition to standard treatment with steroids and/or thymoglobulin in these cases.

Chronic rejection remains the most significant complication affecting long-term graft survival. Chronic rejection (Fig. 147.13) is observed in 10%–15% of pediatric and adult intestinal allografts, but occurs more commonly in isolated intestinal allografts. In adult recipients at the University of Pittsburgh, multivisceral transplants including a liver allograft demonstrated a significantly better chronic rejection–free survival compared with the liver-free intestinal and modified multivisceral transplant recipients.[43] Risk factors for chronic rejection include type of allograft and loss of previous intestinal allograft. The clinical presentation of chronic rejection may include weight loss, chronic diarrhea, intermittent fevers, recurrent subacute bowel obstruction and distal intestinal allograft obstruction, or GI bleeding. Histologically, chronic rejection is characterized by villous blunting, focal ulcerations, epithelial metaplasia, and scant cellular infiltrates on endoscopic mucosal biopsies but can be difficult to diagnose based on just a mucosal biopsy, as larger vessels need to be ascertained. Full-thickness biopsies of intestinal allografts with chronic rejection demonstrate the classical obliterative arteriopathy with thickening of not only intestinal arterioles but also even bigger vessels.

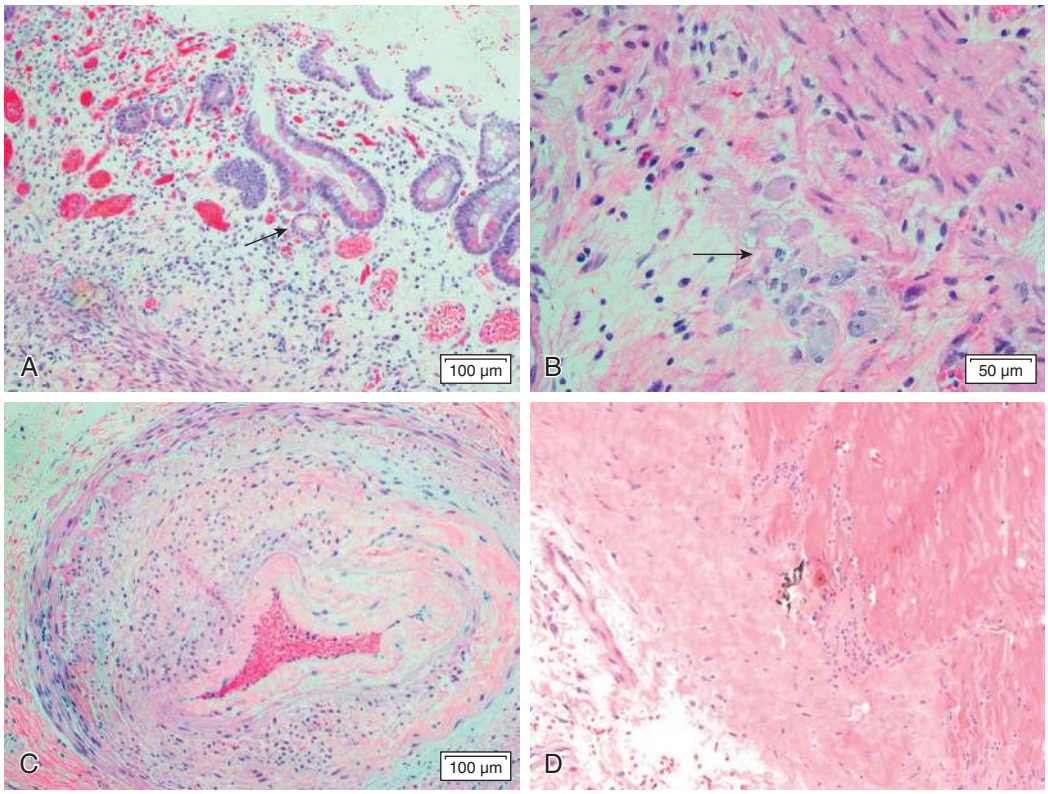

Fig. 147.13 Chronic rejection of intestinal allograft. Mucosa shows loss of villous architecture, chronic ulcers with exudate and granulation tissue, widespread loss of the crypts of Lieberkühn, crypts of Lieberkühn with pyloric gland metaplasia (**A,** *arrow*), neuronal hyperplasia (**B,** *arrow*) and mucosal fibrosis. Histologic findings in resection specimens are obliterative arteriopathy **(C)**, lymphoid deletion, and mesenteric sclerosis **(D)**.

MANAGEMENT OF COMPLICATIONS

Postoperative Hemorrhage

Recipients of intestinal and multivisceral transplants will commonly demonstrate varying degrees of liver dysfunction, qualitative and quantitative platelet abnormalities, and fibrinolysis that can lead to profound intraoperative coagulopathy. Induction intraoperatively with thymoglobulin may also lead to hematologic and clotting diathesis and warrant cessation or delay of the infusion. Intraoperative bleeding can also develop from lysis of vascularized adhesions resulting from previous surgeries and portal hypertension. Transient graft reperfusion coagulopathy mediated by plasminogen activators from the graft may also occur. Every effort is made to address these factors in the operating room, and usually whatever coagulopathy persists postoperatively is mild. Postoperative hemorrhage is most often a technical problem arising from vascular anastomoses or extensive raw peritoneal surfaces. Even mild coagulopathy should be completely corrected if bleeding is suspected in the posttransplant recipients, although caution must be taken to avoid issues with hypercoagulation and thrombosis of the allograft. Any bleeding that causes hemodynamic alteration should be managed by early prompt surgical exploration.

Vascular Complications

Superior mesenteric artery thrombosis is a catastrophic complication that leads to rapid and massive necrosis of the intestinal allograft. Elevation of hepatic enzymes (with liver allografts) and pallor of the intestinal stoma are accompanied by clinical deterioration, usually fulminant sepsis, and hepatic coma (with liver allografts). Isolated small bowel allografts can be explanted with a reasonable expectation of patient survival, but in patients with composite allografts, removal for arterial thrombosis leads to almost certain death in the absence of an immediate retransplant. Clinical suspicion of arterial thrombosis in the immediate postoperative period should be definitively evaluated in the operating room and not delayed by performance of Doppler ultrasound examination. In cases of delayed presentation, arteriography in interventional radiology can often be useful diagnostically and therapeutically.

Acute venous thrombosis also leads to loss of the intestinal allograft without timely surgical intervention. Clinical signs of venous thrombosis include acute massive ascites and stomal congestion. Mesenteric infarction is the ultimate outcome of unresolved venous thrombosis, necessitating explant of the intestinal allograft.

Incomplete obstruction of major inflow or outflow vessels may be suspected based on allograft biopsies or on clinical and laboratory signs of graft dysfunction. Contrast vascular radiographic studies are confirmatory, and the correction is either surgical or endovascular, based on individual assessments and available clinical expertise.

In a recent study focusing on thrombotic vascular complications after pediatric intestinal transplants, 15% of intestine transplant recipients developed arterial or venous thrombosis, with graft loss and patient death occurring in 60% of these patients. The findings of this study highlights that although vascular complications are rare after intestinal transplant, they are associated with high morbidity and mortality.[45]

Gastrointestinal Complications

GI bleeding after intestinal transplantation is an ominous sign that requires timely evaluation. Except for early postoperative bleeding, acute rejection and infectious enteritis are the most likely etiologies

and should be diagnosed or excluded based on endoscopic biopsy results. Arterioenteric fistulae must also be considered, as this can be catastrophic. The diagnosis of rejection relies primarily on histologic evidence but also on the endoscopic appearance of the mucosa. Bleeding from ulcerated EBV- or CMV-induced lesions may be differentiated by gross endoscopic examination, but confirmatory stains and serum PCR testing often help validate the diagnosis. Empiric therapy for rejection of intestinal allografts is rarely indicated except when suspicion on clinical and/or endoscopic evaluation is high, infectious parameters have been low, and obtaining pathologic confirmation is delayed.

Anastomotic leaks may occur in all intestinal transplant recipients, but are more common in pediatric patients. Clinical presentation commonly involves florid sepsis, drainage via abdominal drain, or wound drainage and infection. Confirmation is achieved with oral contrast imaging, although diagnostic laparotomy may be indicated in the setting of sepsis with equivocal imaging studies. Owing to immunosuppression, bowel leaks often do not improve with medical management alone. Almost all bowel leaks require surgical revision, including evacuation of any peritoneal contamination. Resolution is often confirmed via repeat laparotomy.

The propagation of motility patterns in the denervated intestinal allograft is still not fully understood. High allograft stomal output occurs early after transplant, and in the absence of infection or rejection, it can be regulated with agents such as loperamide, diphenoxylate-atropine, paregoric, or pectin. Conversely, poor upper motility often may exist between the native and allograft bowel, and promotility agents may be required.

At the majority of intestinal transplant centers, an ileostomy is created at the time of the initial transplant to allow for frequent endoscopic surveillance of intestinal grafts. In a recent study focused on outcomes related to ileostomy formation and takedown after intestinal transplant, major complications after ileostomy formation occurred in 23% of recipients. The most common complications included prolapse (6%), ischemia (4%), and parastomal hernia (4%).[46] Once the patient's intestinal graft function has been noted to be stable postoperatively for greater than 90 days, an assessment for ileostomy takedown is performed, usually with endoscopy and contrast enema studies to exclude any obstructive or pseudo-obstructive process in the distal bowel. Major complications after ileostomy takedown after intestinal transplant were reported in 28% of patients, with the most common complications being small bowel obstruction (8%), intraabdominal abscess (5%), and wound infection (3%).[46]

Renal Complications

Deterioration of renal function in intestinal transplant recipients remains a significant clinical challenge. Pretransplant renal dysfunction is exacerbated by overall higher target levels of immunosuppression in intestinal transplant recipients compared with other types of transplants, repeated exposure to nephrotoxic antibiotics, and episodes of dehydration with intestinal allograft dysfunction. The incidence of chronic renal failure for intestinal transplant recipients at 5 years posttransplant was noted to be 21.3%, which is significantly higher when compared with other nonrenal transplant recipients.[47] Overall, a review of the Scientific Registry of Transplant Recipients (SRTR) data shows that patients without severe pretransplant renal dysfunction who do not receive a kidney as part of the composite allograft will generally demonstrate a 50% increase in serum creatinine at their 5-year follow-up. In a recent study analyzing 288 adult intestinal transplant recipients, 13% required long-term renal replacement therapy and 6% required renal transplant after intestinal transplant. Three-year survival of intestinal transplant recipients requiring renal replacement therapy was noted to be 20% in this study, highlighting the major mortality risk associated with the development of renal failure in intestine transplant recipients.[48] In intestinal transplant recipients exhibiting signs of renal dysfunction, consideration must be given to decreasing the dose of calcineurin-based immunosuppression by adding rapamycin or other agents to the immunosuppression regimen.

Posttransplant Lymphoproliferative Disorder

The development of PTLD is almost always associated with EBV infection. Posttransplant infection with EBV results in a spectrum of diseases, from mononucleosis syndromes and plasma cell hyperplasia to neoplastic PTLD (Fig. 147.14). In a series of 500 intestinal and multivisceral transplants at the University of Pittsburgh, all but 2 of 57 recipients with PTLD developed the disorder as a consequence of confirmed EBV infection.[11] Early studies found that primary tacrolimus use in pediatric patients was associated with a 15% long-term risk of PTLD, with almost 80% of these cases occurring within the first 2 years after transplant. Achieving an optimal immunosuppression steady state and avoiding excessive therapy intervals appears to be key to minimizing EBV/PTLD complications. Cumulative PTLD-free survival for intestinal transplant recipients undergoing induction immunosuppression has improved to nearly 90%, possibly attributable to a lower incidence of acute rejection (and thus decreased need for escalation of immunosuppression) in addition to improved EBV viral load monitoring.

Patients presenting with PTLD complain of sporadic fever, lethargy, and malaise (and masses or lymphadenopathy). Weight loss, diarrhea, and GI complaints are common, as are signs of graft dysfunction. Standard laboratory evaluation may demonstrate neutropenia, atypical lymphocytosis, anemia, and thrombocytopenia. Further evaluation of PTLD is guided by findings on contrast-enhanced CT scanning of the head, neck, chest, abdomen, and pelvis, with or without endoscopy,

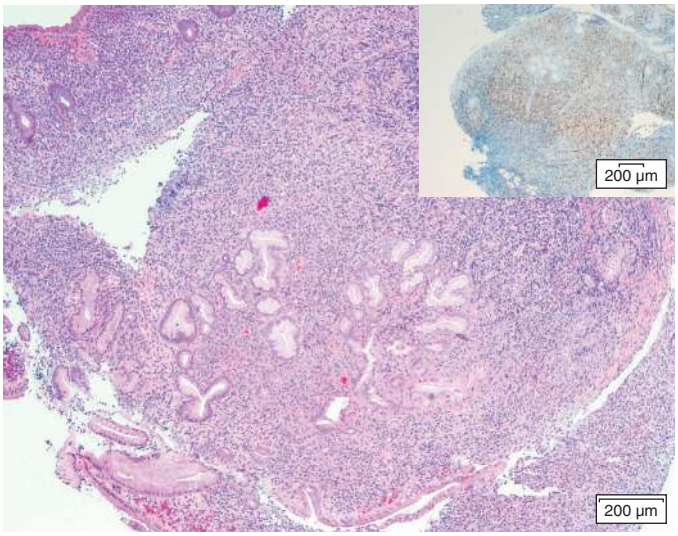

Fig. 147.14 Epstein-Barr virus posttransplant lymphoproliferative disorder (EBV/PTLD). At the early phase of EBV infection, tissue is expanded by scattered EBV encapsulated RNA (EBER)–positive lymphocytes. With disease progression, the number of positive cells increases, lymphocytes become activated and transformed, and ultimately, tissue architecture is effaced by a malignant lymphoproliferative process that replaces the duodenal mucosa seen in this example. The EBER in situ probe is shown in the *inset*.

based on results of noninvasive imaging. Histologic examination of the tissue is optimal, and specimens should be promptly submitted for fresh staining with the EBER-1 probe by experienced pathologists. An evaluation for CD20 staining should also be performed.

Ideally, the treatment of PTLD involves stopping immunosuppression completely, as can be done in most other types of allografts, but with the intestine, this may not be possible. The goal, however, is to lower the level of immunosuppression as much as possible (holding steroids and third agents and lowering the primary agent) and follow very closely with repeat scopes and biopsies looking for signs of imminent or active rejection. PTLD that is unresponsive to lowering/discontinuation of immunosuppression should be treated with monoclonal antibody, usually rituximab, if shown to be CD20 positive by biopsy. Complete remission rates of 60%–70% have been reported in children. The antibody therapy is relatively well tolerated, and for the 20% of patients who have recurrence, retreatment with rituximab can be curative. For PTLD refractory to monoclonal antibody, low-dose cytotoxic chemotherapy and steroids have been used effectively (Gross protocol).

Graft-Versus-Host Disease

Acute graft-versus-host disease (GVHD) results from immunocompetent donor T cells causing damage to recipient tissues after transplantation. The incidence of GVHD (Fig. 147.15) after intestinal transplantation ranges between 5% and 10% and usually occurs within the first 6 months posttransplant.[49] The use of multivisceral and modified multivisceral grafts is associated with a higher incidence of GVHD in intestinal transplant recipients, possibly related to removal of more native lymphatics, followed by replacement with a greater amount of donor lymphatic tissues when compared with intestine transplant recipients or liver/intestine transplant recipients.[50] The major targets of GVHD in intestinal transplant recipients are epithelial cells of skin, bone marrow, the native GI tract, and the native liver. Cardiac muscle involvement is not common but has been described. A recipient with GVHD commonly presents with fever and a maculopapular rash on the upper torso, neck, or palms of hands and feet, which may coalesce to form blisters or more diffuse erythema. Other clinical signs and symptoms include oral lesions, diarrhea, intestinal mucosal ulceration, native liver dysfunction, lymphadenopathy, and bone marrow suppression with pancytopenia. The variability of GVHD focality and severity leads to a wide spectrum of disease, from mild GVHD presenting with fevers and self-limiting rash to more severe forms leading to end-organ damage.

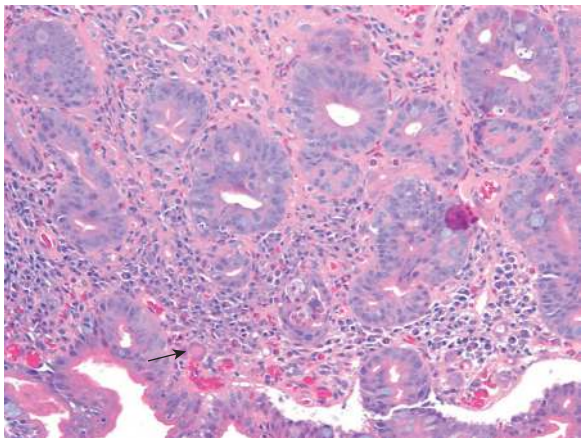

Fig. 147.15 Intestinal allograft graft-versus-host disease (GVHD). Mucosal biopsy of native small intestine showing crypt epithelial apoptosis and lamina propria inflammation. An incidental cytomegalovirus (CMV) inclusion is also noted in this biopsy *(arrow)*.

The diagnosis of GVHD is based on clinical presentation and confirmed histologically when possible. Corticosteroids are the first-line therapy to control epithelial damage caused by GVHD and are effective in around 50% of the cases overall. If unresponsive to steroids, GVHD can usually be controlled by reduction of calcineurin-based immunosuppression, although in some cases the level of immunosuppression needs to be augmented. Other forms of refractory GVHD have been treated successfully using antilymphocytic therapy (e.g., Thymoglobulin) and anti-IL therapy (e.g., Zenapax and Simulect) and anti–tumor necrosis factor (TNF) antibody therapy (e.g., Remicade).

OUTCOMES

Patient and Graft Survival

Outcome data after intestine transplant are available via analysis of two large registries:

1. Intestinal Transplant Registry, which captures worldwide intestine transplant activity
2. SRTR, which captures North American intestine transplant activity

From January 1985 to January 2015, according to the latest update of the Intestinal Transplant Registry, 3067 intestinal transplants have been performed in 84 centers around the world, with 30 centers still currently active.[2] Small bowel transplants alone account for 45% of the total, liver/intestine 31%, and multivisceral/modified multivisceral the remainder.[2] Approximately 48% of grafts overall contained a liver since 2001, which continues to decrease over time. Currently there are 1631 survivors.[2] The leading cause of recipient death is sepsis (65%), followed by graft failure including rejection (10%); lymphoma (5%); technical issues (4%); and then cardiovascular, renal, and liver failure.[2] The retransplantation rate is approximately 10%, with most being retransplanted with a liver included.[2] Intestinal Transplant Registry analysis has shown that intestinal graft and patient survival have improved over the last couple of decades when compared with the era before 2000. Since 2000, overall 1-year graft survival was 71%, overall 5-year graft survival was 50%, and overall 10-year graft survival was 41% and overall 1-year patient survival was 77%, overall 5-year patient survival was 58%, and overall 10-year patient survival was 47%.[2] A more recent analysis of the Intestinal Transplant Registry from 1985 to 2017 with a focus on outcomes of pediatric intestinal transplantation has shown that overall 1-year pediatric intestinal graft survival was 66% and overall 5-year pediatric intestinal graft survival was 48% and overall 1-year pediatric patient survival was 72% and overall 5-year pediatric patient survival was 48%.[51] Liver-inclusive grafts and first-time intestinal transplant was associated with better pediatric graft survival, whereas elective status (presentation from home) at transplant compared with hospitalized status was associated with better pediatric patient survival.[51] Rejection was the most common cause of long-term pediatric intestinal graft loss, and sepsis was the most common cause of patient death.[51] Other important relevant trends observed from the Intestinal Transplant Registry include (1) proportional increase in use of intestine-only grafts over liver-inclusive intestine grafts (Fig. 147.16) and (2) shift towards inclusion of colon graft with intestine grafts (because of perceived posttransplant renal protection with improved fluid absorption and decreased fluid loss associated with colon inclusion with intestine graft).

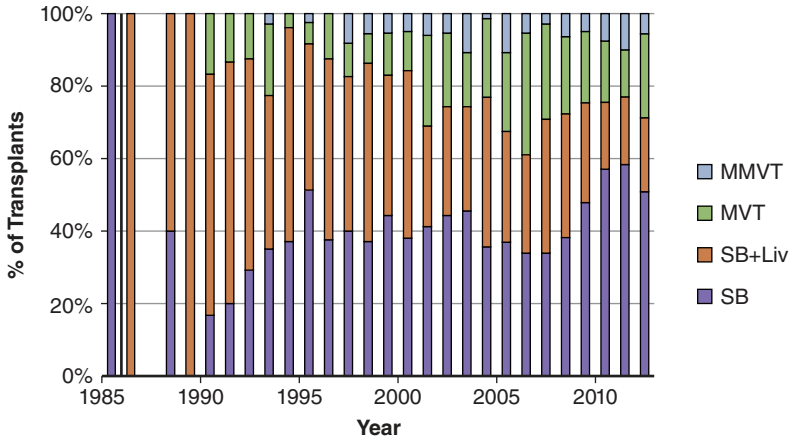

Fig. 147.16 The proportion of small bowel–only grafts (*SB*) has increased over time, whereas the proportion of liver-inclusive small bowel grafts (*SB+Liv*) has decreased over time. (Adapted from Grant D, Abu-Elmagd K, Mazariegos G, et al. Intestinal Transplant Registry report: Global activity and trends. *Am J Transplant.* 2015;15[1]:210–219. doi: 10.1111/ajt.12979. Epub 2014 Dec 1.)

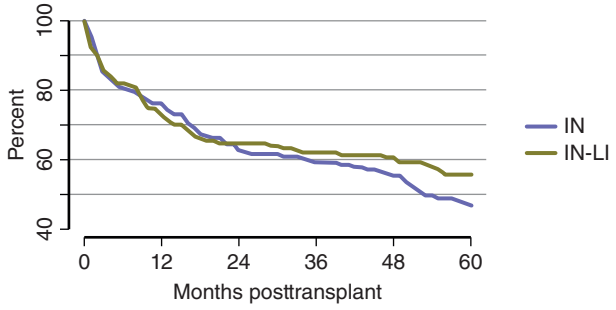

Fig. 147.17 One-year and 5-year graft survival of intestine-only grafts (*IN*) versus liver-intestine grafts (*IN-LI*) (2011–2013). (Adapted from Smith JM, Weaver T, Skeans MA, et al. OPTN/SRTR 2018 Annual Data Report: Intestine. *Am J Transplant.* 2020;20[Suppl s1]:300–339.)

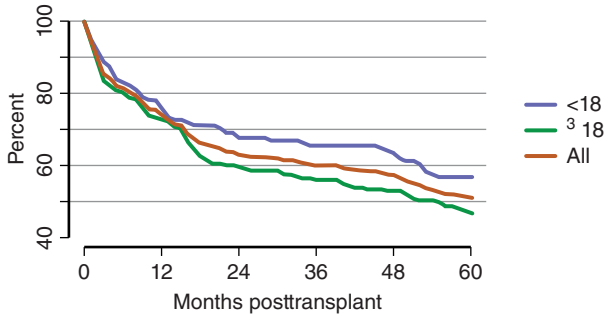

Fig. 147.18 Graft survival of all intestine grafts stratified by age. (Adapted from Smith JM, Weaver T, Skeans MA, et al. OPTN/SRTR 2018 Annual Data Report: Intestine. *Am J Transplant.* 2020;20[Suppl s1]:300–339.)

According to the latest update of the SRTR published in 2018, overall 1-year and 5-year graft survival for all intestinal transplants performed between 2011 and 2013 was 74% and 51%, respectively. Stratified by graft type (for all transplants performed between 2011 and 2013), 1-year and 5-year graft survival were 76% and 47%, respectively, for intestine-only recipients, and 1-year graft and 5-year graft survival was 73% and 56%, respectively, for intestine-liver recipients (Fig. 147.17).[1] Stratified by age group (for all transplants performed between 2011 and 2013), 1-year and 5-year graft survival were 76% and 57% for pediatric recipients versus 74% and 51% for adult recipients (Fig. 147.18).

Based on these large intestinal transplant registries, it can be concluded that short-term outcomes after intestinal transplantation have improved and are now comparable to and possibly better than outcomes after pancreas and lung transplantation. Contributing factors to this marked improvement in outcomes after intestinal transplantation include increased experience among intestinal transplant teams, improvements in anesthesia and critical care, advances in immunosuppression, and advances in the detection and treatment of rejection and opportunistic infection. In contrast to recent achievements in short-term outcomes, long-term survival after isolated intestinal transplantation has not significantly improved. Ten-year patient and graft survival remain 46% and 29%, respectively, for isolated intestinal transplantation and 42% and 39%, respectively, for intestine-with-liver grafts. These results are similar to those reported for lung and combined heart-lung transplantation but compare unfavorably to kidney, liver, and heart transplantations, where 10-year patient and graft survival exceeds 50%.

Long-Term Rehabilitation and Quality of Life

There are only a few reports pertaining to long-term outcomes, especially related to quality of life. This is partly as the field is still relatively new and only a few centers have significant numbers to make a useful assessment. Intestinal transplant recipients have been shown to have improved quality of life (improved overall general health, enteral autonomy, and ability to travel) when compared with patients with intestinal failure awaiting intestinal transplant.[52] A small preliminary study in pediatric recipients with functioning intestinal allografts more than 1-year posttransplant found that quality of life was perceived by recipients to be comparable to that of their peers, whereas parental proxy assessments compared less favorably in terms of physical functioning, general health, and family activities.[53] Younger recipients (5–10 years of age) demonstrated significantly worse outcomes than older recipients (11–18 years of age) in terms of global health assessments, general health perception, and family activities.[54] There have been reports demonstrating significant improvement in certain aspects of psychiatric health after transition from PN to posttransplant PN independence.[54] In these reports, long-term physical and psychiatric rehabilitation was achieved in over 80% of intestinal transplant recipients who survived beyond the sixth postoperative month.[53,54]

The most robust recent paper details 227 adult and pediatric recipients who survived beyond the 5-year milestone.[55] Conditional survival was 75% at 10 years and 61% at 15 years. Nutritional autonomy was achieved in 90% of the survivors. Morbidities with impact on global health included dysmotility (59%), hypertension (37%), osteoporosis (22%), and diabetes (11%) and were observed more in the adult population.[55] Survivors in general were reintegrated into society with self-sustained socioeconomic states. It is also vital to note that nonfunctional social support was one of the most significant survival risk factors. This evidence ties back to the original evaluation process and the importance of teaching and critically assessing adequacy of social support. No matter how good the medical, surgical, and transplant management may be, for continued long-term success, adequate and appropriate social resources are essential. The intestinal and multivisceral transplant process is demanding and forever ongoing for the recipient, the family, and the healthcare professional team. Hence, picking the appropriate recipient for transplantation is vital and, conversely, one of the reasons why all efforts are made to rehabilitate patients without transplantation, if possible, given these long-term concerns.

CONCLUSION

The field of intestinal failure has undergone ebbs and flows, based on medical, surgical, and transplantation advances and outcomes. Intestinal and multivisceral transplantation remains the ultimate therapy, but with improved medical and surgical management, the timing and utility of transplantation have shifted.

Significant improvements in outcomes from intestinal and multivisceral transplantation have been achieved through advances in the multidisciplinary care of intestinal failure, surgical techniques, innovative immunosuppressive strategies, and an improved understanding of intestinal transplantation immunology. These accomplishments, however, remain overshadowed by the remaining fundamental challenge of preventing or minimizing chronic allograft rejection that affects long-term survival. The relatively high waiting list mortality, particularly for infants and adults with concomitant liver failure, requires an ongoing reexamination of national guidelines for multivisceral procurement to maximize the usage of acceptable donor allografts. The limited long-term data on nutritional outcomes and transplantation morbidity indicate good allograft survival and quality of life for those who get through the early period: however, not without some significant morbidity. The limited progress in chronic graft loss, especially in the isolated intestine recipient, hampers wider acceptance of intestinal transplantation. More so, the recent dramatic improvements in the provision of exemplary care in the multidisciplinary intestinal care clinics have significantly altered the need, timing, and type of intestinal allograft needed. Still, until successful tissue engineering or an alternative treatment modality surfaces, intestinal transplant remains the ultimate and definitive form of intestinal failure salvage.

ACKNOWLEDGMENT

The authors of the current chapter would like to acknowledge the work of all the authors (Rajesh K. Aneja, Yu-Tang Chang, Kathryn Felment, Armando Ganoza, Ajai Khanna, Sarangarajan Ranganathan, Jorge Reyes, Jeffrey A. Rudolph Rakesh Sindhi, and Kyle Soltys) involved in preparing this and the previous chapter on this topic, as we have used >40% of the material published in the previous chapter in this updated version.

KEY POINTS

- Intestinal rehabilitation programs have advanced the care of patients with intestinal failure, decreasing the need for intestinal transplantation.
- Early referral to an intestinal transplant center allows for a coordinated approach to determining the optimal timing of transplantation.
- Indications for intestinal transplantation have evolved, with many more patients requiring transplant for limitations in central venous access.
- Intestinal transplantation may be performed in isolation or combined with a liver, pancreas, stomach, and/or colon depending on the indication.
- Antibody-based induction immunosuppressive regimens have grown in popularity, but tacrolimus continues to predominate for maintenance.
- In the current era, 1-year and 5-year graft survival are 74% and 51%, respectively, and patient survival approaches 50% at 10 years.
- Long-term survivors of intestinal transplant have a 90% rate of achieving enteral autonomy and have excellent rehabilitative and developmental outcomes.

Aortic Dissection

Akiko Tanaka and Anthony L. Estrera

INTRODUCTION

Aortic dissection, first described in the 18th century,[1] continues to be one of the most lethal cardiovascular emergencies in the current era despite the evolution in diagnostic modalities, medical management, and surgical techniques and technologies. Herein, we discuss the current practice for diagnosing and managing aortic dissections for optimal outcomes.

PATHOPHYSIOLOGY AND DEFINITION

The aortic wall consists of three layers, the intima, media, and adventitia, in order from the blood flow surface outward. Aortic dissection occurs when the intima is injured. Blood then flows into the media and splits the layer apart, forming a double-barreled aorta (Fig. 148.1). The site of disrupted intima is called as the *entry tear* or the *intimal tear.* The original blood channel is the true lumen, and the newly formed channel is the false lumen. The dissecting plane is most often observed in the outer one-third of the media, where the vasa vasorum runs. The reason the dissection plane develops at this site is unknown. Histologic changes that occur in the aortic media are cystic medial necrosis, elastin fragmentation, fibrosis, and medionecrosis. All of these changes may be seen in the normal aorta and progress with age.[2] Cystic medial necrosis occurs most frequently in the middle part of the media. Elastin fragmentation of the media, either by a congenital disturbance or secondary to smooth muscle cell necrosis, and fibrosis are both observed in the luminal and middle medial layers. Lastly, medionecrosis is most prominent in the luminal media. Thus the medial split may be occurring where the pathologic changes end. Some investigators believe that arteriosclerotic changes of the vasa vasorum lead to its spontaneous rupture[3] and ultimately develops into aortic dissection, thus occurring along the vasa vasorum.

In general, the true lumen is located in the lesser curvature of the aortic arch and then stays in the anteromedial portion of the aorta. Thus the celiac, mesenteric, and right renal artery branches arise from the true lumen, and in many cases, the left renal artery branch arises from the false lumen.[4] Aortic dissection propagates with high pressure, especially when a change in pressure over a change in time (dp/dt) exceeds a certain threshold.[5] The blood in the false lumen may travel back to the true lumen and create a re-entry tear, or it may penetrate out the adventitia and ultimately cause aortic rupture. If the blood oozes into the pericardial space, cardiac tamponade develops.

Ischemia associated with aortic dissection is referred to as *malperfusion*. When end-organ ischemia is not corrected in a timely manner, it can progress to end-organ malfunction with infarction, which is known as *malperfusion syndrome*.[6] Approximately 30%–40% of aortic dissection presents with malperfusion.[6–11] Several mechanisms cause it. An expanded false lumen compresses the true lumen and leads to *dynamic* ischemia (ischemia during systole). The first-order aortic branches pulled out from the true lumen may result in *static* ischemia. Aortic dissection directly extending into the branch itself can cause either *dynamic* or *static* (when the thrombus is formed in the false lumen) ischemia (Fig. 148.2). Lastly, the rare cause of ischemia is intimal intussusception,[12] in which the intima is circumferentially detached and leads to true lumen obstruction.

There is a unique form of aortic dissection known as *intramural hematoma* (IMH), originally reported as an aortic dissection *without* an intimal tear.[13] Historically, bleeding from a ruptured vasa vasorum was speculated to be the cause of IMH.[14] However, a recent report suggests that IMH is a subset of acute aortic dissections,[15] with a small intimal tear and resultant restricted flow in the false lumen leading to thrombosis. IMHs are known to be associated with older age and are less frequent compared with the classical dissection.[16,17] The guidelines of western countries published in the early 2010s recommend treating acute IMHs as classical aortic dissections.[18]

CLASSIFICATION

Time After Onset

The definitions used for the acuity of the disease vary depending on the report and guidelines. Acute, subacute, and chronic are commonly used. The classification by time is vital in treating aortic dissections, as survival after aortic dissection can be stratified by period. American guidelines defined acute as occurring within 2 weeks of onset, subacute between 2 and 6 weeks, and chronic more than 6 weeks.[19] European guidelines defined the subacute phase differently, 14–90 days,[18] which reasonably reflects the period that most commonly requires endovascular interventions.[20] One of the largest multicenter, multicountry registries in the world, the International Registry of Acute Aortic Dissections (IRAD), proposed the use of hyperacute (onset to 24 hours), acute (2–7 days), subacute (8–30 days), and chronic (>30 days) based on their experience.[21] The bottom line is that aortic dissections should be considered acute and unstable up to 14 days from onset.

Extent of Aortic Dissection: DeBakey Classification, Stanford Classification, and New Reporting Standards

There are two commonly used classification systems to describe the extension of aortic dissections. One is the DeBakey classification,[22] which comprises type I, II, and III. Type I depicts the dissections involving the ascending aorta that extend beyond the transverse aortic arch. Type II is aortic dissection confined to the ascending aorta. Type III is aortic dissection without the involvement of the ascending aorta and is further subclassified into IIIa and IIIb: type IIIa localizes the lesion above the diaphragm; type IIIb has dissection extended below the diaphragm. The other system is the Stanford classification,[23] which has two types: A and B. Stanford type A is a combination of DeBakey

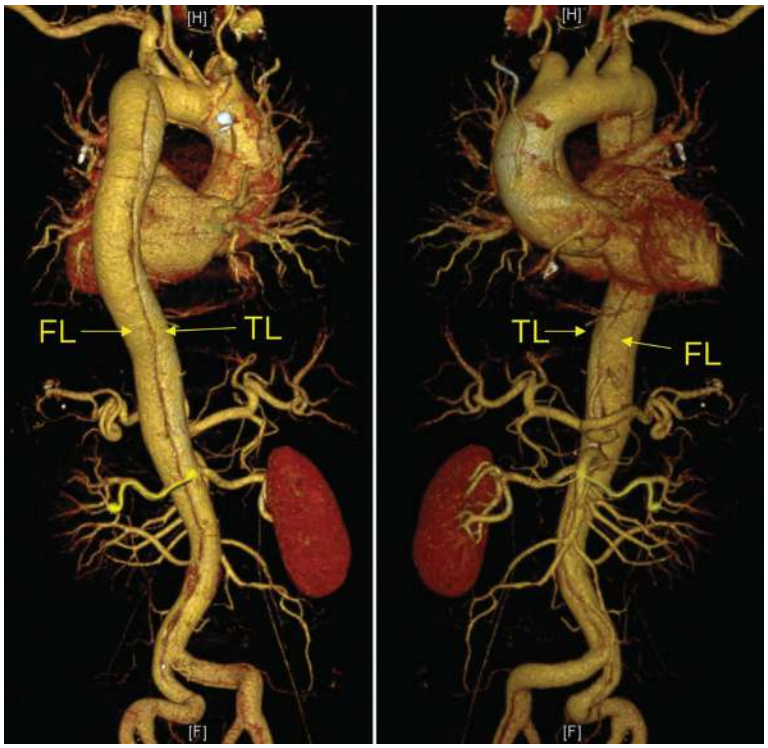

Fig. 148.1 Three-dimensional computed tomographic angiogram of type A aortic dissection. **(A)** anteroposterior view; **(B)**, posteroanterior view. *FL,* False lumen; *TL,* true lumen.

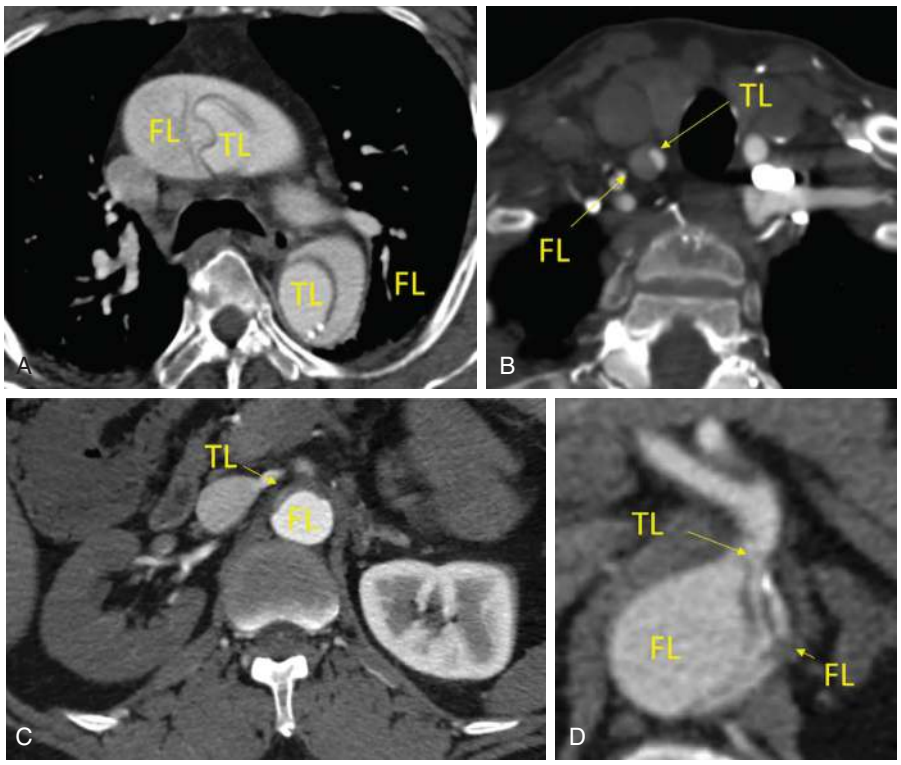

Fig. 148.2 Computed tomography in a patient with malperfusion syndrome (axial view). **(A)** Axial image of a type A aortic dissection at the level just below the tracheal bifurcation. **(B)** The right common carotid artery is dissected and the true lumen is compressed by the false lumen. This patient presented with altered mental status. **(C)** The right renal artery branches off from the compressed true lumen with resultant malperfusion (no enhancement with the contrast). **(D)** The celiac artery branches off from the narrowed true lumen. However, the patient did not present with malperfusion syndrome (normal liver functions, no abdominal pain). *FL,* False lumen; *TL,* true lumen

type I and II; type B is equivalent to type III. However, both classifications left the unclassified, so-called "non-A-non-B aortic dissections" (i.e., dissection extends from the ascending aorta to the aortic arch and from the aortic arch to the descending thoracic aorta).[24] In 2019 the Society of Thoracic Surgeons and Society for Vascular Surgery launched reporting standards, including these ambiguous types,[25] which are expected to be more frequently used in the future.

Clinical Presentation: Complicated vs. Uncomplicated

Clinical classifications with the terms "complicated" and "uncomplicated" are commonly used. These are also important for optimal treatment planning. Complicated aortic dissection includes rupture (impending rupture), intractable pain, uncontrolled hypertension, malperfusion syndrome (malperfusion with end-organ dysfunction), rapid expansion of the aorta, cardiac tamponade, and severe aortic insufficiency. Malperfusion syndrome may present as strokelike symptoms for cerebral ischemia; paraplegia/paraparesis for spinal ischemia; numbness, weakness, or pain for limb ischemia; and abdominal pain or lactic acidosis for visceral ischemia.

EPIDEMIOLOGY AND PROGNOSIS

Aortic dissection is a life-threatening condition, with a reported incidence of 3–6 per 100,000/year.[26] Male-to-female ratio is 2:1.[27] Two-thirds of patients have dissection involving the ascending aorta and present with a mean age of 61 years, whereas the remaining one-third with a disease-free ascending aorta present with a mean age of 64 years.[27] Aortic dissection is reported to correlate with circadian rhythm, activities, and season. It usually occurs during the daytime, with a peak from 8 to 10 A.M.,[28,29] and with winter being the most common season,[30] peaking in January.[31]

When the dissection involves the ascending aorta, deaths before arrival to the hospital may be seen in 21%–35%,[26,32] and mortality in the first 12 hours may reach 50% if untreated. Postmortem imaging studies demonstrated that 8% of out-of-hospital arrests were caused by acute type A aortic dissection.[33] The leading causes of early deaths are tamponade and aortic rupture,[1] followed by visceral ischemia.[34] The mortality rate after surgical repair of Stanford type A aortic dissection is 17%–18%,[27,35] which is superior to that of medical management, reported around 55% in the modern era. In contrast, the mortality rate for Stanford type B aortic dissection after surgical repair exceeds that of medical management (20%–30% after surgical repair vs. 7%–12% with medical management).[27] Early mortality in acute type B dissection is dictated by the presence of complications. In essence, uncomplicated type B aortic dissection has a mortality rate of less than 10% (2% in our experience[36]), whereas that of complicated type B is as high as 50%[37] (19% with medical management in our experience[36]).

It is also vital to treat aortic dissection as a lifelong disease. Continuous expansion of the affected aorta may require subsequent interventions to prevent it from rupture. Even after the open surgical or endovascular treatment for aortic dissection, the dissected aorta often remains in the distal or the proximal lesion. Thus periodical surveillance is crucial in this patient population. Modern literature reports that a need for distal reoperation is seen in 10% of the patients who had repairs for Stanford type A aortic dissection.[10,38–41] Known risks of aneurysmal formation are the size of the descending aorta (especially >40 mm) at the time of presentation of acute aortic dissection and younger age.[42,43] Also, many of these patients present to the emergency department with chest pain or back pain after the repair. It is important to evaluate that this is not the sign of progression of the disease.

RISK FACTORS

Predisposing factors are listed in Box 148.1.[27,44] Hypertension is the most common factor and is seen in 50%–86% of aortic dissections. Obstructive sleep apnea has been proven to be a significant cause of cardiovascular disease, found in 13% of cases.[45] Genetic/congenital factors have also been reported,[46] with Marfan syndrome having the highest prevalence, around 5%.[32,47] Bicuspid aortic valve is present in 2%. Other hereditary diseases may also be underreported, as many do not have physical characteristics, such as with Marfan syndrome. Physical activity such as weightlifting can temporarily cause the blood pressure to shoot over 300 mm Hg and trigger the event.[48] Straining is also a known trigger, as reported in the case of King George II in the 18th century.[1]

CLINICAL PRESENTATION

History taking and physical examination provide vital information for the timely diagnosis of aortic dissection. Patients with acute aortic dissection usually present with a sudden onset of severe pain. The pain is often described as a tearing, worst-ever pain. Shortness of breath is also commonly seen. Other presentations include syncope, abdominal pain, hemiplegia, paraplegia, weakness, and leg pain.[27] The use of drugs, especially cocaine, should be checked.[49] It is essential to ask for family history with not only the aortic disease but also sudden unexplained death, as aortic death may have been the undiagnosed aortic event.[50] History of intracranial aneurysm should also be questioned.[51]

BOX 148.1 Predisposing Factors for Aortic Dissection

Hereditary/Congenital Conditions
Marfan syndrome (FBN1)
Bicuspid aortic valve
Familial thoracic aortic aneurysm and dissections
Turner syndrome
Ehlers-Danlos syndrome (COL3A1)
Loeys-Dietz syndrome (TGFB2/TGFBR1/TGFBR2/SMAD3)
Shprintzen-Goldberg syndrome (FBN1)
Kommerell diverticulum
Aortic coarctation
Polycystic kidney disease (autosomal dominant)
Other gene mutations (ACTA2, MYH11, MYLK, SMAD4, PRKG1, LOX)

Inflammatory/Autoimmune Conditions
Takayasu arteritis
Giant cell arteritis
Syphilitic aortitis

Acquired Conditions
Hypertension
Obstructive sleep apnea
Smoking
Cocaine
Pregnancy
Trauma
Weight lifting
Iatrogenic
- Catheterization
- Cardiac surgery

Clinical findings commonly seen are hypertension, unless tamponade has developed or ruptured. Heart rate and respiratory rate are usually increased. A physical examination may show diminished or absent pulses in the affected limb. Patients with type A dissection may have cardiac murmurs associated with aortic regurgitation or have distant cardiac sound caused by tamponade. Hypoxemia is frequently seen, which is triggered by the systemic inflammatory reaction associated with aortic dissection.[52] Young patients with heritable aortic diseases may not have characteristic features, such as Marfan syndrome (tall stature, long arm span, deformed chest wall, lens dislocation, etc.). Current guidelines recommend immediate consultation to the surgical team in patients at high risk for acute aortic dissection before further imaging or laboratory testing.[19] High-risk patients are people who present with chest, back, or abdominal pain; syncope; or malperfusion symptoms with two or more high-risk features, such as having or suspected heritable aortic disease,[46] abrupt pain in onset, ripping/tearing/sharp/stabbing, physical examination consistent with malperfusion syndromes, murmur of aortic insufficiency, or hypotension/shock.

DIAGNOSIS

Fig. 148.3 depicts a diagnostic and treatment algorithm for aortic dissection. Because of the acutely ill presentation with pain, a blood test with cardiac enzymes and troponins, an electrocardiogram, and a chest x-ray are often performed. There is no single laboratory test that can confirm the diagnosis of aortic dissection alone. Tests should be used as a screening to prepare for possible intervention.[19] Leukocytosis is commonly seen, and anemia and thrombocytopenia are dependent on the progression of the disease.[1] Lactic acidosis may suggest the presence of cardiac tamponade or visceral and/or limb malperfusion. Elevated cardiac enzymes, positive troponins, and ST-T changes in the electrocardiogram are much more frequently seen in native coronary disease. However, they may reflect coronary malperfusion associated with aortic dissection. Chest pain with features at high risk for aortic dissection warrants computed tomography (CT) before proceeding to thrombolysis. A similar scenario can be seen with pulmonary embolism (PE), as patients with both PE and aortic dissection often present with chest pain and shortness of breath. D-dimer is generally elevated in both conditions. A negative D-dimer and a low clinical score for aortic dissection (i.e., patients without the hereditary aortic disease, pain without abrupt onset or not intense, normal physical examination) are helpful to rule out the disease.[53] A CT-PE protocol may provide the diagnosis of aortic dissection, but the phase of contrast and the caudal extent are not optimal and may require another scan or imaging modality, such as echocardiogram. The reported incidence of aortic dissection in patients who had the CT-PE protocol for markedly elevated D-dimer and clinically suspected PE was 2.4%.[54]

Widened mediastinum on a chest x-ray may be seen in 50% of patients. Thus a chest x-ray can be used as a screening test to rule out other causes of the symptoms but may not lead to the diagnosis.

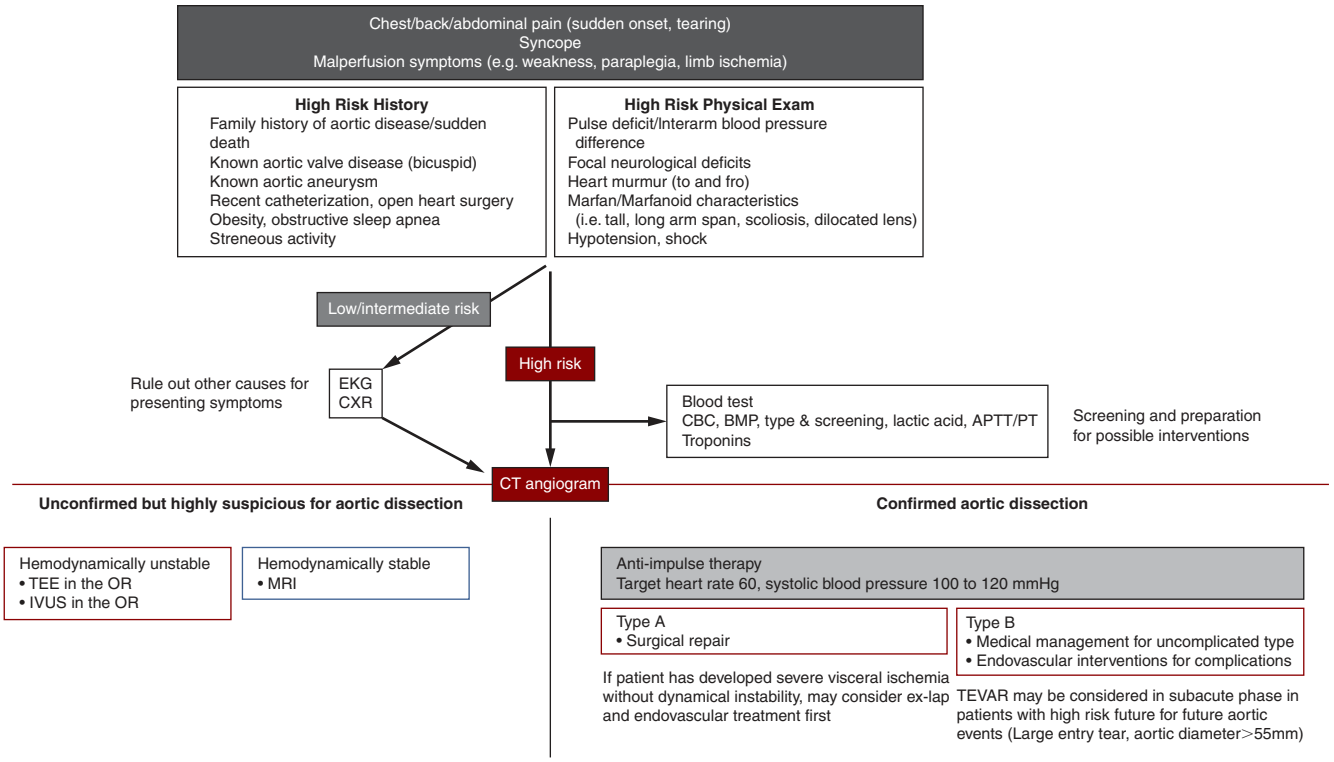

Fig. 148.3 Diagnostic and treatment algorithms of aortic dissection. *APTT/PT,* Activated partial thromboplastin time/prothrombin time; *CBC,* complete blood count; *CT,* computed tomography; *CXR,* chest x-ray; *EKG,* electrocardiogram; *IVUS,* intravascular ultrasound; *MRI,* magnetic resonance imaging; *OR,* operating room; *TEE,* transesophageal echocardiogram; *TEVAR,* thoracic endovascular aortic repair. (Modified from Hiratzka LF, Bakris GL, Beckman JA. 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic disease. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, American Association for Thoracic Surgery, American College of Radiology, American Stroke Association, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society of Interventional Radiology, Society of Thoracic Surgeons, and Society for Vascular Medicine. *J Am Coll Cardiol.* 2010;55[14]:e27–e129.)

Historically, angiogram and transesophageal echocardiogram (TEE) were standard examinations. They have been replaced by CT angiogram, which is now used in 73% of cases as initial imaging modality. (TEE is now only used in 23%.) However, TEE still has a crucial role when the diagnosis is not confirmed with CT, such as in patients with borderline renal function who cannot have contrast injected, those with body habitus resulting in poor-quality CT, or to rule out localized flap in the ascending aorta and aortic root. As TEE requires at least moderate sedation, the patient may be brought to the operating suite and performed under general anesthesia with preparation to open surgery. Electrocardiogram-gated CT is useful with stable patients when obtaining more precise information, such as detecting entry tear. Intravascular ultrasound (IVUS) provides real-time imaging of the aorta, branch vessels, and flap. It can be used for the diagnosis of malperfusion[55] and intraoperative assistance during endovascular procedures by identifying the true and false lumen.[56] Magnetic resonance imaging (MRI) is accurate in the diagnosis of aortic disease with equivalent—or even superior—sensitivities and specificities to those of CT. However, in the acute setting, the long image acquisition and lack of availability prevent it from being the first choice. After making the diagnosis of aortic dissection, surgical consultation should be obtained regardless of the type.

MEDICAL MANAGEMENT FOR ACUTE AORTIC DISSECTION

Regardless of the extent of dissection, it is crucial to initiate anti-impulse therapy without delay. As discussed earlier, dp/dt is the single critical factor that propagates the disease. Thus not only the blood pressure but also the heart rate needs to be controlled, with a target of 100–120 mm Hg in systolic blood pressure and a heart rate of 60 beats per minute or less.[19] Pain control and monitoring are also essential.[19] High dp/dt can progress the dissection and cause pain, and vice versa (pain can result in high dp/dt). Patients should be admitted to the intensive care unit for monitoring. For better control of hemodynamics, intravenous (IV) administration of the drug is recommended. Central venous line and arterial line placement may be encouraged for strict management. Before the placement of an arterial line, peripheral pulses and blood pressures in all the limbs must be examined to ensure that the appropriate site is selected for monitoring, as branch dissection or true lumen compression can result in reduced blood flow to the affected limb and thus blood pressure measurements would be falsely dropped. The first-line agent is IV beta-blockers.[19] Antihypertensive agents are summarized in Table 148.1.[57] In case of a cocaine-induced condition, selective beta-blockers, such as metoprolol and esmolol, should be avoided but mixed alpha-/beta-blockers, such as labetalol, can be given.[58] When a beta-blocker is contraindicated, nondihydropyridine calcium channel blockers are the second choice to control heart rate. If systolic blood pressures remain above 120 mm Hg after adequate heart rate control, angiotensin-converting enzyme inhibitors and/or other vasodilators, such as a dihydropyridine calcium channel blocker or nitroprusside, should be used. It is important not to use the vasodilators before heart rate control, as these agents may cause reflex tachycardia, which will increase dp/dt. Caution is needed when using beta blockade in patients with severe aortic regurgitation because these drugs can cause compensatory tachycardia or worsen heart failure symptoms.

TABLE 148.1 Antihypertensive Therapy

Antihypertensive Agents	Dosing
First-Line Agents	
Esmolol (β1 antagonist)	IV infusion: bolus of 500 μg/kg over 1 min, followed by 50 μg/kg/min, titration up to 300 μg/kg/min
Labetalol (combined α1/β1/β2 antagonist)	IV: bolus of 20 mg over 2 min, repeated incremental dose of 20–80 mg q10min IV infusion: loading dose of 20 mg followed by 1–2 mg/min infusion
Metoprolol	IV: bolus of 5 mg over 2 min, repeat dose q5min up to 3 doses
Second-Line Agents	
Diltiazem (nondihydropyridine calcium channel blocker)	IV infusion: bolus of 0.25 mg/kg over 2 min followed by 5–10 mg/hr infusion, titration up to 15 mg/hr IV infusion: 5 mg/hr, titration by 2.5 mg/hr min up to 15 mg/hr
Additional Vasodilators (After Heart Rate Control)	
Nicardipine (dihydropyridine calcium channel blocker)	IV infusion: 0.3 μg/kg/min, titration q2min with maximum dose of 10 μg/kg/min; hypotensive effect can be unpredictable, may cause cyanide toxicity
Sodium nitroprusside	IV infusion: 5 μg/min, titration by 5 μg/min q5min with maximum dose of 200 μg/kg/min; unsuitable for prolonged use
Nitroglycerin	

INTERVENTIONS FOR ACUTE AORTIC DISSECTION

Two key purposes of aortic intervention are (1) entry tear resection to prevent aortic rupture and (2) redirect blood flow into the true lumen to correct malperfusion. In addition, type A aortic dissection often requires repair of aortic valve insufficiency. Chronic aortic dissections generally follow the surgical/interventional indications for true aneurysms and will not be discussed in this chapter.

Treatment Strategy for Acute Type A Aortic Dissection

Open Surgical Repair vs. Endovascular Repair vs. Medical Management

Open surgical repair remains a mainstay in acute type A aortic dissection, and patients should urgently be taken to the operating suite. As discussed earlier, medical management carries a higher mortality rate compared with surgical repair. Thoracic endovascular aortic repair (TEVAR) for type A aortic dissection has not been established because of challenges in the landing zone, such as close proximity to the coronary arteries and large landing zone diameter, and the presence of aortic regurgitation that warrants surgical repair.[59] Hybrid repair, open surgical repair for ascending and aortic arch, and concomitant distal stent grafting (frozen elephant trunk) have gained influence, with expectations for resolving downstream malperfusion and positive aortic remodeling,[9,60,61] but have not yet become a standard treatment because of additional surgical risks, including cerebral and spinal complications. Both off-the-shelf ascending stent graft and hybrid frozen elephant trunk prostheses (a stent graft integrated to a Dacron graft) are not readily available in the United States and are currently being tested in clinical trials.

Cerebral Protection During Acute Type A Aortic Dissection Repair

Acute type A aortic repair involves the aortic arch and necessitates temporary arrest of cerebral circulation.[62] Thus several cerebral protection strategies are developed to avoid ischemic insults to the brain. Commonly used cerebral protection strategies include simple profound deep hypothermic (below 14°C) circulatory arrest and moderate (20°C–28°C) to deep (14°C–20°C) hypothermic circulatory arrest with cerebral perfusion. There are two methods for cerebral perfusion: retrograde cerebral perfusion via the superior vena cava and antegrade cerebral perfusion with direct cannulation using balloon-tipped catheters or axillary cannulation. Simple deep hypothermic circulatory arrest and retrograde perfusion provide better visualization of the operative field and do not require exposure or manipulation of arch vessels or axillary artery. Thus most surgeons prefer either of these two methods during hemi arch repair, resecting and replacing the ascending aorta and the proximal aortic arch. However, in patients undergoing total arch repair, prolonged circulatory arrest and arch vessel reconstructions are inevitable. Thus some surgeons prefer antegrade cerebral perfusion to further minimize the ischemic injury during total arch replacement.[63]

Extent of Distal Repair in Acute Type A Aortic Dissection

In most of the cases, aortic dissection extends beyond the transverse aortic arch, and complete resection of all the affected lesions is not possible. It is now well known that eliminating the intimal tear is crucial in preventing the imminent rupture and subsequent distal reintervention.[64] Thus the tear-oriented approach that determines the extent of repair as much as needed for the complete resection of the tear[65] has been widely accepted to minimize surgical risks. About 30%–50% of the entry tear is located in the ascending aorta, 25%–30% in the transverse arch,[8,10,66] and 10% in the distal arch or unknown origin in patients presenting with acute type A aortic dissection.[10,67] When the tear is located in the ascending aorta, the proximal arch, or the lesser curvature of the transverse arch, hemiarch replacement is performed. The arch vessels are preserved by beveling the distal anastomosis and extending the posterior suture line beyond the entry tear in this procedure. When the tear is present in the greater curvature of the transverse arch or extending to the arch vessels, total arch replacement is chosen. Other circumstances that warrant total arch replacement are excessive enlargement and rupture of the false channel in the arch[64] and aortic dissection associated with a large aortic arch aneurysm.

Aortic Root Repair During Acute Type A Aortic Dissection

The proximal extension of aortic dissection and associated aortic valve regurgitation is not uncommon to acute type A aortic dissection. Aortic root replacement and valve replacement are often not necessary—aortic reconstruction using circumferential pledgeted sutures and/or surgical glue to approximate the layers is usually sufficient to repair the lesion. However, if the aortic root is dilated over 55 mm or there is a tear in the root itself, aortic root replacement is reasonably considered. In such cases, valve-sparing aortic root replacement to preserve the native aortic valve and reimplanting the valve in the Dacron graft is used, or the entire root is replaced with a valved conduit. In general, bioprosthetic valves do not require anticoagulation but have shorter durability, which is recommended in older patients (above 60–65 years of age) and patients contraindicated for anticoagulation therapy. On the contrary, mechanical valves require permanent anticoagulation but have lifelong durability, which is recommended in younger patients. The valve-sparing technique is technically demanding and not suitable for damaged or degenerative valves. The choice of valve, bioprosthetic vs. mechanical, or valve-sparing should be comprehensively judged based on the patient's age, concomitant comorbidities, condition of the valve (torn, degenerated), experience of the surgeon, and patient's will.

Cardiac Tamponade

The efficacy of preoperative pericardiocentesis in patients with tamponade in the emergency department has been reported.[68] It should only be indicated in patients who do not respond to aggressive IV resuscitation, and routine performance is never recommended. Intermittent, limited drainage of 30–40 mL is usually sufficient enough to maintain systolic pressure around 90 mm Hg. After transferring the patient with cardiac tamponade to the operating suite, care must be taken at the time of anesthetic induction, as the patient is at risk for further decompensation. It is also important for surgeons to communicate with the anesthesiologists that aggressive volume resuscitation is vital, but administration of pressor agents, especially by bolus, should be avoided. Blood pressure will dramatically recover once the tamponade is released, and the bolused agents will abruptly circulate in the body, which will overshoot the pressure and completely rupture the aorta. When opening the pericardial sac, it should be performed in a controlled fashion with a finger applied to the opening. The speed of drainage is adjusted according to the arterial pressure.

Malperfusion in Type A Aortic Dissection

More than 80% of limb malperfusion spontaneously resolved after central aortic repair,[69] and extraanatomic bypass or endovascular intervention is considered if limb ischemia persists after the repair. Similarly, stroke symptoms associated with cerebral perfusion may resolve symptoms in 80% after the aortic repair.[70] Surprisingly, nearly 80% of patients who present with a coma recover.[70] However, hospital mortality in this subset reaches 60%. It is reported that when a central repair was performed within 5 hours of the onset of coma, mortality was 14% and full recovery of consciousness was observed in 86%, whereas those who presented beyond the 5-hour window were 67% and 17%, respectively.[71] Thus it is reasonable to wait for the comatose patient to regain neurologic function if the time from the onset has passed 5 hours. Lastly, in case of mesenteric malperfusion, because of the high mortality rate—reported as high as 89%[7,10,27,38,39]—a staged approach with fenestration or stenting to restore the blood flow to the viscera may be considered in hemodynamically stable patients before the central repair, in particular, when a patient presents with severe tenderness and/or peritonitic signs.

Postoperative Care for Acute Type A Aortic Dissection

The postoperative team bundle report in the intensive care unit should include the extent of aortic dissection, extent of repair, circulatory arrest time, cardiopulmonary bypass time, and transfusion amount—in addition to the patient's baseline demographics. It is also important to notify the care team about concerns, such as malperfusion syndrome present on admission, as even intraoperative findings may suggest a resolution. Visceral malperfusion on arrival warrants serial abdominal examination, and limb malperfusion needs attention for the development of compartment syndrome. Peripheral pulses in all four extremities should be checked, as they will help for early detections of malperfusion in other organs. For example, patients with diminished upper extremity pulses may have cerebral malperfusion, or patients with lower extremity pulses may have visceral ischemia. Serial neurologic assessment is essential, as the surgical repair can

result in cerebral insults from aortic arch manipulation. When there is a known carotid artery dissection with preoperative stroke symptoms, carotid duplex may be indicated to evaluate the need for subsequent intervention if neurologic symptoms persist. Many of the patients with aortic dissection have underlying long-standing hypertension. Thus systolic blood pressure less than 120 mm Hg may be ideal to prevent propagation of the remaining dissection and prevent suture-line bleeding, but in reality, 140 mm Hg may be needed to sustain renal function. Patients should be warmed when the body temperature is below 36°C. During warming, vasodilation is expected, and appropriate fluid resuscitation and adjustment of antihypertensive drips are needed. In addition to routine blood testing, coagulation tests should be checked. The use of hypothermia during aortic repair and consumption of coagulants in the false lumen may cause postoperative coagulopathy. Thromboelastography is also helpful for the diagnosis. Lactic acidosis at the time of arrival to the unit is often seen because of preoperative malperfusion syndrome and intraoperative circulatory arrest. However, persistent lactic acidosis of more than 2–3 hours should trigger further investigations to rule out visceral/limb malperfusion and low cardiac output. After confirming that no further interventions are planned (i.e., re-exploration for bleeding, stenting, fasciotomies) and the patient is hemodynamically stabilize, the patient can be extubated. Postoperative hypoxemia in patients with aortic dissection is not uncommon because of the inflammatory process from the disease and hypothermic circulatory arrest. Urine output should be monitored for volume and color. If oliguria is seen, renal duplex should be obtained to evaluate the blood flow. Wine-colored urine suggests hemolysis that can be associated with paravalvular leakage and a kinked graft. If a mechanical prosthesis has been used to replace the aortic valve, anticoagulation can generally be held for 48 hours postoperatively. Aspirin is given when branches were reconstructed. Guidelines recommend contrast-enhanced CT scan is obtained before discharge to assess the repair and extent of any residual dissection.[19]

Treatment Strategy for Acute Type B Aortic Dissection

Open Surgical Repair vs. Endovascular Repair vs. Medical Management

Unlike type A aortic dissection, medical management is the gold-standard treatment for acute type B aortic dissection, unless symptomatic or complicated. American guidelines recommend TEVAR as the first option to treat acute type B dissection with complications,[19] whereas open repair is reserved for patients who are anatomically unfit for endovascular repair. Approximately one-third of acute type B aortic dissections present as—or progress to—complicated type.[7–11,72]

Favorable long-term outcomes after TEVAR for uncomplicated acute type B aortic dissections during the subacute phase were reported in a randomized controlled study (Investigation of Stent Grafts in Patients with Type B Aortic Dissection, INSTEAD-XL trial) after 2 years of follow-up.[73] Considering the outcomes of INSTEAD-XL and the literature reporting positive remodeling after TEVAR in uncomplicated type B aortic dissection,[74] European guidelines recommended considering TEVAR for the subset. Thus uncomplicated type B dissection patients with high-risk features with late aortic interventions may reasonably receive TEVAR in the subacute phase. There are two other ongoing trials[74] to further prove the safety and durability of TEVAR for uncomplicated type B aortic dissections. In the near future, more aggressive indications of TEVAR in uncomplicated acute type B aortic dissections may be justified. Although IMHs are treated as classical aortic dissections in acute type A, acute type B IMHs should be treated differently from the classical type B. Acute type B IMHs are known to regress in 32% and resolve in 60%,[75] and there is no evidence to treat uncomplicated type B IMHs.

TEVAR for Acute Type B Aortic Dissection

The primary goals of TEVAR are to seal the entry tear and to re-expand the true lumen. The secondary goal is to stabilize the dissected aorta to induce positive remodeling and prevent future complications. The technology has improved over the decade, and low-profile delivery systems (16–26 French) are available. Thus most of the procedures are performed percutaneously. An iliac conduit (a Dacron graft to the iliac artery anastomosed in an end-to-side fashion) may be required in small or diseased iliac/femoral arteries. Four companies supply eight different covered stent grafts to the U.S. market, with anatomic requirements and instructions for use varying based on device: landing zone diameter of 16–45 mm, and most of the devices require at least 20 mm (one with 15 mm) landing zone length. Covered stents are used to close the entry tear, but the distal extension beyond T8 carries higher risks for postoperative spinal cord ischemia. When true lumen compression is seen in the thoracoabdominal aorta, the extension with uncovered stents may be used.

Endovascular Fenestration for Aortic Dissection Complicated with Malperfusion Syndrome

Fenestration of the dissection flap with endovascular intervention can also be used for true lumen expansion. Catheter-based fenestration is performed with either IVUS or fluoroscopic guidance. In general, a dissection septum is punctured with a needle-based re-entry catheter or a catheter with a super-stiff wire to create a hole in the septum.[76,77] Then, a guidewire is passed through the re-entry catheter and across the membrane, and the hole is dilated with balloons large enough to increase the flow in the true lumen. The other technique, named the "cheese-wire" maneuver, snares the guidewire crossing the septum from the contralateral transfemoral access to slice through the membrane.[78] When a static malperfusion is present in the visceral branches, stenting of the branches is performed with a transfemoral, transaxillary, or transbrachial approach.

Descending Thoracic and Thoracoabdominal Aortic Replacement

Open replacement of the descending thoracic and thoracoabdominal aorta is performed via a left posterolateral thoracotomy or thoracoabdominal incision under single-lung ventilation. Partial left heart bypass with pulmonary vein drainage and femoral artery return or full cardiopulmonary with femoral vein drainage (or pulmonary artery drainage) and femoral artery return are used for support. The goal of the operation is to eliminate the entry tear as in type A aortic dissection. During distal aortic repair, the spinal cord, viscera, and kidney are at risk for ischemic insults. Hypothermia, cerebrospinal fluid drainage, and distal aortic perfusion are essential adjuncts to protect the spinal cord. Selective visceral and renal perfusions are applied when these are involved in the repaired segment. The aorta is replaced with a Dacron graft, and intercostal arteries in T8–T12—the levels of a major spinal cord feeder (artery of Adamkiewicz)—are recommended to reattach to the graft to prevent both immediate and delayed spinal cord injury.[19] When complete resection of the dissection is not performed, the distal anastomosis is performed to occlude the false lumen to reconstruct the aorta. If the false lumen has vital branches coming off, the dissection septum in the remaining distal segment is cut to allow the blood to flow as a double-barrel.

Open Aortic Fenestration

This procedure is now rarely performed since the advent of endovascular techniques. A report from the Mayo Clinic in 2002 showed they required the technique in only 1.6% (14/857) of the aortic dissection patients.[4] It is usually reserved for patients requiring expeditious relief of multiorgan ischemia (i.e., a combination of visceral, renal, and limb malperfusion) without degenerative or aneurysmal changes in the affected aorta. It is effective in more than 90% of the cases presenting with end-organ ischemia.[4] The technique does not necessitate single-lung ventilation, and the short clamp time minimizes ischemic insults to organs. The goal of open aortic fenestration is to create a large enough re-entry to allow flow in the true lumen in the thoracoabdominal aorta where the vital branches take off. The supraceliac aorta and infrarenal aorta are clamped, and the longitudinal aortotomy is made in the thoracoabdominal aorta to visualize the branches in case of branch thrombectomies. The dissection septum is excised up to the level of the celiac trunk and below the renal arteries. The aortotomy is then closed with a running suture.

Postoperative Management After Interventions for Acute Type B Aortic Repair

Postoperative management is performed in a similar way to acute type A aortic dissection repair. Strict blood pressure should be performed, in particular, in patients who had open aortic fenestration because of the long suture line in a thin and fragile aorta. In addition, monitoring for spinal cord injury is required. The care team should be informed of the level the aorta was treated, as risks of spinal cord injury are much higher with more extensive repair, and T8–T12 is involved in the treated lesion. When a cerebrospinal fluid drain is placed in the operating suite, it should be drained at the maximum rate of 15 mL/hour to maintain the cerebrospinal pressure below 10 mm Hg. Once the presence of spinal cord ischemia is suspected, the cerebrospinal fluid should be drained without a limit to target the pressure below 5 mm Hg. Systolic blood pressure is raised above 140 mm Hg, blood is transfused to maintain hemoglobin level above 10 mg/dL, and cardiac index is targeted above 2.5 L/min/m^2.

LONG-TERM MANAGEMENT OF AORTIC DISSECTION

Aortic disease is a lifelong, progressive illness. Patient education on compliance with antihypertensive medications and imaging surveillance is imperative (Fig. 148.4). Compliance with beta-blocker use and blood pressure control is warranted to avoid future aortic events.[79] A recent study from Sweden[80] showed that long-term survival after type A aortic dissection repair had similar survival, up to 7 years, when compared with that of age- and sex-matched controls. However, mortality in patients with type A aortic dissection repair acutely rose after 8 years, with a 10-year mortality of 130% compared with the control. The increased mortality is most likely from the progression of the disease. Again, the importance of lifelong surveillance cannot be overemphasized.

CONCLUSIONS

Recognition of patients with high-risk features for acute aortic dissections is essential for timely diagnosis. Chest/abdomen/pelvis CT angiogram is the gold-standard imaging modality to evaluate the aorta and for classifying type A and type B aortic dissections. Strict control of heart rate and blood pressure is initiated without delay, regardless of type. Patients should further be assessed for complications, such as malperfusion syndrome. Acute type A dissection warrants urgent surgical repair, whereas acute type B dissection should be medically treated, unless complications are present or develop. Uncomplicated type B aortic dissection may be indicated for TEVAR to induce positive aortic remodeling and prevent future aortic events. However, before extending this indication, further data acquisition is warranted for feasibility and durability. Imaging surveillance is crucial to screen for aortic dilation during follow-up.

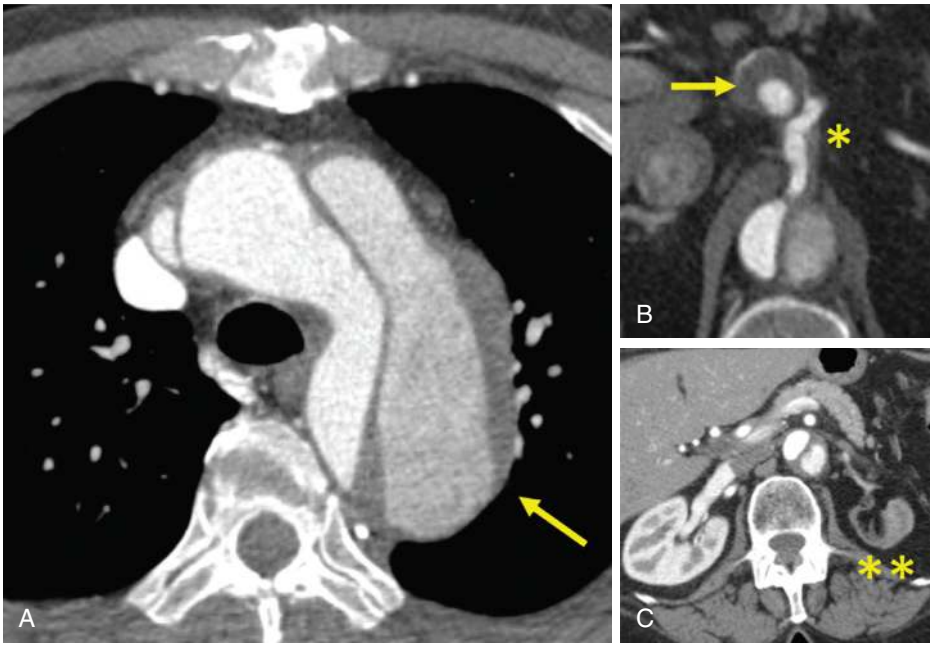

Fig. 148.4 Chronic residual type A aortic dissection (axial view). A proximal descending aortic aneurysm has developed **(A)**, along with a celiac artery aneurysm **(B)**. The left renal artery branches off from the false lumen, and a resultant atrophic left kidney is seen **(C)**. *Arrow,* aneurysmal change; *, dissected celiac artery; **, atrophic left kidney.

KEY POINTS

- Patients highly suspicious for acute aortic dissection should undergo urgent CT angiogram along with surgical consultation.
- After diagnosis is obtained for aortic dissection, anti-impulse therapy with beta-blockers as first-line agents should be initiated without delay. Vasodilators should not be given before heart rate control.
- Open surgical repair remains the mainstay for acute type A aortic dissection.
- Complicated acute type B aortic dissection should undergo endovascular treatment when anatomically applicable.
- Uncomplicated acute type B aortic dissection may benefit from endovascular treatment in the subacute phase.
- Postoperative care of both type A and type B aortic dissection consists of blood pressure management, addressing coagulopathies, and monitoring for malperfusion complications.
- Lifelong imaging surveillance and blood pressure control are warranted in patients with any type of aortic dissection.

Mesenteric Ischemia

Dean J. Arnaoutakis and Thomas S. Huber

INTRODUCTION

Mesenteric ischemia is a generic term that implies inadequate blood flow to the intestines. It is relevant from a clinical standpoint as two separate disease processes: acute mesenteric ischemia (AMI) and chronic mesenteric ischemia (CMI). Although the underlying process is similar (i.e., inadequate intestinal blood flow) between the two conditions, the clinical presentation, diagnostic concerns, and treatment algorithms are different. CMI is usually related to mesenteric artery atherosclerotic occlusive disease and is relevant to intensive care physicians primarily because of the multiple organ dysfunction syndrome (MODS) that occurs after revascularization. AMI can arise from a variety of underlying conditions, including arterial emboli, in situ thrombosis in the setting of mesenteric arterial occlusive disease, mesenteric venous thrombosis, nonocclusive mesenteric ischemia (NOMI), and acute aortic dissections. AMI is relevant to intensivists because it often develops in critically ill patients (e.g., post–coronary artery bypass, acute pancreatitis), and revascularization can lead to a profound inflammatory response. A thorough understanding of both clinical entities is essential for all intensive care physicians. The underlying pathophysiology and treatment of CMI will be discussed first to provide a foundation for addressing AMI. Although not traditionally considered AMI, isolated colon ischemia will also be discussed for completeness.

CHRONIC MESENTERIC ISCHEMIA

Pathophysiology

The underlying pathophysiology of CMI is the inability to achieve postprandial hyperemic intestinal blood flow. Intestinal blood flow in the normal fasting state is fairly modest, but may increase up to 35% after eating, with the magnitude contingent upon the size and composition of the meal.[1,2] The majority of the hyperemic changes occur in the pancreas and small bowel with a peak within 30–60 minutes after eating.[3,4] In patients with significant mesenteric arterial occlusive disease, this postprandial hyperemia is not possible, and patients develop ischemic pain similar to angina pectoris, appropriately termed *mesenteric angina.*

The normal mesenteric circulation is fairly redundant and has a rich collateral network (Fig. 149.1). The celiac axis (CA) communicates with the superior mesenteric artery (SMA) through the superior and inferior pancreaticoduodenal arteries. The SMA communicates with the inferior mesenteric artery (IMA) via the meandering mesenteric artery that travels within the proximal mesentery. This collateral has multiple eponyms, but should be differentiated from the less significant collateral, the marginal artery of Drummond, that is located in the distal mesentery. Lastly, the IMA communicates with the internal iliac artery via the superior and middle hemorrhoidal arteries. The symptoms of mesenteric ischemia usually do not occur unless two of the three mesenteric vessels (i.e., CA, SMA, and IMA) are significantly diseased because of this rich collateral network. However, symptoms may occur with isolated SMA disease in the absence of adequate collaterals.[5–7]

The overwhelming majority of mesenteric artery stenoses are the result of atherosclerosis. A variety of other etiologies have been reported, including neurofibromatosis, fibromuscular disease, rheumatoid disorders, aortic dissection, isolated mesenteric artery dissection, radiation, Buerger disease, and certain drugs, although these are collectively less common. Clinically symptomatic mesenteric artery occlusive disease (i.e., CMI) is relatively rare despite the prevalence of asymptomatic mesenteric artery stenoses. Indeed, a hemodynamically significant mesenteric artery stenosis (>50% diameter reduction) has been reported in up to 27% of patients with peripheral arterial occlusive disease undergoing a catheter-based arteriography[8] and in up to 5%–10% of unselected patients at autopsy.[9] The atherosclerotic process usually involves just the origin of the mesenteric vessels. Patients with occlusive disease in the CA and SMA often have renal artery stenoses, along with disease in the cerebral and lower extremity arteries—these risk factors for atherosclerosis are similar for all vascular beds.

Clinical Presentation and Diagnosis

The appearance and presentation of patients with CMI is fairly characteristic. The typical patients are cachectic, elderly women with a history of extensive tobacco use. Indeed, CMI is one of the few cardiovascular problems more prevalent in women than in men. A recent meta-analysis of almost 19,000 patients undergoing revascularization for CMI (both open and endovascular) reported that the mean age was 68.7 years: 77.8% were women, the majority were smokers, hypertensive, and had evidence of peripheral arterial disease.[10]

Abdominal pain is usually the presenting symptom. It initially occurs postprandially, although it may progress to a persistent nature in the latter stages of the disease process. Unfortunately, the pain has no specific characteristics. As a result of the pain, patients develop a fear of food and avoid eating. The net result is a predictable weight loss with a mean of 20–30 lbs. in several recent clinical series.[11–13] Notably, Mansukhani and colleagues[14] reported that 35% of the patients undergoing mesenteric revascularization for CMI in their series had a body mass index (BMI) >25, and they attributed this to the epidemic of obesity in our country. It should be noted that the etiology of weight loss is presumably from poor nutrition rather than an abnormality in intestinal absorption, although the exact impact of chronic malperfusion on the gut microbiome and enterocyte function has yet to be elucidated. In addition to postprandial abdominal pain, patients may develop nausea, emesis, constipation, and/or diarrhea. Patients with CMI frequently have evidence of diffuse peripheral vascular disease, although there are no characteristic physical examination findings.

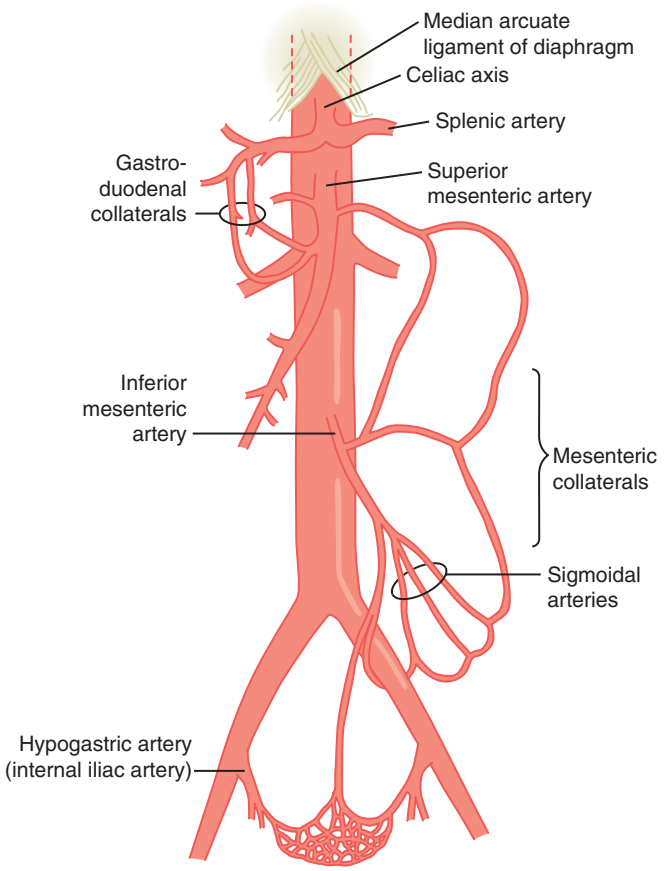

Fig. 149.1 Diagram of the collateral pathways for the mesenteric. The celiac axis and superior mesenteric arteries communicate through the superior and inferior pancreaticoduodenal arteries, respectively. The superior and inferior mesenteric arteries communicate through the meandering artery and the marginal artery of Drummond, with the meandering artery serving as the dominant collateral. The inferior mesenteric artery communicates with the internal iliac artery through the hemorrhoidal vessels. (Modified from Hanson KJ. Mesenteric ischemia syndromes. In Dean RH, Yao JST, Brewster DC, eds. *Current Diagnosis and Treatment in Vascular Surgery.* Englewood Cliffs, NJ: Appleton & Lange/Prentice Hall; 1995:264.)

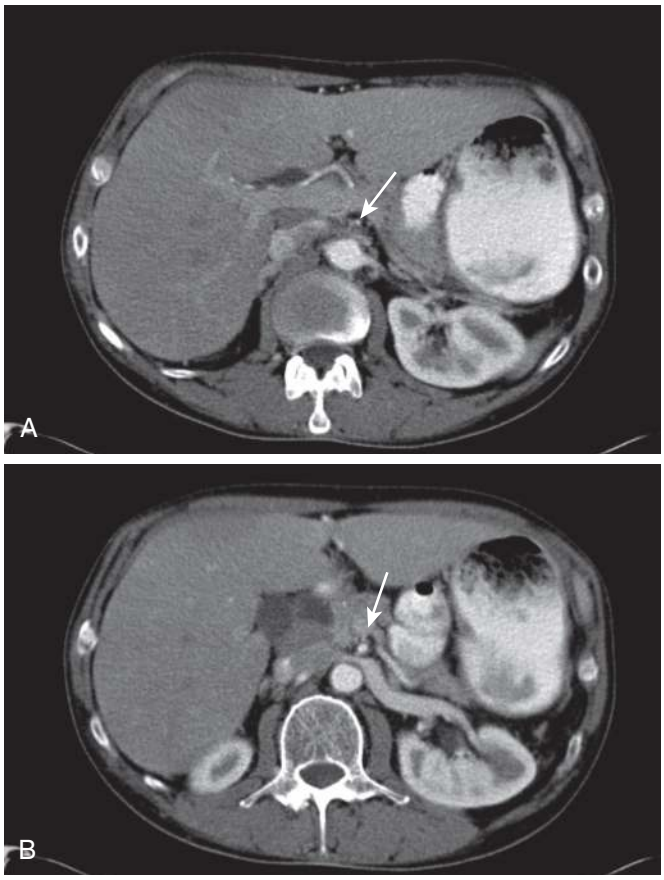

Fig. 149.2 CT arteriograms in a patient with an occluded celiac axis and superior mesenteric artery (SMA). **A.** The origin of the SMA is shown with the arrow. There is no contrast within the lumen of the vessel at this cross section. **B,** The SMA is shown with the *arrow* in this cross section that is 10 mm caudal to the first image. The artery is patent at this level, as reflected by the contrast within the lumen.

The diagnosis of CMI requires the appropriate clinical history and the presence of significant mesenteric artery occlusive disease. The diagnostic approach is a stepwise one with consideration of the more common problems first. Although the appearance and clinical presentation of patients with CMI is fairly characteristic, the differential diagnosis of patients with abdominal pain and weight loss is extensive and includes gastrointestinal malignancy first and foremost. Indeed, CMI is usually not even considered by most primary care providers, and this is reflected by the fact that the mean duration from presentation to diagnosis oftentimes exceeds a calendar year and 2.8 diagnostic tests.[15] The initial diagnostic work-up for patients with abdominal pain and weight loss should include esophagogastroduodenoscopy, colonoscopy, abdominal ultrasound, and an abdominal/pelvic computed tomography (CT) scan.[16,17] Notably, gastric ulcers are relatively common in patients with CMI and likely result from ischemia.[18,19] A surprising number of patients are subjected to cholecystectomy as part of their work-up before the definitive diagnosis of CMI is made.

Mesenteric duplex is an excellent *screening* tool for mesenteric artery stenosis, with reported sensitivity and specificity rates of approximately 80%.[20,21] However, it is technically challenging, operator dependent, and not available in all centers. A variety of criteria have been proposed to grade the severity of stenoses based upon the systolic/diastolic velocities or frequency shifts, with a peak systolic velocity of >275 cm/s and 200 cm/s being reliable predictors of a >70% stenosis in the SMA and CA, respectively.[21,22] A variety of provocative tests have been proposed to unmask clinically significant mesenteric artery stenoses, although their utility is unclear and they have not achieved widespread use.[23,24]

Multidetector helical CT arteriography with 1-mm collimation and three-dimensional reconstructions has largely replaced catheter-based contrast arteriography as the *diagnostic* study of choice for patients with CMI (Fig. 149.2) and is usually sufficient to plan surgical revascularization.[16,17,25–28] CT arteriography is safe, noninvasive, readily available, and accurately identifies occlusive disease in the SMA and CA. Furthermore, it is useful for visualizing large, meandering collateral vessels between the mesenteric vessels that suggest hemodynamically significant stenoses. Additionally, CT is now the first-line diagnostic modality for many other intraabdominal processes.

Catheter-based contrast arteriography is useful for evaluating the mesenteric circulation and has traditionally been used as the definitive *diagnostic* test for CMI (Fig. 149.3A). The major advantage of catheter-based arteriography over CT arteriography is that therapeutic interventions can be performed at the time of the diagnostic procedure. Furthermore, intraarterial pressure measurements can be obtained across a stenosis to determine their hemodynamic significance. However, it is an

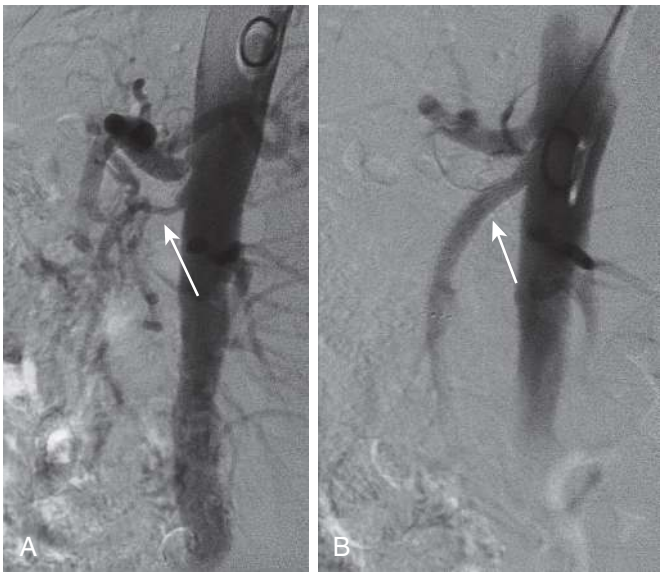

Fig. 149.3 Lateral catheter-based aortogram of a patient with chronic mesenteric ischemia. **A**, There is a moderate stenosis in the proximal superior mesenteric artery (SMA), as shown with the *arrow*. **B,** No residual stenosis is seen in the superior mesenteric artery (SMA) after placement of a covered intraluminal stent.

invasive procedure with a small, yet finite complication rate. A lateral arteriogram is mandatory as part of the examination to accurately assess the origins of the CA and SMA because of their location on the anterior aspect of the aorta. The significant findings on arteriogram include the presence of ostial stenoses of the CA and SMA, large mesenteric collaterals, and central aortic atherosclerosis. A small percentage of patients with CMI may have mesenteric artery aneurysms, presumably from increased flow through the collateral vessels.

Magnetic resonance (MR) arteriography has been used as a diagnostic study for patients with CMI and offers many of the advantages of CT arteriography.[29–31] However, it is not as universally available as CT arteriography. Furthermore, it is not practical and may be contraindicated for many patients, including those in the intensive care unit. Lastly, MR arteriography tends to overestimate the degree of stenosis in the mesenteric vessels.

Treatment Strategies

All patients with CMI require revascularization unless they are so debilitated that intervention is not indicated or they have opted for palliative care.[16,17] The natural history of the untreated CMI is death either from inanition or bowel infarction. The theoretical treatment options include medical management with total parenteral nutrition or revascularization by either endovascular or open surgical techniques. The role of long-term parenteral nutrition is very limited given its complexity, expense, and complications, particularly those associated with the infusion catheters. As such, revascularization via endovascular or open surgery is the mainstay of treatment. Endovascular treatment (i.e., angioplasty with intraluminal stent) has been adopted by most centers as the initial revascularization option given its minimally invasive approach. Open surgical revascularization has been reserved for patients that are not amenable to endovascular treatment, endovascular failures, and a select group of younger, healthier patients. Several meta-analyses comparing open and endovascular revascularization for CMI have reported that the endovascular approach is associated with a lower periprocedure complication rate and a higher longer-term recurrence rate, but no significant difference in perioperative or longer-term mortality.[10,32–35] Notably, the development of recurrent stenoses and the need for remediation have not been associated with a decrease in survival and has not necessarily resulted in the development of AMI. The recent development of lower-profile (i.e., smaller-diameter) angioplasty balloon/stent systems has further extended the applications of the endovascular approach, and reasonable, short-term results have been reported for patients with occluded mesenteric vessels (vs. stenotic) and other complex lesions that have traditionally precluded endovascular intervention.[36,37]

Endovascular Revascularization

The preoperative evaluation before endovascular treatment is essentially the same for all catheter-based contrast arteriography. Patients with a contrast allergy should be treated with an appropriate steroid preparation, and patients with elevated serum creatinine levels (serum creatinine 1.5–2.0 mg/dL) should receive gentle periprocedural hydration.

Percutaneous arterial access can be obtained through either the femoral, brachial, or radial approach. The upper extremity approach is usually favored for therapeutic procedures given the downward orientation of mesenteric vessels off the anterior aspect of the aorta and the vector forces associated with the catheters/sheaths. A flush aortogram is performed in both the anteroposterior and lateral projections. Because most lesions in the SMA and CA are orificial and located in the proximal 2 cm, selective catheterization is not usually necessary unless a distal lesion is suspected or the extent of the lesion cannot be determined. A >50% diameter reduction of the SMA is usually considered clinically significant regardless of whether or not the CA is involved. However, the diagnosis of CMI should be questioned in the presence of an isolated CA stenosis. Symptomatic stenoses can be treated at the time of the diagnostic catheter-based arteriogram (see Fig. 149.3B). The orificial stenoses in the mesenteric vessels are usually refractory to angioplasty alone, and primary stenting with a covered stent is recommended.[16,17] Balloon angioplasty with selective stenting is reserved for midsegment lesions. Balloon-expandable stents (vs. self-expanding stents) are preferred for the orificial stenoses because of their superior radial forces and controlled deployment mechanism. The benefit of covered stents in this location may be related to the physical barrier of the fabric that inhibits the intimal hyperplastic ingrowth.[38–40]

The postoperative care after mesenteric angioplasty/stenting is comparable to that for other peripheral endovascular procedures. Patients are typically observed in the hospital overnight and started on dual antiplatelet therapy. The optimal antiplatelet regimen and duration remains unresolved, but most providers favor 1–6 months of dual antiplatelet therapy.[41,42] Patients should likely be maintained (or started) on a cholesterol-lowering agent (i.e., statin), and there may be a role for rivaroxaban, although the utility of this in the setting of CMI remains poorly defined.[41,43] Most patients notice a marked improvement of their postprandial symptoms shortly after the procedure. A fasting mesenteric duplex ultrasound scan can be obtained on the morning after the procedure to serve as a baseline. Elevated velocities are occasionally noted in the duplex scan despite a technically satisfactory arteriographic result and complete resolution of the preoperative symptoms.[44–46] The explanation for these abnormal duplex findings is unclear, and thus the decision to reintervene is based on the presence of recurrent symptoms and/or a significant progression in the abnormal duplex findings. A repeat duplex examination is performed at 1 month and then every 6–12 months thereafter.[17] Aspirin (81 mg/day) is continued indefinitely after the dual antiplatelet regimen is completed.

Open Surgical Revascularization

The preoperative work-up for patients undergoing open mesenteric revascularization is comparable to that for other major vascular surgical procedures and includes optimization of all organ systems. Multiple

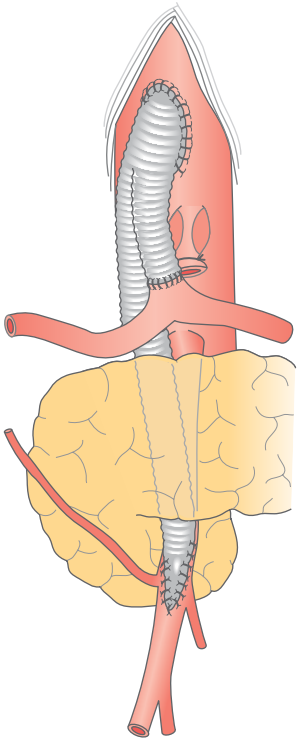

Fig. 149.4 Completed antegrade bypass from the supraceliac aorta to both the celiac axis and the superior mesenteric artery. (From Huber TS, Lee WA. Mesenteric vascular disease: Chronic ischemia. In Cronenwett JL, Johnston W, eds. *Rutherford's Vascular Surgery,* 7th ed. Philadelphia, PA: Elsevier; 2010: Fig. 148.6.)

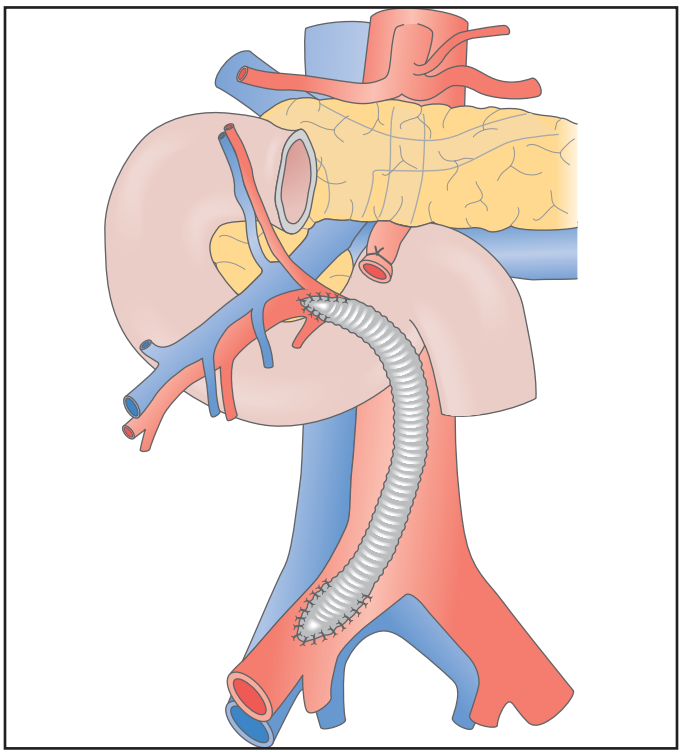

Fig. 149.5 Completed retrograde bypass from the terminal aorta/proximal right common iliac artery to the superior mesenteric artery bypass. (From Huber TS, Lee WA. Mesenteric vascular disease: Chronic ischemia. In Cronenwett JL, Johnston W, eds. *Rutherford's Vascular Surgery,* 7th ed. Philadelphia, PA: Elsevier; 2010: Fig. 148.7.)

algorithms have been developed to reduce the cardiac risk for vascular surgical patients undergoing noncardiac procedures, including those from the American Heart Association and the American College of Cardiology.[47] Importantly, the preoperative work-up should be expedited given the severity of the underlying condition and the potential to progress to AMI. All patients should likely be on an antiplatelet agent and a cholesterol-lowering agent, preferably a statin.[48] A CT or catheter-based contrast arteriogram is mandatory to both confirm the diagnosis and plan the operative procedure.[17] There is no clear role for extended preoperative parenteral alimentation to replete the nutritional stores and, indeed, it may be detrimental.

A variety of open surgical procedures have been reported, although the antegrade aortoceliac/SMA bypass (Fig. 149.4) and the retrograde aorto/iliac-celiac/SMA bypass (Fig. 149.5) are the most common.[11,49] Unfortunately, a randomized controlled trial comparing these two approaches has not been performed because of the relative infrequency of the underlying problem. The advantages of the antegrade aorto-CA/SMA bypass are that both mesenteric vessels are revascularized and the supraceliac aorta (the origin of the bypass) is usually free of atherosclerotic occlusive disease. The major disadvantage is the complexity of the procedure related to aortic exposure and clamping along with tunneling of the bypass graft. In contrast, retrograde aorto/iliac-CA/SMA bypass entails a more straightforward exposure and avoids the need for an aortic cross-clamp, provided that the graft comes off of the iliac artery. However, there is a theoretical concern that the graft is prone to kinking given its obligatory retrograde course that traverses both caudal to cephalad and posterior to anterior. The optimal choice for a specific patient is dictated by their anatomy (i.e., distribution of their occlusive disease), comorbidities, and provider expertise. Notably, neither configuration has been shown to be superior in terms of longer-term patency.[11,17,49]

The immediate postoperative care for patients undergoing revascularization for CMI is frequently complicated by the development of MODS and is distinctly different from that associated with most other abdominal vascular surgical procedures such as aortobifemoral bypass for aortoiliac occlusive disease.[11,50] This propensity to develop MODS likely accounts for the prolonged intensive care and total hospital length of stay and is one of the leading causes of death in the postoperative period. The responsible mechanism for this MODS is likely related to a mesenteric ischemia-reperfusion injury inherent to the revascularization. This process has been shown to induce a severe inflammatory response mediated by cytokines, interleukins, and other inflammatory mediators that can cause both local and distant organ injury.[51] In a detailed study, Harward and colleagues[50] characterized the individual organ system dysfunction after revascularization for both AMI and CMI. They reported that the serum hepatic transaminases (i.e., serum glutamic-oxaloacetic transaminase [SGOT] and serum glutamic-pyruvic transaminase [SGPT]) increased 90- to 100-fold immediately postoperatively and did not normalize for 7–10 days, the platelet counts fell below 40,000 units within 12–24 hours and remained abnormal for the first 3–6 days, and the prothrombin time (PT) and partial thromboplastin time (PTT) became elevated and stayed elevated also for 3–6 days. Perhaps most notably, they reported that the overwhelming majority of patients developed a significant pulmonary injury characterized by an elevated mean shunt fraction and a radiographic picture of the acute respiratory distress syndrome that manifested between 1 and 3 days and persisted for 5–8 days. Jimenez and colleagues[11] documented a 64% incidence of MODS and a 53% incidence of prolonged mechanical ventilation after antegrade revascularization for CMI and further corroborated the findings by Harward and colleagues[50]

The optimal management strategy for patients in the early postoperative period after open mesenteric revascularization is to support the individual organ systems until the dysfunction resolves. Admittedly, not all patients develop organ dysfunction, but the incidence is moderately high and somewhat unpredictable. The optimal ventilator management remains unresolved. Patients are typically extubated in the early postoperative period when they satisfy the various weaning criteria and clinicians have been reluctant to maintain them on mechanical ventilation in anticipation that they may develop a lung injury. However, it is relatively common that they need to be reintubated and started back on mechanical ventilation. The thrombocytopenia and coagulopathy are usually managed expectantly, with platelet and/or plasma transfusions reserved for severely depressed platelet counts and/or any clinical evidence of bleeding. Notably, the report by Harward and colleagues[50] suggested that the inherent coagulopathy after mesenteric revascularization was not responsive to vitamin K. Patients should be started and maintained on total parenteral nutrition throughout the postoperative period until their bowel function returns. This is particularly important given the fact that the majority of patients are severely compromised from a nutritional standpoint. Unfortunately, patients may have a prolonged ileus after revascularization, and total parenteral nutrition may be required until bowel function returns. The bypass should be interrogated with a mesenteric duplex or axial imaging before discharge to confirm the technical adequacy of the reconstruction. Patients with acute changes in their clinical status should also undergo mesenteric imaging to confirm that their bypass is patent. It can be difficult to differentiate between MODS that is a sequelae of the ischemia-reperfusion injury and AMI secondary to bypass graft thrombosis. Serum lactate levels may be helpful in this setting.

All patients who undergo revascularization for CMI require long-term follow-up. Patients are seen frequently in the early postoperative period until all their active issues resolve and then every 6 months thereafter with a mesenteric duplex to confirm graft patency and to identify any graft- or anastomotic-related problems. The proposed surveillance protocol with serial imaging outlined after endovascular revascularization is appropriate after open revascularization.[17] Objective assessment of graft patency is critical and significantly better than the return of symptoms that has been used as a surrogate marker.[52] Recurrent symptoms of CMI should be managed similar to the index presentation in terms of diagnosis and treatment.[17]

Diarrhea is a common complaint after revascularization for CMI and can persist for several months. It is more common in patients with perioperative diarrhea and can be so severe that it necessitates total parenteral nutrition. Notably, Jimenez and colleagues[11] reported that 33% of the patients in their series experienced significant postoperative diarrhea, with 24% experiencing symptoms beyond 6 months. Furthermore, Kihara and colleagues[53] reported that patients had almost 2 stools/day (1.9 ± 0.4) after revascularization for CMI. The etiology of the diarrhea is unclear but may be related to intestinal atrophy, derangements in the gut microbiome, or disruption of the mesenteric neuroplexus.

Outcome

The outcome after mesenteric revascularization for CMI is quite good.[10,32–35] The perioperative mortality rate after open surgical revascularization is <5% in high-volume centers and <15% in series reporting the nationwide experience.[11,12,49,52–57] The mortality rate after endovascular treatment is consistently <5%.[13,58–63] The corresponding complication rates are approximately 30%–50% and 15% for the open and endovascular treatments, respectively. The initial technical success rate for the endovascular treatment is approximately 90%. The objectively documented 5-year patency rates after open revascularization are approximately 75%; patency rates after endovascular treatment are not as well described, but likely fall short of those reported for the open treatment. The 5-year survival after either treatment is approximately 75%, and most patients return to their presymptom weight.

ACUTE MESENTERIC ISCHEMIA

AMI is the endpoint for several distinct disease processes. Mesenteric emboli and in situ thrombosis are the most common etiologies, accounting for approximately 50% and 25% of AMI cases, respectively.[64,65] NOMI (20%), mesenteric venous thrombosis (5%), and aortic dissections account for the remaining cases. The underlying pathophysiology of AMI is that the impaired intestinal perfusion leads to mucosal compromise. This results in the release of the intracellular contents, increased cellular permeability, and influx of substances (including bacteria and lipotoxins) from the lumen of the bowel into the circulation. This can lead to the massive activation of the systemic inflammatory response, resulting in both local and distant organ dysfunction (e.g., lung injury). If the impaired perfusion persists, bowel infarction with perforation and peritonitis ensues. The immediate clinical concerns for patients with AMI are to reverse the underlying clinical condition and prevent bowel infarction. The clinical presentation, diagnostic approach, and treatment for the various causes of AMI are similar, but there are distinct differences that mandate individual consideration. AMI from an embolus will be discussed in depth given the fact that it is the most common etiology, and the respective differences will be highlighted for the other causes. Fortunately, the underlying etiology can usually be determined from the history and clinical setting. Not surprisingly, the morbidity and mortality associated with AMI are significant.[16] The optimal therapy requires prompt diagnosis and definitive treatment, although this is often difficult given the susceptible patient population and common clinical scenarios. Indeed, AMI may be either the cause or the effect of the patient's critical illness.

Embolus

Pathophysiology

The emboli responsible for AMI usually originate from the heart and lodge in the SMA. The intracardiac thrombus is related to atrial fibrillation, an acute myocardial infarction, or a ventricular aneurysm. Patients frequently have prior embolic events from the same source, although they are not necessarily limited to the superior mesenteric artery (e.g., common femoral artery bifurcation presenting with acute lower extremity ischemia), and it is common to have synchronous emboli (e.g., splenic artery). Notably, the material that comprises these macroemboli is quite large in contradistinction to the micron-sized atheroemboli that commonly cause "blue toes" after invasive arteriographic procedures (i.e., artery-to-artery emboli). These macroemboli tend to lodge at areas of narrowing in the arterial circulation, typically branch points (e.g., common femoral bifurcation, popliteal artery bifurcation). The extent of bowel ischemia and/or infarction after an embolus to the SMA is contingent upon the extent of the collateral circulation, the pattern of the arterial occlusion, and the duration of the ischemia. In this setting, the bowel progresses from ischemia to infarction in a time-dependent fashion, although it may remain viable for 6–12 hours. Acute embolic occlusion of the SMA usually results in ischemia/infarction from the midjejunum to the transverse colon because the embolic material frequently lodges at the distal SMA just beyond the origin of the middle colic artery. The duodenum and descending colon are usually spared because they are supplied by branches of the CA and IMA, respectively.

Clinical Presentation and Diagnosis

The diagnosis of AMI from an embolus (or other causes of AMI) may be difficult. The differential list of diagnoses includes all the more common causes of acute abdominal pain. The diagnosis is confounded by the fact that patients are often critically ill, and thus their history/physical examination may not be reliable. Diagnosis requires a high index of suspicion and an aggressive approach because delays adversely affect outcome. This requires an appreciation of the types of patients and clinical scenarios in which AMI occurs, including patients with end-stage renal disease[66] and those sustaining a myocardial infarction or undergoing coronary artery bypass grafting.[67,68]

Patients with AMI from an embolus usually present with diffuse abdominal pain. The classic description of the pain secondary to AMI is "pain out of proportion" to the physical examination findings, although this scenario is not always present. Unfortunately, the pain is neither specific nor localized to a particular abdominal quadrant. Peritoneal signs can be present, but they usually occur late in the process and suggest bowel perforation. Patients often experience nausea, vomiting, and/or diarrhea, but again these are fairly nonspecific. Notably, AMI is a potent cathartic. Similar to the physical examination, the routine chemistry and hematologic laboratory studies are usually nonspecific and insensitive. Patients frequently have mild abnormalities of their laboratory values, including an elevated white blood count, a decreased platelet count, an elevated hematocrit, and a mildly elevated amylase level. The serum lactate level can be elevated, although the associated sensitivity and specificity in this setting are such that they are not recommended in the recent European guidelines.[16] The hemodynamic status of the patients at the time of presentation ranges from normovolemia to profound hypovolemic shock with acidosis and is contingent upon the status of the bowel and the duration of symptoms.

A variety of studies are available to help confirm the diagnosis of AMI secondary to an embolus. Plain abdominal radiographs have been used traditionally for patients with acute abdominal pain and can be helpful to demonstrate "free air" from a perforated viscus. However, patients with AMI frequently have either normal plain radiographs or demonstrate nonspecific findings (e.g., ileus). CT arteriography with 1- to 2-mm cuts has emerged as the diagnostic study of choice for patients with AMI secondary to an embolus.[16,20,69–71] The study is performed using only intravenous contrast because both oral and rectal contrast potentially interfere with the arteriogram itself. Furthermore, the CT arteriogram is likely justified in this setting in patients with compromised renal function, despite the contrast load, given the severity of the underlying AMI. Both stenoses and occlusions in the mesenteric vessels are well demonstrated on CT arteriography. In patients with AMI secondary to an embolus, a "meniscus sign" can often be seen in the mid/distal SMA. The images obtained using the CT arteriogram protocol are also excellent for the nonvascular structures. The significant nonvascular findings of AMI include bowel wall thickening, pneumatosis, bowel/solid organ infarction, and portal venous gas. Notably, Paran and colleagues[71] reported that the majority of patients with portal venous gas had mesenteric ischemia and that the associated mortality rate was 86%. Mesenteric duplex, although an excellent *screening* test for CMI, is not usually helpful in the majority of patients with AMI because abdominal distention/gas precludes the accurate interrogation of the mesenteric vessels.

Standard catheter-based contrast arteriography can be used as an alternative to CT arteriography, and, indeed, has been the traditional imaging study for the mesenteric vessels in the setting of AMI from an embolus or in situ thrombosis. Similar to patients with CMI, it can potentially serve as both a diagnostic test and therapeutic modality because an intervention can be performed at the same time. The major disadvantages are the obligatory time required to obtain the procedure and the small, but finite, complications associated with the contrast agent and arterial access. Given the availability of hybrid operating rooms, diagnostic catheter-based contrast arteriogram could be performed in an operating room with a fixed imaging unit followed by a definitive operative procedure in the same setting/location should the arteriogram confirm the diagnosis.

Laparoscopy offers an additional diagnostic modality for patients with AMI, as it can be used to assess bowel viability, thereby aiding the diagnosis and treatment plan.[72,73] Furthermore, it can be performed at the bedside in the intensive care unit with sedation at some institutions and therefore is feasible for unstable patients with a suspected intraabdominal process. However, laparoscopy likely has a limited role in the diagnosis of AMI but can be helpful if other diagnostic studies are inconclusive. Exploratory laparotomy remains the definitive diagnostic test for patients with AMI. However, the diagnostic studies outlined earlier are usually sufficient.

Treatment Strategies

Patients should be taken emergently to the operating room or imaging suite for definitive treatment once the diagnosis of AMI from an embolus is made. An extensive preprocedure evaluation is unnecessary and potentially harmful in light of the narrow window for salvaging the bowel. There is essentially no role for medical management alone in this setting. Patients should be systemically anticoagulated with heparin to prevent further clot development and started on broad-spectrum antibiotics against enteric organisms. Importantly, patients with AMI are frequently hypovolemic and should be volume resuscitated before the induction of anesthesia. This can be performed fairly expeditiously and should not delay transfer to the operating room or imaging suite.

Both midline and transverse abdominal incisions provide adequate exposure to the mesenteric vessels, and the choice is contingent upon surgeon preference. The diagnosis of AMI from an embolus is usually confirmed by the distribution of the ischemic/infarcted bowel that extends from the mid jejunum to the transverse colon. However, the diagnosis should be further substantiated by interrogating the mesenteric vessels with continuous wave Doppler. The embolus may be extracted from the SMA using a Fogarty thromboembolectomy catheter. Although there are several approaches to the SMA, the easiest approach is to mobilize the duodenum by incising the ligament of Treitz. The SMA courses through the small bowel mesentery at this location and can usually be palpated immediately adjacent to the vein. The arteriotomy in the SMA may be performed either longitudinally or horizontally. Although a longitudinal arteriotomy needs to be closed with a vein patch to prevent narrowing its lumen, it is the preferred approach if the artery has some underlying atherosclerotic disease because it affords greater flexibility in case a bypass is required. Furthermore, the patch repair results in a patulous lumen and obviates any concerns about narrowing the vessel with the transverse arteriotomy.

The management of the bowel for patients with AMI merits further comment. All of the bowel that is obviously dead should be resected, and intestinal anastomoses should be avoided in favor of proximal and distal stomas or simply a stapled closure. This mandates a second procedure to restore bowel continuity, but it allows the bowel (i.e., mucosa of the stoma) to be examined at the bedside during the postoperative period. Furthermore, it avoids using ischemic or borderline ischemic tissues for the anastomosis. Bowel that is ischemic, though not frankly necrotic, should be revascularized and then re-examined before any final decision about resection. A conservative approach is justified in this setting because many of the borderline areas will remain viable after revascularization. Admittedly, the differentiation between viable

and nonviable bowel is difficult. A variety of complicated modalities have been described to help differentiate viable from nonviable bowel in this setting, although they have not been universally adopted. Simple adjuncts include visual inspection for peristalsis, use of continuous wave Doppler to detect arterial signals within the mesentery, and intravenous fluorescein in combination with a Wood's lamp. Notably, approximately 100–150 cm of small bowel is necessary for nutritional absorption.

A decision to perform a second-look operation to reassess the viability of the bowel should be made at the time of the initial procedure. This is routinely performed 24–48 hours after the first procedure, a time sufficient for the marginal bowel to declare itself. A retrospective review has questioned the role of the second-look operation and reported that survival was actually greater in those patients in which it was not performed.[74] Admittedly, there was a tremendous selection bias in this review, and the authors conceded that the experience of the surgeon is likely the key factor regarding the decision to perform a second look. A "damage control" operation may be justified in a small subset of unstable patients with AMI, as suggested by Freeman and Graham.[75] This includes emergent laparotomy, resection of obviously dead bowel, creation of proximal/distal stomas (or simply just stapling off the ends of the bowel), leaving the abdomen open with a negative-pressure vacuum-assisted dressing, and deferring the definitive vascular/gastrointestinal procedure until later.

Endovascular treatment with aspiration embolectomy and SMA thrombolysis (particularly in the setting of in situ thrombosis) have emerged as an alternative to open surgical thrombectomy for patients with AMI.[16,76–80] Notably, the endovascular approach has been recommended as the first-line therapy in the European guidelines for patients with AMI from in situ thrombosis.[16] However, the technical success rate for the endovascular thromboembolectomy and the requisite time for chemical lysis must be balanced against the acuity of the procedure and the potential to progress from ischemic bowel to infarcted bowel. Furthermore, a purely percutaneous approach (vs. a hybrid open and endovascular approach) does not allow direct assessment of the bowel, and the chemical lysis may cause intestinal bleeding from mucosal sloughing. It is conceivable that the endovascular approach may have a role for patients with a subacute presentation.

The postoperative course after embolectomy for AMI is similar to that after revascularization for CMI, although the incidence of postoperative complications and MODS is greater. As noted earlier, revascularization may cause an ischemia-reperfusion injury that affects both local and distant organ systems. Accordingly, patients are at risk for developing an abdominal compartment syndrome. Bladder pressures can be measured, and the abdomen closure can be dissembled if necessary. Patients should be continued on broad-spectrum antibiotics throughout the early postoperative period. Furthermore, they need to be anticoagulated long term because of the potential for recurrent emboli.

Outcome

The mortality rate for patients with AMI is approximately 70%, and this rate has changed very little over the past several decades.[65,81–83] Unfortunately, the majority of the case series tend to encompass all of the etiologies rather than a specific one (e.g., embolus). A systematic review by Schoots and colleagues[81] reported that the mortality rates of AMI from mesenteric venous thrombosis were better than those for arterial problems and that the mortality rates for mesenteric emboli were better than those for in situ thromboses. The aggregate mortality rates in their study by etiology are listed: mesenteric venous thrombosis, 32%; embolus, 54%; NOMI, 74%; in situ thrombosis, 77%. A variety of predictable factors have been associated with mortality in the various case series, including patient age, time to definitive surgery, shock, acidosis, leukocytosis, cardiac status, and coagulopathy.[82,84,85] The majority of deaths in a recent report were related to MODS.[57]

In Situ Thrombosis

Patients with mesenteric artery occlusive disease may also present with AMI secondary to in situ thrombosis. The presentation is superimposed upon the symptoms of CMI in more than 50% of the patients[86] and can usually be differentiated from the other causes of AMI by the history and clinical setting. However, it is important to emphasize that patients may present with AMI as the initial symptom of their mesenteric occlusive disease. The clinical presentation, diagnostic approach, and immediate postoperative care of patients with AMI secondary to in situ thrombosis is similar to that outlined earlier for emboli, although the operative approach is somewhat different.

Patients with AMI secondary to in situ thrombosis require a mesenteric revascularization, either open or endovascular. Although the choice of open revascularization options is somewhat equivocal in the setting of CMI (i.e., antegrade vs. retrograde bypass), retrograde bypass from the infrarenal aorta or common iliac artery is likely the optimal procedure for AMI given the urgency of revascularization (see Fig. 149.5). Interestingly, Scali and colleagues[87] compared the antegrade and retrograde bypass for AMI and reported no differences in perioperative outcome, although the antegrade bypass was associated with a lower reintervention rate long term. The objectives and treatment are somewhat different in the acute setting (i.e., AMI vs. CMI). The main objective is to restore blood flow to the ischemic vascular bed as safely and expeditiously as possible. This usually requires only bypass to the SMA. Patients with isolated CA stenosis rarely develop AMI because the collateral blood flow to the foregut is so good and the liver may be sustained on portal blood flow alone. Prosthetic conduits are relatively contraindicated in the setting of bowel infarction and/or perforation because of the potential for postoperative graft infection, but may be indicted in a "damage control" scenario. Autogenous conduits with either the saphenous or superficial femoral vein are suitable, although the latter may be more durable, but the time to harvest these conduits must be considered.

The role of endovascular treatment for patients with AMI secondary to in situ thrombosis is evolving. The concerns about the urgency of revascularization and the effectiveness of the endovascular procedure outlined previously are relevant, regardless of the etiology (i.e., embolus or in situ thrombosis). Retrograde open mesenteric stenting (ROMS) is a hybrid alternative (i.e., open and endovascular approach) that affords the advantages of both approaches.[88,89] Specifically, it allows assessment of the bowel and is potentially less morbid than the more traditional open revascularization.

Occasionally patients will undergo bowel resection for infarction by a nonvascular surgeon and the diagnosis of mesenteric ischemia will be missed, both preoperatively and intraoperatively. It is important to emphasize that infarction of the bowel is not a spontaneous event, but rather an end-stage complication of another disease process; it is imperative that the etiology of all bowel infarctions be established in an attempt to prevent recurrences. An appropriate imaging study (i.e., CT arteriogram, catheter-based contrast arteriogram) should be obtained in the early postoperative period and the necessary treatment implemented, including anticoagulation and revascularization, in a timely fashion.

Nonocclusive Mesenteric Ischemia

Pathophysiology

NOMI represents an abnormal or paradoxical mesenteric vasoconstriction characterized by the loss of autoregulation. Shock, or "circulatory stress," normally causes mesenteric vasoconstriction in an attempt

to maintain cerebral and/or cardiac perfusion. The mesenteric vasoconstriction ordinarily resolves when the underlying circulatory disorder is corrected; persistent vasoconstriction results in NOMI. There are multiple potential etiologies for NOMI, including cardiogenic shock, sepsis, burn injury, trauma, pancreatitis, digitals, vasopressors, and renal failure.[90–95] Indeed, almost any underlying condition that can precipitate shock or "circulatory stress" may precipitate NOMI.

Clinical Presentation and Diagnosis

Similar to the other causes of AMI, the diagnosis of NOMI requires a high index of suspicion and the proper clinical setting. Patients may develop abdominal pain, although the physical examination is frequently unreliable because of the other active medical issues and altered sensorium. Laboratory abnormalities are common, including acidosis, leukocytosis, elevated lactate levels, and hyperamylasemia, but these are all relatively nonspecific markers of the underlying shock state. Catheter-based contrast arteriography remains the diagnostic study of choice and is also potentially therapeutic.[16] The significant findings on the catheter-based arteriogram for patients with NOMI include segmental stenosis/narrowing of the SMA in a "string of beads" appearance. Furthermore, there is narrowing of the branches of the SMA at their origins, spasm of the mesenteric arcades, and impaired filling of the intramural branches. The catheter-based arteriogram can also be helpful to rule out the other potential causes of AMI. CT arteriography may have a role in the setting of NOMI[96–98]; however, it is somewhat limited by the inability to assess the flow dynamics through the mesenteric vessels. Similar to other settings, the CT arteriography may be helpful to exclude other intraabdominal concerns and other potential causes of AMI.

Treatment Strategies

The initial treatment of patients with NOMI is nonoperative and directed at correcting the underlying condition that precipitated the "circulatory stress." Specifically, patients should be resuscitated in an attempt to improve their cardiac output and systemic perfusion. All vasoactive drugs should be stopped (if possible), and patients should be started on broad-spectrum antibiotics directed against enteric organisms. Furthermore, patients should be systemically anticoagulated unless contraindicated. Despite these efforts, the characteristic mesenteric vasoconstriction may persist. Continuous intraarterial papaverine, administered through an infusion catheter placed into the SMA, may reverse the vasoconstriction.[99,100] A 45-mg test dose of papaverine (i.e., short-acting calcium channel blocker) should be given over 15 minutes and a continuous infusion of 30–60 mg/h should be started if no adverse reactions are encountered. Serial mesenteric arteriograms should be performed to monitor the response to papaverine, with the first performed 1 hour after initiating therapy. The intraarterial infusion may be continued up to 24 hours. It should be noted that the infusion will reverse the mesenteric vasoconstriction only if the underlying hemodynamic instability is corrected. Operative treatment of NOMI should be reserved only for the clinical scenario when bowel infarction is suspected.

Mesenteric Venous Thrombosis

Pathophysiology

Mesenteric venous thrombosis may also result in AMI and is considered in this section for completeness. However, the associated degree of bowel ischemia is usually less than with arterial occlusion from either an embolus or in situ thrombosis. The pathophysiology is similar to venous thrombosis in other vascular beds and may be explained in terms of the Virchow classic triad of stasis, intimal injury, and hypercoagulable states. Mesenteric venous thrombosis results in edema in the bowel wall and the mesentery with significant third-space fluid losses. This may result in bloody ascites and, indeed, a bloody tap at the time of paracentesis may be diagnostic. Progression to bowel infarction is contingent upon the magnitude of the thrombotic burden and its distribution. Clot localized to the portal or superior mesenteric vein does not usually lead to bowel infarction because of the collateral channels, whereas thrombus within the peripheral mesenteric veins is more likely to do so. The natural history of untreated mesenteric venous thrombosis is poor and almost universally progresses from bowel infarction to perforation and death.

Mesenteric venous thrombosis may result from abnormalities in any of the components of the Virchow triad (i.e., stasis, intimal injury, hypercoagulable state). Stasis may result from congestive heart failure or portal hypertension, whereas intimal injury may result from general anesthesia or any number of intraabdominal infectious processes. A hypercoagulable state is perhaps the strongest of the contributory factors and has been identified in up to 90% of patients with mesenteric venous thrombosis.[101–103] Notably, the mesenteric venous thrombosis can be the first presentation of the hypercoagulable condition.

Clinical Presentation and Diagnosis

Patients with mesenteric venous thrombosis usually present with vague, mild abdominal pain. The pain is usually insidious in onset and frequently present for some time before patients seek medical attention. Furthermore, the pain is not usually localized to any specific quadrant. Physical examination is notable only for mild, diffuse abdominal pain. Peritoneal signs suggest bowel infarction, but are only found later in the disease process. An abdominal CT scan is the diagnostic study of choice.[20,104,105] The significant findings include bowel edema and thrombus within the mesenteric veins with inflammation of the vessel wall (Fig. 149.6). Plain abdominal radiographs may suggest abdominal wall edema and are helpful to rule out other causes of the abdominal pain. Standard catheter-based contrast arteriography may be helpful, but is inferior to CT. The arteriographic findings that suggest mesenteric venous thrombosis include arterial spasm with a prolonged arterial phase, opacification of the bowel wall, extravasations of the contrast into the bowel lumen, and visualization of the venous thrombus.

Treatment Strategies

The primary treatment of patients with mesenteric venous thrombosis is anticoagulation to arrest the thrombotic process and potentially

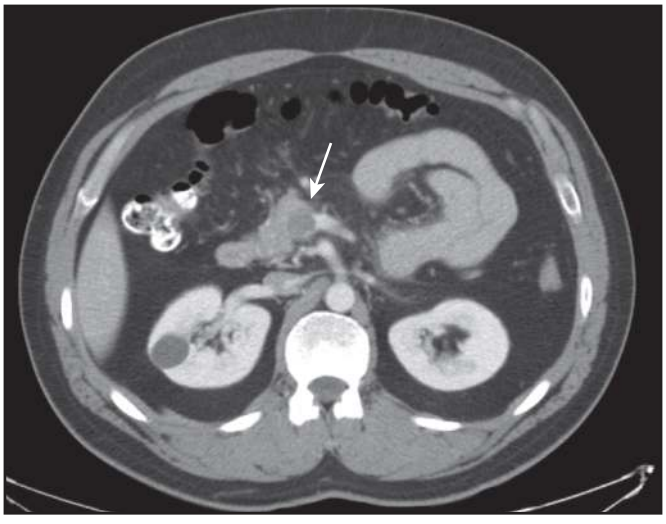

Fig. 149.6 CT scan of a patient with mesenteric venous thrombosis. Note the thrombus in the superior mesenteric vein at its confluence with the splenic vein, as shown with the *arrow*.

facilitate recanalization. Patients should be aggressively anticoagulated with heparin when the diagnosis is made and should be maintained on long-term oral anticoagulation. Similar to patients with massive iliofemoral deep venous thrombosis, it may be difficult to achieve effective anticoagulation initially using the standard dosing schedules for heparin (i.e., 80–100 units/kg bolus, 18 units/kg/h drip), presumably secondary to the clot burden. Larger doses of heparin may be required, and the adequacy of heparinization (e.g., partial thromboplastin time) may need to be monitored more frequently. Although the required dosage of heparin may be unsettling, the potential clot propagation and its associated complications likely exceed any increased risk from bleeding. A hypercoagulable work-up for the standard hematologic abnormalities should ideally be performed before initiation of anticoagulation; however, this laboratory work-up should not delay treatment. Long-term anticoagulation should be continued even in the absence of an identifiable hypercoagulable state because it is likely that many of these patients have some type of hypercoagulable disorder even though it may not be characterized on initial screening. Additionally, patients frequently require fluid resuscitation at the time of diagnosis because of the significant third-space losses from the bowel edema. Nasogastric decompression, broad-spectrum prophylactic antibiotics, and repletion of electrolytes are all useful adjuncts.

Exploratory laparotomy should be reserved for cases in which bowel infarction is suspected. The intraoperative findings include edematous/rubbery bowel, bloody ascites, and thrombus within the mesentery. A wide resection of the bowel should be performed in the presence of infarction. Primary enteric anastomosis is probably safe if the margins of resection are free of thrombus within the mesentery. Proximal and distal stomas (or temporary stapled closures) are advisable if the viability of the bowel at the margins of resection is questionable or if the bowel wall is edematous. Patients are at risk for additional or ongoing thrombosis, with the most common site being the margins of the resection and/or the anastomosis. Mechanical thrombectomy is not advocated at the time of laparotomy because of the extensive clot burden.

The role of endovascular treatment for patients with mesenteric venous thrombosis is evolving, similar to the other causes of AMI. Transhepatic thrombolysis is an option for patients with progressive symptoms despite anticoagulation and those that are not surgical candidates.[105–108] Similar to the concerns with mechanical thrombectomy, the clot burden is very significant and usually extends from the small peripheral collaterals in the mesentery to the portal and mesenteric veins. Furthermore, the transhepatic approach is relatively complicated and associated with a significant bleeding risk in the setting of therapeutic anticoagulation.

Outcome

As noted earlier, the mortality rate (approximately 30%) for mesenteric venous thrombosis is significantly less than for the arterial causes of AMI.[81] Death has been associated with portal vein thrombosis, systemic venous thromboembolism, and obesity. The increased mortality rate associated with venous thromboembolism underscores the importance of early, adequate anticoagulation.

Aortic Dissection

Patients with acute aortic dissection can present with mesenteric malperfusion and AMI. The management of acute aortic dissection is beyond the scope of this chapter, but the topic is included to emphasize the importance of evaluating the status of the mesenteric vessels in all patients presenting with acute dissections. The presence of mesenteric malperfusion significantly increases the mortality rate.[109,110] A variety of endovascular approaches have been used to treat mesenteric malperfusion in this setting.[111,112] Endovascular revascularization is superior to the open approach, given the friability of an acutely dissected vessel wall, provided the patients are candidates from an anatomic and technical standpoint.

Protocols and Algorithms (Fig. 149.7)

Although patients frequently present with abdominal pain, their sensorium may be altered. The diagnosis should be considered in the critical care setting when patients decompensate acutely. The differential diagnosis should be framed within the appropriate clinical setting. A CT arteriogram is the diagnostic test of choice, although a catheter-based contrast arteriogram can be used. The CT findings are fairly characteristic for each of the diagnoses. Emergent revascularization is required in the setting of an embolus and in situ thrombosis; the bowel should be resected as necessary for ischemia/infarction. Preoperative evaluation should include broad-spectrum antibiotics, anticoagulation, and resuscitation. Medical management alone is usually adequate for patients with NOMI and mesenteric venous thrombosis. Intraarterial vasodilation may be required for persistent vasoconstriction in patients with NOMI. Lifetime anticoagulation is required for mesenteric venous thrombosis. Emergent endovascular revascularization is required for patients with acute aortic dissections and mesenteric malperfusion. Exploratory laparotomy and bowel resection should be reserved in patients with NOMI, mesenteric venous thrombosis, and aortic dissections for presumed bowel infarction.

Colon Ischemia

Isolated colon ischemia can occur after both open and endovascular aneurysm repair. Furthermore, it can develop as a complication of hemodynamic shock, similar to NOMI. Ischemic colitis has been reported to occur in approximately 2%–13% of open aneurysm repairs.[113] The reported incidence depends on the diagnostic algorithm and modality (routine sigmoidoscopy vs. selective sigmoidoscopy) and is dramatically increased after ruptured aneurysm repair. Indeed, the incidence of colonic ischemia after ruptured aneurysm repair in patients undergoing routine colonoscopy is approximately 25%–40%.[113,114] The sigmoid colon is affected most frequently, although all the sections of the colon may be involved. The ischemia may result from inadequate resuscitation, disruption of collaterals, and/or failure to revascularize a hemodynamically significant stenosis in the IMA. Interestingly, routine reimplantation of the IMA at the time of aortic reconstruction does not appear to prevent colon ischemia.[115] The ischemic colitis associated with endovascular aneurysm repair is more commonly related to atheroembolism than acute internal iliac artery occlusion, as might be suspected. The prognosis for ischemic colitis after endovascular aneurysm repair is worse than that for open repair.[116]

Patients with ischemic colitis usually present with bloody diarrhea in contrast to patients with AMI, who usually present with abdominal pain. In the most common scenario, patients develop bloody diarrhea on the first or second postoperative day after aortic reconstruction. However, the diagnosis should be considered after aortic reconstruction in the absence of bloody diarrhea in patients with thrombocytopenia, MODS, increasing abdominal pain/peritonitis, and generalized "failure to thrive." The diagnosis may be confirmed by endoscopy. Although sigmoidoscopy is used most frequently, a complete colonoscopy is likely optimal because of the potential involvement of the other colon segments.

Treatment depends on the endoscopic findings and clinical setting. The endoscopic findings range from mucosal ischemia to transmural necrosis. Unfortunately, it is often difficult to differentiate diffuse mucosal ischemia from transmural necrosis. Patients with mucosal ischemia alone should be treated with bowel rest, broad-spectrum antibiotics, fluid resuscitation, total parenteral nutrition, and serial endoscopic examinations. Many of these lesions resolve spontaneously

without long-term sequelae, although colonic strictures may develop in a small subset of patients. Patients with transmural colonic necrosis should undergo laparotomy with resection of the involved segment, a proximal diverting colostomy, and a distal Hartmann pouch.

The reported mortality rate in patients with transmural colon necrosis after aortic reconstruction is approximately 85%.[113] Maintaining antegrade flow through the internal iliac vessels, routinely implanting the IMA, and preserving the colonic collateral circulation may reduce or prevent this adverse outcome. Evaluation of the patency of the mesenteric vessels should be part of the routine preoperative evaluation for aortic repair, and consideration should be given to staged or simultaneous revascularization for significant mesenteric stenoses.

KEY POINTS

Chronic Mesenteric Ischemia

- The underlying pathophysiology of CMI is the inability to achieve postprandial hyperemic intestinal blood flow.
- The symptoms of CMI usually do not occur unless two of the three mesenteric vessels are significantly diseased because of the rich collateral network.
- Patients presenting with abdominal pain and weight loss should initially undergo an expedited evaluation to rule out a gastrointestinal malignancy.
- The diagnosis of CMI is contingent upon the presence of the appropriate symptoms and the presence of significant mesenteric artery occlusive disease within the SMA and CA.
- CT arteriography has largely replaced catheter-based contrast arteriography as the diagnostic study of choice for patients with CMI.
- All patients with CMI require revascularization unless they are so debilitated that intervention is not warranted and/or they have opted for palliative care.
- Endovascular treatment with a covered intraluminal stent has emerged as the initial revascularization option, with open surgical revascularization reserved for patients with lesions nonamenable to endovascular treatment, endovascular failures, and select, younger patients.
- The immediate postoperative care for patients undergoing revascularization for CMI is frequently complicated by the development of MODS.
- The optimal management strategy for patients in the early postoperative period after mesenteric revascularization is to support the individual organ systems until the dysfunction resolves.

KEY POINTS—cont'd

- All patients who undergo revascularization for CMI require longer-term follow-up with duplex surveillance.

Acute Mesenteric Ischemia

- The impaired intestinal perfusion associated with AMI leads to mucosal compromise that can lead to the activation of the systemic inflammatory response and bowel infarction with perforation.
