Mechanical Bowel Obstruction

Albert Hsu, Jens Flock IV, and Andrew J. Kerwin

Mechanical bowel obstruction occurs when there is an occlusion of the lumen of the intestine that causes a blockage of the normal flow of intraluminal contents through the gastrointestinal tract. As a common surgical emergency, 3.2 million cases of bowel obstruction occurred throughout the world in 2015 resulting in 264,000 deaths.[1,2] The small bowel is more much frequently affected compared with the large bowel and is involved in 80% of cases.[3] In the United States, small bowel obstruction (SBO) accounts for 15% of hospital admissions for patients presenting with abdominal pain and more than 300,000 annual hospitalizations.[4] Approximately 20%–30% of these patients will require operative management and contend with significant healthcare costs.[5,6]

ETIOLOGY

In developed countries, intraperitoneal adhesions that develop from prior abdominal surgery are the most common cause of mechanical SBO and account for 55%–80% of cases.[7] Patients who have previously undergone pelvic surgery, specifically colorectal resection, appendectomy, and gynecologic surgery; required prior adhesiolysis for bowel obstruction; or had resection for a malignancy are at increased risk for developing adhesive SBO.[5,8] Malignant neoplasms are responsible for 20% of cases and are most commonly intraperitoneal metastases from primary gastric, pancreatic, colonic, or ovarian malignancies. Hernias account for approximately 10% of cases and result from innate weak points in the abdominal wall or arise from previous surgical incisions.[9]

PATHOPHYSIOLOGY

An obstruction is classified as complete when the intestinal lumen is completely occluded and no amount of gas or fluid is able to pass through the site of obstruction. Intestinal obstruction can lead to severe life-threatening complications if bowel ischemia were to occur.[10] The progression to ischemia begins with bowel dilatation proximal to the site of obstruction, as intraluminal contents are unable to pass. As the bowel dilatation worsens, its absorptive function is lost and fluid and electrolytes accumulate in the intestinal lumen. These events result in an increase in the intraluminal pressure of the bowel that can cause a decrease in blood flow to the intestinal wall leading to ischemia. If malperfusion is severe enough, necrosis of the bowel wall and perforation can occur. The risk for bowel ischemia is greater in the setting of a complete bowel obstruction.

A closed loop bowel obstruction occurs when a segment of intestine is occluded at two different points along its course so that gas and fluid are trapped within this loop of bowel (Fig. 91.1). Because intraluminal pressures are much higher in a closed loop obstruction, there is increased risk for the development of bowel ischemia. This is most commonly caused by an abdominal wall hernia, internal hernia, or volvulus. Strangulation is another serious complication of bowel obstruction that can also lead to bowel ischemia and is more commonly seen with a closed loop obstruction. This occurs when the blood supply from the mesentery to the intestine is occluded, with rapid progression to bowel necrosis and perforation if left untreated.

CLINICAL PRESENTATION

Patients classically present with symptoms of crampy abdominal pain, nausea and vomiting, and constipation.[11] The addition of abdominal distension and obstipation should raise suspicion for the presence of a bowel obstruction. The severity of abdominal pain may be dependent on the degree of the obstruction. A partial obstruction may have an insidious onset over the course of hours or days accompanied by intermittent, crampy pain. A complete bowel obstruction tends to be acute with unrelenting abdominal pain. Fever; tachycardia; tachypnea; severe abdominal pain with involuntary guarding, rigidity, and rebound tenderness on examination; and the presence of leukocytosis or metabolic acidosis may be indicative of bowel ischemia. However, it should be noted that using clinical symptoms and signs has not been found to be accurate in predicting the presence of ischemic gangrenous bowel.[12]

EVALUATION

The evaluation for a mechanical bowel obstruction includes patient history, physical examination, and imaging. Patient history should focus on the severity, character, and duration of the patient's abdominal pain; time since last flatus and bowel movement; and changes in stool color or caliber. On the physical examination, it is important to detect signs of peritonitis; identify prior surgical incisions; and evaluate for ventral, incisional, inguinal, or femoral hernias. A digital rectal examination should be performed to evaluate for a rectal mass and blood per rectum.

It is extremely difficult to discern clinically whether a patient has a complete or partial obstruction. Therefore radiographic imaging is usually required for further evaluation. Radiographic imaging begins with abdominal upright and supine plain x-rays. This may show dilated loops of small bowel containing air–fluid levels. The colon may appear decompressed with an absence of air depending on the location of the obstruction. The presence of free air under the diaphragm indicates a hollow viscous perforation and mandates the need for immediate surgical consultation without the need for additional imaging.

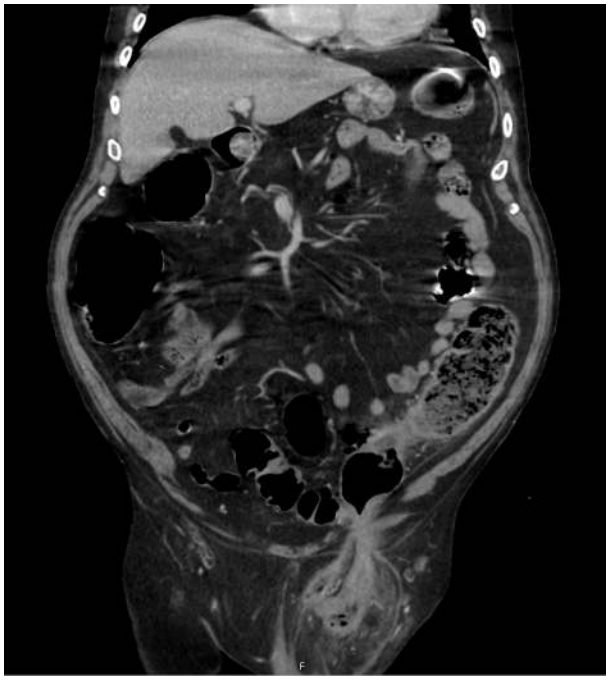

Fig. 91.1 A CT scan showing a closed loop obstruction involving the sigmoid colon caused by an incarcerated inguinal hernia.

Computed tomography (CT) of the abdomen and pelvis should be performed on all patients being evaluated for a bowel obstruction, as it is useful for characterizing the severity of the obstruction, determining the etiology, and revealing the presence of compromised bowel. The sensitivity and specificity of diagnosing a bowel obstruction with CT imaging is 94% and 97%, respectively.[13] CT scan is also fairly accurate in diagnosing a complete obstruction.[14] A common finding of an obstruction is a transition point with dilated bowel proximally and decompressed bowel distally. In postoperative patients, however, bowel dilatation is a common finding, and it may be difficult to differentiate between an ileus and an obstruction. Other findings on CT may include a target sign or mesenteric swirling suggestive of a volvulus or an internal hernia. Unlike plain x-rays, CT imaging with intravenous contrast can show signs that may indicate bowel ischemia. These findings include bowel wall thickening and edema, poor enhancement of the bowel wall, pneumatosis intestinalis, portal or mesenteric venous gas, and ascites.

MANAGEMENT

Patients commonly present with signs of dehydration and mild electrolyte abnormalities. A metabolic panel may show the depletion of sodium, chloride, or potassium, and a complete blood count may show leukocytosis and hemoconcentration. Isotonic fluid such as lactated Ringer's solution or 0.9% normal saline should be administered for resuscitation, and electrolyte abnormalities should be corrected if necessary. If operative intervention is indicated, patients should be resuscitated before surgery. A Foley catheter should be inserted so that urine output can be measured and used as a marker of end-organ perfusion to guide fluid resuscitation.

A subset of patients may present with more severe physiologic derangements in the form of hypovolemic shock, metabolic acidosis, or acute kidney injury. The development of sepsis and septic shock in a patient with presumed bowel obstruction is indicative of bowel ischemia and should prompt surgical intervention. Respiratory compromise can occur with severe bowel distension elevating the diaphragm and abdominal pain and discomfort limiting inspiratory effort. Depending on the severity of the acute physiologic derangements, patients may require admission to an intensive care unit (ICU) for hemodynamic monitoring and aggressive fluid resuscitation before operative intervention. Potassium repletion should be done judiciously with close monitoring in the setting of acute kidney injury. In addition, the pH of 0.9% normal saline is around 5.5, and caution should be taken with its use in resuscitation, as infusing large amounts can cause or worsen metabolic acidosis.[15]

Patients should be made nil per os. A nasogastric tube should be placed for gastric decompression to improve patient comfort and reduce the risk of vomiting and aspiration. The nasogastric tube can also evacuate swallowed air, limiting further bowel distension. Antibiotics are not routinely administered for uncomplicated mechanical bowel obstruction. They should be administered in the perioperative setting if operative intervention is warranted and concern for sepsis caused by bowel ischemia, necrosis, or perforation exists. Severe sepsis and septic shock can also occur after surgery for strangulated gangrenous bowel, as relieving the strangulation can cause the release of endotoxin and other inflammatory mediators into the bloodstream.[16] These patients should be admitted to the ICU and receive treatment based on the Surviving Sepsis Guidelines.[17]

The decision for operative versus nonoperative management of a patient with a mechanical SBO is a challenging one largely based upon clinical judgment. The morbidity and mortality risks associated with an operation are weighed against the likelihood of worsened outcomes caused by a delay in appropriate management. Patients with peritonitis on physical examination, systemic toxicity, an acutely incarcerated or strangulated hernia, and findings of pneumatosis or perforation on imaging studies should undergo emergent surgery. There is a low threshold for operative intervention when CT scan findings are suggestive of possible bowel ischemia and closed loop obstruction.

Patients without clinical or radiologic signs of bowel compromise are managed nonoperatively with close clinical monitoring that comprises serial abdominal examinations. Nonoperative management is overall successful in 65%–80% of patients. Any clinical deterioration should prompt urgent operative intervention. Traditional surgical dogma has endorsed immediate surgery for patients with a complete SBO. Recent practice guidelines have recommended that patients without signs of bowel ischemia can safely undergo initial nonoperative management while cautioning that complete obstruction has a higher risk of failure.[18] The four concerning signs of bowel ischemia are fever, leukocytosis, tachycardia, and localized abdominal tenderness. Patients with SBO often present with mild tachycardia and leukocytosis, but these should resolve with hydration and pain relief. If one or more of these signs progress, concern for bowel ischemia should prompt the need for operative intervention. A hypertonic water-soluble contrast agent should be administered to patients being observed, as it can be therapeutic by accelerating the resolution of adhesive bowel obstruction.[19,20] Additionally, the lack of contrast in the colon by 24 hours after administration is predictive of failure of nonoperative management and should prompt early operative intervention.[21] Nonoperative management should not extend beyond 3–5 days, as the obstruction is unlikely to resolve at this point. An exception is early postoperative SBO (without obvious sign of ischemia), which can generally be managed conservatively for up to 2 weeks.[22] The risk of surgery during this postoperative time is significant because of the nature of abdominal adhesions that increases the risk for iatrogenic injury.

KEY POINTS

- Patients may present with severe physiologic derangements in the form of metabolic acidosis, acute kidney injury, and hypovolemic shock.
- Patients with peritonitis on physical examination, systemic toxicity, an acutely incarcerated or strangulated hernia, and findings of pneumatosis or perforation on imaging studies should undergo emergent surgery.
- A CT scan should be obtained in all patients suspected of having a bowel obstruction.
- Patients without clinical or radiologic signs of bowel compromise may safely undergo nonoperative management of mechanical SBO.
- Nonoperative management consists of fluid resuscitation, correction of electrolyte disturbances, close monitoring of resuscitative efforts. and nasogastric tube decompression.
- Administration of hypertonic water-soluble oral contrast is both diagnostic and therapeutic for the management of adhesive SBO.
- Delay in appropriate management in the setting of bowel compromise is associated with increased morbidity and mortality.

Toxic Megacolon and Ogilvie's Syndrome

Chasen Ashley Croft and Maria Estela Alfaro-Maguyon

Acute megacolon refers to a syndrome defined by abnormal colonic distention in the absence of mechanical obstruction. Megacolon may be a manifestation of Ogilvie's syndrome or toxic megacolon. The sequelae of these disorders results in diffuse colonic dysmotility. Ogilvie's syndrome is an eponym for acute colonic pseudo-obstruction (ACPO).[1,2] Critical illness–related colonic ileus (CIRCI) is characterized by constipation for several days without marked colonic distention and may herald development of Ogilvie's syndrome.[3] Ogilvie's syndrome is believed to be a functional disturbance of colonic motility often observed in hospitalized patients as a result of hemodynamic, metabolic, pharmacologic, inflammatory, or postoperative conditions.[4] In toxic megacolon, the distention is caused by severe colitis and is associated with systemic manifestations or toxicity. Although usually attributed to inflammatory bowel disease (IBD), most notably ulcerative colitis (UC), toxic megacolon may manifest in the critically ill as a complication of severe infectious colitis, most frequently caused by *Clostridium difficile*. Both Ogilvie's syndrome and toxic megacolon are medical emergencies that, if left untreated, result in intestinal barrier failure, colonic ischemia, perforation, and multiple organ failure (MOF). This chapter focuses on toxic megacolon and Ogilvie's syndrome in critically ill patients admitted to the intensive care unit (ICU) and provides management and prevention strategies for each disease process.

CLINICAL FEATURES

Ogilvie's or Acute Colonic Pseudo-Obstruction

The clinical features of Ogilvie's syndrome include abdominal distention, with or without abdominal pain, in hospitalized or institutionalized patients with serious underlying medical and surgical conditions.[2,5,6] Patients usually present with constipation; however, passage of flatus or stool is reported in up to 40% of patients.[2] Bowel sounds may be normal, diminished, or hyperdynamic. Leukocytosis and fever are more common in patients with ischemia or perforation, but also occur in those who have not developed these complications. According to Laplace's law, the pressure required to stretch the walls of a hollow viscus decreases in inverse proportion to diameter.[7] Therefore progressive colonic distention causes the highest tension in the wall of the cecum and is most likely to be the site of perforation. The risk of cecal perforation increases sharply when cecal diameter is greater than 12 cm and when this distention has been present for longer than 6 days.[8] A diameter of 9–12 cm has been suggested as a sign of impending perforation.[2,4] Institutionalized patients with chronic constipation or chronic dysmotility can have a chronically distended cecum with diameter over 12 cm without clinical manifestation. The 12-cm diameter warning must therefore be individualized. If the diagnosis and treatment are delayed, progressive distention may cause peritoneal signs, abdominal compartment syndrome, respiratory compromise, sepsis, ischemia, perforation, MOF, and death.

Toxic Megacolon

Toxic megacolon is the late, life-threatening complication of inflammatory or infectious colitis. Patients present with fever, leukocytosis, abdominal distention, and tenderness, with or without signs of local or generalized peritonitis. Both IBD and infectious colitis classically present with diarrhea, but constipation may herald the onset of megacolon, delaying diagnosis. In addition to these findings, patients may present with dehydration, altered consciousness, electrolyte disturbances, hypoalbuminemia, and hypotension. In severe cases, septic shock and MOF may ensue.[9,10] Factors that may trigger or predispose to the development of toxic megacolon have been identified; these include severe hypokalemia; discontinuation or rapid tapering of corticosteroids, sulfasalazine, or mesalazine; use of antidiarrheal agents; and use of antidepressants.[11] Barium enema and colonoscopy may cause worsening distention that further impairs colonic blood supply, leading to worsening ischemia and perforation. Colonoscopy and barium enema are contraindicated in patients with clinical or radiographic features of toxic megacolon because of the risk of perforation.

PATHOGENESIS OF ACUTE MEGACOLON

Colonic Ileus and Ogilvie's Syndrome

The pathophysiology of Ogilvie's syndrome is not fully understood. Current literature suggests an imbalance in autonomic regulation of the colonic motor function, leading to excessive parasympathetic suppression and sympathetic stimulation. This results in an aperistaltic colon.[12,13] In addition to autonomic dysregulation, neurotransmitters (e.g., substance P and vasoactive intestinal polypeptide [VIP]), inflammatory mediators (e.g., tumor necrosis factor [TNF], interleukin-1 [IL-1]), metabolic derangements, and pharmacologic interventions also play a crucial role in the development of Ogilvie's syndrome.[14] Electrolyte disturbances are common and often multifactorial. For example, the inflamed colon loses its capacity to reabsorb salt and water, and the rate of potassium excretion into the lumen may be markedly increased because of inflammatory diarrhea. Metabolic alkalosis secondary to volume depletion and potassium loss is associated with poor prognosis. Metabolic acidosis suggests the presence of ischemic colitis.

Postoperative motility disturbances are inevitable after abdominal surgery and result from a complex interaction of neurogenic and inflammatory mechanisms. The extent of parasympathetic suppression and sympathetic activation depends on the amount of surgical stimulation, as demonstrated by Bueno and colleagues in experimental studies in dogs.[15] Surgical manipulation triggers two different, distinct phases of postoperative ileus. The first or early phase is neurally mediated and is activated during and immediately after surgery. During this phase, intestinal manipulation initiates release of norepinephrine via the sympathetic nerves from the spinal cord, in addition to nitric oxide

(NO) and VIP release via vagal nerve stimulation, abolishing the motility of the entire gastrointestinal tract.[16,17] This phase ceases once the abdomen is closed. The second, long-lasting phase of postoperative ileus involves the inflammation of the intestinal muscularis. During this phase, activation of peritoneal mast cells triggers release of vasoactive and proinflammatory substances, such as histamine and proteases, which recruit leukocytes and temporarily increase mucosal permeability. This allows luminal bacteria or bacterial products to enter the lymphatics. This likely represents the key event that triggers the next stage of the inflammatory cascade: activation of resident macrophages. Once activated, resident macrophages release cytokines such as TNF and subsequent upregulation of inducible nitric oxide synthetase (iNOS) and cyclooxygenase-2 (COX-2), further blunting the contractile response of the inflamed tissues.[18] In addition, in vivo animal studies have demonstrated that endogenous opioids released peripherally can modulate gastrointestinal (GI) motor and secretory functions.[19] Opioid receptors are stimulated by endogenous opioids, which are secreted locally upon stress. Once activated, they inhibit acetylcholine release from motor neurons and promote transmitter release from inhibitory neurons.[20] In addition to stimulation by endogenous opioids, exogenous opioids, commonly used for analgesia, also act upon peripheral opioid receptors in the GI tract, inhibiting GI motility.

CIRCI may be related to circulating bacteria or bacterial products and/or proinflammatory cytokines, following a similar mechanism as previously described. Colonic ileus also has been associated with ischemia-reperfusion injury, causing energy deficit, functio laesa, and oxidant-mediated tissue damage. Finally, distal colonic distention induces inhibition of proximal colonic motility, the so-called *colo-colonic reflex,* thereby perpetuating a vicious cycle.[21]

BOX 92.1 Clinical Factors Predisposing to Ogilvie's Syndrome or Acute Colonic Pseudo-Obstruction

Cardiovascular
- Heart failure, stroke
- Gut ischemia

Critical Illness
- Severe sepsis
- Acute pancreatitis
- Shock or hypoxemia

Postoperative State or Trauma
- Intestinal manipulation
- Peritonitis
- Immobility and dehydration
- Vertebral, pelvic, or hip fracture/surgery
- Retroperitoneal hematoma

Metabolic Factors
- Hypokalemia and hyperglycemia
- Hypothyroidism, diabetes mellitus
- Liver or renal failure
- Amyloidosis

Drugs
- α-Adrenergic agonists, dopamine[18]
- Clonidine and dexmedetomidine[36]
- Opioids
- Anticholinergics, calcium channel antagonists
- Antipsychotics[39,40]
- Antidepressants
- High-dose phosphodiesterase inhibitors

Gastrointestinal Infections
- Cytomegalovirus, herpes zoster
- Tuberculosis

Neurologic
- Transection of the spinal cord
- Low spinal cord disease
- Parkinson disease

Obstetric
- Cesarean section
- Normal delivery

PREDISPOSING FACTORS

Ogilvie's Syndrome

ACPO was first described by Sir William Heneage Ogilvie's in two patients who had retroperitoneal tumors invading the celiac plexus, which led him to suggest sympathetic deprivation as the etiology of the massive distention.[5] The vast majority of patients presenting with Ogilvie's syndrome have the syndrome in association with a predisposing factor. Clinical factors predisposing to Ogilvie's syndrome are summarized in Box 92.1.[1,2,6] In a large retrospective series of 400 patients, Vanek and Al-Salti reported the most common predisposing conditions associated with Ogilvie's syndrome were nonoperative trauma (11%), infections (10%), and cardiac disease (10%).[6] Although nonsurgical factors predisposing to Ogilvie's syndrome are frequent, surgical operations remain the most common cause of this syndrome. Of these, Ogilvie's syndrome is most likely to occur after obstetric/gynecologic, abdominal/pelvic, trauma, orthopedic/spine, and cardiac procedures. These procedures account for 50%–60% of all Ogilvie's cases.[22] Exogenous catecholamines have dose-dependent effects on intestinal motility; low doses promote and high doses suppress motility. α-Adrenergic agonists and dopamine are stronger inhibitors of acetylcholine release than β-adrenergic agents. Dopamine, in addition to inhibiting upper GI motility, inhibits distal colonic motility. Antipsychotic agents such as clozapine, haloperidol, and olanzapine have been associated with life-threatening forms of Ogilvie's syndrome.[23] One explanation of these gastrointestinal side effects is their antimuscarinic properties. Opioids suppress GI motility through activation of mu-opioid receptors, which inhibit the release of acetylcholine from the myenteric plexus. The outcome of this interaction is the decreased levels of cyclic adenosine monophosphate (cAMP) and calcium with a reduction in excitatory neurotransmitter release that ultimately leads to decreased peristalsis.[12,20] Opioid agonists inhibit GI wall motility, impair reabsorption of fluid from the lumen, and impair relaxation of the internal anal sphincter.[24] Additional predisposing factors such as severe metabolic derangements, sepsis, GI infections, and spinal cord injuries have also been implicated in the development of Ogilvie's syndrome.

Toxic Megacolon

Acute toxic megacolon was originally described in 1950 as a complication of IBD. Currently, the incidence of toxic megacolon in IBD has substantially decreased with advances in the management of severe colitis. Over the course of the last decade, the list of etiologic factors was expanded by a vast array of inflammatory and infectious conditions: bacterial colitides such as *C. difficile*, *Staphylococcus* spp., *Salmonella* spp., *Shigella* spp., and *Campylobacter* spp.; in addition, viral (e.g., cytomegalovirus [CMV], human immunodeficiency virus [HIV] and herpesvirus) and parasitic *(Entamoeba)* infections have been associated with toxic megacolon.[25,26] However, the most common cause of acute toxic megacolon in the critically ill is pseudomembranous colitis caused by *C. difficile*. Although many conditions have been associated with the development of toxic megacolon, the precise pathophysiology is not fully understood. Causes of toxic megacolon are summarized in Box 92.2.

Clostridium Difficile Infection

C. difficile is a gram-positive, spore-forming, toxin-producing, anaerobic rod bacterium. Less than 5% of the healthy adult population is colonized with this bacterium (see Chapter 135 for more details).[27] An estimated 30% of hospitalized patients become colonized with *C. difficile,* although most of these patients remain asymptomatic. Pathogenic strains produce two major exotoxins: toxin A (enterotoxin/Tcd A) and toxin B (cytotoxin/Tcd B).[28] Purified toxin A possesses potent enterotoxic and proinflammatory activities. Toxin B has been previously reported to exhibit no enterotoxic activities; however, recent studies have described enterotoxic and proinflammatory activities in human intestinal xenografts in mice.[29] It has been postulated that toxins A and B act synergistically to activate

BOX 92.2 Disorders Associated With Toxic Megacolon

Inflammatory Bowel Disease

cell-signaling molecules, including transcription factor, nuclear factor kappa B (NF-κB), and mitogen-activated protein kinases in monocytes, leading to production and release of proinflammatory cytokines. Toxin A leads to an increased secretion of fluid within the digestive tract, mucosal inflammation, and structural damage. Toxin B, in most cases, is responsible for the major problems associated with infection and is estimated to have 10 times more impact on the gastrointestinal tract than toxin A.[30] Recently, a hypervirulent strain has been identified. This strain, referred to as *NAP1/BI/027,* is responsible for the outbreaks of highly virulent pathogens. A deletion in this strain's *tcdC* gene, which is a negative regulator of toxin production, causes production of both toxins A and B to increase by 16-fold to 23-fold.[27,31] This strain is also more resistant to fluoroquinolones, has hypersporulation capacity, and produces an additional toxin, toxin C. The hypersporulation capacity potentially accounts for the enhanced transmission in hospitals compared with previous strains.

Colonic proliferation of *C. difficile* is thought to occur when the bacterial environment has been altered by current or previous exposure to antibiotics.[27] Historically antibiotics such as clindamycin, cephalosporins, and certain penicillins were most commonly associated with *C. difficile* colitis. More recently, fluoroquinolones have been implicated as a more frequent cause of this infection. The risk of acquiring the organism increases with prolonged hospital stay and institutionalization, and may be spread by nosocomial transmission. It has been postulated that susceptibility is further increased with the concurrent use of gastric acid–inhibiting drugs by facilitating increased survival of *C. difficile* spores. A complete list of factors associated with *C. difficile* infection can be found in Box 92.3.

DIAGNOSIS OF ACUTE MEGACOLON

The diagnosis of acute megacolon is suggested by the clinical presentation. Thorough history and physical examination should be obtained for all patients with acute abdominal distention and may help identify the underlying cause (see Boxes 92.2 and 92.3). Mild cases typically present with abdominal pain and cramping, constipation or diarrhea, and low-grade fever. More severe cases may present with significant abdominal tenderness and signs of systemic inflammation, such as fever, leukocytosis, and electrolyte abnormalities. Plain abdominal radiography is essential in the diagnostic workup, which will show varying degrees of colonic dilation. Dilation is most pronounced in the cecum, ascending, and right transverse colon. The cecal diameter may range from 6 to 20 cm. "Cutoffs" are common at the splenic flexure and descending colon (Fig. 92.1). Dilation of the left colon may occur as

BOX 92.3 Factors Associated With Colonization and Subsequent Infection With *Clostridium difficile*

Disruption of Indigenous Microflora
- Antibiotics suppressing indigenous microflora
- Cancer chemotherapeutics with antimicrobial activity
- Preoperative bowel preparation

Opportunity of Infection
- Prolonged hospital stay

Microbial Factors
- Toxigenicity and adhesion

Diminished Gastrointestinal Defense
- Reduced or suppressed gastric acid secretion
- Parenteral nutrition
- Postpyloric enteral nutrition
- Gastrointestinal surgery

Antibody Response of the Host

Poor Underlying Condition
- Old age
- Cancer
- Renal insufficiency
- Long-term use of corticosteroids
- Bedridden state

Fig. 92.1 Plain abdominal radiograph of patient with respiratory insufficiency caused by severe emphysema and Ogilvie's syndrome 10 days after dynamic hip screw implantation for femoral fracture. Dilatation is most pronounced in the cecum and ascending colon. Gas and fecal pattern in the distal colon is normal. The patient was successfully treated with intravenous neostigmine.

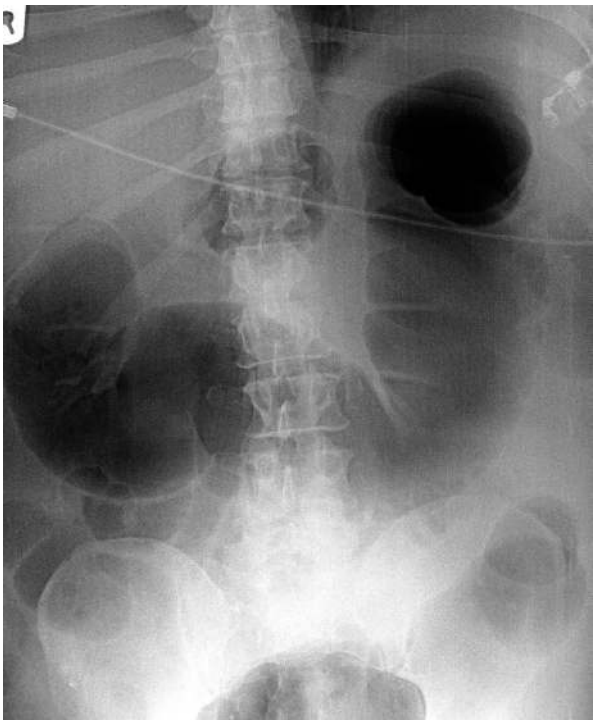

Fig. 92.2 Plain abdominal radiograph of a patient with Ogilvie's syndrome 11 days after surgery for a ruptured aneurysm of the abdominal aorta. Dilatation (probably the result of ischemia) is present in both the right and left colon. The syndrome was resolved with vasodilators and intravenous neostigmine.

well (Fig. 92.2). The distribution of colonic dilation may be caused by different origins of the proximal and distal parasympathetic nerve supply of the colon. Air/fluid levels may be seen in the small bowel, indicating a paralytic ileus. The differential diagnosis of acute colon distention in a critically ill patient should include mechanical obstruction, infectious colitis with toxic megacolon, and Ogilvie's syndrome. Prompt evaluation of a patient with acute megacolon should involve excluding mechanical obstruction and other causes of toxic megacolon, such as *C. difficile* colitis, and assessment for signs of peritonitis or perforation, which indicates a surgical emergency. Mechanical obstruction is excluded if air is visible in all colonic segments, including the rectosigmoid junction. If the diagnosis is in question, mechanical obstruction can be excluded by performing a computed tomography (CT) scan. The clinical or radiographic features of a toxic megacolon are an absolute contraindication to barium enema or the administration of laxatives. Toxic megacolon is diagnosed based on clinical signs of systemic toxicity combined with radiographic evidence of colonic dilation (diameter >6 cm).[32] Pneumatosis of the bowel wall or free intraperitoneal air on CT scan indicates the need for urgent surgical consultation.

If toxic megacolon is suspected, fresh stool should be submitted for laboratory culture, and stool should be screened for the presence of toxigenic *C. difficile*. Commercially available nucleic acid amplification tests (NAATs) such as polymerase chain reaction (PCR) for the rapid detection of *C. difficile* infection (CDI) are inexpensive, highly sensitive, and allow results to be available within hours. These tests should only be used in patients with documented diarrhea. An alternative method for the detection of CDI requires a two-step procedure. The patient should first be screened for the presence of glutamate dehydrogenase (GDH), an enzyme produced by *C. difficile* in relatively large amounts compared with toxins A and B. Although GDH testing is sensitive, it is not as specific for CDI, because this enzyme is produced by both toxigenic and nontoxigenic organisms. GDH-negative specimens require no further testing. GDH-positive specimens must undergo additional screening either by NAAT or by toxins A and B enzyme immunoassay (EIA) testing, followed by NAAT if the EIA results are discordant.[33] Final results take 2–5 days. After an initial negative result, repeat testing within 48 hours should be discouraged, as conversion to a positive result occurs in less than 5% of patients.[34] Studies have shown that both toxins A and B EIA and toxigenic cultures may remain positive for as long as 30 days in patients who have resolution of symptoms. Therefore "test for cure" studies may complicate clinical care, resulting in unnecessary prolongation of treatment, and should not be performed. Surveillance cultures of feces are advocated to detect other pathogens such as enterotoxin-producing *Clostridium prefringens, Staphylococcus aureus,* and *Klebsiella oxytoca*. Blood cultures should be obtained in any patient presenting with toxic megacolon.

Limited endoscopy (e.g., flexible sigmoidoscopy) with biopsy may be valuable in differentiating etiologic causes; however, full colonoscopy bears the high risk of perforation and is therefore contraindicated. IBD is characterized by diffusely abnormal crypt structure, whereas normal crypt architecture is seen in bacterial colitis. Mild cases of *C. difficile* colitis are associated with nonspecific findings of colitis, such as friability of the mucosal surface. In severe cases, focal ulcerations covered by purulent material, or pseudomembranes, interspersed with normal intervening mucosa, may be seen. Although pathognomonic for CDI, these lesions are not uniformly present and may not be present throughout the entire colon.

MANAGEMENT

Ogilvie's Syndrome

Medical Management

An essential concept to the management of Ogilvie's syndrome is prevention. Many hemodynamic, surgical, and metabolic derangements have been implicated with the development of Ogilvie's syndrome. Strategies to prevent this condition in the critically ill are highlighted in Box 92.4. Life-threatening complications may occur if treatment is delayed. Supportive therapy is the preferred initial management and should be instituted in all patients with uncomplicated ACPO (absence of ischemia, peritonitis, cecal diameter >12, and/or significant abdominal pain).[35] Concomitantly, conditions that impair colonic motility must be corrected. Patients should be made nil per os (NPO) and intravenous fluids administered to restore euvolemia. Nasogastric decompression should be initiated in patients with concomitant paralytic ileus. Electrolyte and metabolic abnormalities, including phosphorous,

BOX 92.4 Strategies to Prevent Ogilvie's Syndrome in the Critically Ill

- Early resuscitation of the circulation
- Minimizing prolonged infusion of high doses of α-adrenergic drugs
- Minimizing the use of dopamine
- Minimizing the prolonged use of opioids
- Use of thoracic epidural anesthesia
- Minimally invasive or laparoscopic surgery
- Selective decontamination of the digestive tract
- Avoiding antibiotics that disrupt the growth of anaerobic fecal bacteria
- Early oral or enteral feeding
- Avoidance of proton pump inhibitors
- Early mobilization and ambulation
- Promoting timely defecation

magnesium, calcium, and thyroid functions, should be corrected via parenteral administration. Blood cultures and empiric antibiotics should be administered if sepsis is clinically suspected. Offending medication use, such as opioids, anticholinergic agents, norepinephrine, and dopamine, should be minimized or discontinued if possible. Optimal body positioning, such as prone positioning with the hips elevated on pillows or the knee-chest position with the hips held high, often aids in spontaneous evacuation of flatus.[2,5] These positions should be alternated with right and left lateral decubitus positions regularly, when feasible. Use of a rectal tube may also aid in decompression. Serial abdominal examinations, assessing for signs of peritonitis or free perforation, should be performed and plain abdominal radiographs should be obtained every 12–24 hours. Osmotic laxatives lead to increased gas formation in the colon and should be avoided.[36] The reported success of conservative management is variable, with rates from 77% to 96%.[32,37] Deterioration or nonresolution of symptoms despite maximal medical therapy within 48–72 hours of initiating therapy should prompt reconsideration of the management plan.

If these measures are ineffective beyond 48–72 hours, either pharmacologic therapy or endoscopic decompression should be considered as the next step in the treatment algorithm.[32] Intravenous neostigmine is the drug of choice. Neostigmine is a short-acting anticholinesterase parasympathomimetic agent commonly used for postoperative reversal of nondepolarizing neuromuscular blockade and in the treatment of myasthenia gravis. Parasympathetic stimulation can result in bradycardia, asystole, hypotension, bronchospasm, and hypersalivation. Coadministration of glycopyrrolate may be useful in preventing the side effects of the medication, including hypersalivation and bronchospasm.[38] Close observation and monitoring with telemetry in a controlled setting are warranted. In a double-blind, randomized placebo-controlled trial of 21 patients with a cecal diameter of at least 10 cm despite 24 hours of conservative therapy, 10 out of 11 patients randomized to receive an infusion of 2 mg neostigmine had prompt colonic decompression, and 1 responded after subsequent retreatment.[39] None of the 10 patients randomized to placebo experienced resolution, but all 7 in whom neostigmine was openly administered subsequently responded. In a double-blind, placebo-controlled prospective study in critically ill, ventilated patients with CIRCI, continuous infusion of neostigmine at 0.4–0.8 mg/h resulted in defecation in 80% of patients, with no reported adverse events.[3] Continuous-infusion neostigmine is associated with greater bowel diameter reduction at 24 hours and may be associated with decreased side effects compared with bolus dosing.[40] The 2019 American Society for Gastrointestinal Endoscopy guidelines recommend pharmacologic therapy with neostigmine (2 mg over 3–5 minutes) with appropriate cardiovascular monitoring. For patients who do not respond to a first dose of neostigmine, a second dose is recommended. For those patients refractory to bolus dosing of neostigmine, alternative routes of neostigmine administration, including subcutaneous or continuous intravenous infusion, are recommended.[32,41] Contraindications to the use of neostigmine include intestinal or urinary obstruction, presence of ischemia or perforation, pregnancy, uncontrolled cardiac arrhythmias, severe active bronchospasm, known hypersensitivity reaction, and renal insufficiency.[2,3,32] Unfortunately, relapse of Ogilvie's syndrome after the initial response to medical therapy occurs in 40% of patients, and more invasive therapies may be required.[42]

Invasive Interventions

Once medical management has failed, endoscopic decompression is the initial invasive procedure of choice for patients with marked cecal distention (>10 cm) of significant duration (>3–4 days), not improving after 24–48 hours of supportive therapy, and who have contraindications to or fail neostigmine treatment.[4] Colonoscopy should be performed by an experienced endoscopist without the administration of bowel preparation using water infusion and minimal to no insufflation. If insufflation is required, the use of carbon dioxide rather than air is the preferred gas agent, as liberal use of air insufflation may lead to perforation.[35] Advancing the scope to the level of the proximal hepatic flexure is usually sufficient to obtain adequate decompression.[7] Gas should be aspirated and the viability of the mucosa assessed during slow withdrawal of the scope. If signs of ischemia are present, the procedure should be aborted. Successful decompression has been achieved in 70%–80% of patients; however, the recurrence rates are as high as 50%.[2,43] To increase therapeutic benefit, decompression tube placement at the time of colonoscopy may reduce recurrence, but controlled trials with this intervention are not available. It is important to exclude perforation before performing endoscopic decompression, with a plain abdominal x-ray performed within several hours before the procedure, especially in patients with fever, leukocytosis, or worsening abdominal pain.[35] Studies comparing endoscopic decompression and pharmacologic treatment are limited.

Surgical management is rarely necessary and should be reserved for patients who have failed pharmacologic and endoscopic management or those who have clinical signs of colonic ischemia or perforation. Surgical options include a venting stoma (cecostomy) or colectomy.[6] Ogilvie's syndrome is one of the few conditions where cecostomy is indicated in patients with prohibitive morbidity. Tube cecostomy should be performed only in patients without evidence of ischemia or perforation. It can be performed laparoscopically or through a limited right lower quadrant incision. A large Foley catheter is left in place for 2–3 weeks to allow venting of the colon. Cecostomy is an effective treatment and can be performed under local anesthesia, but is associated with significant morbidity.[44] In cases of ischemia or perforation, laparotomy is indicated. Segmental or subtotal resection may be performed, as dictated by the extent of colon involvement. In the event a colectomy is needed, an end stoma and mucous fistula should be performed and anastomosis avoided.

An alternative method of decompression includes percutaneous endoscopic colostomy of the cecum (PEC-cecum). PEC-cecum tubes can be placed radiographically or endoscopically with reported success rates up to 100%.[35] However, PEC-cecum is not recommended as a routine option and should only be used in select cases after multidisciplinary assessment of inoperable candidates.[45] Complications associated with PEC-cecum include wound infection, bleeding, hematoma, perforation, granuloma, or buried bumper.

Toxic Megacolon

Medical Management

The initial goal of treatment is to reduce the severity of colitis so as to restore normal colonic motility and decrease the likelihood of perforation.[25] Patients should be monitored closely in an ICU with frequent examinations to assess for clinical deterioration. A surgical consultation should be obtained on admission, although medical treatment is successful in about 50% of patients. Complete blood counts, electrolyte panels, and serial plain abdominal films are reviewed every 12 hours initially, until clinical improvement has been observed. Conditions impairing colonic motility must be corrected (see Box 92.1). In general, patients will require adequate resuscitation, electrolyte and vitamin replacement, early optimization of circulation, and, if necessary, mechanical ventilation. A nasogastric tube should be placed to decompress the GI tract. Early total parenteral nutrition has shown no survival benefit and should be reserved for patients who have evidence of long-standing malnutrition in the absence of bacteremia, especially if they are likely to undergo surgery. However, enteral nutrition should be initiated as soon as possible and tolerance of enteral feeds monitored by

gastric volume residuals. Antimotility agents should be discontinued, and antiperistaltic agents for diarrhea are absolutely contraindicated.

Systemic antibiotics, administered empirically, are necessary to reduce septic complications and peritonitis. Empiric antibiotics should cover both gram-negative and anaerobic species, as guided by local susceptibility patterns and fecal surveillance cultures. It is important to select antibiotics that least inhibit the indigenous colonic flora, and in the case of *C. difficile,* the offending antibiotic should be discontinued. De-escalation of antibiotics should ensue, without delay, once final microbiologic data are obtained.

Patients with toxic megacolon caused by IBD should be treated with high-dose intravenous corticosteroids. Steroid treatment should be started immediately and not be delayed pending microbiologic results. Most authors recommend hydrocortisone 100 mg or equivalent every 6 hours or by continuous infusion. Steroid use should be reevaluated on a regular basis and discontinued once an exclusively infectious etiology of toxic megacolon has been established. Patients with IBD-related toxic megacolon who do not respond to intravenous glucocorticoids within 3 days should receive infliximab as the second-line therapy, and cyclosporine should be reserved for those who cannot tolerate infliximab.[46,47]

In patients with toxic megacolon caused by severe *C. difficile* colitis, the first step is to stop the offending antibiotic and to give vancomycin 125 mg orally, four times a day.[33] Treatment should not be delayed while awaiting microbiologic confirmation of CDI. Findings suggestive of severe, *complicated* CDI include admission to the ICU, hypotension with or without required use of vasopressors, fever ≥38.5°C, mental status changes, white blood cell count ≥35,000 or <2000 cells/mm^3, serum lactate levels >2.2 mmol/L, or evidence of end-organ failure. If any of these finding are present, the vancomycin dosing should be increased to 500 mg orally four times a day with the addition of metronidazole 500 mg intravenously every 8 hours. Vancomycin retention enemas (vancomycin 500 mg in 500 mL saline per rectum four times a day) should also be administered.[33] Fecal microbial transplant has been used successfully in *C. difficile* patients with severe colitis, including toxic megacolon, but the indications, outcomes, and risks of this approach are not well defined.[48–51]

Surgical Management

Patients unresponsive to medical treatment should undergo prompt surgical resection. Surgical intervention should be considered if a patient has progressive signs of organ failure despite optimal medical therapy; CT scan findings suggestive of worsening disease; or signs of peritonitis, abdominal compartment syndrome, colonic necrosis, full-thickness ischemia, or perforation. However, because of a lack of prospective randomized studies, it is difficult to identify the optimal point for surgical intervention in patients with severe, fulminant CDI, and mortality ranges from 35% to 80%.[52] Subtotal colectomy with end ileostomy is considered the procedure of choice when urgent or emergent surgery is required. More recently, Neal and colleagues published their experience with an alternative surgical approach: diverting loop ileostomy and colonic lavage.[53] In this technique, an ileostomy is created and intraoperative colonic lavage is performed with a warmed polyethylene glycol (PEG) solution via the ileostomy. Postoperatively, the patients received antegrade vancomycin flushes (500 mg in 500 mL lactated Ringer's) every 8 hours for a duration of 10 days. Mortality was reduced from 50% to 19% among patients treated using this novel technique. There are not currently enough data to support the routine use of this procedure; however, it remains an alternative approach for the treatment of fulminant *C. difficile* colitis.

SUMMARY

Ogilvie's syndrome manifests with massive dilation of the colon in the absence of mechanical obstruction. Evaluation involves exclusion of mechanical obstruction, cessation of offending agents, and selective use of neostigmine and colonic decompression. With appropriate management, colonic pseudo-obstruction usually resolves within several days. Toxic megacolon is a diagnosis based on clinical signs of systemic toxicity in combination with radiographic evidence of colonic dilation. The goal of treatment is to reduce the effects of colonic inflammation and prevent perforation. Timely treatment with broad-spectrum antibiotics combined with cessation of causative agents will help minimize the morbidity associated with this disease process. Surgery should be reserved for those patients who fail to respond to medical management or show signs of ischemia or perforation. A high index of suspicion and early recognition of both Ogilvie's syndrome and toxic megacolon are crucial to optimal management.

KEY POINTS

- Ogilvie syndrome, or acute colonic pseudo-obstruction (ACPO), is a syndrome of massive colonic dilation in the absence of mechanical obstruction that develops in critically ill patients with serious underlying medical and surgical conditions.
- Conservative therapy is the initial preferred management.
- Numerous contributory metabolic, infectious, and pharmacologic factors are associated with Ogilvie's syndrome. These factors should be identified and corrected early in the treatment.
- Neostigmine is effective in a majority of cases of Ogilvie's syndrome. Colonic decompression may be required.
- Toxic megacolon is a syndrome of nonobstructive colonic dilation associated with systemic toxicity.
- Empiric antibiotics with gram-negative and anaerobic coverage should be initiated early in the course of treatment.
- Surgical intervention should be reserved for those patients who fail optimal medical management or show clinical signs of colonic ischemia or perforation.

Severe Gastrointestinal Bleeding

Tyler J. Loftus and Martin D. Rosenthal

Gastrointestinal bleeding is common, and severe bleeding often requires intensive care unit admission. Optimal management requires hemostatic resuscitation, management of antiplatelet and anticoagulant agents, acid suppression, and a multidisciplinary approach to localization for hemorrhage control, summarized in Fig. 93.1.

RESUSCITATION

For patients with acute upper gastrointestinal bleeding, restrictive transfusion strategies (i.e., red cell transfusion when hemoglobin falls below 7 g/dL) decreases mortality and morbidity relative to liberal transfusion strategies.[1,2] It is reasonable to maintain a higher threshold (e.g., hemoglobin 9 g/dL) in patients with ischemic cardiovascular disease.[3] Although there is a lack of high-level evidence to inform decisions regarding red cell transfusion strategies specifically for acute lower intestinal bleeding, it seems prudent to adopt a restrictive transfusion strategy for these patients as well.[4,5] In cases of hemorrhagic shock, hemostatic resuscitation should proceed with balanced administration of red cells and plasma, in addition to platelet transfusions for patients with thrombocytopenia or the use of antiplatelet medications.[6]

MANAGEMENT OF ANTIPLATELET AGENTS

Management of antiplatelet therapy for patients with severe gastrointestinal bleeding depends on the indication for and type of antiplatelet therapy. When the indication is primary prevention of cardiovascular events, antiplatelet therapy should be discontinued.[7] When the indication is secondary prevention of cardiovascular events in patients with known cardiovascular disease, low-dose aspirin monotherapy should be continued, and for patients receiving dual antiplatelet therapy, aspirin should be continued and the nonaspirin antiplatelet agent should be held for up to 1 week.[8–10] If dual antiplatelet therapy is indicated for cardiac percutaneous intervention within the prior 30 days or an acute coronary syndrome within the prior 90 days, it is reasonable to continue dual antiplatelet therapy, given the high risk of myocardial infarction and death associated with discontinuation of dual antiplatelet therapy.[11]

MANAGEMENT OF ANTICOAGULANTS

When severe gastrointestinal bleeding occurs in the context of therapeutic anticoagulation, the anticoagulant should be discontinued, and reversal should be considered. Intravenous administration of vitamin K and prothrombin complex concentrates effectively reverses warfarin. Increasingly, direct thrombin inhibitors (e.g., dabigatran) and factor Xa inhibitors (e.g., rivaroxaban, apixaban, edoxaban, and fondaparinux) are used to prevent embolic stroke in nonvalvular atrial fibrillation and to prevent and treat venous thromboembolism. When patients present within 2–3 hours of ingesting anticoagulants, administration of activated charcoal may decrease their intestinal absorption, but will also impair endoscopic visualization of the gastrointestinal mucosa. Hemodialysis can remove dabigatran from the bloodstream, but is ineffective in removing factor Xa inhibitors because they are highly protein-bound.[12] Idarucizumab, a specific monoclonal antibody, also reverses dabigatran.[13] Fresh frozen plasma and cryoprecipitate have limited efficacy in reversing direct thrombin inhibitor and factor Xa inhibitors.[14] For cases of severe bleeding, prothrombin complex concentrates and the antifibrinolytic agent tranexamic acid may be considered, though evidence supporting their use specifically for gastrointestinal bleeding is limited, and they are associated with thromboembolic complications.[12] It seems prudent to perform rapid thromboelastography and administer tranexamic acid if pathologic thrombolysis is identified, though this area remains controversial. Emerging evidence suggests that andexanet alfa effectively reverses factor Xa inhibitors with an acceptable safety profile, but further investigation is required before routine clinical use can be recommended.

LOCALIZATION AND TREATMENT

Clinical assessment often allows differentiation between upper gastrointestinal bleeding proximal to the ligament of Treitz and lower intestinal bleeding. Brisk upper gastrointestinal bleeding presents with hematemesis or hematochezia (maroon or red blood passed through the rectum), whereas slower upper gastrointestinal bleeding allows oxidation of blood products, resulting in coffee-ground emesis or melena (black, tarry stools).[15] In cases of melena, gastric tube placement can help differentiate between upper and lower etiologies. Gastric fluid containing bile and no blood effectively rules out upper gastrointestinal hemorrhage. In addition, blood urea nitrogen–to–serum creatinine ratios greater than 30:1 suggest upper gastrointestinal sources of hemorrhage, likely related to heme absorption and metabolism.[16] Further diagnosis and management are typically guided by initially upper or lower endoscopy.

UPPER GASTROINTESTINAL BLEEDING

Upper gastrointestinal bleeding occurs in 60–160/100,000 people in the United States annually and is associated with 4%–10% mortality.[17–20] The differential includes esophageal variceal hemorrhage—accounting for approximately 10%–20% of all cases and more prevalent among patients with portal hypertension—and nonvariceal hemorrhage, usually caused by peptic ulcer disease, esophagitis, gastritis, and Mallory-Weiss tears.[21] Rare causes include Dieulafoy lesions, tumor, vascular malformation, hemobilia, and aortoenteric fistula. Etiologies of gastrointestinal bleeding are listed in Table 93.1. When upper gastrointestinal bleeding is suspected and nasopharyngeal and

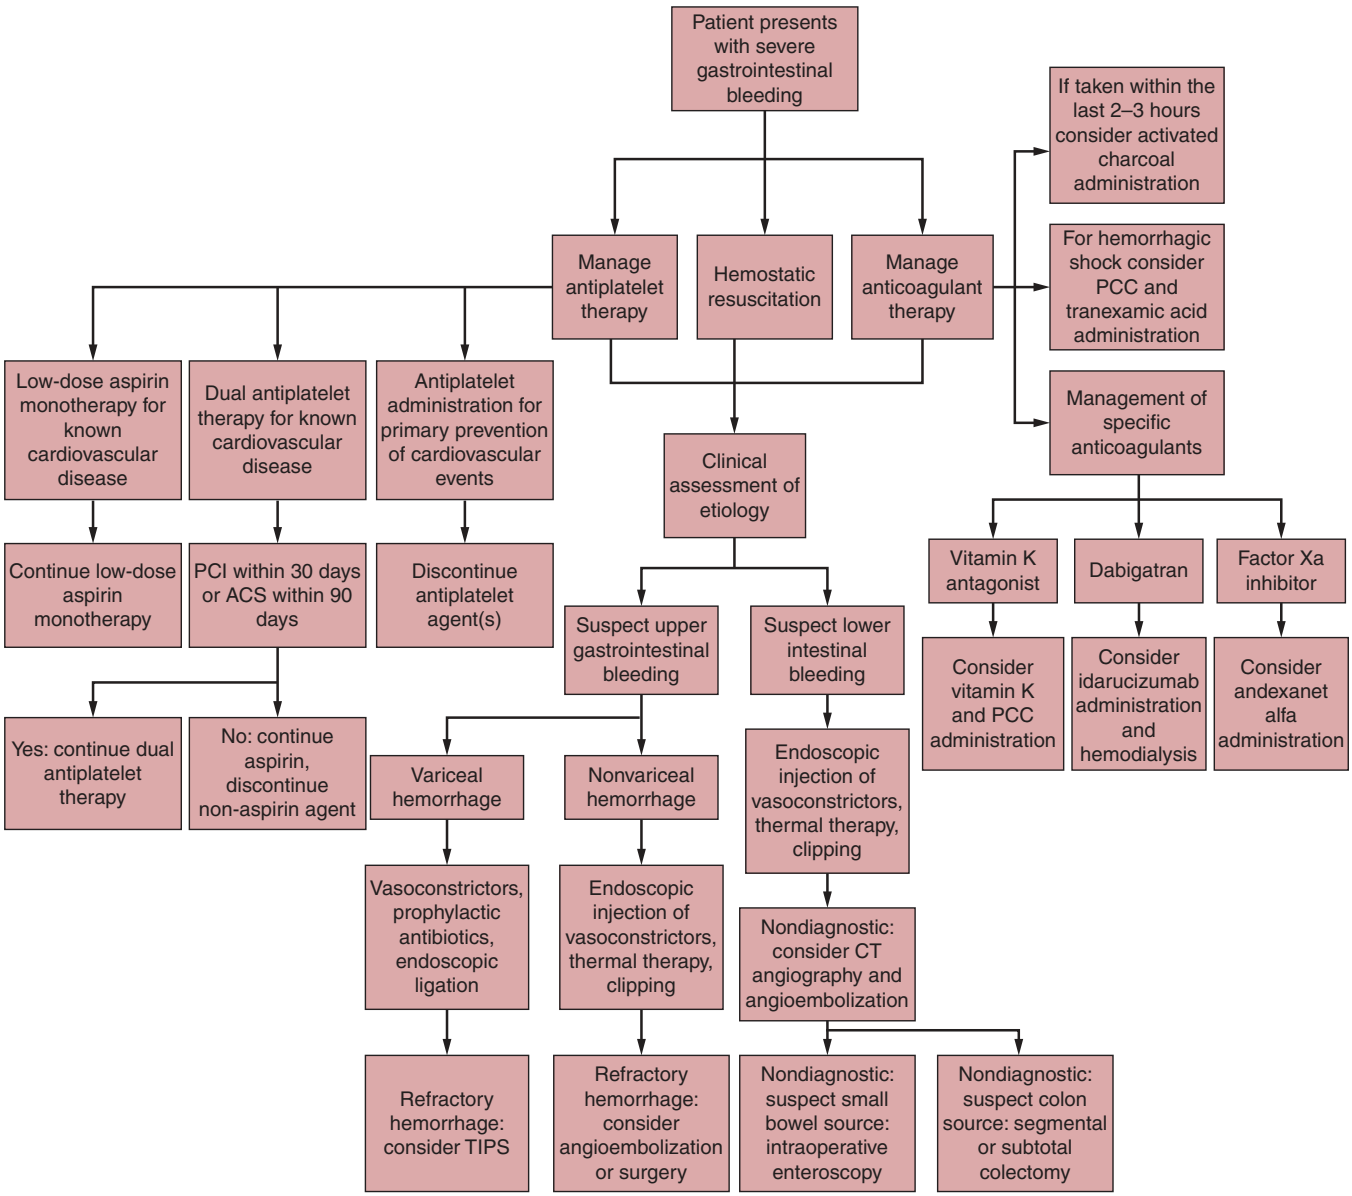

Fig. 93.1 Severe Gastrointestinal Bleeding Management Algorithm. *ACS,* Acute coronary syndrome; *CT,* computed tomography; *PCI,* percutaneous coronary intervention; *PCC,* prothrombin complex concentrate; *TIPS,* transjugular intrahepatic portosystemic shunt.

oropharyngeal sources have been ruled out, upper endoscopy establishes the etiology.

Management of variceal hemorrhage in patients with cirrhosis should ideally include splanchnic vasoconstrictors (e.g., terlipressin/vasopressin or octreotide), prophylactic antibiotics (e.g., norfloxacin or ceftriaxone), acid suppression with proton pump inhibitors, and endoscopic variceal ligation.[22,23] If these measures fail to resolve hemorrhage, transjugular intrahepatic portosystemic shunt placement should be performed early, ideally within 24–48 hours of admission.[24] If these measures are not feasible, a Sengstaken-Blakemore tube can be used to temporize massive bleeding from esophageal varices through balloon compression. For patients with isolated gastric varices, gastric devascularization and splenectomy should be considered.[25] Management of portal vein thrombosis should be determined on a case-by-case basis, weighing the risks and benefits of anticoagulation in terms of worsening portal hypertension and recurrent variceal hemorrhage versus bleeding complications.

Management of nonvariceal upper gastrointestinal hemorrhage depends on the etiology. Most can be managed endoscopically with injection of vasoconstrictors, thermal therapy with electrocoagulation or argon beam coagulation, and clipping. If endoscopic therapy is not feasible, fails once in the context of an ulcer greater than 2 cm or associated hypotension during rebleeding, or fails twice, surgical management and angiographic embolization should be considered.[26,27] Angiographic embolization is most likely to be successful in cases of discrete, localized arterial hemorrhage. Surgical management of refractory hemorrhage from a gastric ulcer typically includes ulcer excision and closure of the gastric defect, with intraoperative biopsy to assess for the presence of malignancy.[28]

Surgical management of refractory hemorrhage from a prepyloric or duodenal ulcer may consist of oversewing the ulcer plus vagotomy or performing a formal gastric resection, including the antrum, with reconstruction by Billroth I, Billroth II, or Roux-en-Y gastrojejunostomy techniques plus vagotomy. Between these options, the latter has the

TABLE 93.1 Principal Causes of Upper and Lower Gastrointestinal Bleeding, Approximating Descending Order of Prevalence

Upper Gastrointestinal Bleeding	Lower Intestinal Bleeding
Variceal hemorrhage	Diverticulosis
Peptic ulcer disease	Hemorrhoids
Esophagitis	Ischemic colitis
Gastritis	Colorectal polyps or neoplasms
Mallory-Weiss tears	Angiodysplasia
Dieulafoy lesions	Postpolypectomy bleeding
Tumor	Inflammatory bowel disease
Vascular malformation	Infectious colitis
Hemobilia	Stercoral ulceration
Aortoenteric fistula	Colorectal varices
	Radiation proctopathy
	NSAID-induced colopathy

NSAID, Nonsteroidal antiinflammatory drug.

advantage of including both antrectomy and vagotomy to reduce gastrin and acetylcholine stimulation of hydrochloric acid production by parietal cells, and is associated with a lower incidence of recurrent bleeding, with similar mortality rates.[29,30] However, when discrete bleeding from the gastroduodenal artery at the base of a posterior duodenal ulcer can be identified though a pyloromyotomy or duodenotomy, hemorrhage can be effectively managed with three-point ligation of the gastroduodenal artery—cephalad, caudad, and medial, to ligate proximally, distally, and the transverse pancreatic branches, respectively—with vagotomy.[28,31]

LOWER INTESTINAL BLEEDING

Lower intestinal bleeding occurs in approximately 36/100,000 people in the United States annually and is associated with 2%–9% mortality.[17,20,32,33] Common causes of acute lower intestinal bleeding, in descending order of prevalence, include diverticulosis, hemorrhoids, ischemic colitis, colorectal polyps or neoplasms, angiodysplasia, postpolypectomy bleeding, inflammatory bowel disease, and infectious colitis; rare causes include stercoral ulceration, colorectal varices, radiation proctopathy, and nonsteroidal antiinflammatory drug (NSAID)–induced colopathy. Etiologies of gastrointestinal bleeding are listed in Table 93.1. Lower intestinal bleeding usually resolves spontaneously, and is thus less likely to require emergency interventions. For most patients presenting with lower intestinal bleeding, colonoscopy is the initial diagnostic and therapeutic procedure of choice.[3]

Early colonoscopy (i.e., within 12–24 hours of presentation) is associated with greater likelihood of obtaining a definitive diagnosis and shorter hospital length of stay.[34–36] Preparation with polyethylene glycol or a similar solution is ideal, although the cathartic effects of intraluminal blood products along with cleaning of colonic mucosa during the procedure can provide adequate visualization.[37] Similar to upper gastrointestinal hemorrhage, most cases can be managed endoscopically with injection of vasoconstrictors, thermal therapy with electrocoagulation or argon beam coagulation, and clipping.[38]

When colonoscopy is nondiagnostic or hemorrhage is brisk, computed tomography (CT) angiography is useful for localization, detecting bleeding as slow as 0.3 mL per minute.[37] This can facilitate targeted, selective interventional angiography and embolization.[39] Provocative angiography with administration of heparin, nitroglycerin, or thrombolytics may increase the likelihood of identifying the origin of hemorrhage, but also risks worsening hemorrhage.[40] This technique should only be attempted when a surgical team and operating room are available.

In contrast to upper gastrointestinal bleeding—with rich collateral circulation—lower gastrointestinal angiographic interventions target end arteries, and are thus more likely to lead to ischemia requiring surgical resection. Video capsule endoscopy can noninvasively identify small bowel sources of bleeding. When the etiology of bleeding cannot be identified by other means, laparotomy and intraoperative enteroscopy can identify the source in approximately 80% of all cases.[41] Lower intestinal hemorrhage secondary to ischemic colitis, inflammatory bowel disease, and tumors is less likely to respond well to endoscopic and angiographic management.[3] In such cases, surgical resection of the involved bowel should be a primary consideration. It is important to localize the site of hemorrhage as precisely as possible before proceeding with bowel resection. When upper gastrointestinal and small bowel hemorrhage have been ruled out and a discrete source of lower intestinal bleeding cannot be identified, it is acceptable to perform subtotal colectomy, but this approach is associated with increased mortality and morbidity relative to targeted, segmental colectomy, particularly in elderly patients with multiple comorbidities and increased risk for dehydration secondary to high ileostomy output.[42,43]

PROGNOSIS

For patients with upper gastrointestinal hemorrhage, the Glasgow Blatchford score accurately predicts requirements for endoscopic interventions and mortality.[44] Endoscopic visualization of pathology can estimate the likelihood of recurrent bleeding based on visualization of active bleeding (high risk), visible nonbleeding vessels or adherent clot on an ulcer (intermediate risk), or clean ulcer base (low risk). Among patients with lower intestinal bleeding, risk factors for recurrent bleeding or death include tachycardia, hypotension, ongoing hematochezia, age greater than 60 years, serum creatinine greater than 1.7 mg/dL, and unstable or clinically significant comorbidities.[45]

KEY POINTS

- Hemostatic resuscitation should proceed with restrictive transfusion strategies when possible.
- Management of antiplatelet agents depends on the indication for antiplatelet therapy.
- Management of anticoagulants depends on the type of agent and urgency of reversal.
- Variceal hemorrhage is managed with vasoconstrictors, prophylactic antibiotics, and endoscopic ligation, with salvage by TIPS.
- Nonvariceal upper gastrointestinal hemorrhage is managed primarily with endoscopic techniques and secondarily by angioembolization or surgery.
- Lower intestinal hemorrhage is initially managed with endoscopic techniques, then with angiography, and then with intraoperative enteroscopy for small bowel sources and subtotal or segmental colectomy for colorectal sources.

Core Principles of Renal Physiology and Pathophysiology in Critical Illness

Emily J. See, Daniel Leisman, Clifford Deutschman, and Rinaldo Bellomo

INTRODUCTION

The kidney plays a key role in maintaining solute, water, and acid-base homeostasis. Some or all of these roles may be impaired in critically ill patients because of processes that disrupt glomerular, tubular, or interstitial function. This chapter will cover the core principles of renal physiology and pathophysiology relevant to the intensive care setting.

STRUCTURES OF THE NEPHRON

The Glomerulus

The glomerulus is the filtering unit of the kidney (Fig. 94.1). Located in the renal cortex, it is composed of a tuft of capillaries that filter plasma across a semipermeable barrier. The glomerular filtration barrier consists of three layers: the fenestrated endothelial cells of glomerular capillaries, the glomerular basement membrane, and specialized epithelial cells called *podocytes.* Mesangial cells surrounding the glomerular capillaries have contractile properties that alter the surface area available for filtration. After passing through the barrier, the filtrate collects in the Bowman space, encased by the Bowman capsule, before it passes into the renal tubule.

Proximal Tubule

The proximal tubule is a hollow structure outlined by a single layer of epithelial cells that extends from the Bowman space to the loop of Henle (see Fig. 94.1). It is a key site for the reabsorption of sodium, water, bicarbonate, phosphate, potassium, calcium, and organic solutes (e.g., glucose, citrate, urea, and amino acids; Table 94.1). Transport occurs either paracellularly (across tight junctions) or transcellularly (across the apical and basolateral membrane of the epithelial cells). The resorptive function of the proximal tubule is enhanced by amplification of the luminal cell membrane into a "brush border" and by densely packed mitochondria on the basolateral cell surface, which supply energy for the active transport of solutes.

The Loop of Henle

The loop of Henle is divided into three segments: the thin descending limb, the thin ascending limb, and the thick ascending limb (see Fig. 94.1). Its primary function is to concentrate the urine by the countercurrent system. The countercurrent system is responsible for generating the osmotic gradient within the interstitium that increases from the renal cortex (~290 mOsm/kg) to the inner medulla (~1200 mOsm/kg). This is achieved by means of its U-shaped configuration and variable permeability to sodium and water.[1] The thin descending limb is highly permeable to water but impermeable to sodium, whereas the thin and thick ascending limbs are impermeable to water but permeable to sodium, which is reabsorbed passively in the thin ascending limb and actively in the thick ascending limb. The thick ascending limb is also a primary site for magnesium reabsorption and urea secretion (see Table 94.1).

Macula Densa

The macula densa lies at the apex of the nephron between the thick ascending limb and the distal convoluted tubule, adjacent to the parent glomerulus. The cells of the macula densa detect the composition of the tubular fluid and provide feedback to the afferent and efferent arterioles to control renal blood flow (RBF) and glomerular filtration rate (GFR) in a process called *tubuloglomerular feedback* (TGF).

Distal Convoluted Tubule

The distal convoluted tubule is a short nephron segment located between the thick ascending limb and the collecting duct (see Fig. 94.1). The early distal convoluted tubule participates in the reabsorption of sodium, potassium, calcium, and magnesium (see Table 94.1). It is impermeable to water, making it the final diluting segment of the kidney. The late distal convoluted tubule contains three cell types. Principal cells reabsorb sodium and water and secrete potassium under the control of antidiuretic hormone (ADH) and aldosterone, respectively. Alpha-intercalated cells secrete hydrogen ions, reabsorb bicarbonate, and either reabsorb or secrete potassium, depending on the plasma concentration. Beta-intercalated cells secrete bicarbonate and reabsorb hydrogen ions.

Collecting Duct

The collecting duct connects the distal convoluted tubules of individual nephrons to calyces or directly to the renal pelvis (see Fig. 94.1). Like the late distal convoluted tubule, the collecting duct contains principal and alpha- and beta-intercalated cells. Collecting ducts are classified as cortical or medullary ducts; the proportion of intercalated cells (which are responsible for acid-base balance) decreases as the collecting duct enters the medulla. Urea is reabsorbed in the medullary collecting duct in response to ADH, which up-regulates urea transporters, increasing interstitial osmolality and enhancing the osmotic gradient of the countercurrent system.

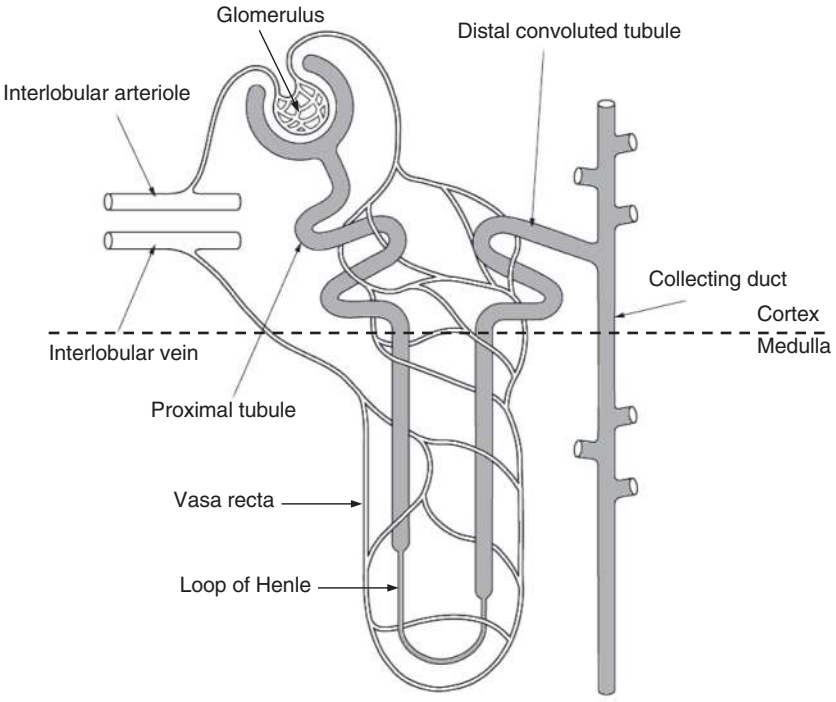

Fig. 94.1 Structures of the nephron.

Renal Vasculature

Blood is delivered to the glomerular capillaries via the renal artery, interlobar artery, arcuate artery, interlobular artery, and afferent arteriole. Glomerular capillaries are composed of a single layer of endothelial cells, encased by the glomerular basement membrane and interdigitating podocyte processes. Capillaries drain into the efferent arteriole, which gives rise to the peritubular capillaries and vasa recta. The vasa recta are a series of vascular loops that supply oxygenated blood and nutrients to the cortex and medulla and return reabsorbed water and solutes to the circulation. The vasa recta converge to form the interlobular vein, arcuate vein, interlobar vein, and renal vein before emptying into the inferior vena cava.

The arrangement of vasa recta capillaries within the medulla is an important determinant of medullary oxygen delivery. The U-shaped configuration of these vessels ensures that the medullary osmotic gradient is maintained, such that solute entry and water loss in the descending branches is balanced by solute loss and water entry in the ascending branches ("countercurrent exchange"). Like solutes and water, oxygen can also diffuse directly from descending to ascending branches of the vasa recta, creating an environment of low oxygen tension in the medulla. This mode of oxygen shunting, coupled with low oxygen delivery and high metabolic activity, makes the medulla particularly prone to hypoxemia.

GLOMERULAR FILTRATION, RENAL BLOOD FLOW, AND METABOLISM

Glomerular Filtration Rate

The glomerulus initiates the formation of urine by producing a filtrate that enters the tubular lumen. The rate of filtrate production, the GFR, is determined by hydrostatic and oncotic pressure gradients between the glomerular capillary and Bowman space, in addition to the ultrafiltration coefficient, according to the equation:

$$GFR = k_f(P_{GC} + \pi_{BS}) - (P_{BS} + \pi_{GC})$$

where

P_{GC} = the hydrostatic pressure in the glomerular capillary
P_{BS} = the hydrostatic pressures in Bowman spaces
π_{GC} = the oncotic pressure in the glomerular capillary
π_{BS} = the oncotic pressure in Bowman spaces
k_f = the ultrafiltration coefficient, which reflects the permeability of the glomerular filtration barrier

In healthy young adults, the normal GFR is approximately 120–130 mL/min/1.73m^2. The proportion of plasma filtered across the glomerulus (the GFR divided by the plasma flow rate) is referred to as the *filtration fraction*. Under normal conditions, it is roughly 0.2.

The previous equation provides important insight into the manner in which different renal pathologies can all reduce GFR. For example, urinary obstruction leads to congestion in the tubular lumen, which increases P_{BS}. Hypovolemic shock decreases RBF, which lowers P_{GC}. Direct damage to the filtration barrier, such as from immunologic injury, initially causes the filtration barrier to become leaky, which increases k_f, but with time, the filtration barrier becomes occluded secondary to thrombosis, which reduces k_f. RBF does not directly determine GFR, but contributes indirectly by influencing P_{GC}. Increases in P_{GC}, π_{BS}, or k_f all raise the filtration fraction.

Renal Blood Flow

To maintain a stable RBF across a range of systemic arterial pressures, the kidney employs two main autoregulatory mechanisms: the myogenic reflex and TGF. The myogenic reflex arises from the physical properties of smooth muscle: increased intravascular volume stretches

TABLE 94.1 Site of Reabsorption of Water and Solutes Along the Nephron

	Site of Reabsorption	Contribution to Reabsorption
Sodium	Proximal tubule	60%–70%
	Loop of Henle	20%–30%
	Distal tubule	5%–10%
	Collecting duct	3%–5%
Water	Proximal tubule	60%–70%
	Loop of Henle	10%–20%
	Collecting duct	10%–20%
Bicarbonate	Proximal tubule	80%–90%
	Loop of Henle	10%–15%
	Collecting duct	0%–5%
Potassium	Proximal tubule	60%–70%
	Loop of Henle	20%–30%
	Distal tubule	0%–10%
	Collecting duct	0%–30%
Calcium	Proximal tubule	60%–70%
	Loop of Henle	20%–30%
	Distal tubule	5%–10%
	Collecting duct	5%–10%
Magnesium	Proximal tubule	20%–30%
	Loop of Henle	50%–60%
	Distal tubule	5%–10%
Phosphate	Proximal tubule	80%–90%
	Loop of Henle	5%–10%
	Distal tubule	0%–5%
Glucose	Proximal tubule	100%
Amino acids	Proximal tubule	100%
Urea	Proximal tubule	50%–60%
	Loop of Henle	(Secretion 50%)
	Collecting duct	50%–60%

TABLE 94.2 Effect of Vascular Mediators on Renal Blood Flow and Glomerular Filtration Rate

	Action	Effect	Δ RBF	Δ GFR
Sympathetic nervous system	Afferent > efferent arteriole vasoconstriction	↓ P_{GC}	↓	↓
	Decreased glomerular capillary surface area	↓ k_f		
Catecholamines[1]	Afferent arteriole vasoconstriction	↓ P_{GC}	↓	↓
	Efferent arteriole vasoconstriction	↑ P_{GC}		
Angiotensin-II[1]	Efferent > afferent arteriole vasoconstriction	↑ P_{GC}	↓	↔
	Mesangial cell contraction	↓ k_f		
Adenosine	Afferent arteriole vasoconstriction	↓ P_{GC}	↓	↓
	Efferent arteriole vasodilatation	↓ P_{GC}		
	Inhibition of renin release			
Natriuretic peptides	Afferent arteriole vasodilatation	↑ P_{GC}	↑	↑
	Efferent arteriole vasoconstriction	↑ P_{GC}		
Nitric oxide	Afferent arteriole vasodilatation	↑ P_{GC}	↑	↑
	Efferent arteriole vasodilatation	↓ P_{GC}		
PGE_2 and PGI_2 Histamine	Afferent > efferent arteriole vasodilatation	↑ P_{GC}	↑	↑
	Afferent arteriole vasodilatation	↑ P_{GC}	↑	↔
	Efferent arteriole vasodilatation	↓ P_{GC}		
Bradykinin	Afferent > efferent arteriole vasodilatation	↑ P_{GC}	↑	↔

GFR, Glomerular filtration rate; k_f, ultrafiltration coefficient of the glomerular filtration barrier; P_{GC}, hydrostatic pressure in the glomerular capillary; *PGE_2,* prostaglandin E_2; *PGI_2,* prostacyclin; *RBF,* renal blood flow.
[1]In states of vasodilatation and/or shock, these agents counteract alterations in vascular tone to restore RBF and preserve GFR.

arteriolar walls, which increases vascular smooth muscle contractile force to promote vasoconstriction. TGF responds to chemical stimuli. Increased renal perfusion pressure increases sodium delivery to the macula densa, which triggers the release of adenosine triphosphate (ATP) into the extracellular space and conversion of ATP to adenosine.[2,3] Adenosine causes vasoconstriction of the afferent arteriole and inhibits the release of renin from the juxtaglomerular apparatus. A reduction in renin reduces angiotensin II levels, inducing efferent arteriolar relaxation and reducing RBF and GFR. TGF is impaired by loop diuretics, renin-angiotensin-aldosterone system (RAAS) inhibitors, and in the setting of chronic kidney disease (CKD). Either the myogenic reflex or TGF may be overcome in the setting of critical illness with low renal perfusion pressure.

Autoregulatory mechanisms leverage the ability of the glomerular microcirculation to alter resistance in preglomerular and postglomerular vessels independently (Table 94.2). If afferent arterioles preferentially constrict, RBF, P_{GC}, GFR, and filtration fraction fall. If efferent arterioles preferentially constrict, RBF decreases but P_{GC}, GFR, and filtration fraction will increase because vascular resistance increases distal to the glomerulus. This is a key concept: net constriction or dilatation of afferent arterioles changes RBF and GFR in the same direction, whereas net changes in efferent arteriolar tone change RBF and GFR in opposite directions.

Renal Metabolism

The high metabolic demand of the kidney is driven by the active reabsorption of filtered solutes via the Na^+-K^+-ATPase pump. The density of these pumps is particularly high in the proximal tubule and thick ascending limb of the loop of Henle. The proximal tubule is dependent on aerobic metabolism (using fatty acids, ketone bodies, and amino acids as substrates) and is susceptible to hypoxia. The cells in this region generate glucose from lactate to provide substrate for the loop of Henle, where glycolytic capacity is high as a result of low ambient oxygen.

Disruption of bioenergetics and mitochondrial function is a major pathophysiologic event in the development of renal injury.

Measuring Glomerular Filtration Rate

GFR can be estimated by examining the clearance of any substance that is produced at a constant rate, only metabolized by the kidney, freely filtered at the glomerulus, and neither secreted nor reabsorbed along the tubule. The gold standard for measuring GFR is urinary inulin clearance (an exogenous filtration marker). However, this measurement requires continuous intravenous infusion, which is impractical in most clinical settings. Other exogenous filtration markers (e.g., Tc-DPTA) are available but are equally cumbersome. Although the clearance of the endogenous filtration marker creatinine is the most widely used approach to GFR in clinical practice, the physiology of critical illness may render it invalid for several reasons. First, creatinine is not produced at a constant rate in most critical illness states, and its concentration may be diluted by fluid resuscitation. Second, certain medications (e.g., sulfonamide antibiotics) alter tubular creatinine secretion, which affects creatinine concentration without reducing GFR. Third, equations to estimate GFR from plasma creatinine are not valid in critically ill patients. Cystatin-C, another endogenous marker, may perform better during acute illness because it is not dependent on muscle mass or metabolic activity. Cystatin-C is a plasma protein synthesized by nucleated cells at a constant rate and is almost completely filtered at the glomerulus. Older age, female sex, steroid use, and hyperthyroidism are associated with lower synthesis rates. However, the higher cost of cystatin-C and the lack of standardized assays limit its wider use.

Renal Functional Reserve

In states of increased stress and intact nephron mass, the kidney is capable of augmenting GFR and tubular function through nephron recruitment and increased RBF.[4] The difference between maximal capacity and baseline function is termed the *renal functional reserve.* Glomerular reserve can be quantified by measuring GFR at baseline and after an oral or intravenous protein load (1–1.2 g/kg) that stimulates RBF.[5] Tubular reserve can be assessed by administering intravenous furosemide ("furosemide stress test"), which is actively secreted in the proximal tubule. Natriuresis and increased urine flow confirm the integrity of tubular function.[6] In critically ill patients, this test has been used to predict progression of early acute kidney injury (AKI) and successful discontinuation of renal replacement therapy.[7] The role of recruitable renal functional reserve as a potential therapeutic target is being explored.[8]

PHYSIOLOGIC FUNCTIONS OF THE KIDNEY

Regulation of Sodium Reabsorption

Sodium is the principal determinant of extracellular volume. Almost all filtered sodium is reabsorbed along the course of the nephron. Sodium reabsorption is driven by the Na^+-K^+-ATPase on the basolateral membrane.[9] The enzyme maintains a low intracellular sodium concentration by moving sodium into the interstitium. This effect creates a gradient for the entry of sodium from the tubular lumen via transporters on the apical membrane (Fig. 94.2). The main site of sodium reabsorption is the proximal tubule, where apical sodium reabsorption occurs via solute-specific symporters (cotransport with glucose, amino acids, phosphate, citrate) and antiporters (cotransport with hydrogen ions). In the thick ascending limb, apical sodium is transported via the Na^+-K^+-$2Cl^-$ cotransporter, which is a key component of the countercurrent system. This cotransporter is the site of action for loop diuretics; mutations in this cotransporter are found in Bartter syndrome. Apical sodium reabsorption in the distal convoluted tubule occurs via the thiazide-sensitive Na^+-Cl^- cotransporter.[10,11] That cotransporter is the site of action of thiazide diuretics; mutations at that site are found in Gitelman syndrome.[12] In principal cells of the distal convoluted tubule and collecting duct, sodium is reabsorbed apically via the epithelial sodium channel (ENaC), which is the site of action of potassium-sparing diuretics.

Regulation of Water Reabsorption

Water is passively reabsorbed with sodium by specialized membrane channels called *aquaporins.* Aquaporin-1 channels are constitutively expressed on the apical and basolateral membranes of the proximal tubule and thin descending limb, making them highly permeable to water. The thick ascending limb and distal convoluted tubule have no aquaporin channels and are impermeable to water. In principal cells, apical aquaporin-2 channels (under the control of ADH) and basolateral aquaporin-3 and -4 channels absorb water.

Regulation of Free Water and Isotonic Fluid Volume

To maintain sodium and water balance, the kidney regulates two interdependent but distinct compartments: free water and isotonic fluid. Free water refers to water that is not associated with a dissolved particle. Isotonic fluid refers to fluid with a physiologic osmolarity of roughly 280–300 mOsm/L. Modelling free water and isotonic fluid as distinct components of total body fluid is useful to distinguish two physiologic states: dehydration and volume depletion. Dehydration refers to loss of free water. Volume depletion refers to loss of total body fluid, which can occur regardless of free water balance.

The free water compartment is primarily controlled by ADH release from the posterior pituitary in response to increased plasma osmolality or reduced mean arterial pressure. ADH exerts three main actions on the kidney: up-regulation of Na^+-K^+-ATPase activity in the loop of Henle, increased permeability of the inner medullary collecting duct to urea (reducing inner medullary osmolarity to as low as 600 mOsm/L), and increased insertion of aquaporin-2 channels into the apical membrane of the cells of the distal nephron. At very high levels, ADH is also a potent vasoconstrictor (i.e., vasopressin). Inappropriately high ADH secretion (i.e., syndrome of inappropriate ADH secretion) is a common cause of hypotonic hyponatremia. Reduced ADH secretion (i.e., central diabetes insipidus) or resistance to the action of ADH at the kidney (i.e., nephrogenic diabetes insipidus) leads to hypertonic hypernatremia. Because renal reabsorption of free water is almost exclusively driven by ADH, and because urine osmolarity has a reciprocal relationship with free water content, the urine osmolarity can be taken as a direct measure of renal ADH activity.

Isotonic fluid volume is regulated by the opposing actions of the RAAS and the natriuretic peptides. RAAS activation initiates with the release of renin from the juxtamedullary apparatus in response to three stimuli: decreased afferent arteriolar distention, decreased delivery of sodium to the macula densa, or increased renal sympathetic nervous system activity. Renin converts angiotensinogen (released from the liver) to angiotensin I, which is then converted to angiotensin II by the primarily endothelial-bound angiotensin-converting enzyme 1 (ACE 1). Angiotensin II induces vasoconstriction of efferent and afferent arterioles and contraction of mesangial cells, which reduces RBF. It acts directly on the early proximal tubule to increase sodium resorption via the Na^+-H^+ antiporter, which functionally represents the resorption of isotonic volume. Angiotensin II also promotes volume retention indirectly by stimulating aldosterone release by the adrenal granulosa. Aldosterone acts in the late distal convoluted tubule and collecting duct to increase sodium reabsorption by up-regulating the synthesis and membrane insertion of apical ENaC and

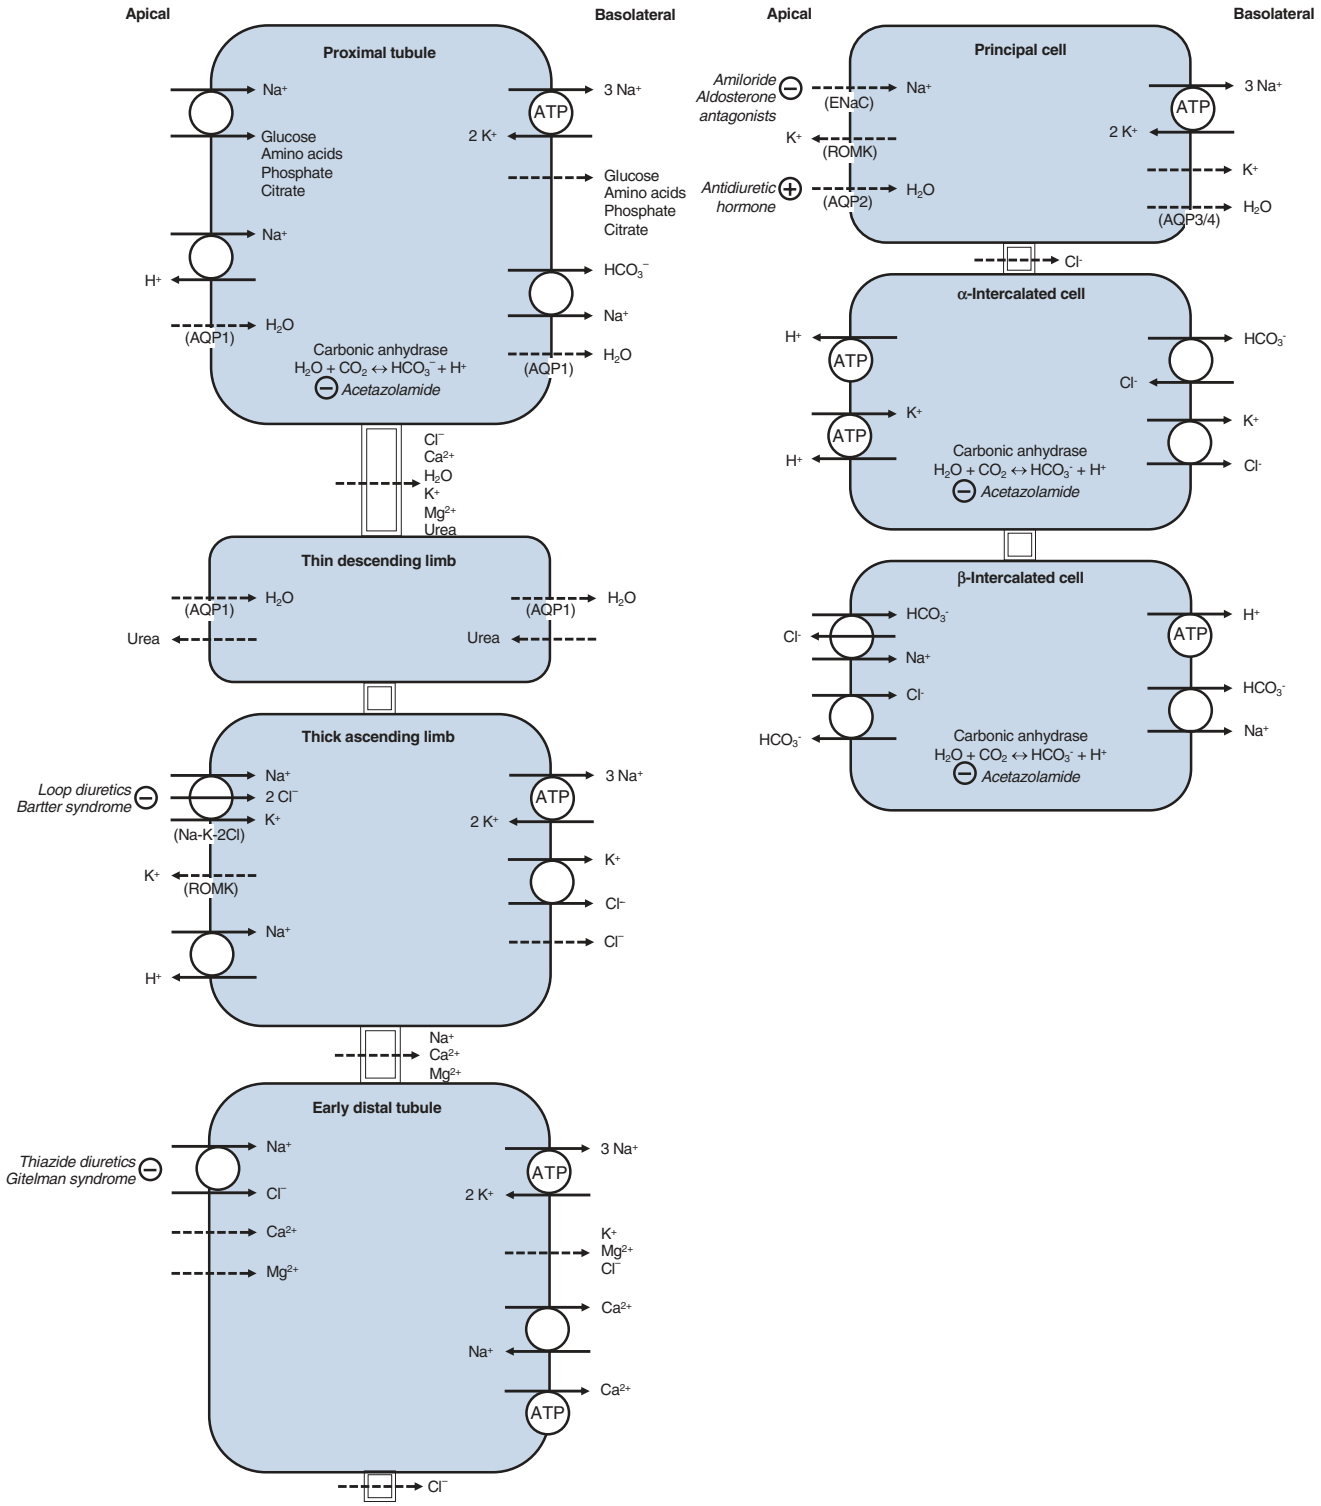

Fig. 94.2 Basolateral and apical receptors responsible for coordinating reabsorption of solutes and water along the course of the nephron.

enhancing the activity of the basolateral Na^+-K^+-ATPase. The net effect of RAAS activation in the kidney is therefore volume retention. Estimating RAAS activity is more complex than estimating ADH activity. Urinary sodium was classically felt to represent RAAS activation. However, this has many limitations in the intensive care setting and is unlikely to be reliable.

The volume-retaining properties of angiotensin II and aldosterone are opposed by the actions of the natriuretic peptides, such as atrial natriuretic peptide (ANP). These peptides have vasodilatory properties and reduce the total volume of body fluid by inducing natriuresis. Release of ANP is triggered by increased atrial stretch from volume expansion. At the glomerulus, ANP constricts the efferent arteriole,

dilates the afferent arteriole, and relaxes the mesangium, which increases RBF and GFR. In the proximal tubule, ANP reduces sodium reabsorption by inhibiting the Na^+-HCO_3^- cotransporter. In the late distal convoluted tubule, it directly inhibits the ENaC. ANP also reduces RAAS effects by inhibiting renin release. The net effect of ANP is therefore volume excretion.

To estimate the comparative excretion of free water and isotonic fluid, free water clearance can be calculated according to the equation:

$$ClH_2O = V - (U_{osm} \times V/P_{osm})$$

Where
V = urinary flow rate
U_{osm} = urinary osmolarity
P_{osm} = plasma osmolarity

When ClH_2O is positive, free water is being excreted in excess of isotonic fluid. When ClH_2O is negative, free water is being retained. This information can be used to diagnose inappropriate fluid retention or excretion, including occult diuretic resistance in patients who produce large urine volumes without significant natriuresis.

Regulation of Bicarbonate and Hydrogen Ion Movement

The kidney contributes to acid-base balance on many levels, the full biology of which is beyond the scope of this chapter. Central to this role, however, is its regulation of the movement of bicarbonate and hydrogen ions. The proximal tubule is the main site of bicarbonate reabsorption in the nephron. Intracellular water dissociates into hydrogen ions and OH^-. The electrochemical gradient generated by the Na^+-K^+-ATPase encourages secretion of hydrogen ions into the tubular lumen via the apical Na^+-H^+ exchanger. After entering the tubular lumen, hydrogen ions combine with filtered HCO_3^- to form carbonic acid (H_2CO_3). Carbonic acid dissociates into CO_2 and H_2O (under the action of luminal carbonic anhydrase), and both are passively reabsorbed into the cell. The OH^- generated by the dissociation of intracellular water combines with the reabsorbed CO_2 to form HCO_3^- (under the action of intracellular carbonic anhydrase), which is reabsorbed into the interstitium via the basolateral Na^+-HCO_3^- cotransporter. Impairments in Na^+-HCO_3^- transporter function produce type 2 renal tubular acidosis.

The alpha-intercalated cells of the distal convoluted tubule are the primary site for acid excretion. The apical H^+-ATPase drives secretion of hydrogen ions into the tubular lumen, where it combines with the remaining 10% of filtered HCO_3^-. Under the action of luminal and intracellular carbonic anhydrase, HCO_3^- is reabsorbed into the interstitium by the basolateral Cl^--HCO_3^- exchanger. Impaired function of the apical H^+-ATPase pump or basolateral Cl^--HCO_3^- transporter produce type 1 renal tubular acidosis. Luminal hydrogen ions also combine with urinary buffers (NH_3 to form NH_4^+ and HPO_4^{2-} to form $H_2PO_4^-$). Acid excretion in the distal nephron is further enhanced by the apical H^+-K^+-ATPase pump.

Regulation of Potassium

Potassium is reabsorbed passively via a paracellular mechanism in the proximal tubule and by paracellular and transcellular (Na^+-K^+-$2Cl^-$ and K^+-Cl^- cotransporter) pathways in the thick ascending limb. In the distal convoluted tubule and collecting duct, potassium can either be actively reabsorbed by intercalated cells (H^+-K^+-ATPase and K^+-Cl^- cotransporter) or secreted by principal cells. Secretion occurs under the control of aldosterone, which increases basolateral Na^+-K^+-ATPase activity and augments the number of open apical ENaC and potassium channels. Excessive renal potassium loss occurs in the setting of increased luminal flow to the distal nephron (e.g., loop or thiazide diuretics), volume depletion with activation of RAAS, Bartter or Gitelman syndromes, hyperaldosteronism, and types 1 and 2 renal tubular acidosis. Hyperkalemia caused by reduced renal excretion occurs with AKI, CKD, acidemia, potassium-sparing diuretics, RAAS inhibitors, or type 4 renal tubular acidosis.

Other Roles

The kidney is also involved in erythropoiesis and vitamin D metabolism. Erythropoietin is produced by peritubular fibroblasts in the juxtamedullary cortex in response to low oxygen tension and extracellular volume to achieve a hematocrit of ~45%.[13] Renal vitamin D metabolism involves the conversion of 25-hydroxyvitamin D (calcidiol) to 1,25-dihydroxyvitamin D (calcitriol) in the proximal tubules. Calcitriol acts on the gut, bone, and kidney to increase intestinal absorption of calcium, increase bone resorption, and reduce calcium and phosphate excretion. These functions are commonly compromised in the setting of CKD.

DIURETICS

The site of action, molecular target, and physiologic effect of commonly used diuretics in the intensive care unit (ICU) are summarized in Table 94.3.

TABLE 94.3 The Site of Action, Molecular Target, and Physiologic Effect of Commonly Used Diuretics

	Site of Action	Molecular Target	Physiologic Effect	Comments
Loop diuretics *Furosemide, bumetanide*	Thick ascending limb	Na^+-K^+-$2Cl^-$	Natriuresis 20%–25%	Highly protein-bound Enter tubule by secretion in proximal tubule Increase calcium excretion
Thiazide diuretics *Chlorothiazide, hydrochlorothiazide, chlorthalidone*	Distal tubule	Na^+-Cl^- cotransporter	Natriuresis ~5%	Partial inhibition of carbonic anhydrase and Cl^--HCO_3^- exchanger Increase calcium reabsorption
Potassium-sparing diuretics *Amiloride, spironolactone, eplerenone*	Distal tubule and collecting ducts	ENaC	Natriuresis 1%–2%	Amiloride directly blocks ENaC Spironolactone/eplerenone block the mineralocorticoid receptor, reducing synthesis of ENaC and Na^+-K^+-ATPase Hyperkalemia and mild metabolic acidosis
Carbonic anhydrase inhibitor diuretics *Acetazolamide*	Proximal tubule	Carbonic anhydrase	Minimal natriuresis	Reduced reabsorption of bicarbonate, sodium, and chloride Useful for correction of metabolic alkalosis

DISORDERS OF FUNCTION: ACUTE KIDNEY INJURY

Epidemiology

AKI is a clinical syndrome that describes the abrupt loss of GFR over 7 days or less. It affects as many as two-thirds of critically ill patients, of whom 10%–15% require renal replacement therapy. AKI is associated with early and late adverse outcomes.[14–16]

Etiology

AKI can be caused by processes that induce glomerular, tubular, or interstitial injury. In critically ill patients, common causes include shock, sepsis, trauma, cardiac or major noncardiac surgery, burns, cardiorenal or hepatorenal syndrome, or exposure to nephrotoxic agents. Injury is generally mediated by ischemia or direct toxicity.[17] Ischemic injury occurs in the context of sustained and significant alteration in RBF.[18] Reduced oxygen delivery disrupts mitochondrial function, which depletes cellular ATP. Nephron segments at greatest risk of ischemic injury include those with a high metabolic activity (e.g., proximal tubule and thick ascending limb) and those with lower physiologic oxygen tension because of their location in the medulla (e.g., thick ascending limb). Nephrotoxic injury occurs after exposure to exogenous or endogenous compounds that are directly toxic to the kidney or that alter renal hemodynamics.[19] Exogenous nephrotoxins include aminoglycosides, amphotericin, nonsteroidal antiinflammatory drugs (NSAIDs), and radiocontrast media. Endogenous nephrotoxins include hemoglobin or myoglobin.

Epithelial Cell Injury

Tubular epithelial cell injury arises because of ischemia, restoration of RBF (i.e., reperfusion), or direct cytotoxicity. It manifests as effacement and loss of the proximal tubule brush border, sloughing of tubular cells into the lumen, formation of casts from cell debris, obstruction and dilatation of the tubule, and back-leak of filtrate into the interstitium because of loss of adhesion molecules.[20,21] These changes impair solute reabsorption and increase the delivery of sodium chloride to the macula densa, leading to activation of the TGF mechanism with afferent arteriolar vasoconstriction and reduced GFR.[22] Increased sympathetic nervous activity and release of vasoconstrictors increase renal vascular resistance and further impair GFR.[23,24] Therapies aimed at reversing vasoconstriction (e.g., administration of low-dose dopamine or ANP) have failed to consistently influence AKI outcome.[25,26]

Endothelial Cell Injury

Injury to vascular endothelial cells impairs GFR via multiple mechanisms. Decreased production of nitric oxide synthase and prostaglandin impairs autoregulation; endothelial cell swelling and outer medullary congestion lead to hypoxia; dysregulation of the coagulation cascade damages the endothelial barrier function; and up-regulation of leukocyte adhesion molecules promotes neutrophil recruitment, release of proinflammatory mediators, and oxidative stress.[27,28] Cumulatively, these changes disrupt microcirculatory flow and further compromise oxygen delivery.

Oxidative Stress and Mitochondrial Injury

Oxidative stress and mitochondrial injury have emerged as important contributors to injury in AKI.[29,30] In highly oxidative states, such as in ischemia-reperfusion injury or after exposure to pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs), the formation of reactive oxygen species (ROS) and reactive nitrogen species (RNS) exceeds the capacity of counteractive antioxidant systems, which creates an environment of oxidative stress. High levels of oxidative stress damage the outer mitochondrial membrane, resulting in membrane permeabilization and the efflux of mitochondrial contents (including calcium, proapoptotic proteins, ROS, and RNS) into the cytoplasm. Release of ROS and RNS causes direct damage to lipids, proteins, and DNA. Influx of water and solutes from the cytoplasm into the mitochondrial matrix also occurs after membrane permeabilization. This promotes osmotic swelling and can lead to mitochondrial fragmentation and rupture.

The mitochondrial response to oxidative stress is to coordinate metabolic reprogramming: oxygen consumption is decreased, energy allocation is reprioritized, and mitophagy and cell-cycle arrest are initiated.[31] Clearance of damaged mitochondria by mitophagy is an adaptive change that may enhance cell survival.[32] Entering cell-cycle arrest is similarly protective because it prevents division of potentially damaged cells. Biomarkers of cell-cycle arrest (including TIMP-2 and IGFBP-7) have been proposed as early indicators of "renal stress" that could be used to detect the impending onset of AKI before creatinine elevation.[33] If oxidative stress is sustained and/or severe, programmed cell death may be initiated (i.e., apoptosis).[31]

Recovery After AKI

Renal injury activates a series of intrinsic repair processes, which may be adaptive or maladaptive. Adaptive repair involves cellular dedifferentiation, proliferation, migration, and differentiation to re-establish the structural integrity of the nephron and restore its function.[34] The capacity for adaptive repair is dependent on the availability of progenitor cells and surviving tubular epithelial cells, which are determined by the duration and severity of insult, and by baseline renal status.[35] Maladaptive repair describes a state of persistent inflammation with release of profibrotic cytokines, proliferation of myofibroblasts, deposition of extracellular matrix, and the development of interstitial fibrosis and tubular atrophy.[36] Vascular rarefaction and chronic ischemia culminate in glomerulosclerosis, loss of renal functional reserve, glomerular hypertension, and the development of acute kidney disease (AKD) and CKD.[37] AKD is the term used to describe the course of disease after AKI in patients in whom pathophysiologic processes in the kidney are ongoing or recurrent. It has been defined by the Acute Dialysis Quality Initiative (ADQI) group as a condition in which AKI is present for between 7 and 90 days after an inciting event. Studies suggest that the outcomes after AKD are at least as poor as after AKI.[38]

SPECIFIC ACUTE KIDNEY INJURY SYNDROMES

The purpose of this section is to provide an overview of key pathophysiologic processes for the most commonly encountered AKI syndromes in the ICU. A detailed description of the pathophysiologic processes underlying these syndromes, and within the context of the disorder as a whole, is outside the scope of this chapter.

AKI in Cardiac Surgery

The pathophysiology of AKI in cardiac surgery is multifactorial. Cardiopulmonary bypass induces injury through aortic cross-clamping (ischemia and reperfusion), loss of pulsatile flow, systemic inflammation, and hemolysis. Arterial cannulation can destabilize atherosclerotic plaques leading to embolism. Hemodynamic changes relating to cardiac dysfunction, severe bleeding, and administration of potent vasopressors worsen ischemia and oxidative stress. Perioperative administration of radiocontrast dyes, aminoglycoside antibiotics, loop diuretics, NSAIDs, and RAAS inhibitors may cause direct nephrotoxicity or impair autoregulation of renal blood flow.

AKI in Sepsis

Sepsis-induced AKI (SIAKI) is a specific pathophysiologic entity arising from the direct effect of sepsis on the kidney. Sepsis can also, however, cause AKI indirectly, through hypotension or therapies administered during resuscitation (e.g., antimicrobials, normal saline, or high-dose

vasopressors). The traditional paradigm of sepsis-induced renal ischemia caused by hypotension and vasoconstriction has been challenged by several pieces of emerging evidence. First, septic patients without hemodynamic instability still develop AKI. Second, plasma from septic patients induces cellular changes indicative of AKI in vitro. Third, RBF has been observed to increase (rather than decrease) in both animal and human studies.[39,40]

Recent evidence suggests that SIAKI reflects a complex interaction of renal macrocirculatory and microcirculatory dysfunction, increased inflammation and oxidative stress, activation of the coagulation cascade, and disordered cellular energetics. Despite an increase in cardiac output and RBF, vasodilatation of the efferent arteriole (possibly driven by inadequate angiotensin signaling) creates a condition of low postglomerular pressure, which reduces GFR.[41,42] Blood flow to the kidney is also believed to be more heterogeneous in sepsis, with variable expression of inducible nitric oxide synthase promoting intrarenal shunting of blood from the ischemia-prone medulla to the cortex.

Release of PAMPs and DAMPs by pathogens and injured cells, and their recognition by Toll-like receptors, triggers proinflammatory mediator release, leukocyte adhesion, platelet activation, and initiation of the clotting cascade. Enhanced ROS generation coupled with antioxidant depletion contributes to oxidative stress and uncoupling of mitochondrial respiration in the proximal tubule and its surrounding microvasculature. Although apoptosis can occur, it is not a prominent histologic feature of SIAKI.[43]

AKI in Rhabdomyolysis

AKI is a common complication of rhabdomyolysis. After muscle injury, myoglobin is released from skeletal muscle, freely filtered by the glomerulus, and metabolized by epithelial cells. When the capacity for metabolism is exceeded, myoglobin appears in the urine, becomes concentrated along the nephron, and precipitates with the Tamm Horsfall protein in the distal convoluted tubule. Experimental models suggest that renal injury is mediated by hypovolemia from sequestration of fluid in injured muscles, intrarenal vasoconstriction from activation of the RAAS, direct injury to proximal tubule cells from free chelatable iron, and obstruction of the distal convoluted tubules by casts.[44] An acidic urine promotes proximal tubule injury and cast formation.[45] Although weakly correlated to creatinine kinase level, the risk of AKI appears to be low when peak levels are below 15,000–20,000 U/L.[46]

AKI Resulting From Drug Toxicity

Many drugs commonly used in critically ill patients can cause AKI. Aminoglycosides are filtered by the glomerulus and enter proximal tubule cells by endocytosis. Cytoplasmic aminoglycoside acts directly and indirectly on mitochondria to disrupt ATP production and initiate apoptosis.[47] NSAIDs can contribute to renal injury by causing interstitial nephritis or by reducing production of prostaglandins, which reduces renal perfusion and is especially relevant in states of reduced RBF.[48] Amphotericin B is believed to cause both toxic and ischemic injury.[49] It creates pores in the cell membrane of proximal tubular cells, which allows back-diffusion of hydrogen ions (which impairs urinary acidification) and triggers apoptosis (which decreases renal concentrating ability and increases potassium wasting). Afferent arteriolar vasoconstriction mediated by TGF reduces RBF and GFR and causes medullary hypoxia. Vasoconstriction may be attenuated by salt loading, which reduces the sensitivity of the TGF system. Administration of contrast media can cause AKI by increasing the concentrations of adenosine, endothelin, and intracellular calcium, which cause afferent arteriolar vasoconstriction.[50] In the past, use of high-osmolality compounds also induced diuresis and natriuresis by activating the TGF mechanism. In hospitalized patients, AKI occurring shortly after administration of iodinated contrast may or may not be causally related.

AKI in Cardiorenal Syndrome

Cardiorenal syndrome describes the bidirectional interaction between the function of the heart and kidney. Of its five subtypes, type 1 cardiorenal syndrome describes the processes through which acute heart failure can precipitate AKI. Right heart dysfunction leads to increased renal venous pressure, whereas left ventricular dysfunction is associated with a low cardiac output state. These hemodynamic derangements trigger a variety of compensatory mechanisms, including activation of the RAAS and sympathetic nervous system and increased release of ADH (i.e., vasopressin) and endothelin. The result is vasoconstriction, sodium and water retention (with urinary sodium generally <25 mEq/L), decreased renal perfusion, and ischemia. In some patients, diuretic therapy may decrease GFR because of a decline in ventricular preload, whereas in other patients, diuretic therapy may increase GFR by reducing renal venous pressure.

AKI in Hepatorenal Syndrome

Hepatorenal syndrome represents an end-stage complication of cirrhosis with severe portal hypertension. Portal hypertension creates significant hemodynamic derangement, characterized by marked splanchnic arterial vasodilation, a progressive rise in cardiac output, and a fall in systemic vascular resistance. These changes trigger intense activation of the RAAS and sympathetic nervous system, leading to intrarenal vasoconstriction, a decline in GFR, increased sodium resorption, and the development of ascites. Although cardiac output initially increases, eventually the cardiac output is insufficient to compensate for the degree of vasodilation. Hepatorenal syndrome is frequently accompanied by electrolyte and acid-base disturbances, including hypervolemic hyponatremia, hypokalemia, and an anion gap metabolic acidosis.

KEY POINTS

- The functional unit of the kidney, the nephron, is composed of a filtering unit (glomerulus), several specialized segments for the reabsorption of solutes and water (proximal tubule, loop of Henle, and distal convoluted tubule), and a collecting duct.
- Blood flow to the kidney is tightly controlled by sophisticated autoregulatory mechanisms, which preserve the GFR and renal oxygen delivery across a range of systemic arterial pressures.
- Sodium is the principal determinant of extracellular volume, and its reabsorption is regulated by the opposing actions of the RAAS and natriuretic peptides.
- Because energy is required for the active reabsorption of solutes, renal function is dependent on metabolism and the kidney is prone to hypoxic, ischemic, and oxidative injury.
- AKI describes the abrupt reduction in GFR that occurs because of one or more insults that damage tubular epithelial and vascular endothelial cells and disrupt mitochondrial function.

ANNOTATED REFERENCES

Chawla LS, Davison DL, Brasha-Mitchell E, et al. Development and standardization of a furosemide stress test to predict the severity of acute kidney injury. *Crit Care.* 2013;17:207.

This cohort study of critically ill patients investigated the impact of administering a dose of furosemide to individuals with early AKI to assess their progression to stage 3 AKI. They found that the furosemide stress test performed well as an assessment of tubular function and had reasonable predictive capacity to identify patients with severe and progressive AKI.

Gottschalk CW, Mylle M. Micropuncture study of the mammalian urinary concentrating mechanism: Evidence for the countercurrent hypothesis. *Am J Physiol.* 1997;196:927–936.

This basic science study described the differences in fluid osmolality between each nephron segment and vasa rectas of various rodents, confirming the hypothesis that the mammalian nephron functions as a countercurrent multiplier system.

Langenberg C, Bellomo R, May C, et al. Renal blood flow in sepsis. *Crit Care.* 2005;9(4):363–374.

This systematic review of studies describing changes in renal blood flow in human and experimental sepsis identified that cardiac output was a key determinant of renal blood flow during sepsis. In the setting of decreased cardiac output, renal blood flow was typically decreased, whereas in the setting of increased cardiac output, renal blood flow was maintained or increased. This provides important insight into the nature of renal blood flow in sepsis.

Sun D, Samuelson LC, Yang T, et al. Mediation of tubuloglomerular feedback by adenosine: Evidence from mice lacking adenosine 1 receptors. *Proc Natl Acad Sci U S A*. 2001;98:9983–9988.

Using mice lacking adenosine 1 receptors, this study demonstrated the central role of adenosine in juxtaglomerular signalling through the tubuloglomerular feedback mechanism in response to an increase in loop of Henle flow rate.

Tumlin JA, Murugan R, Deane AM, et al. Outcomes in patients with vasodilatory shock and renal replacement therapy treated with intravenous angiotensin II. *Crit Care Med*. 2018;46:949–957.

A post hoc analysis of the ATHOS-III randomized trial of angiotensin II in catecholamine-resistant vasodilatory shock provided important insight into the role of angiotensin signaling in SIAKI. The authors observed that patients with an elevated serum angiotensin I/angiotensin II ratio were more likely to have AKI, that patients receiving continuous renal replacement therapy (CRRT) at enrollment who received angiotensin II had a greater than 20% absolute survival advantage, and that markedly elevated serum renin levels appeared to identify a subset of treatment responsive vs. nonresponsive patients.

Clinical Assessment of Renal Function

Jason Kidd, Kate S. Gustafson, and Todd W.B. Gehr

Five to fifteen percent of patients in intensive care units (ICUs) experience acute deterioration in renal function.[1,2] Renal dysfunction substantially adds to the morbidity and mortality of critically ill patients. Moreover, changes in renal function directly affect drug clearance. Thus a means to assess renal function is essential for the optimal management of patients with critical illness. This chapter reviews selected aspects of renal physiology with an emphasis on measurement of renal function, consequences of altered function, and approaches to improving renal function. The focus is on measurement and optimization of glomerular filtration rate (GFR) and renal blood flow (RBF).

RENAL BLOOD FLOW

Under physiologic conditions, blood flow to the kidneys is approximately 20% of the cardiac output. This high rate of blood flow (1–1.2 L/min) is particularly remarkable because the kidneys make up just 0.5% of the total body weight. The high blood flow rate is caused by, at least in part, the unique anatomic arrangement of the renal vasculature, with the interlobar and arcuate vessels offering little resistance to flow. The interlobular arteries originate from the arcuate vessels in a parallel arrangement, and the afferent arterioles also arise in a parallel arrangement from the interlobular vessels. It is this parallel arrangement that accounts for the low resistance in the RBF because the total resistance of n equals parallel paths, each with a resistance R, which is R/n^3. The major resistance vessels in the kidney are the afferent and efferent arterioles that bind the glomerular capillary network. Although total resistance is a function of resistance across each of these vessels, it is a unique feature of the kidney that variations in individual resistances across the afferent and efferent arterioles may lead to alterations in glomerular capillary pressure and, hence, the GFR.[3]

Despite a wide range of perfusion pressures, under most conditions, the RBF and GFR are relatively constant, a process described as autoregulation. The term *autoregulation* generally refers to the relative constancy of the GFR over a range of perfusion pressures and to the regulation of RBF. Emphasis has been placed on the preglomerular vasculature, mainly the afferent arterioles, as the major site at which renal perfusion is regulated. However, studies also suggest that the larger vessels, such as the interlobular vessels, respond to a variety of vasoactive stimuli and participate in an autoregulatory phenomenon. A variety of hypotheses have been generated to explain the autoregulatory response of the kidney with respect to the RBF. There is evidence to suggest that neural, humoral, or intrarenal factors are involved in the regulation of renal circulation.[4]

The renin–angiotensin pathway has a significant effect on renal hemodynamics. Renin, which is elaborated in the juxtaglomerular cells, is released in response to a decrease in renal perfusion pressure and to altered sodium chloride delivery to the ascending limb and macula densa cells. Increased renin secretion leads to augmented angiotensin II (AII) formation at the local nephron level. AII affects renal vascular resistance through modulation of both afferent and efferent arterioles, with the major effect being on the efferent arterioles.

Renal eicosanoids affect renal hemodynamics. Eicosanoids are biologically active fatty acid products of arachidonic acid and are synthesized in the kidney in response to a variety of stimuli, with local release and effect on the renal vasculature. Stimulation of the cyclooxygenase pathway and prostaglandin synthetases leads to the formation of endoperoxides (PGG_2 or PGH_2), prostaglandins (PGD_2, PGE_2, $PGF_{2\alpha}$, or PGI_2), and thromboxane A_2 (TXA_2). Leukotrienes are synthesized through a pathway involving the enzyme lipoxygenase. In the kidney, the major products of arachidonic acid metabolism are PGE_2 and PGI_2 and, to a lesser extent, $PGI_{2\alpha}$. These compounds have a predominant effect of relaxing renal vascular smooth muscle and lead to vasodilatation, whereas TXA_2 is a vasoconstrictor prostanoid. It is believed that in disease states, endogenous vasodilator prostaglandins have a protective function to maintain renal perfusion and the GFR in response to vasoconstrictor stimuli, including AII and enhanced sympathetic nervous system activity. In contrast, release of vasodilatory prostaglandins is inhibited by nonsteroidal anti-inflammatory drugs.

Other vasoactive compounds that affect renal circulation include plasma and glandular kallikreins and kinins and endothelium-derived vasoactive factors, such as nitric oxide and endothelin.[4] Among the catecholamines, α- and β-adrenergic agonists are known to affect renal vascular tone by causing vasoconstriction and vasodilatation, respectively. In addition, dopamine in low doses leads to renal vasodilatation. Atrial natriuretic peptide and purinergic agents, such as adenosine, have also been shown to participate in modulating renal circulation.

The effect of vasoactive mediators on renal circulation is likely to be influenced by changes in salt intake and extracellular fluid (ECF) volume and by hydration status. For example, the influence of AII on renal hemodynamics is greater in sodium depletion, which activates the sympathetic nervous system. In response to mild nonhypotensive hemorrhage, renal hemodynamics are relatively well maintained. However, with further reductions in volume associated with more severe hemorrhage, renal ischemia mediated by activation of the renin–angiotensin system, renal efferent adrenergic nerves, and circulating catecholamines may occur.[4]

Modification of dietary protein and amino acid intake may affect renal hemodynamics. Dietary protein intake in excess of 1 g/kg/day has been associated with renal vasodilatation, as have infusions of casein hydrolysates and amino acids.[5,6] Conversely, chronic consumption of a low-protein diet may be associated with renal vasoconstriction.

Measurement of Renal Blood Flow

The RBF is measured conventionally by the clearance of infused para-aminohippurate (PAH), which is cleared almost totally from the

arterial plasma by both filtration and secretion. Thus its clearance approximates the rate of renal plasma flow (RPF):

$$RPF = U_{PAH} \bullet V/P_{PAH}$$

where U_{PAH} and P_{PAH} refer to urine and plasma PAH concentration, respectively, and V is the urine flow rate in milliliters per minute.

The RBF can be estimated by correction for hematocrit (Hct):

$$RBF = RPF/[1-Hct]$$

Although available, this test is rarely used in clinical practice. In fact, direct quantitation of the RPF and RBF is rarely indicated outside research studies; however, sometimes it is necessary to document that the kidneys are being perfused. In this case, one of three additional methods may be used: (1) selective arteriography, including computed tomography (CT) angiography and magnetic resonance (MR) angiography, (2) Doppler ultrasonography, and (3) external radionuclide scanning. Because the latter two methods are noninvasive, they are preferred. With respect to the nuclide study, until recently, scanning was usually performed using ^{125}I-iodohippurate sodium; however, the poor radiologic characteristics of ^{131}I limit its use in renal imaging.[7] More recent evidence suggests that other agents, such as ^{127}I-orthoiodohippurate and ^{99m}Tc-L,L-ethylenedicysteine, are superior to ^{125}I-iodohippurate sodium.[7,8]

Clinical Correlates

Although a significant amount of data has been obtained to indicate a complex relationship between neurocirculatory factors and renal hemodynamics, several points can be made from a clinical perspective. Optimization of cardiac output and ECF volume, including the intravascular space, is essential for the maintenance of renal perfusion. In particular, because the effects of vasoactive compounds such as AII and catecholamines are accentuated in the presence of renal hypoperfusion and volume contraction, attention should be given to the assessment of ECF volume, with correction of any deficits, and to optimize cardiac function. Frequently, pharmacologic agents have been employed to maintain renal perfusion in situations in which this may be compromised. Specifically, there has been widespread use of the so-called *low-dose* or *renal-dose dopamine infusions.* This is based on the observation that in low doses (<3 μg/kg/min), dopamine leads to renal vasodilatation.[9] At higher doses, renal vasoconstriction may occur.

The beneficial effects of dopamine infusion have not been documented in patients who exhibit evidence of intravascular volume depletion, and the use of dopamine has been shown to be ineffective beyond a short period of infusion.[9–11] Thus although infusions of renal-dose dopamine for 24–36 hours may be beneficial under the appropriate circumstance, there is no evidence supporting the long-term use of this agent. Furthermore, reports suggest that adverse outcomes are associated with the use of dopamine.[11] In patients with acute decompensated heart failure and renal dysfunction, the addition of low-dose dopamine did not enhance decongestion or improve renal function when added to diuretic therapy.[12] Continuous infusions of fenoldopam mesylate, a potent dopamine A_1 receptor agonist, have been employed in an attempt to preserve renal function in a variety of clinical settings. A meta-analysis of 16 randomized trials in critically ill patients showed that fenoldopam significantly reduced the risk of acute kidney injury, need for renal replacement therapy, and in-hospital death.[13]

Beyond anecdotal evidence, there are no compelling data to support the use of other potential vasodilator substances such as prostaglandins. Although high-protein feeding and amino acid infusions may increase the RBF by undefined mechanisms, there is no justification in using these therapies solely from a hemodynamic point of view.[5,6]

GLOMERULAR FILTRATION RATE

Of the 500–700 mL of plasma delivered per minute to the kidneys (corresponding to an RBF of 1–1.2 L/min), 20%–25% is filtered. Glomerular filtration is a major function of the kidney and averages approximately 130 mL/min/1.73 m^2 in normal males and 120 mL/min/1.73 m^2 in normal females. Estimation or direct assessment of the GFR remains one of the most important measurements of renal function and is widely used in clinical practice.

Measurement of Glomerular Filtration Rate

The GFR is classically measured as the clearance of inulin (C_{In}), a fructose polymer with a mean molecular weight of approximately 5 κDa. Because this substance is not present endogenously, it must be given by constant infusion after a loading dose. Inulin is available commercially but is expensive, often difficult to obtain, and cumbersome to use. As a result, the C_{In} is rarely used in clinical practice except for research protocols. Although the C_{In} is generally measured chemically, ^{3}H- and ^{14}C-labeled inulins are also available but are expensive.

Other radiolabeled nuclides have been found to be satisfactory substitutes for inulin and have advantages in the measurement of GFR.[7,8,14,15] In particular, ^{99m}Tc-labeled diethylenetriamine pentaacetic acid (DTPA) and ^{125}I- or ^{131}I-labeled iothalamate clearances closely approximate C_{In}.[16,17] ^{99m}Tc-DTPA has been used and found to give values that correlate closely with the C_{In} in ICU patients.[18,19] In addition, the clearance of gentamicin has been used in a limited fashion to measure GFR.[20,21] At the present time, it is not common for the GFR to be measured directly. Rather, the GFR is estimated by endogenous creatinine clearance (C_{Cr}) or serum creatinine determination (see later discussion).

The normal values for the GFR obtained previously apply for individuals from teenage years through approximately 35 years. Thereafter, the GFR declines in most individuals. Although this decline was formerly thought to occur at a relatively constant rate of approximately 10 mL/min per decade,[22–24] more recent data obtained in a longitudinal manner indicate that this reduction is not so predictable.[25] In addition, a circadian rhythm for GFR has been described.[26,27] GFR is maximal in the day, whereas a minimal value during the night has been found in normal individuals. It is not known whether this circadian pattern of GFR occurs in critically ill hospitalized patients.

CREATININE CLEARANCE AND SERUM CREATININE

Creatinine Clearance

The C_{Cr} enjoys widespread use as a reasonable gauge of GFR when great precision is not demanded, which it rarely is in clinical practice. The use of creatinine as a marker of the GFR has the advantage that creatinine is endogenously produced and easily measured by inexpensive methods. Creatinine, like inulin, is freely filtered and absorbed minimally, if at all, by the tubules. However, creatinine is secreted, and the contribution of secretion to total excretion is greater as the GFR decreases and serum creatinine rises. At GFRs below 40 mL/min, the C_{Cr} exceeds the C_{In} by 50%–100%.[16,28] When GFR is significantly depressed and it is deemed important to get a more precise measurement of GFR, one of the previously mentioned methods to estimate the GFR directly might be used. Additionally, because the C_{Cr} overestimates the GFR and the clearance of urea underestimates the GFR, the mean value of simultaneously obtained creatinine and urea clearances has been shown to provide a close estimation of the C_{In} when the latter is below 20 mL/min.[29]

Because cimetidine competes with creatinine for tubular secretion (see later), administration of cimetidine may increase the accuracy of both creatinine clearance in 24-hour collections (when given for several days beforehand) and 4-hour, water-loaded clearances.[30–32] Taking advantage

of this effect results in a more accurate estimate of the GFR. Specifically, the C_{Cr} obtained in the presence of cimetidine (400 mg as a priming dose followed by 200 mg every 3 hours) yielded values that closely approximate C_{In}.[30,31] Volume expansion in humans causes a small rise in the GFR, whereas volume depletion, severe heart failure, hypotension, anesthesia, surgery, trauma, sepsis, and even mild intestinal bleeding without frank hypotension may depress the GFR substantially.

Various methods are available to measure creatinine. Creatinine is frequently measured using the Jaffé alkaline picric acid reaction. Although this method is widely used, this reaction also measures other chromogens, which may lead to a false elevation in the estimated serum creatinine (S_{Cr}) measurement. Substances such as acetoacetate (in ketoacidosis), pyruvate, ascorbate, 5-flucytosine, certain (but not all) cephalosporin antibiotics, and very high urate artifactually raise S_{Cr} in normal subjects by 0.5–2 mg/dL.[33–39] These substances are excreted into the urine but contribute trivially compared with overall urine creatinine (U_{Cr}). Thus noncreatinine chromogens affect the S_{Cr} but have little effect on the U_{Cr}.

In individuals with normal renal function, the contribution of serum noncreatinine chromogens in raising the S_{Cr} is approximately equal to the contribution of secretion to creatinine excretion, such that the C_{Cr} closely approximates the GFR. As the GFR decreases, the contribution of noncreatinine chromogens to the total measured S_{Cr} becomes less than the secreted moiety, and the C_{Cr} overestimates GFR to a greater extent. Direct enzymatic creatinine measurements are not affected by noncreatinine chromogens. Very high levels of serum glucose (>1000 mg/dL) and 5-flucytosine may interfere with the enzymatic reaction, whereas high levels of bilirubin (>5 mg/dL) affect the autoanalyzer method[37] and lead to falsely low S_{Cr} values. The use of catecholamines—particularly dopamine and dobutamine—can underestimate serum creatinine concentrations by some enzymatic methods.[38] It is therefore important to know the method by which a given laboratory measures S_{Cr}. Competing for the same proximal tubular organic base secretory site as creatinine, certain pharmacologic agents may suppress this process and lead to a rise in the S_{Cr}. Trimethoprim, probenecid, dronedarone, pyrimethamine, salicylate, antiretroviral agents, cobicistat, many chemotherapeutic agents (olaparib, rucaparib, imatinib, bosutinib, sorafenib, sunitinib, crizotinib, gefitinib, pazopanib), and cimetidine, but not ranitidine, are organic bases that inhibit creatinine secretion competitively and can result in a mild elevation in the S_{Cr}, usually 0.5 mg/dL or less.[39–43]

As with all clearance methods, the C_{Cr} is subject to errors that may amount to as much as 10%–15%. In addition to potential problems in estimating the S_{Cr} and U_{Cr}, errors in timing of urine collection, incomplete collection, and inaccurate measurement of urine volume are other factors that contribute to errors.[44] Although 24-hour U_{Cr} clearances have been widely used, no specified period is required for the clearance to be obtained. In fact, shorter collection periods of several hours may be more accurate in patients passing adequate amounts of urine (not oliguric), particularly if the patient is not in a steady state (see later). To reduce errors in volume measurement, one can induce water diuresis in stable subjects before beginning the test,[45] although this is rarely practical in the ICU setting. Nevertheless, because many ICU patients have indwelling Foley catheters, it should be possible for accurately timed urine collections to be obtained and for the C_{Cr} to be measured with reasonable accuracy.

Serum Creatinine

Because of the practical and technical problems in obtaining estimates of the GFR by clearance methods, renal function is most commonly estimated by following the S_{Cr} in hospitalized patients. Creatinine is formed nonenzymatically from creatine and phosphocreatine in skeletal muscle cells and is normally present in the serum at a concentration of 0.8–1.4 mg/dL in adults and 0.3–0.6 mg/dL in children and pregnant subjects. This process is irreversible, is temperature and pH dependent, and occurs at a constant rate. The measured S_{Cr} depends on the method of measurement, as discussed previously, the GFR, rate of creatinine production, volume of distribution (e.g., S_{Cr} is lower in anasarca), and extent of its tubular secretion and intestinal degradation.[3] Because creatinine production is closely related to muscle mass, the S_{Cr} is generally less in females than in males and decreases as muscle mass is lost with aging or debilitating illnesses.

The relationship between the S_{Cr} and C_{Cr} (and hence GFR) can be described by a rectangular hyperbola[44]; however, this relationship applies in the steady state and assumes a constant rate of creatinine production (Fig. 95.1). Thus a doubling of the S_{Cr} reflects a 50% decrease in C_{Cr}, a fourfold increase in the S_{Cr}, a 75% drop in the GFR, and so on. Because creatinine production may not remain constant, the S_{Cr} may underestimate the decrease in GFR in critically ill patients who have a decrease in muscle mass secondary to an ongoing catabolic state. Moreover, it should be appreciated that the S_{Cr} is an insensitive marker of change early in the course of renal disease. Thus a 33% fall in the GFR may raise the S_{Cr} from 0.8 to 1.2 mg/dL, a value still within the normal range. If the prior value is not known, this fall in the GFR may go unrecognized.

The S_{Cr} provides a close estimate of the GFR only in the steady state. With an abrupt decrease in the GFR, as may occur in acute renal failure, creatinine production would be expected to continue unchanged, but because of the decrease in the GFR, creatinine excretion will be impaired. As a result, the S_{Cr} increases until a new steady state is obtained, at which time the amount of creatinine produced equals the amount filtered (GFR − S_{Cr}) and excreted (U_{Cr} − V). Depending on the extent of damage and decrease in the GFR, it may take several days for a new steady state to be achieved. Therefore after an insult leading to an abrupt decrease in the GFR, the S_{Cr} rises progressively over the next several days. This should not be interpreted as a new insult each day, but rather that a steady state has not yet been obtained. While the S_{Cr} is changing, its absolute value cannot be used as an accurate measure of the decrease in the GFR. If an accurate measurement of the GFR is needed during this time, a short C_{Cr} can be obtained.

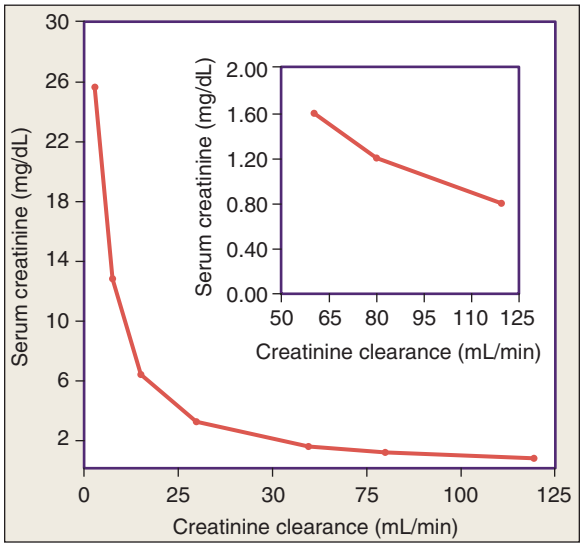

Fig. 95.1 Relationship Between Creatinine Clearance and Serum Creatinine. In steady state, serum creatinine should increase twofold for each 50% reduction in creatinine clearance. *Inset* represents enlarged view of changes in serum creatinine as creatinine clearance decreases from 120 to 60 mL/min. If serum creatinine is 0.8 mg/dL when creatinine clearance is 120 mL/min, creatinine clearance can decrease by 33% such that increased serum creatinine is still within normal range.

Many equations have been developed to estimate the C_{Cr} based on the S_{Cr} without collection of urine.[46,47] Box 95.1 is a compilation of the more commonly used equations.[48] These equations generally take into consideration muscle mass (estimated as body weight), sex (males having a higher GFR than females), and age. Aging, hepatic diseases, excessive muscle wasting, severe muscular atrophy or dystrophy, hyperthyroidism, paralysis, and chronic glucocorticoid therapy are associated with reduced creatinine generation.[18] In addition, particularly at low levels of GFR, correction for nonrenal creatinine metabolism is recommended.[49,50] One of the most commonly used equations is that developed by Cockcroft and Gault[51]:

$$C_{Cr} = \frac{(140 - \text{age}) \bullet \text{lean wt in kg}}{72 \bullet S_{Cr}}$$

where age is expressed in years. The preceding expression is used for men. The formula for women is the preceding formula multiplied by 0.85.

The reliability of the Cockcroft-Gault equation as a measure of the GFR has been assessed in patients with diabetes, pregnant women with renal disease,[52] obese individuals,[53] elderly individuals,[54,55] and African Americans with hypertensive renal disease.[56] It has also been assessed in critically ill patients.[57] These studies have indicated that the accuracy of GFR estimates using the Cockcroft-Gault equation is similar to or greater than 24-hour C_{Cr} and that the precision is better. This equation seems to be most accurate for estimating the GFR when the latter is in the range of 10–100 mL/min.[53,56,57] The advantage of this formula is that it is simple and underscores the essential determinants of C_{Cr}.

The Modification of Diet in Renal Disease (MDRD) study equation previously gained widespread acceptance by most clinical laboratories, which now routinely report estimated GFRs across populations when serum creatinine testing is ordered.[58–60] Major limitations included imprecision and underestimation of the measured GFR at high GFRs (GFR >60 mL/min/1.73 m^2). The MDRD equation is generally more precise than the Cockcroft-Gault equation.[61]

Limitations at higher GFRs prompted a further modification by the Chronic Kidney Disease Epidemiology Collaboration Research Group.[62] This equation offers improved precision, especially with higher GFRs up to 90 mL/min/1.73 m^2.

Serum Cystatin C

Because of the limitations in using creatinine as a marker for the GFR, there has been an ongoing search for alternative GFR markers. To this end, cystatin C has emerged as a possible candidate biomarker. Cystatin C is a low-molecular-weight protein of 13.3 kDa and is expressed by all nucleated cells. It is cleared by glomerular filtration and metabolized in the kidney. And it is not secreted by the tubules like creatinine. Serum cystatin C levels are minimally affected by demographics such as race and muscle mass. Although initially thought to be an ideal GFR marker, a number of factors may influence cystatin C levels other than GFR. These include hyperthyroidism, malignancy, corticosteroid use, diabetes mellitus, leukocyte count, albumin concentration, and C-reactive protein levels. Despite such limitations, cystatin C use is increasing and analytical methods are standardized. Cystatin C, like creatinine, has been employed in equations that more accurately estimate the GFR. By using both creatinine and cystatin C, even more accuracy in determining the GFR can be obtained, especially in populations with higher baseline levels for GFR. Cystatin C will likely continue to emerge as an important biomarker for the estimation of GFR and the CKD-EPI cystatin C calculation became more commonly used.[63]

BOX 95.1 Common Equations for Estimating Glomerular Filtration Rate or Creatinine Clearance

Cockcroft-Gault (C_{Cr} • BSA/1.73 m^2)

For men: $C_{Cr} = [(140 - \text{age}) \bullet \text{weight(kg)}]/S_{Cr} \bullet 72$

For women: $C_{Cr} = ([(140 - \text{age}) \bullet \text{weight (kg)}]/S_{Cr} \bullet 72) \bullet 0.85$

Jellife (1) (C_{Cr} • BSA/1.73 m^2)

For men: $(98 - [0.8 \bullet (\text{age} - 20)])/S_{Cr}$

For women: $(98 - [0.8 \bullet (\text{age} - 20)])/S_{Cr} \bullet 0.90$

Jellife (2)

For men: $(100/S_{Cr}) - 12$

For women: $(80/S_{Cr}) - 7$

Mawer

For men: $\text{weight} \bullet [29.3 - (0.203 \bullet \text{age})] \bullet [1 - (0.03 \bullet S_{Cr})]$

For women: $\text{weight} \bullet [25.3 - (0.175 \bullet \text{age})] \bullet [1 - (0.03 \bullet S_{Cr})]$

Bjornsson

For men: $[27 - (0.173 \bullet \text{age})] \bullet \text{weight} \bullet 0/S_{Cr}$

For women: $[25 - (0.175 \bullet \text{age})] \bullet \text{weight} \bullet 0.07/S_{Cr}$

Gates

For men: $\left(89.4 \bullet S_{Cr}^{-1.2}\right) + \left(55 - \text{age}\right) \bullet \left(0.447 \bullet S_{Cr}^{-1.1}\right)$

For women: $\left(89.4 \bullet S_{Cr}^{-1.2}\right) + \left(55 - \text{age}\right) \bullet \left(0.447 \bullet S_{Cr}^{-1.1}\right)$

Salazar-Corcoran

For men: $[137 - \text{age}] \bullet [(0.285 \bullet \text{weight}) + (12.1 \bullet \text{height}^2)/(51 \bullet S_{Cr})]$

For women: $[146 - \text{age}] \bullet [(0.287 \bullet \text{weight}) + (9.74\ \text{height}^2)/(60 \bullet S_{Cr})]$

CKD-EPI 2021 eGFRcr equation

$$\text{eGFRcr} = 142 \times \min(\text{Scr}/\kappa, 1)a \times \max(\text{Scr}/\kappa, 1) - 1.200 \times 0.9938^{\text{Age}} \times 1.012 \text{ [if female]}$$

where: Scr = serum creatinine in mg/dL
κ = 0.7 (females) or 0.9 (males)
a = −0.241 (female) or −0.302 (male)
min(Scr/κ, 1) is the minimum of Scr/κ or 1.0
max(Scr/κ, 1) is the maximum of Scr/κ or 1.0
Age (years)

CKD-EPI 2021 eGFRcr-cys equation

$$\text{eGFRcr-cys} = 135 \times \min(\text{Scr}/\kappa, 1)a \times \max(\text{Scr}/\kappa, 1) - 1.200 \times \min(\text{Scys}/0.8, 1) - 0.323 \times \max(\text{Scys}/0.8, 1) - 0.778 \times 0.9961^{\text{Age}} \times 0.963 \text{ [if female]}$$

where: Scr = serum creatinine in mg/dL
κ = 0.7 (females) or 0.9 (males)
a = −0.219 (female) or −0.144 (male)
min(Scr/κ, 1) is the minimum of Scr/κ or 1.0
max(Scr/κ, 1) is the maximum of Scr/κ or 1.0
Scys = serum cystatin C in mg/L
Age (years)

New Equations Used to Estimate eGFR without the use of Race

Equations for estimating glomerular filtration rate using serum creatinine or cystatin previously incorporated age, sex and race to estimate measured eGFR, however, race is a social and not biologic construct. Recently, a new eGFR equation without race has been developed and is now in the process of being implemented widely.[64-65]

CKD-EPI 2021 eGFRcr equation

$$eGFRcr = 142 \times \min(Scr/\kappa, 1)a \times \max(Scr/\kappa, 1)\text{-}1.200 \times 0.9938^{Age} \times 1.012 \text{ [if female]}$$

where: Scr = serum creatinine in mg/dL
κ = 0.7 (females) or 0.9 (males)
a = −0.241 (female) or −0.302 (male)
min(Scr/κ, 1) is the minimum of Scr/κ or 1.0
max(Scr/κ, 1) is the maximum of Scr/κ or 1.0
Age (years)

CKD-EPI 2021 eGFRcr-cys equation

$$eGFRcr\text{-}cys = 135 \times \min(Scr/\kappa, 1)a \times \max(Scr/\kappa, 1)-1.200 \times \min(Scys/0.8, 1)-0.323 \times \max(Scys/0.8, 1)-0.778 \times 0.9961^{Age} \times 0.963 \text{ [if female]}$$

Age (years)

Serum Urea Nitrogen

Less accurate as a marker of GFR than the S_{Cr}, serum urea nitrogen (SUN) (or blood urea nitrogen [BUN]) is still used extensively in clinical practice to estimate renal function. Although this was the earliest available indicator of renal function, several other factors should be appreciated regarding the use of this substance. Urea, like creatinine, is freely filtered and is retained in the blood as the GFR falls. However, in contrast to creatinine, urea may be reabsorbed to a significant extent. The excretion of urea tends to be increased with increasing urine flow rates, whereas its excretion is reduced when tubular fluid reabsorption is enhanced. Of greater importance, urea production is more variable than that of creatinine. Produced in the liver, urea increases with high protein intake, amino acid infusions, and hypercatabolic states. In addition, endogenous sources of protein, such as absorbed hemoglobin from gastrointestinal bleeding, may contribute to increased urea synthesis. Even at a constant GFR, SUN may rise in subjects on high-protein intake and fall with protein restriction or on refeeding of previously starved, nonhypercatabolic subjects.

Several pharmacologic agents may also affect urea nitrogen formation. Tetracyclines may lead to an increase in SUN by an antianabolic effect without any detectable change in the GFR, whereas glucocorticoids and severe illnesses or trauma do the same by inducing endogenous protein hypercatabolism. Because of the widespread use of hyperalimentation in ICU patients, impairment in renal function is often associated with a marked disproportion in the elevation of SUN compared with S_{Cr}. For this reason, an issue is raised as to whether SUN elevation itself poses an important threat to patients if the GFR is in a range that should not lead to enhanced morbidity by itself. In those circumstances, it is useful to measure the rate of urea appearance (or generation) to estimate whether other factors such as gastrointestinal bleeding, excessive amino acid infusions, and protein administration are contributing to the increase in SUN above that expected by a decrease in the GFR.[48,49] Urea nitrogen (UN) appearance can be determined from urine urea nitrogen (UUN), SUN, and body weight as follows:

$$UN = UUN \bullet V + \Delta \text{body pool UN}$$

where UUN • V is the 24-hour UN excretion, and Δ body pool UN = 0.6 − nonedematous weight (kg) • Δ SUN/day.

If the weight is changing[48,49]:

$$\Delta \text{ body pool UN} = \left(0.6 \bullet \text{nonedematous weight} \bullet \Delta \text{SUN}\right) + \left(\Delta \text{ weight} \bullet \text{final SUN}\right)$$

Nitrogen balance (BN) is equal to:

$$BN = IN - UN - NUN$$

where IN is the urea nitrogen intake and NUN is nonurea nitrogen excretions.[49]

NUN, which includes fecal nitrogen, urinary creatinine, uric acid, and unmeasured nitrogen, averages 0.031 g nitrogen/kg/day.[49] Data obtained from the measurements just described may be quite useful in evaluating the cause of disproportionate elevations in SUN. If a patient is in the steady state (with a stable weight and SUN), BN = 0, and IN can be estimated from UN + NUN.[49] Because catabolism, except for *severe* trauma and burns, is usually 2–4 g nitrogen per day, additional conclusions can be drawn if the patient is not in the steady state. For example, if it is known that IN is less than UN + NUN, gastrointestinal bleeding with or without excess catabolism would be suggested. Similarly, one can evaluate if an increase in SUN is a reflection of excessive exogenous protein and amino acid administration (usually >1.5 g/kg/day; g UN 0.16 = g protein or amino acids). If the IN is above the UN, such as in severe liver disease, the clinician might more carefully evaluate changes in weight and SUN in addition to clearances because the latter may be more severely depressed than initially suspected.

FUTURE METHODOLOGIES

A number of emerging methods and technologies are currently under investigation for measuring GFR. ProEnkephalin A 119-159 is a precursor peptide (5 κDa) found in the adrenal medulla, nervous and immune systems, and kidney. Its concentration is inversely proportional to GFR, and it is a novel and useful predictor of acute kidney injury (AKI).[66] Real-time measurement of GFR is also on the horizon using 3,6-diamino02,5-bispyrazine as a tracer measurement via transdermal patch shows good correlation with GFR.[67] Another novel method uses two visible fluorescent injectates to simultaneously measure plasma volume and GFR.[68] These methods will hopefully allow the clinician to estimate GFR on a real-time basis in order to aid in the diagnosis of chronic kidney disease (CKD) and AKI.

SODIUM BALANCE AND EXTRACELLULAR FLUID VOLUME

Sodium is the primary cation of the ECF, present at a concentration of 140–142 mmol/L. The volume of the ECF is approximately 20% of the total body weight and represents one-third of the total body water. Regulation of ECF volume is governed by factors regulating sodium balance and sodium excretion.[69]

Under physiologic conditions and in the steady state, sodium balance is maintained because the amount of sodium excreted equals that which enters the body by oral and intravenous routes. The excretion of sodium excretion and fraction of filtered sodium that is excreted (FE_{Na}) can be readily determined. Absolute sodium excretion

is measured as the product of urine sodium concentration and urine volume:

$$Na^{+}\ \text{excretion} = (U_{Na} \bullet V)$$

The FE_{Na} can be determined as follows:

$$FE_{Na} = U_{Na} \bullet V/GFR \bullet S_{Na}$$

For practical reasons, C_{Cr} ($= U_{Cr} \cdot V/S_{Cr}$) is used to estimate the GFR, such that:

$$FE_{Na} = U_{Na} \bullet V/U_{Cr} \bullet V/S_{Cr} \bullet S_{Na}$$

Because V in the numerator and denominator cancels out:

$$FE_{Na} = U_{Na}/S_{Na} \bullet S_{Cr}/U_{Cr}$$

Thus the FE_{Na} can be calculated from sodium and creatinine determined in a random urine sample and serum (or plasma) simultaneously. The resulting calculation is expressed as a percentage by multiplying by 100. This test is of value in the setting of acute renal failure to aid in distinguishing a prerenal from a renal parenchymal etiology.[70] It is not usually helpful in aiding in the diagnosis of urinary tract obstruction or in the presence of underlying chronic renal insufficiency. The reason for the difficulty in interpreting chronic renal insufficiency can be illustrated by the following considerations. At a GFR of 130 mL/min and a dietary sodium intake of 3 g of sodium (130 mmol), an individual in sodium balance will excrete 0.5% of the filtered load ($FE_{Na} = 0.5\%$). For sodium balance to be maintained at lower levels of the GFR with the same sodium intake, the FE_{Na} must be increased progressively. Successive decreases in the GFR by 2 from 130 would result in FE_{Na} of 1%, 2%, 4%, and 8%, respectively. Thus interpretation of the FE_{Na} in a patient with acute renal failure superimposed on chronic renal insufficiency is problematic unless the prior steady-state FE_{Na} is known, but this is rarely the case.

The fractional excretion of chloride (FE_{Cl}) has been suggested to be more accurate than that of sodium in helping to distinguish prerenal from parenchymal causes of acute renal failure.[71] This is particularly so in the situation in which acute renal failure occurs with simultaneous metabolic alkalosis. If the urine contains substantial amounts of bicarbonate urinary pH ($U_{pH} > 7$), sodium excretion increases to maintain electroneutrality. Under these circumstances, the FE_{Na} may give misleading information, but the FE_{Cl} can be used to obtain the same information.

Although urinary sodium excretion can be used to help make determinations with respect to the ECF volume under certain circumstances, this may be fraught with potential errors. No laboratory test is available to provide this information. Rather, an astute clinician must rely on bedside evaluation complemented, where appropriate, with measurements of central venous pressure and pulmonary capillary wedge pressure to assist in making determinations with respect to the ECF volume status. For example, a low FE_{Na} (<1%) in the setting of acute renal failure usually indicates a decrease in renal perfusion but does not provide information on the status of the patient's ECF volume. Because a low FE_{Na} can be seen with either ECF volume contraction or severe congestive heart failure, these conditions must be distinguished at the bedside. Moreover, sometimes a low FE_{Na} exists even in the presence of parenchymal renal disease, such as acute glomerulonephritis, severe burns, and radiocontrast nephropathy. Finally, administration of potent diuretic agents can alter the FE_{Na} and may result in misleading interpretations. For this reason, urine samples should be obtained before diuretics are administered. However, it may not be possible to obtain urinary sodium or chloride values while a patient is not receiving diuretics. In this setting, the fractional excretion of UN has been employed to distinguish prerenal from renal causes of AKI. In a well-hydrated individual, the Fe_{UN} is 50%–65%,[72] whereas in the oliguric prerenal azotemic individual, the Fe_{UN} is below 35%. The use of Fe_{UN} in the setting of AKI has not attained widespread acceptance because of variable results in comparative trials.[72,73]

There is now ample evidence that in a patient in positive sodium balance, diuretic therapy should not be used without simultaneously restricting sodium intake, including intravenous saline, if negative sodium balance and reduction in edema fluid are desired.[74] In general, this requires restriction of dietary sodium intake, usually to less than 2 g of sodium per day (0.88 mmol) if the patient is in an edema-forming state. Although diuresis can be affected even with liberal sodium intake, this requires higher doses of diuretics and more frequent administration of these agents. The coexistence of hyponatremia should not deter clinicians from restricting sodium intake, but rather should cause them to address solute-free water intake as well. Under certain circumstances, obligatory intakes make it difficult to achieve optimal restriction to assist diuresis. That is, with various pharmacologic drips, blood products, and feeding regimens necessary in acutely ill patients in the ICU, restricting sodium intake may become a difficult problem. Under those circumstances, increasing doses of diuretics, including continuous infusions of loop diuretics, may be required.

KEY POINTS

- Acute deterioration of renal function is common in the ICU and contributes significantly to overall morbidity and mortality.
- The serum creatinine concentration often underestimates the decrease in GFR and may be abnormal only after marked reductions in GFR.
- Using equations to estimate renal function should be routine in the ICU.

ANNOTATED REFERENCES

Chertow GM, Sayegh MH, Allgren RL, et al. Is the administration of dopamine associated with adverse or favorable outcome in acute renal failure? *Am J Med.* 1996;101:49–53.
One of the first large, randomized trials exploring the use of low-dose dopamine (<3 μg/kg/min) and high-dose dopamine in ICU patients. The study revealed that there was no evidence that low-dose dopamine improved survival or obviated the need for dialysis and its use should be discouraged.

Inker LA, Eneanya J, Coresh H. New Creatinine- and Cystatin C-Based Equations to Estimate GFR without Race. *N Engl J Med* 2021; 385: 1737–49.
Comprehensive review of the development of a new equation to predict GFR without the use of race.

Robert S, Zarowitz BJ, Peterson EL, et al. Predictability of creatinine clearance estimates in critically ill patients. *Crit Care Med.* 1993;21:1487–1495.
Creatinine clearance, inulin clearance, and estimates of GFR based on the Cockcroft-Gault equation were compared in 20 ICU patients. This study emphasized the inaccuracies of obtaining creatinine clearances in the ICU setting. The Cockcroft-Gault equation accurately predicted GFR as determined by inulin clearances.

Wharton WW, III Sondeen JL, McBiles M, et al. Measurement of glomerular filtration rate in ICU patients using ^{99m}Tc-DTPA and inulin. *Kidney Int.* 1992;42:174–178.
This study in 18 ICU patients compared clearances of inulin, creatinine, and ^{99m}Tc-DTPA with estimated Cockcroft-Gault clearance. The clearance of DTPA correlated best to inulin clearance throughout the entire range of clearances studied. DTPA clearance was also simple and inexpensive to perform in the ICU setting.

Wilcox CS, Mitch WE, Kelly RA, et al. Response of the kidney to furosemide: I. Effects of salt intake and renal compensation. *J Lab Clin Med.* 1983;102:450–458.
Classic study on the pharmacodynamics of furosemide showing the importance of salt intake and homeostatic mechanisms activated by diuretic use.

Biomarkers of Acute Kidney Injury

Anja Haase-Fielitz and Michael Haase

EPIDEMIOLOGY OF ACUTE KIDNEY INJURY IN THE INTENSIVE CARE UNIT

Acute kidney injury (AKI) is a significant problem in intensive care unit (ICU) patients and carries a high mortality rate and long-term morbidity. AKI is defined according to the Kidney Diseases Improving Global Outcomes (KDIGO) criteria,[1] including three alternatively applied components: (1) serum creatinine increase (from baseline of >27 micromol/L or >0.3 mg/dL within a maximum of 48 hours or >50% within a maximum of 7 days), (2) reduced urine output (<0.5 mL/kg/hr over 6 hours), or (3) initiation of acute renal replacement therapy. Incidence of AKI in the ICU has been reported to be about 50%,[2] with 32% at stage 1, 16% at stage 2, and 52% at stage 3. In 13.5% of patients treated in the ICU, renal replacement therapy is initiated. AKI requiring renal replacement therapy in the ICU has a high mortality rate, often reaching over 50%. The most common causes of AKI in the ICU include sepsis/septic shock, major surgical procedures, acute cardiac decompensation/cardiac shock, and nephrotoxins.[2,3] Approximately 30% of patients have preadmission chronic kidney disease.

A major obstacle to the development of improved treatment strategies for AKI in critically ill patients is the absence of sensitive and specific biomarkers available to the clinician with a short laboratory turn-around time.[4] Therapeutic measures are sometimes started late in the course of AKI. The optimum time to start renal replacement therapy in the ICU is unknown. Therefore there is a need to understand whether and how novel kidney biomarkers with short turn-around time may be able to complement clinical decisions in ICU patients.

This chapter briefly highlights biologic characteristics of current tools in AKI diagnosis and of novel kidney biomarkers with short turn-around times and test results available to the clinician within 2 hours. This is followed by information on clinical characteristics of such biomarkers of AKI. Biologic and clinical characteristics of other published novel kidney biomarkers are summarized at the end of the chapter.

BIOLOGIC CHARACTERISTICS OF CURRENT TOOLS IN AKI

Serum creatinine (SCr) and urine output are used to diagnose AKI. Creatinine is generated in muscles from the nonenzymatic conversion of creatine and phosphocreatine. SCr concentrations carry the highest validity under stable physiologic conditions, but SCr is not sensitive or specific in the setting of AKI. SCr may change because of nonrenal factors independent of kidney function (e.g., age, gender, race, muscle mass, nutritional status, total parenteral nutrition, and infection).[5,6] Also, inhibition of tubular secretion (e.g., during intake of piperacillin/tazobactam) may increase SCr concentrations.[7] Moderate to severe abnormalities of thyroid or adrenal gland function may affect SCr independent of kidney function, with lower SCr concentrations in the setting of hyperthyroidism or hypercortisolism. SCr is not sensitive to the loss of kidney function reserve, as evidenced by the small change in SCr after the loss or donation of a kidney with one normal remaining kidney.[8] Alterations in SCr may lag several days behind actual changes in glomerular filtration rate (GFR).[6,9]

Both a decrease and lack of decrease of urine output are frequently not helpful in diagnosing or ruling out AKI. Urine output and urine output–modifying circumstances (e.g., hypovolemia) and treatments (fluids, diuretics) carry inherent impediments, limiting their sensitivity and specificity in AKI diagnosis. Specifically, diuretic administration in the setting of hypervolemia management or fluid administration in the setting of hemodynamic instability might limit the use of urine output for diagnosing or ruling out AKI. However, diuretic administration applied in euvolemic patients as a tubular stress test[10] may assess kidney tubular responsiveness.[11]

A biomarker independent of SCr and urine output limitations or a biomarker that is released into the blood or urine by the injured kidney may be a more sensitive and specific marker of AKI. In addition, earlier detection of AKI with a kidney-specific biomarker may result in earlier nephrology consultation, more optimal dosing of antibiotics in ICU patients, avoidance of nephrotoxic agents, and even patient-individualized timing of initiation of renal replacement therapy (RRT).

BIOLOGIC CHARACTERISTICS OF NOVEL AKI BIOMARKERS WITH SHORT TURN-AROUND TIMES

Recently, clinically available biomarkers of AKI with short laboratory turn-around times to the clinician have been described, including cystatin C, neutrophil gelatinase–associated lipocalin (NGAL), and cell-cycle arrest markers (TIMP-2/IGFBP7). All of those are available on clinical laboratory platforms or point-of-care devices with biomarker measurements of less than 60 minutes. Cystatin C, NGAL, and cycle arrest markers have CE marking, making the tests commercially available in Europe for supporting the clinician estimating AKI risk in critically ill patients. Cystatin C measurements are approved by the Food and Drug Administration (FDA) as an aid in the diagnosis and treatment of renal diseases. Cell-cycle arrest markers (TIMP-2/IGFBP7) have also been approved by the FDA to be used in conjunction with clinical evaluation in patients 21 years of age or older who currently have or have had within the past 24 hours acute cardiovascular and/or respiratory compromise and are ICU patients as an aid in the risk assessment for moderate or severe AKI within 12 hours of patient assessment. Renal handling of these biomarkers is shown in Fig. 96.1.

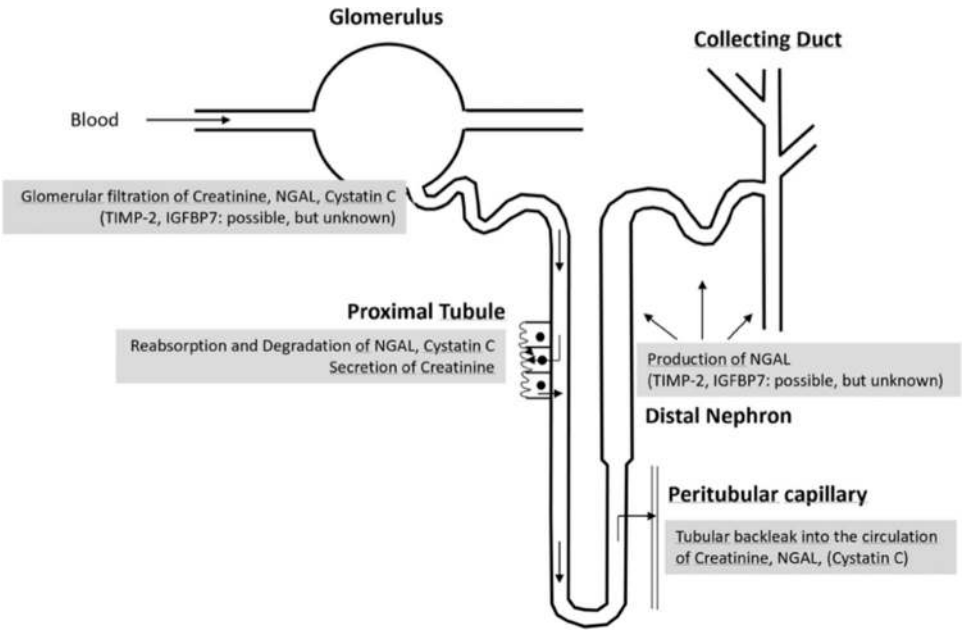

Fig. 96.1 The processing of AKI biomarkers cystatin C, NGAL, and cycle arrest markers by the kidneys.

Novel biomarkers of AKI that are not clinically available within a short turn-around time are summarized next, including IL-6, IL-18, KIM-1, and L-FABP.

Serum Cystatin C

Cystatin C is a 13-kDa protein produced by all nucleated cells at a constant rate. It is freely filtered by the glomerulus, completely reabsorbed by the proximal tubules, and is not secreted by the renal tubules.[12] Thus some of the limitations of SCr—for example, the effect of muscle mass, diet, gender, and tubular secretion—may not be a problem with cystatin C. Cystatin C is a better marker of GFR than SCr.[13–15] Increases in cystatin C occur sooner after changes in kidney function than change in SCr.[8,16] In critically ill patients, serum cystatin C correlated better with GFR than did creatinine and was diagnostically superior to creatinine.[16] Serum cystatin C was found to be better than SCr in the detection of AKI in critically ill children.[17]

There are limitations to the use of cystatin C as a marker of GFR. Abnormalities of thyroid function[18] and glucocorticoid therapy[19,20] may affect cystatin C independent of kidney function, with higher serum cystatin C concentrations in the setting of hyperthyroidism or prednisolone intake >10 mg/d. However, in critically ill patients, the effect of thyroid function appears to be nonclinically relevant.[21] The evidence regarding the impact of inflammation is limited; however, in a study with 327 ICU patients, the impact of sepsis on the levels of serum cystatin C in AKI and non-AKI patients was determined.[22] The change in cystatin C or creatinine did not differ significantly between the septic and nonseptic patients with or without AKI. Similarly, in a study with critically ill children, levels of cystatin C were not substantially increased in the setting of sepsis.[23]

Neutrophil Gelatinase–Associated Lipocalin

NGAL was originally isolated from the supernatant of activated neutrophils and identified as a polypeptide covalently bound to gelatinase.[24] It is expressed in a variety of human tissues, including lung, liver, and kidney, in various pathologic states. Human NGAL is a polypeptide with a molecular weight of 25 kDa covalently bound to gelatinase from human neutrophils. Although the majority of NGAL is in a monomeric form, NGAL also occurs as dimers and trimers and in a complex with neutrophil gelatinase. The 25-kDa monomeric NGAL form is secreted by injured kidney tubule epithelial cells, whereas the dimeric form is predominantly secreted by neutrophils.[25] The major ligands for NGAL are siderophores,[26] which are ferric ion-specific chelating compounds.[27] The iron status of NGAL is a critical determinant of biologic activity. Iron-containing NGAL binds to cell surface receptors such as megalin, gets internalized, and releases its bound iron. The increased intracellular iron concentration drives the regulation of iron-dependent genes. NGAL has been implicated in the differentiation of renal tubule epithelial cells and nephrons.[28] Preclinical studies identified NGAL to be one of the most up-regulated genes and proteins in the kidney early after AKI in animal models.[29a] NGAL protein expression was detected predominantly in tubule epithelial cells that were undergoing proliferation and regeneration, suggesting a role in the repair process. NGAL protein was also detected in the urine and plasma in animal models of AKI, where it preceded the increase in plasma creatinine concentrations. Urine NGAL is derived predominantly from epithelial cells of the distal nephron, although a fraction may come from the systemic pool escaping reabsorption because of proximal tubular injury.[29] Plasma NGAL originates not only from the damaged kidneys (via tubular backleak) but also from extrarenal organs. Recent evidence has emerged to implicate a potentially important pathophysiologic link between NGAL and cardiorenal syndrome. NGAL induces cardiomyocyte apoptosis by increasing intracellular iron accumulation.[30] Renal NGAL expression rapidly increased after acute inflammation and/or injured renal tubular epithelia, in particular after damage from ischemia-reperfusion injury (IRI) and toxin exposure. A reporter mouse responsive to ischemia/reperfusion or toxic stimuli allowed detection of NGAL expression in "real time" in vivo.[31] Volume depletion did not cause NGAL expression in the kidney or in the urine, thus indicating that NGAL can be an important clinical tool to discriminate patients with "prerenal azotemia" from those with AKI and therefore "true" structural damage. Finally, NGAL levels peak approximately 6 hours after tubular injury and follow a dose-response curve with respect to severity of injury.[32,33]

Cell-Cycle Arrest Markers

Replication is one of the most energy-consuming processes cells undergo. If, during the cell cycle, the cell will have not sufficient energy to replicate, the cell will undergo cell-cycle arrest to avoid cell death as a result of energy failure.[34] Therefore cell-cycle arrest is considered to be a major mechanism of down-regulation of energy expenditure that tubular epithelial cells may use to resist or recover from different insults. Even if insults may not actually destroy cells, tissue inhibitor of metalloproteinase-2 (TIMP-2) and insulin-like growth factor binding protein-7 (IGFBP7) may signal in autocrine and paracrine fashions. Therefore TIMP-2 and IGFBP7 have been recently described as an "alarm" spreading to adjacent cells, although this has not yet been shown for the kidney.[34] The cellular source and pathophysiologic role of these markers in AKI are unknown' however, one study showed that nonrenal organ failures in sepsis did not result in increased [TIMP-2]·[IGFBP7],[34] and other studies showed no increase of [TIMP-2]·[IGFBP7] in critically ill patients without AKI.[35] TIMP-2 and IGFBP7 have been found to be predictors of the development of human AKI.[35] Both cell-cycle arrest markers are inducers of G1 cell-cycle arrest occurring during the early phases of cellular stress,[36,37] a key mechanism implicated in AKI. TIMP-2 and IGFBP7 may increase in response to inflammation, oxidative stress, ultraviolet radiation, drugs, and toxins.[34,36,37] Sustained cell-cycle arrest will result in a senescent cell phenotype and lead to fibrosis. In turn, urine TIMP-2 and IGFBP7 values were not elevated in patients with stable chronic morbidities who did not have AKI.[38]

CLINICAL CHARACTERISTICS OF AKI BIOMARKERS WITH SHORT TURN-AROUND TIMES

Serum Cystatin C

The performance of serum cystatin C and SCr as biomarkers of GFR in 47 critically ill patients was compared with GFR measured using urine clearance of iohexol.[39] The areas under the ROC curve (AUCs) to detect a GFR of less than 60 mL/min were 0.80 and 0.94 for SCr and serum cystatin C, respectively. It was concluded that serum cystatin C outperforms SCr for the detection of an impaired GFR in critically ill patients.[39]

Serum cystatin C rapidly detects AKI in the ICU.[40] In a meta-analysis including data from 11 countries involving 3336 patients, serum cystatin C was reported to be predictive of AKI with an AUC of 0.84 if measured within 24 hours after ICU admission. Most studies in this meta-analysis found serum cystatin concentration >1.1 mg/L to be predictive.[41] Another meta-analysis including 2332 predominantly critically ill patients reported a 4.4 times increased risk of initiation of RRT if baseline serum cystatin C was increased.[42]

In another meta-analysis with 1079 ICU patients, cystatin C was predictive of the need for initiation of RRT, with AUC of 0.77, similar to the predictive value of contemporaneous serum creatinine with AUC 0.76.[43] In turn, serum cystatin C concentrations <2.5 mg/L with an AUC of 0.74 were predictive of successful 60-day discontinuation of RRT in critically ill patients.[44] Serum cystatin C was an independent risk factor for AKI, with an odds ratio of 4.5 per mg/L increase in 624 neurosurgical critically ill patients.[45]

In a study of 198 patients without known chronic kidney disease who underwent noncardiac major surgery and developed new-onset AKI in the first 48 hours after admission to the ICU, cystatin C predicted nonrecovery from AKI (within 7 days), with an AUC of 0.68, and improved a related statistical model enriched with clinical variables to AUC 0.80.[46]

Use of a vancomycin dosing algorithm according to estimated GFR (eGFR) using both an SCr and serum cystatin C–based CKD-EPI equation improved goal steady-state vancomycin trough concentrations compared with creatinine clearance based on the Cockcroft-Gault formula.[47]

Although SCr and cystatin C increase subsequent to a loss of renal filtration function, markers of acute tubular injury or cell stress may indicate structural kidney damage.

NGAL

NGAL is an early biomarker of AKI in critically ill patients. In 140 pediatric patients on mechanical ventilation,[48] the mean and peak urine NGAL concentrations increased with maximum AKI severity. Urine NGAL concentration rises in AKI 2 days before a 50% or greater rise in SCr. In a meta-analysis including more than 13,000 patients,[49] irrespective of meta-analytic approach, AKI definition, or subgroup assessment and considering several known NGAL confounders, NGAL diagnostic accuracy for the prediction of SCr-based AKI in adult critically ill patients was moderate to good (for overall AKI, moderate to severe AKI, RRT: AUC 0.73/0.78/0.75 for urine NGAL and AUC 0.77/0.82/0.87 for plasma NGAL) (Table 96.1). The estimated time from NGAL sampling to diagnosis of AKI was 69 hours (interquartile range (IQR) 33–107).[49] Moreover, in this meta-analysis, AUC values, classification, and test performance indices (sensitivity, specificity, predictive values) of NGAL for severe AKI were similar to those previously reported for the cell arrest markers TIMP-2 and IGFBP7.[50,51]

The optimal cutoff points of urine and plasma NGAL for the prediction of moderate to severe AKI in 245 critically ill patients were >80 ng/mL (sensitivity 70%, specificity 77%) and >150 ng/mL (sensitivity 79%, specificity 73%).[52] In this study, NGAL was also shown to be a marker of persistence of AKI for 48 hours or longer. Accordingly, the optimal cutoff points of urine and plasma NGAL (measured at the start of AKI stage 2/3) for the prediction of persistent AKI were similar with >80 ng/mL and >150 ng/mL. The ability of plasma NGAL to predict AKI in adult ICU patients was confirmed in another study.[53] In a prospective cohort study of NGAL in the ICU, using a cutoff of >155 ng/mL, the sensitivity and specificity of plasma NGAL to predict AKI were 82% and 97%, respectively (AUC 0.92). Of the patients who required RRT, all of them had plasma NGAL of >300 ng/mL. Plasma NGAL increased 48 hours before AKI was diagnosed. The study concluded that plasma NGAL at ICU admission was an early biomarker of AKI in adult ICU patients.[53]

TABLE 96.1 NGAL as a Biomarker of AKI in the ICU

		AKI		MODERATE TO SEVERE AKI		RRT
Covariate	N	AUC (95% CI)	N	AUC (95% CI)	N	AUC (95% CI)
Plasma NGAL	10	0.77 (0.76–0.78)	8	0.82 (0.81–0.83)	6	0.87 (0.86–0.87)
Urine NGAL	6	0.73 (0.72–0.75)	5	0.78 (0.78–0.81)	4	0.75 (–)

(From Albert C, Haase M, Albert A, Zapf A, Braun-Dullaeus RC, Haase-Fielitz A. Biomarker-Guided Risk Assessment for Acute Kidney Injury: Time for Clinical Implementation? Ann Lab Med. 2021 Jan;41(1):1-15. doi: 10.3343/alm.2021.41.1.1.)

A multicenter study of serum NGAL was performed in 143 critically ill children with systemic inflammatory response syndrome (SIRS) or septic shock during the first 24 hours of admission to the pediatric ICU.[54] There was a significant difference in the serum NGAL between healthy children, critically ill children with SIRS, and critically ill children with septic shock. Serum NGAL was significantly increased in critically ill children with AKI compared with those without AKI. Thus serum NGAL is a highly sensitive but nonspecific predictor of AKI in critically ill children with septic shock. Another study of NGAL in the ICU determined the influence of sepsis on NGAL in adult critically ill patients admitted with normal SCr.[55] Data from patients with SIRS, severe sepsis, or septic shock without AKI and patients with septic shock and concomitant AKI were analyzed. Peak levels of plasma NGAL were not significantly different between septic shock patients with and without AKI. Urine NGAL was a good predictor (AUC 0.86), whereas plasma NGAL was a poor predictor (AUC 0.67) of AKI within the next 12 hours in patients with septic shock.[55] The authors concluded that plasma NGAL is raised in patients with SIRS, severe sepsis, and septic shock and should be used with caution as a marker of AKI in ICU patients with septic shock. Urine NGAL was more useful for predicting AKI, as the levels were not elevated in septic shock patients without AKI.

The predictive value of urine NGAL, plasma NGAL, and serum cystatin C to differentiate among sustained, transient, and absent AKI was compared in 700 ICU patients in a prospective cohort study.[56] Urine NGAL was the only biomarker that could significantly differentiate sustained from transient AKI on ICU admission. The study concluded that urine NGAL measured on ICU admission can be used to differentiate patients with sustained AKI from patients with transient AKI or without AKI.

In a prospective study of serum NGAL in 109 critically ill patients at the initiation of RRT, serum NGAL was a strong independent predictor for 28-day survival.[57]

The diagnostic accuracy of plasma NGAL for the early detection of AKI and the need for RRT in an adult ICU was examined in a study of 307 consecutive adult patients admitted to a general medical/surgical ICU.[58] Peak plasma NGAL concentrations increased with worsening AKI severity.[58]

In a prospective observational study, 106 ICU patients were included to determine whether a panel of novel and traditional renal markers is superior to conventional renal markers in predicting RRT requirements.[59] Urine NGAL, serum cystatin C, and Acute Physiology and Chronic Health Evaluation (APACHE) II score were significant independent predictors of RRT. The combination of serum cystatin C and APACHE II score proved to be the best for detecting patients without AKI on ICU entry (AUC 0.78). The study concluded that the combination of a marker of GFR with one of tubular injury was the best predictor of RRT.

The ability of plasma NGAL and urine NGAL compared with SCr-based eGFR to predict severe AKI was determined in patients on ICU admission.[60] Urine and plasma NGAL performed better than SCr or eGFR (AUC 0.79/0.75 vs. 0.65/0.67) for the prediction of moderate to severe AKI in 498 critically ill patients with eGFR >60 mL/min/1.73 m^2.

It has become apparent that using clinical adjudication in conjunction with routine laboratory parameters may be insufficient in complex acute conditions such as AKI. In this regard, a recent prospective observational study found that a clinician's risk assessment for major adverse kidney events or AKI alone using information of NGAL test results measured on ICU arrival after cardiac surgery in addition to all other clinical information available was superior to clinical risk assessment without information of the NGAL test result.[61] Parikh and colleagues also reported cost savings in favor of biomarker measurement and adjustment of treatment.[62]

Finally, a systematic review and meta-analysis comparing a watchful waiting strategy with early initiation of RRT in critically ill patients found that randomized controlled trials (RCTs) that enrolled a surgical population and a population with high plasma NGAL had favorable outcomes in the early RRT initiation group compared with the late RRT initiation group. The authors concluded that results should be interpreted with caution and that further information from large-scale, well-designed RCTs should be obtained to provide a more definitive answer regarding biomarker-complemented, optimal timing of RRT initiation and optimal RRT duration.[63]

In summary, NGAL appears to be a potentially useful biomarker of AKI and the need for RRT. However, there is variation among studies, and conditions such as sepsis, chronic obstructive pulmonary disease, cardiac dysfunction, age (NGAL seems superior in children), sex, and baseline renal function may affect the sensitivity and specificity of NGAL as a biomarker of AKI in the ICU.[64] Thus there are limits in the interpretation of NGAL in AKI. In addition, plasma NGAL and urinary NGAL assays have detected different molecular forms of NGAL, and these various molecular forms have different predictive values as biomarkers of AKI.[65] Before NGAL is routinely and cost-effectively used in the ICU, further work is needed to describe the natural history of AKI and NGAL physiology in the ICU. Future studies should focus on accurate, early identification of AKI and the identification of new therapies.[66]

Cell-Cycle Arrest Markers

In one study, 340 candidate biomarkers were measured in the urine of critically ill ICU patients with sepsis or one or more risk factors for AKI such as hypotension and major trauma. In the initial analysis, the biomarkers were ranked by their ability to predict moderate to severe AKI within 12–36 hours. The two best biomarkers were the cell-cycle arrest proteins IGFBP7 and TIMP-2, which are both inducers of G1 cell-cycle arrest, a key mechanism implicated in AKI.[35] In a validation study ("Sapphire study") in 728 critically ill patients, the primary endpoint was moderate to severe AKI (KDIGO stage 2–3) within 12 hours of sample collection.[35] The combination of TIMP-2 and IGFBP7 ([TIMP-2]•[IGFBP7]) demonstrated an AUC of 0.80 (0.76 and 0.79 alone) for the primary endpoint. Urine concentrations of [TIMP-2]•[IGFBP7] were significantly superior to previously described markers of AKI, none of which achieved an AUC of more than 0.72 for the endpoint defined. Hoste and colleagues reported in the Opal study an AUC of 0.79 for moderate to severe AKI using [TIMP-2]•[IGFBP7].[50]

Several studies focused on identification and characterization of cutoff concentrations for AKI (Table 96.2). In the Topaz study, in 420 ICU patients, a predefined cutoff value of [TIMP-2]•[IGFBP7] was prospectively validated for risk assessment in AKI diagnosed by a clinical adjudication committee.[51] Critically ill patients with urinary [TIMP-2]•[IGFBP7] >0.3 had seven times the risk of AKI compared with critically ill patients with a test result <0.3. Sensitivity for the designated "high sensitivity cutoff" (0.3 ng/mL^2/1000) was 89% in both Sapphire[35] and Opal[50] studies, and specificity was 50% and 53%, respectively. For 2.0 ng/mL^2/1000 (which designated a high specificity cutoff), sensitivity was 42% and 44% and specificity was 95% and 90%, respectively. A recent meta-analysis[49] on the diagnostic performance of [TIMP-2]•[IGFBP7] for AKI reported a sensitivity for the 0.3 ng/mL^2/1000 cutoff of 0.76 and specificity of 0.48 within 12 hours of ICU admission. The sensitivity and specificity for the 2.0 ng/mL^2/1000 cutoff were 42% and 94%, respectively.

In addition, urinary [TIMP-2]•[IGFBP7] is associated with an increased risk of 9 months mortality or dialysis after AKI.[67] Furthermore,

¶ Calculated as LR+/LR−.

in several studies the combination of urinary [TIMP-2]•[IGFBP7] was examined to predict renal recovery in critically ill patients with AUC 0.68,[68] AUC 0.62,[69] and AUC 0.79,[70] with the latter study demonstrating eGFR improvement to be the best predictor of renal recovery (AUC 0.87). A proteome analysis exploring novel kidney markers in the urine of critically ill patients with AKI and early recovery ($n = 12$) compared with late recovery ($n = 12$) identified eight candidates, among them NGAL and IGFBP7.[71] In a validation study ($n = 28$), AUC for AKI recovery was 0.74 for urine IGFBP7 and 0.70 for urine NGAL. AUC for prediction of mortality was 0.68 for IGFBP7 and 0.81 for NGAL.

In several studies, the combination of TIMP-2 and IGFBP7 was used for clinical decision making. In a study cohort of 276 patients undergoing cardiac surgery, Meersch and colleagues[72] found that implementation of an AKI care bundle according to the KDIGO practice guidelines compared with standard care reduced the frequency and severity of AKI in high-risk patients identified by [TIMP-2]•[IGFBP7] >0.3 ("high sensitivity cutoff"). Likewise, using the same cutoff, Göcze and colleagues[73] identified patients at risk after major abdominal surgery and used the KDIGO care bundle in identified patients (intensified care group) compared with standard care in the control group. They found reduced AKI severity, postoperative SCr increase, length of ICU, and hospital stay in the intensified care group compared to control. Göcze and colleagues also reported cost savings in favor of biomarker measurement and adjustment of treatment, accordingly.[73]

BIOLOGIC AND CLINICAL CHARACTERISTICS OF OTHER NOVEL AKI BIOMARKERS

Interleukin-6

Interleukin (IL)-6 is a proinflammatory cytokine and has been studied as a predictor of AKI. In one clinical trial, 547 patients from the placebo group of the Prospective Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) data set were studied.[74] Of these 547 patients, 127 (23.2%) developed AKI. Using multivariate Cox regression, the predictors of AKI were log IL-6 and the APACHE II score. Similarly, IL-6 is a proinflammatory acute phase response cytokine that has been found to be elevated in the urine of pediatric[75] and adult[76,77] patients with acute tubular injury.

The Program to Improve Care in Acute Renal Disease (PICARD) was a prospective multicenter cohort study designed to examine the natural history and outcomes of critically ill ICU patients with established AKI.[78] Among other cytokines, IL-6 was determined in a subset of 98 patients from the PICARD study at the time of enrollment and then weekly for the duration of their hospital stay. Patients were enrolled into PICARD at the time of their nephrology consultation and thus had established AKI. IL-6 was significantly elevated compared with those in healthy controls. Increased serum levels of IL-6 at baseline were significantly correlated with increased in-hospital mortality in AKI patients. Thus the cytokine response in patients with AKI is significantly dysregulated. When cytokine values were further adjusted for the severity of illness (APACHE III scores), only IL-6 remained an independent predictor of mortality. Thus IL-6 may be an important biomarker of outcomes in patients with AKI.

In summary, in both patient and animal studies, early AKI is associated with a proinflammatory burst that is characterized by early increases in serum IL-6. Such a proinflammatory burst may also be linked with other complications in the ICU, such as acute lung injury.[79]

Interleukin-18

IL-18 is a proinflammatory cytokine that plays a role in both innate and acquired immune response.[80–82] Studies in humans have demonstrated that urinary IL-18 is an early predictive biomarker of AKI in the ICU.[83] On multivariable analysis, urinary IL-18 values predicted the development of AKI (defined as a 50% increase in SCr) 24 and 48 hours later. On diagnostic performance testing, urinary IL-18 demonstrated an AUC of 73% to predict AKI in the next 24 hours. The presence of sepsis in both control and AKI patients did not have a significant effect on urinary IL-18. On multivariate analysis, the urinary IL-18 value on the day of initiation of mechanical ventilation for acute respiratory distress syndrome was a strong predictor of mortality.[83] The finding that urinary IL-18 is an early biomarker of AKI in critically ill adults was reproduced in children.[84] Urinary IL-18 rises before SCr does in nonseptic critically ill children, predicts the severity of AKI, and is an independent predictor of mortality.[84]

The ability of urinary IL-18, measured within 24 hours of ICU admission, to predict the need for acute dialysis in 451 ICU patients was prospectively investigated.[85] The highest median urinary IL-18 levels were observed in patients with sepsis at enrollment, those receiving acute dialysis, and those who died within 28 days of ascertainment. After adjustment for a priori selected clinical predictors, urinary IL-18 was an independent predictor of a composite outcome of death or acute dialysis within 28 days. The study concluded that urinary IL-18 predicted poor clinical outcomes in a broadly selected critically ill adult population.

In a study with 101 critically ill patients with AKI, the APACHE III score had an AUC 0.87 and serum IL-18 had an AUC 0.85 in terms of in-hospital mortality.[86] However, after cardiac surgery, IL-18 measured at ICU admission appears not to be predictive of AKI.[87] Urinary IL-18 as a biomarker of AKI in various clinical settings was analyzed in a meta-analysis of prospective studies.[88] Subgroup analysis showed that the AUC of urinary IL-18 to predict AKI was 0.66 in ICU or coronary care unit patients.

Kidney Injury Molecule-1

Kidney injury molecule-1 (KIM-1) is a putative epithelial cell adhesion molecule containing a novel immunoglobulin domain. KIM-1 mRNA and protein are expressed at low levels in normal kidneys but are increased in postischemic kidneys.[89] Both KIM-1 and NGAL concentrations gradually increased until AKI diagnosis in 700 adult critically ill patients. KIM-1 was a good discriminator at the time of AKI only (AUC 0.73).[90] However, KIM-1 remains to be proven as an early biomarker of AKI and prognosis in the ICU.

Liver Fatty Acid–Binding Protein

Fatty acid–binding proteins (FABPs) are a family of carrier proteins for fatty acids and other lipophilic substances, including eicosanoids and retinoids. FABPs also transport lipophilic molecules from the outer cell membrane to intracellular receptors such as peroxisome proliferator-activated receptors.

Urinary and serum liver-FABP (L-FABP) were measured in 80 critically ill patients.[91] Urinary L-FABP levels in patients with septic shock were significantly higher than those in patients with severe sepsis without shock, patients with AKI, or healthy subjects. Serum L-FABP levels showed no significant differences between patients with septic shock, patients with severe sepsis, patients with AKI, and healthy subjects.

The diagnostic and prognostic abilities of urinary L-FABP in heterogeneous critically ill patients were determined.[92] Urine NGAL and L-FABP were measured in 145 medical and surgical patients at the time of ICU admission. AKI patients had significantly higher levels of urinary NGAL and L-FABP and higher mortality rates than non-AKI patients. The AUC was 0.77 for NGAL and 0.78 for L-FABP for the diagnosis of AKI. On multivariate Cox analysis, urinary L-FABP was an independent predictor for 90-day mortality. Thus urinary L-FABP

is promising both for the diagnosis of AKI and for the prediction of prognosis in heterogeneous ICU patients.[92]

Of 152 critically ill adults with early AKI, urine L-FABP demonstrated an AUC of 0.79 for injury progression, dialysis, or death within 7 days, which improved to 0.82 when added to the clinical model (AUC 0.74).[93]

Combinations of AKI Biomarkers

The classical biomarker paradigm is that one test detects one disease—for example, troponin for acute myocardial infarction and prostate-specific antigen for prostate cancer. However, AKI is a complex disease with multiple causes, and it is possible that a panel of biomarkers may be necessary. In summary, more than one biomarker may be necessary to obtain sufficient sensitivity and specificity for AKI screening.

CONCLUSION

The clinical application of biomarkers is difficult in critically ill patients because the timing of the renal insult is often unknown, sepsis may lead to false positives, and the pathophysiology of AKI in sepsis patients is complex and not caused only by ischemia and hypotension. Plasma biomarkers may be an indication of the severity of disease rather than of true AKI. Finding the ideal biomarker of AKI and prognosis in the ICU is a subject of intense investigation. Problems and prospects related to biomarker investigation in ICU patients have been reviewed in depth. However, despite the issues mentioned earlier, there are multiple promising serum and urinary biomarkers of AKI for refinement of risk assessment in the ICU, including cystatin C, NGAL, or the combination of TIMP-2 and IGFBP7, all of them detecting AKI before the rise in SCr and predicting the outcome in patients with AKI. Also, these biomarkers have already proven in initial studies to contribute to improved care and outcome. Ultimately, larger disease control and outcome studies are necessary to determine the impact of biomarker screening on reducing the burden of disease.

ACKNOWLEDGMENT

We thank Dr. Charles L. Edelstein for his work as chapter author for the previous edition of this textbook.

KEY POINTS

- Accurate risk assessment and early recognition of AKI in critically ill patients is still a pressing issue.
- During the past several years, the evidence for novel AKI biomarkers with test results available within a short time, including cystatin C, NGAL, and the combination of cell-cycle arrest markers TIMP-2 and IGFBP7, has increased.
- There is evidence that serum cystatin C is a more accurate and earlier marker of kidney filtration function in critically ill patients compared with SCr. Limitations of serum cystatin C are few.
- NGAL and the combination of TIMP-2 and IGFBP7 predict AKI and initiation of RRT 12 hours to 2 days before the event occurs.
- Novel kidney biomarker–complemented clinical decision making has been tested in a few RCTs achieving amelioration of AKI.
- There is a cacophony of other novel kidney biomarkers with their test results not yet available within a short time, including cytokines, L-FABPs, KIM-1, and many more.

Water Metabolism

Elchanan Fried and Charles Weissman

Water is the body's most abundant component. Without ingesting sufficient fresh water, humans can survive for just a few days. Ingested water, plus water produced endogenously, must be appropriately excreted to maintain homeostasis. In the human body, water has many functions: intracellular, intravascular, and extracellular carrier of essential substances; body coolant, lubricant, reactant, and product in metabolic reactions; and shock absorber (e.g., cerebrospinal fluid [CSF] surrounding the brain). In critically ill patients, water metabolism and balance present special challenges. Patients are often admitted to the intensive care unit (ICU) with disordered water homeostasis, yet it can also be disturbed by ICU treatments.

Water accounts for 50%–67% of an average person's weight. Because fat has a lower percentage of water and women tend to have more fat, their proportion of water is lower (52%–55%) than that of men (60%). Water percentage is lower in the elderly and obese. A 70-kg man has ~40 L of water: ~25–27 L intracellularly, ~7 L extracellularly, and ~4 L intravascularly. Liquid water is the body's most common molecule, although some water is found in hydrated compounds. Hypovolemia and hypervolemia significantly threaten life. Therefore the body defends fluid volume and osmolarity within very narrow ranges.

WATER INGESTION AND PRODUCTION

Water is ingested via the gastrointestinal tract or infused via venous or interosseous routes. Water intake is regulated by thirst, although normally humans sufficiently self-regulate their intake so that thirst is only occasionally activated. Thirst is also activated by salty food, hot weather, and exercise. The latter two cause sweating and increased respiratory water loss. Adequate water intake is ~3 L/day for men and ~2.2 L/day for women.

Thirst. Thirst, the neurally induced motivation to find and consume water, is vital for defending against hypovolemia. Hypovolemic thirst is triggered when body water levels decrease by ~2%–3%. Hypertonic thirst occurs when osmolality increases to >290 mOsm/kg. Hypotension and hemorrhage also stimulate thirst. Peripheral and central mechanisms detect and react to these physiologic perturbations, leading organisms to seek and ingest appropriate fluids and fluid volumes. Drinking stimulates oral and pharyngeal receptors, thereby providing hypothalamic input to end the thirst sensation. Thirst ends even before plasma tonicity is reduced, likely preventing water overingestion. Thirst sensation is so powerful that normal subjects do not become hypernatremic if they have access to water. The inability to find, detect, react, request, or drink water adequately can cause severe illness and even death. The inability to self-regulate water intake—for example, during anesthesia and critical illness—makes patients totally dependent on caregivers to prevent and treat water disorders.

In the elderly, decreased kidney function, physical and cognitive problems, blunted thirst, and polypharmacy increase dehydration risk. There is also reduced renal sodium conservation (altered renal tubular function, greater peripheral atrial natriuretic peptide [ANP] concentrations but with reduced renal effects, lower renin–angiotensin–aldosterone secretion), decreased renal water excretion (lower renal blood flow, glomerular filtration rate, and distal renal tubular diluting capacity; greater renal passive water reabsorption and antidiuretic hormone [ADH] secretion), and reduced solute delivery caused by poor nutrition, limiting free water excretion. However, during dehydration, ADH secretion is often reduced, causing increased urinary output, and thus worsening the dehydration. A water-loss dehydration prevalence of up to 30% is observed in the elderly with concomitant morbidity.[1] A positron emission tomography study revealed age-associated changes in central nervous system (CNS) satiation patterns in response to hyperosmolarity, which were associated with inadequate hydration.[2] Paradoxically, elderly patients with worsening heart failure have increased thirst.[3]

Metabolic water production. Water is the principal end product of nutrient oxidation (Table 97.1). Although more water molecules are produced per mole of fat than per mole of glucose (129 vs. 36) per kilocalorie, overall, aerobically oxidized carbohydrates contribute to ~15% more water molecules than lipids.[4] An increased metabolic rate increases metabolic water production.

Water Loss

Water is lost through many routes, but mainly through the kidneys. Urine volume and composition depend on hydration status and the osmole load. Fecal losses are generally small, whereas sweating can cause large losses.

Renal function. Renal function, the major mechanism defending against disordered water balance, protects blood osmolarity within a narrow range by altering urine osmolarity over a wide range (50–1200 mOsm/L). Concentrated urine is formed by creating an osmotic gradient that progressively increases from the corticomedullary border to the tip of the inner medulla.[5] When the body must rid itself of excess water, urine can be diluted to as low as 50 mOsm/L.

Aging reduces the maximum urine-concentrating ability. Compared with younger individuals, those aged 60–79 years had a ~20% reduction in maximum urine osmolality, a ~50% decrease in the ability to conserve solute, and a 100% increase in minimum urine flow rate.[6]

Insensible losses. Insensible losses include transepidermal diffusion and evaporation of solute-free water plus evaporative water loss from the respiratory tract. Total insensible losses, ~800 mL/day in unstressed adults, are equally divided between skin and respiratory tract losses. Activity increases respiratory water losses so that active adults

TABLE 97.1 Water and the Human Body

Water Balance

Water balance = (water intake + metabolic water production) − water loss
~5%–10% of body water turns over daily
Total body water (estimate): Children = 0.6 × (wt, kg)
Adult men = 0.6 × (wt, kg)
Adult women = 0.5 × (wt, kg)

Recommended Water Intake

Average energy expenditure (EE) and environmental exposure = 1.0 mL/kcal EE
Increased activity, sweating, and solute load = 1.5 mL/kcal EE

Metabolic Water

Water produced by metabolism (usually oxidation) of endogenous substrates. Approximately 250–350 mL water/day (3–4 mL/kg/day).
Example: Glucose oxidation:

$$C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O$$

Metabolism produces ~110 g water/100 g fat, 41 g water/100 g protein, and 55 g water/100 g starch
~3 g water released per gram metabolized glycogen

Water Loss

Respiratory water loss (250–350 mL water/day) is influenced by temperature and humidity of inspired air
Urinary loss depends on water and solute intake
Insensible losses—skin and respiratory system = 0.7 L/day
Fecal loss—0.1 L/day
Sweating—0.1 L/day
Disease-associated losses—nasogastric drainage, vomiting, diarrhea

Water and Heat Loss

Heat exchange = radiation ± conduction ± convection (+ evaporation)
Heat gain via radiation, conduction, and convection plus endogenous body heat production
Heat loss via radiation, conduction, convection, and evaporation
Sweat evaporation
Heat of water vaporization = 580 calories/g at normal skin temperature
580 calories/g = heat loss to cool down 580 g of water 1°C
Evaporation rate influenced by
- Water temperature at air-water interface
- Air temperature
- Humidity of surrounding air—higher humidity lowers evaporation rate
- Area of air-water interface
- Water's chemical composition—vaporization rate decreases as salt content increases
- Wind speed
- Sweat that drips or is wiped off does not contribute to cooling
- Burn patients lose much water and heat through evaporation from open wounds; therefore they should be treated in warm humid environments and burned areas covered

can lose up to 50 mL/h. Age reduces transepidermal water losses.[7] In febrile patients, insensible losses can increase by fourfold to sixfold.[8]

Respiratory water losses are affected by many factors (see Table 97.1). In normal subjects, mouth breathing resulted in 42% greater water loss compared with nose breathing.[9] Cold exposure increases the need to humidify and warm inspired gases, thus increasing water losses. Using heat-and-moisture-retaining face masks during sleep reduced these losses.[10] In critically ill patients, rapid spontaneous respiratory rates increase respiratory water losses, whereas endotracheal tubes bypass the natural warming and humidifying mechanisms, requiring inspiratory gases to be artificially humidified and warmed.

Sweating. Sweating is mainly a mechanism of thermoregulation, although it also occurs in response to psychologic stress (see Table 97.1). Sweating involves the secretion of water-rich liquid by the eccrine glands located throughout the body surface and secretion of protein-, lipid-, and steroid-containing sweat by the apocrine glands found in the axilla, mammary, perineal, and genital areas. Thermoregulatory sweating mainly involves eccrine secretion occurring in response to intrinsic (fever, exercise) and extrinsic stimuli (elevated environmental temperatures). Maximum adult sweat rates can be 2–4 L/h during intense exercise.

Regulation of Water Balance

Regulating water balance involves central and peripheral volume and osmolarity sensors, providing neural input to the brain and other organs, thereby activating a cascade of endocrine and local activity.

Antidiuretic hormone (ADH)/arginine vasopressin (AVP). ADH is a peptide produced by the neurons of the hypothalamic paraventricular and supraoptic nuclei as a prohormone, prepropressophysin (preprovasopressin), comprising ADH, neurophysin II, and copeptin.[11] Neurons containing osmoreceptors have excitatory synapses with prohormone neurosecretory cells. ADH, bound to the carrier protein neurophysin II, then travels down the pituitary stalk (infundibulum) axons to the posterior pituitary, where it is stored and secreted into the circulation. Plasma osmolarity and plasma ADH concentration have a linear relationship above the osmoregulatory threshold for ADH secretion. This threshold determines when decreased intravascular volume and blood pressure effect ADH release. The threshold is more permissive during hypovolemia. As the hypovolemia worsens, nonosmotically regulated ADH release can persist despite significant hyponatremia.[11]

ADH production and secretion are also stimulated by angiotensin II and decreased blood volume detected by atrial stretch-sensitive low-pressure/vascular volume baroreceptors. A 5%–10% blood volume decrease is necessary for substantial ADH release. ADH is also secreted when carotid sinus and aortic arch baroreceptors detect a 10% blood pressure drop. Copeptin, the C-terminal fragment of the prohormone, is more stable than ADH. Copeptin plasma concentrations are often used as an ADH surrogate.

ADH levels increase the water permeability of distal renal tubules and collecting ducts, thus increasing water reabsorption and resulting in greater urine osmolarity and reduced renal water excretion. ADH binds to vasopressin-2 receptors on renal epithelial cells. These G-protein–coupled receptors activate adenylyl cyclase, converting adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). Increased cAMP increases the transcription of the aquaporin-2 gene (Aqp2), increasing aquaporin-2 in collecting duct cells and triggering the fusion of aquaporin-2 water channels to the apical membranes of distal tubule and collecting duct epithelial cells, allowing water to move down an osmotic gradient into the nephron.[12] Aquaporin-3, located on the opposite side of the nephron, permits water leaving the nephron to be reabsorbed into the blood. ADH also upregulates aquaporin-3.

cAMP also activates protein kinase A, leading to protein phosphorylation (aquaporin-2 and thiazide-sensitive sodium chloride cotransporter) and upregulating expression of urea transporters, thereby increasing urea permeability of the collecting duct. There is also greater sodium absorption across the ascending loop of Henle. These

two effects further increase distal tubular and collecting duct water reabsorption, resulting in concentrated/hyperosmotic urine, which facilitates body water conservation.

Renin–angiotensin–aldosterone system (RAAS). RAAS is a hormonal system stimulated by changes in renal blood flow. When renal blood flow or blood pressure decreases, juxtaglomerular (JGE) cells in the renal afferent arterioles activate prorenin, which is cleaved to the protease renin (also called *angiotensinogenase*). The renin-producing JGE cells also have β_1-adrenoreceptors, which, when activated by catecholamines, rapidly and significantly stimulate renin release.[13] Renin is secreted into the circulation, where it converts angiotensinogen, an α_2-globulin synthesized by the liver, to angiotensin I. Plasma renin activity plays a major role in determining the rate that angiotensin I is formed from the large amount of angiotensinogen circulating in the plasma.[14] Angiotensinogen production is enhanced by estrogen, thyroxin, and glucocorticoids. There is evidence that cytokines (e.g., interferon-γ, interleukin [IL]-6) also induce angiotensin production, a possible mechanism for maintaining blood pressure during sepsis[15,16]

Angiotensin I is then converted to angiotensin II by angiotensin-converting enzyme (ACE), a glycoprotein found mainly in the lungs but also in endothelial cells and plasma. ACE also breaks down the potent vasodilator bradykinin, providing another mechanism for increasing blood pressure. Angiotensin II, a potent vasoconstrictor, increases systemic blood pressure and decreases renal medullary blood flow and glomerular filtration by vasoconstricting afferent and efferent arterioles. These changes increase sodium and water reabsorption in the loop of Henle. Hydrogen ions are excreted, coupled with bicarbonate reabsorption. Angiotensin II's effects are attributable to its enhancing proximal and distal sodium/hydrogen ion exchanger, basolateral membrane sodium/bicarbonate ion cotransporter, sodium/potassium ion ATPase activity, and distal tubular epithelial sodium channel. Angiotensin II also stimulates posterior pituitary ADH release, further causing water retention.

Angiotensin II's major actions occur via the stimulation of AT1 receptors located in the kidney, brain, heart, blood vessels, and adrenal cortex. The activated receptor couples to G proteins, activating phospholipase C and generating diacylglycerol and inositol trisphosphate. The latter increases cytosolic Ca^{2+} concentrations, which then activate intracellular kinases such as protein kinase C and tyrosine kinases. The activated AT1 receptor also inhibits adenylate cyclase. Angiotensin II also stimulates lower-affinity AT2 receptors, leading to effects opposite those caused by AT1 receptor stimulation. AT2 receptors lower blood pressure by increasing nitric oxide production, enhancing sodium excretion, and inhibiting renin production.[17] The latter action is a feedback loop designed to limit further angiotensin II production.

Angiotensin II also stimulates adrenal cortical aldosterone synthase, which synthesizes aldosterone from deoxycorticosterone. Aldosterone regulates blood pressure by binding to the mineralocorticoid receptors of the renal distal tubular and collecting duct epithelial cells, thereby increasing expression and activity of ion channels in the distal nephron. By upregulating and activating the basolateral Na-K-ATPase pumps, aldosterone increases renal tubular sodium and water reabsorption while boosting the excretion of hydrogen ions and potassium, thereby increasing body fluid volume and blood pressure.

The endocrine RAAS system is augmented by an RAAS with intrarenal paracrine, autocrine, and intracrine activity. Angiotensinogen produced intrarenally is converted by local renin to angiotensin I, which is then metabolized by ACE to angiotensin II and by ACE2 to angiotensin I–VII.[18] ACE is secreted by proximal and distal tubules, collecting ducts, and renal endothelial cells. Although most local effects are attributed to angiotensin II operating through AT1 receptors, angiotensin I–VII, operating through Mas receptors, counteract many of the

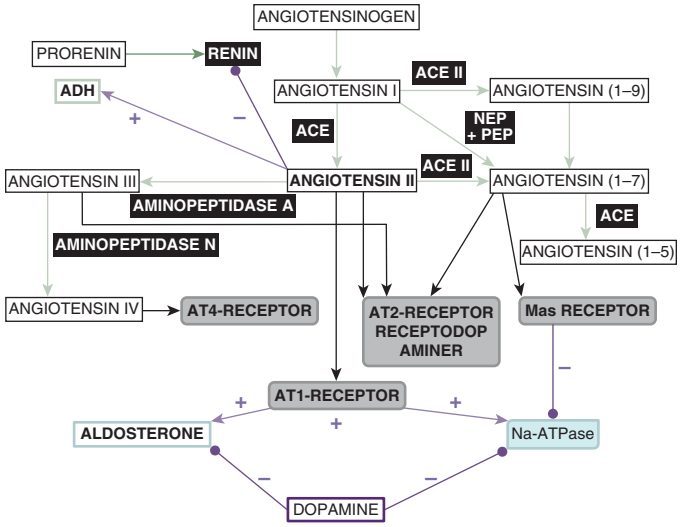

Fig. 97.1 RAAS System Plus Its Interactions with ADH and Dopamine.
ACE, Angiotensin-converting enzyme; *ADH,* antidiuretic hormone.

effects of angiotensin II/AT-1, leading to diuresis, natriuresis, and renal vasodilation (Fig. 97.1). Other local mediators include angiotensin III (angiotensin II–VIII) working via the AT1 receptors and angiotensin IV through the AT4 receptors.[19] Intrarenal angiotensin IV increases cortical blood flow and decreases sodium transport. In addition to the extracellular processing of these mediators, there is evidence that angiotensin II and angiotensin 1–7 also exist intracellularly.[20]

Natriuretic factors (peptides). Natriuretic factors consist of a peptide family involved in water and sodium homeostasis that counteract RAAS effects. A-type natriuretic peptide (ANP), released by atrial myocytes in response to atrial distention secondary to elevated blood volume,[21] is also secreted in response to sympathetic stimulation (α- and β-stimulation), angiotensin II, and endothelin. Cardiac ventricles, brain, adrenal glands, and kidneys (where it also acts as an autocrine/paracrine factor) are additional synthesis sites. ANP decreases circulating water and sodium, reducing atrial distention, and ultimately, lowering blood pressure. Another family member is brain natriuretic peptide (BNP), a peptide so named because it was first identified in porcine brain, although in humans it is mainly released by the cardiac ventricles in response to excessive cardiomyocyte distention. Biologically inactive circulating N-terminal fragments of ANP and BNP prohormones are used as biomarkers.

ANP and BNP increase glomerular filtration rates, reduce sodium and water reabsorption, inhibit renin release, and in proximal tubules, inhibit angiotensin II activity. The natriuretic peptides bind to natriuretic peptide receptor-A (NPR-A), which are membrane guanylate cyclases characterized by a single protein containing both a receptor and enzyme that produce cyclic guanosine monophosphate (cGMP).[22] cGMP targets cGMP-dependent protein kinases, cGMP-gated ion channels, and cGMP-regulated cyclic nucleotide phosphodiesterases [23] Changes in these enzymes and channels cause vasorelaxation, inhibit medullary collecting duct sodium reabsorption, and increase the glomerular filtration rate by dilating afferent and constricting efferent arterioles. This leads to greater glomerular capillary hydraulic pressure that enhances ultrafiltration. ANP, more effectively than BNP, stimulates cGMP production. ANP-induced diuresis and natriuresis occur, in part, by the V2 receptor–mediated action of ADH in the collecting ducts. Natriuretic peptide–induced increases in water and sodium excretion protect the body from overhydration. In pathologic conditions, such as congestive heart failure, ANP and BNP are stimulated by atrial overload secondary to the heart's inability to adequately empty.

Dopamine. The importance of dopamine in water homeostasis remains unclear, although renal production is increased by volume expansion, leading to natriuresis and water loss. Dopamine, synthesized in the renal proximal tubule from circulating L-dopa by L-amino acid decarboxylase, increases the glomerular filtration rate and diminishes sodium reabsorption in proximal tubules and collecting ducts. Dopamine, via D1 receptors, increases cAMP generation by stimulating adenyl cyclase and, via D1/D5 receptor heteromers, stimulates phospholipase C, inhibiting both the Na-K-ATPase pump and sodium/hydrogen ion exchanger-3. D2-like receptors (D2, D3, and D4), which inhibit adenyl cyclase, also inhibit Na^+-H^+ exchanger 3, although the effects of D1 receptors are more dominant. Caveolin-1, a membrane scaffolding protein, helps organize the D1-receptor signaling pathway and intracellular effects.[24, 24a] Renal dopamine production increases as dietary salt intake increases. Renal dopamine is thought to be responsible for regulating over 50% of net renal salt and water excretion when salt intake is increased. Dopamine also decreases aldosterone secretion[25] and inhibits the antinatriuretic effects of angiotensin II.[26] Dopamine is metabolized by the enzymes catechol-O-methyltransferase and monoamine oxidase. Some of the effects of ANP are likely mediated by dopaminergic mechanisms.[15]

Prostaglandins. Local renal prostaglandin (PGE_1 and PGE_2) generation occurs mainly in the distal nephron and is associated with increased basolateral membrane Na-K-ATPase.[27] This leads to greater renal blood flow, often despite decreased effective circulating volume. PGE_2 counteracts excessive sodium and water reabsorption by inhibiting the Na^+K^+-$2Cl^-$ cotransporter in the thick ascending loop of Henle, leading to natriuresis.

Endothelin. Endothelin-1 is a 21–amino acid, predominantly endothelium-derived peptide that operates via autocrine and paracrine mechanisms. In normal subjects, its plasma concentrations are inversely related to glomerular filtration rate (GFR).[28] Endothelin-1 inhibits Na^+ and water reabsorption, thus reversing ADH-mediated osmotic water permeability.[29] This occurs via intrarenal ET_B receptors located in vascular endothelium, vascular smooth muscle, and tubular epithelial cells lining the length of the nephron (with high density in the medullary collecting ducts).[30] Activation of these receptors induces vasorelaxation through the production of nitric oxide and prostacyclin, in addition to direct inhibition of renal tubular sodium uptake and increased urinary water excretion.[31]

Evaluating Water Balance

There are various ways to evaluate water balance (Table 97.2). In the ICU, water balance is generally assessed using body weight and fluid input-output. However, both methods have limitations.

WATER METABOLISM DISORDERS

Abnormal (hypervolemic or hypovolemic) water balance attributable to various intrinsic and extrinsic etiologies results in ICU admissions when the physiologic derangement endangers survival and/or requires treatment under close monitoring.

Hypervolemic Disorders

Hypervolemic disorders are caused by excessive water ingestion and/or the inability to excrete excess body water.

Water intoxication. The classic example of abnormal positive water balance is water intoxication (water poisoning or hyperhydration), where an individual consumes very large volumes of water. Such excess water intake overwhelms the kidney's capacity to excrete water (maximum daily renal capacity ~15 L), despite maximal dilution (urine osmolarity of ~50 mOsm/L).[32,33] This situation results in hyponatremia, hypochloridemia, and hypokalemia. Brain edema occurs secondary to the extracellular to intracellular concentration gradient, leading to headache, delirium, seizures, coma, and death. Other symptoms include nausea, vomiting, twitching, and muscle weakness.

Water intoxication (psychogenic polydipsia) is largely observed in psychiatric patients (predominantly in schizophrenia but also in anorexia nervosa). It is hypothesized that schizophrenics who develop water intoxication have impaired hippocampal regulation, resulting in increased ADH secretion in response to psychological stimuli.[34] Another cause might be the drugs used to treat schizophrenia.[35] Forced water intake in children (such as that associated with suspected child abuse) can also lead to water intoxication, as can excessive drinking in marathon runners and military trainees.[36] Excessive water drinking among users of the recreational drug ecstasy (3,4-methylenedioxymethamphetamine) can cause water intoxication.[37]

Iatrogenic causes of water intoxication include excessive, rapid water ingestion before pelvic ultrasound examinations and transurethral resection of the prostate syndrome. The latter occurs when a large volume of nonconducting (electricity) water plus glycine irrigation solution is absorbed through the prostatic veins and sinuses. The amino acid glycine is rapidly metabolized, causing water overload, hypoosmolarity, and hyponatremia. The introduction of bipolar cautery, which does not disperse electric current, permits using electrolyte-containing irrigation solutions (e.g., normal saline), thereby preventing hypoosmolarity and hyponatremia but not fluid overload. The absorption of water-glycine distention medium during operative hysteroscopy can also lead to intravascular volume overload and water intoxication.

Treatment of water intoxication involves water restriction and loop diuretics. Hypertonic saline is rarely required and should only be considered in cases of severe hyponatremia. Too rapid a correction of hyponatremia can result in central pontine myelinosis.

Syndrome of inappropriate antidiuretic hormone secretion (SIADH). SIADH causes hyponatremia and hypoosmolality because of impaired water excretion secondary to inappropriate, continued secretion or action of ADH despite normal or increased plasma volume. ADH promotes water reabsorption without affecting sodium reabsorption, leading to dilutional hyponatremia because of water excess rather than sodium deficiency.

Excessive water reabsorption activates volume receptors, causing the secretion of natriuretic peptides and natriuresis. Eventually, a steady state is reached with urinary sodium excretion matching sodium intake. Therefore only when water intake exceeds the reduced urine output does hyponatremia develop. Importantly, hyponatremia does not occur with severely restricted water intake. In addition to inappropriate ADH secretion, SIADH may include inappropriate thirst sensation, leading to water intake in excess of free water excretion. This increased water intake helps maintain hyponatremia.

SIADH includes hyponatremia, inappropriately elevated urine osmolality (>100 mOsm/kg), and reduced serum osmolality in a euvolemic patient (Fig. 97.2). SIADH should be considered when these findings occur in the setting of otherwise normal cardiac, renal, adrenal, hepatic, and thyroid function; absence of diuretic therapy; and absence of other factors that stimulate ADH secretion such as hypotension, severe pain, nausea, and stress.

Impaired ADH regulation in SIADH:

- Type A—erratic, unregulated ADH release unrelated to plasma osmolality.
- Type B—modest, constant ADH secretion.

TABLE 97.2 Evaluating Water Balance

Quantifying Input and Output

Clinical computation

Fluid balance = input (all intravenous and enteral intakes) − output (urine, GI, other drainages)

Often does not include

Intake: Accurate quantification of blood products, irrigation fluids

Output: Diarrhea, fluid lost into linens and bandages, insensible losses (skin, respiratory), sensible losses (sweating caused by fever, surface exudation from burns)

Body Weight

Fluid balance = Δ body weight

Requires accurate scale and bed taring

Tare weight = weight of bed without patient but with sheets, pillows, etc.

Net weight (patient weight) = gross weight (total weight) − tare weight

Urine Specific Gravity

U_{sg} = density of urine/density of water

Range: 1.003–1.035

Euhydration: 1.010–1.026

High-molecular-weight substances (e.g., glucose, protein, and radiographic contrast) can increase U_{sg} >1.035.

Serum and Plasma Osmolality/Osmolarity

Osmolarity = osmoles of solute/liter solution

Osmolality = osmoles of solute/kilogram solvent

Urine and plasma osmolalities should be measured but can be estimated

Calculated serum osmolarity (when using SI units [mmol/L])

Calculated serum osmolarity = $2(Na^+) + 2(K^+)$ + glucose + urea (BUN)

OR

Calculated serum osmolarity = $2(Na^+)$ + glucose + urea (BUN)

Calculated serum osmolarity (when Na^+ is mEq/L and glucose and BUN are [mg/dL])

Calculated serum osmolarity = $2[Na^+]$ + [glucose]/18 + [BUN]/2

Normal serum osmolality: 275–290 mOsm/kg; 295–300 mOsm/kg indicates impending dehydration; >300 mOsm/kg indicates dehydration

Urine: specific gravity vs. osmolality

Unlike specific gravity, osmolality is unaffected by the number and size of particles in solution; urine containing glucose and/or protein will have a specific gravity greater than osmolality

U_{sg} = 1.020–1.030 corresponds to osmolality of 800–1200 mOsm/kg H_2O

U_{sg} = 1.005 is an osmolality <100 mOsm/kg H_2O

Normal kidneys can concentrate urine to an osmolality four times greater than serum and dilute urine to 25% of serum osmolality.

Electrolyte–Free Water Clearance

Electrolyte–free water clearance ($T^e_{H_2O}$) − amount of water in urine free of solutes

$T^e_{H_2O} = V([U_{NA} + U_K]/P_{NA}) - 1$

V = total urine volume

U_{NA} = urine (Na^+)

U_K = urine (K^+)

P_{NA} = plasma (Na^+)

Positive $T^e_{H_2O}$ = water is being excreted (e.g., causing hypernatremia)

Negative $T^e_{H_2O}$ = water is being reabsorbed (e.g., causing hyponatremia)

Free Water Deficit

In hypernatremia, estimated free water deficit

$$\text{Water deficit} = \text{TBW} * (\{\text{serum[Na]}/140\} - 1)$$

TBW = estimated total body water: men, 0.6*Wt (kg); women, 0.5*Wt (kg); in the elderly and those significantly dehydrated: men, 0.5*Wt (kg); women, 0.4*Wt (kg)

This estimate does not account for ongoing water (i.e., insensible, urine, GI tract) or isoosmotic fluid (i.e., osmotic diuresis, diarrhea) losses that continue to contribute to water deficit.

Bioelectric Impedance

Noninvasive method used to estimate total body water based on the assumption that only body water conducts electricity, whereas fat, which has little water content, restricts the flow of current. However, this technique is limited by the assumptions used, such as assuming that fat-free mass has a constant hydration of 73%.[67]

BUN, Blood urea nitrogen; *GI,* gastrointestinal.

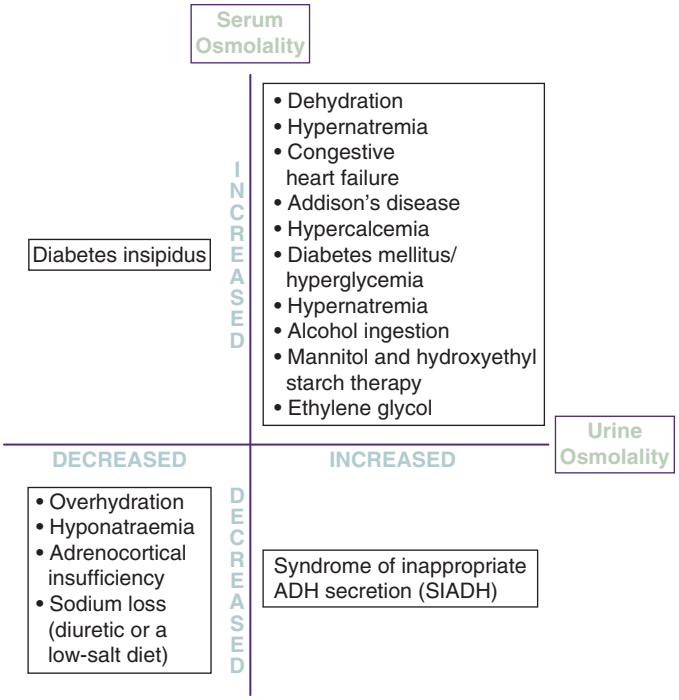

Fig. 97.2 Relationships Between Serum and Urine Osmolality.

- Type C—("reset osmostat")—downward resetting of the osmostat. Plasma sodium concentrations are regulated at a lower level and continue to fall without therapy.
- Type D—normal osmoregulation. ADH secretion varies appropriately with the plasma osmolality, but urine is concentrated even if ADH release is suppressed (e.g., vasopressin receptor is constituently activated, production of antidiuretic compound other than ADH, postreceptor defect in transferring aquaporin-2 water channels).

Classification of SIADH etiology:

- CNS disorders (e.g., stroke, hemorrhage, infection, inflammation, trauma, neurosurgery, acute intermittent porphyria). Must differentiate SIADH from cerebral salt wasting (ADH secretion is secondary to reduced extracellular fluid volume).
- Ectopic (paraneoplastic) ADH production by tumors (small cell lung carcinoma in 75% of cases).
- Pulmonary diseases (pneumonia, asthma, atelectasis, pneumothorax).
- Drugs that mimic ADH, stimulate ADH release, potentiate ADH effects, or have unclear mechanisms (e.g., exogenous ADH analogs such as vasopressin, desmopressin, selective serotonin reuptake inhibitors [SSRIs], phenothiazines, tricyclics, carbamazepine, cyclophosphamide, vincristine).
- Hormonal deficiency (hypothyroidism, hypopituitarism, Addison disease).
- Postoperative (likely mediated by pain afferents), transsphenoidal surgery.
- Symptomatic HIV infection.
- Hereditary/genetic—(e.g., gain-of-function mutation of arginine vasopressin receptor type 2—nephrogenic syndrome of inappropriate antidiuresis—causing constitutive receptor activation).
- Aging.
- Unknown origin/idiopathic.

Acute treatment includes water restriction and treating the underlying cause (e.g., stopping the offending drug, treating pneumonia, meningitis). In severe symptomatic cases associated with neurologic complications, hypertonic saline is administered to gradually correct hyponatremia. Loop diuretics can be useful by aiding water excretion. However, too rapid correction of serum sodium concentrations, especially in asymptomatic patients, can result in neurologic impairment from central pontine myelinolysis. Another complication of aggressive sodium correction is severe hypernatremia.

Pharmacologic treatment for SIADH includes vasopressin receptor antagonists (vaptans), which competitively bind to V2 receptors. An advantage of these agents is their ability to reduce the need for severe fluid restriction, while correcting hyponatremia within a short time. During the initial 24 hours of administration, it is critical to prevent overly rapid correction of hyponatremia. Discontinuing vaptan therapy for more than 5–6 days requires monitoring for hyponatremic relapse. Therefore it is prudent to taper the vaptan dose while restricting fluid intake. Side effects include thirst, polydipsia, and urinary frequency. Vaptans are ineffective in inappropriate antidiuresis caused by constitutive activating mutations of V2 receptors.

Oral urea is a new-old therapy that is now more available and that serves as an osmotic agent to increase urinary free water excretion. European clinical guidelines recommend the use of urea and discourage the use of vasopressin receptor antagonists (vaptans).[38,39]

Another treatment for SIADH is demeclocycline, a macrolide antibiotic, which induces nephrogenic diabetes insipidus by reducing adenylate cyclase expression, cAMP generation, AQP2 gene transcription, and AQP2 abundance in the renal medulla. Its frequent side effects include nausea and skin photosensitivity.

Cerebral (renal) salt-wasting syndrome (CSW). CSW is the extracellular volume depletion caused by abnormal sodium transport in patients with intracranial disease (but can also occur in patients without cerebral disease) and normal adrenal and thyroid function.[40] CSW usually develops in the week after brain insult. Its duration is usually brief (2–4 weeks) but can last for several months. Both SIADH and CSW present with low serum osmolality, elevated urine osmolality, and high urinary sodium concentrations. The basic difference is that in CSW, there is hypovolemia, whereas in SIADH, there is euvolemia or mild hypervolemia. Urinary sodium concentrations are elevated in SIADH and CSW (>40 mEq/L). However, urinary sodium excretion (urinary sodium concentration [mEq/L] × urinary volume [L/24 h]) is much higher than sodium intake in CSW but usually equals sodium intake in SIADH. Therefore net sodium balance is negative in CSW. Failure to distinguish CSW from SIADH in hyponatremic brain-injured patients can lead to inappropriate therapy with fluid restriction.

In CSW, excessive sodium is lost in the proximal tubule, leading to reduced effective circulating volume. The two proposed mechanisms are the excessive secretion of natriuretic peptides (BNP and C-type natriuretic peptide [CNP]) and the loss of renal sympathetic stimulation. Both the mechanisms reduce proximal and possibly distal sodium transport. The ensuing hypovolemia leads to baroreceptor activation increasing ADH secretion and water conservation in an attempt to return to a euvolemic state. In contrast, SIADH is caused by an inappropriate euvolemic increase in ADH secretion. Depressed sympathetic drive and increased BNP concentrations are also associated with decreased renin and aldosterone concentrations, further inhibiting sodium retention.

The decreased serum sodium concentration associated with CSW reduces serum osmolality, and a tonicity gradient develops across the blood-brain barrier, causing or exacerbating cerebral edema. Symptoms include lethargy, agitation, headache, altered consciousness, seizures, and coma. Treatment involves correcting intravascular volume depletion and hyponatremia, plus replacing persistent urinary sodium loss with intravenous normal or hypertonic saline solutions. Saline infusion corrects the hypovolemia, removing a potent stimulus for ADH secretion, increasing free water excretion, and correcting the

hyponatremia. There are reports of favorable responses to mineralocorticoid therapy. Once the patient is stabilized, enteral salt supplementation should be considered.

Hepatic cirrhosis. Regardless of etiology (alcoholic, chronic hepatitis, autoimmune, genetic, cryptogenic), cirrhosis involves the loss of normal hepatic architecture and irreversible liver damage. Cirrhosis changes splanchnic circulation, causing mechanical obstruction to the portal flow and portal hypertension. Ascites occurs when portal pressures of >12 mm Hg cause intrahepatic sinusoidal hypertension. If portal pressure decreases to <12 mm Hg (e.g., after portosystemic shunt), ascites usually disappears. Presinusoidal portal hypertension (e.g., portal vein thrombosis) does not cause ascites in the absence of another predisposing factor.

In addition to the mechanical obstruction to portal flow, cirrhosis is associated with an increased portal venous inflow secondary to splanchnic arterial vasodilation and the opening of portosystemic collaterals. The latter, because of increased circulating vasodilators, such as nitric oxide and prostacyclin, reduces systemic vascular resistance and arterial pressure. Cardiac output increases in compensation. This hyperdynamic pattern can be found in cirrhotic patients even before ascites develops. In response to cirrhosis-associated vasodilation, endogenous vasoconstrictors and sodium-retaining neurohumoral mechanisms activate (RAAS, sympathetic nervous system, ADH) in an attempt to normalize perfusion pressure. The net effect is sodium and water retention. However, cirrhotics are effectively intravascularly volume depleted despite increased extracellular sodium stores, plasma volume, and cardiac output. As the disease progresses, solute-free water excretion is increasingly impaired because of the increased ADH secretion. Reduced water excretion plus ascites accumulation adds to total body fluid overload. The intravascular depletion leads to further "compensation," including nonosmotic ADH secretion, worsening excess water retention, hypoosmolality, and dilutional hyponatremia. Nonosmotic ADH secretion is mediated via atrial, ventricular, aortic arch, and carotid sinus baroreceptors, which stimulate hypothalamic ADH release. This ADH secretion is paradoxical because serum osmolarity is low. The net result is enhanced sodium and water retention, which attempts to correct the depleted circulatory volume. Sodium retention occurs despite increased total body extracellular sodium concentrations. RAAS activation encourages water retention, which contributes to the development of hypervolemic hyponatremia. However, hypovolemic hyponatremia secondary to diuretic treatment is more common than hypervolemic hyponatremia.[41] Hyponatremia severity correlates with worsening survival and morbidity. Hyponatremia is an important prognostic marker before and after hepatic transplantation.

Other factors implicated in the development of hyponatremia and associated with cirrhosis include decreased renal PGE_2 production and slower ADH metabolism. Resistance to the natriuretic action of ANP may play a role in sodium retention. Renal perfusion in cirrhosis with ascites depends on a delicate equilibrium between the degree of stimulation of vasoconstrictor systems (sympathetic nervous system, RAAS) and the activity of intrarenal vasodilator compounds (prostaglandins and nitric oxide). Imbalance between systemic vasoconstriction and local renal vasodilation can result in progressive renal failure (hepatorenal syndrome).[42,43]

Stressed states. Exudation of protein-rich intravascular fluid from plasma to the extracellular space resulting in relative intravascular hypovolemia is the hallmark of stressed states (sepsis, pancreatitis, burns). It also occurs in ovarian hyperstimulation syndrome, anaphylaxis, viral hemorrhagic fevers, influenza, snakebite envenomation, ricin poisoning, and some immunotherapies including chimeric antigen receptor (CAR) T-cell therapy (cytokine release syndrome). Such exudation leads to sequelae, including acute respiratory distress syndrome, diffuse edema, and abdominal compartment syndromes. Plasma ADH, angiotensin, and aldosterone are usually increased during the initial phase of septic shock and burns and decrease later in the course.[44] Extravascular fluid shifts diminish as the patient convalesces. The greater the fluid accumulation, the greater the morbidity and mortality. There is currently no direct treatment for this condition.

The endothelium tightly controls intravascular fluid exchange from the circulation to the tissues. Dysfunction of this barrier causes fluid exudation and edema. Various mechanisms appear involved in increasing membrane permeability. The main function of vascular endothelial (VE)-cadherin, a cell adhesion molecule localized to endothelial cell junctions, is regulating and forming a homophilic calcium-dependent bond with a twin on an adjacent cell. The cytoplasmic domain of VE-cadherin is bound to catenins, which attach to the cytoskeletal structure. When endothelial cells are exposed to permeability factors, they contract via myosin-actin crossbridge cycling, resulting in the dissociation of VE-cadherin from its adjacent homolog, forming gaps between the endothelial cells. In addition, the endothelial glycocalyx, a carbohydrate-rich layer lining the luminal surface of the entire vascular endothelium, is thinned, contributing to capillary permeability. Permeability factors include proinflammatory cytokines (tumor necrosis factor [TNF], IL-6, IL-8, interferon-γ, IL-1β), nuclear transcription factors (high-mobility group box 1 [HMGB1]), transforming growth factor, and vascular endothelial growth factor (VEGF). These factors likely operate through the MyD88-ARNO-ARF6-signaling axis while also diminishing VE-cadherin expression.[45] VE-cadherin is internalized by VEGF-induced signaling through VEGF receptors and undergoes tyrosine phosphorylation, leading to greater VE cell detachment and transendothelial permeability. Matrix metalloproteases (e.g., MMP-9, gelatinase b) have been implicated as degrading interendothelial adherens junction proteins. An associated mechanism is activation of Rho-A GTPase, which increases actomyosin contractility, inducing intercellular junction breakdown and enhancing permeability.[46]

Hypovolemic Disorders

Diabetes insipidus (DI). DI, polyuria (defined as a urine output exceeding 3 L/day in adults and 2 L/m^2 in children) caused by plasma ADH deficiency or renal resistance to ADH's effects, is characterized by the failure to appropriately concentrate urine.

In the absence of ADH (<0.5 pg/mL), renal collecting duct membranes become impermeable to water (fewer aquaporin-2 water channels), thereby allowing the formation of dilute filtrate in proximal nephrons. This results in the excretion of relatively large urine volumes of low osmolality (≥100 mOsm/kg), causing hypovolemia and even hypotension. These stimulate hypothalamic osmoregulators, encouraging water intake via thirst. With normal thirst and access to water, fluid intake increases to compensate for most of the water loss. Consequently, even in the complete absence of vasopressin, urine output and fluid intake increase in parallel, maintaining plasma osmolality within the normal range. Severe dehydration and hypernatremia occur when access to water or intravenous fluids is lacking or there is coexisting thirst deficiency.

The most common cause of DI is inadequate neurohypophyseal ADH secretion, resulting in partial or complete central DI. Nephrogenic DI is characterized by normal ADH secretion with varying degrees of renal resistance to its antidiuretic effect. Another mechanism is the suppression of ADH secretion by excessive water intake, as seen in primary polydipsia. ADH insufficiency can rarely result from increased metabolic clearance during pregnancy because of the placental production of the aminopeptidase vasopressinase, which rapidly

degrades ADH, causing a fourfold to sixfold increase in ADH metabolism. In most women, the pituitary compensates by producing more ADH. In some women, presumably those with diminished ADH secretory reserves, polyuria develops. This usually occurs during the third trimester and spontaneously resolves after placental delivery.

Central DI can be caused by defects along the ADH neurosecretory pathway, including genetic mutations affecting ADH synthesis and packaging, damage to ADH-producing magnocellular neurons or the supraopticohypophyseal tract, and disorders of neurohypophyseal hormone release. Five percent of central DI cases are familial/genetic; >50 mutations have been identified in the AVP-neurophysin II gene (chromosome 20), and other loci have been described. Thirty to fifty percent of cases are considered "idiopathic" (autoimmune, aberrant posterior pituitary blood supply). Other causes include neoplasms involving the hypothalamus (craniopharyngiomas, germinomas, metastatic disease of the posterior pituitary [breast or lung cancer]) and granulomas (sarcoidosis, tuberculosis, granulomatosis with polyangiitis, Langerhans cell histiocytosis [histiocytosis X]). In the ICU, common causes are trauma—for example, closed head injury, postcraniotomy, anterior communicating artery (ACA) aneurysmal rupture causing subarachnoid or intracerebral hemorrhage (ACA aneurysms and their treatment can compromise hypothalamic blood supply), brain abscess, subdural hemorrhage (DI persisted for 3 months in 8% of survivors), and ischemic brain injury.[47] Transient or permanent DI occurs in 8%–9% of endoscopic transsphenoidal surgeries.

Nephrogenic DI may reflect an intrinsic renal defect, a congenital condition (primary nephrogenic DI caused by mutations of the genes encoding vasopressin V2 receptor [*AVPR2*] and aquaporin [*AQP2*]), or may be acquired secondary to metabolic disease or medication. It is characterized by complete or partial deficiency to the renal antidiuretic response to normal or increased ADH concentrations. Adults generally have an acquired form. Normal aging can also result in partial nephrogenic DI. In terms of drugs inducing nephrogenic DI, lithium is the most common offender, with nephrogenic DI reported in 25%–55% of patients receiving lithium. With long-term use, lithium-induced DI can become irreversible. Hypercalcemia and hypokalemia can partially block renal ADH action. Hereditary forms of nephrogenic DI are caused by defective renal ADH V2 receptor (males with X-linked recessive defect in chromosome region Xq28) or aquaporin-2 genes.

Adipsic DI is a condition where impaired thirst complicates deranged water balance. It is closely associated with ACA aneurysm clipping and is characterized by dramatic increases in plasma ADH concentrations during nonosmotic stimuli such as hypotension. This situation reflects intact supraoptic and paraventricular nuclei and the posterior pituitary with abnormalities of the anterior pituitary osmoreceptors. Vascular supply to this latter area is from small arterioles supplied by the ACA. Disrupting this blood supply causes infarction that impairs ADH secretion response to thirst or hyperosmolarity.

A diagnosis of DI is made when urine volume is markedly increased and urine osmolality is very low (<100 mmol/kg), which is associated with elevated plasma osmolality (>300 mmol/kg) and serum sodium concentrations (>145 mmol/L). However, other causes of polyuria must be excluded—for example, excessive fluid resuscitation, osmotic diuresis, hypertonic saline infusion, and so on. When basal plasma osmolality and sodium are within normal ranges, osmotic stimulation with a formal water deprivation test or hypertonic saline infusion (if necessary) to achieve plasma osmolality of >295–300 mOsm/kg is indicated. If there is no change in the water loss despite fluid deprivation, the type (central or nephrogenic) of DI should be determined by monitoring the response to administered ADH or 1-deamino-8-D-arginine vasopressin (DDAVP-desmopressin), a synthetic ADH analog. A significant increase in urine osmolality 1–2 hours after subcutaneously or intravenously injecting 1 μg of DDAVP indicates insufficient endogenous ADH and probable central DI. Little or no increase in urinary concentration indicates renal resistance to ADH and severe nephrogenic DI. Some cases are not as straightforward and require further evaluation with a 2-day therapeutic trial of DDAVP, magnetic resonance imaging (MRI) of the hypothalamus and pituitary, and plasma ADH and copeptin measurements.

While diagnosing and identifying the cause of the DI, it is imperative that adequate fluid intake is maintained. The treatment for central DI is either intravenous ADH (vasopressin) or oral, intranasal, or parenteral DDAVP. DDAVP is a synthetic ADH analog with a longer half-life than the native hormone. In nephrogenic DI, therapeutic options are only partially effective: a low-sodium diet, thiazide diuretics, prostaglandin E synthetase inhibitors, and nonsteroidal antiinflammatory drugs may partially decrease urine volume. The potassium-sparing diuretic amiloride is used in lithium-induced nephrogenic DI (it induces natriuresis and reduces lithium uptake in the distal tubules and collecting ducts, blunting lithium's inhibition of water reabsorption). Pregnancy-associated DI can be controlled with vasopressinase-resistant DDAVP but not ADH.[48]

Osmotic diuresis. Osmotic diuresis is characterized by increased urination caused by nonreabsorbed solutes (e.g., glucose and urea) in renal proximal tubules. Increased osmotic pressure within the tubule causes luminal water retention, reducing water reabsorption and increasing urine output. When blood glucose exceeds 160–180 mg/dL, the proximal tubule is overwhelmed, causing glycosuria. Osmotic urea diuresis is common in the ICU, associated with high-protein nutrition, high corticosteroid doses, and resolving acute renal failure. Hypernatremia ensues because of the greater urinary loss of water than electrolytes.[49]

Therapeutic agents (e.g., mannitol) are used to increase urine output and decrease extracellular fluid volume. Mannitol, freely filtered by the glomerulus and not reabsorbed, acts as an osmotic diuretic, increasing urinary losses of electrolyte-free water. Osmotic substances increase blood osmolarity, thereby pulling water from the interstitial space and increasing GFR and urine output. Failure to replace fluid losses can lead to volume depletion and hypernatremia. However, if very high doses of hypertonic mannitol are infused, or if it is administered to patients with preexisting renal failure, mannitol is retained in the circulation. The resulting plasma osmolality increase, like that produced by hyperglycemia, causes osmotic movement of water out of cells, leading to extracellular fluid volume expansion and dilutional hyponatremia. This can result in intravascular fluid overload, especially if the excess fluid and osmotic substances cannot be excreted.

Osmotic diuresis generally leads to significant free water losses and can cause or contribute to hypernatremia. However, with glycosuria secondary to uncontrolled diabetes mellitus, diabetic ketoacidosis, and hyperosmolar hyperglycemic state, most patients are mildly hyponatremic. The serum sodium concentration reflects the balance between the dilutional effect of water moving out of cells in response to the hyperglycemia-induced increase in serum osmolality (dilutional hyponatremia—i.e., true hypertonic hypervolemic hyponatremia) and the increased water excretion due to glycosuria-induced osmotic diuresis.

Treating water losses secondary to osmotic diuresis involves reducing the nonreabsorbed solute either by stopping its administration (e.g., mannitol) or treating the underlying pathologic condition (e.g., reduce blood glucose concentrations). Furthermore, excessive dehydration should be treated and prevented by administering sufficient fluid with close monitoring of serum and urine electrolytes plus urine output.[50]

Cold diuresis. Cold or cold-induced diuresis occurs during exposure to a hypothermic environment and during mild to moderate

accidental and therapeutic hypothermia. During therapeutic hypothermia, cold diuresis is most apparent during the induction phase.[51] Cold diuresis is characterized by increased sodium and chloride excretion, leading to enhanced water loss, decreased blood volume, and increased blood viscosity. The latter augments the increased viscosity secondary to the hypothermia. Vasoconstriction and hypovolemia caused by hypothermia are most problematic; thus vasodilation during rewarming must be countered by fluid resuscitation to avoid hypotension.

Possible causes of cold diuresis include the redirection of blood from vasoconstricted extremities to the core, leading to increased core fluid volume. The latter leads to increased renal blood flow and diuresis. ADH appears to be involved in cold diuresis. Some investigators report decreased ADH, whereas others report that although ADH concentrations are elevated, cold exposure inhibits renal V2 receptors, decreasing V2 receptor mRNA expression and inducible renal medullar AQP-2 water channel protein expression.[52] ANP does not appear to be involved in cold diuresis.

Heat and exercise-induced disorders. Sweat is hypoosmotic relative to plasma; hence, excessive sweating can lead to significant water loss, reaching >2.5 L/h during strenuous exercise.[53] Sweat sodium concentrations range from 15 to 90 mmol/L, with an average of 40 mmol/L. As sweating increases, sodium secretion rates proportionally increase. However, heat acclimatization lowers sodium chloride concentration. The rate of sweat potassium losses appears to be indirectly related to the sweat flow rate.[54] Maintaining normal hydration during exercise maintains cardiovascular and thermoregulatory responses. Whenever possible, oral, rather than intravenous (IV), rehydration should be performed. Although IV fluids rehydrate faster, the benefits are often transient, with the major limitation being the bypassing of the oropharynx. Oropharyngeal stimulation influences thirst sensation, ADH release, cutaneous vasodilation, and mean arterial pressure.[55] Therefore drinking water plus electrolyte solutions to minimize dehydration is necessary during and after significant exercise and heat exposure. To maintain adequate hydration, elite athletes, ingest ~200–800 mL/h. Less acclimatized participants should not drink as much as possible, but according to the stimulation of thirst and no more than 400–800 mL/h.

In collapsed marathon runners, there are significant incidences of both hypernatremia with hyperosmolality and hyponatremia with hypoosmolality. The latter is often the result of hyperhydration, caused by considerable water ingestion, and may be exacerbated by nonosmotic ADH secretion.[56] Hypernatremia results when water loss via sweating is associated with a low or insufficient fluid intake.[57] Hyponatremia, hyperthermia, hypertonic hypernatremia, orthostatic hypotension caused by decreased peripheral resistance, and dehydration can each contribute to cerebral dysfunction.[58,59] Moreover, it is crucial to differentiate between hypernatremia and hyponatremia because the immediate management differs. Administering hypotonic fluids to severely hyponatremic patients may cause fatal cerebral edema, evidenced by seizures and/or coma. Therefore laboratory testing to determine serum sodium concentration is vital to direct therapy.

Heat stress illness (HSI), also called *heat-related illness,* includes benign rash, heat syncope, heat cramps, heat exhaustion (most common HSI), and heat stroke (most severe form). During 2001–2010, ~28,000 HSI hospitalizations occurred in 20 states.[60] HSI occurs during heat exposure with and without exercise, with greater thermoregulatory heat strain occurring during high humidity because of decreased environmental evaporative capacity. Obesity, heart failure, preexisting neuropsychiatric disorder, psychotropic drug intake (e.g., phenothiazines, cocaine), and strenuous outdoor work[61] are associated with increased HSI risk. HSI development and severity are significantly related to hydration status and ability to sweat.[62,63] HSI is exacerbated by hypovolemia and plasma hyperosmolality, which inhibit thermoregulatory responses, such as cutaneous vasodilation and sweating.[64] Elevated core temperature does not stimulate ADH secretion except with increased serum osmolality.[65] HSI treatment includes rapid cooling, fluid replacement, and physiologic support.

CONCLUSION

Maintaining homeostatic water balance is a vital body function commonly disordered in critically ill patients because of combinations of their acute illness, underlying chronic diseases, treatments, and aging. Modern critical care medicine needs to better understand water metabolism, especially the microcirculatory consequences of edematous and overhydrated states. Such a better understanding should influence treatment—for example, whether to treat with saluretic diuretics that enhance sodium excretion or with aquaretics that increase water excretion.[66]

KEY POINTS

- Water, the liquid of life for all organisms, has many functions: carrier of essential substances; body coolant, lubricant, reactant, and product in metabolic reactions; and shock absorber.
- Water homeostasis is controlled by thirst, the ability to find and ingest water, kidney function, sweating, and endogenous systems.
- Endogenous systems active in water metabolism include ADH, the RAAS system, natriuretic peptides, dopamine, and renal intracrine mechanisms.
- Environmental conditions—extreme heat and cold—can cause disordered water homeostasis, as can diarrhea, drugs, excessive water ingestion, and disorders of endogenous systems (DI, SIADH).
- In stressed states (e.g., sepsis, burns, and trauma), plasma ADH and aldosterone are increased during the initial phase, accompanied by extravascular exudation of protein-rich fluids.
- Critically ill patients are totally dependent on their care providers for maintaining water homeostasis and for preventing and correcting disordered homeostasis.

Advanced Techniques in Blood Purification

Antoine Streichenberger, Pauline Sambin, Celine Monard, and Thomas Rimmelé

INTRODUCTION

During the last decade, several blood purification techniques have been developed. Blood purification techniques are extracorporeal treatments that can either be combined with renal replacement therapy (RRT) or used as standalone methods. Their common objective is to remove from the blood proteins or cells that may have deleterious effects. These techniques are mostly used in septic shock, targeting endotoxins, cytokines, proinflammatory cells, or even bacteria and viruses.

Most randomized controlled trials (RCTs) have failed so far to demonstrate an improved survival with the initiation of extracorporeal blood purification sessions in sepsis. Numerous biases from published trials have been underlined, including the heterogeneity of studied populations, timing of treatment initiation, dose, and duration of the therapy. This was specifically reinforced in the 2016 Surviving Sepsis Campaign. Given the lack of positive RCTs, no recommendations relating to blood purification techniques in sepsis could be made, and further research was encouraged.[1] The same reservations apply to artificial liver support systems that are not routinely implemented in intensive care units (ICUs) because of the lack of conclusive RCTs.

This chapter will first describe the dysregulated immune response observed in sepsis and the potential targets of extracorporeal blood purification in this specific context. Second, the main blood purification techniques and related literature will be presented. Finally, we will review the indications for blood purification outside sepsis and the liver support technology.

PATHOPHYSIOLOGY OF DYSREGULATED IMMUNE RESPONSE IN SEPSIS AND TARGETS FOR BLOOD PURIFICATION TECHNIQUES

The Dysregulated Immune Response in Sepsis

Pathophysiology of the immune response in septic shock is usually described in two phases. During the first phase, a massive dysregulated proinflammatory component, also called a *cytokine storm,* is associated with tissue damage, organ injuries, and early mortality. During the second phase, the predominant antiinflammatory component, triggering immunoparalysis, is responsible for nosocomial infections, viral reactivations, and late mortality.[2]

During pathogen invasion (either bacteria, viruses, fungi, or parasites), numerous molecular signals are activated, driving the immunoinflammatory response. These alerts are triggered by pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs)[3,4]. PAMPs are described as the "molecular signature" of pathogens. They are not produced by the host, but they are expressed at the pathogen surface and include endotoxins at the surface of gram-negative bacteria, double-stranded ribonucleic acid (RNA) produced by most viruses, and beta-glucans and mannans found in fungi. DAMPs are endogenous molecules, such as high-mobility group box 1 or extranuclear deoxyribonucleic acid (DNA), released during tissue damage.[5,6] DAMPs are released during sepsis but also during specific conditions such as burns, trauma, surgery, or acute pancreatitis, triggering a sterile inflammatory response.[7–10] Both PAMPs and DAMPs are recognized by pattern recognition receptors (PRRs), which are ubiquitous on the surface of innate immune cells. Importantly, activation of PRRs by PAMPs or DAMPs leads to the appropriate synthesis of cytokines and the immune response. However, in septic shock, the inflammatory response is dysregulated and leads to a massive release of cytokines (interleukin [IL]-1, IL-17, IL-6, tumor necrosis factor [TNF]-alpha) and an intense activation of complement.

Concomitantly, immunosuppressive patterns also appear, mainly consisting of a reduced antigen-presenting cell function and reduced human leukocyte antigen–DR isotype (HLA-DR) expression on monocytes (mHLDA-DR), which correlates with mortality and lymphocyte apoptosis.[11–13] Lymphopenia is also a marker of immunosuppression in sepsis and has a poor prognosis. The massive production of the antiinflammatory IL-10 cytokine participates in sepsis-induced immunosuppression as well.[14]

Immunomodulatory Therapies and Targets for Extracorporeal Blood Purification

Along with antibiotics, controlling the site of infection, and symptomatic treatment, numerous intravenous treatments targeting specific pathways such as IFN-γ, rhIL-7, and TNF-alpha have been tested to modulate the immunoinflammatory cascade in sepsis.[15] Unfortunately, all these treatments have failed to demonstrate any benefits on morbidity and mortality.[15] Again, some authors have highlighted sepsis "heterogeneity" with regard to the site of infection, pathogens, genetic background, and premorbid conditions. Other experts have argued that all these molecules target a specific pathway of the immune response, whereas a more global approach might be more efficient. Based on this second hypothesis, extracorporeal blood purification techniques have been developed to control the dysregulation of the immune system with the removal from the blood a large panel of components that participate in the inflammatory response.

Several extracorporeal techniques have been developed during the last two decades. They target different mediators of the immunoinflammatory response, which can be endotoxins, cytokines, proinflammatory cells, or pathogens such as bacteria and viruses. Most techniques are developed towards one particular target, but some are able to remove two or more mediators (e.g., cytokines and endotoxins) (Fig. 98.1). Contrary to intravenous treatments, blood purification techniques are nonselective.

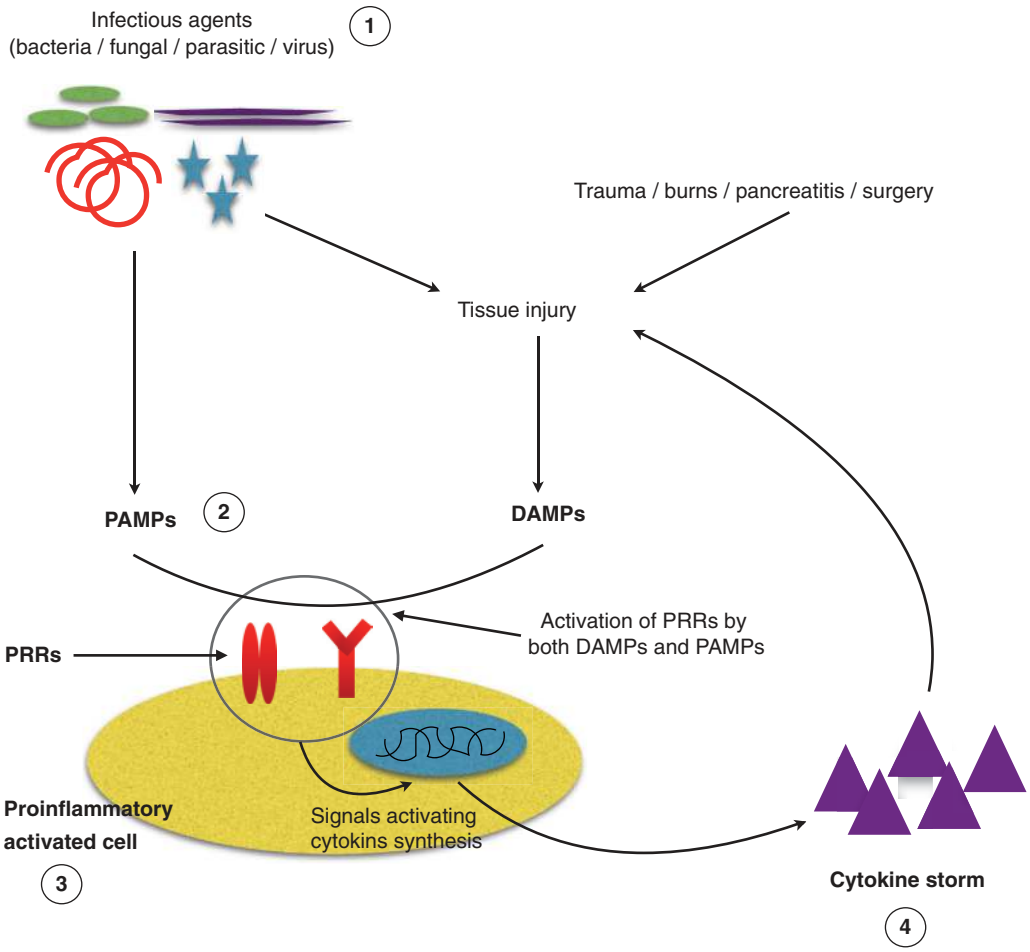

Fig. 98.1 The immunoinflammatory response to sepsis and targets for extracorporeal blood purification. Blood purification targets shown include (1) Removing pathogens from the blood; (2) Removing endotoxins and other PAMPs from the blood; (3) Removing proinflammatory cells from the blood; and (4) Removing cytokines from the blood. *DAMPs,* Damage-associated molecular patterns; *PAMPs,* pathogen-associated molecular patterns; *PRRs,* pattern recognition receptors.

As this immunoinflammatory response seems to represent a "final common pathway," these techniques may be proposed in sepsis, but also in trauma, burns, pancreatitis, and other inflammatory situations causing a dysregulated immunoinflammatory response (see Fig 98.1).

BLOOD PURIFICATION TECHNIQUES FOR SEPSIS

Most of the techniques described subsequently refer to hemoperfusion. Its principle is as follows: the blood runs through a cartridge, and some blood components are fixed on an adsorbent material. Adsorption relies on binding chemical interactions between the targeted circulating molecule and the sorbent. The purpose of these is to remove a significant proportion of the targeted molecule from the blood compartment. We describe next each technique with the details of its targets and its mechanisms of action (Fig. 98.2).

Endotoxin Removal

Two major hemoperfusion devices are available for endotoxin removal. First, the adsorption properties of polymyxin-B have been used in a hemoperfusion cartridge named Toraymyxin (Toray, Tokyo, Japan) since 1993. Polymyxin-B is an antibiotic with great affinity for endotoxin, thanks to ionic and hydrophobic interactions. However, its intravenous use is impossible because of renal and neurologic toxicities. In this hemoperfusion cartridge, polymyxin-B is covalently bound to the fibers. The clinical effects of a polymyxin-B hemoperfusion treatment (typically two 2-hour hemoperfusion sessions 24 hours apart) have been widely studied over the last two decades. Interestingly, this technique represents the current standard of care for abdominal septic shock in Japan. In 2007 Cruz and colleagues reviewed the performance of this hemoperfusion cartridge on septic patients, based on evidence gathered from 1998 to 2006.[16] They found a positive effect on mean arterial pressure (MAP), oxygenation, and a decrease in vasopressor use, to the point that the risk ratio for mortality was 0.53 (95% confidence interval [CI] 0.42–0.65) in the polymyxin-hemoperfusion group. This study was an incentive for further RCTs, mainly focusing on gram-negative abdominal sepsis because of likely high levels of circulating endotoxin in this clinical context. The EUPHAS trial showed encouraging results, consistent with those previously reported by Cruz and colleagues' meta-analysis. This study was even stopped early because of a significant improvement in 28-day mortality (adjusted hazard ratio [HR], 0.36; 95% CI 0.16–0.80; $P = 0.01$) after the intermediate analysis.[17] The ABDOMIX trial was conducted subsequently and included a greater number of patients with similar inclusion criteria.[18] However, it did not find such promising outcomes, with, conversely, a nonsignificant increase in 28-day mortality (odds ratio [OR], 1.5872; 95% CI 0.85–2.93; $P = 0.14$) in the intervention group. Importantly, the

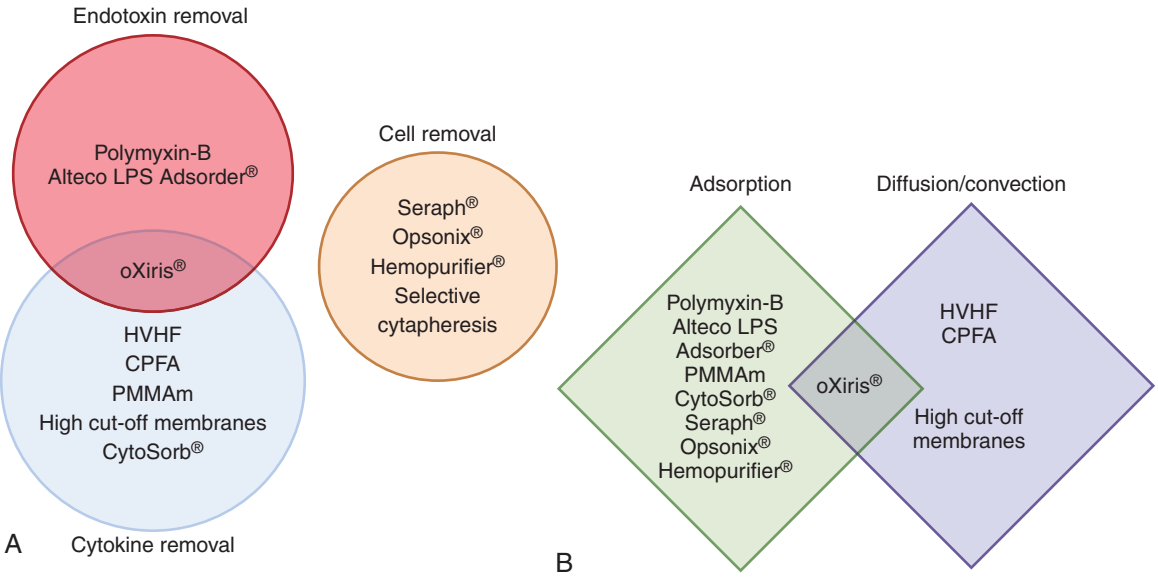

Fig. 98.2 Blood purification techniques. **A,** Targets. **B,** Mechanisms of epuration. *CPFA,* Coupled plasma filtration and adsorption; *HVHF,* high volume hemofiltration; *LPS,* lipopolysaccharide; *PMMAm,* modified PMMA.

mortality rates in the control group greatly differed in these two studies. Lately in 2018, the randomized blinded EUPHRATES trial included a selected population of patients presenting with high levels of circulating endotoxin activity (defined as an endotoxin activity assay [EAA, no unit] ≥0.60) rather than empirically suspected gram-negative sepsis (e.g., of abdominal origin)[19]. The results of this large-scale analysis ($n = 450$) failed to demonstrate a reduction in 28-day mortality. It was nevertheless later speculated that patients with EAA ≥0.90 could bear an endotoxin burden exceeding the adsorption capacities of Toraymyxin. A post hoc analysis was performed, focusing on the subpopulation of patients with EAA between 0.6 and 0.9.[20] In this particular subgroup, 28-day mortality was lower in the hemoperfusion group (OR, 0.52; 95 % CI 0.27–0.99; $P = 0.047$). Evidence was recently found that Toraymyxin hemoperfusion also showed immunomodulation properties, improving mHLA-DR expression in septic patients.[21] This latest input supports the need for further research focusing on a specific selected population and optimal timing for polymyxin-B hemoperfusion initiation.

Another technology aimed at removing circulating endotoxin is the Alteco LPS adsorber (Alteco Medical AB, Lund, Sweden). This cartridge contains a polyethylene matrix covered in a specially designed synthetic peptide engineered for endotoxin adsorption thanks to high affinity for the lipid A moiety of the endotoxin. In a nonrandomized fashion, Adamik and colleagues tested this device on a few selected patients ($n = 18$) and were able to demonstrate an improvement from baseline in terms of EAA levels and clinical outcomes but no difference in ICU mortality between groups.[22] The ASSET trial (NCT02335723) designed as a feasibility study of this device was unfortunately stopped because of patient recruitment issues in 2017.

Cytokine Removal

Using Renal Replacement Therapy

A significant proportion of patients with septic shock develop acute kidney injury (AKI) and require RRT during their ICU stay. Techniques combining RRT and blood purification for sepsis could be of interest for these patients.

High-volume hemofiltration (HVHF) is a continuous renal replacement therapy (CRRT) technique exhibiting a higher ultrafiltration rate than usual (more than 50 mL/kg/h) and targeting improved removal of middle-molecular-weight hydrophilic molecules (i.e., cytokines). Promising experimental and preclinical works were published from 1990 to 2010, but the multicenter RCT IVOIRE published in 2013 was disappointing.[23–26] It did not find any significant mortality reduction, a finding that was confirmed in two subsequent meta-analyses.[27,28]

Increasing membrane permeability or adsorptive properties could confer with standard hemofilters' additional blood purification properties. Used in continuous venovenous hemofiltration (CVVH), high cut-off membranes (i.e., sieving coefficient >40 kDa) are able to remove middle-molecular-weight inflammatory mediators such as IL-6 and IL-1, but with the inconvenience of an important albumin leakage.[29–31] However, the use of such membranes in a diffusive modality allows albumin loss to be minimized and to simultaneously remove middle-molecular-weight molecules.[32–34] In 2016 Chelazzi and colleagues retrospectively studied a small series of patients treated with CVVH using high cut-off membranes.[35] They reported a significantly decreased mortality rate (37.5 vs. 87.5%; $P = 0.03$) compared with the controls. RCTs exploring the outcomes of the use of high cut-off membranes in septic AKI are still needed to draw more robust conclusions regarding the effects of these membranes.

The polymethylmethacrylate (PMMA) membrane has adsorption properties because of its symmetric microporous structure. It removes cytokines and immunoglobulin light chains. Thus its use in septic patients has been studied successfully with respect to intermediate outcomes such as hemodynamics, blood lactate, and IL-6 levels.[36] However, the suitability of this membrane was questioned because of the very high rates of clotting and clogging observed. The PMMA component was modified to address this defect, allowing it to preserve its adsorbing abilities while limiting its high thrombogenicity.[37] CRRT with the modified PMMA membrane has not yet been studied in septic AKI.

Coupled plasma filtration and adsorption (CPFA) is a technique combining blood purification and RRT. First, plasma is separated from total blood and is run through a nonspecific charcoal sorbent cartridge, which adsorbs cytokines. The plasma then returns to the circuit, where conventional RRT with hemofiltration occurs through a standard hemofilter. Recently, the COMPACT2 trial (NCT01639664) assessed high doses of CPFA. This study was terminated early because of to a highly

suspected increased mortality rate in the treatment group. Consequently, CPFA is no longer proposed for septic shock management.

Hemoperfusion

The CytoSorb hemoperfusion cartridge (CytoSorbent, Monmouth Junction, NJ) contains polymer beads with adsorption properties (surface adsorption and pore capture). This adsorption process affects small- to middle-molecular-weight hydrophobic agents: inflammatory mediators (both pro- and anti-), myoglobin, bilirubin, PAMPs, and DAMPs, as shown in various studies.[38,39] This device can be used as a standalone treatment or can be coupled with an RRT circuit, and the same cartridge can be used for up to 24 hours. In both situations, it should be administered daily for 2–7 days (24-hour sessions). Early initiation (i.e., less than 24 hours from the moment when septic shock is uncontrolled despite usual care) seems to lead to better patient outcomes.[40,41] In the several RCTs available, CytoSorb was unable to decrease patient mortality, although blood lactate levels and hemodynamic parameters improved.[42–44] Interestingly, in the most recent of these RCTs, a significant IL-6 clearance was observed, whereas its circulating levels did not differ.[43] Hypotheses to explain this observation are the following: either IL-6 clearance might diminish the levels of cytokine inside organ tissues with an unchanged blood level, or adsorption, being a concentration-dependent mechanism, means that CytoSorb should be delivered to patients presenting with higher circulating IL-6 levels (i.e., IL-6 levels >1000 pg/mL, whereas median levels in that study reached only 565 pg/mL).

Endotoxin and Cytokine Removal

The oXiris membrane (Baxter, Meyzieu, France) is an RRT hemofilter with enhanced adsorption properties, targeting cytokine and endotoxin removal at the same time. oXiris represents an advanced version of the AN69 polyacrylonitrile membrane, coated with polyethyleneimine (PEI) and pregrafted with heparin. The whole bulk of the membrane is able to bind cytokines, like the previous versions of AN69 membranes. PEI ensures better biocompatibility and allows for endotoxin adsorption thanks to its positively charged amino groups. Standard oXiris treatment sessions are recommended to last 24 hours, although the filter life span may be longer (up to 72 hours).

Malard and colleagues recently showed that oXiris in vitro clearances of cytokines and endotoxins were comparable to that of CytoSorb and Toraymyxin, respectively.[38] Few good-quality studies regarding the outcomes associated with the use of oXiris in septic AKI are available. In a randomized cross-over study, Broman and colleagues showed significantly improved cytokine and endotoxin clearances compared with standard CRRT, lower blood lactate level, and a decreased need for vasopressors.[45]

Most of the available data on oXiris are observational. Schwindenhammer and colleagues studied 31 patients and reported a lower-than-expected in-hospital mortality rate in the most severe septic patients treated with oXiris[46]. In a propensity-matched cohort, a beneficial effect of oXiris treatment was found in terms of hemodynamics, urinary output, and PaO_2/FiO_2 ratio, as compared with standard RRT.[47] RCTs are now warranted to draw robust conclusions about the impact of oXiris on patient outcome in sepsis-induced AKI (ECRO NCT03426943, ENDOTOX NCT01948778).

Cell Removal

More recently, a variety of binding components have been developed aiming at removing pathogens and/or inflammatory cells.

Removing Pathogens

The Seraph 100 Microbind Affinity Blood Filter (ExThera Medical, Martinez, CA) is a hemoperfusion device composed of heparin-grafted polyethylene beads. It can be used in a series within an RRT circuit or as a standalone hemoperfusion treatment. Heparan-sulfate is a glycosaminoglycan that can bind pathogens; it shares its affinity with heparin, which is very similar. A large number of bacteria, parasites, and viruses were found to interact with the Seraph.[48–50] A safety study took place in Germany on patients with septic shock requiring RRT. No adverse events occurred (NCT02914132). However, the clinical impact of Seraph treatment has yet to be investigated.

Still in an early stage of development, a hemoperfusion device using the FcMBL protein has shown interesting results in animal models. The FcMBL protein (Opsonix, Wakefield, MA) is an engineered molecule containing the properties of opsonin mannose-binding lectin (MBL) that natively adheres with PAMPs to the Fc domain (i.e., the unchanging section) of human immunoglobulin. Hemadsorption using FcMBL could trap both pathogens as a whole or their debris once destroyed by antimicrobial therapy.[51] Such a device is currently in testing and has shown favorable outcomes in septic mouse models, displaying a certain level of synergy with antibiotics.[52]

The Hemopurifier (Aethlon Medical, San Diego, CA) is a technique using coupled plasmapheresis and adsorption to clear blood-circulating viruses. After separation, plasma is put in contact with a lectin protein found in the common snowdrop (*Galanthus nivalis* agglutinin), which has a powerful affinity for the glycoproteins found on the envelope of some viruses. This device is not yet available except for research. It was successfully applied to treat a patient with Ebola virus and showed significant clearance of circulating hepatitis C virus.[53,54]

Removing Inflammatory Cells

Cytapheresis targeting activated white blood cells is currently under study. Pino and colleagues developed a synthetic biomembrane able to catch activated leukocytes that can be plugged within a CRRT circuit.[55] A preliminary safety study on septic patients requiring RRT reported improved survival compared with case-matched controls, but this was not confirmed by the RCT conducted subsequently.[56,57] On a side note, some of the aforementioned hemoperfusion devices (e.g., CytoSorb) targeting inflammatory mediators could clear activated white blood cells, as shown by Rimmelé and colleagues.[58] That effect could participate in the overall immunomodulatory result.

BLOOD PURIFICATION FOR NONSEPTIC INDICATIONS

Nonseptic Inflammatory States

Acute pancreatitis usually has a mild course, with a global mortality rate below 1%. However, around 10% of patients will develop severe acute pancreatitis (SAP), involving extrapancreatic tissues and other organ systems, with a much higher mortality rate. The outcome and pathophysiology of SAP are closely related to early systemic inflammation and cytokine release. Treatments based on antioxidants, platelet-activating antagonists, antibodies against mediators of inflammation such as TNF-alpha, or nonsteroidal antiinflammatory drugs all failed to demonstrate improvement of morbidity and mortality in RCTs.[59,60]

In a meta-analysis, Hu and colleagues analyzed 12 trials (4 RCTs and 8 prospective studies) investigating blood purification techniques, mainly HVHF, in SAP. This meta-analysis demonstrated a significant lower incidence of mortality and ICU length of stay in the blood purification group (OR, 0.60; 95% CI 0.38–0.94). However, this improvement was no longer significant when only RCTs were taken into account (OR, 0.56; 95% CI 0.21–1.49).[61] The ongoing PACIFIC trial, a prospective multicenter case-control study, aims at investigating whether or not early administration of hemoperfusion with CytoSorb in patients with SAP can improve hemodynamic parameters.[62]

Extracorporeal blood purification techniques can also be proposed for severely burned patients. Indeed, these patients exhibit a prolonged and fulminant inflammatory state, with high levels of proinflammatory and antiinflammatory mediators.[63] Peng and colleagues evaluated hemoperfusion with polymyxin-B immobilized fibers in septic burned patients (total body surface area [TBSA] ≥50%). The use of polymyxin-B columns in these patients infected with gram-negative bacteria decreased levels of endotoxin, IL-1β, IL-6, IL-8, and TNF-alpha.[64] Less data are available regarding the use of PMMA membrane for burned patients. Nakae and colleagues reported three cases with severe burn injury (TBSA >30%) treated with CVVH and a PMMA membrane and observed a reduction in IL-6 levels in all three patients.[65] Another interesting point consists in the ability of CytoSorb to remove myoglobin in vitro,[66] which might be a promising therapy for rhabdomyolysis that occurs in conjunction with thermal injury, but no data are available for humans.

Blood purification techniques might also be used for severe trauma patients, although no data are available in humans. McKinley and colleagues showed in a rat model of hemorrhagic shock and traumatic brain injury a better survival (86% vs. 47%) in the group undergoing hemoperfusion with CytoSorb.[67]

Blood purification might also be interesting in other diseases in which the immunoinflammatory response is dysregulated. We can, for instance, mention cardiorenal syndromes or cancers like T-cell lymphoma causing cytokine release syndrome (CRS) with some chemotherapies. Recently, Stahl and colleagues published a case report of a 65-year-old male patient undergoing refractory shock on grade 4 CRS after chimeric antigen receptor (CAR) T-cell treatment for diffuse large B-cell lymphoma.[68] After failure of conventional treatment, including IL-6 blockers, they reported that a wide range of proinflammatory cytokines were lowered by more than 50% compared with their initial concentration after 24 hours of treatment with CytoSorb. Interestingly, the substantial decrease of IL-6, interferon (IFN)-gamma, TNF-alpha, and IL-1 was followed by significant hemodynamic improvement. An RCT investigating extracorporeal treatment with CytoSorb in patients with severe CRS is ongoing (NCT04048434).

Artificial Liver Support Systems

The liver is a complex organ responsible for vital functions such as protein synthesis, heat production, and detoxification. The European Association for the Study of the Liver distinguishes acute liver failure in healthy liver (ACL) from acute on chronic liver failure, in which cirrhosis is decompensated by an acute injury (ACLF). These two syndromes have different pathophysiologies, etiologies, and outcomes. Importantly, and since the end of the twentieth century, artificial livers have been developed to be used as supportive therapy until liver transplantation (bridge-to-transplant) or liver regeneration (bridge-to-recovery) has occurred.

The most described devices are the molecular adsorbent recirculating system (MARS, Gambro Hospal GmbH, Planegg-Martinsried, Germany), the single-pass albumin dialysis (SPAD), and the fractionated plasma separation and adsorption system (FPSA, Prometheus, Fresenius Medical Care, Bad Homburg, Allemagne).[69] These systems, based on albumin dialysis, are supposed to remove from the blood albumin-bound toxins that accumulate during liver failure. These toxins are potentially involved in the development of liver encephalopathy, hepatorenal syndrome (HRS), cardiovascular failure, and immunosuppression. In addition, these devices can theoretically remove plasmatic nitric oxide (NO) and cytokines such as TNF-alpha, IL-6, or IL-10, although the contribution of those to multiple organ failure in ALF or ACLF is still unknown.[70] Evidence has shown that artificial liver support systems may replace, at least partially, the liver detoxification function. However, clinical data on improved survival are very conflicting, and these devices are also very costly.

The MARS is a complex device in which treatment occurs in three steps (Fig. 98.3). First, the blood is dialyzed through the MARS membrane (a high-flux dialysis membrane) where albumin-bound toxins are released in a dialysate enriched with albumin, according to the diffusion principle. Second, the albumin in the dialysate is regenerated while toxins are cleared when passing through two adsorbing columns that contain activated charcoal and anion exchange resin. Third, the albumin circuit itself is dialyzed in the RRT circuit, cleaning the blood from water-soluble molecules and toxins (see Fig. 98.3).

To date, few meta-analyses have reported outcomes of MARS-treated patients. In 2015 Tsipotis and colleagues analyzed 10 RCTs including 620 patients with ACL or ACLF treated with MARS (7 RCTs) or Prometheus (3 RCTs). They showed an improvement in liver encephalopathy with albumin dialysis (relative risk [RR], 1.55; 95% CI 1.16–2.08); however, no benefit in mortality was observed (RR, 0.95; 95% CI 0.84–1.07).[71] He and colleagues conducted a separate

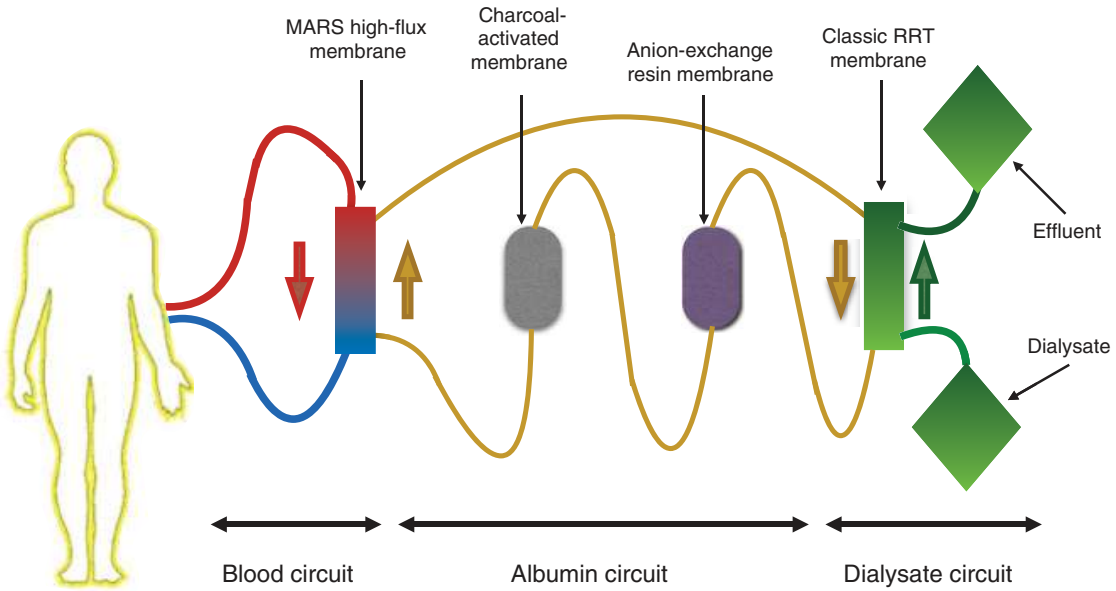

Fig. 98.3 The molecular adsorbent recirculating system (MARS).

meta-analysis of trials involving patients with ALF or ACLF exclusively treated with MARS. They found that MARS therapy significantly reduced mortality compared with standard care (RR, 0.61; 95% CI 0.38–0.97; $P = 0.04$). However, the authors also highlighted that many patients were finally not included because they went to transplantation first, resulting in the low number of patients (n = 49) finally analyzed. There was no significant survival benefit in ACLF patients treated with MARS (RR, 0.88; 95% CI 0.74–1.06; $P = 0.16$).[72]

The SPAD is an artificial liver device in which the blood is dialyzed with an albumin-containing dialysate. After diffusion through the membrane, albumin-bound toxins are removed with the dialysate. With SPAD, albumin is not regenerated (in contrast with the MARS and Prometheus systems); therefore high amounts of albumin are required. Sponholz and colleagues in a controlled crossover study compared the detoxification capacity and clinical outcomes of SPAD (4% albumin dialysate solution; 700 mL/h dialysis flow rate) with MARS (20% albumin flow rate equal to the blood flow rate, 2000 mL/h dialysis flow). They observed similar reductions in bilirubin levels between the two devices. Interestingly, in contrast with other studies, neither MARS nor SPAD reduced cytokine levels. The effects of MARS and SPAD on liver encephalopathy and hemodynamic parameters were small and similar.[73] Of note, another randomized crossover trial comparing MARS with SPAD is currently ongoing (NCT02310542).

The FPSA (i.e., Prometheus) system uses the patient's own albumin to first enter the circuit through the AlbuFlow membrane. Then, the albumin is purified from its bound toxins, using a neutral resin adsorber and an anion-exchange column and returns to the blood circuit. The blood is run through a second circuit for conventional high-flux hemodialysis before being returned to the patient. The efficacy of Prometheus has recently been confirmed by Grodzicki and colleagues, who found significant decreases in serum ammonia, bilirubin, aspartate aminotransferase, alanine aminotransferase, urea, and creatinine in patients with ALF.[74] Sentürk and colleagues found similar results in their study in which 27 patients with ALF or ACLF underwent several sessions of albumin dialysis with Prometheus. They observed a significant decrease in total bilirubin, ammonia, blood urea nitrogen, serum creatinine levels, and liver encephalopathy scores.[75] In 2012 Kribben and colleagues published the HELIOS study, a multicenter RCT comparing the use of Prometheus with standard medical care in patients with ACLF. They could not demonstrate any survival improvement at day 28 (66% vs. 63%, $P = 0.70$) and at day 90 (47% vs. 38%, $P = 0.35$), and the study was interrupted early because of futility. However, among the subgroup of patients with severe liver failure (Model for End-Stage Liver Disease [MELD] >30), probability of survival at day 90 was greater for patients treated with Prometheus (48% vs. 9%, $P < 0.05$).[76]

Among other devices, the Advanced Life Support System (ADVOS) showed promising results in animal studies.[77] This device is composed of three circuits: a standard RRT circuit, an albumin running circuit, and a third circuit for regeneration and detoxification of toxin-loaded albumin. In 2017 Huber and colleagues confirmed positive results in an observational trial of 14 patients treated with ADVOS, demonstrating significant hemodynamic and biochemical improvements.[78]

CONCLUSION

Extracorporeal blood purification techniques are designed to clear excessive inflammatory mediators from the blood. This removal is nonspecific, but most of the techniques target a group of molecules (such as cytokines or endotoxins), activated white blood cells, or pathogens. The rationale for use is that removing harmful intermediaries could avoid triggering the unwanted cytokine storm and the following immunoparalysis responsible for poor outcome in patients with sepsis. These properties of blood purification could also apply to nonseptic inflammatory shocks such as acute pancreatitis and severe burns. So far, improved outcomes have been shown regarding secondary criteria (e.g., hemodynamics, oxygenation), but none of the techniques has shown conclusive evidence regarding survival.

Nevertheless, as stated by the Surviving Sepsis Campaign, research on this topic should be continued, as septic shock remains deadly and immunomodulation could be a leading treatment option in this context. Treatment timing and patient selection need to be carefully addressed in future trials. Blood levels of cytokines and endotoxin should be monitored to decide on the best treatment to use. Techniques allowing for simultaneous RRT should be kept for patients requiring RRT, and standalone therapies should be preferred for those without AKI. Artificial liver support systems are proposed for the removal of albumin-bound toxins.

Lately, extracorporeal blood purification has been suggested for the treatment of severe SARS-CoV-2 infections. These patients experience hyperinflammation, and therefore blood purification has been proposed in various ways to prevent pulmonary and other organ damage. For now, only case reports or case series have been published, and additional data are warranted to draw robust conclusions on the effects of these therapies in patients with COVID-19.[79]

KEY POINTS

- Blood purification techniques aim at removing different components from the blood, targeting the dysregulated immunoinflammatory response.
- Mostly described in sepsis, blood purification techniques may also be proposed in acute pancreatitis, trauma, burns, and cancer.
- The lack of morbidity and mortality improvement in RCTs may possibly be explained by significant heterogeneity in these trials in terms of indications, timing of initiation, and patient populations.
- Most of the artificial liver support systems are based on albumin dialysis. These systems are supposed to remove albumin-bound toxins from the blood.
- These devices are not routinely implemented in ICUs because of the lack of conclusive RCTs.

Fluid and Volume Therapy in the ICU

Todd W. Robinson and Barry I. Freedman

The goals of fluid administration are to optimize tissue oxygenation by augmenting intravascular volume, improving left ventricular preload, and increasing cardiac output.[1] This chapter reviews the timing and considerations for choice of therapy in volume repletion and the effects of fluid volume overload in the postresuscitation period.

TIMING OF INITIAL VOLUME THERAPY

Studies from the early 2000s suggested that earlier recognition and treatment of septic shock correlated with improved outcomes. In a report by Rivers and colleagues, the Early Goal-Directed Therapy Collaborative Group randomized subjects to receive either intensive treatment for septic shock within the initial 6 hours of therapy or standard therapy provided in the emergency department.[2] Standard and early goal-directed therapy (EGDT) groups received antibiotics, vasoactive medications, and intravenous (IV) fluid for volume resuscitation. Goals for fluid administration included infusion of crystalloid in 500-mL boluses every 30 minutes with a target central venous pressure of 8–12 mm Hg as a marker of effective repletion of intravascular volume and response to fluids. Although the total volume of fluid administered by 72 hours was equivalent, the EGDT group received substantially more IV fluid in the first 6 hours of treatment. Compared with the standard therapy group, significant improvements related to in-hospital mortality were observed in the group assigned to earlier administration of volume-based resuscitation in conjunction with other therapies, including the optimization of central venous oxygen saturation with red blood cell transfusions and use of inotropes, if necessary. In-hospital mortality was 30.5% in the EGDT group, compared with 46.5% in the standard therapy group ($P = 0.009$). Replication of results in other studies prompted guidelines for the treatment of sepsis to include early volume repletion as part of protocol-based, quantitative resuscitation to reverse tissue hypoperfusion.[3,4] In the Surviving Sepsis Campaign, initial resuscitation recommendations for the first 6 hours included treatment aimed at maintaining a central venous pressure of 8–12 mm Hg, a mean arterial pressure more than or equal to 65 mm Hg, urine output more than or equal to 0.5 mL kg/hr, and mixed venous oxygen saturation greater than 65%.[5] In 2018 the Surviving Sepsis guidelines were further revised to accelerate this protocol-driven timeline and include recommendations for initiating fluid resuscitation within 1 hour for hypotension or lactatemia.[6]

Meeting hemodynamic stabilization endpoints in such a manner with goal-directed therapy and other supportive measures remains desirable in most cases, especially in patients who prove to be fluid responsive. However, other multicenter studies that have re-examined this topic have not replicated survival benefits, and the advantages of aggressive EGDT have been questioned. The Australasian Resuscitation in Sepsis Evaluation (ARISE) study examined EGDT resuscitation in patients with septic shock.[7] Sixteen hundred patients were randomized to EGDT or usual care. On average, patients in the EGDT group were treated with more IV fluid in the initial 6 hours of therapy compared with those randomized to usual care. Those in the EGDT group were also more likely to receive red blood cell transfusions. At 90 days, no significant differences were observed in patient survival. In-hospital mortality, the duration of organ support, and the length of hospital stay were also similar. The Protocol-based Care for Early Septic Shock (ProCESS) investigative group showed comparable results, with no benefits found with EGDT.[8] ProCESS was a prospective multicenter trial that randomized 1341 emergency department patients with septic shock to receive 6 hours of protocol-based EGDT, protocol-based standard therapy, or usual care. The investigators did not require placement of central venous catheters, administration of inotropes, or blood transfusions in the protocol-based standard therapy group, as compared with the use of these therapies in the EGDT group. Overall, the total volume of fluid administered during the 6-hour study period was reported as being significantly different between the groups. Again, no differences in survival were observed at 90 days. There was also no significant impact on 1-year mortality, the duration of time spent on mechanical ventilation, or the duration of time on renal replacement therapy. ProMISe was a pragmatic randomized trial that examined mortality and other critical illness outcomes in patients with septic shock across 56 hospitals in England.[9] Participants were randomized to either EGDT or usual care. A total of 1260 patients were enrolled, and there were no statistically significant between-group differences in mortality or the other secondary outcomes, including adverse events and quality of life. Additionally, EGDT increased the cost of care for these critically ill patients. Fig. 99.1 shows the relative risk of mortality in EGDT versus usual care in these four major randomized controlled trials.

TYPE OF VOLUME THERAPY

When deciding on IV fluid therapy, the choices can be broadly classified into three major categories. Crystalloid fluids have long been considered the mainstay of volume replacement in the hospital setting and include normal saline (NS), lactated Ringer's (LR) solution, Hartmann's solution, and other balanced salt solutions such as Plasma-Lyte. A second broad category includes colloid preparations such as albumin, hydroxyethyl starch (HES), dextran, and gelatin. Finally, blood products, including packed red blood cells, can be used for volume repletion in the treatment of hypoperfusion caused by inadequate circulating volumes. Table 99.1 compares the osmolality and composition of human plasma and common isotonic crystalloid fluid preparations.

CRYSTALLOIDS VERSUS COLLOIDS

The choice between crystalloids and colloids as therapeutic fluids in the intensive care unit (ICU) has long been a topic of debate and

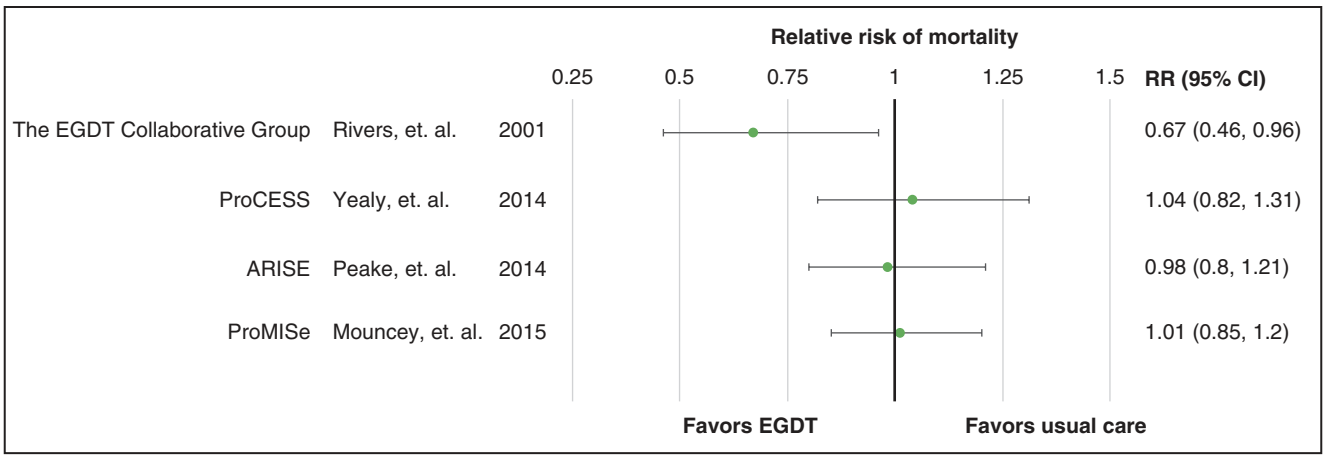

Fig. 99.1 Relative risk of mortality in early goal-directed therapy vs. usual care.

TABLE 99.1 Osmolality and Composition of Plasma Versus Common Isotonic Crystalloid Fluid Preparations

	Plasma	0.9% Normal Saline (NS)[a]	Lactated Ringer's (LR)[b]	Plasma-Lyte-LYTE A (PL)[c]	Sterile Water With 150 mEq/L Sodium Bicarbonate[d]
Osmolality (mOsmol/L)	280–310	308 (calc)	273 (calc)	294 (calc)	300 (calc)
Sodium (mEq/L)	135–145	154	130	140	150
Potassium (mEq/L)	4.0–5.0	–	4.0	5.0	–
Chloride (mEq/L)	95–110	154	109	98	–
Calcium (mEq/L)	2.2–2.6	–	2.7	–	–
Magnesium (mEq/L)	1.0–2.0	–	–	3.0	–
Lactate (mEq/L)	0.8–1.8	–	28	–	–
Acetate (mEq/L)	–	–	–	27	–

investigation. In an analysis of multiple population studies, Goldwasser and Feldman observed that mortality was inversely associated with serum albumin levels.[10] With each 2.5 g/L lower serum albumin concentration, a correlative 24%–56% increase in risk of death was detected. This relationship held true in healthy populations and in those who suffered from acute and chronic illnesses. Several mechanisms for the protective effects of the albumin molecule have been explored. Among these, infused albumin reportedly has free radical scavenging antioxidant properties that may have clinical importance.[11] Moreover, the proposed advantages for prescribing colloid over crystalloid fluid in resuscitation strategies for critically ill patients include concepts based on hemodynamic Starling's principles and the role of plasma oncotic pressure. Theoretically, large colloid molecules that persist in the circulation enhance water reabsorption from the interstitial space and maintain the volume within the vasculature for longer periods.[12] Ideally, this characteristic would reduce the large fluid volumes that are often required for resuscitation and improve clinical outcomes.[13]

Prospective randomized trials examining the potential benefits of albumin and colloids in lieu of crystalloid solutions for volume repletion have yielded variable results. For example, there are investigations that demonstrated benefit with albumin administration and support its clinical safety. In one such study, a group of 100 patients with hypoalbuminemia in the ICU were randomized to receive (versus not receive) albumin as part of their treatment regimen.[14] The groups were well matched and had similar baseline serum albumin concentrations and Acute Physiology and Chronic Health Evaluation II (APACHE II) scores. Significant improvements in Sequential Organ Failure Assessment (SOFA) scores were observed in the albumin-treated group. Interestingly, significant decreases in fluid gains were also seen in the albumin-treated group. These results led the investigators to suggest that treatment with albumin may lead to better outcomes in critically ill patients with hypoalbuminemia. Similarly, the Saline versus Albumin Fluid Evaluation (SAFE) study was a large trial that included nearly 7000 ICU patients with trauma, acute respiratory distress syndrome (ARDS), and severe sepsis.[15] The participants were randomized to receive either 4%

albumin or NS for intravascular fluid resuscitation. In a subgroup analysis of patients with severe sepsis, those in the albumin-treated group had a significantly lower heart rate and a significantly higher central venous pressure on days 1–3.[16] No between-group differences were detected in the total SOFA score, and similar numbers of patients required renal replacement therapy in the saline- and albumin-treated groups. Multivariate logistic regression analysis revealed that the adjusted odds ratio (OR) for death in the albumin-treated versus saline-treated group was 0.71 (85% confidence interval [CI]: 0.52–0.97; $P = 0.03$), suggesting that albumin treatment may decrease the risk of death in severe sepsis. Furthermore, data from a meta-analysis suggested that albumin administration is safe. In 55 trials that evaluated many different types of patients, including those with trauma, burns, hypoalbuminemia, and ascites, albumin administration did not adversely affect mortality.[17]

In contrast to studies suggesting benefit with albumin therapy in sepsis, other large prospective randomized trials failed to support a clear benefit of infusing albumin over crystalloid solutions in patients in the ICU setting. In the larger and more diverse group of original SAFE study participants discussed earlier, investigators found no between-group differences in death or new episodes of single- or multiorgan system failure between those treated with albumin versus saline.[15] There was also no significant difference in the number of days spent in the ICU, length of hospital stay, or days of renal replacement therapy in the subgroup analyses. Similarly, the Colloids Versus Crystalloids for the Resuscitation of the Critically Ill (CRISTAL) trial examined outcomes for ICU patients with shock from sepsis, trauma, or hypovolemia who were randomized to treatment with colloid solutions compared with crystalloids.[18] In addition to 4% and 20% albumin, the colloid arm of CRISTAL included gelatins, dextrans, and HES. At 28 days after study enrollment, even though colloid resuscitation was associated with fewer days of mechanical ventilation and more days without vasopressor therapy, no significant differences in mortality were observed between the patients who received colloids and those who received crystalloids. Patients with severe sepsis have also been randomized to receive crystalloid plus albumin therapy compared with crystalloids alone. In the more than 1800 randomized patients in the Albumin Italian Outcome Sepsis (ALBIOS) study, significantly higher mean arterial pressures and lower net fluid gains were observed in the albumin plus crystalloid therapy group.[19] However, the investigators also noted that the total daily amount of fluids administered did not differ between the groups and, more importantly, there were no significant differences in patient survival at 28 or 90 days between the groups. The Cochrane analysis of pooled data on this topic also found no evidence that colloids reduced the risk of death compared with crystalloids in the treatment of critically ill patients.[20] Overall, there remains a paucity of data to suggest that clear benefits exist for administering albumin or other colloid solutions instead of crystalloids in critically ill patients requiring volume repletion. The lack of resounding benefit is compounded by the high cost of albumin, which also makes it less attractive for routine use.[20]

There is also evidence suggesting that colloid solutions such as albumin may be associated with harmful effects. Though they tended to have higher critical illness severity scores, patients in the Sepsis Occurrence in Acutely ill Patients (SOAP) study who received albumin at any time during their ICU stay had a higher risk of death.[21] A systematic review of 37 randomized trials comparing crystalloid with colloid administration also hinted at safety concerns. The investigators found that colloid resuscitation was associated with a 4% increase in the absolute risk of mortality (95% CI, 1.00–1.08) and concluded that the difference in the effect of the colloids was not related to the types of inciting injuries.[22]

The harm associated with colloid infusion may be more pronounced with respect to specific organ systems or types of colloids. In a post hoc analysis of the SAFE study, albumin administration in patients with traumatic brain injury was associated with higher mortality compared with those who received crystalloids.[23]

HYDROXYETHYL STARCH

Convincing evidence for harm was reported for critically ill patients treated with the synthetically derived HES. Of 7000 randomized patients in the Crystalloid versus Hydroxyethyl Starch Trial (CHEST), there was no significant mortality difference in those resuscitated with NS versus HES.[24] However, there was a significant difference in adverse outcomes. Of 3352 patients receiving HES, 235 (7.0%) experienced a kidney-related adverse outcome that ultimately required renal replacement therapy. In comparison, only 196 of 3375 (5.8%) required this intervention in the NS group (relative risk 1.21 [95% CI, 1.00–1.45]; $P = 0.04$). Additional studies also suggest harm. Among patients with sepsis who were randomized to receive IV fluid resuscitation with HES versus Ringer's acetate, the risk of death at 90 days was higher in those who received HES.[25] In that study, patients with sepsis who were treated with HES were also more likely to require renal replacement therapy. In major abdominal surgery, patients have also been randomized to either HES or saline in the postoperative period. There were no differences in mortality or adverse events within 14 days of the surgery.[26] The commonality between these findings have been confirmed in meta-analysis data from more than 35 trials in which HES was associated with a significantly increased risk of mortality and acute kidney injury (AKI).[27] Mechanistically, the total mass of the HES molecule has been proposed as directly toxic to renal proximal tubular cells, leading to the pathologic sequence of events that culminates in AKI.[28] This is contrary to other reports suggesting that it is the origin of the HES molecule (potato or corn), the carrier solution, or the effects of systemic inflammation that may be damaging to kidney cells.

ALBUMIN USE IN SELECT CLINICAL SETTINGS

Just as there are clinical situations in which the infusion of albumin and colloid solutions may be harmful, there are also specific circumstances where these fluids could have important and beneficial roles in the treatment of critically ill patients. In a randomized, nonblinded clinical trial that examined 126 patients with cirrhosis and spontaneous bacterial peritonitis, participants were randomized to treatment with either IV antibiotics alone or IV antibiotics with albumin.[29] The dose of albumin administered was 1.5 g/kg at diagnosis, with another 1 g/kg infused on day 3. In the patients who received albumin in addition to antibiotics, statistically significant reductions in renal impairment and death were observed. Additionally, a recent meta-analysis in 688 burn shock patients reported that treatments that included IV albumin were associated with statistically significant reductions in mortality and in the occurrence of compartment syndrome.[13] Although larger, prospective randomized trials are needed to guide management in burn shock resuscitation, these results suggest that albumin has the potential to improve outcomes.

In the majority of cases that require volume resuscitation in the ICU, there does not seem to be a robust signal favoring infusion of albumin or other colloid therapies over crystalloid fluids as first-line treatment for hypovolemia and septic shock. Crystalloids remain the treatment of choice in most settings.

CHLORIDE-RESTRICTIVE AND BALANCED CRYSTALLOID STRATEGIES

Increasing evidence indicates that isotonic crystalloid fluid preparations are not uniform or equivalent with respect to their side effect and

physiologic profiles. Despite isotonicity, NS is hyperchloremic relative to plasma (see Table 99.1). In animal studies, the effects of high chloride levels have been implicated in severe renal vasoconstriction, the suppression of plasma renin activity, and reduced glomerular filtration rate.[30–32] In healthy human volunteers, magnetic resonance imaging studies have demonstrated that infusions of NS can cause significant reductions in renal blood flow velocity and reductions in the perfusion of renal cortical tissue.[33]

Organ hypoperfusion is common in critically ill patients, but lactic acid production alone is not sufficient to explain all cases of metabolic acidosis in the ICU.[34–36] In addition to the aforementioned renal hemodynamic changes, IV fluids with superphysiologic concentrations of chloride, such as NS, have been associated with development of hyperchloremic metabolic acidosis. McFarlane and Lee observed this phenomenon while studying surgical patients randomly assigned to receive either 0.9% NS or Plasma-Lyte 148 during major abdominal surgery.[37] Patients receiving NS had significantly higher serum chloride concentrations, lower serum bicarbonate concentrations, and higher base deficit measurements compared with those who received Plasma-Lyte 148. Administration of NS has reproducibly been associated with decreases in serum bicarbonate levels or acidemic-range arterial pH values.[33,38–40] Extracellular dilution of buffer caused by the infusion of large volumes of fluid that lack bicarbonate may explain some of these changes.[41] Another hypothesis employs the strong ion difference (SID) theory of acid-base evaluation to describe these effects. In the SID theory, acidosis can occur if the apparent difference between strong cations and anions in solution is reduced.[42] As such, hyperchloremia caused by excessively larger gains in chloride (anion) concentration may contribute to the metabolic acidosis that has been observed with NS administration.[43–46]

In large-cohort observational studies, the deleterious physiologic effects of hyperchloremia and NS administration are reflected in clinical outcomes. In 22,851 surgical patients with normal preoperative kidney function and normal serum chloride concentrations, postoperative hyperchloremia was associated with higher 30-day mortality, longer hospital stay, and more frequent postoperative kidney dysfunction.[47] A similar study in more than 30,000 adult patients undergoing major abdominal surgery found that those who received NS had more postoperative complications, including infection, renal failure requiring dialysis, and blood transfusions.[48] Among patients in the ICU with sepsis, a retrospective analysis of more than 50,000 patients showed that balanced fluid administration (e.g., LR) was associated with a significantly lower in-hospital mortality (19.6% vs. 22.8%; relative risk, 0.86; 95% CI, 0.78–0.94).[49] Similarly, among patients with systemic inflammatory response syndrome, in-hospital mortality was lower when the total chloride load was reduced.[50] Yunos and colleagues detected adverse events associated with chloride-liberal IV fluid administration in critically ill ICU patients.[51] These investigators conducted a prospective, open-label pilot study that examined patients in an academic ICU. Patients were treated with standard IV fluids during a 6-month control period, after which NS and other chloride-rich fluids were restricted to specialty-attending approval. The primary outcomes included a rise in serum creatinine concentration from baseline and incident AKI as defined by RIFLE (Risk, Injury, Failure, Loss, and End-stage kidney disease) classification. During the intervention period, saline administration decreased significantly. When the study periods were compared, those who received chloride-restrictive therapy had a lower mean rise in serum creatinine concentration while in the ICU and the incidence of AKI was significantly diminished. After adjustment for covariates, an increased risk of requiring renal replacement therapy was observed in the chloride-liberal cohort.

Historically, prospective trials examining chloride-liberal versus balanced crystalloid solutions were predominately focused on perioperative and trauma patients. When comparing resuscitation with 0.9% NS versus Plasma-Lyte A in 65 trauma patients, administration of Plasma-Lyte resulted in a lower frequency of hyperchloremia and was associated with greater correction of acid-base abnormalities.[52] However, investigators found no significant differences in cumulative urine output, measures of resource use, or mortality between those resuscitated with saline versus Plasma-Lyte at 24 hours. Similarly, a report in 60 patients undergoing abdominal aortic aneurysm repair revealed that intraoperative randomization to LR or NS (double-blinded) resulted in a higher frequency of acidosis requiring bicarbonate therapy in those receiving NS, but did not significantly affect the duration of mechanical ventilation, length of ICU stay, length of hospital stay, or postoperative complications.[53] In patients undergoing kidney transplantation, the use of NS versus balanced crystalloids has been associated with a higher incidence of metabolic acidosis; however, fluid type did not negatively affect kidney allograft function as determined by serum creatinine concentration on postoperative day 3.[38,54]

Contemporary meta-analyses have also examined the question of balanced crystalloids versus isotonic saline in critically ill patients.[55] Results from data in six randomized controlled trials and a total cohort consisting of nearly 20,000 patients found no significant difference in in-hospital mortality (11.5% vs. 12.2%; OR 0.92; 95% CI 0.85–1.01; $P = 0.09$). Differences in AKI, overall ICU mortality, and need for renal replacement therapy were also similar between groups.

In 2018 a large, prospective, multicenter, cluster-randomized clinical trial with more than 15,000 critically ill adults provided strong support to the clinical trend of using more balanced physiologic crystalloid solutions relative to formulations such as NS.[56] The SMART investigators studied critically ill participants who were randomized to either NS versus LR or Plasma-Lyte. The cohorts were well matched for ICU admission diagnosis, vasopressor support, and baseline kidney function. The primary outcome included kidney outcomes and a composite of death from any cause. There were significantly fewer adverse kidney outcomes in the LR group compared with NS ($P = 0.04$). There was also a trend toward fewer new episodes of renal replacement therapy ($P = 0.06$) and development of persistent renal dysfunction ($P = 0.08$) in the LR group. A secondary analysis of these data was performed in patients with a specific sepsis diagnosis.[57] Of the original 15,802 SMART participants, 1641 had a diagnosis of sepsis. When this group was analyzed, there was a significant improvement for in-hospital 30-day mortality when patients received balanced fluids versus NS, and the results were also favorable in terms of 30-day mortality, adverse kidney events, and vasopressor use.

Although additional large clinical trials that continue to directly compare various crystalloid solutions in patients with sepsis and other common ICU conditions are needed, based on the aforementioned evidence, the role for chloride-restrictive alternatives to NS in patients who have developed (or are at risk for developing) metabolic acidosis and/or renal insufficiency will likely continue to grow and gain clinical favor in the ICU.

Concerns with administering physiologically balanced solutions more closely matched to serum, for example, LR, have included the perceived risk of hyperkalemia because of their higher potassium concentrations. Even in clinical situations potentially associated with a higher risk for hyperkalemia, evidence supports that these balanced solutions are generally safe with appropriate monitoring. For example, in a prospective randomized trial of patients with rhabdomyolysis, treatment with LR was not associated with significant differences in serum potassium concentration compared with treatment with NS.[58] In patients with diabetic ketoacidosis, in which serum potassium levels

can rise because of the combination of hyperosmolality, insulin deficiency, and AKI, patients who were resuscitated with balanced Plasma-Lyte instead of NS had faster resolution of acidosis and lower 6- and 12-hour serum potassium concentrations.[59] After kidney transplantation, patients who received NS had higher frequencies of hyperkalemia relative to those who received LR.[38]

BLOOD TRANSFUSIONS

In critically ill patients with severe blood loss and hemorrhagic shock, blood transfusions are a foundation of treatment. In patients suffering from sepsis and other acute illnesses, red blood cell transfusions have been used to enhance oxygen delivery to poorly perfused tissue as a supplement to other fluid resuscitation and vasopressor/inotropic support. Unfortunately, data sufficient to guide management and support the benefit of red blood cell transfusion in critically ill patients with sepsis have yet to emerge.

Observational studies have detected possible mortality benefits with red blood cell transfusions in critically ill patients with sepsis.[60,61] Among the European ICUs that participated in the SOAP study, multivariate analysis of more than 3000 patients revealed that blood transfusions were not associated with significantly higher mortality rates. In matched-pair propensity analysis, a higher 30-day survival rate was observed in the group that had a transfusion at any time while in the ICU ($P = 0.004$).[60] In contrast, other multicenter and randomized trials have not shown similar benefit. In 838 critically ill patients in the ICU that were randomized to receive either restrictive or liberal blood transfusion strategies when hemoglobin concentrations were less than 9.0 g/dL, the in-hospital mortality was significantly lower when patients were treated with a limited transfusion strategy (22.2% vs. 28.1%, $P = 0.05$).[62] In an examination of 45 observational cohort studies that combined data from 272,596 critically ill patients, red blood cell transfusions were linked with increased morbidity and mortality.[63] The pooled OR for death generated from the results of 12 studies was 1.7 (95% CI, 1.4–1.9). Transfusions were also associated with infectious complications, risk for developing multiorgan dysfunction syndrome, and ARDS.

The Surviving Sepsis guidelines include recommendations to provide blood transfusions in order to maintain hematocrits above 30% during the first 6 hours of resuscitation if there is evidence of tissue hypoperfusion after adequate repletion of the circulating volume. Guidelines for transfusion after the resolution of tissue hypoperfusion aim to keep the hemoglobin concentration between 7.0 g/dL and 9.0 g/dL in most patients.[5] To examine these target values, Holst and colleagues randomized approximately 1000 patients with septic shock and hemoglobin concentrations ≤9 g/dL to receive red blood cell transfusions to hemoglobin thresholds of 7 g/dL or 9 g/dL.[64] Those who were randomized to the higher hemoglobin target were transfused a median of four units of blood, whereas a median of one unit was given to those in the lower hemoglobin target group. At 90 days, there was no significant difference in mortality between the groups. These results held true after adjusting for baseline risk factors. In addition, there was no significant difference in the number of ischemic events, severe reactions, or use of life support between the two groups. As such, the optimal hemoglobin target in patients with sepsis in the ICU remains uncertain, and based on the available current evidence, administering blood transfusions when the hemoglobin is above 7 g/dL does not appear to provide a significant benefit to infusion of crystalloids alone.

EFFECTS OF VOLUME OVERLOAD

Volume therapy in critically ill patients aims to avoid and reverse the consequences of hypoperfusion and end-organ damage. Because of the large volumes of IV fluid that are often required, deleterious effects from volume overload can develop during the management of shock and in the postresuscitation period. These effects may be manifested systemically, for example, by hypertension and increased myocardial demand, pulmonary congestion with respiratory failure, and/or peripheral edema.[65]

Evidence supports that fluid resuscitation resulting in clinical volume overload is not beneficial to critically ill patients and negatively affects clinical outcomes. An early signal came from a retrospective study of patients with sepsis.[66] Achieving a net negative fluid balance greater than or equal to 500 mL within the first 3 hospital days correlated with improved survival independent of age, critical illness, and kidney function. The previously mentioned SOAP study evaluated more than 3000 ICU patients with sepsis. One of the most significant predictors of death was a net positive fluid balance, and multivariate regression analysis implicated positive fluid balance as an independent predictor of outcome despite disease severity.[67] Similarly, the Vasopressin and Septic Shock Trial (VASST) investigators determined that more positive fluid balance was significantly associated with an increase in mortality.[68] In these patients with sepsis, the cumulative mean fluid balance was 11 L fluid positive by postenrollment day 4. In patients who received conservative fluid management after the initial resuscitation, equating to net "even" or negative fluid balance on at least 2 consecutive days during the first week after the onset of septic shock, lower in-hospitality mortality was observed.[69] Volume overload is not only associated with increasing mortality but also with greater use of related medical interventions, including thoracentesis and the prescription of diuretic agents.[65] Higher cumulative fluid balance has been associated with both acute lung injury (ALI) and ARDS.[70] Both disorders portend poorer ICU outcomes. In contrast, more conservative fluid management strategies are associated with shorter durations of mechanical ventilation and improved outcomes in patients with ALI.[71,72] In patients admitted to the ICU with cancer, mean cumulative fluid balances exceeding 1.1 L in 24 hours were more frequently observed in the nonsurvivors.[73] Among patients admitted to the neurosurgical ICU for subarachnoid hemorrhage, positive net fluid balances after 3 days predicted the occurrence of vasospasm by transcranial Doppler and was associated with a longer length of hospital stay.[74]

Volume overload is common in critically ill patients who develop AKI, particularly with oliguria. In patients who require renal replacement therapy, fluid overload at the time of dialysis initiation has been associated with a higher 90-day mortality.[75] These differences in mortality persist after adjusting for disease severity, the timing of initiation of renal replacement therapy, dialytic modality, and sepsis. Additionally, patients enrolled in the Program to Improve Care in Acute Renal Disease (PICARD) study who had evidence of volume overload when the serum creatinine concentration was at its peak had significantly lower chances of recovering kidney function; their OR for death was 2.07 (95% CI, 1.27–3.37) when volume overload was present at dialysis initiation.[76]

However, there is no clear prescription for avoiding the unintended complications of volume overload. Management decisions that limit or restrict aggressive fluid resuscitation may lead to poorer outcomes. In 1490 patients who were randomized to restrictive fluid intake with a goal of net zero fluid balance around major abdominal surgery vs. traditional practices, those who had a restrictive regimen suffered a significantly higher rate of AKI without a difference in disability-free survivial.[77]

Complicating the issue is the fact that the assessment of volume overload and cumulative fluid balance is often subjective; results may be inconsistent because of errors in recording intakes and outputs and inaccurately measuring patient weights. A positive fluid balance might not correlate with clinical evidence of volume overload.[65] Furthermore, objective measurements of volume status, such as central venous

pressure readings, may not always correlate with fluid balance. Additional clinical trials are necessary to further guide clinical decision making in volume administration.

CONCLUSION

Replenishing and maintaining an adequate intravascular volume in critically ill patients remains somewhat of an art, without a universally applicable "recipe" to guide fluid replacement. Individualization of care is required, often balancing the administration of vasopressors with proper fluid repletion. Nonetheless, randomized trials support several guiding principles that appear to optimize patient outcomes (Table 99.2). In sepsis, early goal-directed fluid administration using IV crystalloids before colloids or blood products remains a mainstay of therapy in patients who lack active blood loss or symptomatic anemia. In the settings of cirrhosis with peritonitis and possibly severe burns, albumin infusion along with crystalloids may improve outcomes. Infusion of HES appears to be associated with higher complication

TABLE 99.2 Major RCTs Evaluating Type of Fluid With Mortality and Dialysis Outcomes in the ICU

First Author	Year	Journal	Type of Fluid	n	Mortality Outcome	*P*	Dialysis Outcome	*P*
Colloids								
Finfer (SAFE)[15]	2004	NEJM	Albumin vs. Saline	6997	No difference	0.87	No difference in RRT days	0.41

*Meta-analysis of 38 clinical trials.

rates, particularly AKI. Prescription of chloride-containing crystalloids has begun to lose favor based on the desire to avoid the adverse effects of hyperchloremia and metabolic acidosis. Finally, excessive transfusion of packed red blood cells for sepsis-induced hypoperfusion in lieu of crystalloids appears to provide little benefit. Hemoglobin levels above 7 g/dL do not seem to improve outcomes. It remains imperative to avoid volume overload, electrolyte abnormalities, and acid-base imbalance when replenishing intravascular volume in critically ill ICU patients.

KEY POINTS

- Before considering the administration of colloids or blood products in critically ill patients with an inadequate vascular volume, intravenous crystalloids remain the mainstay of volume repletion therapy (except in the settings of active bleeding or symptomatic anemia).
- In patients with cirrhosis and accompanying peritonitis, albumin infusion along with IV crystalloids may improve outcomes.
- Administration of HES appears to be associated with higher complication rates, particularly AKI.
- NS is losing favor for volume resuscitation based on its risk of inducing hyperchloremia and metabolic acidosis.
- Excessive transfusion of packed red blood cells in patients with sepsis and hypoperfusion appears to provide little added benefit to the infusion of crystalloids alone.

Acute Kidney Injury

Elwaleed A. Elhassan

Acute kidney injury (AKI) is recognized as one of the most serious complications in critically ill patients. It is strongly associated with higher short- and long-term mortality, increased resource utilization, and a higher risk for the development of chronic kidney disease (CKD) and end-stage kidney disease (ESKD).[1] AKI is defined as a sudden decrease in the glomerular filtration rate (GFR) occurring over a period of hours to days.[2] AKI is not a single disease, but rather a loose collection of various syndromes as heterogeneous as sepsis, cardiorenal syndrome, and urinary tract obstruction, which can often coexist.[3] Historically, AKI has been categorized according to the anatomic location of the presumed insult into prerenal, intrinsic renal, and postrenal AKI. However, the diverse nature of AKI, resulting from multiple etiologies with different pathophysiologies, has given way to specific descriptive syndromes, such as sepsis-associated AKI, nephrotoxic AKI, and cardiorenal syndrome.[3]

AKI can result from decreased renal perfusion not severe enough to cause cellular injury, such as in hypovolemia, systemic vasodilation, or acute worsening of cardiac function. If renal tubular and glomerular structure are presumably intact but solute clearance is limited, the injury is termed *prerenal azotemia*. If renal dysfunction is related to an obstruction of the urinary outflow tract, it is termed *postrenal azotemia*. AKI can also result from a renal insult, such as nephrotoxic exposure, glomerular or interstitial inflammatory process, or in the setting of a systemic syndrome like sepsis. Prerenal azotemia and renal injury caused by sepsis, ischemia, and nephrotoxins are responsible for most episodes of AKI.[4] The term *acute tubular necrosis (ATN)* was employed because of the demonstration of patchy necrosis of the tubular cells from autopsy studies late in the course of the disease. However, when performed, kidney biopsy findings in some conditions, such as sepsis and shock, show near absence of tubular necrosis despite profound kidney dysfunction. Furthermore, prerenal azotemia and intrinsic acute tubular necrosis can, and often do, coexist in the same patient. Because of the patchy nature of ATN, it is possible that some regions of the kidneys can have severe morphologic and functional ATN, whereas other parts may be structurally intact, awaiting only reperfusion to resume normal filtration. Therefore the use of the terms prerenal azotemia and ATN can be misleading and is becoming more questioned.[3,5]

Renal blood flow is approximately 1200 mL/min and constitutes 20% of cardiac output. Given this apparently generous perfusion, it may seem surprising that the kidneys are so susceptible to hemodynamic insults. The majority of perfusion (80%–90%), however, is to the renal cortex, where glomerular filtration occurs. The medulla is designed to concentrate and dilute urine. During urine concentration, the high osmotic gradient required for the reabsorption of water is associated with a low rate of blood flow. In fact, oxygen tension in the outer medulla in the region of the metabolically active thick ascending limb of Henle is only around 10 mm Hg.[6] This combination of low blood flow and diminished oxygen tension in a metabolically active environment makes the kidneys very susceptible to ischemic injury.

RENAL HYPOPERFUSION

Renal hypoperfusion is a consequence of the reduction in renal perfusion without cellular injury. As such, this is a reversible process if the underlying cause is corrected. It may be secondary to decreased blood volume (e.g., vomiting, hypovolemia, and hemorrhage), or it may be caused by a reduction in the effective arterial blood volume (e.g., congestive heart failure and cirrhosis). Further, the administration of medications that interfere with the normal autoregulatory ability of the kidney can contribute to prerenal azotemia. In settings of diminished renal perfusion, the administration of nonsteroidal antiinflammatory drugs (NSAIDs) or renin–angiotensin–aldosterone system (RAAS) inhibitors can precipitate overt prerenal azotemia. During prerenal azotemia, the RAAS becomes activated secondary to a decrease in renal blood flow, accompanied by increased activity of the adrenergic nervous system. Increased levels of angiotensin II and adrenergic activation increase proximal reabsorption of sodium, whereas aldosterone increases sodium reabsorption in the distal tubule. Together, these actions decrease the urine sodium concentration to less than 20 mmol/L and fractional excretion of sodium to less than 1%.[7] Therapy of prerenal AKI involves reversing the underlying cause, such as volume replacement or discontinuation of offending agents.

POSTRENAL CAUSES OF AKI

Postrenal AKI occurs when there is a bilateral (or unilateral in the case of a single kidney) obstruction of urine flow. In this setting, intratubular pressure increases and, in turn, decreases the net glomerular filtration pressure. Obstruction of urine flow is a relatively uncommon cause of AKI and is more frequent in the community than in the intensive care unit (ICU). Postrenal AKI can be divided into renal and extrarenal causes. Extrarenal causes include prostatic disease, pelvic malignancy, and retroperitoneal disorders. Intrarenal causes include crystal deposition, as occurs in ethylene glycol ingestion, or uric acid nephropathy in tumor lysis syndrome. Cast formation and tubular obstruction also occur in light-chain diseases, such as multiple myeloma. Possible postrenal causes of AKI should be evaluated with renal ultrasonography and the measurement of postvoid residual urine in the bladder (>50 mL is abnormal). It is important to rule out these causes rapidly because the potential for renal recovery is inversely related to the duration of obstruction.

INTRINSIC AND SYNDROMIC CAUSES OF AKI

Intrinsic causes of AKI can affect the glomerulus, vasculature, interstitium, or tubule. Suspicion of glomerulonephritis or vasculitis should be raised in a patient with renal failure who has an active urine sediment with red cells and red cell casts. In contrast, acute interstitial nephritis can present with pyuria and white cell casts in the urine; on occasion, hematuria is also present. Most cases of AKI from interstitial nephritis are drug related, commonly the result of antibiotics or NSAIDs. Recovery usually occurs with the removal of the offending agent and may be hastened by a short course of steroids: for example, 1 mg/kg per day of prednisone for approximately 1–1.5 months.[8] Intrinsic renal failure is often termed ATN, although, as explained earlier, this is a histologic diagnosis that is rarely confirmed by biopsy. ATN can be broadly classified into ischemic ATN, when it follows prolonged renal hypoperfusion, and toxic ATN, when it results from exposure to nephrotoxic drugs (such as antibiotics, contrast media, or chemotherapeutic agents) or endogenous toxins (such as myoglobin and uric acid). These toxins can have a direct cytotoxic effect on renal epithelial cells, affect intrarenal hemodynamics, or cause precipitation of metabolites or crystals, among others.[3] The most common cause of AKI in critically ill patients is sepsis. The pathophysiology of sepsis-associated acute kidney injury (S-AKI) remains incompletely understood. Previously, S-AKI was considered primarily a disease of the renal macrocirculation[9] resulting from global renal ischemia, cellular damage, and ATN. However, an increasing body of evidence suggests that S-AKI can occur in the absence of overt signs of hypoperfusion and clinical signs of hemodynamic instability.[10] A consistent finding in septic patients, independent of the severity of AKI, is the presence of microcirculatory dysfunction, inflammation, and adaptive bioenergetic response to injury.[11] The role of these mechanistic theories in the genesis of S-AKI and the potential therapeutic implications have been reviewed.[10]

Another form of AKI in the hospital is connected with the use of contrast media. Many studies have shown that contrast-related AKI, defined by small decrements in kidney function, is associated with increased mortality. However, a recent analysis using the Bradford Hill criteria points to significant uncertainty on a causal link between contrast and AKI.[12] Because other factors (e.g., medications, hypotension, or atheroemboli) can precipitate AKI after such exposure, the term *contrast-associated acute kidney injury (C-AKI)* has gained favor.[13] The pathogenesis of AKI in this setting involves both the hemodynamic and toxic effects of contrast. Contrast media cause renal vasoconstriction and medullary ischemia, in addition to direct tubular toxicity.[14] Preexisting renal disease, the use of contrast medium at a high volume (>350 mL or >4 mL per kilogram), and repeated administration within 72 hours after initial administration have been shown to be associated with an increased risk.

DEFINITION AND DIAGNOSIS

AKI is the abrupt decrease in GFR with resultant retention of urea and other nitrogenous waste products along with dysregulation of body fluids and electrolytes. The term *acute kidney injury* was proposed by the Acute Kidney Injury Network (AKIN) as an alternative to acute renal failure to encompass the entire range of insufficiency based on data showing that a small change in serum creatinine influences outcome. The Acute Dialysis Quality Initiative (ADQI) group proposed a consensus categorized definition, the RIFLE criteria.[15] Subsequently, AKIN proposed a revision of the RIFLE criteria[16–18] to better account for small changes in serum creatinine not captured by RIFLE criteria. Several large observational trials confirmed the validity of the RIFLE and AKIN revised criteria, as increasing severity of AKI was associated with increasing risk of death.[19,20] The Kidney Disease: Improving Global Outcomes (KDIGO) Clinical Practice Guidelines for AKI included a revision to the definition of AKI while retaining the AKIN staging criteria, and these are now globally embraced (Table 100.1).[21] In an international cross-sectional study using these criteria, 57.3% of ICU patients met KDIGO criteria for AKI.[22] The adjusted odds ratio for in-hospital mortality was progressive with the stage of AKI. All criteria mentioned earlier have the greatest utility in epidemiologic studies and in designing clinical trials in AKI. Despite this progress, the sensitivity and accuracy of AKI criteria have been generally acknowledged to remain limited by a reliance on the imperfect assessment methods on which they are built: namely, urine output and serum creatinine. Multiple novel biomarkers are being extensively studied for early diagnosis and prognostication of AKI (Table 100.2).[23] AKI is a clinical diagnosis that requires making changes in kidney function in the clinical context of the patient. Although sepsis is well recognized as the leading cause of AKI in the critically ill, it has been shown that 40% of critically ill patients develop sepsis after AKI.[24] This suggests that AKI may increase the risk of sepsis. Furthermore, both sepsis and AKI are clinical diagnoses, and it is usually difficult to define the precise time either of these syndromes begin. Therefore the term S-AKI has been introduced to acknowledge the uncertainty around the attribution of etiology.[10] S-AKI is defined as AKI in the presence of sepsis (based on Sepsis-3, the current consensus definition of sepsis) without other significant contributing factors explaining AKI or characterized by the simultaneous presence of both Sepsis-3 and KDIGO criteria.

There are several limitations to the use of serum creatinine and urine output for the diagnosis of AKI. There is no consensus method to establish baseline serum creatinine in the absence of previous values. Moreover, creatinine rise is often delayed and could be blunted in sepsis because of decreased creatinine production in addition to aggressive fluid resuscitation. Urine output is insensitive to detect AKI compared with creatinine, is less reliable outside the ICU setting, and

TABLE 100.1 Criteria and Staging for Acute Kidney Injury

Stage	Serum Creatinine	Urine Output
1	1.5–1.9 times baseline OR ≥0.3 mg/dL (26.5 micromol/L) increase	<0.5 mL/kg/h for 6–12 h
2	2.0–2.9 times baseline	<0.5 mL/kg/h for ≥12 h
3	3.0 times baseline OR Increase in serum creatinine to ≥4.0 mg/dL (353.6 micromol/L) OR Initiation of renal replacement therapy OR In patients <18 years, decrease in eGFR to <35 mL/min per 1.73 m^2	<0.3 mL/kg/h for ≥24 h OR Anuria for ≥12 h

Data from KDIGO clinical practice guideline for acute kidney injury. *Kidney Int.* 2012;2(Suppl. 1):8.
eGFR, Estimated glomerular filtration rate.
Minimum criteria for acute kidney injury include an increase in serum creatinine (SCr) by ≥0.3 mg/dL (26.5 micromol/L) observed within 48 hours; or an increase in SCr to ≥1.5 times baseline, which is known or presumed to have occurred within the prior 7 days; or urine volume <0.5 mL/kg/h for 6 hours.

TABLE 100.2 Biomarkers Used for Detection of Acute Kidney Injury

Type of Biomarker	Subclass of Biomarker	Examples of Biomarkers	Comments
Functional biomarker of AKI	Biochemical markers of glomerular filtration/function	Serum creatinine, serum cystatin c, proenkephalin, visible fluorescent injectates	Serum creatinine remains the gold standard, but other novel markers of glomerular function have been shown to rise earlier and with the same accuracy as creatinine. Injectables may represent the future of GFR measurement, with the injection of small dextrans providing rapid determination of GFR at the bedside. May be elevated in the setting of CKD
	Global assessment of nephron function	Urine output	Urine output detects less severe AKI compared with creatinine and can be affected by diuretics and other drugs. Generally needs indwelling catheter for reliable measurement, with measurements being less frequent outside the ICU
	Global assessment of nephron capacity	Furosemide stress test, renal reserve testing	These tests interrogate the kidney's capacity for increased function via protein loading (hyperfiltration) or diuretic responsiveness
Damage/injury biomarkers	Global assessment of nephron injury	Urinalysis	Urinalysis can detect injury along the entire nephron (from glomerulus to tubules); although scoring systems exist, none has been widely validated in any setting of AKI
	Biochemical biomarkers of renal tubular injury	Urinary NGAL, urinary KIM-1, soluble FAS	These remain an area of intense AKI research but have yet to be widely validated in the setting of human AKI
AKI risk biomarkers	Biochemical biomarkers of AKI risk	TIMP2*IGFBP7, plasma NGAL	Increasingly available for clinical use, these markers quantify an individual patient's risk for impending AKI
	Biomarkers of AKI risk	Electronic alerts, electronic risk algorithms	Several alerts have shown their ability to predict the impending development of sepsis and AKI separately. Using these alerts in concert with biochemical biomarkers may help to enrich AKI detection and risk stratification

AKI, Acute kidney injury; *CKD,* chronic kidney disease; *GFR,* glomerular filtration rate; *ICU,* intensive care unit; *IGFBP7,* insulin-like growth factor binding protein-7; *KIM-1,* kidney injury molecule-1; *NGAL,* neutrophil gelatinase–associated lipocalin; *TIMP2,* tissue inhibitor of metalloproteinase-2. can be affected by diuretics and other drugs. Urinalysis and urine microscopy may aid identification of S-AKI. Observational studies have shown that S-AKI shows more renal tubule epithelial cells and cast elements compared with nonseptic AKI.[25,26] Patients with S-AKI had higher urine microscopy scores when compared with those with AKI from other causes.[27] Thus urine sediment may help establish the cause of AKI, but its sensitivity is poor. Several biomarkers have been developed and may assist in the early detection of AKI in patients with sepsis (see Table 100.2). Further studies are required to establish any of these or other potential biomarkers as practical diagnostic tools in the early clinical diagnosis of AKI. Such tools may facilitate timely and aggressive therapeutic interventions. A specific one worth mentioning is the furosemide stress test (FST). This test was proposed as a tool for determining the risk of AKI progression.[28] It uses a protocolized dosage of furosemide (1.0 mg/kg of furosemide to diuretic-naive subjects and 1.5 mg/kg in subjects with prior furosemide exposure) in patients with AKI stages 1–2 to determine the risk of progression to stage 3 AKI or requirement for renal replacement therapy (RRT). The cutoff for predicting AKI progression during the first 2 hours after FST was a urine volume of less than 200 mL with high sensitivity and specificity. Since the original publication of the FST by Chawla and colleagues, this test has been prospectively validated to predict worsening AKI among critically ill patients and used to identify patients for randomization to different RRT initiation times.[29,30] Two other recently developed biomarkers of cell cycle arrest are tissue inhibitor of metalloproteinases 2 (TIMP2) and insulin-like growth factor binding protein-7 (IGFBP7).[3] Those markers have been incorporated into the first diagnostic test for AKI approved by the US Food and Drug Administration (FDA): Nephrocheck (Astute Medical, San Diego, CA). Unlike damage markers, TIMP2 and IGFBP7 can be released in response to noninjurious, noxious stimuli and thus serve as kidney stress markers.[31,32]

EPIDEMIOLOGY AND OUTCOMES

The incidence of AKI is now believed to be significantly higher than previously thought, with over 50% of patients in the ICU developing stage 1 AKI at some point during the course, whereas stages 2 and 3 AKI are considerably less.[33] Sepsis remains one of the most common sources of AKI, and S-AKI is strongly associated with poor clinical outcomes. Precise estimation of the incidence of S-AKI is difficult, given the many confounders common in critically ill patients.[23] Bagshaw and colleagues found sepsis considered responsible in 47.5% of an international cohort of 753 critically ill patients with AKI. Moreover, they demonstrated that S-AKI was associated with higher risk of in-hospital mortality and longer duration of hospitalization.[34] More recently, a larger international consortium showed similar findings.[1] The Sepsis Occurring in Acutely ill Patients (SOAP) cohort study recruited patients admitted to 198 ICUs across Europe.[35] About a third of this cohort had sepsis, whereas AKI occurred in half of the cases and was associated with an ICU mortality of 41%.

About two-thirds of AKI episodes resolve within 7 days.[36] When a case does not resolve or relapse occurs with subsequent lack of resolution, substantially worse clinical outcomes are expected. AKI is now increasingly recognized as having a bidirectional relationship with CKD in hospitalized patients. Although preexisting CKD increases the susceptibility toward the development of AKI, AKI has also been found to accelerate the development of CKD. After recovery from AKI, patients carry the risk of developing CKD, ESKD, and death.[37] The severity of

AKI, RRT requirement, and recovery status during hospitalization has been shown to determine the risk of progression to CKD.[38,39] Over 1 year, CKD developed in 21%, 30%, and 79% of 105 survivors with AKI reversal, recovery, and nonrecovery, respectively.

PREVENTION AND TREATMENT

In light of its dismal outcome, it is imperative that therapies to prevent or ameliorate AKI be developed. The fundamental principles of prevention of AKI are identifying patients at risk and timely instituting appropriate protective measures. Recently reviewed evidence has focused on clinical risk prediction, novel kidney damage biomarkers, automated electronic alerts embedded within electronic health records, and the concept of the renal angina index.[40] If prerenal factors contribute, they should be identified and intravascular volume maintained or rapidly restored. Patients deemed at increased risk should have appropriate drug adjustment, discontinuation, or avoidance of nephrotoxins, including unnecessary exposure to contrast media (Fig. 100.1). Beyond such seemingly obvious interventions, only a limited number of preventive treatments are potentially available.

Fluid resuscitation. Prompt resuscitation of the circulation with administration of intravenous fluids is a key component of sepsis management. High-quality resuscitation care of the patient with sepsis includes an initial modest bolus of resuscitation fluid (30 mL/kg within the first 3 hours) followed by a frequent assessment with dynamic measures of fluid responsiveness to determine whether additional fluids or

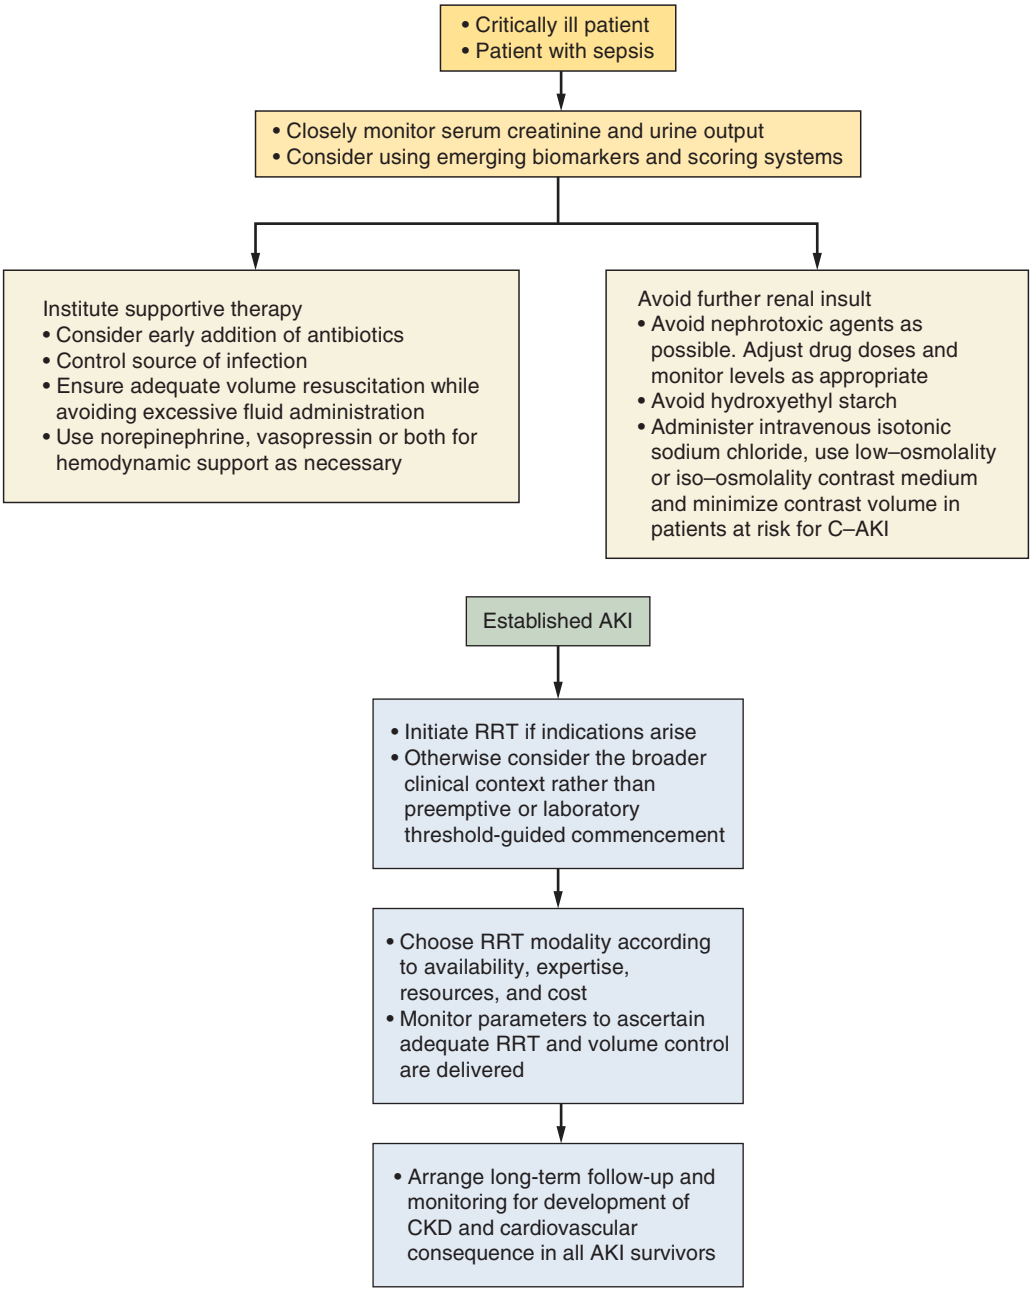

Fig. 100.1 Recommendations for the Evaluation and Treatment of Acute Kidney Injury. *AKI*, Acute kidney injury; *C-AKI*, contrast-associated acute kidney injury; *CKD*, chronic kidney disease; *RRT*, renal replacement therapy.

vasoactive drugs are indicated.[41] Recent studies have shown that protocolized resuscitation strategies did not improve outcomes, but a minimal degree of resuscitation is needed to mitigate the risk of adverse outcomes. When volume replacement is indicated, both crystalloids (e.g., isotonic saline and Ringer's lactate) and colloid-containing solutions (e.g., albumin solution and colloidal substances) have been used to replace the extracellular fluid deficit. Crystalloids are the most common form of volume replacement, but their effect on plasma volume is limited. Colloidal substances, such as albumin, dextran, and hydroxyethyl starches (HESs), because they are macromolecules, are better retained within the intravascular space and have a greater effect on plasma volume. Albumin has been used for decades, but it is expensive. In view of the absence of evidence of a mortality benefit from albumin and its increased cost compared with crystalloids, albumin may be avoided according to a Cochrane Group systematic review.[42] Dextran cannot be recommended for plasma volume expansion because of serious side effects, such as coagulation abnormalities and increased development of AKI. Hyperoncotic starch solutions should be avoided in sepsis and in all other patients at risk for AKI, as multiple studies have shown that HESs are associated with increased risk of AKI and need for RRT compared with a variety of crystalloid solutions.[43–46]

Although crystalloids remain the first choice for fluid therapy in critically ill patients, there may be differences in renal outcomes among them. Isotonic 0.9% saline is widely available and is inexpensive, but is hyperchloremic relative to plasma. A large-volume resuscitation using isotonic saline may be associated with the development of a hyperchloremic metabolic acidosis. A number of clinical trials tested the differential effects of the so-called balanced crystalloids (chloride concentrations <110 mmol/L) compared with isotonic saline on clinical outcomes. The recent Saline Against Lactated Ringer's or Plasma-Lyte in the Emergency Department (SALT-ED) and Isotonic Solutions and Major Adverse Renal Events (SMART) trials found fewer major adverse kidney events.[47,48] Both trials found about 1% absolute risk reduction for major adverse kidney events by 30 days in patients treated with balanced crystalloid. However, a subsequent meta-analysis of 21 randomized controlled trials found no convincing evidence of an effect of balanced crystalloids on in-hospital mortality or AKI when compared with isotonic saline.[49] Until further research is available, balanced crystalloids may be preferred in patients in whom large volumes of fluids are administered (e.g., >2 L) in addition to those with hyperchloremic acidosis.

Fluid overload. As previously pointed out, aggressive fluid therapy is crucial to the successful management of both sepsis and AKI. However, septic AKI may not be characterized by hypoperfusion. Clear evidence shows that in addition to the risks of underresuscitation, in the setting of AKI, volume overload from aggressive overresuscitation is also harmful, creating a J- or U-shaped curve for resuscitation and mortality.[23,50] The pathogenetic mechanism may involve renal edema, which, in an encapsulated organ, may induce congestion and ischemia.[51] Fluid bolus therapy, combined with the oliguria of AKI, is likely to lead to fluid accumulation in septic patients.[52] Fluid accumulation was associated with adverse outcomes and increased mortality in multiple studies,[53–55] with persistent and abundant data demonstrating harm in a variety of patient populations, including those with septic AKI. In contrast, in the setting of major abdominal surgery, a fluid-liberal strategy was associated with lower rates of AKI and no difference in disability-free survival. This was based on a recent large-scale international pragmatic trial that investigated the impact of fluid restriction on the development of organ dysfunction after major abdominal surgery.[56] Future investigations are still needed to determine the ideal fluid strategy for the prevention of septic and postoperative AKI.

Supportive care. Earlier and appropriate antimicrobial therapy, along with septic source control, has been associated with lower risk of AKI.[57,58] For each hour that appropriate antimicrobial therapy was delayed, the risk of AKI increased by approximately 40%. Moreover, earlier antimicrobial therapy was associated with a greater likelihood of kidney recovery within 24 hours. Nephrotoxic therapies, such as treatment with aminoglycosides, vancomycin particularly when combined with piperacillin-tazobactam[59] and amphotericin B, should be used with caution to prevent kidney injury. Systematic surveillance for nephrotoxic medication exposure and AKI risk can lead to sustained reductions in avoidable harm.[58] Strict therapeutic drug monitoring should be considered when applicable.

Diuretics are frequently used in patients with AKI, especially in an attempt to convert oliguric into nonoliguric AKI. Furosemide is not associated with any significant clinical benefits in the prevention or treatment of acute renal failure in adults.[60] Although the use of loop diuretics in early or established AKI facilitates management of fluid overload, hyperkalemia, and hypercalcemia, any active role in the prevention or amelioration of the AKI course remains unproven. Therefore if diuretics are employed, care must be taken to avoid delaying the initiation of dialysis if clinically necessary. Metabolic acidosis is one of the complications of AKI. The administration of bicarbonate in patients with metabolic acidosis (pH <7.2) and severe AKI may help to delay or avoid unnecessary RRT.[61] By increasing pH to levels >7.3, bicarbonate therapy reduced 28-day mortality and the need for dialysis. However, in patients with lactic acidosis, the primary aim of therapy is reversal of the underlying disease (e.g., shock, sepsis).

Vasopressor support. Although hemodynamic monitoring is of unproven benefit, it is the standard of care in order to guide vasopressor drug institution after fluid resuscitation. This typically includes physical examination or invasive monitoring (e.g., central venous catheter, arterial cannula, and even cardiac output monitoring in some cases) in severely ill patients. If patients remain hypotensive (e.g., mean arterial pressure [MAP] <65 mm Hg) after adequate intravascular volume expansion, restoration of MAP will require the addition of vasopressor drugs.[3] Because such agents cause vasoconstriction, there has been concern about their use in AKI. Norepinephrine is recommended as a mainstay of therapy for septic shock treatment, showing the ability to increase MAP and improve renal perfusion.[62] Compared with norepinephrine, vasopressin showed similar outcomes and no increased adverse events.[63,64] These data suggest that vasopressin is a viable first-line alternative to norepinephrine. Dopamine is not recommended for renal protection and is associated with more adverse events than norepinephrine.[65]Angiotensin II is a potent vasopressor without inotropic or chronotropic properties. Clinical trials have demonstrated this novel vasoconstrictor may improve patient outcomes in the setting of vasodilatory shock and outcomes in the setting of shock-associated severe AKI.[66,67] Fenoldopam, a selective dopamine receptor-1 agonist, resulted in less adverse renal outcomes but not decreased mortality.[68]

GLYCEMIC CONTROL AND NUTRITIONAL SUPPORT

It has been proposed that tight glycemic control can reduce the incidence and severity of AKI in critically ill patients. However, studies have highlighted significant concerns regarding the effectiveness and safety of using intensive insulin therapy with tight glycemic control to prevent or ameliorate morbidity and mortality of AKI or other forms of organ injury. The international Normoglycemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation (NICE-SUGAR) study enrolled over 6000 patients and set out to determine the risk/benefit of tight glycemic control in critically ill patients.[69] It

showed that in contrast to conventional insulin therapy, intensive glucose control increased mortality among these patients. A blood glucose target of ≤180 mg/dL resulted in a lower mortality than a target of 81–108 mg/dL. Therefore it may be prudent to use conventional insulin therapy in ICU patients at risk of AKI to target plasma glucose of 140–180 mg/dL to avoid hypoglycemia. Nutritional support in patients with AKI does not differ significantly from that of critically ill patients. AKI affects water, electrolyte, and acid-base balance, but it also induces changes in protein, carbohydrate, and lipid metabolism. Although requirements vary based upon the underlying catabolic state, patients with AKI should be supplemented with 20–30 kcal/kg body weight per day. Even in hypermetabolic states such as sepsis, energy expenditure is rarely greater than 130% of the calculated basic energy expenditure. Protein requirement increases with the severity of the underlying illness and with initiation of RRT. Whereas nondialysis patients with only mild to moderate illness require only 0.8–1.2 g/kg per day, critically ill patients or patients who are on RRT generally require 1.2–1.5 g/kg per day or more.[70] Dietary restrictions on potassium, phosphorus, sodium, and fluid intake (1–1.5 L per day, except if volume depleted) are generally indicated.

SPECIAL TYPES OF AKI

Abdominal compartment syndrome. *(ACS)* is defined as intraabdominal hypertension (IAH) with intraabdominal pressure (IAP) greater than 20 mm Hg with or without an abdominal perfusion pressure less than 60 mm Hg accompanied by end-organ dysfunction.[71] Epidemiologic studies differ widely in their report of the incidence and prevalence of ACS in the ICU. However, there is agreement that the occurrence of IAH during the ICU stay is an independent predictor of patients' outcome.[72] This was reflected in studies conducted by Malbrain and colleagues and Vidal and colleagues showing significantly higher mortality rates and a higher incidence of organ failure or dysfunction—predominantly renal and pulmonary.[73,74] A large systematic review and meta-analysis of studies identified multiple risk factors for IAH and ACS in ICU patients; many were specific to the type of patient population under study. These risk factors include large-volume crystalloid resuscitation, the presence of shock/hypotension, obesity, sepsis, abdominal surgery, severe acute pancreatitis, and ileus development.[75] Several mechanisms have been reviewed as the etiology for IAH-induced renal dysfunction and failure.[72] The World Society of the Abdominal Compartment Syndrome proposed a management algorithm centered mostly on expert opinion that is based on the principles of serial IAP monitoring, optimization of systemic organ perfusion, IAP control, and reducing potential end-organ damage and surgical decompression for refractory ACS.[76]

Contrast-associated acute kidney injury. Multiple trials and meta-analyses have compared intravenous isotonic sodium bicarbonate with isotonic sodium chloride for the prevention of C-AKI, on the hypothesis that urinary alkalinization would reduce contrast-induced generation of injurious oxygen free radicals. The results of these analyses were inconclusive, and they collectively formed the basis for the recent Prevention of Serious Adverse Events Following Angiography (PRESERVE) study.[77] This was a double-blind trial that randomly assigned 5177 high-risk patients undergoing nonemergency angiography to receive intravenous isotonic sodium bicarbonate or intravenous isotonic saline, in addition to oral acetylcysteine or oral placebo, for the prevention of a primary composite endpoint of death, need for dialysis, or persistent impairment in kidney function. The trial showed no significant difference in the incidence of the primary outcome or in the incidence of C-AKI. Thus our recommendation for preventing contrast nephropathy in high-risk patients is to seek an alternative procedure not requiring contrast when possible. If that is not feasible, adequate hydration with isotonic sodium chloride should be performed.

Acute kidney injury in critically ill cancer patients. Cancer patients are particularly at risk for AKI secondary to infection and sepsis, tumor lysis syndrome, kidney damage induced by immunosuppression after hematopoietic stem cell transplantation, and direct effects from the primary malignancy.[78,79] The development of AKI can further jeopardize cancer treatment, increase the toxicity, and/or reduce the delivery of chemotherapy and exclude patients from clinical trials. AKI requiring RRT is more common in ICU patients with cancer compared with those without cancer, and hospital mortality rates are high in cancer patients with AKI, especially when RRT is required.[80]

ROLE OF THE NEPHROLOGIST IN THE ICU

There are wide variations in the probability and timing of nephrology consultation in patients with AKI. The role of the nephrologist in managing ICU AKI patients also depends on the ICU model: that is, "closed" where the intensivist treats patients with AKI without input from a nephrologist versus "open" where management would be combined. Although "closed" models are reported to result in fair patient outcomes,[81] integrating nephrologists into the care of critically ill patients from the early stages of AKI has been shown to be associated with a lower incidence of progression to severe AKI, lower mortality, and enhanced patient recovery.[82,83] Given their in-depth understanding of AKI and RRT technologies,[84] nephrologists are proficient at delivering dialytic and nondialytic treatment options for patients with AKI and in transitioning patients between these two treatment options based on each patient's changing clinical status. They can facilitate transition of AKI-RRT to outpatient dialysis, aid in proper follow-up and management of patients at risk of progressive CKD, and assist in avoiding or discontinuing RRT when treatment is futile or not consistent with the patient's goals of therapy.[85] Early follow-up by a nephrologist after an AKI episode in those requiring RRT was associated with improved survival.[86]

RENAL REPLACEMENT THERAPY

Indications and Timing

As mentioned previously, about half of patients in the ICU develop AKI. Of those, an estimated 8%–12% receive RRT for severe AKI.[22] The optimal timing of the initiation of dialysis is not defined. There is little disagreement in commencing dialysis in the presence of life-threatening conditions, such as diuretic-resistant volume overload, refractory hyperkalemia, acidosis, or overt symptoms and signs of uremia (e.g., encephalopathy and pericarditis). Medical treatment approaches for hyperkalemia result in intracellular shifts of potassium. When intermittent hemodialysis (IHD) is used to correct hyperkalemia after such measures have been used, dialytic potassium removal will be reduced, and higher serum levels of postdialysis potassium can occur.[87] Metabolic acidosis is common in severe AKI, but can be corrected with bicarbonate and rarely requires urgent dialysis if not accompanied by volume overload or uremia. Some poisons, drug overdoses, and toxic compounds can contribute to acid-base disturbances and AKI. In such cases, dialysis can be supportive and facilitate the removal of these substances and their metabolites. In acute salicylate poisoning, RRT is indicated when the patient exhibits altered mental status, pulmonary or cerebral edema, renal impairment, fluid overload that prevents the administration of sodium bicarbonate, or clinical deterioration despite aggressive and appropriate supportive care.[88]

Ethylene glycol and methanol poisoning are important causes of anion-gap metabolic acidosis and can be cleared by dialysis. Metformin-associated lactic acidosis may be an indication for dialysis, especially in critically ill patients at risk of death. In particular, such patients demonstrate a low pH (<6.9) and high serum lactate and metformin concentrations.[89]

The ideal time to consider RRT in AKI when "conventional" indications are absent has long been a perplexing challenge for clinicians. The lack of high-quality evidence has contributed to decisional uncertainty and practice variation.[90,91] Potential advantages of accelerated initiation of RRT include early control of electrolyte and acid-base derangements and uremia, avoidance of volume overload, and clearance of inflammatory mediators. However, evidence that such effects translate into clinical benefits is sparse. Randomized controlled clinical trials focused on the timing of RRT initiation in critically ill patients with AKI have recently been reported. The Early Versus Late Initiation of Renal Replacement Therapy in Critically Ill Patients With Acute Kidney Injury (ELAIN) trial was a single-center trial that enrolled 231 mostly surgical patients, comparing early RRT (starting within <8 hours of fulfilling KDIGO stage 2 AKI) with delayed RRT (starting within <12 hours of developing KDIGO stage 3 AKI or upon an absolute indication).[92] The trial demonstrated a mortality benefit of early RRT compared with delayed treatment. The Artificial Kidney Initiation in Kidney Injury (AKIKI) trial was a multicenter trial that compared two strategies for starting RRT in 620 mixed critically ill patients with AKI who were receiving mechanical ventilation and/or vasoactive agents. The early strategy started RRT within <6 hours of fulfilling KDIGO stage 3 AKI, and the delayed strategy started upon fulfilling clinical criteria related to worsening AKI or its complications.[93] There was no difference in mortality; however, the RRT utilization differed significantly, with only half of patients in the delayed strategy receiving RRT compared with almost all in the early strategy. The IDEAL-ICU study was a multicenter, randomized, controlled trial that compared patients with early-stage septic shock and AKI but without life-threatening complications to receive RRT within 12 hours after documentation of failure-stage AKI (early strategy) or after a delay of 48 hours if renal recovery had not occurred (delayed strategy).[94] Follow-up data at 90 days showed that mortality did not differ significantly between the two groups. Notably, 38% of patients in the delayed-initiation group did not receive RRT. The findings of these clinical trials leave the question of elective RRT initiation in the absence of compelling indications incompletely resolved. The Standard versus Accelerated Initiation of RRT in AKI (STARRT-AKI) study is ongoing. This multinational trial completed enrollment of its target of 2866 patients with KDIGO stage 2 or 3 AKI who do not have an emergent indication for RRT. Enrolled patients were randomly assigned to either early (within 12 hours) or delayed RRT initiation.[95] Pending further evidence, we agree with the KDIGO group that RRT should be initiated emergently when life-threatening changes exist. However, a clinical judgment considering the broader clinical context, the presence of conditions that can be modified with RRT, and trends of laboratory tests, rather than using any specific parameters, should be employed when making the decision to initiate RRT.[21] Finally, it is important to consider the volume status when deciding the time for initiating RRT because volume overload, as previously discussed, appears to be an important factor associated with mortality in AKI. Table 100.3 depicts acceptable indications for initiating RRT in the ICU.

TABLE 100.3 Potential Indications for Renal Replacement Therapy in the ICU

Nonobstructive oliguria (urine output <200 mL/12 h) or anuria
Refractory severe acidemia
Refractory hyperkalemia (K^+ >6.5 mmol/L)*
Uremia (encephalopathy, pericarditis, neuropathy, myopathy)
Severe dysnatremia (Na^+ >160 or <115 mmol/L)
Clinically significant organ edema (especially lung) unresponsive to diuretics
Drug overdose with dialyzable toxin
Coagulopathy requiring large amounts of blood products in a patient at risk for acute respiratory distress syndrome
NOTE: Any one of these indications is sufficient to consider initiating renal replacement therapy. Two of these indications make renal replacement therapy desirable.

*Intermittent hemodialysis removes K^+ more efficiently than continuous modalities.

Renal Replacement Therapy Modality

In the ICU, acute RRT includes standard IHD, prolonged intermittent renal replacement therapies (PIRRTs; e.g., sustained low-efficiency dialysis [SLED]), continuous renal replacement therapies (CRRTs), and peritoneal dialysis (Table 100.4). RRT is required in severe AKI to remove uremic toxins and maintain fluid, electrolyte, and acid-base balance. All modalities are effective therapies that may be used and exchanged according to the hemodynamic status or coagulation problems of the patient. A recent meta-analysis compared clinical outcomes among critically ill adults with AKI treated with CRRT, IHD, and SLED.[96] The RRT modality was not associated with in-hospital mortality or dialysis dependence. The authors concluded that they did not find a definitive advantage for any RRT modality on short-term patient or kidney survival.

PIRRTs have demonstrated comparable or better clinical outcomes to CRRT in small clinical trials.[97,98] SLED is performed by using dialysis machines to deliver a slow dialysate flow for periods ranging from 8 to 12 hours per day, depending on the needs of the patient and tolerance to ultrafiltration. Advantages of this technique include high hemodynamic tolerance, excellent solute-removal capability, and the capacity to be instituted using regular hemodialysis machines without acquiring new equipment. CRRT represents a spectrum of modalities that provides continuous support for severely ill patients with AKI. These include continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF), which involve both convective and diffusive therapies. CRRT has been advocated in patients with AKI because of its enhanced ability to remove inflammatory mediators, which may provide benefit in septic patients, particularly using convective modes of continuous therapy while maintaining hemodynamic stability. However, there are no studies clearly showing superior clinical outcomes with different CRRT modes. The main disadvantage of CRRT is the need for prolonged anticoagulation to prevent clotting of the filter. This can be done with low-dose systemic heparin; however, there remains the risk of bleeding or heparin-induced thrombocytopenia. Regional citrate anticoagulation (RCA) is increasingly used in some centers. A number of clinical studies have shown advantages of RCA compared with heparin resulting in prolonged circuit life, reduced incidence of hemorrhagic complications, and lower transfusion needs.[99] On the basis of these data, the KDIGO Clinical Practice Guidelines recommend the use of RCA as the preferred anticoagulation modality for CRRT in patients without contraindications for citrate, even in the absence of an increased bleeding risk or deranged coagulation. The guidelines also highlighted potential drawbacks to RCA, including the necessity of complex protocols and risk of metabolic complications.

TABLE 100.4 Comparison of Various RRT Modalities

	IHD	SLED	CRRT
Cost	+	++	++++
Duration	4 hours daily/alternate days	8–12 hours daily/alternate days	24 hours (though actually achieves less on average)
Hemodynamic instability	Least suitable	Good	Most compatible
Compatible with extracorporeal life support	No	No	Yes
In raised intracranial pressure	Increases	Can increase	Usually no change
Anticoagulation	Can be omitted	Can be omitted	Predilution can be used to maintain circuit
Serum concentration of renally cleared drugs	Major fluctuations	Some fluctuation	Least fluctuation
Vascular access	AV fistula or nontunneled or tunneled catheter	AV fistula or nontunneled or tunneled catheter	Nontunneled or tunneled catheter
Compatible with supporting large-volume infusions (antibiotics, nutrition, etc.)	No	Would need to be daily and longer sessions	Most compatible
Mobilization	Most compatible	Could be compatible if done at night/rest time	Not compatible—would need to be discontinued

AV, Arteriovenous; *CRRT*, continuous renal replacement therapy; *IHD*, intermittent hemodialysis; *SLED,* sustained low-efficiency dialysis.
Modified from Ahmed AR, Obilana A, Lappin D. Renal replacement therapy in the critical care setting. *Crit Care Res Pract.* 2019;16;2019:6948710.

In the absence of definitive data to support a particular modality, the modalities of RRT should be viewed as complementary, with the choice of RRT modality influenced by availability, expertise, resources, cost, and physician preference. The current KDIGO recommendations suggest that CRRT is preferable over intermittent therapies in patients who are hemodynamically unstable and/or have cerebral edema. Selection of RRT in special groups of patients has been reviewed.[100] In patients with acute brain injury or increased intracranial pressure, CRRT is generally preferred over IHD, which may worsen neurologic status. A decline in neurologic status may result from the compromise of cerebral perfusion pressure during intradialytic hypotension. Alternatively, cerebral edema and intracranial pressure may be enhanced by rapid intracellular solute-mediated volume shifts. Because the rates of volume and solute removal are slower during CRRT, this modality is seemingly better tolerated by patients with brain injury or increased intracranial pressure at risk for acute herniation. CRRT may also be preferred among those with fulminant hepatic failure and patients with severe chronic metabolic disturbances such as hyponatremia. In contrast, IHD is the preferred modality with intoxications because of its more rapid clearance of toxins.

Peritoneal dialysis is an alternative modality for AKI in which vascular access may be difficult, in conditions where anticoagulation may be problematic, in underresourced regions, or after large disasters with mass casualties. Single-center studies have shown similar or better outcomes for selected patients treated with high-volume or tidal peritoneal dialysis compared with IHD or CRRT.[101,102]

Adequate Therapy Dosing

IHD is most commonly provided on a thrice-weekly or every-other-day schedule. In chronic hemodialysis patients, adequacy of dialysis is primarily determined by the level of small-solute (urea) clearance. This is reflected by the *Kt*/*V* formula, where *K* is the dialysis membrane clearance of urea, *t* is the time on dialysis, and *V* is the volume of distribution of urea, which is equal to the total body water content. As seen from the formula, one can increase the time on dialysis or increase the dialyzer clearance to enhance urea clearance. Dialyzer clearance depends on blood flow and dialysate flow rates, in addition to the inherent properties of the membrane. Regarding IHD dosing, the VA/NIH Acute Renal Failure Trial Network Study (ATN study) did not find a benefit for a more intensive strategy for RRT.[103] This study compared IHD (hemodynamically stable patients) with sustained low-efficiency dialysis (hemodynamically unstable patients) performed three (less intensive) versus six (more intensive) times a week in 563 critically ill patients with AKI and failure of at least one nonrenal organ or sepsis. The prescribed *Kt*/*V* per session was 1.2–1.4, and the actual delivered mean dose was 1.3 in the less intensive arm. The 60-day mortality rate and percentage of patients recovering renal function were similar in both groups. The Hannover Dialysis Outcome study was a prospective randomized, parallel group study that used intensified extended dialysis (dosed to maintain plasma urea levels <90 mg/dL) versus standard dialysis (dosed to maintain plasma urea levels between 120 and 150 mg/dL) on 14- and 28-day mortality and renal function.[104] The mortality and frequency of renal function recovery were similar between the two groups. Based on these two well-designed and performed clinical trials, it appears that increasing urea target clearances does not improve mortality or rates of renal recovery. Therefore at least the smaller dose used in these trials should be pursued, with monitoring of the delivered dose of therapy to ascertain a minimum delivery of *Kt*/*V* of 1.2 per treatment when intermittent RRT in AKI patients is used. Nevertheless, applying the concept of *Kt*/*V* remains controversial in patients with AKI because urea generation and urea distribution volume are not constant or accurately measurable. Moreover, few AKI patients are in metabolic steady state, and many show a high protein catabolic rate or have a fluctuating volume status and renal function.[105] Based on these arguments, the European Renal Best Practice position statement does not recommend using *Kt*/*V* as a measure of dialysis dose when using IHD and suggests that its duration be adapted to allow maintenance of metabolic and volume status.[106] Currently there are no standards for dose prescription of PIRRT. Daily laboratory and clinical parameters can be used to assess for adequacy of dialysis. Regarding CRRT, much of the dosing guidelines stem from two large-scale, multicenter, randomized controlled trials. In the aforementioned VA/ATN study, 201 patients received CVVHDF in the less intensive arm (mean delivered effluent of 22 mL/kg/min) and 179 in the intensive therapy group (mean delivered effluent of 36 mL/kg/min). The higher dose of CRRT did not influence mortality or renal recovery. The Randomized Evaluation of Normal versus Augmented Level of RRT (RENAL) study was conducted at 35 centers throughout Australia

and New Zealand.[107] It compared the effects of postdilutional CVVHDF doses of 25 and 40 mL/kg/h on the 24-day and 90-day mortality rates of 1508 critically ill AKI patients. Treatment with a higher-intensity regimen did not reduce the mortality at 90 days. In conclusion, the results of the two well-designed and executed VA/ATN and RENAL clinical trials did not show any benefit of higher CRRT doses for critically ill AKI patients beyond a threshold necessary to optimize clinical outcome. Therefore when using CRRT for treating such patients, the dose to be targeted may be the minimal one used in these trials: 20–25 mL/kg/h. Notably, observational studies have suggested that the actual delivered effluent volume during CRRT is substantially less than the prescribed dose.[108] Therefore to ascertain that the target dose is delivered despite potential therapy interruptions, we recommend an effluent flow rate of approximately 25 mL/kg/h. Unfortunately, the clinical trials of RRT dose evaluated only a fixed-dose prescription; it remains uncertain whether a fixed dose is appropriate for all critically ill patients or whether RRT dose should be individualized, dynamic, and continuously adapted to changing clinical status.[109]

Medication Dosing

During AKI, drugs normally eliminated by the kidney exhibit a markedly decreased clearance. As the physiochemical characteristics of the drugs affect the removal by dialysis and hemofiltration, the amount of the drug removed during these procedures may be sufficient to require supplemental dosing. For patients on hemodialysis, a supplemental dose of the drug is most commonly administered at the completion of the dialysis session. Drug clearance with CVVH is through convective transport and approximates the unbound drug concentration in plasma multiplied by the ultrafiltration rate.[110] Drugs with molecular weights of less than 500 Da are readily removed by either conventional hemodialysis or CVVH, but those with higher weights of 1000–5000 Da are eliminated more efficiently by CVVH because of the use of high-flux membranes that allow the passage of larger molecules.

The volume of distribution greatly affects the clearance of a drug, in that drugs with large volumes of distribution are likely to be bound to a greater extent in the tissues. In this setting, only a small amount has access to the vasculature at any time. For such drugs, clearance with CVVH is greater than with intermittent therapies because of the continuous nature of the clearance. The extent of protein binding of a drug is important because the protein–drug complex has a molecular weight greater than 50,000 Da. At this size, neither intermittent nor continuous therapies will efficiently remove the drug. However, the extent of protein binding is dependent on pH, uremia, concentration of free fatty acids, heparin therapy, and relative concentrations of drug and protein. In critically ill patients, serum albumin is often decreased, thereby making more drug available for clearance during RRT. Because of the potential medication toxicities, in addition to the need to maintain therapeutic levels of multiple medications, it is important to consider and adjust dosing during AKI and with RRT. Dosages of medications must be adjusted for the type of RRT and for the specific characteristics of the drug. In septic patients, the altered volume of distribution increases drug half-life and affects the protein-binding capacity of many antimicrobials. The variability in body size and fluid composition often determines delayed achievement of antibiotic pharmacodynamic targets and results in potentially subtherapeutic antibiotic concentrations at the infection site.[111]

CONCLUSION

Despite extensive clinical experience and improvements in supportive care, the mortality rate of critically ill patients with AKI remains high. Sepsis is the most common cause of AKI in the ICU. Current tools to diagnose AKI are suboptimal; thus biomarkers are being developed to better detect and prognosticate AKI. Specific treatment for AKI is still lacking; therefore prevention is key. Optimal volume management, appropriate antimicrobial therapy, and avoidance of further renal insults are imperative once AKI is established. Timely and efficient RRT provisions are frequently necessary in critically ill patients with AKI.

KEY POINTS

- S-AKI is a common complication in hospitalized and critically ill patients. It is associated with extremely high mortality and increases the risk of developing chronic comorbidities.
- Blood urea nitrogen and creatinine are the most common parameters measured, but they are not sensitive indicators of renal dysfunction in an acute setting. Intense ongoing research is characterizing the diagnostic and prognostic roles of injury biomarkers to improve supportive care and clinical outcomes.
- The FST accurately predicts patients at increased risk for severe AKI and requirement for RRT.
- Balanced solutions appear to minimally decrease the risk of major adverse kidney events in critically ill patients.
- Pretreatment with isotonic saline is similar to isotonic bicarbonate, and treatment with acetylcysteine is similar to placebo in reducing the risk of kidney-related outcomes after contrast procedures.
- Early nephrology consultation may lead to improved outcomes and facilitate interventions and transitions of care for patients with AKI.
- Dialysis initiation should be based on the broad clinical context and patient needs rather than any specific threshold.
- RRT modalities for critically ill patients are comparable and complementary. CRRT is preferable over intermittent therapies in patients who are hemodynamically unstable and/or have cerebral edema.
- When using intermittent dialysis in AKI, monitoring the delivered dose of therapy is recommended to ascertain the minimum delivered Kt/V of 1.2 per treatment. With CRRT, effluent flow rates of at least 20 mL/kg/h should be attained.

Urinary Tract Obstruction

John Montford, Scott Liebman, and Isaac Teitelbaum

A patent urinary tract is necessary for optimal kidney function. Under normal circumstances, urine passes unimpeded from the renal pelvises to the tip of the urethra. Obstruction can occur anywhere along this pathway and may lead to both acute and progressive kidney parenchymal damage.

Several definitions may be encountered when considering urinary tract obstruction:

- *Obstructive uropathy* refers to any disorder that interferes with drainage of the urine. It may be acute or chronic and either partial or complete; the resulting symptom complex typically depends on both the acuity and severity.
- *Obstructive nephropathy* refers to cases in which obstructive uropathy causes a decline in kidney function.
- *Hydronephrosis* refers to dilatation of the urinary collecting system and is usually, but not exclusively, seen in obstructive disorders. Nonobstructive pathogenesis of hydronephrosis includes vesicoureteral reflux or excessive flow through the collection system, such as with habitual water drinking or diabetes insipidus. Common anatomic variants, including the presence of an extrarenal pelvis and duplicated collecting systems, are also associated with hydronephrosis on imaging.

EPIDEMIOLOGY

Urinary tract obstruction is a common disorder. On autopsy, 3.1% of adults have hydronephrosis.[1] Data from the Healthcare Cost and Utilization Project's Nationwide Inpatient Sample (based on ICD-9 codes) indicate that 1.75% of all hospital discharges are complicated by either hydronephrosis or obstruction.[2] When hydronephrosis is excluded, urinary tract obstruction occurs in approximately 1% of hospital discharges.[2] Urinary tract obstruction accounts for approximately 10% of community-acquired acute kidney injury[3–5] and is a factor in 2.6% of acute kidney injury cases in the intensive care setting.[6]

ETIOLOGY

Many disorders may lead to urinary tract obstruction. A useful classification is to first separate pathology arising from within the urinary tract itself (intrinsic obstruction) from those diseases that arise outside the urinary tract causing external compression of the system (extrinsic obstruction). This discussion will also consider upper (from the renal pelvis to the ureterovesicular junction [UVJ]) and lower (from the bladder to the urethra) urinary tract obstruction separately.

Intrinsic Obstruction

Intrinsic urinary tract obstruction may be the result of pathology within the lumen *(intraluminal)* or within the walls of the collecting system *(intramural)*.

Intraluminal Causes

Obstruction at the level of the renal tubules may be the result of crystal-induced disease, uric acid nephropathy (as in tumor lysis syndrome), or cast nephropathy caused by multiple myeloma. Crystal-induced nephropathy has been classically described with sulfadiazine, acyclovir, indinavir, triamterene, and methotrexate.[7] Published case reports also implicate orlistat[8] and ciprofloxacin.[9]

Nephrolithiasis is a common cause of upper urinary tract obstruction at the level of the ureter, with the size of the stone determining the likelihood of obstruction. Stones $\leq$2 mm, 3 mm, 4–6 mm, and $>$6 mm will pass spontaneously 97%, 86%, 50%, and 1% of the time, respectively.[10] Typically, the obstruction occurs at one of the three narrowest portions of the ureter: the ureteropelvic junction (UPJ), the UVJ, or the point where the ureter crosses over the pelvic brim. Neoplasms, blood clots, and sloughed renal papillae are rarer causes of intraluminal obstruction at the level of the ureter.

The causes of intraluminal obstruction at the level of the bladder are similar to those affecting the ureter, with urolithiasis, blood clots, and neoplasms being the most common. Worldwide, infection with *Schistosoma haematobium* with resulting fibrosis is a common cause of bladder obstruction.[11] Although schistosomiasis is rare in industrialized nations, it should be suspected in patients from endemic areas such as Africa and the Middle East presenting with urinary tract obstruction.

Intramural Causes

Congenital malformations of the genitourinary tract can cause intramural obstruction of the upper urinary tract. UPJ obstruction (UPJO) warrants specific mention, as it is the most common congenital genitourinary disorder likely to present in adulthood. Kinks, valves, or an adynamic segment of ureter results in failure of peristalsis at the UPJ.[12] The widespread use of maternal prenatal ultrasound (US) has led to increased antenatal diagnosis of UPJO. The diagnosis can be made by US, intravenous urography (IVU), or in equivocal cases, isotope renography (see later imaging section).

Another intramural cause of upper urinary tract obstruction is ureteral stricture caused by genitourinary tuberculosis (GU TB). Although rare in the developed world, GU TB complicates up to 40% of patients with extrapulmonary tuberculosis.[13] Hematogenous spread of mycobacteria can seed the renal cortex and ureters, causing inflammation with resultant fibrosis, obstruction, and secondary infections.[13] Seeding of the retroperitoneum and bladder can also lead to complications in patients with GU TB.

More common are disorders affecting the neuromuscular control of the lower urinary tract such as cerebrovascular accidents,[14] spinal cord injury,[15] multiple sclerosis,[16] and diabetic neuropathy,[17] which may lead to bladder outlet obstruction. Multiple medications, including anticholinergics, opioid analgesics, nonsteroidal antiinflammatory

agents, alpha-adrenoreceptor agonists, benzodiazepines, and calcium channel blockers, have also been associated with urinary retention.[18] Stricture of the urethra may also lead to obstruction.

Extrinsic Compression

Pregnancy is typically associated with right-sided dilation of the renal pelvis, calyx, and ureter. Hormonal mechanisms and mechanical compression from an enlarging uterus and ovarian vein plexus have been implicated in these changes.[19] Clinically meaningful obstruction from the gravid uterus is extremely rare.

Malignancies can cause obstruction by several different mechanisms. Local ureteric compression may be seen in metastatic cancers of the cervix, bladder, and prostate and with expanding retroperitoneal soft tissue masses. Alternatively, the ureters may be compressed or encased by metastatic retroperitoneal lymphadenopathy.[20]

Retroperitoneal fibrosis may lead to the obstruction of one or both ureters via inflammation. It is an uncommon disorder, with a reported incidence rate of 1.3 cases per million population and a male:female ratio of 3.3:1.[21] Although the majority of these cases are idiopathic (>75%),[22] numerous conditions are suspected to cause retroperitoneal fibrosis, including malignancies, medications, infection, trauma, radiation, and IgG4-related systemic disease.[23,24] Treatment of idiopathic retroperitoneal fibrosis is initially with steroids, but recurrences are common. Case reports have described the use of cyclophosphamide, azathioprine, colchicine, mycophenolate, or tamoxifen for treatment relapses or steroid-resistant disease, although conclusive data are absent.[22]

Abdominal aortic aneurysms (AAAs) may also cause obstruction caused by compression of the ureter or via inflammation. A published series of 999 cases of inflammatory AAA found preoperative hydronephrosis in 7.4% of these cases.[25] The clinician must always bear in mind that hydroureter and/or hydronephrosis may be absent in obstruction caused by retroperitoneal processes. Thus one must maintain a high degree of suspicion and use alternative imaging modalities when considering these disorders.

Extrinsic compression of the lower urinary tract is more common in males, and the cause is usually either benign prostatic hypertrophy (BPH) or prostate cancer. The etiology of urinary tract obstruction is summarized in Box 101.1.

BOX 101.1 Causes of Urinary Tract Obstruction

Intrinsic Causes

Intraluminal

Renal Tubules

Crystal-induced disease
Uric acid nephropathy
Cast nephropathy (in multiple myeloma)

Upper Urinary Tract

Nephrolithiasis
Neoplasms
Blood clots
Sloughed renal papillae

Lower Urinary Tract

Urolithiasis
Blood clots
Neoplasms
Schistosomiasis

Intramural

Upper Urinary Tract

Congenital ureteropelvic junction obstruction
Genitourinary tuberculosis

Lower Urinary Tract

Disorders affecting neuromuscular control
- Cerebrovascular accident
- Spinal cord injury
- Multiple sclerosis
- Diabetic neuropathy

Medications
- Anticholinergic agents
- Opiates
- Nonsteroidal antiinflammatory agents
- Alpha-adrenoreceptor antagonists
- Benzodiazepines
- Calcium channel blockers

Urethral structure

Extrinsic Causes

Upper Urinary Tract

Pregnancy
Malignancy
Retroperitoneal fibrosis
Abdominal aortic aneurysms

Lower Urinary Tract

Benign prostatic hypertrophy
Prostate cancer

CLINICAL PRESENTATION

The clinical presentation of urinary tract obstruction depends on the location, duration, and severity of obstruction and may therefore be quite variable.

Pain

Acute ureteral obstruction often presents with severe flank pain, otherwise known as *renal colic*. This is usually the result of urolithiasis but may be the result of other causes of ureteral obstruction (see earlier). Obstruction causes increased intraluminal pressure and spasm of the ureteral muscles, which are responsible for the colicky pain.[26] Partial ureteral obstruction may present with a chronic dull pain. Bladder outlet obstruction may lead to distention and subsequent abdominal discomfort.

Changes in Urine Output

One pitfall in the diagnosis of obstruction is the expectation that patients will be anuric. Although this is true of patients with the obstruction of all functioning renal mass—complete bilateral ureteral obstruction, complete obstruction of a solitary functioning kidney, or complete obstruction distal to the bladder neck—this is not the case in patients with less severe disease. The degree of urine output does not reliably predict the presence or absence of obstruction. Patients may present with normal urine output or even polyuria because of the effects of obstruction on renal salt and water handling (reviewed later).

Lower Urinary Tract Symptoms

Obstruction of the lower urinary tract often presents with some or all of a constellation of symptoms known collectively as *lower urinary tract symptoms* (LUTS). LUTS include voiding symptoms (difficulty

urinating, incomplete emptying), postmicturition symptoms (postvoid dribbling), and storage symptoms (urgency, frequency, hesitancy, incontinence).[27] Alternatively, patients with lower urinary tract obstruction may be asymptomatic.

Renal Dysfunction

If asymptomatic, the initial clue to the underlying obstruction may be elevated serum creatinine on blood drawn for an unrelated reason. As urinary tract obstruction may be asymptomatic, it should be considered in the differential diagnosis of unexplained kidney failure. If blood work is not obtained during the course of the obstruction, the kidney function may deteriorate such that patients present with uremic symptoms and the need for dialysis.

Infection

The urinary retention associated with lower urinary tract obstruction provides an excellent culture medium for bacteria. Patients may present with cystitis, pyelonephritis, or sepsis. An obstructing renal stone may also be a nidus for infection. Recurrent infection should raise suspicion for possible anatomic abnormalities, especially in men. In one study, 25 out of 83 men (30%) with a febrile urinary tract infection had anatomic lesions in the lower urinary tract, supporting imaging of the lower tract in men with this presentation,[28] although data in men younger than 45 years old refute this.[29]

Laboratory Values

There are no laboratory values specific to obstruction. Blood tests may show no abnormalities or may show values consistent with kidney failure (elevated blood urea nitrogen, creatinine, potassium, and phosphorus levels and decreased calcium, bicarbonate, and hemoglobin values). The blood tests may also be indicative of renal tubular acidosis (RTA; see later). The urinalysis may be bland or may include red blood cells (in the setting of a stone or malignancy) or white blood cells (in the setting of infection). Significant albuminuria is uncommon, although low-grade proteinuria can be observed, especially in the setting of infection. An experienced observer may also be able to discern crystals in freshly voided urine. The fractional excretion of sodium (FE_{Na}) may be less than 1% in acute obstruction, but it is generally greater than 1% when the obstruction is chronic, owing to renal tubular dysfunction.

IMAGING IN URINARY TRACT OBSTRUCTION

Various imaging modalities may be used to diagnose obstruction: plain abdominal radiography, US, computed tomography (CT), IVU, retrograde pyelography, and nuclear scanning. It is important to understand the indications and limitations of each modality.

Plain Abdominal Radiography

Abdominal radiography (kidney, ureter, and bladder [KUB]) is often the first imaging modality performed in patients with acute flank pain. Although most stones are composed of calcium and should in theory be visible, only 59% of stones are detected on plain film.[30] Compared with CT scanning, the sensitivity and specificity of abdominal films were 45%–59% and 77%, respectively.[30] Further, plain films may not always be able to differentiate phleboliths from calculi. This limits the utility of plain abdominal films to the diagnosis of recurrent disease in those with known radiopaque stones.

Ultrasound

US is inexpensive, does not expose the patient to radiation, and is typically readily available. Its accuracy in detecting hydronephrosis makes

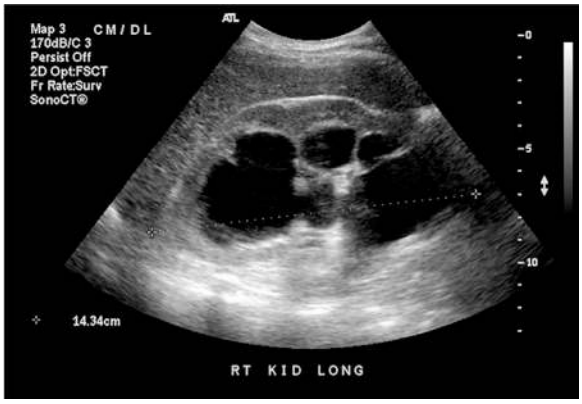

Fig. 101.1 Typical appearance of a hydronephrotic kidney showing renal pelvis and calyceal dilatation. Note the increase in the kidney length (14.34 cm) compared with normal (~10–11 cm).

US a good screening tool for obstruction in patients with unexplained kidney failure or patients with suspected lower urinary tract obstruction (Fig. 101.1). When CT is used as a reference, US has a traditionally reported sensitivity of 24% and a specificity of 90% for the detection of kidney stones and is likely to miss those less than 3 mm in size.[31] Another disadvantage of US compared with CT is that bowel gas may obscure visualization of the ureters.[32] Other conditions such as parapelvic cysts and renal artery aneurysms may mimic hydronephrosis on US.[32] These conditions are easily distinguished via CT scanning.

In a large multicenter randomized controlled trial of adults presenting to the emergency department with suspected nephrolithiasis, US was found to be noninferior when compared with CT in regard to the rates of repeat hospitalizations for missed high-risk diagnoses and adverse events.[33] Additionally, US is the imaging modality of choice when radiation is contraindicated, such as in pregnant women and children.

Computed Tomography

CT has a high sensitivity (96%) and specificity (98%) in the evaluation of acute flank pain and suspected nephrolithiasis (Fig. 101.2); although, as noted earlier, US may be a better first choice because of its lack of radiation. With CT, the retroperitoneum is also well visualized, making it ideal to detect retroperitoneal fibrosis or obstruction caused by retroperitoneal lymphadenopathy. In addition to defining the

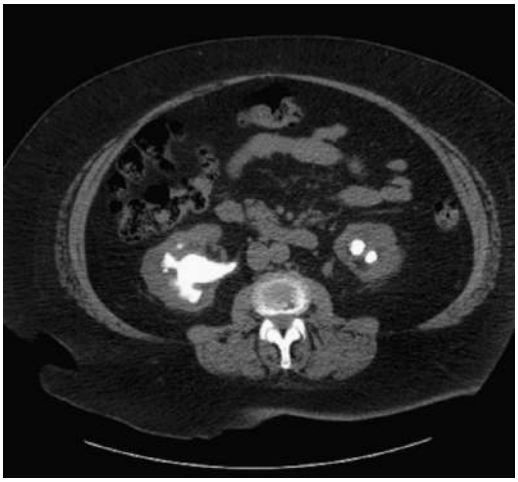

Fig. 101.2 Bilateral nephrolithiasis on an unenhanced computed tomography scan. Note the staghorn appearance in the right kidney.

anatomy of the collecting system, CT has the added benefit of visualizing other organ systems, thereby providing information regarding other conditions in the differential diagnosis of acute flank pain.

One concern raised with CT scanning is the high radiation dose administered. Each CT scan is equivalent to approximately 10 KUBs.[34] The reported dose of radiation, quantified in millisieverts (mSv), was significantly higher in patients initially undergoing CT (14.1 mSv) versus US (4.7–6.5 mSv) when presenting to the emergency department with acute flank pain and suspected nephrolithiasis.[33] Furthermore, this initial radiation exposure was cumulative and persisted at 6 months with CT (17.2 mSv) versus US (9.3–10.1 mSv) regardless of subsequent imaging.[33] Lower-dose-radiation CT protocols have previously been investigated. One study found that lower-dose-radiation CT scans (equivalent to that of plain film) have a sensitivity of 97% and a specificity of 96% for the diagnosis of acute renal colic when compared with the standard dose. The lower-dose CT was inferior at detecting stones less than 3 mm in size,[35] which may impair its ability to diagnose non–collecting system pathology. Because of these limitations, it is unclear whether spiral CT will remain the initial imaging procedure of choice for the evaluation of suspected nephrolithiasis.

Isotope Renography

In conventional renography, radiographic tracers, such as ^{99m}Tc-mercaptoacetyltriglycine (MAG3), are injected into the patient's bloodstream and renal uptake and excretion are measured with a scintillation counter (Fig. 101.3). This test provides functional information by demonstrating decreased excretion in an obstructed kidney. The sensitivity of the test may be enhanced by administering a loop diuretic during the scan, where the increased urine flow may unmask an occult obstruction. Isotope renography is often used to determine the degree to which anatomic obstruction (based on radiographic hydronephrosis) is causing functional obstruction.

For example, excretion can be normal despite the presence of hydronephrosis from a parapelvic cyst, duplicated ureter, or extrarenal pelvis. Alternatively, isotope renography can be useful to determine if functional obstruction is present despite little radiographic evidence of obstruction (such as in a patient with clinical suspicion of retroperitoneal fibrosis). One important limitation of isotope renography is that radiotracer uptake may be diminished and excretion prolonged with severely compromised glomerular filtration rate (GFR). This may lead to both false-negative and false-positive results, limiting its use in such situations.[36] Renography also does not provide detailed anatomic information.

Intravenous Urography

IVU, in which the collecting system is imaged after the administration of intravenous (IV) contrast, was historically the study of choice for patients with acute flank pain. The need to administer nephrotoxic IV contrast and the delay in obtaining information render IVU less attractive than a CT scan.[37]

Retrograde Pyelography

US and CT scanning have largely superseded retrograde pyelography for the diagnosis of obstruction. Retrograde pyelography may be indicated when obstruction is highly suspected on clinical grounds, the US is negative for hydronephrosis, and the patient is unable to receive IV contrast.[1]

PATHOPHYSIOLOGY OF OBSTRUCTION

Urinary tract obstruction may cause intrinsic kidney dysfunction. The most important effects are changes in renal blood flow, increased tubular hydrostatic pressure (as a result of increased ureteral pressure), and the development of fibrosis in long-standing obstruction. Specific tubular derangements in sodium, water, potassium, acid, and divalent cation handling occur as well.

Changes in Renal Blood Flow, Tubular Hydrostatic Pressure, and Glomerular Filtration Rate

Various animal models have provided a basis for understanding the renal hemodynamic changes with urinary obstruction. The initial renal response to obstruction follows a triphasic pattern.[38] During the first 2 hours of obstruction, there is an initial increase in both renal blood flow and ureteral pressure. This is followed by a brief (2–3 hours) period in which renal blood flow declines because of increased afferent arteriolar resistance, yet ureteral pressures continue to rise. Ultimately, the decrease in

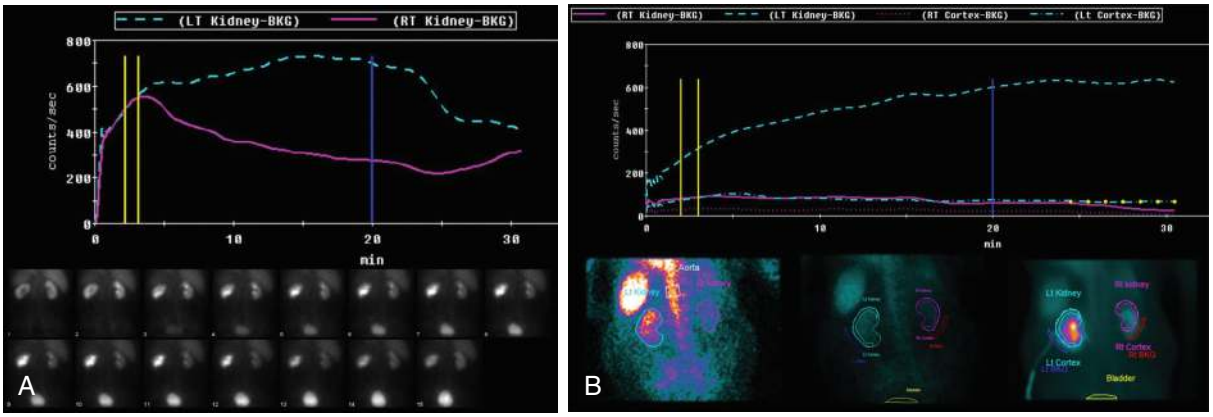

Fig. 101.3 Isotope renography. **A,** ^{99m}Tc-mercaptoacetyltriglycine-renogram performed on a 54-year-old male with large benign intraabdominal mass causing radiographic unilateral ureteral obstruction. Note that radiotracer peak uptake *(yellow vertical lines)* is normal in the right kidney, whereas tracer uptake is delayed in the obstructed left kidney. Furosemide administration *(blue vertical line)* resulted in reversal of the partial functional obstruction. Time-sequence images of radiotracer uptake are shown. **B,** Mag-3 renogram of a 78-year-old male with stage 4 metastatic bladder cancer with retroperitoneal metastases and bilateral, chronic ureteral obstruction. Images obtained after bilateral percutaneous nephrostomy tubes revealed a marginally functioning left kidney and completely nonfunctional right kidney. Perfusion *(lower left panel),* t = 0 tracer uptake *(lower middle panel),* and time-averaged tracer uptake *(lower right panel)* images are shown.

renal blood flow leads to a decrease in ureteral pressure, with the pressure returning to normal levels by 10–12 hours after obstruction.

The GFR, which is determined by Starling forces between the glomerular capillary and renal tubules, is initially diminished by transmitted tubular hydrostatic pressure but is maintained by the augmented renal blood flow. Unresolved obstruction leads to persistent afferent arteriolar constriction and a sustained decrease in both renal blood flow and GFR.

Structural Changes, Maladaptive Cell Signaling, and Renal Fibrosis

Early in ureteral obstruction, dilatation of the ureter and renal pelvis causes mechanical compression of the medulla and cortex, with tubular injury progressing in a retrograde manner.[39] Injured tubular epithelial cells lose polarity and de-differentiate, secreting chemokines that recruit circulating myeloid cells. A complex feed-forward loop of inflammatory cell signaling and oxidative stress ensues in the renal microenvironment.[40,41] If obstruction is not reversed, cellular apoptosis, senescence, capillary rarefaction, and the formation of atubular glomeruli are observed.[41] These changes ultimately result in the deposition of fibrillar collagen, with the contraction and loss of renal parenchymal volume typical of an end-stage kidney.

As with other progressive renal diseases, angiotensin-2 (AT-2) plays a central role in the perpetuation of renal parenchymal damage in chronic obstructive nephropathy. Independent of its vasoconstrictive properties, AT-2 has many other biologic functions, including the upregulation of several profibrotic mediators such as transforming growth factor beta-1, tumor necrosis factor alpha, and nuclear factor kappa B.[42]

Given the importance of the renin-angiotensin system in promoting renal injury after obstruction, antagonizing AT-2 would appear to be a viable strategy to attenuate injury. Although human data are lacking, animal data show benefits, provided the intervention is conducted after renal development is complete.[41]

Tubular Function

Tubular responses to unilateral or bilateral obstruction differ, with bilateral obstruction (or unilateral obstruction in a patient with a solitary kidney) being much more severe and having more important clinical implications. The following discussion will be limited to bilateral obstruction. Urinary tract obstruction impairs all aspects of renal tubular function, including the ability to transport sodium, potassium, and hydrogen and to regulate urine concentration.

Sodium Reabsorption

Upon release of a bilateral obstruction, sodium excretion increases five to nine times that of normal.[43] Because the GFR is also decreased because of the obstruction, the FE_{Na} may be 20 times higher than normal.[43] Clinically, this failure of sodium reabsorption may manifest as hypovolemia.

Sodium reabsorption in the kidney is accomplished by various apical membrane transporters, which are coupled to the basolateral sodium-potassium ATPase. Many of these transporters, including the sodium/proton exchanger, sodium-phosphate cotransporter, sodium-potassium-2/chloride cotransporter, and thiazide-sensitive cotransporter, are down-regulated during and after the release of the obstruction.[44] Recent studies suggest that the amiloride-sensitive epithelial sodium channel may be down-regulated as well.[45] In addition to the down-regulation of transporters, up-regulation of atrial natriuretic peptide, a potent stimulus for sodium excretion, has been demonstrated during and after the release of bilateral obstruction.[46]

Renal Water Handling

Several mechanisms render the kidneys unable to either concentrate or dilute urine after the release of an obstruction. In the case of urinary concentration, the sodium-potassium-2/chloride cotransporter is required to establish the medullary concentration gradient needed for osmotic water movement out of the collecting tubule. Dilution requires the removal of solute in both the loop of Henle and distal convoluted tubule via the sodium-potassium-2/chloride cotransporter and the thiazide-sensitive cotransporter, respectively. Osmotic diuresis caused by retained solutes may also lead to an inability to conserve water.

In addition to the effects of abnormal sodium reabsorption on water metabolism in the postobstructed kidney, animal data have demonstrated a direct role of antidiuretic hormone in the concentrating defect as well. Many studies have shown a down-regulation of aquaporins in the obstructed kidney,[47–49] which may persist for weeks, accompanied by a long-term defect in urinary concentration.[47] Clinically, this inability to conserve water may manifest as nephrogenic diabetes insipidus and hypernatremia.

Acid-Base and Potassium Balance

Clinically, obstructed or postobstructed patients often manifest a hyperkalemic, hyperchloremic metabolic acidosis. Although this may be solely the result of the decreased GFR, some patients have persistent metabolic abnormalities long after the release of obstruction and stabilization of GFR.[50] Human data have revealed several pathophysiologic mechanisms. The majority of patients studied have a distal RTA, characterized by a urinary pH above 5.5 despite the presence of a systemic acidosis.[50] Abnormalities in sodium transport in the distal nephron (see earlier) may render this tubular segment unable to generate the lumen negative transepithelial difference needed for proton excretion—a so-called voltage-dependent defect.[51] This voltage defect can also lead to potassium retention and hyperkalemia.

Other patients are able to acidify their urine to a pH below 5.5. These patients have low plasma levels of aldosterone with subsequent hyperkalemia, diagnostic of a type 4 RTA.[50] The underlying mechanism in this case is decreased ammoniagenesis, most likely because of the hyperkalemia, although the hypoaldosteronism may also contribute.[51] Patients with a type 4 RTA retain the ability to lower their urine pH and usually have a mild, self-limited acidosis, whereas those with a classic distal (type 1) RTA cannot excrete acid, and the resultant acidosis may be severe.

Animal studies have also demonstrated down-regulation of key renal acid-base transporters in urinary tract obstruction, including the cortical and medullary sodium hydrogen exchanger and several basolateral sodium-bicarbonate transporters.[52]

Postobstructive Diuresis

The release of bilateral obstruction (or unilateral obstruction of a solitary kidney) may lead to a profound diuresis. Several mechanisms have already been described. Defects in sodium and water handling predispose to large urinary losses of both. The osmotic load of retained solutes also contributes. Much of the diuresis is appropriate, however, in that previously retained solute and water must be excreted. Typically, postobstructive diuresis is mild and transient and requires no treatment. Often the degree and duration of this diuresis are worsened by overzealous fluid administration in the face of a large, but potentially appropriate, urine output.

The clinical manifestations of postobstructive diuresis that require treatment include volume depletion and hypernatremia (which may be managed by the administration of iso-osmotic and hypo-osmotic fluid, respectively). Careful attention to potassium, magnesium, phosphorus, and calcium levels is also warranted.

Other Tubular Functions

After the release of bilateral obstruction, phosphorus excretion rises proportionally to sodium excretion.[43] This may be mediated by a decrease in

the number of proximal sodium/phosphate cotransporters.[44] Magnesium excretion also rises, likely from decreased absorption in the thick ascending loop of Henle because of a decrease in the transepithelial voltage difference created by the decreased sodium-potassium-2/chloride cotransporter activity.[43] Calcium handling after obstruction is unclear and differs depending on the species of animal studied.[43]

TREATMENT

Management of obstructive uropathy depends on the location, severity, symptomatology, and etiology of the obstruction, in addition to the presence of concomitant factors such as infection or a decline in kidney function. The clinical scenario guides timing and whether initial management should be conservative or aimed at reestablishing the patency of the urinary tract. Chronic asymptomatic partial obstruction does not need emergent release, whereas acute, complete obstruction accompanied by infection, pain, or evidence of kidney dysfunction needs prompt intervention.

Lower urinary tract obstruction may be relieved simply by placing a urethral catheter. The combination of alpha-blockers and 5-alpha-reductase inhibitors has been shown to reduce symptoms of BPH and prevent urinary retention in men.[53] Additionally, alpha-blockers initiated at the time of urethral catheter placement may facilitate their subsequent removal once decompression has been achieved.[54] Upper urinary tract obstruction should be managed with either percutaneously inserted nephrostomy tubes or via retrograde (i.e., via cystoscope) ureteral stenting.

Factors that may cause or exacerbate obstruction, such as constipation or the use of medications associated with urinary retention, should be addressed. Other supportive measures such as antibiotics and IV hydration should be instituted if clinically warranted. The metabolic abnormalities of kidney failure, particularly hyperkalemia, should be addressed. If needed, dialysis should not be withheld while awaiting decompressive therapy.

Should the obstruction be chronic and the kidney deemed nonfunctional, it may be appropriate to proceed with nephrectomy if there is persistent pain or unresolved infection, such as in cases of xanthogranulomatous pyelonephritis. This decision requires an estimate of the likelihood of recovery of kidney function.

RECOVERY OF KIDNEY FUNCTION

Whether or not an obstructed kidney will regain function is of paramount importance to the clinician and may dictate whether aggressive interventions are indicated or if the affected kidney should be removed. Unfortunately, data addressing this question, particularly human data, are scant. Currently, there are no methods available that reliability predict kidney recovery after relief of an obstruction,[43] although one recent study found that a GFR of less than 10 mL/min in the obstructed kidney and abnormal renal perfusion (determined via isotope renography) predicted poor recovery in patients with unilateral ureteral occlusion.[54]

Animal studies demonstrate that the likelihood of renal recovery diminishes with longer duration of obstruction.[43] Even with the recovery of GFR, there may be ongoing injury and progressive long-term kidney damage after the release of the obstruction, likely the result of interstitial fibrosis associated with prolonged urinary tract obstruction.[54] In humans, the cutoff point at which renal function is unlikely to return has not been determined, and partial recovery has been seen even after months of obstruction,[55] suggesting that all obstructions should be relieved and followed by serial determinations of kidney function. If desired, a kidney biopsy may be performed to assess the degree of interstitial fibrosis and provide prognostic information.

KEY POINTS

- Urinary tract obstruction may be caused by pathology anywhere from the renal tubules to the tip of the urethra and should be considered in all cases of unexplained kidney injury.
- Upper urinary tract obstruction may present as renal colic with or without hematuria. Lower tract obstruction may present with frequency, urgency, nocturia, hesitancy, and incomplete emptying. Urinary tract obstruction may also be completely asymptomatic.
- The presence of urine output does not exclude urinary tract obstruction.
- Because of its sensitivity, CT is the most commonly used initial imaging modality for suspected nephrolithiasis; however, this practice has been challenged by recent data comparing US with CT.
- Renal tubular dysfunction may manifest as sodium wasting, abnormal water handling, and acidosis with or without hyperkalemia.
- Release of obstruction may result in postobstructive diuresis. The diuresis is usually an appropriate response to the retention of nitrogenous waste products.
- Recovery of renal function is dependent on the duration of obstruction, with reports of recovery in patients who were dependent on dialysis for months.

Contrast-Induced Acute Kidney Injury

Edward G. Clark, Ayub Akbari, and Swapnil Hiremath

Iodinated contrast agents, which are administered intravascularly for medical imaging, are widely used pharmaceutical agents: more than 80 million doses were estimated to be administered annually over a decade ago.[1] Although vital for diagnostic and therapeutic purposes, their use can sometimes result in impairment of kidney function, resulting in a condition called *contrast-induced acute kidney injury* (CI-AKI) (previously known as *contrast-induced nephropathy*). In most cases, kidney dysfunction caused by contrast exposure is mild, transient, and only detected by sensitive tests. Clinically significant kidney injury is much less common, especially among individuals with previously normal kidney function.

CI-AKI has been traditionally defined as an absolute increase of 0.5 mg/dL (44 μmol/L) or a relative increase of 25% in serum creatinine within 72 hours of receiving an iodinated contrast agent, in the absence of another explanatory etiology.[2] However, the AKI Network and subsequently the Kidney Disease: Improving Global Outcomes (KDIGO) definitions (absolute increase in serum creatinine of 0.3 mg/dL [26.4 μmol/L] or a relative increase of 50% within 48 hours) have gained popularity in recent years.[2–4] These definitions, however, are mainly used for research purposes and are likely to evolve further as the use of biomarkers (such as tissue inhibitor of metalloproteinases 2 [TIMP-2] and insulin-like growth factor binding protein-7 [IGFBP-7]) further penetrates the clinical arena. For clinical purposes, severe AKI requiring renal replacement therapy (RRT, i.e., dialysis) is much more important. However, even milder forms of AKI, as defined earlier, are significant, because they not only result in longer hospital stays but also because they are associated with increased long-term morbidity and mortality.[5,6]

Awareness of the factors predisposing to contrast-associated nephrotoxicity has increased over time to the point that clinicians may now overestimate the risk associated with some specific medical conditions. However, the increasing use of radiographic contrast media, possibly combined with increasing age and comorbidities of the treated population, has contributed to the continuing importance of CI-AKI. In reality, given the mild and transient nature of the AKI in most cases, it is the association with subsequent clinical adverse events that drives the current interest in preventing CI-AKI.

EPIDEMIOLOGY

CI-AKI is often mentioned as the most common iatrogenic cause of AKI and overall the third most common cause of AKI in the hospital setting based on old and outdated literature.[7,8] The overall incidence of AKI requiring dialysis has been gradually increasing, but this appears largely driven by the increasing comorbidity in the population rather than more contrast use.[9] The actual incidence of AKI after contrast-enhanced imaging has been reported to vary from as low as 1% to as high as 30% and depends on the nature of the contrast administered and the underlying risk factors in the patient population.[10–15] In addition, these estimates are clouded by the fact that AKI after contrast administration can often be caused by other etiologies (e.g., acute tubular necrosis from cardiogenic shock in a patient with acute coronary syndrome undergoing coronary angiography or severe sepsis in a patient undergoing a contrast-enhanced computed tomography [CT] scan, or atheroembolic renal disease),[16,17] leading some researchers to use the term *contrast-associated AKI* or *postcontrast AKI*.[18]

The risk of CI-AKI varies with the route of administration. Typically, after elective coronary angiography, about 10%–15% of patients may develop AKI (as defined by the rise in creatinine), although the incidence of severe AKI requiring dialysis is much lower, at less than 1%. The incidence of AKI after intravenous administration of contrast (as with contrast-enhanced CT scans) is believed to be much lower. A prospective study reported this incidence at 2.5% overall, with the risk sequentially increasing as the underlying baseline kidney function decreases.[19] However, other studies have questioned whether the true incidence of contrast nephropathy after intravenous contrast is this high, given that there are underlying fluctuations in serum creatinine levels.[20] In the last decade, large epidemiologic studies that incorporated propensity-matched controls who did not receive contrast made a reasonable case that there is little additional increase in AKI after intravenous contrast administration when adjusted for the underlying baseline risk of AKI.[21–27] However, despite the fact that confounding can be accounted for in these analyses, selection bias, in addition to residual confounding cannot be excluded. As an example, patients perceived to be at high risk of AKI according to the treating clinician may not receive contrast and hence may be overrepresented in the controls in such studies. As an example, in one such analysis, contrast administration seemed to be associated with a lower risk of AKI, which is an implausible result merely reflecting underlying selection bias, as mentioned earlier.[27] Nevertheless, the totality of evidence suggests that the risk of true CI-AKI is low in most patients, especially after intravenous contrast and with preserved kidney function.

The most important underlying risk factor for the development of CI-AKI is compromised baseline kidney function. The incidence is less than 2% in the unselected general population but has been reported to be as high as 20%–30% with the addition of decreased kidney function and other risk factors.[28] The incidence of CI-AKI increases in a graded manner as the severity of the underlying kidney function worsens. Among patients undergoing percutaneous coronary intervention, the risk of CI-AKI has been reported[28] to be just under 20%, with a baseline glomerular filtration rate (GFR) of less than 60 mL/min/1.73 m^2, compared with less than 1% in unselected populations.[29] These numbers mostly describe AKI, not necessarily CI-AKI. With IV contrast, there are mixed data on the difference in AKI with lower GFR.[22,26]

Among critically ill patients, one propensity score–matched study suggests that intravenous contrast (CT) was associated with higher AKI and need for dialysis among patients with GFR <45 mL/min/1.73 m^2 (odds ratio [OR] 2.72, 95% confidence interval [CI] 1.14–6.46), though with a very low absolute risk increase of 4.2%.[23] However, no such effect was seen in another study in critically ill patients with sepsis.[24]

Other risk factors for CI-AKI described in the literature include diabetes, older age, cirrhosis, proteinuria, and other comorbid conditions, including congestive heart failure, hypotension, volume depletion, and concomitant administration of other nephrotoxic agents (e.g., nonsteroidal antiinflammatory drugs). It is unclear if some of these risk factors constitute an additional risk after adjusting for the underlying GFR. In addition, some of these risk factors, such as hypotension and congestive heart failure, are risk factors for AKI, mostly from ischemic acute tubular necrosis (ATN), irrespective of contrast administration. Risk scores that include these factors identify patients at risk of AKI from ATN, not necessarily CI-AKI, and hence should be interpreted with caution.

Metformin is often considered to be a risk factor for CI-AKI (because the package insert advises withholding it for at least 48 hours before contrast imaging), but this is untrue. In patients who develop AKI, there is a higher incidence of metformin-associated lactic acidosis, which is associated with a high fatality rate. However, metformin-associated lactic acidosis only occurs in a fraction of those patients who are not only taking metformin but also either have unstable kidney function at baseline or do develop severe CI-AKI and in whom the recognition of kidney failure does not result in discontinuation of the metformin.[30,31]

Among patients who are already dialysis dependent, either on peritoneal dialysis (in which they often do have significant residual kidney function) or on hemodialysis, contrast imaging does not cause a decline in the residual kidney function.[32–34] There is no role for early or intensive dialysis to remove contrast material in these patients.

PATHOPHYSIOLOGY

Decreased renal blood flow, tubular cell damage, and tubular obstruction are the most commonly described pathways to AKI occurring after contrast administration.[35] Coronary angiography and left ventriculography have been shown to cause a decrease in renal blood flow measured directly using renal artery catheterization.[36] In addition, animal data suggest differential vasoconstriction of afferent more than efferent arterioles, causing a direct effect on decreasing GFR.[37] The vasoconstriction also occurs in the renal medulla via decreased blood flow in the vasa recta.[38] Tissue hypoxia then results in free radical release, leading to oxidant damage to the tubular cells from reactive oxygen species.[38] Contrast agent uptake in tubular cells has been reported to be via the brush border enzyme dipeptidase-1, and CI-AKI may be related to volume depletion and dependent on resident renal phagocytes, interleukin-1, and leucocyte recruitment.[39] Tubular filtration of relatively higher osmolar contrast media also results in osmotic diuresis, increasing medullary oxygen consumption and exacerbating the medullary hypoxia. Additionally, reabsorption of water leaves a high concentration of viscous contrast material in the tubules, which can result in intratubular physical obstruction.[35]

CLINICAL FEATURES AND DIAGNOSIS

Patients with CI-AKI are generally asymptomatic but have an acute rise in serum creatinine concentration 24–72 hours after the administration of the contrast agent.[40] Kidney failure is usually nonoliguric in mild cases, but it may be oliguric, especially if there is significant preexisting renal impairment.[41] Clinically significant deterioration is unlikely if the serum creatinine concentration does not increase by more than 0.5 mg/dL within 24 hours.[40] To make an unequivocal diagnosis of CI-AKI, other potential causes of AKI must be ruled out. Prerenal factors, atheroembolic disease, and other nephrotoxic insults should be excluded.[16,17] The relatively rapid onset and typical course may help differentiate CI-AKI from other causes of AKI. Urinalysis may be unremarkable or may show granular casts, tubular cells, or small amounts of proteinuria. Fractional excretion of sodium is usually low and is unhelpful in differentiating CI-AKI from prerenal, volume-responsive causes of AKI.[41] Because this is a clinical diagnosis, the criteria in Table 102.1 may be helpful to determine if an AKI episode should be attributed to contrast.[42]

PROGNOSIS

Usually, the natural course of CI-AKI is peak creatinine (i.e., reflecting the lowest point of kidney function) occurring between 24 and 72 hours after contrast administration followed by relatively rapid improvement over the next few days, back to baseline serum creatinine levels by 7–14 days.[40] Overall, less than 1% of patients with CI-AKI will develop kidney failure that requires dialysis, and a smaller proportion of such patients (estimated at 10%–50%) will remain dialysis-dependent. The minority that do remain dialysis-dependent consist of a mixture of patients who had true CI-AKI along with those who had

TABLE 102.1 Diagnostic Criteria for Contrast-Induced Acute Kidney Injury (CI-AKI)

Essential Criteria	Major Criteria	Minor Criteria
• Contrast exposure • Presence of AKI stage 2 (AKIN)	• Preexisting GFR <30 • Absence of sepsis or hypotension • Absence of other nephrotoxic exposure • Biopsy diagnosis of acute tubular injury not caused by pigment or other specified forms (myeloma, etc.) • Absence of embolic signs • Absence of RBC/WBC casts	• Preexisting GFR <45 • Arterial contrast • High-dose contrast • Nephrogram on subsequent noncontrast imaging • Oliguria

A diagnosis of CI-AKI could be confirmed on the basis of two essential with three major criteria, OR two essential with two major, two minor criteria.

atheroembolic disease or other causes of AKI that often occur in the population.[16,17] Nevertheless, despite the fact that most patients with CI-AKI recover, a large body of literature has emerged showing that an episode of AKI is associated with poor long-term outcomes, with a faster decline in kidney function and higher rates of subsequent RRT requirement, in addition to higher rates of hospitalization for heart failure and all-cause mortality.[5,43]

Although the association of CI-AKI with adverse clinical outcomes has been clearly and consistently shown, it is not yet known whether CI-AKI is on the causal pathway to these outcomes or if it is merely a marker of patients who are at high risk of these events.[44–46] If the latter is true, CI-AKI may indeed be a less important health issue. Future trials using a variety of interventions with different mechanisms of action showing parallel diminution in CI-AKI and adverse events are required to establish more robust evidence for causality.

PREVENTION

The most effective method of preventing CI-AKI is to not give iodinated contrast unless absolutely essential, especially in patients at high risk, such as those with advanced kidney disease. Unfortunately, the risks with contrast-enhanced magnetic resonance imaging in this patient population (i.e., the risk of nephrogenic systemic fibrosis from gadolinium)[47–50] also limit the imaging options, though these risks are much lower with the currently used group II gadolinium compounds.[51] Given the elective nature of the nephrotoxic insult that allows for attempting prophylaxis, many different interventions have been tested for CI-AKI prevention. Many of the studies are contradictory, and the numbers of systematic reviews and meta-analyses are also quite high, so the reader needs to look at the entire body of literature in order to interpret the data.[52]

FLUID ADMINISTRATION

Type of Fluid

Periprocedural volume administration has been the mainstay of preventive efforts and presumably works by reducing the concentration of the contrast medium in the tubules, improving medullary blood flow (via suppression of vasopressin), and increasing the urinary flow itself.[35] Isotonic saline has been shown to be superior to half-normal (0.45%) saline.[29] There has been significant research in the possible superiority of a bicarbonate-based strategy compared with normal saline, under the hypothesis that the resultant alkaline urine in the tubules will decrease free radical formation and the subsequent oxidant tubular damage. However, the initial promise from the first trial has been belied by the results of subsequent larger trials and meta-analyses.[53–56] In particular, the Prevention of Serious Adverse Events Following Angiography (PRESERVE) trial included 5177 patients undergoing angiography and did not report any difference in the incidence of AKI with bicarbonate compared with saline (OR, 0.93; 95% CI 0.72–1.22 for a composite endpoint of death, dialysis, or 50% rise in creatinine).[57,58] Another approach with very promising results relied on using left ventricular end-diastolic pressure (LVEDP) to guide fluid administration in patients undergoing cardiac catheterization, with a relative risk of 0.41 (95% CI 0.22–0.79; $P = 0.005$) for CI-AKI compared with the standard saline protocol.[59] This trial also showed a reduction in clinically meaningful outcomes (reduction in persistent renal impairment and all-cause mortality at 6 months), although the number of events was small. Another point to be noted is that the intervention group received significantly larger amounts of fluid (mean 1727 mL compared with 812 mL in the control group), thus questioning the role of LVEDP-guided therapy vis-á-vis more fluid alone. Further, LVEDP measurement is not practical in many settings, such as intravenous contrast administration with CT scans, especially in outpatient settings.

Route of Fluid

Small trials have tested oral hydration strategies compared with intravenous strategies, and although they may be as effective, the small numbers of events in these trials preclude any definitive recommendations at this stage.[60] Oral salt and water may be a reasonable option for the outpatient setting if hydration is warranted and the intravenous routine is not feasible.

Any Volume Expansion

The examination and the discussion earlier concluded that volume expansion is beneficial and decreases the risk of AKI after contrast administration. However, this presumption has been upended by two Dutch noninferiority trials. The A Maastricht Contrast-Induced Nephropathy Guideline (AMACING) trial enrolled 660 patients to intravenous hydration with normal saline compared with no prophylaxis.[61] Only two patients in both arms required dialysis, and there was no difference in any of the outcomes studied. The Kompas trial enrolled 523 patients to receive no prophylaxis or rehydration with 250 mL of sodium bicarbonate and also reported no difference in outcomes, with AKI in 11 versus 7 patients and no patients requiring dialysis.[62] Both of these trials included patients with a GFR >30 mL/min/1.73 m^2. Hence in patients with GFR >30 mL/min/1.73 m^2, no hydration is needed. Among those with a GFR <30 mL/min/1.73 m^2, especially with arterial contrast such as angiography, intravenous hydration may still be considered.

CHOICE AND VOLUME OF CONTRAST AGENT

Because the direct kidney damage occurs as a result of the contrast agent, significant research has been performed with respect to the physicochemical properties, specifically, the ionicity, osmolality, and viscosity, of the contrast agents and modifications to decrease CI-AKI (Table 102.2) for the classification of the different types). High-osmolality contrast agents, such as diatrizoate, have been shown to be worse with respect to low-osmolality agents and are thus no longer used in routine clinical practice.[63] When low-osmolality contrast agents were compared with iso-osmolar contrast agents (mainly iodixanol), the first

TABLE 102.2 Classification of Iodinated Contrast Media

Ionicity	Relative Osmolality	Osmolality (mOsm/kg H_2O)	Examples
Ionic monomers	High osmolality	1500–1900	Diatrizoate, iothalamate, metrizoate, iodamide, ioxithalamate
Ionic dimers	Low osmolality	600	Ioxaglate
Nonionic monomers	Low osmolality	500–700	Iopamidol, iohexol, iomeprol, iopentol, iopromide, ioversol, ioxitol, metrizamide
Nonionic dimers	Iso-osmolal	290–320	Iodixanol, iotrolan

trial showed a significantly lower risk of CI-AKI with iodixanol compared with iohexol[64]; however, subsequent larger trials have had different results.[15,65] Systematic reviews and meta-analyses have suggested the possibility of a small nonsignificant benefit with iodixanol but with significant heterogeneity. This heterogeneity has been resolved either by grouping trials based on the route of contrast (e.g., there is a lower risk of CI-AKI in intraarterial contrast imaging with iodixanol use)[66] or by specific contrast agents (e.g., iodixanol resulted in less CI-AKI compared with iohexol but not with other low-osmolar agents).[67] The volume of contrast agent administration also matters, suggesting a lower risk of CI-AKI with lower doses. A ratio of the volume (of contrast dose in mL) to creatinine clearance (variously from >2.6 to >4) has also been reported to be associated with a higher risk of CI-AKI, suggesting that the higher the creatinine clearance, the lower the necessary volume of contrast agent.[68,69]

PROPHYLACTIC RRT

Hemodialysis and hemofiltration, which are performed soon after contrast administration, have been studied for CI-AKI prevention with mixed results.[70] The rationale for doing this is to help remove the offending iodinated contrast material, especially in patients with reduced kidney function who may not be able to clear it quickly. However, biologically, the iodinated contrast material injected into, say, the coronary circulation or the left ventricle for ventriculography reaches and causes damage to the nephrons within a few cardiac cycles, so the efficacy of removing the contrast agent after the length of time it takes to set up RRT is not very plausible. Indeed, the results of the largest trial studying this were emphatically negative.[71,72] Other trials have reported a decrease in the proportion of patients with a decrease in creatinine clearance on the fourth day post contrast administration[73] or even in in-hospital mortality.[74] These trials are very challenging to interpret, given that the hemofiltration or hemodialysis itself would change creatinine clearance directly, and it is not possible to tease the effect of RRT on creatinine clearance from the effect of the CI-AKI attenuation. In addition, these procedures have inherent risks, such as those associated with central line placement and hemodynamic issues with the RRT procedure itself.[70,75]

PHARMACOLOGIC STRATEGIES

N-Acetylcysteine

N-acetylcysteine (NAC) replenishes endogenous glutathione, acts as a biologic antioxidant, and may also possess antiinflammatory effects. It has been reported to reduce the risk of CI-AKI in a small trial[76]; however, subsequent trials have provided conflicting results. Heterogeneity with respect to the dose and route of administration, and the possible effect of NAC on creatinine levels rather than kidney function, have made it difficult to determine the true efficacy of NAC.[77,78] Two large trials resolve this dilemma. The Acetylcysteine for Contrast-induced nephropathy Trial (ACT) included 2308 patients and measured not just CI-AKI on the basis of the change in creatinine but also clinical events, such as the need for RRT and mortality, and did not show any benefit of NAC.[79] The PRESERVE trial, with 5177 patients, also showed little benefit with NAC, with an OR of 1.02 (955 CI 0.78–1.33) for the primary outcome and no difference in dialysis, death, or hospitalization.[58] Arguments regarding the benign nature of NAC should take into account that the intravenous route can cause anaphylactoid reactions.[80] In addition, although NAC is not expensive, oftentimes, it has been used in place of—rather than in addition to—truly effective prophylactic strategies such as volume expansion.[81] Thus NAC has no role in CI-AKI prevention strategies.

DIURETICS

Diuretics, by their inherent effect, can increase urine flow and have been investigated for CI-AKI prevention because they may have a diluting effect on the iodinated contrast agent being filtered in the tubules. By themselves, the use of furosemide and mannitol has actually been shown to be detrimental[82] and increases the incidence of CI-AKI, which is not entirely unsurprising, given the protective effect of volume expansion. More recently, however, the use of furosemide in addition to intravenous fluids (in the "RenalGuard" system), dosed to achieve a urine output of >300 mL/hr, at which point contrast administration is permitted, with subsequent titration of intravenous fluids (and furosemide as required) to match urine output, has been shown to be more effective than hydration alone.[83,84] Of note, both the RenalGuard system and the LVEDP-guided hydration strategies result in a higher volume administered to the intervention group than to the controls, and the nature of both designs allows this to be performed in a safe manner.

STATINS

Statins have been found to be protective compared with placebo, in addition to when high-dose statins (e.g., atorvastatin 80 mg) are compared with low-dose statins in the prevention of CI-AKI.[85,86] However, these trials have been conducted in patients undergoing coronary angiography and/or interventions and not patients receiving intravenous contrast, and typically enrolled limited numbers of patients with chronic kidney disease; therefore these results cannot be easily translated into such populations. Last, under most current guidelines, the typical patient profile undergoing coronary angiography should be on a statin in the long term and not just for CI-AKI prevention.[87]

OTHERS

Small trials with ascorbic acid, calcium channel blockers, dopamine, fenoldopam, atrial natriuretic peptides, prostaglandin E1, theophylline, and nonselective endothelin antagonists have all either failed to show any benefit in CI-AKI prevention or have shown benefit in small trials that need replication.[88–92]

MANAGEMENT

In most instances, CI-AKI never becomes clinically evident, and kidney function returns to baseline within 2 weeks. In more severe cases, management is no different from that for AKI of any other cause.[4] Careful control of fluid and electrolyte balance, avoidance of further nephrotoxic insults, attention to nutrition, and surveillance for complications are generally all that is required, although dialysis may be necessary in the occasional patient. Indications for dialysis are no different from those in other patients with AKI, taking into account clinical and biochemical factors such as hyperkalemia and volume overload. Prophylactic hemodialysis soon after the administration of a contrast agent in patients with high serum creatinine concentrations has had inconsistent effects, as previously noted. Moreover, dialysis should not be performed for routine removal of contrast medium after imaging in previously dialysis-dependent patients.[34]

CONCLUSION

CI-AKI remains a concern, especially with interventions involving intraarterial contrast or in patients with advanced kidney disease. However, especially in the critical care setting when a prompt diagnosis can be lifesaving, the concern of kidney injury should not overrule the

need for contrast-based imaging. CI-AKI is not common in the absence of risk factors, and these are generally detectable with a history and physical examination and the determination of the serum creatinine concentration. Because CI-AKI can be associated with other adverse clinical outcomes, preventive measures are advisable, especially with advanced preexisting kidney disease when there is a risk that the patient may require dialysis. Although CI-AKI is associated with later adverse events, causality has not been proven, and the efficacy of preventive measures directed at CI-AKI in preventing these associated events has not been established. At this time, the optimal approach to preventing CI-AKI, which is summarized in the "Key Points" section, includes minimizing the contrast dose, using either iodixanol or a low-osmolar contrast agent other than iohexol, and using isotonic sodium bicarbonate or saline in high-risk patients. Whether volume expansion is beneficial at all in high-risk patients is worthy of study.[93] Finally, supportive care is indicated if severe CI-AKI does occur.

ACKNOWLEDGMENTS

SH, AA, and EC receive research salary support from the Department of Medicine, University of Ottawa. SH has received funding from the Canadian Institutes of Health Research for studying CI-AKI. We would like to thank Jennifer Kong for her assistance in the manuscript preparation.

KEY POINTS

- Assess the risk of CI-AKI in patients requiring a contrast imaging test.
  - Use the National Cardiovascular Data Registry (NCDR) risk score if the patient is undergoing percutaneous coronary intervention.[94]
  - For patients undergoing intravenous contrast administration, consider an estimated glomerular filtration rate <30 mL/min/1.73 m^2 as the principal risk factor.
  - Additional risk factors include diabetes mellitus and unstable kidney function.
- Assess the risk/benefit of the proposed contrast imaging, and consider alternative imaging in high-risk patients. In the context of critical illness, the risk of CI-AKI and its consequences may often be outweighed by the potential risks associated with a delayed or missed diagnosis as a result of inadequate imaging.
- Use the lowest possible dose of contrast media; consider using iodixanol or a low-osmolar contrast agent (other than iohexol).
- In high-risk patients, correct dehydration, hold diuretics, and consider intravenous fluids if there are no contraindications. Either normal (0.9%) saline or isotonic sodium bicarbonate, started at an initial rate of 3 mL/kg/hr at least 1 hour before and continued at 1 mL/kg/hr for 6 hours later, is commonly recommended.
- In high-risk patients, monitor creatinine within 24–72 hours post contrast administration.

Glomerulonephritis

Dhruti P. Chen, Ronald J. Falk, and Gerald A. Hladik

Over half of all critically ill patients develop some degree of acute kidney injury (AKI), and nearly 5% require renal replacement therapy (RRT). For those patients with severe AKI requiring RRT, mortality can be as high as 70%, and up to 30% of surviving patients remain dialysis dependent.[1–6] AKI may be a consequence of prerenal causes resulting in hypoperfusion of the kidneys, intrinsic kidney disease, and postrenal or obstructive causes. In critically ill patients, most cases of AKI are related to ischemic or toxic acute tubular injury, which are treated with supportive measures and are often reversible. Acute glomerulonephritis (GN) accounts for about 4% of all cases of AKI.[7] In addition to supportive care, initiation of correct treatment is paramount for patient and renal survival. The focus in this chapter is on GN, a cause of AKI for which there is often disease-specific therapy.

GLOMERULONEPHRITIS

In GN, patients present with nephritic syndrome characterized by hematuria, proteinuria, AKI, edema, and hypertension.[8] Hematuria may be microscopic or macroscopic. The urine sediment demonstrates dysmorphic red blood cells (RBCs) and RBC casts. Urinary protein excretion typically exceeds 1 gram per day, and the degree of proteinuria can be rapidly assessed using simultaneous measurement of the urine protein-to-creatinine ratio (urine PCR) and the urine albumin-to-creatinine ratio (urine ACR). In general, the urine albumin-to-protein ratio (urine ACR/urine PCR) exceeds 0.5 in patients with glomerular disease. In contrast, an albumin-to-protein ratio of <0.4 is most consistent with tubular proteinuria when the urine PCR is <3. In some instances, patients may have nephrotic-range proteinuria (>3 g/d) with associated clinical manifestations, including edema, hypoalbuminemia, and hyperlipidemia. Leukocyturia with or without white blood cell casts may be observed with GN of inflammatory origin.

In renal biopsy series of patients with unexplained AKI, the most common diagnoses included various forms of GN (pauci-immune GN, immunoglobulin [Ig]A nephropathy, postinfectious GN, lupus nephritis, anti–glomerular basement membrane [anti-GBM] disease) and acute interstitial nephritis (AIN).[7,9–11] Indeed, the third most common cause of end-stage renal disease (ESRD) in the United States and Europe is GN.[8] Distinguishing the type of GN with kidney biopsy is critical for diagnosis and for assessing the degree of acute versus chronic disease, which helps guide treatment and informs prognosis.

The most aggressive form of GN is described clinically as rapidly progressive glomerulonephritis (RPGN). Rather than a single disease entity, RPGN is the most severe clinical presentation of many glomerular diseases that are divided into renal-limited etiologies and systemic diseases that involve the kidneys (Table 103.1). RPGN is defined as rapidly declining renal function, progressive oliguria, hematuria, proteinuria, and hypertension.[8] Although many critically ill patients may have hematuria associated with infection or trauma, hematuria and AKI should always prompt consideration of acute GN. Kidney ultrasound characteristically shows normal to slightly enlarged kidneys, although reduced kidney size may be present when the diagnosis is delayed. Kidney biopsy reveals a high degree of glomerular injury with extensive crescent formation (Fig. 103.1). Importantly, the transition from acute cellular crescentic disease to chronic, irreversible injury may occur rapidly over days. The rapid progression of such cases constitutes a need for prompt diagnosis with early intervention and therapy to interrupt a natural progression to chronic kidney disease. In adults, the most common cause of RPGN is pauci-immune GN associated with antineutrophil cytoplasmic antibodies (ANCAs), followed by immune-complex diseases such as lupus nephritis or mixed cryoglobulinemia. Anti-GBM disease (formerly called *Goodpasture disease*) is less common.[8,12] Immunofluorescence microscopy shows pauci-immune staining in ANCA-associated GN; linear IgG staining of the GBM in anti-GBM disease; and immune complex deposition in lupus nephritis, IgA nephropathy, and infection-related GN.

Pulmonary-renal syndrome, characterized by RPGN and diffuse alveolar hemorrhage (DAH), is a medical emergency requiring early aggressive treatment.[13–15] Untreated, it is associated with high mortality and rapid progression to ESRD. Admission to the intensive care unit (ICU) and mortality are related to both the disease itself and infectious complications. The clinical presentation is typically characterized by dyspnea, cough, hemoptysis, and in some cases fever, with chest radiography documenting pulmonary infiltrates. It may be difficult to distinguish from pneumonia, especially in patients without hemoptysis. Roughly 30% of patients with DAH do not have hemoptysis. The presence of renal dysfunction and hematuria in patients presenting with pulmonary symptoms should raise suspicion for a pulmonary-renal syndrome. Although Goodpasture syndrome was first used in 1958 to describe patients presenting with pulmonary hemorrhage and GN,[16] the most common cause of pulmonary-renal syndrome is ANCA-associated vasculitis.[8] Anti-GBM disease (formerly Goodpasture disease) now refers to the triad of DAH, RPGN, and the presence of anti-GBM antibodies. It is the second most common cause of pulmonary-renal syndrome. Much less common causes of pulmonary-renal syndromes are systemic lupus erythematosus (SLE), thrombotic microangiopathies, and other forms of systemic vasculitis.

A thorough history and physical examination may provide evidence for a systemic vasculitis (e.g., scleritis, purpuric rash, oral or sinus lesions). Bronchoscopy is critical to confirm DAH and evaluate for infection. The gold standard for diagnosis is renal or pulmonary biopsy, but critically ill patients are often at high risk for these procedures. The majority of patients have either ANCA-associated

TABLE 103.1 Diseases Associated With Rapidly Progressive Glomerulonephritis and Pertinent Laboratory Studies

RENAL LIMITED	
IgA nephropathy	
Infection-related glomerulonephritis	Low complement, streptococcal serologies, bacterial cultures
ANCA-associated glomerulonephritis (pauci-immune glomerulonephritis)	ANCA titers
Anti-GBM disease (Goodpasture syndrome)	Anti-GBM antibodies
SYSTEMIC DISORDERS	
Lupus nephritis	Low complement, ANA, dsDNA antibodies
ANCA-associated small vessel vasculitis	ANCA titers
Anti-GBM disease	Anti-GBM antibodies
Henoch-Schönlein purpura	None
Cryoglobulinemic vasculitis	Low complement, cryoglobulins, hepatitis C serologies, positive rheumatoid factor

ANCA, Antineutrophil cytoplasmic antibodies; *ANA,* antinuclear antibodies; *dsDNA,* double-stranded DNA; *GBM,* glomerular basement membrane; *IgA,* immunoglobulin A.

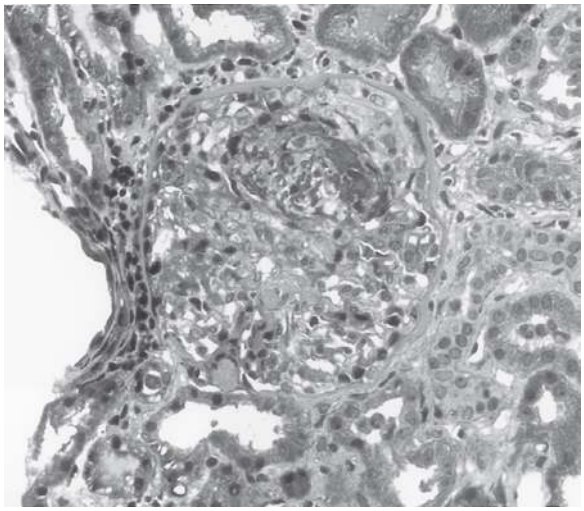

Fig. 103.1 Rapidly Progressive Glomerulonephritis. Cellular crescent is present in glomerulus (4- to 8-o'clock position), with fibrinoid necrosis of the glomerular capillary tuft (×200, trichrome).

vasculitis or anti-GBM disease. Because both diseases are treated similarly in the acute setting of RPGN and DAH, treatment with plasma exchange, corticosteroids, and cyclophosphamide may be initiated rapidly before the availability of serologic results.

PAUCI-IMMUNE NECROTIZING GLOMERULONEPHRITIS

Pauci-immune necrotizing GN or ANCA-associated GN may present as a systemic vasculitis, pulmonary-renal syndrome, or renal-limited disease. The spectrum of disease includes microscopic polyangiitis (MPA), granulomatosis with polyangiitis (GPA), and eosinophilic granulomatosis with polyangiitis (EGPA or Churg-Strauss disease).[17,18] Kidney biopsy shows focal and segmental crescentic GN, fibrinoid necrosis, and an absence of Ig or complement within the glomeruli by immunofluorescence microscopy. Either anti-myeloperoxidase (MPO) or anti–proteinase 3 (PR3) antibodies are detectable in most patients. However, a minority of patients with characteristic clinical manifestations of these diseases and pauci-immune GN do not have detectable antibodies.

The mortality of untreated disease is roughly 90% at 2 years after disease onset.[19] However, advances in treatment have led to improved patient outcomes, with 80%–85% of patients achieving remission with effective immunosuppressive strategies.[20] Treatment consists of pulse intravenous (IV) methylprednisolone followed by oral corticosteroids and IV cyclophosphamide, rituximab, or both.[14,21–26] Even patients who are dialysis dependent on presentation often recover kidney function with appropriate treatment. Poor prognostic indicators for patient and renal survival are the presence of DAH, severe kidney dysfunction at the time of diagnosis, a high degree of glomerular injury and tubulointerstitial fibrosis on biopsy, and older age.[27–32] Patients with DAH have a high mortality rate, and plasma exchange may improve patient survival. Coagulation factors should be replaced in patients with active hemorrhage.[19,33–36] For severe pulmonary disease, a few patients have been successfully treated with extracorporeal membrane oxygenation (ECMO).[37,38] Patients with severe renal disease have a greater likelihood of renal recovery when treated with plasma exchange.[28,30,35,39,40]

With appropriate treatment, roughly 80%–90% of patients achieve remission.[19,27,33,41,42] Treatment resistance is more common in females, African Americans, and patients with severe renal disease. Relapse is more common in patients with anti-PR3 antibodies and in those with pulmonary and upper respiratory tract involvement. MPO ANCA is more commonly associated with MPA or renal-limited vasculitis. The ANCA-associated vasculitides (AAVs) follow a remitting and relapsing course, with the exception of drug-induced AAV (e.g., levamisole-adulterated cocaine, hydralazine),[43] making long-term monitoring a key component to patient and kidney survival.

ANTI–GLOMERULAR BASEMENT MEMBRANE GLOMERULONEPHRITIS

Anti-GBM disease (formerly Goodpasture disease) presents as DAH and RPGN with evidence of anti-GBM antibodies on serologic testing that target the noncollagenous domain of the α3 chain of type IV collagen. Kidney biopsy shows linear deposition of antibodies, most commonly IgG and C3, along the GBM with glomerular crescent formation. It is the most aggressive form of RPGN,[12] and roughly 30%–40% of patients present with renal-limited disease without pulmonary involvement. It commonly affects Caucasians in a bimodal age distribution with peaks during the third and seventh decades.[14,44–46]

Untreated disease is highly fatal, and death is usually caused by pulmonary hemorrhage or renal failure. Treatment with therapeutic plasma exchange, cytotoxic agents, and corticosteroids was introduced in the 1970s, resulting in improved patient and renal survival.[47] In patients with pulmonary and renal involvement, plasma exchange is crucial for rapid clearance of anti-GBM antibodies[48] and should be continued daily until antibodies are undetectable.[46] Long-term outcomes are related to the degree of pulmonary compromise and renal dysfunction at presentation. With appropriate treatment, survival rates may exceed 90% for acute disease, but patients requiring RRT on initial presentation have lower survival rates.[45,46,49] In fact, in patients with renal-limited anti-GBM disease requiring RRT

at presentation, less than 10% recover renal function at 1 year despite treatment with plasma exchange, corticosteroids, and cyclophosphamide.[45,49]

In contrast, patients with serum creatinine (SCr) levels below 5.7 mg/dL on presentation in one study had 100% 1-year patient and 95% renal survival.[50] In addition to dialysis dependence and elevated SCr, predictors of poor renal outcome include oligoanuria, high anti-GBM antibody titers, and a high percentage of glomeruli with crescent formation and extensive tubulointerstitial disease on kidney biopsy.[44,48,50,51] Although patient and renal survival is generally worse with anti-GBM disease than with ANCA-associated disease, late recurrence of anti-GBM disease almost never occurs, whereas recurrence of ANCA-associated disease is common.[12,46]

Both ANCA-associated vasculitis and anti-GBM disease are rare. Interestingly, a subset of patients have both types of antibodies detected on serologic studies. Approximately 15%–30% of patients with ANCA-associated disease also have anti-GBM antibodies, whereas only 5%–10% of patients with anti-GBM antibodies also have detectable ANCA titers.[12,45,46,52–54] Although outcome data are limited in this small group of patients, the outcomes of these patients may be better than patients with only anti-GBM antibodies.

LUPUS NEPHRITIS

Lupus nephritis occurs in 50%–60% of patients with SLE during the first 10 years of disease and is present in 35% of patients at initial diagnosis of SLE.[55] Less than 5% of patients present with RPGN or pulmonary renal syndrome. The incidence of ESRD attributed to lupus nephritis is higher among blacks and Hispanics.[56] In one study, up to 62% of blacks with lupus nephritis progressed to ESRD, compared with 19% of Caucasians.[57] In addition to history and physical examination, evaluation includes analysis of the urine sediment, because lupus nephritis may present as nephritic or nephrotic syndrome despite normal serum chemistries, quantitation of proteinuria, complement levels, and serologies for ANA and anti-dsDNA antibodies. Though the presence of cellular casts and/or proteinuria >0.5 g/d is consistent with the diagnosis of lupus nephritis, renal biopsy is critical for diagnosis, prognosis, and guiding treatment.

Kidney biopsy is used to classify lupus nephritis into six categories: class I (minimal mesangial lupus GN), class II (mesangial proliferative lupus GN), class III (focal proliferative lupus GN), class IV (diffuse proliferative lupus GN), class V (membranous lupus GN), and class VI (advanced sclerosing lupus GN).[58–60] Proliferative lesions in class III/IV lupus nephritis have poor renal survival without aggressive treatment. These classes often present with hematuria, proteinuria, hypertension, and AKI. Sclerosing lupus nephritis is a chronic, irreversible lesion that carries a poor prognosis.

Treatment of the more severe forms of lupus nephritis includes pulse methylprednisolone followed by oral corticosteroids and IV cyclophosphamide.[61–64] Similar to treatment of pauci-immune GN, pulse IV cyclophosphamide is preferred over oral cyclophosphamide to decrease the risk of hemorrhagic cystitis. Over 80% of patients respond to treatment.[61,65] Importantly, about 5%–10% of patients who require RRT initially recover enough kidney function to become dialysis independent after treatment.[66] Plasma exchange did not show additional benefit in a clinical trial using standard glucocorticoid plus cyclophosphamide for proliferative lupus nephritis induction therapy.[67] Plasma exchange may have a role in select patients with lupus nephritis and concomitant microangiopathy caused by antiphospholipid antibodies or ADAMSTS13 antibodies.[68] Studies comparing mycophenolate mofetil (MMF) to cyclophosphamide show equivalence, but not superiority, of one agent over the other. However, relapse appears more common in patients treated with MMF.[69–72] Induction should be followed by maintenance therapy—the preferred agent being MMF with low-dose prednisone. Depending on response and side effects, additional cyclophosphamide or azathioprine may be considered.[61,73–75] Other therapies under investigation include abatacept and belimumab, but they are not accepted as lupus nephritis induction or maintenance therapies at this time.

Poor prognostic indicators at the beginning of treatment include male gender, African American race, severe hypertension, antiphospholipid syndrome (APS), and delayed initiation of immunosuppressive therapy. After induction treatment, poor prognostic indicators are failure to achieve remission at 6 months and uncontrolled hypertension.[61,76] About one-third to half of patients will have relapse of disease. In some patients, recurrence of disease may be preceded by falling complement levels and rising anti-dsDNA titers. However, some patients with severe lupus nephritis have negative serologic studies.[61,77] Patients with only partial remission often recur sooner than patients with complete remission, and they are more likely to progress to ESRD.[78] All patients with a history of lupus nephritis should be carefully monitored for recurrence of disease, and repeat renal biopsy is often needed to guide treatment decisions.

INFECTION-RELATED GLOMERULONEPHRITIS

Bacterial, viral, fungal, protozoal, and helminth infections may all result in infection-associated GN. Poststreptococcal glomerulonephritis (PSGN) presents as a classic nephritic syndrome occurring about 1–6 weeks after bacterial infection. It most commonly occurs in children after a skin or pharyngeal infection with a nephritogenic strain of group A beta-hemolytic *Streptococcus* (GAS).[79,80] Although PSGN remains the most common cause of acute nephritic syndrome in the pediatric population in developing countries, the incidence of this disease has declined dramatically in the industrialized world. Recently, cases of infection-related GN (IRGN) caused by *Staphylococcus* and gram-negative bacteria have become more prevalent, especially in the setting of bacterial endocarditis and ventriculovascular shunt infections. In contrast to cases associated with GAS, renal insufficiency associated with *Staphylococcus* and other infections occurs while the patient is actively infected.

Children present with a classic nephritic syndrome with hematuria, proteinuria, hypertension, edema, and mild renal impairment. Severe hypertension with encephalopathy and seizures is uncommon and may require admission to the ICU.[81,82] Laboratory findings demonstrate depressed complement levels (CH50 and C3), consistent with activation of the alternative complement cascade; levels return to normal by 8–10 weeks.[17] Serologic studies may be used to confirm recent streptococcal infection, particularly with recent pharyngitis.[83,84] Renal biopsy demonstrates endocapillary proliferation and granular deposition of immune complexes by immunohistology.[79,83,85,86]

The acute nephritic syndrome usually resolves in 7–14 days, and the prognosis of children with PSGN is excellent. However, roughly 10%–20% of children have persistent urinary abnormalities, including proteinuria and hematuria.[6,8,84,87–89] Treatment is generally supportive, with antihypertensives and diuretics as needed in the acute phase. Active infections should be treated, and prophylactic antibiotics are often indicated in endemic situations and for household contacts in regions with high prevalence of disease.

In contrast to children, outcomes for IRGN in adults in the industrialized world are much worse, particularly for patients with underlying chronic disease or risk factors, including diabetes, cancer, alcoholism, liver disease, or IV drug use.[17,79,80,90–93] Elderly patients often present with AKI, congestive heart failure, and nephrotic-range proteinuria. Treatment

consists of supportive care, including diuretics, antihypertensives, or RRT and eradication of the infection. Although evidence is lacking from randomized controlled trials, pulse IV methylprednisolone can be considered in patients with extensive glomerular crescents and RPGN based on management of other glomerulonephridities.[17] One-quarter to one-half of patients have persistent renal dysfunction, and as many as 15% may progress to ESRD.[90–92,94] Long-term prognosis is worse in patients with persistent proteinuria >1 g/d after 6 months, and these patients should receive angiotensin-converting enzyme inhibitor or angiotensin receptor blocker therapy.[17]

Other important causes of infection-related GN include cryoglobulinemic GN caused by hepatitis C virus (HCV), hepatitis B virus (HBV) or human immunodeficiency virus (HIV) infection. Signs and symptoms of systemic disease may include palpable purpura (dermal-renal syndrome), arthralgias or arthritis, and peripheral neuropathy.[95] Laboratory findings may include hypocomplementemia (especially undetectable C4), elevated rheumatoid factor (RF), circulating cryoglobulins, and positive viral serologies and nucleic acid testing. Kidney biopsy demonstrates intraluminal thrombi on light microscopy with immunoglobulin and C3 deposition on immunohistology. In addition to appropriate antiviral therapy, management of cases of rapidly progressive kidney disease may include plasma exchange, rituximab or cyclophosphamide, and antiviral therapy.[95–97]

IgA NEPHROPATHY

IgA nephropathy (IgAN) is an extremely common form of GN worldwide defined by dominant or codominant staining with glomerular IgA on kidney biopsy.[98] It commonly presents in the second or third decade of life—in North America it affects males twice as commonly as females.[99] The majority of patients present with macroscopic hematuria coinciding with an upper respiratory tract or gastrointestinal infection. Patients may develop hypertension and varying degrees of proteinuria and hematuria. Crescentic IgAN is associated with nephrotic-range proteinuria, severe hypertension, and rapidly declining renal function in less than 10% of cases.[100,101] Severe acute renal failure at initial presentation may also be the result of acute tubular necrosis caused by macroscopic hematuria. No specific laboratory study to date can establish the diagnosis; renal biopsy is required. The extent of changes by light microscopy is variable but is predictive of clinical outcome, and immunohistology demonstrates mesangial IgA deposits.

The long-term prognosis of patients with IgAN is highly variable, but many patients develop progressive renal failure. Progression to ESRD is approximately 15%–25% at 10 years and 25%–30% at 20 years after diagnosis.[102]

In all patients, hypertension should be aggressively treated with renin-angiotensin blockade and other agents if necessary.[17,103] In patients with significant proteinuria (>1 g/d) and declining renal function despite blood pressure control and antiproteinuric therapy, corticosteroids or immunosuppressive agents may be considered. Corticosteroids appear to reduce the risk of progression to ESRD and decrease proteinuria in selected patients.[104–108] Immunosuppressive medications such as cyclophosphamide or azathioprine should be reserved in rare cases of RPGN and crescentic GN.[17,100,102] Predictors of disease progression include degree of renal dysfunction at diagnosis, significant proteinuria, hypertension, and evidence of chronic disease by renal biopsy.[99,109,110]

IgA VASCULITIS

IgA vasculitis (IgAV, formerly named *Henoch-Schönlein purpura* [HSP]) is a systemic disease characterized by a distinct nonthrombocytopenic palpable purpuric rash, arthritis or arthralgias, gastrointestinal involvement, and IgAN. It occurs in children much more commonly than in adults. The classic presentation is sudden onset of rash, progressing from nonblanching erythematous macules, to urticarial papules, to purpura, with a symmetric distribution on the extensor surfaces of the distal extremities and buttocks.[111,112] Children present more frequently with gastrointestinal manifestations and fevers, whereas adults often have more severe renal involvement along with joint symptoms.[113,114] Renal involvement occurs in roughly one-third of children and two-thirds of adults.[115] The most common manifestation is microscopic hematuria with or without RBC casts and no or mild proteinuria.[116]

Renal involvement in IgAV is usually more severe at presentation than IgAN, but most children completely recover.[113,117,118] Estimates of recovery and chronic kidney disease vary widely, but the prognosis for renal recovery is worse in adults. Poor prognostic indicators include renal dysfunction and significant proteinuria at presentation, hypertension, and extensive glomerular disease by renal biopsy.[114,115,118,119] Treatment is primarily supportive care, and trials to date do not support any specific treatment regimen.[120] Corticosteroids may be useful in the short term, especially in the management of arthralgias and abdominal pain, but there is no clear evidence that prednisone prevents serious long-term renal disease.[121,122] Kidney Disease Improving Global Outcomes (KDIGO) recommendations suggest persistent IgAV be treated as isolated IgAN with corticosteroid therapy.[17] There are limited reports on the use of plasmapheresis for management of severe disease.[123,124] Two adults with severe systemic manifestations refractory to corticosteroids and immunosuppressive agents were treated with plasmapheresis, with subsequent improvement.[125]

THROMBOTIC MICROANGIOPATHIES

Thrombotic microangiopathy (TMA) is characterized by organ injury caused by widespread thrombosis of arterioles and capillaries, with intraluminal platelet aggregation and vessel wall thickening in the setting of thrombocytopenia and microangiopathic hemolytic anemia (MAHA).[126–128] The underlying pathophysiologic cause of TMA is endothelial damage caused by a variety of insults. Primary TMA syndromes include thrombotic thrombocytopenic purpura (TTP), Shiga toxin–mediated hemolytic uremic syndrome (HUS), drug-induced syndromes, complement-mediated syndromes, and metabolism-mediated disorders. Systemic disorders, including severe hypertension; pregnancy-associated syndromes, including severe preeclampsia/HELLP syndrome; and autoimmune disorders, including SLE,[129] catastrophic antiphospholipid syndrome, and scleroderma (systemic sclerosis), may present with microangiopathic anemia and thrombocytopenia not unlike primary TMA. However, in these cases management is focused on the primary disease process.

The classic pentad of findings in TTP includes MAHA, thrombocytopenia, neurologic symptoms and signs, impaired renal function, and fever.[126–128] Neurologic symptoms may dominate, presenting as confusion, headache, seizures, and coma. Renal manifestations are usually more prominent in HUS, and the typical presentation in children includes MAHA, thrombocytopenia, and AKI. Laboratory hallmarks include MAHA with schistocytes on peripheral smear, elevated lactate dehydrogenase levels, and thrombocytopenia, with platelets usually less than 60,000/μL.

Remarkable progress has been made in elucidating the molecular basis for TTP and HUS. TTP occurs as both hereditary (Upshaw-Shulman syndrome) and acquired forms related to either the deficiency or presence of antibodies that disrupt the function of a zinc metalloprotease, ADAMTS 13 (a disintegrin and metalloprotease with thrombospondin type 1 motif 13).[127,128,130] This protein is involved in

the cleavage of von Willebrand factor (vWF), and deficiency of ADAMTS 13 leads to the accumulation of large multimers of vWF, which bind platelets, leading to microvascular thrombosis. Historically, untreated TTP had a mortality rate of over 90%. However, mortality has fallen to 10%–20% with the advent of treatment using plasma exchange.[131,132] Other therapies include glucocorticoids and rituximab in the case of refractory or relapsing disease.[133,134] Hereditary forms require treatment with fresh frozen plasma or cryosupernatant that contains ADAMSTS 13. Because hereditary TTP is rare, acquired TTP is the presumed diagnosis in new cases.

HUS is the most common cause of AKI in children and presents with hemolytic anemia, thrombocytopenia, and AKI.[126,135–137] The classic or diarrheal form of HUS (D + HUS) occurs most commonly after diarrheal infection with Shiga toxin–producing *Escherichia coli* (*E. coli* O157:H7), which accounts for 90% of cases. The peak incidence occurs in children younger than 5 years of age. The illness begins with abdominal cramps and nonbloody diarrhea, followed by hemorrhagic diarrhea in 70% of patients. As the diarrheal illness is improving, patients develop severe renal failure, anemia, and thrombocytopenia. These children are often critically ill, and roughly one-half to two-thirds of patients require RRT. About 70% of patients will require RBC transfusions, and 25% will have neurologic involvement. Over the last few decades, mortality rates have fallen from roughly 40%–50% to 3%–5%, primarily as a result of aggressive supportive care with RBC transfusions and RRT as needed. Numerous therapies for HUS have been investigated without clear benefit, and treatment remains largely supportive. Treatment of the diarrheal illness associated with *E. coli* O157:H7 with antibiotics is associated with increased risk of developing HUS. Spontaneous resolution occurs 1–3 weeks after disease onset, and the majority of patients demonstrate renal recovery. Unfortunately, some children develop ESRD, and up to 40% have long-term sequelae, including chronic kidney disease, persistent proteinuria, and hypertension. Nondiarrheal-associated HUS occurs in a minority of patients and may be associated with other infections such as *Streptococcus pneumoniae*.

A small percentage of patients with HUS have sporadic or familial forms, known as *complement-mediated HUS* (previously called *atypical HUS*). These patients have defects in the regulation of the alternative complement pathway, and mutations have been described in complement factor H, complement factor I, and membrane cofactor protein.[127,128,132] Mortality rates are highest in patients with complement factor H mutations, and most survivors progress to ESRD. Patients with severe complement-mediated HUS, such as those with complement factor H and complement factor I mutations who are at increased risk for ESRD, should receive treatment with eculizumab.[138] Other supportive measures may include RBC and platelet transfusions and provision of dialysis and nutritional support as indicated.

An extensive variety of drugs have been associated with TMA. Although the mechanism of action as to why certain drugs cause this phenomenon is not completely understood, it is hypothesized to be either an immune-mediated effect or direct drug toxicity.[139] The immune-mediated effect occurs when a drug induces formation of antibodies that ultimately react with endothelial cells, platelets, and neutrophils. This results in platelet microthrombi with platelet consumption and thrombocytopenia in addition to microvascular damage. The formation of these antibodies is triggered by the presence of the drug itself or an active metabolite of the drug. Thus once the drug is cleared from the system, no new organ damage occurs.[140] Drugs that cause TMA include quinine, gemcitabine, quetiapine, and oxaliplatin.[141,142]

A small percentage of patients with APS present with "catastrophic" APS characterized by acute TMA involving the small vessels of multiple organs.[143] The disease progresses over days to weeks and commonly affects the kidneys, lungs, central nervous system, heart, and skin. The kidney is the most common organ affected, with renal involvement in over 70% of patients. Renal disease manifests as malignant hypertension and AKI, with 25% of patients requiring RRT. Mortality is estimated at 50% of patients, and treatment based on case reports includes management of cause (e.g., infection), systemic anticoagulation, corticosteroids, and plasma exchange to remove anticardiolipin antibodies with or without IV Ig.[144]

Scleroderma renal crisis presents as AKI with abrupt onset of moderate to severe hypertension and may be accompanied by encephalopathy, seizures, or flash pulmonary edema.[145] A subset of patients may not be hypertensive, but have blood pressures higher than baseline values, portending a worse prognosis.[146] Roughly 10% of patients develop scleroderma renal crisis, usually occurring within 4 years of disease onset. The risk is greatest with diffuse cutaneous disease. Antecedent treatment with high-dose corticosteroids increases the risk of scleroderma renal crisis.[147,148] Patients demonstrate MAHA, thrombocytopenia, proteinuria, microscopic hematuria, and marked increases in plasma renin. In the past, untreated disease had a dismal prognosis, with less than 10% survival. The use of angiotensin-converting enzyme (ACE) inhibitors has revolutionized treatment; acute mortality rates are now below 25% with appropriate treatment.[145,149,150] About half to two-thirds of patients will require RRT, but half of those patients recover sufficient renal function to become dialysis independent. Poor outcomes are associated with SCr level >3 mg/dL at the initiation of ACE inhibitor therapy, dialysis dependence, poor blood pressure control, male gender, older age, and congestive heart failure. Patients with scleroderma renal crisis who do not require RRT have 90% survival rates at 5 years. In contrast, patients who become dialysis dependent have only 40% survival at 5 years. Early recognition and treatment are critical for both patient and renal outcomes. ACE inhibitors should be initiated rapidly and continued even if patients develop progressive renal failure or require RRT.

KEY POINTS

- Many underlying causes for AKI resulting from intrinsic renal disease are reversible. Because the transition of active glomerular lesions to irreversible scar occurs rapidly, prompt diagnosis and early intervention are crucial.
- Pulmonary-renal syndrome constitutes a medical emergency. Studies demonstrate that early aggressive treatment improves patient and renal survival.
- Detailed history and physical examination is important for distinguishing renal-limited disease from systemic diseases.
- Initial evaluation should include basic chemistries, evaluation of urine sediment, complete blood counts with peripheral blood smear review, assessment for proteinuria, and renal ultrasound.
- Serum complement levels are important tools in distinguishing causes of GN: (1) normal serum complement (IgAN, IgAV, pauci-immune necrotizing GN, and anti-GBM) and (2) depressed serum complement (immune complex GN, including infection-related GN and lupus nephritis).
- Depending on the clinical scenario, additional evaluations may include ANCAs, anti-GBM antibodies, antinuclear antibodies (ANAs), anti–double-stranded DNA (dsDNA) antibodies, serologies for streptococcal infection, viral serologies, and bacterial cultures.
- The diagnosis of most glomerular syndromes requires kidney biopsy. However, critically ill patients are often at increased risk for complications, and it may be necessary to proceed with treatment in the absence of kidney biopsy in certain situations.

Interstitial Nephritis

Elizabeth S. Kotzen, Evan M. Zeitler, and Gerald A. Hladik

Acute interstitial nephritis (AIN) is an important cause of acute kidney injury (AKI) characterized by inflammation of the renal interstitium and tubules, sparing the glomeruli and vasculature.[1] It is more properly called *acute tubulointerstitial nephritis* (Fig. 104.1). The disorder results from an inflammatory reaction, often of the hypersensitivity type.[2] Biopsy series show that AIN is present in 6.5%–27% of kidney biopsies performed for unexplained AKI; it is probably the third most common cause of AKI in hospitalized patients, following prerenal AKI and acute tubular necrosis (ATN).[3,4]

Medication-associated AIN is the most frequent etiology (50%–85% of cases) (Table 104.1); other etiologies include autoimmune disorders (0%–41% of cases) and infections (2%–16% of cases) (Table 104.2).[5–8] Systemic disorders associated with biopsy-proven AIN include systemic lupus erythematosus (SLE), sarcoidosis, Sjogren syndrome, and IgG4-related disease (Table 104.3).[3,5,9] A subset of patients with AIN have tubulointerstitial nephritis and uveitis (TINU) syndrome, which is characterized by AIN and bilateral uveitis. TINU comprises 5%–22% of biopsy-proven AIN.[6–8,10] Furthermore, AIN may be present in the context of a drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome. Allopurinol is one of the more common culprit drugs associated with DRESS.[11] Critically ill patients are routinely treated with medications associated with AIN, including antibiotics, NSAIDs, proton pump inhibitors, and diuretics (see Table 104.1).[2,7,12] Immune checkpoint inhibitors are recent additions to available therapy that cause AIN.[13]

Prompt recognition of AIN is important in order to identify inciting drugs that should be discontinued to minimize ongoing kidney injury. The prototypical example of AIN is methicillin-associated AIN. The first case series described a classic triad of fevers, eosinophilia, and pyuria within 8–36 days after exposure.[14] Unfortunately, this classic triad occurs in only 5%–10% of patients with AIN and does not provide a useful diagnostic strategy to identify patients with the condition.[2,3,15] Measurement of urinary eosinophils has previously been touted as a diagnostic test for AIN. This test is no longer recommended because of poor sensitivity and specificity.[3,16] The fractional excretion of sodium (FeNa) is commonly calculated in the evaluation of AKI to distinguish between prerenal AKI and ATN; however, there is no characteristic FeNa value that distinguishes AIN from other causes of AKI.[3]

The most typical presentation of AIN is nonoliguric AKI, although a minority of patients may develop oliguria and dialysis dependence.[12] Clinical signs and symptoms that are suggestive (but not diagnostic) of AIN in the context of unexplained AKI include recent exposure to a drug implicated in AIN (see Table 113.1), morbilliform rash, elevated serum eosinophils, pyuria, and the presence of white blood cell casts on urine microscopy. Hematuria and low-level proteinuria may be present. Biomarkers are under investigation, and further study may bring about a noninvasive diagnostic approach to AIN in the future.[17] For now, kidney biopsy remains the only validated way to diagnose AIN.[3]

Typically, kidney manifestations develop, on average, 10 days after initiation of the inciting medication, with 80% of patients developing kidney manifestations within 21 days of the drug exposure.[2] It is important to note that the classic description of drug-induced AIN as an acute process occurring within a few weeks after exposure to the offending medication is too narrow. Renal manifestations may occur as soon as a few days after exposure (especially in the setting of prior exposure) or many months after the exposure (nonsteroidal antiinflammatory drugs [NSAIDs] are often associated with a 6- to 18-month period of exposure before development of renal dysfunction).[8,12] Additionally, the kidney injury may be acute, subacute, or chronic.[8,12] Risk factors for

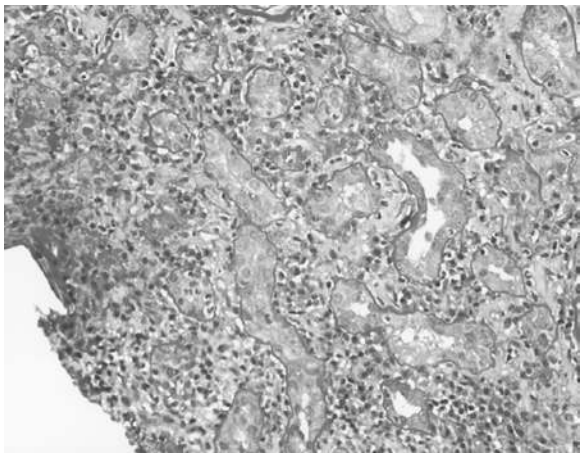

Fig. 104.1 Acute Interstitial Nephritis. Diffuse, predominantly mononuclear cell infiltrate is present within an expanded and mildly edematous interstitium, and periodic acid–Schiff (PAS)-positive tubular basement membranes have wrinkling. Foci of tubulitis are also present (×200, PAS).

TABLE 104.1 Medications Most Frequently Associated With Acute Interstitial Nephritis

Antibiotics: beta-lactams, rifampin, fluoroquinolones
Antiinflammatories: NSAIDs, 5-aminosalicylates
Proton pump inhibitors
Immune checkpoint inhibitors
Allopurinol
Anticonvulsants: phenytoin, carbamazepine, phenobarbital
Diuretics: thiazides, loop diuretics, triamterene
Herbal medications

NSAID, Nonsteroidal antiinflammatory drug.

TABLE 104.2 Pathogens Associated With Infection-Related Acute Interstitial Nephritis

BACTERIAL INFECTIONS
Brucella
Chlamydia
Corynebacterium
Enterococcus
Escherichia coli
Francisella
Legionella
Leptospirosis
Streptococcus
Treponema
Yersinia

FUNGAL INFECTIONS
Candida
Coccidioidomycosis
Histoplasmosis

MYCOBACTERIAL INFECTIONS
Mycobacterium tuberculosis
Mycobacterium kansasii
Mycobacterium haemophilum

PARASITIC INFECTIONS
Leishmania
Toxoplasma

VIRAL INFECTIONS
Adenovirus (kidney transplant recipients)
Cytomegalovirus
Epstein-Barr virus
Polyomavirus (kidney transplant recipients)

TABLE 104.3 Systemic Diseases Associated With Interstitial Nephritis

Antineutrophil cytoplasmic antibody (ANCA)–associated vasculitis
Antitubular basement membrane antibody–associated interstitial nephritis
Drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome
Hypocomplementemic tubulointerstitial nephritis
Immunoglobulin G4–related disease
Sjögren syndrome
Systemic lupus erythematosus
Tubulointerstitial nephritis and uveitis (TINU) syndrome

adverse renal outcomes include older age, delay of diagnosis, and recurrent AIN episodes, which often happen either because of TINU syndrome or because of re-exposure to the offending drug.[8]

The cornerstone of treatment for AIN is removal of the suspected offending agent. In the case of drug-induced AIN, any potentially causative medication should be stopped whenever possible. When present, underlying infections should be identified and treated. If indicated, dialysis should be provided.

Corticosteroids are commonly used in the treatment of AIN. However, high-quality evidence is lacking and is derived from retrospective trials. The three largest retrospective studies reached discordant conclusions.[2,15,18] Of note, in the two studies that did not find a benefit of steroids, patients who received steroids had higher pretreatment serum creatinine levels. In contrast, a benefit was observed in steroid-treated patients in the study in which the treatment and control groups had similar baseline serum creatinine levels. Prospective randomized controlled trials regarding the use of corticosteroids in AIN are required.

A recent retrospective study of 182 patients with biopsy-proven AIN treated with corticosteroids revealed 41% complete recovery of kidney function, 45% partial recovery, and 13% with no improvement in kidney function. Five percent of patients were dialysis-dependent at 6 months follow-up.[19]

In the absence of evidence from prospective randomized trials to guide treatment, we recommend the following approach to management, which is generally in line with other expert recommendations:[2,12,20]

1. In the event of unexplained AKI, after excluding obstructive AKI with imaging and evaluating for ATN and acute glomerulonephritis with urine microscopy, consider removal of medications frequently associated with AIN when possible.
2. For unexplained AKI requiring dialysis, kidney biopsy should be performed as soon as feasible. For unexplained AKI not requiring dialysis, we perform kidney biopsy if there is no improvement in kidney function within 5–7 days of withdrawal of the potentially offending medication.
3. If the biopsy confirms AIN, with minimal fibrosis present on the biopsy, we pursue a trial of corticosteroids as follows: prednisone 1 mg/kg per day (max 80 mg per day) for 1–3 weeks. In severe or dialysis-dependent AIN, we would consider an initial 3-day pulse of 500 mg intravenous methylprednisolone before initiation of oral corticosteroids. The severity of inflammatory morphologic changes on biopsy also helps to guide our decisions about the duration of therapy and whether to employ pulse methylprednisolone. If no response is observed within 3 weeks, the prednisone can be rapidly tapered. Prednisone is generally tapered more slowly in responsive patients, with up to 8 weeks of total steroid exposure. There is evidence that there is no benefit in continuing steroid treatment for >8 weeks.[19]

Some authors have maintained that AIN resulting from NSAID exposure is less likely to respond to corticosteroid therapy. However, Gonzalez and colleagues found benefit of corticosteroids in NSAID-induced AIN. Therefore it is reasonable to consider corticosteroid therapy in patients with NSAID-induced AIN.

Mycophenolate mofetil (MMF) was found to provide possible benefit in a case series of eight patients with steroid-resistant AIN. MMF has also been used in 14 patients who experienced recurrent AIN upon steroid discontinuation.[8,21]

KEY POINTS

- The diagnosis of AIN should be considered in patients with AKI and sterile pyuria or systemic manifestations of hypersensitivity, especially when temporally associated with medication initiation or infection.
- Medications, particularly antibiotics, are responsible for over two-thirds of cases of AIN.
- A definitive diagnosis of AIN can only be made with kidney biopsy.
- Treatment of drug-induced AIN begins with discontinuation of the causative agent. Treatment with corticosteroids is an important adjuvant when discontinuation of the causative agent alone is not sufficient to produce improvement in kidney function.

Antimicrobial Stewardship

*Marin H. Kollef** and *Scott T. Micek*

Antimicrobial stewardship is an important concept that is pertinent to virtually every clinician. Its goals are to combat the emergence of resistance, improve clinical outcomes, and decrease healthcare costs (Fig. 105.1).[1–7] In this chapter, we will focus on the advances in and obstacles to antimicrobial stewardship as outlined in Table 105.1 by breaking this discussion into two major areas: optimization of antimicrobial therapy and avoidance of unnecessary antibiotic administration.

OPTIMIZATION OF ANTIMICROBIAL THERAPY

Appropriate Antimicrobial Selection

Appropriate antibiotic therapy is the cornerstone of management in septic shock and in any serious infection requiring intensive care unit (ICU) care and has a great influence on hospital mortality. Appropriate antibiotic therapy is defined as an initial antimicrobial regimen that demonstrates in vitro activity against the isolated organisms responsible for the infection, whereas inappropriate antibiotic therapy is defined as an initial regimen demonstrating a lack of in vitro activity against the causative pathogens.[8] The administration of inappropriate initial antibiotic therapy can lead to treatment failures and adverse outcomes.[9–15] Similar associations between the administration of inappropriate initial antimicrobial therapy and greater mortality have been shown for bloodstream infections by *Candida*.[16–18] Moreover, the importance of treating all pathogens associated with serious infection is further emphasized by a retrospective analysis of patients with severe sepsis and septic shock.[19] For the entire cohort, the number needed to treat with appropriate antimicrobial therapy to prevent one patient death was 4.0 (95% confidence interval [CI], 3.7–4.3). The importance of early appropriate antibiotic selection was also demonstrated in a recent randomized trial among patients with *Escherichia coli* or *Klebsiella pneumonia* bloodstream infection and ceftriaxone resistance demonstrating that definitive treatment with piperacillin-tazobactam compared with meropenem resulted in greater 30-day mortality.[20] This study also highlights the importance of early identification of antibiotic resistance to optimize antimicrobial prescription in order to improve patient outcomes.

*Conflicts of Interest: Dr. Kollef's effort was supported by the Barnes-Jewish Hospital Foundation.

The importance of selecting appropriate initial antimicrobial therapy has been emphasized in the most recent Surviving Sepsis Guidelines.[21] The guidelines recommend that initial empiric antiinfective therapy include one or more drugs that have activity against all likely pathogens (bacterial and/or fungal or viral) and that the antibiotics penetrate, in adequate concentrations, into the tissues presumed to be the source of sepsis (grade 1B).[21] This guideline urges clinicians to use the patient's history (including drug intolerances), recent receipt of antibiotics, underlying disease, clinical syndrome, and susceptibility patterns of pathogens in the community and hospital and that have been previously documented to colonize or infect the patient when making decisions regarding initial antimicrobial regimen selection.

Timing of Antibiotic Administration

In addition to selecting an appropriate antimicrobial regimen, the timing of antibiotic delivery is an essential element in determining the outcome of critically ill patients with infection. Several studies have found strong relationships between delays in effective antimicrobial initiation and in-hospital mortality for serious infections, including ventilator-associated pneumonia (VAP) and septic shock.[22,23] A meta-analysis of randomized and observational studies evaluating the impact of goal-directed bundles on the outcomes of patients with septic shock found that timely antibiotic administration was statistically more common among patients receiving protocolized management of septic shock.[24] Members of the Surviving Sepsis Campaign subsequently performed a retrospective analysis of a large data set collected prospectively from 165 ICUs in Europe, the United States, and South America.[25] In-hospital mortality was 29.7% for the cohort as a whole, and there was a statistically significant increase in the probability of death associated with the number of hours of delay for the first antibiotic administration.

Timely administration of effective antibiotics seems to be an important element in determining the outcome of critically ill patients. As discussed later, prediction tools for the presence of antibiotic resistance and rapid diagnostics may allow for a more rapid administration of appropriate therapy. However, emergency departments and ICUs should also ensure that they have processes in place to obtain and deliver antibiotic therapy expeditiously once the order for such therapy is received from the treating physicians.

The use of treatment bundles for the management of patients with sepsis and septic shock has been associated with lower hospital mortality

thought to be caused primarily by the earlier administration of antibiotics.[26,27] However, these treatment bundles fail to examine important clinical issues, including whether antibiotic therapy is necessary in all patients with presumed sepsis, the dosing strategies and duration of antibiotics, and whether the administered antibiotic regimen is active against the offending pathogens. The success of sepsis treatment bundles has now been used, in part, by the authors of the Surviving Sepsis Campaign Guidelines to recommend the use of broad-spectrum antibiotics within 1 hour of presentation in all patients with clinically suspected sepsis.[28] However, a recent editorial has attempted to focus attention on the problems associated with the overuse of antibiotics in patients with possible sepsis.[29] This editorial highlights the difficulties in establishing an accurate diagnosis of sepsis attributed to underlying infection, the adverse consequences associated with routine administration of antibiotics in critically ill patients, and the problem of equating sepsis with the more severe condition of septic shock.[29] Recent pleas have emerged from the Infectious Diseases Society of America, emergency medicine thought leaders, and critical care thought leaders urging for more rational approaches for directing antibiotic therapy in complex patients and eliminating the 1-hour sepsis bundle.[30–33]

Adequate Dosing of Antimicrobials and Pharmacokinetic/Pharmacodynamic Considerations

In addition to delivering timely appropriate antibiotic regimens, adequate drug concentrations at the site of infection are needed to optimize clinical outcomes. Beta-lactam and carbapenem antibiotics are time-dependent antimicrobials whose activities are primarily related to the duration the free drug concentration exceeds the pathogen minimum inhibitory concentration (T_{FREE}/MIC).[34–36] Many factors influence the pharmacokinetics of antimicrobials in critically ill patients. Hypoalbuminemia, large-volume crystalloid administration, large pleural effusions or abdominal ascites, catecholamines, augmented renal clearance (ARC), and renal replacement therapies can all significantly alter infection site concentrations of administered antibiotics.[37]

In VAP treatment, particularly for gram-negative bacteria (GNB), dose and duration of treatment might need to be augmented despite having selected an appropriate initial regimen. For instance, meta-analyses of tigecycline showed an increased mortality in nosocomial pneumonia, particularly VAP driven by GNB infections.[38–40] A randomized trial of patients with hospital-acquired pneumonia (HAP) found that tigecycline with or without ceftazidime had inferior cure rates to imipenem-cilastatin with or without vancomycin across all pathogens.[41] The hypothesis that the tigecycline dose (75 mg every 12 hours) was too low to achieve high enough concentrations above the MICs of pathogens prompted a higher-dose study (100 mg every 12 hours) compared with imipenem-cilastatin.[42] Similarly, ceftobiprole, a cephalosporin with activity against methicillin-resistant *Staphylococcus aureus* (MRSA) and an extended GNB spectrum equivalent to ceftazidime or cefepime, was compared with linezolid and ceftazidime in patients with HAP/VAP.[43] Even though it achieved similar cure rates in patients with HAP, ceftobiprole was inferior to linezolid and ceftazidime in patients with VAP, in large part thought to be a result of the underdosing of ceftobiprole in critically ill patients. This concern has led to a doubling of the dose of ceftolozane/tazobactam for the treatment of HAP/VAP.[44]

Critically ill patients display different pharmacokinetics; therefore newer drug administration strategies for beta-lactams and carbapenems have been investigated to include the use of prolonged infusions in order to optimize antibiotic delivery to infection sites. Several recent meta-analyses suggest that prolonged infusions of beta-lactam and carbapenem antibiotics may be associated with improved outcomes in critically ill patients.[45–47] However, the results from the largest multicenter trial performed to date of prolonged antibiotic infusion in critically ill patients failed to demonstrate any mortality benefit.[48]

One of the best examples of the need for proper antibiotic dosing and drug exposure at the site of infection was recently demonstrated in a multicenter trial.[49] These investigators aimed to determine whether beta-lactam antibiotic dosing in critically ill patients achieves concentrations associated with maximal activity and whether antibiotic concentrations affect patient outcome. Of the 248 patients treated for infection, 16% did not achieve a T_{FREE}/MIC ratio greater than 1 at 50% of the dosing interval, and these patients were 32% less likely to have a positive clinical outcome. Positive clinical outcome was associated with a T_{FREE}/MIC ratio greater than 1 at both 50% and 100% of the dosing intervals. These data suggest that many critically ill patients experience adverse outcomes as a result of inadequate antibiotic exposure.

Duration of Antibiotic Therapy

For most critically ill patients, empiric antibiotic courses of 7–8 days of treatment should suffice, unless specific infections are identified, such as bacteremia, fungemia, endocarditis, osteomyelitis, or meningitis, which would require longer treatment durations. The data supporting the use of shorter courses of antibiotic therapy are probably strongest for VAP, depending on clinical severity, rapidity of clinical improvement, and most important, the underlying microbiology.[50–53] The exceptions to shorter courses of antibiotic therapy in VAP are the difficult-to-treat pathogens such as *Pseudomonas aeruginosa* and other nonfermenters that experience higher recurrence rates with shorter treatment regimens.[50] At least one randomized trial has found a greater mortality among patients with *P. aeruginosa* VAP receiving only 7 days of treatment.[54] Longer durations of treatment for nonfermenting GNB may be most important in situations where antibiotic exposure in the lung is limited by host factors such as increased volume of drug distribution and ARC.

The inflammatory biomarker procalcitonin has been shown to aid in limiting the duration of antibiotic exposure for patients with VAP and other types of infections.[55–57] However, other clinical trials have failed to replicate these findings. A study performed in nine ICUs in Denmark enrolled 1200 critically ill patients to receive either the "standard-of-care-only," receiving treatment according to the current international guidelines and blinded to procalcitonin levels, or the "procalcitonin arm," in which current guidelines were supplemented with a drug-escalation algorithm and intensified diagnostics based on daily procalcitonin measurements.[58] Although there was no mortality difference, length of stay in the ICU was increased by 1 day in the procalcitonin arm. A recent multicenter trial from Australia that enrolled 400 patients with suspected bacterial infection/sepsis also failed to demonstrate reductions in the overall median number of antibiotic treatment days with the use of procalcitonin.[59] Similarly, a large U.S. study failed to show a reduction in antibiotic duration among patients with suspected lower respiratory tract infections.[60]

In summary, clinicians should be aware that 7–8 days of therapy should suffice for empiric antibiotic therapy in most ICU patients. However, even shorter courses of empiric therapy should be used when the presence of infection is excluded, and longer treatment regimens may be required when dealing with specific host- and pathogen-related factors such as ARC, increased volume of distribution, and presence of infection with *P. aeruginosa* or other nonfermenters. It is probably most important to critically review all antibiotics on a daily basis to ensure that they are indeed necessary and, if so, that they are delivered in adequate concentrations.[61]

Augmented Renal Clearance

ARC is defined as an 8-hour creatinine clearance more than or equal to 130 mL/min/1.73 m^2. One recent study has suggested that over 65% of ICU patients have ARC on at least one occasion during the first 7 days of their critical illness.[62] ARC has been linked with subtherapeutic beta-lactam[63] and glycopeptide concentrations[64] and increased therapeutic failures in patients receiving antimicrobial therapy, resulting in adverse patient outcomes.[54,65,66] However, several recent studies have cast doubt on whether ARC is associated with excess mortality, especially when antibiotic dosing is optimized.[67,68] One group of investigators has developed a scoring system to identify patients at high risk for ARC based on the following factors: age of 50 years or younger (6 points), trauma (3 points), and Sequential Organ Failure Assessment (SOFA) score of 4 or less (1 point).[69] A subsequent study found that the ARC score was 100% sensitive and 71.4% specific for detecting ARC.[70] Monte Carlo pharmacokinetic simulations demonstrated increased time at therapeutic antibiotic levels with the use of extended infusion dosing in the setting of ARC at drug cost savings of up to 66.7% over multiple intermittent dosing regimens. In addition to ARC, the use of renal replacement therapies can result in underexposure of antibiotics at the site of infection, requiring careful dosing adjustments.[71] Further research is required to determine the influence of ARC on the outcomes of critically ill patients and how to optimize antimicrobial therapy when ARC is present.

Therapeutic Drug Monitoring

Therapeutic drug monitoring (TDM) for beta-lactams and carbapenems can be accomplished by several methodologies, allowing serum concentrations of antibiotics to be assessed in order to optimize delivery and minimize the occurrence of toxicity.[72,73] However, the use of TDM for antibiotics other than vancomycin, aminoglycosides, and voriconazole has not become a routine or standard practice in most ICUs. Recent studies have demonstrated the ability of TDM to identify the need for antibiotic dosing adjustments in the setting of continuous renal replacement therapy resulting from excess serum antibiotic concentrations[74] and during treatment of multidrug-resistant (MDR) *P. aeruginosa* with fluctuating renal function.[75] Unfortunately, at the present time, large variations exist in the types of beta-lactams tested, the patients selected for TDM, drug assay methodologies, pharmacokinetic/pharmacodynamic targets, and dose adjustment strategies employed among critically ill patients.[76] An ongoing trial assessing continuous infusion of piperacillin-tazobactam guided by TDM in patients with sepsis should provide needed clarity to this issue.[77]

AVOIDANCE OF UNNECESSARY ANTIBIOTIC ADMINISTRATION

Deescalation of Empiric Antibiotic RegimensAntimicrobial deescalation is a clinical approach to empiric antibiotic therapy of serious infections that attempts to balance the need for appropriate initial therapy with the need to limit unnecessary antimicrobial exposure in order to curtail the emergence of resistance.[78] A deescalation approach usually requires initial combination antimicrobial treatment targeting nonfermenting GNB and MRSA.[79] However, depending on the clinical presentation, patient risk factors, and local epidemiology, other pathogens such as *Candida* species and *Clostridium difficile,* especially when diarrhea is present, may also need to be covered. Once the microbiologic results are available and the patient's clinical response is observed, the antibiotic regimen can be narrowed based on the susceptibilities of the identified pathogens. Our local experience, and that of other groups, bears this out in demonstrating that the administration of appropriate initial antibiotic therapy with subsequent antimicrobial deescalation is associated with improved survival and shorter hospital stays.[80–82] Moreover, local antibiotic deescalation guidelines have been able to successfully limit the use of broad-spectrum antibiotics targeting GNB in patients with skin and skin structure infections, representing an example of antimicrobial stewardship.[83,84]

Computer decision support systems have also been employed to facilitate antimicrobial deescalation practices in the ICU setting. Thursky and colleagues employed a real-time microbiology browser and computerized decision support system for pathogen isolate–directed antibiotic prescription and found significant reductions in the proportion of patients prescribed carbapenems, third-generation

cephalosporins, and vancomycin.[85] Similarly, our hospital has developed an automated decision support system with real-time access to patients' prior antibiotic exposures and microbiologic results.[86] Our experience with this system has shown that the use of inappropriate therapy can be reduced by almost 50% and that access to these data assist in the performance of timely deescalation.[86] Similar outcomes have been achieved using pharmacist-driven diagnostic testing for antimicrobial deescalation in community-acquired pneumonia (CAP).[87] However, the impact of antimicrobial de-escalation as a casual contributor to survival and not simply representing a marker of disease severity is still controversial.[88]

Use of Antibiotic Resistance Prediction Tools

Knowledge of patient risk factors for the presence of infection with antibiotic-resistant pathogens should be a routine part of antibiotic decision making. For example, antibiotic-resistant pathogens are more commonly found in patients with CAP who have healthcare–associated risk factors (recent hospitalization, admission from a nursing home, or recent antibiotic treatment).[89,90] However, a recent meta-analysis found that the current definition employed for healthcare–associated pneumonia (HCAP) did not accurately identify infections attributed to antibiotic-resistant pathogens, providing further support for the use of more specific criteria to make this clinically important determination.[91]

Shindo and colleagues demonstrated that independent risk factors for antibiotic-resistant bacteria occur in patients diagnosed with both CAP and HCAP, including prior hospitalization, immunosuppression, previous antibiotic use, gastric acid–suppressive therapy, tube feeding, and nonambulatory status.[92] Another Japanese study prospectively applied a therapeutic algorithm based on the presence of risk factors for MDR pathogens in a multicenter cohort study of patients with CAP and HCAP.[93] These investigators found that MDR pathogens were more common in patients with HCAP than in those with CAP. Moreover, these same investigators found that using these risks in a unified algorithm allowed antibiotic therapy to be simplified in the majority of patients with CAP.[93]

Potential benefits derived from the use of computerized systems include improvements in the efficiency and costs of existing stewardship programs, improvements in clinicians' knowledge regarding the treatment of infectious diseases, and improvements in pathogen prediction.[94,95] Thiel and colleagues demonstrated that the implementation of a standardized order set for patients with sepsis—that is currently automated and includes orders for antimicrobial therapy—resulted in more appropriate initial antimicrobial therapy and improved clinical outcomes in patients with severe sepsis and bacteremia.[96]

Unfortunately, antibiotic prediction tools can also lead to overuse of broad-spectrum agents. The 2016 Infectious Diseases Society of America/American Thoracic Society (IDSA/ATS) updated guidelines for hospital- and ventilator-acquired pneumonia recommend MRSA coverage if the local resistance patterns are unknown or greater than 10%–20% and, similarly, double antimicrobial coverage for *P. aeruginosa* if the local resistance patterns for monotherapy are unknown or greater than 10%.[97] They also incorporated patient-specific risk factors, such as recent intravenous antibiotic administration; need for mechanical ventilation or renal replacement therapy; and even the presence of shock, acute respiratory distress syndrome, or structural lung disease. However, a recent study of 3562 patients with HAP found that the IDSA/ATS guidelines would result in 56% of HAP cases being empirically treated for MRSA, whereas 23% would be treated with antipseudomonal agents even though cultures for MRSA and antibiotic-resistant gram-negative rods were positive in only 5.17% and 2.30% of patients, respectively.[98] Looking forward, new artificial intelligence/machine learning techniques will be iteratively developed so we may move beyond labeling an infection by where it is diagnosed and instead focus on a patient-specific cumulative risk for MDR pathogens, leading to highly tailored empiric therapy and less overuse of broad-spectrum antibiotics.[99]

Biomarker Guidance of Antibiotic Therapy

Procalcitonin has demonstrated utility, especially in the ambulatory setting, in guiding decisions regarding antimicrobial therapy.[55–57] However, not all experiences with procalcitonin-guided decision making have shown reductions in duration of antibiotic exposure.[58,59] A recent comprehensive literature review of procalcitonin-guided antibiotic management in critically ill patients found that the diagnostic value of serum procalcitonin concentrations to discriminate among systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, and septic shock was unestablished.[100] On the other hand, at least two meta-analyses suggest that procalcitonin guidance can be used to shorten the duration of antimicrobial therapy in the ICU setting.[101,102] The routine use of procalcitonin as an aid in antibiotic decision making should depend on whether a particular ICU has an already established culture of successful antimicrobial deescalation and stewardship.[100]

The serum markers (1,3)-β-D-glucan and galactomannan have been used in identifying pathogens associated with invasive fungal infections to assist clinicians in guiding antifungal therapy. Based on their high negative predictive value in the appropriate clinical setting, the most suitable use of these markers seems to be in excluding the presence of invasive fungal infections.[103,104] However, one study suggests that the use of (1,3)-β-D-glucan is the most rapid method for the identification of intraabdominal candidiasis in order to provide timely therapy in such patients.[105] In addition, an investigation that measured galactomannan levels in bronchoalveolar lavage (BAL) fluid obtained from ICU patients lends support to its use in pathogen identification and early treatment of pulmonary infection.[106] Nonetheless, a more recent study only showed modest agreement between galactomannan in BAL fluid and validated clinical diagnostic criteria for invasive fungal disease.[107] These markers of infection certainly have the potential to enhance stewardship—primarily through deescalation once a fungal infection has been excluded—and future clinical experience with these markers will determine if this potential can be fully realized.[108]

Formalized Antimicrobial Stewardship Programs and Telemedicine

Formally implemented antimicrobial stewardship programs (ASPs) have been associated not only with reduced infection rates but also with significant cost saving associated with reductions in the defined daily doses of antimicrobials targeted by the ASP.[84,109,110] ASPs have been shown to increase the appropriateness of therapy for serious infections such as CAP and to increase the number of infectious disease consultations, which might also dramatically improve patient outcomes, including mortality, hospital length of stay, and rates of readmission by providing a more precise antibiotic prescription.[84,111–113] These attributes of ASPs account for why they are now recognized as mandatory components of hospital quality improvement efforts.

A recently updated meta-analysis of ASPs has solidified the benefits of these quality improvement initiatives.[114] This meta-analysis found that ASPs could significantly result in less antimicrobial usage and reductions in *C. difficile* infections and colonization or infection with

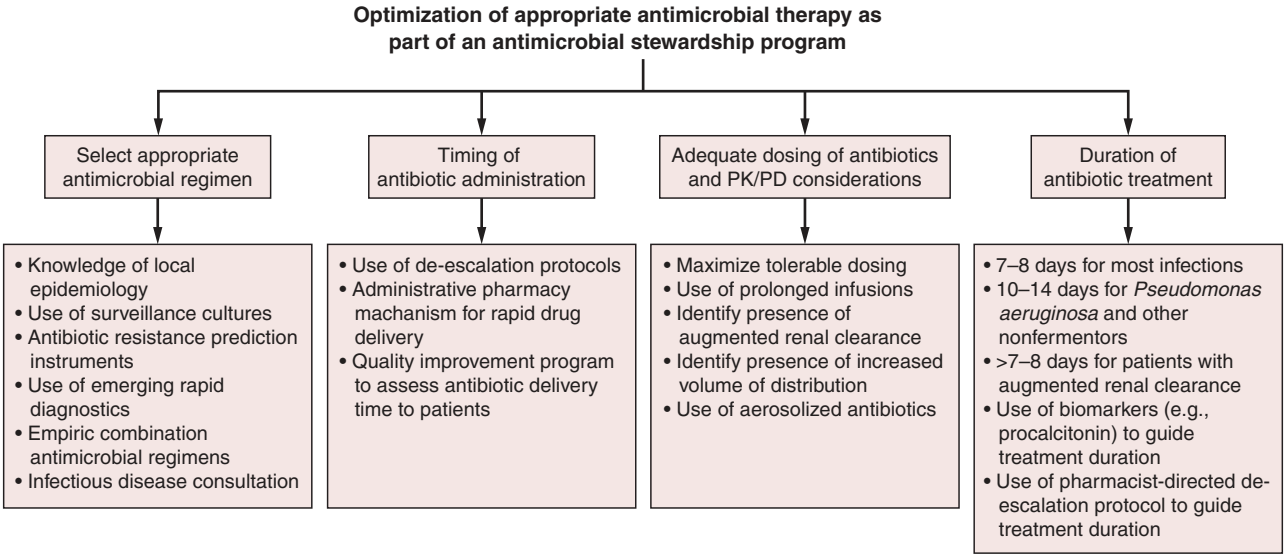

Fig. 105.2 Optimization of appropriate antimicrobial therapy as part of an antimicrobial stewardship program.

antibiotic-resistant bacteria.[114] Additionally, more effective antibiotic prescribing practices for pneumonia because of the presence of an ASP were associated with a significant reduction in mortality, whereas practices aimed at decreasing excessive antibiotic prescribing were not associated with any significant increase in mortality.

Telemedicine is emerging as a feasible strategy for implementing antibiotic stewardship, especially in hospitals lacking infectious disease consultants and preexisting robust stewardship programs.[115–117] Given the increasing complexity of decision making in infectious diseases, advancements in telemedicine will likely drive future use of this strategy for stewardship.[118]

Rapid Microbiologic Diagnostics

Conventional microbiologic procedures typically require several days for isolation, identification, and antimicrobial susceptibility testing of isolated bacteria from clinical samples, including blood, respiratory tract, urine, and sterile site specimens. A number of molecular platforms currently exist for the rapid identification of pathogens and antibiotic susceptibility. These include polymerase chain reaction (PCR), multiplex PCR, matrix-assisted laser desorption-ionization time-of-flight (MALDI-TOF) mass spectrometry (MS), fluorescent in situ hybridization, immunochromatography, nuclear magnetic resonance, and volatile organic compound analysis, with each having specific advantages and disadvantages.[119] Additionally, automated microscopy methods such as the Identification/Antimicrobial Susceptibility Testing (ID/AST) system (Accelerate Diagnostics, Tucson, AZ) have been developed using both genomic and phenotypic technologies to provide pathogen identification and antimicrobial susceptibilities in a rapid manner.[120]

The potential benefit of rapid microbiologic diagnostics (RMDs) on patient outcomes with serious infections is illustrated by several recent studies. Clinical samples from patients with monomicrobial gram-negative bacteremia were tested and compared between the Accelerate Pheno System and standard-of-care methods, including Verigene and Bruker MALDI Biotyper systems for ID and the Vitek 2 system for AST.[121] ID mean time was 21 hours for MALDI-TOF MS, 4.4 hours for Verigene, and 3.7 hours for the Accelerate Pheno System. AST mean time was 35 hours for Vitek 2 and 9.0 hours for the Accelerate Pheno System. If the Accelerate Pheno System results had been available to inform patient care, 25% of patients could have been put on active therapy sooner, whereas 78% of patients who had therapy optimized during hospitalization could have had therapy optimized sooner. These findings are similar to those found at our institution employing similar diagnostic approaches.[122]

CONCLUSION

Although antimicrobial therapy is frequently prescribed, clinicians should realize that these important therapeutic agents should be used wisely. Judicious use of antibiotics serves to combat the emergence of resistance, improve clinical outcomes, and decrease costs. Clinicians should realize the advances that have been made with regard to antimicrobial stewardship and use these tools, and any future advances, to promote improved antimicrobial use. We are currently at a crossroads where antimicrobial stewardship offers us an opportunity to move forward in terms of enhancing the treatment of antibiotic-resistant infections for years to come (Figs. 105.2 and 105.3). ICU clinicians must be leaders in ensuring that their institutions have robust and effective ASPs.[123]

KEY POINTS

- All ICUs should participate in active ASPs directed at optimizing the use of antimicrobials in critically ill patients.
- The ASPs should focus on both optimizing the delivery of antimicrobial agents to infected patients and avoiding the unnecessary use of these agents.
- Optimal antibiotic administration can be achieved by ensuring appropriate selection of drugs, timely administration of antibiotics, adequate dosing of these agents, avoidance of prolonged durations of therapy, and adjustments in delivery of drugs based on the physiology of critically ill patients (e.g., potential use of higher drug doses and/or prolonged infusions in the setting of augmented renal clearance and increased volume of distribution).
- Minimizing the unnecessary use of antibiotics can be achieved with the use of deescalation strategies, use of antibiotic resistance prediction tools or biomarkers, and in the future, rapid diagnostics for pathogen detection and antimicrobial susceptibility.

Prevention and Control of Nosocomial Pneumonia

Richard G. Wunderink

Pneumonia causes 79% of all infectious deaths in the United States and is a leading cause of death around the world.[1] Although community-acquired pneumonia (CAP) causes most of these deaths, nosocomial pneumonia, both hospital-acquired pneumonia (HAP) in general and the ventilator-associated pneumonia (VAP) subset, remains an important cause of mortality and morbidity in the critically ill.[2] Preventing pneumonia in the critically ill is a daunting task, and even controlling the incidence is difficult. Although complete prevention of nosocomial pneumonia is unlikely,[3] substantial progress has been made.

With a prevalence of 21.8%, pneumonia remains the most common nosocomial infection,[4] including in the intensive care unit (ICU).[5] The incidence varies significantly among different types of ICU patients. Postoperative patients, especially those undergoing cardiothoracic, neurosurgical, and trauma-related surgery, appear to have the highest rates.[6] Coronary care unit patients appear to have the lowest rates; medical, respiratory, and other surgical patients demonstrate intermediate rates.

Despite significant improvements in other important nosocomial infections, the prevalence of nosocomial pneumonia has not decreased.[4] However, prevention strategies discussed in this chapter have substantially changed the clinical presentations of HAP/VAP. VAP rates have decreased as prevention strategies effectively decrease the incidence of early-onset (within 7 days of intubation) VAPs.[7] Conversely, VAP now occurs in a subset of patients who enter a vicious cycle of prolonged ventilation, which increases the risk of pneumonia, leading to further prolongation of ventilation and high risk of recurrent pneumonia. One major factor characterizing these patients is the dramatic increase (from 18.7% to 29.9% over 13 years) in the proportion of pneumonia patients with any immunocompromising condition.[8]

A distinction should be made between prevention of all nosocomial pneumonia and prevention of life-threatening nosocomial pneumonia. Differential effects of prevention strategies have resulted in a shift in the etiology of VAP. For example, methicillin-resistant *Staphylococcus aureus* (MRSA) caused up to 30% of VAPs in the past,[9,10] whereas more recent studies find rates as low as 7%.[10,11] Conversely, the frequency of pneumonia multidrug-resistant (MDR) strains of Enterobacterales has progressively increased for both HAP and VAP. Prevention of HAP/VAP due to *Pseudomonas aeruginosa, Acinetobacter* species, and MDR Enterobacterales, especially carbapenem-resistant Enterobacterales (CRE), is more likely to affect mortality. Unfortunately, the most effective strategies to prevent pneumonia work predominantly or exclusively in early-onset VAP and therefore have not resulted in a significant improvement in mortality. Conversely, one of the most consistent adverse effects of VAP (including early-onset) is a prolonged duration of mechanical ventilation. Because duration of ICU stay is the principal determinant of cost of care, prevention measures may be cost-effective even if they do not result in improved mortality.

The other major shift in nosocomial pneumonia epidemiology in the ICU is that HAP precipitating the need for mechanical ventilation is now more common than VAP.[12] The influence of endotracheal intubation is so dominant that ICU-acquired pneumonia was once considered almost synonymous with VAP. Endotracheal intubation increases the rate of nosocomial pneumonia between 3-fold and 21-fold.[9] HAP associated with mechanical ventilation appears to have an equal risk of MDR pathogens and higher crude mortality rates than VAP.[12,13] Even in the ICU, increased use of noninvasive ventilation and high-flow oxygen delivery results in more HAP patients who are not intubated. Therefore prevention strategies need to be extended outside the ICU and to non-intubated patients to make further progress in preventing overall pneumonia rates and associated morbidity and mortality.

Lack of diagnostic accuracy severely compromises efforts to prevent HAP/VAP.[14,15] Etiologic diagnosis is particularly difficult in patients who are not intubated. Radiographic interpretation is also problematic. The National Nosocomial Infections Surveillance (NNIS) definition of infectious ventilator-associated complication (IVAC), which does not require a chest radiograph in the definition,[15] is neither sensitive nor specific, and VAP prevention strategies to alter the frequency of this entity have been disappointing.[16] Others ignore the need for abnormal chest radiographs and instead combine VAP with a newly defined ventilator-associated tracheobronchitis (VAT).[17–19] Whether VAT is an early stage of VAP and progresses to VAP is still debatable.

PATHOGENESIS

Two keys to prevention and control strategies are a clear understanding of the underlying pathogenesis of nosocomial pneumonia and a comprehensive approach to prevention. The benefit of both is best demonstrated by a study deploying seven interventions to prevent HAP in high-risk patients with an automatically triggered order set in a large integrated healthcare system.[14] These interventions (Table 106.1) were based on the pathogenesis of HAP. Over a 6-year period, HAP rates decreased from 5.9 to 1.79/1000 admissions ($P = 0.003$), with mortality decreasing from 1.05 to 0.34/1000 admissions and highly significant decreases in broad-spectrum antibiotics.

The essence of nosocomial pneumonia pathogenesis involves three basic steps:

1. Colonization of the oropharynx with pathogenic microorganisms
2. Aspiration of oropharyngeal contents into the lower respiratory tract
3. Overwhelming of the lower respiratory tract's host defense mechanisms.

Effective prevention and control measures can be analyzed by their effect on one or more of these steps.

TABLE 106.1 Interventions for High-Risk Patients to Prevent Hospital-Acquired Pneumonia

Aggressive mobilization
Upright posture for meals
Careful swallow evaluation before any feeding
Attention to sedation levels
Elevated head of bed for sleep
Rigorous oral care
Feeding tube care

From Lacerna CC, Patey D, Block L, et al. A successful program preventing nonventilator hospital-acquired pneumonia in a large hospital system. *Infect Control Hosp Epidemiol.* 2020;41(5):547–552.

Despite the simplicity of this paradigm, assumption that the pathogenesis of all types of HAP/VAP is the same would be naive and incorrect. An example is the role of gastric colonization preceding oropharyngeal colonization, the basis for attention to enteral feedings and stress ulcer prophylaxis in VAP prevention. Although possibly important for pneumonia caused by Enterobacterales, gastric and enteric colonization has no role in the pathogenesis of *S. aureus* or *P. aeruginosa* pneumonia, the two common causes of VAP. Conversely, daily chlorhexidine baths did not prevent VAP in a trauma population but did significantly decrease VAP from MRSA.[20] Therefore prevention strategies should be individualized to the patients, pathogens, and mechanisms prevalent in a specific ICU.

COLONIZATION WITH PATHOGENIC MICROORGANISMS

The major antecedent event to most nosocomial pneumonias is colonization of the oropharynx with pathogenic bacteria. The oropharynx is not sterile, but the character of the normal flora is remarkably constant. A variety of factors alter the normal flora, allowing replacement by more pathogenic microorganisms. The importance of the normal flora is illustrated by the adverse effects of iseganan, an antimicrobial peptide active against almost all bacteria.[21] Oropharyngeal application of iseganan did not significantly decrease VAP rates but was associated with a trend for increased mortality.

Time of exposure to these selective forces within the hospital is critical. Early-onset pneumonia, even early-onset VAP, tends to be caused by less pathogenic microorganisms characteristic of CAP such as streptococci, *Hemophilus influenzae,* or methicillin-sensitive *S. aureus*. Most selective forces are introduced in the hospital environment itself, rather than specifically in the ICU. Therefore patients who develop pneumonia during the first few days of ICU admission or mechanical ventilation are at risk for MDR pathogens if preceded by a 3- to 5-day hospital stay. Many of the same factors also operate in skilled-care nursing facilities and lead to the designation of healthcare–associated pneumonia (HCAP). Although this term has been abandoned,[22] the risk factors remain.

Previously, colonization of the oropharynx by gram-negative enteric bacilli, generally from the Enterobacterales order, was emphasized. As part of the normal bowel flora, oropharyngeal colonization occurred by one of two main routes. The first is reflux of bacteria into the stomach from the duodenum, with subsequent gastroesophageal reflux into the esophagus and oropharynx. Colonization and proliferation in the stomach are critical intermediate steps in this pathway. Therefore many prevention strategies logically target the stomach. The other route is self-inoculation by the fecal-oral route, through contamination of equipment or the hands of healthcare providers or the patient.

The pattern with Enterobacterales does not apply to all HAP/VAP pathogens. None of *S. aureus*, *P. aeruginosa*, and *Acinetobacter* species, common causes of VAP, have a typical colonization pattern like that of Enterobacterales. *S. aureus* is a normal colonizer of the skin and the nasopharynx. Antegrade colonization of the oropharynx from the nose, especially with the use of nasogastric tubes in many critically ill patients, can occur quite easily. Lack of nasal colonization, detected on admission screening, effectively excludes MRSA as a cause of HAP/VAP. *Acinetobacter* is found on moist body surfaces and in the gingival crevices of patients with poor oral hygiene. *P. aeruginosa* is usually not part of normal bowel flora but is ubiquitous in the environment. One of the unique aspects of *Pseudomonas* VAP is the appearance of tracheal colonization before oropharyngeal colonization.[23] Because colonization of the stomach is not an important intermediary step for these pathogens, prevention measures directed at the stomach are not likely to affect pneumonia caused by them. Conversely, both MRSA and *Acinetobacter* colonization can be decreased with the use of chlorhexidine whole-body bathing.[20]

Recent data from the lung microbiome have suggested that gram-negative pathogens may potentially cause pneumonia without antecedent oropharyngeal colonization. A gut-specific *Bacteroides* strain was found to be increased in patients with acute respiratory distress syndrome (ARDS) and/or sepsis.[24] This finding may represent hematogenous spread of enteral pathogens to the lung via gut translocation, independent of oropharyngeal colonization, and may explain the association of septic shock and ARDS with the risk of MDR pathogens.[25] Protection of the gastrointestinal (GI) brush border with enteral nutrition or selective decontamination of the digestive tract (SDD) may be more important in some of these patients in addition to those with chemotherapy-induced mucositis.

AVOIDANCE OF ANTIBIOTICS

The single most important factor that leads to colonization of the oropharynx with pathogenic microorganisms is use of systemic antibiotics, especially broad-spectrum, that include coverage of gram-positive pathogens.[26] Antibiotic killing of the usual oropharyngeal flora gives pathogens a selection advantage; at the same time, some pathogens are also eliminated. For this reason, antibiotics function more as amplifying agents rather than as true causes of colonization. The pathogenic microorganisms must still reside in the area normally, such as nasopharyngeal carriage of *S. aureus,* or be transferred from other sites, including the environment to colonize. Thus pneumonia can still occur despite avoidance of antibiotics. However, the causative microorganisms are more likely to be less virulent pathogens or even normal flora, such as alpha-hemolytic streptococci, and less likely to lead to life-threatening pneumonia.

Diagnostic strategies for fever in the ICU that result in the use of fewer antibiotics have been associated with lower mortality.[27] Shorter courses and fewer antibiotics for documented infections in critically ill patients have also been associated with a decreased risk of superinfection.[28–30] Although avoiding antibiotics may have only a small effect on the risk of developing the first episode of pneumonia, limiting their usage has a major effect on secondary pneumonia and infection-related death in the ICU.

Topical Antibacterial Agents

In contrast to systemic antibiotics, the use of topical antibiotics for the prevention of colonization may be beneficial. In general, strategies rely on controlling pathogenic microorganisms at specific sites, despite the

effect on normal flora. Topical agents generally do not have the toxicity of systemic agents, and although the use of topical antibiotics can lead to MDR isolates, the risk may not be as great as with systemic antibiotics.

Selective Digestive Decontamination of the Digestive Tract

By far the most extensively studied and most aggressive form of topical antibiotic strategy to prevent colonization is SDD. Although the specific agents used in different studies vary, the major focus is on controlling oropharyngeal colonization by sterilizing almost the entire GI tract, including the large bowel. SDD is discussed more extensively in Chapter 110.

Topical Oropharyngeal Agents

Controlling colonization of the oropharynx alone has also generated interest because little disruption of the normal bowel flora is expected by treating only the primary area of concern. Oropharyngeal decontamination alone appears to be equivalent to SDD for the prevention of VAP.[31] Chlorhexidine oral rinse has been the most extensively studied.[32] Unfortunately, different concentrations of chlorhexidine have been used and different populations have been compared. The strongest support for efficacy is for the 2% concentration. Chlorhexidine may not be able to prevent infection with MDR pathogens such as *Pseudomonas* and *Acinetobacter*.[33] Oral decontamination with other agents, such as povidone/iodine and antimicrobial peptides,[21] has not demonstrated benefit. Universal decolonization of patients with daily chlorhexidine for 5 days and nasopharyngeal mupirocin demonstrated lower MRSA bacteremia and surgical site infection rates but no effect on pneumonia.[34]

Aerosolized Antibiotics

The earliest studied form of topical colonization prevention was aerosolized antibiotics. In the early era of mechanical ventilation, daily aerosolized polymyxin B resulted in a dramatic decrease in the rate of gram-negative VAP.[35] Not surprisingly, routine use was soon complicated by the emergence of antibiotic-resistant microorganisms. This feature, combined with a lack of mortality benefit, led to abandonment of this strategy. Aerosolized ceftazidime did not decrease VAP rates in trauma patients but did not increase MDR pathogen colonization either.[36] A recent variation of this practice is to use aerosolized antibiotics for purulent tracheobronchitis, thought to be a precursor to VAP.[37]

AVOIDANCE OF INCREASED GASTRIC pH

The normally acidic environment of the gastric lumen is extremely effective in preventing colonization with either swallowed oropharyngeal flora or refluxed enteric flora. Several prevention strategies focus on this aspect of prevention.

Stress Ulcer Prophylaxis

Because GI bleeding from stress ulceration was at one time a substantial problem in ventilated patients and a major cause of death, prophylaxis against stress ulceration was considered critical for ventilated patients. This generated a debate regarding the optimal GI bleeding prophylaxis, which has evolved over the last few decades. Initially, antacids were found to be inferior to histamine-2 blockers (H2 blockers). In addition to increasing gastric pH, antacids increase gastric volume, probably an independent risk factor for VAP. Subsequently sucralfate was hypothesized to be superior to H2 blockers because it did not affect gastric pH and might have intrinsic antibacterial properties. No clear-cut benefit of sucralfate over H2 blockers in reducing VAP was found, whereas a slight but consistent increase in GI bleeding has been documented.[38] Proton pump inhibitors (PPIs) appear equivalent to H2 blockers.[39]

However, the incidence of stress mucosal ulceration has decreased markedly as a result of better hemodynamic resuscitation, improved ventilatory strategies, and earlier use of enteral nutrition. Several multivariate analyses found PPIs associated with increased pneumonia rates, including HAP/VAP,[40,41] HCAP, and even CAP.[42] Based on this concern, the need for stress ulcer prophylaxis at all in most mechanically ventilated patients has been questioned. Multicenter placebo-controlled trials have not found a benefit in either mortality or even GI bleeding, with inconsistent increases in VAP rates.[38,43] Ironically, GI prophylaxis had been encouraged as part of a ventilator/VAP bundle in many institutions. A subgroup of patients at increased risk for GI hemorrhage can be identified, and patients without these high-risk factors may not need prophylaxis.[43,44]

Enteral Nutrition Strategies

Malnutrition is clearly associated with an increased risk of pneumonia and increased mortality in the critically ill. In addition to classic effects on cell-mediated immunity, an effect specific to pneumonia is increased binding of gram-negative bacilli, including *Pseudomonas,* to epithelial cells.[23]

Enteral administration of nutrition is the preferred route for treating and preventing malnutrition in the critically ill, although parenteral nutrition in high-risk patients is preferable to no nutrition.[45] Meta-analysis has suggested that patients can even be fed soon after GI surgery.[46,47] However, continuous enteral nutrition infusions may increase both gastric pH and gastric volume, increasing VAP risk.[48,49] A randomized trial found that the risk of VAP was increased with early aggressive feedings compared with low-level enteral nutrition (approximately 20% of goal feeding rate).[50] The lower rate was chosen to avoid atrophy of the microvilli of the enteric mucosa, potentially avoiding gut translocation. The increased risk of VAP was attributed to an increased risk of aspiration, also seen in a surgical series.[47] However, meta-analysis of early vs. delayed enteral nutrition suggests a mortality benefit and probable decreased risk of VAP with early feedings.[51] A balance between potential risks would be early initiation of enteral feeding but avoidance of high gastric residuals and gastric distention. Neither bolus feedings[52] nor acidification of enteral feedings[53] improved VAP rates but were associated with increased adverse consequences.

MODIFIED ENDOTRACHEAL TUBES

Bacteria can adhere to the polyvinyl chloride surface of endotracheal tubes through secretion of a glycocalyx. Protected from systemic antibiotics and host defense mechanisms, microorganisms in this glycocalyx can become a source of reinoculation of the lower respiratory tract. This mechanism may explain the high recurrent VAP rates, particularly for *Pseudomonas*. A silver-impregnated endotracheal tube demonstrated a lower incidence of VAP and a delay in onset in those that do develop VAP,[54] although cost remains a barrier to routine use.

CROSS-INFECTION

The role of cross-contamination in the ICU should never be underestimated. Cross-contamination can cause colonization with specific pathogenic bacteria in a patient who has no other risk factors for that microorganism. In particular, *P. aeruginosa* and MRSA appear to have the greatest potential to cause cross-contamination and subsequent infection.

By far the most important factor in cross-infection is handwashing among caregivers. Multiple studies document poor infection control

practices of medical personnel, including physicians and bedside nurses. The risk of inadequate handwashing increases with the intensity of care needed for an individual patient and with the number of patients per nurse.[55] Use of an alcohol-based, self-drying hand wash appears to be effective and to increase compliance with handwashing.[56,57] Routine decolonizing also appears to decrease rates of cross-infection.[34]

Avoiding cross-contamination via medical equipment is also important. Contaminated equipment remains a major cause of epidemic outbreaks of nosocomial pneumonia. Any clustering of VAP, especially when caused by an unusual microorganism, should raise this possibility. Respiratory therapy equipment is particularly suspect, and adherence to standards for the sterilization of ventilators, bronchoscopes, and other reusable equipment should be rigorous.

ASPIRATION

The role of aspiration in nosocomial pneumonia is probably the least controversial, although the possibility of hematogenous spread from GI tract to lung has been raised.[24] Aerosolization, the third major mechanism for microbes to gain access to the lung, is rare outside of contaminated respiratory therapy equipment. Evidence from a variety of sources documents the importance of aspiration, although the definition of aspiration may vary.

LARGE-VOLUME ASPIRATION

Large-volume aspiration is clearly a risk factor in nonintubated ICU patients. Although the aspirated material itself may not be infectious, such as enteral feedings, aspiration of a large bolus clearly predisposes to pneumonia. Large-volume aspiration may result in ARDS, which by itself is associated with an increased risk of VAP.[25] Predisposing factors for this type of aspiration are GI, such as protracted vomiting from bowel obstruction or GI bleeding, and neurologic, including seizures, induction of anesthesia, and alcohol intoxication. Two components of the successful HAP prevention program (see Table 106.1) are specifically directed at preventing aspiration.[14]

Appropriate endotracheal intubation is actually a protective factor for this type of aspiration acutely, and tracheostomy may be useful for chronic issues with aspiration. Once large-volume aspiration has occurred, selective use of bronchoscopy to extract solid material that might occlude a bronchus and cause a postobstructive pneumonia is one of the few preventive measures of benefit. Empirical antibiotics, especially prolonged courses, do not clearly prevent pneumonia but do select for more virulent microorganisms.

SMALL-VOLUME ASPIRATION

Aspiration of a smaller volume of secretions is also associated with pneumonia in both intubated and nonintubated patients. Neurologic disease with inability to protect the upper airway is consistently documented as a risk factor for pneumonia. In this situation, aspiration occurs before or in conjunction with endotracheal intubation. The bolus can be either oropharyngeal secretions or gastric secretions. In the former situation, a large inoculum of oropharyngeal flora can reach the lower respiratory tract, and clinical pneumonia usually occurs within 48–72 hours. High levels of amylase in bronchoalveolar lavage (BAL) fluid is a marker of this risk.[58]

Prevention of pneumonia from acute small-volume aspiration is probably best achieved by prophylactic antibiotics. Prospective observational studies have suggested that antibiotics early in the course of mechanical ventilation are associated with a lower incidence of pneumonia.[48,59] However, two prospective, randomized trials of short-course (2 days or less) beta-lactam prophylaxis in patients intubated for nontraumatic coma provide the best evidence.[60,61] In both studies, the incidence of subsequent VAP in the prophylaxis group was decreased by at least 40% compared with the control group that did not receive any antibiotic. These findings have also been independently corroborated by a before/after quality improvement study[62] and the many SDD studies that find decreased pneumonia incidence only if a short course of systemic antibiotics was included with the topical antibiotics. Prophylactic antibiotics are of benefit only in the initial intubation of patients not previously hospitalized for a significant period. Efficacy of the short course is dependent on the fact that the aspirated bolus contains mainly normal oral flora rather than a high concentration of MDR pathogens. Continuing antibiotics for longer courses has no additional benefit.[63]

This prevention strategy seems to contradict the importance of avoiding unnecessary antibiotics discussed earlier. Two aspects of this strategy outweigh the potential downside of increased risk of oropharyngeal colonization with more pathogenic bacteria. First, the antibiotics are continued for 48 hours or less. Second, the 40% lower risk of pneumonia in patients given prophylaxis avoids a subsequent longer course of antibiotics, often with a broader-spectrum agent.

MICROASPIRATION

Microaspiration is by far the most important form of aspiration in endotracheally intubated patients. Oropharyngeal secretions pool above the cuff of the endotracheal tube in most intubated patients. Extremely small volumes of secretions can pass below the cuff during small movements of the endotracheal tube associated with head repositioning, high airway pressures, coughing, and other activities. Up to 45% of patients have abundant aspiration (as documented by measurable pepsin in ≥65% of tracheal aspirates) in the first 48 hours post intubation.[64] Because oropharyngeal secretions contain 10^6–10^{10} bacteria/mL, even 0.1 mL of secretions can present a significant challenge to the host defenses of the lower respiratory tract.

Shorter Duration of Endotracheal Intubation

The risk of VAP is not linear; the greatest risk occurs early, with a 3%/day risk in the first week, 2%/day in the second week, and 1%/day subsequently.[59] In addition, early-onset VAP (within 5–7 days of intubation) has the lowest attributable mortality.[9,65] Therefore the sooner the patient is extubated, the lower the cumulative risk of pneumonia and the lower the risk of lethal nosocomial pneumonia.

The best strategy is avoiding intubation completely. Management of many patients with noninvasive ventilation (NIV) is now standard practice in most ICUs. However, patients who fail NIV appear to have an increased duration of subsequent endotracheal intubation and thus an increased risk of VAP. Careful selection of candidates for NIV and early abandonment in unsuccessful cases are critical to decreasing the pneumonia risk. The use of high-flow nasal cannulas as an alternative to NIV may also decrease the risk of pneumonia and days of ventilation.[66]

Even when patients are intubated, variations in the duration of mechanical ventilation for the same type and severity of critical illness suggest that efforts to shorten this duration are the most viable approach to preventing VAP. Several protocolized strategies have demonstrated a significant benefit,[67] including daily interruption of sedation and daily assessment of ability to wean.[68–71] The overall benefit is partially attributable in part to lower VAP rates, which in turn decrease the duration of ventilation.

The downside of an aggressive extubation strategy is the association between reintubation and a threefold increase in risk of VAP.[72,73] Need for reintubation re-exposes the patient to the risk of small-volume aspiration. In addition, colonization of the oropharyngeal secretions by

more pathogenic bacteria is more likely because of the prior episode of intubation, and short-course antibiotics will not have the same beneficial effect. Therefore although avoiding or shortening the duration of mechanical ventilation is clearly a laudable goal, an increase in the risk of VAP may occur with an overly aggressive approach.

Avoidance of Ventilator Tubing Manipulation

Condensation of exhaled gas in the expiratory limb of the tubing or from humidifiers in the inspiratory limb can become heavily colonized with bacteria. Instillation of this liquid bolus into the patient's airway during manipulation of the tubing or movement of the patient can present a significant bacterial challenge to the lower respiratory tract defenses. The most consistent evidence that ventilator tube manipulation may increase the risk of VAP is that increasing the interval between changes of the ventilator tubing decreases the incidence of VAP. Most institutions no longer change ventilator tubing unless gross contamination is present.

Meta-analysis of randomized controlled trials of heat and moisture exchangers (HMEs) rather than heater-humidifiers suggested a 30% reduction in VAP rates, especially if the patient was ventilated for more than 7 days.[74] Increased rates of endotracheal tube occlusion secondary to inspissated secretions with the use of HMEs and other considerations, especially cost, determine the frequency of their use.

Transporting patients outside the ICU, usually for diagnostic procedures, is also associated with an increased risk of VAP.[73] In a prospective study, 24% of patients requiring transport outside of the ICU developed VAP, compared with only 4% of patients who did not. The need for ventilation by bagging, changing ventilators, moving the patient out of bed, and other aspects of the process all increase the possibility of inadvertent introduction of condensate from the ventilator tubing into the patient. In addition, unintentional extubation is greater when transferring ventilated patients.

Maintenance of Artificial Airway Cuff Pressure

Adequate pressure (generally $\geq$25 cm H_2O) to maintain a seal around the cuff of artificial airways is critical to prevent microaspiration. Maintaining continuous control of tracheal cuff pressure resulted in a decrease in VAP incidence from 22 to 9.7 confirmed cases/1000 ventilator days.[64] Maintenance of cuff pressures may also decrease proximal airway secretions, the hallmark for the diagnosis of VAT.[37] The addition of low levels of positive end-expiratory pressure (PEEP) has been associated with decreased aspiration[75] and risk of VAP,[76] possibly partially because of the greater attention to tracheal cuff pressures required in patients on PEEP. Inattention to tracheal cuff pressure may cancel the benefit of other airway interventions, such as specially designed tubes and continuous aspiration of subglottic secretions.[77]

Modified Endotracheal Tubes

A variety of modifications of the endotracheal tube itself have been designed to decrease microaspiration. Most attempt to minimize the longitudinal folds seen in standard tracheal cuffs by changing either the type of material or the shape of the cuff.[78] No significant difference in VAP rates has been found in tapered versus cylindrical or polyurethane versus polyvinyl chloride cuffs.[79]

An endotracheal tube that allows continuous aspiration of subglottic secretions (CASS) pooled above the endotracheal tube cuff has been the most extensively studied modification. This tube has an extra channel with the lumen on the dorsal surface, just above the level of the inflatable cuff. One clinical practice guideline found the greatest level of evidence for VAP prevention was demonstrated with CASS.[80] Studies of CASS have variably demonstrated lower VAP rates[81,82] but mainly in early-onset VAP. No decrease in VAP caused by MDR microorganisms and no mortality differences have been demonstrated. Consistent with this pattern, the benefit is obviated if the patient receives antibiotics early in the course of mechanical ventilation,[77] similar to the benefit of prophylactic antibiotics in early-onset VAP.[60] Pneumonia can also occur if the system malfunctions, usually a result of plugging of the lumen or low cuff pressures, allowing secretions to drain into the distal trachea rather than collecting above the cuff. These factors and the high cost have limited the use of this modality.

Early Tracheostomy

Tracheostomy has several potential benefits for the prevention of VAP. The glottis is not held open by the endotracheal tube and the vocal cords can be opposed, decreasing the risk of aspiration significantly. The security of a tracheostomy may allow greater mobilization and a greater amount of time spent in the upright position, also decreasing aspiration. Routine tracheostomy may be one explanation for the leveling off of VAP incidence after several weeks of mechanical ventilation. Early reports of an increased risk of pneumonia with tracheostomy were compromised by lack of adjustment for prior duration of mechanical ventilation, inaccurate diagnosis (with some tracheostomy site infections classified as pneumonia), and variable surgical techniques. The benefit of early tracheostomy remains unsettled but likely of greater benefit in patients with brain injury or other serious neurologic insults.[83–85] Technique may also matter, with early tracheostomy performed by the percutaneous dilatational technique more beneficial.[84]

SEMIRECUMBENT POSITIONING

The degree of gastroesophageal reflux is significantly greater in supine patients than in semirecumbent patients.[86] Not only is reflux greater, but bowel flora colonized the oropharynx and bronchial tree in 68% of patients ventilated in the supine position, compared with only 32% in the semirecumbent position. A prospective, randomized trial clearly demonstrated that both clinically suspected and microbiologically confirmed cases of VAP were more common in patients ventilated in the supine position (8% of clinically suspected VAPs versus 34% for semirecumbent).[49] Supine body position (odds ratio 6.8) and enteral nutrition (odds ratio 5.7) were both independent risk factors for VAP, with the highest frequency in patients receiving enteral nutrition in the supine position (14 of 28; 50%).

Avoiding the supine position as much as possible is a simple and effective preventive measure that should be practiced in all ICUs.[80] However, compliance with elevation of the head of the bed to 45 degrees is difficult, and achieving lower degrees of elevation are not associated with decreased VAP rates.[87] Lateral Trendelenburg positioning did not substantially decrease VAP rates,[88] and prone positioning may actually increase rates.[89] Early mobilization of ventilated patients to both sitting upright at the bedside and actual ambulation not only decreases pooling of secretions and microaspiration but also appears to shorten the duration of ventilation.[90]

Avoidance of Gastric Overdistention

Even in a semirecumbent position, many patients still have gastroesophageal reflux and microaspiration when given enteral feedings. The major issue is overdistention of the stomach. The first is use of nasoenteric tubes rather than nasogastric tubes. Although attractive theoretically, meta-analysis of randomized, controlled trials did not show a benefit for VAP prevention by postpyloric feeding compared with gastric feeding.[91] The major limitation is the difficulty in placing postpyloric tubes.

The second strategy is the use of gastric prokinetic agents, such as metoclopramide. An additional benefit of these agents is increased

tone of the lower esophageal sphincter, potentially decreasing the risk of reflux while increasing gastric emptying. Once again, a randomized, controlled trial failed to confirm the benefit of using this agent to decrease the risk of VAP.[39]

OVERWHELMING LOWER RESPIRATORY TRACT HOST DEFENSES

An underappreciated fact regarding nosocomial pneumonia is that despite aspiration of oropharyngeal secretions documented to contain pathogenic bacteria, only a minority of colonized patients actually develop pneumonia. In the classic study of Johanson and colleagues, only 23% of patients with gram-negative colonization of the oropharynx subsequently developed pneumonia.[92] Others have shown that quantitative culture levels of microorganisms equivalent to those found in pneumonia can transiently appear in routine nonbronchoscopic BAL samples without causing clinical VAP.[93] Thus the two steps described earlier—colonization by pathogens and aspiration—are necessary, but not sufficient, causes of nosocomial pneumonia.

The third step in the pathogenesis of nosocomial pneumonia—overwhelming lower respiratory tract defenses—is the least studied or understood. One major reason for this lack of emphasis may be that the causes are heterogeneous and patient dependent, rather than the stereotypical steps of colonization and aspiration. As infection control and patient safety efforts have become more effective, the remaining patients who do develop VAP are likely to have significant defects in host immunity. Patients who develop VAP should generally be considered to have a form of acquired immunosuppression.[94] The more frequent occurrence of other nosocomial infections in patients with VAP supports this concept. In addition, some VAP patients develop multiple separate episodes of VAP,[95] suggesting disproportionate compromise of lower respiratory tract defenses.

Many of the causes of compromised lower respiratory tract defenses are caused by the underlying disease or critical illness precipitating ICU admission and need for mechanical ventilation. However, several risks generic to most ICU patients may be targets for prevention.

MINIMIZING ANTIBIOTIC USE

Rather than being sterile, lung alveoli harbor a normal bacterial flora. This recognition raises important issues in understanding the development of HAP/VAP. The normal lung microbiome is similar to that of the normal oropharynx, predominantly streptococci, but also anaerobes, *Hemophilus,* and *Mycoplasma,* but at significantly lower concentrations.[96,97] These normal flora therefore represent an important component of host defense adversely affected by systemic antibiotics, similar to the oropharynx and the GI tract. *Pseudomonas* pneumonia is virtually never seen without prior antibiotic exposure and develops with progressive monolithic replacement of the normal heterogeneous lung microbiome in response to antibiotic pressure.[98] Minimizing the effect of antibiotics on VAP may occur with enteral probiotics,[99] but lung-specific therapy is not available. Consistently, diagnostic strategies for VAP that result in less antibiotic treatment[27,30] and earlier discontinuation in culture-negative patients[100] have resulted in improved mortality and less superinfection.

CORTICOSTEROIDS

Systemic corticosteroids have well-documented antiinflammatory effects that can influence immune function. The difficulty in determining the effect of corticosteroids on the risk of VAP is the competing beneficial effect on other risk factors for VAP. An example is the use of corticosteroids may allow earlier extubation of a patient intubated for an exacerbation of asthma, thereby lowering the risk of VAP. This dual effect probably holds true for most cases in which corticosteroids are used acutely for critically ill patients. The potential benefits begin to be outweighed by adverse consequences after more prolonged courses.

TRANSFUSIONS

A common cause of immunosuppression is red blood cell transfusions. This effect of transfusions has been known for decades and was used therapeutically in the past for pre-transplantation management of patients with end-stage renal disease. The trigger for red blood cell transfusion varies widely among institutions and even among individual practitioners. A more restrictive transfusion policy may avoid compromising host immunity. A conservative transfusion policy was associated with equivalent mortality to more liberal transfusions in most ICU patients[101] and decreased VAP rates in trauma patients.[102]

KEY POINTS

- Two keys to prevention and control strategies are a clear understanding of the underlying pathogenesis of nosocomial pneumonia and a comprehensive approach to prevention.
- A distinction should be made between the prevention of all nosocomial pneumonia and the prevention of life-threatening nosocomial pneumonia, usually caused by MDR pathogens.
- Pathogenesis of nosocomial pneumonia can be broken down into three basic steps: colonization of the oropharynx with pathogenic microorganisms, aspiration, and overwhelming of the lower respiratory tract's host defense processes.
- The most important factor in colonization of the oropharynx with pathogenic microorganisms and compromise of distal lung defenses is the suppression of normal flora at these sites by systemic antibiotics, especially broad-spectrum antibiotics.
- The risk of VAP is time dependent, so any maneuver that decreases the duration of mechanical ventilation will decrease pneumonia rates.
- Avoiding the supine position as much as possible in ventilated patients and maintaining adequate tracheal cuff pressure are simple and effective measures to prevent microaspiration and should be practiced in all ICUs.
- Causes of the relative immunocompromise that allows bacteria to overwhelm local host defenses in the lung are heterogeneous and patient dependent, unlike the stereotypical steps of colonization and aspiration.

Antimicrobial Agents With Primary Activity Against Gram-Negative Bacteria

Michael S. Niederman, Despoina Koulenti, and Jeffrey Lipman

Gram-negative bacteria are ubiquitous microorganisms of particular concern, especially the gram-negative bacilli (GNB), because of the fast spread of multidrug resistance (MDR). GNBs have intrinsic abilities to find new pathways of resistance and to transmit genetic material that allows other bacteria to become resistant as well (i.e., resistance acquisition via horizontal gene transfer). Mutations lead to new phenotypes with modified antibiotic targets, such as ribosomal mutation, whereas genes encoding drug efflux permeases and genes encoding antibiotic-modifying enzymes, such as beta-lactamases, are most often acquired via horizontal transfer.[1,2] Specifically, the development of extended-spectrum beta-lactamases that confer resistance to penicillins and cephalosporins and of carbapenemases that confer resistance to carbapenems, as well, is considered of critical importance. It is noteworthy that in the World Health Organization (WHO) priority list, all the critical priority (Priority 1) microorganisms are gram-negative—carbapenem-resistant *Acinetobacter baumanni* (CRAB), carbapenem-resistant *Pseudomonas aeruginosa*, third-generation cephalosporin-resistant and carbapenem-resistant *Enterobacteriaceae* (CRE); the vast majority of the high-priority ones (Priority 2).[3]

In the intensive care setting GNBs are responsible for multiple infections, such as bloodstream infections, ventilator-associated pneumonia (VAP), device-associated infections, intraabdominal infections (IAIs), urinary tract infections (UTIs), and soft tissue infections. MDR GNBs represent a healthcare burden and are associated with poor outcomes (i.e., increased morbidity and mortality).[4] The antimicrobial agents most commonly used in the intensive care unit (ICU) to combat MDR GNBs include beta-lactams, fluoroquinolones, aminoglycosides, polymyxins, and newly introduced tetracyclines.

It should be highlighted that several reports have demonstrated suboptimal concentrations of antimicrobial agents in critically ill patients when conventional dosing schemes were used.[5] Therefore during the last decade, apart from the efforts to develop new antimicrobial agents, research has focused on optimization of the use of the currently available antimicrobial agents in the critical care setting, aiming for both improvement of clinical outcomes and limiting resistance emergence.[6,7] For dose optimization, alternative dosing schemes have been recommended, based on the pharmacokinetic and pharmacodynamic (PK/PD) characteristics of the antimicrobial agents and dosing individualization. For dosing individualization, nomograms validated in critically ill patients and dosing software can be used; however, therapeutic drug monitoring (TDM)–guided dosing is recommended as the safer and more effective means to achieve optimal antimicrobial exposures.[7–11]

In this chapter we summarize the characteristics of the classes of antimicrobial agents used in the critical care setting for GNBs, including "older" antimicrobial agents that have been "reintroduced" as salvage treatments, and introduce novel approved antimicrobial agents.

BETA-LACTAMS

Beta-lactams include penicillins, cephalosporins, carbapenems, and monobactams. They share a four-membered beta-lactam ring. Aztreonam is a monobactam that contains only the beta-lactam ring. In penicillins, the beta-lactam ring is connected to a five-membered thiazolidine ring and a side chain that distinguishes the different penicillins; in cephalosporins, it is connected to a six-membered sulfur-containing dihydrothiazine ring and two side chains that distinguish the different cephalosporins, whereas in carbapenems, the beta-lactam ring is connected to a five-membered thiazolidine ring that contains a carbon double bond instead of sulfur, and a side chain differentiates the different members of the class.[12]

Mode of Action of Beta-Lactams

Beta-lactams exert bactericidal action by inhibition of the synthesis of the peptidoglycan layer of the cell wall: via acylation of penicillin-binding protein transpeptidase enzymes (PBPs), they inhibit the cross-linkage of the peptidoglycan chains with subsequent bacteriolysis and cell death.[13–15] The efficacy of a beta-lactam antimicrobial agent is determined, at least in part, by its ability to reach the target PBPs and its binding affinity to various PBPs.[13–16]

Resistance to Beta-Lactams

Resistance to beta-lactams occurs via (1) PBP modifications that decrease their binding affinity (mainly in gram-positive bacteria), (2) loss or deficiency of outer membrane proteins that decrease permeability (in gram-negative bacteria), (3) presence of efflux pumps that force out the beta-lactams, and (4) hydrolysis by beta-lactamases (chromosomally encoded or via plasmids or transposons).[17–20] Beta-lactamase production is the most common mechanism of beta-lactam resistance in clinically important gram-negative bacteria and is largely responsible for GNB resistance in hospitals and, particularly, in the critical care setting.[20] Beta-lactamases are mainly classified either based on their molecular structure (i.e., their amino acid sequence) or based on their function.[21–23] Molecular classification is the simplest and least controversial approach, whereby beta-lactamases are divided into four classes, A, B, C, and D (Ambler classification).[21] The hydrolysis of the classes A, C, and D is done though an active-site serine, whereas class B includes metalloenzymes that hydrolyze beta-lactam through at least one active-site zinc.[21] The functional classification, on the other hand, relates the varied beta-lactamases to their clinical role and classifies

them in three groups with several subgroups.[22,23] Group 1 are cephalosporinases belonging to class C of molecular classification (including the AmpC beta-lactamases) that inactivate most cephalosporins and aztreonam and are not inhibited by clavulanate or tazobactam, and, moreover, in the case of large production, particularly in hosts with decreased beta-lactam accumulation, can inactivate carbapenems, especially ertapenem.[22,24–26] Group 2 are serine beta-lactamases belonging to molecular classes A and D and represent the largest group, as they include the extended-spectrum beta-lactamases (ESBLs) that hydrolyze third-generation cephalosporins and aztreonam (subgroup 2be), found in GNBs, particularly *Enterobacteriaceae.*[22,23] ESBLs are another beta-lactamase of particular concern, as the number of nosocomial infection outbreaks caused by ESBL-producing GNBs is high and ever increasing, and in many parts of the world ESBL-producing strains are endemic.[22,27–33] Group 3 are metallo-beta-lactamases (MBLs), a unique group both structurally and functionally, with the ability to hydrolyze carbapenems (although some serine beta-lactamases have also acquired this ability); the imipenemase (IMP) and Verona integron metallo beta-lactamase (VIM) that have appeared globally, mainly in lactose nonfermenting GNBs but also in *Enterobacteriaceae*, belong to this group.[22,23,34] Contrary to the serine beta-lactamases, MBLs have poor hydrolytic capability for monobactams and are not inhibited by clavulanic acid or tazobactam.[22,23] Functional classification is more subjective than the molecular one; nevertheless, it correlates the properties of a specific beta-lactamase with the microbiologic resistance profile for an isolate that is more useful in the medical setting.[22,23] Finally, regarding resistance to beta-lactams, it should be emphasized that although ESBL- and AmpC- producing GNBs are susceptible to carbapenems, carbapenemase-producing strains have been rapidly increasing worldwide (and are already endemic in several countries) and represent a serious public health threat, as these strains generally display MDR, including all beta-lactams and aminoglycosides and fluoroquinolones.[35–37]

Spectrum of Activity of Beta-Lactams

Beta-lactam antimicrobial agents have a wide spectrum of activity against gram-positive and gram-negative aerobic and anaerobic bacteria. However, each individual class of beta-lactams has a unique microbiologic spectrum. Natural penicillins are seldom used in critical care settings because they lack activity against beta-lactamase–producing bacteria. The class of cephalosporins is categorized into five generations depending on their temporal discovery and their spectrum of activity.[38] The first- and second-generation cephalosporins generally have only limited use in the critical care setting. Third-generation cephalosporins include the parenterally administered cefotaxime, ceftazidime, cefoperazone, ceftizoxime, and ceftriaxone.[39] They provide a broad coverage of gram-negative bacteria, with expanded activity against the *Enterobacteriaceae* and *Streptococcus pneumoniae* but lack activity against enterococci, methicillin-resistant *Staphylococcus aureus* (MRSA), *Listeria monocytogenes, Stenotrophomonas maltophilia*, and many *Acinetobacter* spp. Based on their antipseudomonal activity, cefoperazone and ceftazidime have clinically useful potency against *P. aeruginosa.* Third-generation cephalosporins can be hydrolyzed by ESBL-producing GNBs. The fourth-generation cephalosporins, cefpirome (not available in the United States) and cefepime, have improved penetration to the outer membrane of gram-negative bacteria because of an additional quaternary ammonium group.[15] Their spectrum is the widest of all cephalosporins: against gram-negative bacteria, their activity is similar to ceftazidime, but they are less susceptible to inactivation by AmpC beta-lactamases, whereas against gram-positives, they have activity similar to cefotaxime and ceftriaxone.[15,38,40] Resistance to fourth-generation cephalosporins is increasing, and they can be inactivated by many new ESBLs and carbapenemases.[15] Moreover, therapy for infections by ESBL-producing strains with maintained susceptible minimum inhibitory concentrations (MICs) is controversial.[15,41] Both third-generation (especially ceftriaxone and cefotaxime) and fourth-generation cephalosporins penetrate the blood-brain barrier.[15,38]

Ceftaroline and ceftobiprole are considered fifth-generation cephalosporins and are the first ones with anti-MRSA activity. Their activity against gram-negative bacteria corresponds to that of the third-generation cephalosporins (i.e., they are hydrolyzed by ESBL and AmpC beta-lactamases).[42,43] Ceftaroline was approved by the Food and Drug Administration (FDA) in 2010 and by the European Medicines Agency (EMA) in 2012 for the indication of community-acquired pneumonia (CAP) and complicated skin and soft tissue infections (cSSSIs).[44–46] Ceftobiprole has been approved in several European countries and in Canada for the treatment of CAP and hospital-acquired pneumonia (HAP), excluding VAP, but is not approved in the United States.[43,44] For further details on the anti-MRSA cephalosporins, ceftaroline and ceftobiprole, we refer the reader to the relevant chapter (i.e., antimicrobial agents against gram-positive bacteria).

The carbapenems are the broadest-spectrum beta-lactams and are typically reserved for severe nosocomial infections. Imipenem is degraded by the enzyme dehydropeptidase-1 (DHP-1) of the renal tubules and is combined with cilastatin, a DHP-1 inhibitor, whereas meropenem, doripenem, and ertapenem have increased stability towards the action of DHP-1.[47] Carbapenems have a broad spectrum of in vitro activity, covering gram-positive bacteria, excluding MRSA and *Enterococcus faecium,* and gram-negative bacteria, excluding *S. maltophilia*, and anaerobes. Imipenem/cilastatin and meropenem are typically reserved for severe nosocomial infections, having established efficacy in the treatment of a variety of infections, including complicated UTIs (cUTIs; including pyelonephritis), complicated IAIs (cIAIs), SSSIs, CAP, nosocomial pneumonia (including VAP), meningitis (meropenem only), and febrile neutropenia.[47] In general, doripenem has been demonstrated to have better in vitro activity than imipenem and similar or slightly better activity than meropenem against *P. aeruginosa.*[48] However, its clinical use is more limited compared with meropenem and imipenem, as its approved indications include cIAIs and cUTIs (including pyelonephritis) only, whereas there is a labeling warning for increased risk of death for VAP patients.[49,50] Ertapenem's spectrum of activity is less wide compared with imipenem, meropenem, and doripenem, as it is inactive against important lactose nonfermenting GNBs, including *P. aeruginosa* and *A. baumannii*, in addition to against Enterococci, and it is more suited for community-acquired than for nosocomial infections. Because of its favorable pharmacokinetic properties, it is also suitable for outpatient intravenous (IV) antimicrobial treatment.[47] Carbapenems are stable against ESBL and AmpC beta-lactamase–producing GNBs but are susceptible to carbapenemases and MBLs.[51,52]

Aztreonam is a monobactam with broad aerobic gram-negative activity, but it lacks efficacy against gram-positive bacteria and anaerobes.[14]

Combination of Beta-Lactams with Beta-Lactamase Inhibitors

One strategy for achieving beta-lactamase stability is combining beta-lactams with beta-lactamase inhibitors, such as clavulanate, sulbactam, and tazobactam and, more recently, with novel inhibitors such as avibactam, vaborbactam, relebactam, zidebactam, nacubactam, and taniborbactam.[53] Although beta-lactamase inhibitors lack antibacterial activity at clinically relevant concentrations, they preserve and enhance the antibacterial activity of the partner beta-lactam against beta-lactamase–producing pathogens. For the co-formulation of a

beta-lactam/beta-lactamase inhibitor, two main factors are taken into consideration, namely the activity of the inhibitor against the beta-lactamases that the partner beta-lactam is susceptible to and the similarities in the PK properties between the partners to warrant structural integrity protection of the beta-lactam throughout a given dosing interval.[53] Ampicillin/sulbactam is active against gram-positive bacteria, including *Enterococcus* spp., gram-negative cocci, and certain strains of *Enterobacteriaceae* (not ESBL-producing ones).[54–56] Ticarcillin/clavulanate and piperacillin/tazobactam have a broader spectrum of activity, including *P. aeruginosa, Enterobacteriaceae,* and several anaerobes. Piperacillin has better antipseudomonal activity than ticarcillin.[57,58] However, the resistance rates of *P. aeruginosa* to piperacillin/tazobactam in the ICU are significantly increasing worldwide, necessitating optimization of drug exposure or combination therapy to ensure the efficacy against it.[59–62]

PK/PD of Beta-Lactams

Beta-lactam antibacterial agents are generally hydrophilic, with a low volume of distribution (V_d) similar to the extracellular fluid, and the main route of elimination is the kidneys (although in piperacillin/tazobactam, biliary excretion may be important, and ceftriaxone has significant biliary excretion as well).[63] Frequent physiologic alterations in critically ill patients, such as increased V_d because of sepsis and/or fluid resuscitation and augmented renal clearance (increased glomerular filtration rates [GFR], lead to inadequate (subtherapeutic) concentrations of beta-lactams.[64,65] On the other hand, acute renal injury may lead to higher plasma concentrations and increased toxicity. The protein binding of beta-lactams is moderate (30%–50%) to low (<30%); however, they are members of a class with high protein binding, which includes ertapenem (~95%), ceftriaxone, flucloxacillin, and oxacillin. For these agents, the hypoalbuminemia that is common in critical illness may lead to low unbound concentrations towards the end of the dosing interval, because of the higher clearance of the (increased) free fraction.[8,66] The in vivo half-lives of beta-lactams vary.[38,47]

Beta-lactams are time-dependent killing antibiotics; the PK/PD index associated with optimal beta-lactam activity is the percentage of time that the free serum concentration is above the pathogen MIC (% *f*T>MIC).[8] Data from critically ill patients suggest that longer beta-lactam exposures (e.g., 100% fT>MIC) and higher concentrations (e.g., 2–5 × MIC) than previously described may be beneficial with maximal killing effect and suppressed bacterial resistance.[8,67–70] Finally, a recent analysis of pooled data of critically ill patients with monomicrobial gram-negative bloodstream infections reported that beta-lactam fCmin/MIC >1.3 was a significant predictor of a positive clinical outcome and recommended it as an antibiotic dosing target.[71]

Dosing and Monitoring of Beta-Lactams

As mentioned earlier, because of the physiologic alterations of critically ill patients, conventional antibiotic dosing of beta-lactams antimicrobial agents may lead to subtherapeutic concentrations.[72,73] A recent position paper on TDM of antimicrobial agents in critical care recommended an initial loading dose of beta-lactams followed by prolonged infusion, continuous or extended (3–4 hours), in order to maximize PK/PD target attainment and possibly improve clinical outcomes.[8] The panel recommended routine TDM of beta-lactams to optimize dosing of critically ill patients, achieving therapeutic targets in the critically ill populations, and at the same time, minimizing toxicity. For continuous administration, samples can be taken any time point during the infusion (with target Css>MIC).[8] For intermittent administration, minimum concentration (*Cmin*) should be monitored (with target 100% fT>MIC); sampling should occur 24–48 hours after treatment initiations, with one sample taken 30 minutes before or just before the administration of the following dose.[8]

Prolonged dosing of beta-lactams. Some evidence exists that suggests better outcomes are achieved with prolonged administration of beta-lactams (i.e., continuous or extended 3-hour IV infusions) compared with the standard intermittent administration, especially for critically ill patients with infections by resistant GNBs.[74–78] Although results from randomized controlled trials (RCTs) are controversial, a meta-analysis of three RCTs comparing continuous with standard intermittent bolus administration of beta-lactam antibiotics in septic critically ill patients found decreased hospital mortality with continuous beta-lactam administration, but no difference in clinical cure rates.[79] BLING III is an ongoing, prospective, international phase III RCT with a recruitment target of 7000 critically ill patients with sepsis, which compares continuous with intermittent administration of beta-lactams (piperacillin-tazobactam or meropenem), aiming to provide evidence to support one method of administration over the other.[80]

Synergy of Beta-Lactams in Combination with other Antimicrobials

Synergy (i.e., effect of a combination greater than expected based on individual antimicrobial agents) is frequently reported with the combination of a cell wall–active antimicrobial, such as a beta-lactam, with other agents, most commonly, an aminoglycoside or a fluoroquinolone, even against pathogens with higher MICs. Several studies have demonstrated survival benefit from early administration of such a combination therapy in patients with sepsis and septic shock.[81–83] Other studies have not shown benefit from a combination, such as an RCT in patients with septic shock in a country with a quite low level of MDRs, which failed to demonstrate a decrease in organ failure when fluoroquinolones were added to carbapenems.[84] Nevertheless, it should be noted that for the empiric management of septic shock, the Surviving Sepsis Campaign guidelines suggest the empiric combination of at least two antibiotics of different antimicrobial classes, targeting the most likely potential pathogens, noting that the recommendation is weak and the quality of evidence low.[85,86]

Adverse Events of Beta-Lactams

Beta-lactams are the most commonly reported antibiotic classes to cause allergic drug reactions, especially penicillins (~10%) and cephalosporins (less than penicillins; 1%–7%), whereas the incidence of allergic reactions caused by carbapenems is lower (<3% in the general population).[12,14,87,88] Immediate hypersensitivity reactions are immunoglobulin E (IgE)–mediated and usually occur within 6 hours (typically within 1 hour) from last drug administration, whereas the nonimmediate hypersensitivity reactions are mediated by the T cells and may occur any time after the first drug administration, typically after several days of treatment.[89] Immediate reactions usually present with symptoms and signs from the skin (e.g., itching, rash, angioedema), the upper and lower respiratory system (e.g., sneezing, nasal congestion, hoarseness, wheezing), the gastrointestinal system (e.g., mild abdominal pain, nausea, diarrhea), and the cardiovascular system (e.g., tachycardia, hypotension); they can appear isolated or in combination as severe anaphylaxis. Nonimmediate hypersensitivity reactions are most commonly manifested with maculopapular exanthema and urticaria.[12]

Penicillins can cause gastrointestinal disturbances, particularly diarrhea, but hematologic toxicity is rare.[13,90] Also, high doses of penicillins cause abnormalities of platelet aggregation, while Coombs-positive hemolytic anemia is a rare adverse event.[13,91,92] Renal toxicity of penicillins varies and can range from allergic angiitis to interstitial nephritis.[93]

Cephalosporins have low toxicity and are generally safe and well tolerated.[38] The most frequent adverse reactions of cephalosporins include nausea, vomiting, lack of appetite, and abdominal pain.[38] Less common reactions include hypersensitivity reactions, drug-induced immune hemolytic anemia, pseudomembranous colitis, disulfiram-like reactions, vitamin K deficiency, and enhancement of the nephrotoxicity of aminoglycosides.[38]

Carbapenems are generally well-tolerated. The most common adverse events include gastrointestinal disturbances, such as nausea, vomiting and diarrhea, headache, dermatologic reactions such as rash, and injection site effects such as phlebitis.[14] As carbapenems have minimal hepatic metabolism, clinically significant hepatotoxicity is rare, although mild-to-moderate asymptomatic increases in serum aminotransferases may occur, but rapidly resolve after drug discontinuation.[94] Also, carbapenems are considered to have low propensity for nephrotoxicity, coagulation disorders, and *Clostridium difficile* diarrhea.[14] Seizures are the most serious adverse event, particularly for imipenem (1%–2% compared with 0.1%–0.3% for the other carbapenems), especially when higher doses are used (≥4 g/day).[95,96] Although seizures are overall rare, the incidence increases in cases with renal impairment, lower body weight, and history of seizures or other central nervous system (CNS) comorbidities.[96–98] Carbapenems do not have significant drug interactions, although concomitant administration with valproic acid may lead to subtherapeutic levels of valproic acid.[99]

Aztreonam is generally well tolerated, with more common adverse events including infusion site reactions such as phlebitis, gastrointestinal disturbances (nausea, vomiting, and diarrhea), and rash.[14]

It should be noted that the more aggressive beta-lactam dosing to account for altered drug PK in critically ill patients might have led to excessive drug exposure being increasingly reported over the last decade.[8] TDM of beta-lactams, apart from helping to optimize exposures, can help in decreasing related toxicities.[8] C_{min} samples at steady state, or even earlier when dosing software is used, can help avoid overexposure to beta-lactams.[10,100]

Cross-reactivity of beta-lactams. Although subjects can be sensitized by any of the beta-lactam's components, the side chains are those structures that have the main contribution to immunologic recognition and therefore cause cross-reactivity among beta-lactam antibiotics.[12] The immunologic cross-reactivity related to the common β-lactam ring (i.e., cross-reactivity between all beta-lactams) is very rare, especially in subjects with T-cell–mediated allergy.[12] If a complete allergy workup cannot be performed and there is an urgent need to use a beta-lactam, the evaluation can be done with skin tests with beta-lactam agents that do not share identical/similar side chains with the culprit agent; in case of negative results, the alternative beta-lactam can be administered with graded challenges. In case of patients with history of mild, nonimmediate beta-lactam hypersensitivity reaction and no time available for delayed pretreatment skin test reading, the administration of a full dose of a beta-lactam structurally unrelated to the culprit is an option.[12]

Novel Approved Beta-Lactamase/Beta-Lactamase Inhibitor Combinations

Ceftolozane/Tazobactam

Ceftolozane/tazobactam is a combination of the novel oxyimino-aminothiazolyl cephalosporin ceftolozane with the irreversible beta-lactamase inhibitor tazobactam.[101,102] It was approved in 2014 by the FDA for the indication of cUTIs and for cIAIs in combination with metronidazole, whereas EMA approval was granted in 2015 for cIAIs, acute pyelonephritis, and cUTIs.[43,103] In 2019 the EMA approved ceftolozane/tazobactam for the indication of HAP/VAP as well.[43,103]

Mode of Action, Spectrum of Activity, and Resistance Mechanisms. Ceftolozane/tazobactam is active mostly against gram-negative pathogens, including *Enterobacteriaceae* and *P. aeruginosa,* whereas its activity against gram-positive pathogens and anaerobes is very limited.[104,105] Ceftolozane's MIC against *P. aeruginosa* is 9–16 times lower than the MICs of ceftazidime, imipenem, and ciprofloxacin, having also an earlier in vitro and a faster in vivo killing than ceftazidime.[101] Nevertheless, it is still vulnerable to the action of Ambler class A (e.g., ESBLs) and class C beta-lactamases (although the stability to AmpC enzymes varies).[101] Although tazobactam seems to add little to the antipseudomonal activity of ceftolozane, this addition does provide ceftolozane stability against several class A and C enzymes produced by other GNBs and thus increases ceftolozane's coverage, including several ESBL-producing strains, particularly of the CTX-M family, and in part strains producing AmpC.[15,106] Ceftolozane/tazobactam does not have appreciable activity against GNBs producing *Klebsiella pneumoniae* carbapenemases (KPCs) or MBLs or class D beta-lactamases (e.g., OXA-carbapenemases).[107,108] Resistance mechanisms to the action of ceftolozane/tazobactam include production of class A beta-lactamases (some of ESBLs and most of KPCs), class B MBLs, class D carbapenemases (OXA-48-like), and hyperproduction of AmpC (not in *P. aeruginosa*).[43,53]

PK/PD. Ceftolozane/tazobactam has dose-independent linear PKs and has a relatively short half-life of 2.7 hours in healthy, uninfected adults, without significant accumulation after multiple doses.[109] The protein binding of ceftolozane/tazobactam is low (16%–21% for ceftolozane and 30% for tazobactam).[110] It is renally cleared with minimal metabolism, and the clearance of tazobactam is not affected by the combination with ceftolozane. Both ceftolozane and tazobactam penetrated well into the lung parenchyma, with the epithelial lining fluid (ELF) to plasma area under the inhibitory curve (AUC) ratio of 48% and 44%, respectively.[111,112]

Clinical efficacy. In a phase II RCT (NCT01147640) that compared ceftolozane/tazobactam in combination with metronidazole with meropenem in cIAIs, the microbiologic success was 100% against *P. aeruginosa* (100%), and *K. pneumoniae* and 89.5% against *Escherichia coli* (89.5%).[113] In a phase III RCT (NCT01345929) in patients with cUTIs, superiority was demonstrated for ceftolozane/tazobactam compared with levofloxacin, with microbiologic eradication at test-of-cure (TOC) 88.9% and 74.4%, respectively.[43,114] ASPECT-NP, a double-blind phase III RCT (NCT02070757) that compared ceftolozane/tazobactam with meropenem (3 g ceftolozane/tazobactam versus 1 g meropenem IV every 8 hours for 8–14 days) in patients with gram-negative nosocomial pneumonia (VAP or ventilated HAP) demonstrated noninferiority of ceftolozane/tazobactam on both clinical cure at TOC and mortality at day 28.[115] It is noteworthy that based on the ELF/plasma ratio, the dose used in the ASPECT-NP trial is double the dose used for cIAIs and cUTIs.[115,116] Regarding resistance development, in the ceftolozane/tazobactam arm of a phase III RCT, no emergence of nonsusceptibility was reported for any participant with susceptible *P. aeruginosa* at baseline.[115,117]

Dosage. See Table 107.1 for dosages.[118–121] The recommended duration of treatment is 7 days for cUTIs, including acute pyelonephritis; 4–14 days for cIAIs; and 8–14 days for HAP/VAP.[121]

Adverse events. Mild to moderate nausea, headache, constipation, diarrhea, and pyrexia were the most common (≥3%) adverse reactions in pooled phase III RCTs of cUTIs and cIAIs.[122] There are warnings related to decreased efficacy in a subgroup of patients with baseline CrCl of 30–50 mL/min, serious anaphylactic reactions in patients with hypersensitivity to beta-lactams, and *C. difficille*–associated diarrhea.[121]

TABLE 107.1 Recommended Adult Dosing Regimens and Dosing Alterations*

Antimicrobial Agents	Adult Dose§§	Dosing Alteration (Renal or Hepatic Impairment)
B-Lactams ±		
Ampicillin/ sulbactam	1.5–3 g q6h *Note: Off-label doses of 24 g have been suggested for CRAB (18 g ampicillin + 6 g sulbactam)*	CrCl 15–29 mL/min: 1.5–3 g q12h CrCl 5–14 mL/min: 1.5–3 g q24h CRRT: 1.5–3 g q8–12h
Ticarcillin/ clavulanate	3.1 g q4–6h	CrCl 30–60 mL/min: 3.1 g LD, then 2 g q4h CrCl 10–30 mL/min: 3.1 g LD, then 2 g q8h CrCl <10 mL/min: 3.1 g LD, then 2 g q12h CRRT: 2–3.1 g q6–8h
Piperacillin/ tazobactam	2.25–4.5 g q6h	CrCl 40–60 mL/min: 3.75–4.5 g q6h CrCl 20–40 mL/min: 2.25–3.375 g q6h CrCl: <20 mL/min: 2.25 g q6–8h CRRT: 4.5 g q6–8h

TABLE 107.1 Recommended Adult Dosing Regimens and Dosing Alterations—cont'd

Antimicrobial Agents	Adult Dose§§	Dosing Alteration (Renal or Hepatic Impairment)
Ertapenem	1 g q24h	CrCl <30 mL/min: 500 mg q24h CRRT: 500 mg–1 g q24h
Doripenem	500 mg q8h	CrCl 30–50 mL/min: 250 mg q8h CrCl 10–29 mL/min: 250 mg q12h CRRT: 500 mg q8h
Aztreonam	1–2 g q8h	CrCl 10–29 mL/min: 500 mg–1 g q8h CrCl <10 mL/min: 500 mg–1 g q12h CRRT: 2 g q12h
Cefiderocol	Cr Cl 90–<120: 2 g q8h (3-hr IV infusion) Augmented CrCl ≥120: 2 g q8h	CrCl 60–<90: 2 g q8h CrCl 30–<60: 1.5 g q8h CrCl 15–< 30: 1 g q8h ESRD (CrCl <15) with/without IHD: 0.75 g q12h CRRT: Base the dosage on the effluent flow rate: • ≤2 L/hr: 1.5 g q12h • 2.1–3 L/hr: 2 g q12h • 3.1–4 L/hr 1.5 g q8h • ≥4.1 L/hr: 2 g q8h
Aminoglycosides†		
Gentamicin and tobramycin	1.5–2.5 mg/kg q8h or 5 mg/kg q24h once-daily dose recommended	CrCl 40–59 mL/min: 1.5–2.5 mg/kg q12h CrCl 20–39 mL/min: 1.5–2.5 mg/kg q24h CrCl <20 mL/min: Redose when trough levels <1 μg/mL CRRT: Redose when trough levels <1 μg/mL
Amikacin	7.5 mg/kg q8h or 15 mg/kg q24h once-daily dose recommended	CrCl 40–59 mL/min: 5–7.5 mg/kg q12h CrCl 20–39 mL/min: 5–7.5 mg/kg q24h CrCl <20 mL/min: Redose when trough levels <5 μg/mL CRRT: Redose based on trough levels <5 μg/mL
Plazomicin≠	15 mg/kg q24h	CrCl ≥60 and <90: 15 mg q24h CrCl ≥30 and <60: 10 mg q24h CrCl ≥ 15 and <30: 10 mg q48h CrCl <15 and CRRT: insufficient information to recommend a dosage regimen
Fluoroquinolones		
Ciprofloxacin	400 mg q8–12h	CrCl 5–29 mL/min: 200–400 mg q18–24 h CRRT: 400 mg q12h
Levofloxacin	750 mg q24h	CrCl 20–49 mL/min: 750 mg q48h CrCl 10–19 mL/min: 750 mg initially, then 500 mg q48h CRRT: 750 mg initially, then 500–750 mg q24h
Omadacycline^	LD on D1: 200 mg once (60-min IV infusion) or 100 mg twice (30-min IV infusion) Maintenance dose: 100 mg q24h (30-min IV infusion)	*No dosage adjustment is warranted in patients with renal or hepatic impairment*
Polymyxins		
Colistin (polymyxin E)‡	LD of CMS: 300 mg CBA (~9 million IU) Daily maintenance dose of CMS (CrCl ≥90): 360 mg CBA daily dose (10.9 million IU)	CrCl / mg CBA daily dose[4] / million IU daily dose[4] CrCl 80–<90: 340 / 10.30 CrCl 70–<80: 300 / 9.00 CrCl 60–<70: 275 / 8.35 CrCl 50–<60: 245 / 7.40 CrCl 40–<50: 220 / 6.65 CrCl 30–<40: 195 / 5.90 CrCl 20–<30: 175 / 5.30 CrCl 10–<20: 160 / 4.85 CrCl 5–<10: 145 / 4.40 CrCl : 0 130 / 3.95 Intermittent HD: On a nondialysis day, CMS dose of 130 mg CBA/day (~3.95 million IU/day); on a dialysis day, administration of a supplemental dose of CMS 40 mg CBA (~1.2 million IU) or 50 mg CBA (~1.6 million IU) for a 3- or 4-hour IHD session, respectively; SLED: 10% of the CMS dose should be added to the baseline daily dose per SLED-hour CRRT: CBA 440 mg/day (~13.3 million IU/day)
Polymyxin B‡	LD: 2.0–2.5 mg/kg for polymyxin B (equivalent to 20,000–25,000 IU/kg) Maintenance dose: 1.25–1.5 mg/kg (equivalent to 12,500–15,000 IU/kg) q12h	Unnecessary renal dose adjustments may lead to underexposure and clinical failure

Tetracyclines		
Tigecycline	Initial dose 100 mg, then 50 mg q12h (30–60 min IV infusion) *Off-label high dose:* Initial dose 200 mg, then 100 mg q12h	*Severe hepatic impairment (Child-Pugh C):* Initial dose 100 mg followed by 25 mg q12h
Eravacycline	1 mg/kg q12h (1-hr IV infusion)	*Severe hepatic impairment (Child-Pugh C):* On D1: 1 mg/kg q12h From D2: 1 mg/kg q24h *Concomitant use of a strong cytochrome P450 isoenzymes (CYP)3A inducer:* 1.5 mg/kg q12h
Miscellaneous		
Fosfomycin	[5]Dose for CrCl >80: 12–24 g in 2–3 divided doses	*% of the considered appropriate dose if the renal function was normal* CrCl 40–<30: 70% (in 1–2 divided doses) CrCl 30–<20: 60% (in 1–2 divided doses) CrCl 20–<10: 40% (in 1–2 divided doses) CrCl 10: 20% (in 1–2 divided doses) IHD q48h: 2 g at the end of each HD session Postdilution CVVHF: no dose adjustment Predilution CVVHF or other types of CRRT: no available data

CBA, Colistin base activity; *CMS,* colistimethate (also known as colistin methanesulfonate); *CRAB:* carbapenem-resistant *A. baumannii; CrCl,* creatinine clearance; *CRRT,* continuous renal replacement therapy; *CVVHF,* continuous venovenous hemofiltration; *ESRD,* end-stage renal disease; *h,* hours; *HD,* hemodialysis; *IHD,* intermittent hemodialysis; *LD,* loading dose; *min,* minutes; q, every; *SLED:* sustained low-efficiency dialysis,

*Data compiled from package insert information and references included in the relevant sections of the chapter.

CrCl in mL/min, calculated using the Cockcroft-Gault formula.

±Renal replacement therapy can efficiently eliminate most beta-lactam antimicrobial agents.

†For aminoglycoside dosing, adjusted body weight should be used: (0.45 × [total body weight − ideal body weight] + ideal body weight). For plazomicin, however, the dosage should be calculated using TBW; for patients with TBW greater than IBW by ≥25%, adjusted body weight should be used.

‡For colistin, dosing should be based on adjusted body weight. For polymyxin B, the dose should be based on total body weight; PK data do not support capping an upper absolute loading dose in milligrams in obese patients, but there are limited data with administration of >200 mg per infusion.

§§All administration is intravenous; dosing is for serious, life-threatening infections.

∞In critically ill patients with augmented renal clearance, dose of 3 g/8 h achieved respective PD targets.

#On hemodialysis days, administer the dose at the earliest possible time after completion of dialysis; for critically ill patients undergoing CVVHF, a population PK model-guided evaluation of ceftolozane/tazobactam dosing suggested a front-loaded regimen: a single loading dose of 3 g followed by 0.75 g/8 h.

≠Assessment of creatinine clearance before initiation and daily afterwards is recommended; for TDM, the plasma collection time is approximately 30 minutes before the second dose, targeting to maintain plasma trough concentrations <3 μg/mL.

^Omadacycline must not be administered with any solution containing multivalent cations (e.g., calcium and magnesium) through the same intravenous line.

[1]IV infusion of 2 hours; in patients with a supranormal CrCl (>150 mL/min), prolongation of the infusion duration to 4 hours is recommended.

[2]IV infusion of 5–60 minutes in patients with supranormal CrCl and standard dose, an infusion time of 60 minutes may be preferable.

[3]High doses for cSSTI confirmed or suspected to be caused by *S. aureus* with an MIC to ceftaroline of 2 mg/L or 4 mg/L to ceftaroline; high dose to be administered as 120-minute IV infusion.

[4]To achieve a desired target plasma colistin $C_{ss,avg}$ of 2 mg/L for patients with narrow windows of creatinine clearance; daily dose administered in two divided doses 12 hours apart; in cases of renal impairment, the loading dose and the maintenance dose should be adapted to renal function that should be monitored daily.

[5]The high-dose regimen in three divided doses should be used in severe infections known or expected to be caused by less susceptible bacteria. Acute osteomyelitis and nosocomial lower respiratory tract infections: 12–24 g in two to three divided doses; cUTI: 12–16 g in two to three divided doses; Bacterial meningitis: 16–24 g in three to four divided doses. Safety data for doses >16 g/day are limited; special caution advised. Individual doses must not exceed 8 g.

Ceftazidime/Avibactam

Ceftazidime/avibactam is a combination of the cephalosporin ceftazidime and the novel beta-lactamase inhibitor avibactam.[102] It was approved by the FDA in 2015 for the indications of cUTIs, including acute pyelonephritis, and, in combination with metronidazole, cIAIs, and in 2018 it was approved for hospital-acquired bacterial pneumonia (HABP)/ventilator-associated bacterial pneumonia (VABP).[123,124]

Mode of Action, Spectrum of Activity, and Resistance Mechanisms. Although ceftazidime is resistant to hydrolysis by several older narrow-spectrum beta-lactamases (such as TEM-1 or SHV-1) or by most of the class D carbapenemases, it is hydrolyzed by class A ESBLs and class C beta-lactamases (AmpC type) and carbapenemases, such as KPCs and MBLs.[43,53] Avibactam is a diazabicyclooctane, a first-in-class non-beta-lactam beta-lactamase reversible inhibitor without intrinsic antimicrobial activity, which binds covalently to beta-lactamases by a process that, contrary to beta-lactam beta-lactamase inhibitors, does not involve hydrolysis.[43,101,125,126] When avibactam is combined with ceftazidime, it protects ceftazidime from hydrolysis by class A and C beta-lactamases and increases its antimicrobial activity.[43,125,127] In in vitro studies, it is active against >99.9% of meropenem-, ceftazidime- and piperacillin/tazobactam-resistant isolates of *Enterobacteriaceae* and *P. aeruginosa,* including KPC and OXA-48 producers.[127,128] Although ceftazidime/avibactam covers ESBL-producing and most KPC-producing isolates, it is inactive against MBL-producing ones.[129–131] The addition of avibactam does not provide any additional activity towards the limited antimicrobial spectrum of ceftazidime against gram-positive microorganisms and anaerobes.[43] Combinations of ceftazidime/avibactam with aztreonam, meropenem, amikacin, and fosfomycin have been reported to be synergistic in vitro against MDR *K. pneumoniae* and *P. aeruginosa.*[132] Regarding resistance development, the main mechanism to ceftazidime/avibactam includes production of class B MBLs, hyperexpression of efflux pumps, porin alteration, increased expression of the *eblaKPC* gene or mutations on-loop of KPC enzymes, whereas mutations in PBPs occur rarely.[53]

PK/PD. Ceftazidime/avibactam has linear PKs.[43] The V_d after multiple doses is 17 L and 22.2 L for ceftazidime and avibactam, respectively.[123] The protein binding of ceftazidime/avibactam is low (<10% for ceftazidime and 5.7%–8.2% for avibactam).[123] It is primarily renally excreted as unchanged drug (>80% of ceftazidime and >95% of avibactam).[133] It has modest lung penetration, and in a phase I study of healthy subjects, the mean ELF/plasma ratio was 35% and 31% for avibactam and ceftazidime, respectively, and the concentration increased in a dose-dependent way.[134]

Clinical efficacy. Ceftazidime/avibactam demonstrated noninferiority in several phase III RCTs: versus doripenem in a phase III RCT (RECAPTURE; NCT01595438) in hospitalized adult patients with cUTIs; versus the best available treatment (BAT) in patients with cUTIs or cIAIs caused by ceftazidime-resistant strains (REPRISE; NCT01644643); combined with metronidazole versus meropenem in patients with cIAIs (NCT01726023); and versus meropenem in patients with HAP, including VAP (REPROVE; NCT01808092).[135–138]

Dosage. See Table 107.1 for dosages.[123,139] The recommended duration of treatment is 5–14 days for IAIs and 7–14 days for cUTIs and HABP/VABP.[123,139]

Adverse events. Ceftazidime/avibactam is generally well tolerated, usually with mild adverse events. The most frequent events were gastrointestinal disturbances, such as diarrhea and/or nausea and/or vomiting (≥5% in patients with cIAIs (combined with metronidazole) and in patients with HABP/VABP and 3% in patients with cUTIs).[123] Other adverse events include hypokalemia, liver function test alteration, headache, and fever.[43] Less common (<1%) adverse events include blood count alterations such as eosinophilia, thrombocytosis or thrombocytopenia, candidiasis, and seizures.[123] There is a warning about decreased efficacy in patients with cIAIs with baseline CrCl of 30–50 mL/ min and a recommendation of at least daily monitoring of CrCl and dose adjustment accordingly.[123]. In the phase III trial in patients with cIAIs, mortality in the subgroup with baseline CrCl 30–50 mL/min was 19.5% and 7% for the ceftazidime/avibactam plus metronidazole arm and the meropenem arm, respectively, but patients in the ceftazidime/avibactam arm received 33% lower daily doses than suggested.[123] There are also warnings related to hypersensitivity reactions, *C. difficile* diarrhea, and CNS reactions, especially in patients with renal impairment.[123]

Meropenem/Vaborbactam

Meropenem/vaborbactam is a combination of the broad-spectrum carbapenem meropenem and the novel cyclic boronic acid–based beta-lactamase inhibitor vaborbactam.[101] Approval was granted by the FDA in 2017 for the indication of cUTIs.[140] In 2018 the EMA granted marketing authorization for meropenem/vaborbactam for the indications of cUTIs, including pyelonephritis, cIAIs, HAP (including VAP), bacteremia associated or suspected to be associated with any of the previously mentioned indications, and infections caused by aerobic GNBs with limited treatment options.[141,142]

Mode of Action, Spectrum of Activity, and Mechanisms of Resistance. Meropenem covers a wide range of gram-positive, gram-negative, and anaerobic bacteria and is stable to hydrolysis by penicillinases and cephalosporinases.[43] Nevertheless, it is vulnerable to hydrolysis by other beta-lactamases, such as serine beta-lactamases and MBLs.[101] Vaborbactam exerts potent inhibition of serine beta-lactamases of class A (including ESBLs and KPCs) and class C (including AmpC) by forming reversible covalent bonds with them, and although it does not have intrinsic antimicrobial activity, when combined with meropenem, it provides protection to meropenem against degradation by these enzymes.[101,143,144] Vaborbactam does not inhibit class B (MBL)– and class D (OXA)-beta-lactamase–producing strains.[43,101,106,145] Therefore the spectrum of activity of meropenem/vaborbactam is that of meropenem, supplemented with activity against several serine beta-lactamase–producing strains.[43,101,143] Combined with vaborbactam, a decrease of meropenem's MIC against most *Enterobacteriaceae* ranging from 2- to >1024-fold, in addition to activity close to 100% against KPC-positive *Enterobacteriaceae* isolates, have been reported.[146,147] Vaborbactam does not increase the activity of meropenem against strains of *P. aeruginosa* with MDR phenotypes mediated by porin changes and/or efflux mechanism changes or against *A. baumannii* strains producing primarily class D (OXA-type) beta-lactamases.[43,147] Also, resistance to meropenem/vaborbactam has been reported in *S. maltophilia, Elizabethkingia,* and *Aeromonas.*[43,148] It should be noted that vaborbactam does not enhance meropenem's activity against gram-positive bacteria and anaerobes.[43,147]

The main mechanisms of resistance to meropenem/vaborbactam include class B MBLs, class D carbapenemases (OXA-48-like), porin alterations (e.g., loss of outer membrane porins OmpK36 and 35 used by vaborbactam to penetrate the bacterial cell, decreased expression of other porins), and hyperexpression of efflux pumps.[43,53] In summary, meropenem/vaborbactam is active against most *Enterobacteriaceae,* particularly KPC-producing strains, in addition to ESBL- and AmpC-producing ones, but is inactive against MBL- and class D–producing strains, whereas for *P. aeruginosa* it has similar activity as meropenem.[53]

PK/PD. The V_d of meropenem/vaborbactam at steady state is 20.2. L and 18.6 L, the protein binding is 2% and 33%, and the half-life is 1.22 and 1.68 hours for meropenem and vaborbactam, respectively.[43,140] Meropenem/vaborbactam is primarily renally excreted.[140,141] Meropenem has a minor pathway of metabolism by hydrolysis (22%),

whereas vaborbactam is not metabolized, but excreted unchanged in the urine.[140,141] The lung disposition profile is favorable, with ELF-to-plasma unbound concentration ratios of 65% for meropenem and 79% for vaborbactam in healthy subjects.[43,149]

Clinical efficacy. Meropenem had similar efficacy to piperacillin/tazobactam (clinical success and microbiologic eradication) in a phase III RCT (TANGO I study; NCT02166476) in patients with cUTIs.[150] In another open-label, phase III RCT (TANGO II study; NCT02168946) in patients with cUTIs, IAIs, HABP/VABP, or bacteremia caused by CRE, meropenem/vaborbactam achieved increased clinical cure rate and decreased 28-day all-cause mortality versus BAT, along with decreased nephrotoxicity.[151]

Dosage. See Table 107.1 for dosages.[140,141] The recommended duration of treatment is up to 14 days: 5–10 days for cUTIs and IAIs, 7–14 days for HAP/VAP, and duration according to the site of infection for bacteremia and MDR GNB infections with limited treatment options.[140,141]

Adverse events. Meropenem/vaborbactam has a favorable safety profile, similar to comparators. In the phase III TANGO II clinical trial, the most common (≥3%) adverse events reported for meropenem/vaborbactam included headache, phlebitis, and diarrhea, and other adverse events occurring ≥1% included hypersensitivity, nausea, increases of alanine and aspartate aminotransferases, pyrexia, and hypokalemia.[140,151,152] There are warnings related to hypersensitivity reactions, seizures, and other CNS reactions; *C. difficile*–associated diarrhea; and decreased levels of valproic acid when coadministered with meropenem.[140]

Imipenem/Cilastatin/Relebactam

Imipenem/cilastatin/relebactam is a novel triple antimicrobial agent that combines the carbapenem imipenem, the dehydropeptidase inhibitor cilastatin, and the novel beta-lactamase inhibitor relebactam.[106] It was approved by the FDA in 2019 for the cUTIs, including pyelonephritis, and cIAIs caused by susceptible GNBs when there are limited or no alternative options; in 2020 it was approved for HABP/VABP as well.[153,154] EMA approval was granted in 2020 for the indications of HAP (including VAP), bacteremia with to (or suspected to be associated with) HAP/VAP, and infections caused by gram-negative microorganisms with limited treatment options.[155,156]

Mode of Action, Spectrum of Activity, and Resistance Mechanisms. Imipenem/cilastatin/relebactam covers *Enterobacteriaceae* and lactose nonfermenting GNBs.[101] Relebactam, which is structurally related to avibactam, inhibits class A and C beta-lactamases and enhances the antimicrobial spectrum of imipenem/cilastatin, increasing the activity of imipenem against most *Enterobacteriaceae* and *P. aeruginosa,* as shown by a 2- to 128-fold and 8-fold decrease of MIC, respectively.[157–159] Imipenem/cilastatin/relebactam is active against *E. coli* (including ESBL- and KPC-producing isolates), *K. pneumoniae* (including ESBL, KPC, AmpC, and imipenem-resistant *K. pneumoniae* expressing AmpC beta-lactamases or KPC carbapenemases), and *P. aeruginosa* isolates with AmpC expression or outer membrane protein D (OprD) deficiency.[101,160,161] Nevertheless, it is inactive against *A. baumannii;* imipenem-resistant isolates of *Enterobacteriaceae* producing IMPs, VIMs, or NDM MBLs; and *P. aeruginosa* producing IMP or VIM MBLs.[101] Moreover, although there is a theoretical background for activity against OXA-producing isolates, the reported data are variable, and a quite recent surveillance study failed to demonstrate such activity.[162] It has similar gram-positive activity as imipenem/cilastatin. The main mechanisms of resistance to imipenem/cilastatin/relebactam include production of class B MBLs, class D carbapenemases (OXA-48-like), specific class A carbapenemases (such as GES), hyperexpression of KPC, and porin alterations.[53] In summary, imipenem/cilastatin/relebactam can be used for various resistant *Enterobacteriaceae* (such as ESBL-, KPC-, and AmpC-producing ones), excluding MBL- and class D–producing strains, and for carbapenem-resistant *P. aeruginosa,* as relebactam reinstates imipenem's activity in 80% of imipenem-resistant *P. aeruginosa* strains.[53]

PK/PD. The best PD predictor of activity of relebactam in animal and in vitro models is $fAUC_{0-24hr}$/MIC.[154] The half-life of relebactam is approximately 1.2 hours.[154] The steady-state V_d of imipenem/cilastatin/relebactam is 24.3 L, 13.8 L, and 19 L, respectively, and the protein binding is 20%, 40%, and 22%, respectively, and independent of concentration.[154] Imipenem/cilastatin/relebactam is mainly renally excreted by glomerular filtration and active tubular secretion.[155] Relebactam has minimal metabolism, and >90% is excreted unchanged in the urine, whereas the percentage of imipenem and cilastatin that is excreted unchanged is 63% and 77%, respectively.[154] Relebactam and imipenem have similar penetration to ELF, with exposure relative to plasma 55%.[163]

Clinical efficacy. The FDA granted approval to imipenem/cilastatin/relebactam based on the results of two phase II RCTs that compared it with imipenem/cilastatin in patients with cIAIs (NCT01506271) and cUTIs (NCT01505634).[164–165] Imipenem/cilastatin/relebactam also demonstrated noninferiority compared with piperacillin/tazobactam in a phase III RCT (RESTORE IMI-2; NCT02493764) conducted in bacterial HAP and VAP.[166] In another phase III RCT (RESTORE IMI-1 study; NCT02452047) that included only infections by imipenem-nonsusceptible but colistin- and imipenem/cilastatin/relebactam-susceptible pathogens (HAP/VAP, cUTIs, cIAIs), imipenem/cilastatin/relebactam monotherapy had similar efficacy to an imipenem/cilastatin and colistin combination.[167]

Dosage. For dosages, see Table 107.1.[154] The FDA recommends a duration of treatment ranging from 4 to 14 days depending on the severity and location of the infection and clinical response, whereas the EMA recommends 7–14 days for HAP/VAP.[154,155]

Adverse events. Treatment-related adverse events in the RESTORE IMI-2 trial were 11.7% and 9.7% for imipenem/cilastatin/relebactam and piperacillin/tazobactam, respectively.[166] In RESTORE IMI-1, the serious adverse events of the imipenem/cilastatin/relebactam arm were 16% compared with 31% of the imipenem/cilastatin plus colistin arm, and the nephrotoxicity was 10% and 56%, respectively.[167] The most common (≥2%) adverse events of imipenem/cilastatin/relebactam include gastrointestinal disturbances (diarrhea, nausea, vomiting), increases of alanine and aspartate aminotransferases, infusion site reactions/phlebitis, pyrexia, and hypertension.[154] Other adverse events include blood and lymphatic system disorders (agranulocytosis, increased eosinophils, hemolytic anemia, seizures, hepatobiliary disorders including jaundice and liver failure, rash, increased lactate dehydrogenase, and positive Coombs test).[154] There are warnings regarding hypersensitivity, seizures, and CNS adverse reactions; avoidance of concomitant use with valproic acid because of the risk of decreased serum concentrations of valproic acid and breakthrough seizures; and *C. difficile* diarrhea.[154] Concomitant use of imipenem/cilastatin/relebactam with ganciclovir should be avoided (unless the expected benefit outweighs the risk), as there are reports of cases of generalized seizures when used with imipenem/cilastatin.[154]

Novel Siderophore Cephalosporins

Cefiderocol is the first siderophore cephalosporin, and in 2019, was granted approval by the FDA for the treatment of adults with cUTIs, and in 2020 it was approved also for the treatment of bacterial HAP and VAP caused by susceptible GNBs: *A. baumannii* complex, *E. coli*, *Enterobacter cloacae* complex, *K. pneumoniae*, *P. aeruginosa,* and *Serratia marcescens.*[168,169] The EMA approved cefiderocol in 2020.[170,171]

Mode of Action, Spectrum of Activity, and Resistance Mechanisms. Cefiderocol has a unique structure, that is, combination of a catechol-type siderophore with a cephalosporin core that has similar side chains to cefepime and ceftazidime, which enhances its stability against many beta-lactamases, such as ESBLs and carbapenemases. Cefiderocol chelates with ferric ion and, apart from entering the gram-negative bacteria by passive diffusion via membrane porins like the other beta-lactams, it uses their iron uptake system to penetrate the siderophore-iron complex pathway, bypassing their outer membrane barriers. Its unique mode of action enables cefiderocol to overcome resistance by decreased porin expression. Moreover, the chelation with iron provides cefiderocol resistance to hydrolysis by all beta-lactamases (Ambler class B included).[1,101] As soon as it is within the periplasmic space, cefiderocol dissociates from iron and binds to PBPs, particularly PBP3, inhibiting peptidoglycan synthesis like the other beta-lactams.[172]

Cefiderocol is active against a wide range of gram-negative bacteria, including both lactose-fermenting, such as *E. coli*, *Klebsiella* spp., *Enterobacter* spp., *Proteus* spp., *Providencia* spp., *Salmonella* spp., *Yersinia* spp., and *Vibrio* spp., and nonfermenting GNBs, such as *Acinetobacter* spp., *Pseudomonas* spp., *Burkholderia* spp., and *S. maltophilia*. Cefiderocol is stable against many beta-lactamases, such as ESBLs (e.g., CTX-M) and carbapenemases (e.g., Ambler class B metallo-beta-lactamases [NDM, VIM, IMP] and serine-type beta-lactamases [OXA-23, OXA-48-like, OXA-51-like, OXA-58]).[173] However, cefiderocol has weak in vitro activity against aerobic gram-positive bacteria and anaerobic bacteria, demonstrating high MICs.[173,174] Reduced susceptibility to cefiderocol may occur via the mutation or differential expression of specific iron-transporters.[175]

PK/PD. The PD target best associated with the efficacy of cefiderocol is similar to the other cephalosporins. Cefiderocol appears to display linear pharmacokinetics, its V_d is 18 L, it has an elimination half-life of 2.72 hours, the protein binding (mainly albumin) is 40%–60%, and it is primarily renally excreted unchanged.[174] Cefiderocol appears to distribute fast and in parallel from plasma to ELF, with lung penetration of approximately 24%, whereas the penetration to alveolar macrophage seems to be much lower; further studies in critically ill patients are needed.[174,176]

Clinical efficacy. In an open-label phase III RCT (CREDIBLE-CR study; NCT02714595) conducted in critically ill patients with infections caused by carbapenem-resistant GNBs (sepsis/bloodstream infection, cUTI, healthcare–associated pneumonia [HCAP]/HAP/VAP), cefiderocol was compared with BAT.[177] Patients in the cefiderocol arm received monotherapy, whereas the BAT arm mostly received combination therapy (more frequently, colistin-based regimens).[172] In the CR-mITT population, clinical cure rates at TOC were comparable between arms overall and for each individual disease state, but all-cause mortality at day 14, day 28, and day 49 was numerically higher in the cefiderocol arm, particularly in patients with HCAP/HAP/VAP and bloodstream infections/sepsis.[172] The greater mortality imbalance was at day 49 in patients with *A. baumannii*.[172] In another phase III RCT (APEKS-NP study; NCT03032380) cefiderocol was compared with meropenem (both combined with linezolid for at least 5 days) in patients with HAP, VAP, or HCAP and demonstrated noninferiority with respect to mortality.[178,179] A phase II RCT that compared cefiderocol with BAT in patients with bloodstream infections is still ongoing.[180]

Dosage. For dosages, see Table 107.1.[170] The recommended duration is 7–14 days.[170]

Adverse events. Based on data of the clinical trials, cefiderocol appears to be well tolerated and with a similar safety profile as other cephalosporins. In the CREDIBLE-CR trial the reported treatment-related adverse events were 14.9% in the cefiderocol arm versus 22.4% in the BAT arm; the most common adverse events for cefiderocol, with incidence ≥10%, were diarrhea, increased transaminases, pleural effusion, and chest pain. It should be noted that cefiderocol has a labeled warning for an increase in all-cause mortality that was observed in patients treated with cefiderocol compared with BAT in the CREDIBLE-CR trial; the increased mortality occurred in patients with nosocomial pneumonia, bloodstream infections, or sepsis.[170,177]

FLUOROQUINOLONES

Fluoroquinolones were discovered in the early 1960s and are antimicrobial agents with a broad spectrum of activity. The most commonly used members of the class are ciprofloxacin, levofloxacin, and moxifloxacin, and recently the use of a new fluoroquinolone, delafloxacin, was approved.

Mode of Action of Fluoroquinolones

The action of fluoroquinolones is exerted by bacterial DNA synthesis inhibition; bacterial cell death follows this action.[181] Fluoroquinolones target two members of the topoisomerase enzymatic class, namely DNA gyrase and topoisomerase IV, that are essential for DNA replication: it appears that they trap the enzyme-DNA complexes after strand breakage and before resealing, generating a DNA break that the cell is unable to repair.[182] In gram-negative bacteria, the DNA gyrase is considered the most susceptible to fluoroquinolone inhibition, whereas in gram-positive bacteria, topoisomerase IV is considered the most susceptible one.[181]

Spectrum of Activity of Fluoroquinolones

Fluoroquinolones have activity against a wide range of both gram-positive and gram-negative organisms.[181] Levofloxacin and moxifloxacin are potent against penicillin-sensitive or -resistant *S. pneumoniae* but inactive against MRSA. Over the years, increasing resistance has reduced the usefulness of fluoroquinolones against gram-negative bacteria, especially in the critical care setting. Ciprofloxacin is considered the most potent fluoroquinolone against gram-negative bacteria, with the lowest MIC values, but a higher levofloxacin dose can be used to achieve similar efficacy. For common resistant ICU GNBs, fluoroquinolones are used in combination with beta-lactams.

Resistance to Fluoroquinolones

Mutations in target enzymes (DNA gyrase and topoisomerase IV) and in efflux pumps are the main mediators of resistance to fluoroquinolones.[183] Specifically, amino acid substitutions in genes encoding subunits of the target enzymes lead to structure alterations and, consequently, decreased fluoroquinolone-binding affinity, whereas in gram-negative bacteria, mutations that alter the outer membrane porin proteins can decrease the passive diffusion of fluoroquinolones into the cells.[183] It should be noted that mutations are selected first in the more susceptible target (i.e., A gyrase in gram-negative bacteria and topoisomerase IV in the gram-positive ones).[183] Additional mutations increase the resistance further, with the most resistant strains having mutations in several genes. Fluoroquinolone resistance can be also mediated by plasmids that protect cells from the lethal effects of quinolones.[183]

PK/PD of Fluoroquinolones

Fluoroquinolones have excellent oral bioavailability that approaches 100%.[184] The large V_d after rapid oral absorption suggests adequate

tissue concentrations. Fluoroquinolones are moderately lipophilic antibiotics and, apart from levofloxacin, their V_d generally is not affected by critical illness. It should be noted that in order to avoid chelation, oral fluoroquinolones should be administered at least 2 hours before or 6 hours after medications containing polyvalent cations (e.g., magnesium- or aluminum-containing antacids, sucralfate, iron supplements, or multivitamins containing zinc or iron).[184] Steady-state concentrations are achieved in 24, 48, and 72 hours for ciprofloxacin, levofloxacin, and moxifloxacin, respectively.[8] Protein binding for most of the members of the class is moderate to low. Fluoroquinolones have good penetration into multiple sites of the human body.[181] Ciprofloxacin and levofloxacin are excreted renally as unmetabolized drug, necessitating dosing adjustments in renal insufficiency.[181] Moxifloxacin does not require dose adjustments in renal impairment and, although is mainly metabolized in the liver, does not need adjustment in hepatic impairment either.[181]

Fluoroquinolones exhibit "concentration-dependent" bactericidal activity, with a steady-state AUC (AUC 0–24)/MIC ratio representing the best predictor of clinical efficacy.[8] Nevertheless, it should be noted that for optimal bactericidal activity, higher *C*max/MIC ratios (> 8–20 xMIC) might also be necessary. Higher AUC 0–24/MIC (≥125) are needed against gram-negative organisms compared with gram-positive ones (25–30).[185] On the other hand, for resistance emergence suppression in infections by GNBs, even higher AUC 0–24/MIC ratios (>100–200) are needed.[8]

Dosing and Monitoring of Fluoroquinolones

In critically ill patients a fluoroquinolone dosing regimen that maximizes the AUC 0–24/MIC (i.e., use of a loading dose and higher maintenance doses) might be required. A recent position paper on TDM use in critical care neither recommends nor discourages the use of TDM.[8] Taking into consideration the high PK variability in critically ill patients and the high propensity of resistance emergence, the expert panel notes that TDM might be useful, especially when MICs are close to breakpoint.[8] Fluoroquinolone TDM monitoring should be AUC/MIC based, with two samples taken 2 hours and 6 hours after dosing, with a target of *f*AUC0–24/MIC ≥80. In the case of *C*max/MIC monitoring, one sample should be taken 30 minutes after the end of infusion, targeting for *C*max/MIC ≥8–12. Regarding toxicity, the clinical PK/PD thresholds are unclear.[8]

Adverse Events of Fluoroquinolones

The most common adverse events are gastrointestinal and CNS stimulation.[181] Although less common, fluoroquinolones have also been related to a range of possible severe adverse events.[181] Disabling and potentially irreversible serious adverse reactions that have occurred together have been associated with fluoroquinolone use, including tendinitis and tendon rupture (such as Achilles tendon, rotator cuff, biceps, thumb), peripheral neuropathy, and CNS effects (such as insomnia, seizures, hallucinations, insomnia, depression, and severe headaches).[181,184] Fluoroquinolones should be avoided in patients with myasthenia gravis, as they can cause exacerbation.[181,184] Hypersensitivity reactions and *C. difficile* diarrhea may occur with administration of fluroquinolones.[181,184] Fluoroquinolones may alter the serum glucose concentration (hypoglycemia or hyperglycemia), especially in patients with a history of diabetes on hypoglycemic agents.[181] QTc interval prolongation and arrhythmias, including potentially fatal torsades de pointes arrhythmias, have been associated with the use of ciprofloxacin, levofloxacin, and moxifloxacin, particularly in patients with uncorrected hypokalemia or receiving class IA or III antiarrythmics.[184,186,187] There are reports of fluoroquinolone-associated seizures; however, certain causality is still under debate.[188–191] A warning was issued by the FDA in 2016 noting that in certain infections risks may outweigh the benefits of fluoroquinolone use.[192] Fluoroquinolones are a frequent target of antimicrobial stewardship programs aiming to optimize prescribing and decrease related adverse events.[193]

Novel Approved Fluoroquinolones

Delafloxacin

Delafloxacin, an anionic fluoroquinolone, was approved by the FDA in 2017 for the treatment of acute bacterial skin and skin structure infections (ABSSSIs) caused by designated susceptible bacteria, and in 2019 it was approved for the indication of bacterial CAP as well.[184,194,195]

Mode of Action, Spectrum of Activity, and Resistance Mechanisms. Delafloxacin exerts its action similarly as the other members of the class; however, unlike the other fluoroquinolones, it is regarded as a dual target agent (i.e., a fluoroquinolone with nearly equivalent affinity for both DNA gyrase and topoisomerase IV).[193] This property might explain its broad in vitro activity against both gram-negative and gram-positive bacteria, including MRSA (also MRSA with mutations in the quinolone resistance–determining region that confer resistance to both ciprofloxacin and levofloxacin), atypical bacteria, and mycobacteria.[193,196] Delafloxacin has the ability to penetrate *S. aureus* biofilms.[193] Moreover, the unique anionic property of delafloxacin provides increased potency in acidic environments, with a reported 2-fold to 32-fold decrease in MICs.[197] In vitro, delafloxacin had similar activity against *Enterobacteriaceae* as ciprofloxacin and levofloxacin, whereas for *P. aeruginosa* delafloxacin had similar activity as ciprofloxacin.[198] Against high-resistant-ciprofloxacin *Enterobacteriaceae* strains from UTIs, delafloxacin was inactive against all ESBL- and KPC-producing strains.[197]

PK/PD. Delafloxacin is fast absorbed after oral administration, but unlike other fluoroquinolones, its mean bioavailability is only 58.8% and compared with IV delafloxacin, the *C*max of oral administration was lower.[184,199,200] The V_d of delafloxacin nears the total body water, and the protein binding, mainly albumin, is approximately 84%.[199,200] A bioexponential decrease in plasma concentrations is demonstrated, with a half-life of 6–8 hours and steady state reached in 3 days for both IV and oral formulations.[199] Glucuronidation is the main metabolic pathway of delafloxacin; however, 50% or more of a single oral or IV dose of delafloxacin can be found unchanged in the urine.[184] As with the other fluoroquinolones, delafloxacin has concentration-dependent bactericidal activity and similar PD predictors for optimal efficacy.[184] An fCmax/MIC ratio of 12 or an AUC/MIC ratio of 100–125 correlates best with efficacy against gram-negative bacteria.[193] Delafloxacin's exposure increases with decreased renal clearance, whereas hepatic impairment seems to have no significant impact.[184]

Clinical efficacy. Delafloxacin demonstrated similar efficacy versus vancomycin plus aztreonam in two phase III RCTs in patients with ABSSIs (PROCEED studies: NCT01811732 and NCT01984684), and in obese patients, cure rate as assessed by the investigators was higher.[201–203] In a phase III RCT (DEFINE-CABP study; NCT02679573) in patients with community-acquired bacterial pneumonia (CABP) delafloxacin monotherapy (IV with potential switch to oral) was noninferior to moxifloxacin (IV with potential switch to oral and potential blinded switch to IV linezolid in case of MRSA confirmation).[204]

Dosage. Delafloxacin is administered at a dose of 300 mg by IV in a 60-minute infusion every 12 hours or a 450-mg tablet orally every 12 hours (see Table 107.1).[184] The recommended duration of treatment is 5–14 days and 5–10 days for ABSSSI and bacterial CAP, respectively.[184]

Adverse events. Delafloxacin was generally well-tolerated in clinical trials.[193] The most common adverse events reported in phase I and II trials were gastrointestinal (i.e., low- to moderate-intensity diarrhea, nausea, and vomiting), and in phase III trials the three most common ones (>5%) were diarrhea, nausea, and infusion site extravasation. In contrast to other fluoroquinolones, delafloxacin has not been associated with significant effects on the QTc interval.[205] Delafloxacin has several warnings and precautions (i.e., boxed warning about serious adverse reactions, including tendinitis and tendon rupture, peripheral neuropathy, CNS effects, and exacerbation of myasthenia gravis).[184] The majority are those in common with the other fluoroquinolones; however, delafloxacin has an additional warning related to its IV vehicle, the sulfobutylether-B-cyclodextrin (SBECD), which may accumulate in the case of moderate or severe renal impairment, and close monitoring of serum creatinine is advised.[206]

AMINOGLYCOSIDES

Aminoglycosides are commonly used in many ICUs, especially if resistant gram-negative infections are suspected, usually in combination with other antimicrobial agents, particularly beta-lactams. The most frequently used aminoglycosides in the ICU are amikacin, gentamicin, and tobramycin, and recently, a new aminoglycoside, plazomicin, was granted approval.[207,208]

Mode of Action of Aminoglycosides

Aminoglycosides, discovered in the 1940s, are an important element of the antimicrobial arsenal.[209] They are cationic antibiotics binding passively to negatively charged portions of the outer membranes of gram-negative bacilli and competitively displacing cell wall Mg^{2+} and Ca^{2+} that link lipopolysaccharides, interfering with transportation across the cell membranes.[209] Inside the cell they exert their antimicrobial activity by binding with high avidity and irreversibly to the 16S ribosomal RNA (rRNA) of the 30S subunit of prokaryotic ribosomes in a region that decodes the messenger RNA (mRNA), resulting in disruption of protein synthesis.[210] The avidity of binding presents variability between the different aminoglycosides, depending on the number of amino groups of each one.[209] In gram-positive bacteria, aminoglycoside uptake is reduced by the thicker outer cell wall membranes.[209] Aminoglycosides are generally bactericidal, and their efficacy can be enhanced in several cases by the combination with cell wall inhibiting antimicrobial agents such as beta-lactams and glycopeptides.[210]

Spectrum of Activity of Aminoglycosides

The primary action of aminoglycosides is directed against gram-negative bacteria and mycobacteria.[210] They are especially potent against *Enterobacteriaceae,* but they are also active against *Yersinia pestis, Francisella tularensis,* and lactose nonfermenting GNBs such as *P. aeruginosa* and *A. baumannii.*[210] There are some differences, however, between the different members of the group regarding their in vitro efficacy against different microorganisms.[209] Gentamicin is a potent agent against *Enterobacteriaceae*. Tobramycin has slightly higher activity than gentamicin against *P. aeruginosa* and *Acinetobacter* spp. Amikacin, despite generally having higher MICs than gentamicin against *Enterobacteriaceae,* usually (>80%) remains active against isolates that have acquired resistance to both gentamicin and tobramycin.[209] Against gram-positive bacteria, aminoglycosides are active against methicillin-sensitive *S. aureus* (MSSA). Although MRSA, streptococci, and enterococci are resistant, aminoglycosides are successfully used in combination with other drugs to provide synergistic effect.[209]

Resistance to Aminoglycosides

Bacterial resistance to aminoglycosides can be intrinsic or acquired. Intrinsic resistance may be nonenzymatic (i.e., mutations in the 16S rRNA that confer resistance) or enzymatic (i.e., methylating enzymes modifying 16S rRNA).[211] It should be noted that anaerobic bacteria have intrinsic resistance to aminoglycosides.[209] The main mechanisms of acquired resistance include reduced entry, the presence of efflux pumps (or a combination of both), and enzymatic modification of the drug.[209] Aminoglycoside-modifying enzyme genes are mostly transferred by plasmids and transposons and can result in rapid spread of resistance.[212,213]

PK/PD of Aminoglycosides

The members of the aminoglycoside class share similar PK properties: they are hydrophilic, rapidly distributed from the vascular to extravascular space, have low protein binding (10%–20%), have low V_d,(in healthy adults 0.2–0.3 L/kg), and are primarily excreted unchanged (>90%) by the kidneys with clearance proportional to the glomerular filtration rate (there is a need for dose adjustment in renal impairment).[8,209] The pathophysiologic changes that occur in critically ill patients significantly affect both V_d (significantly increased) and clearance, with a risk for subtherapeutic levels when clearance is augmented or toxic levels in the case of development of renal impairment.[8] In obese individuals, the V_d increases less than expected or even possibly decreases.[214]

The activity of aminoglycosides in vitro is reduced in anaerobic environments and/or environments with acidic PH, which may be particularly relevant in cases of empyema or abscess.[215] Because of their structural and chemical characteristics, aminoglycosides cross biologic membranes poorly, apart from the renal tubular cells and, possibly, the inner ear cells that might possess an inherent transport mechanism.[209] Aminoglycosides cross the blood-brain and cerebrospinal fluid (CSF) barriers poorly, achieving low concentrations in the CSF. They can be instilled in the lumbar sac or intraventricularly for meningitis caused by susceptible aerobic GNB in rare cases that such treatment is necessary.[216] Systematic administration of aminoglycosides achieves low concentrations in the respiratory secretions, and the penetration into the ELF ranges from 32% to 54% compared with serum.[217] Adjunctive inhaled (nebulized) amikacin has been used along with IV standard-of-care treatment for patients with VAP and ventilator-associated tracheobronchitis (VAT) caused by GNBs, but results of clinical trials have not supported its use yet. The results of a recent study suggested that ELF components might inhibit amikacin-mediated bacterial killing, even when amikacin's ELF concentrations are high.[218] Results from infection models regarding optimal dose/dosing interval for inhaled amikacin should be considered in future clinical trials.[218]

Aminoglycosides demonstrate "concentration-dependent" bactericidal activity, have a postantibiotic effect (PAE) (i.e., persistent suppression of bacterial growth after a short antibiotic exposure that is longer with higher concentrations), and show synergism with other antimicrobial agents with cell-wall activity.[8,219] The optimal Cmax is considered to be ≥8–10 × MIC, but recent data have claimed that the AUC 0–24/MIC ratio might better predict their activity and judge target attainment as well in extended-interval dosing of aminoglycosides.[8,220,221]

Dosing and Monitoring of Aminoglycosides

For systematic use, aminoglycosides can be administered IV or intramuscularly. IV, they are usually administered over a period of 15–30 minutes; however, in case of larger doses, it is reasonable to increase the infusion time up to 60 minutes to avoid the rapid rise in serum levels and decrease the potential risk of neuromuscular blockade.[209] It should be noted that aminoglycosides should not be administered at

the same time and same IV line as beta-lactams, because this would lead to inactivation of the aminoglycosides.[222,223] The optimal dosing strategy of aminoglycosides has been debated. Traditionally, the total daily dose of aminoglycoside based on the patient's renal function was administered divided into multiple times per day or, less frequently, the total once-daily dosing. However, once-daily dosing appears to have similar or even better clinical efficacy and may delay the nephrotoxicity onset if used in short durations.[224] Therefore a single high dose with extended intervals is currently recommended in patients with gram-negative infections.[8] Moreover, administration of a higher-than-standard aminoglycoside dosing regimen might be required for critically ill patients.[225–227] Results of PD evaluation of plasma and ELF exposures of amikacin against susceptible *P. aeruginosa* using a dynamic in vitro hollow-fiber infection model suggested that the use of high-dose amikacin may improve its efficacy because of rapid elimination of susceptible bacteria, whereas the efficacy of the subsequent doses may be reduced given the fast amplification of less susceptible bacteria.[228]

Therapeutic monitoring of serum concentrations of aminoglycosides to reguide dosing is essential for both efficacy and toxicity.[8] It has been reported that TDM-guided dosing with Bayesian dose adaptation of gentamicin administered for gram-negative infections led to a decrease of both hospital stay and nephrotoxicity.[229] For critically ill patients specifically, important alterations of V_d and CL have been widely described, and TDM should be routinely performed.

For *C*max/MIC monitoring, one sample should be taken 30 minutes after the end of infusion targeting *C*max/MIC ≥8–10 × MIC.[8,220,221] *C*min monitoring is recommended for treatment of more than 3 days, with one sample taken 30 minutes or just before the next dosing, targeting *C*min for amikacin <2.5 mg/L and for gentamicin/tobramycin <0.5 mg/L; the clinical *C*min threshold for ototoxicity and nephrotoxicity is >5 mg/L and >1 mg/L for amikacin and gentamicin/tobramycin, respectively. However, a recent position paper recommended AUC-based monitoring, with the first sample taken 30 minutes after the end of infusion and the second taken between 6 and 22 hours postinfusion, with target AUC 80–120 mg h/L.[8]

An international survey on aminoglycoside use in ICUs reported that short courses of high doses were mainly used in patients with septic shock, but wide variability existed between different units.[207] The most commonly used aminoglycoside was amikacin (66%), followed by gentamicin (33%) and, in the vast majority (98%), were prescribed in combination with other antimicrobial agents, mostly beta-lactams (96%).[207] TDM was performed in approximately half of the cases (C_{max} in 47% and C_{min} in 57%).[207]

Adverse Events of Aminoglycosides

Nephrotoxicity represents the most common adverse effect of aminoglycosides. Reported rates vary widely from 0% to 50%, with most reports in the range of 5%–25%; this variability may be attributed to different definitions used, different tests, or different clinical settings.[209] The typical presentation of aminoglycoside-related nephrotoxicity is nonoliguric acute kidney injury (AKI) occurring 7–10 days after the onset of treatment.[209] Factors that increase the risk of nephrotoxicity include patient-related factors (older age, preexisting renal disease, volume depletion and hypotension/shock, liver dysfunction), recent aminoglycoside use, larger doses, frequent dosing intervals, longer duration of therapy (≥3 days), concomitant use of other nephrotoxic drugs (e.g., vancomycin, amphotericin B, diuretics, foscarnet, nonsteroidal antiinflammatory drugs [NSAIDs], cyclosporin, tacrolimus, angiotensin-converting enzyme/angiotensin receptor blocker [ACE/ARB]), and use of IV radiocontrast agents.[209] Another serious adverse event of aminoglycosides is ototoxicity that can manifest as auditory (cochlear) or vestibular toxicity.[209] The reported frequency of ototoxicity also varies widely: 2%–10% and 3%–14% for cochlear and vestibular toxicity, respectively.[209] Cochlear and vestibular toxicity may be unilateral or bilateral.[209] Cochlear toxicity may appear days to weeks after discontinuation of aminoglycosides, and high-frequency hearing loss can occur with no symptoms.[209] The true frequency of vestibular toxicity is very difficult to determine, as patients may have suffered severe injury long before the initiation of symptoms.[209] Reported risk factors for ototoxicity include older age, longer treatment duration, impaired renal function, concomitant use of loop diuretics, concomitant use of vancomycin, associated bacteremia, liver dysfunction, hypovolemia, and degree of temperature elevation.[209,230,231] Ototoxicity and nephrotoxicity have been associated with high Cmin and AUC exposures over days.[8]

A rare but severe and potentially lethal adverse event after aminoglycoside administration is the neuromuscular blockade that may lead to flaccid paralysis and respiratory depression.[232] The mechanism of neuromuscular blockade is both presynaptic (inhibition of acetylcholine release) and postsynaptic (blockage of acetylcholine receptor).[209] Risk factors include rapid rise of aminoglycosides in the serum, concomitant use of drugs that interfere with the neuromuscular transmission (e.g., D-tubocurarine, succinylcholine, or similar), hypomagnesemia, hypocalcemia, and may be use of calcium channel blockers, and the role of myasthenia gravis as a risk factor is controversial.[209]

Novel Approved Aminoglycosides

Plazomicin. Plazomicin is a new semisynthetic aminoglycoside for IV use. It was approved by the FDA in 2018 for adult cUTIs, including acute pyelonephritis, in patients with limited or no alternative treatment options.[233]

Mode of Action, Spectrum of Activity, and Resistance Mechanisms. Plazomicin is derived by the addition of an N1 2(S)-hydroxy aminobutyryl and a hydroxyethyl substituent at the 6 position of sisomicin; these structure modifications protect plazomicin from most aminoglycoside-modifying enzymes (AMEs), which typically inactivate previous aminoglycosides, but not against 16S ribosomal methyltransferases that reduce aminoglycoside affinity for the ribosomal target.[101,233,234]

The antibacterial spectrum of plazomicin covers GNBs, including CREs.[101] It is more active against *Enterobacteriaceae* than against lactose-nonfermenting GNBs; it is inactive in vitro against *A. baumannii and S. maltofilia,* and its activity against *P. aeruginosa* is variable.[101,233] The activity of plazomicin against gram-positive bacteria is similar to that of other aminoglycosides; although it demonstrated in vitro activity against *S. aureus* and *Staphylococcus epidermidis,* it is inactive against streptococci (including *Streptococcus pneumoniae*) and enterococci.[208,233] As with the other members of the class, it is inactive against anaerobes.[233] Although plazomicin is active in vitro against CRE and aminoglycoside-resistant *Enterobacteriaceae* containing AMEs, such as acetyltransferases, phosphotransferases, and nucleotidyl-transferases, it is not active against ribosomal (16S mRNA) methyltransferase-containing strains found in most NDM-1-producing *Enterobacteriaceae* that are also resistant to other aminoglycosides, and may have reduced activity against *Enterobacteriaceae* with efflux pump or porin underexpression.[101,233,235,236] Synergy studies have evaluated in vitro the combination of plazomicin with older antimicrobial agents, such as piperacillin/tazobactam and ceftazidime, against MDR *Enterobacteriaceae,* including isolates with aminoglycoside and beta-lactam-resistance, with promising results.[237,238] Also, plazomicin combined with colistin, meropenem, or fosfomycin had synergistic activity against VIM-1– and KPC-2–producing *K. pneumoniae* isolates, whereas combination with meropenem or imipenem showed in vitro synergy against *A. baumannii.*[239,240]

PK/PD. Plazomicin, similar to the other aminoglycosides, is poorly absorbed orally and should be administered parenterally.[208] The V_d of plazomicin is 18–31 L, protein binding is 20% (concentration-independent), it has a half-life of approximately 3.5 hours when renal function is normal, and it is mainly renally eliminated like the other aminoglycosides, without metabolism to an appreciable extent.[101,208,233,241] The lung penetration of plazomicin is quite poor, with ELF to plasma ratio of AUC approximately 13% (similar to the 14% of amikacin).[233,241]

Clinical efficacy. Plazomicin has demonstrated noninferiority in phase III RCTs, in cUTIs, and in acute pyelonephritis compared with meropenem (EPIC study; NCT02486627).[242] In another phase III open-label RCT (CARE study; NCT01970371), plazomicin was compared with colistin (both combined with meropenem or tigecycline) in patients with bloodstream infections or cUTIs (including acute pyelonephritis) or HAP/VAP caused by CRE, and plazomicin showed favorable microbiologic response and decreased all-cause mortality at day 28.[237,243]

Dosage. For dosages, see Table 107.1.[233] The recommended duration for the treatment of cUTI, including pyelonephritis, is 4–7 days.[233]

Adverse events. In the phase III trials plazomicin was generally well-tolerated, and adverse effects were comparable between plazomicin and meropenem arms, with diarrhea, hypertension, headache, nausea, vomiting, and hypotension the most commonly reported ones (>1%).[233] There were no clinically significant events potentially related to ototoxicity.[241] Regarding renal function, increases of ≥0.5 mg/dL in serum creatinine occurred in 7.0% and 4% in the plazomicin and meropenem arms, respectively; after the last follow-up visit, it was assessed that plazomicin conferred an additional 2.3% in serum creatinine rise over the background rate of the patients at any time during the study. The incidence of nephrotoxicity was higher when plasma trough levels were ≥3 μg/mL (36% versus 5%, respectively).[208,233] Neuromuscular blockade has not been reported in the clinical trials of plazomicin to date; however, it is reasonable to be administered with caution in patients with neuromuscular diseases such as myasthenia gravis or when a neuromuscular blocking agent, such as succinylcholine, is administered. There are boxed warnings in the prescribing information of plazomicin regarding nephrotoxicity, ototoxicity, neuromuscular blockade, and fetal harm if administered in pregnancy.[233]

TETRACYCLINES

Tetracyclines are a class of bacteriostatic antibacterial agents that were discovered in the late 1940s. They exert their action by inhibiting bacterial protein synthesis, primarily by reversibly binding to the 30S ribosomal unit, while they also suppress bacterial adhesion to human cells, and thus reduce their pathogenicity.[244] They have a broad spectrum of antibacterial activity, including gram-positive and gram-negative bacteria, atypical bacteria, mycobacteria, and protozoan parasites.[244] The PD parameter that correlates best with activity of tetracyclines is the $fAUC_{0–24}$/MIC ratios. Tetracyclines inhibit bone growth and cause tooth discoloration/enamel hypoplasia and should not be used during tooth development (last half of pregnancy, infancy, and childhood to 8 years).[244]The first-generation tetracyclines include chlorotetracycline, oxytetracycline, tetracycline, and demeclocycline; the second generation includes doxycycline and minocycline; and the glycylcycline tigecycline belongs to the third generation. Very recently novel semisynthetic tetracyclines were branded: the fluorocycline eravacycline and the aminomethylcycline omadacycline.[101,244] In this chapter we only present the members of the class that are more relevant to the critical care setting (i.e., tigecycline, eravacycline, and omadacycline).

Tigecycline

Tigecycline is the first glycylcycline, a class of semisynthetic tetracyclines. It has been approved based on noninferiority studies by both the FDA (2005) and EMA (2006) for the treatment of adults with CSSSIs and cIAIs, and the FDA also granted approval to tigecycline for bacterial CAP in 2009.[245] During the last decade it has been used as salvage treatment for CRE and CRAB infections.[245]

Mode of Action, Spectrum of Activity, and Resistance Mechanisms. Tigecycline has the same mode of action as other tetracyclines, but it is specifically designed to overcome the common mechanisms of resistance against tetracyclines. Specifically, it has been developed by attaching an *N*-alkyl-glycylamido moiety to the 9-position of minocycline, and this addition confers unique microbiologic properties (i.e., tigecycline demonstrates fivefold higher binding affinity to ribosomes compared with older tetracyclines) and is able to overcome resistance mediated by acquired efflux pumps and/or ribosomal protection mechanisms.[246] Although tigecycline is generally considered bacteriostatic, it exerts bactericidal activity against isolates of *S. pneumoniae* and *Legionella pneumophila.*[247] Tigecycline is active against a wide variety of gram-positive and gram-negative aerobic and anaerobic bacteria and atypical bacteria.[245] It covers *Staphylococcus* spp. (methicillin-sensitive and methicillin-resistant strains), *Streptococcus* spp., and *Enterococcus* spp.; it is highly active against community-acquired MRSA and against vancomycin-resistant enterococci strains.[245] Against gram-negative bacteria, tigecycline has good activity against most *Enterobacteriaceae,* excluding *Proteus* spp., *Morganella* spp., and *Providencia* spp. and against lactose-nonfermenting GNBs, including *A. baumannii* and *S. maltophilia*, whereas *P. aeruginosa* and *Burkholderia cepacia* represent notable exceptions.[245] It should be noted that although tigecycline used to be considered one of the most active agents against *A. baumannii,* susceptibility has been reduced over recent years.[245,248] Moreover, high resistance of *Enterobacteriaceae* to tigecycline has been reported in several countries around the world.[245] In Europe, 11.4% of carbapenem-resistant *Enterobacteriaceae* in the SENTRY surveillance program were nonsusceptible to tigecycline, and in the United States resistance rates from 9.2% to 38.5% have been reported.[245,249,250]

The mechanisms of resistance against tigecycline are not fully unraveled. Overexpression of efflux pumps is the most common reported mechanism in gram-negative bacteria, whereas ribosomal alterations have been described in both gram-negative and gram-positive tigecycline-resistant bacteria.[251–253]

PK/PD. The steady-state V_d of tigecycline is high, 500–700 L, and the protein binding is 71%–89% (nonlinear plasma protein binding, with a decrease in unbound fraction as concentration increases).[247,254] It penetrates rapidly to the tissues with resulting low serum concentration that may confuse the assessment of the relationship between serum concentrations and outcomes.[254] It has a long half-life (37–64 hours), as it is released slowly from the tissues.[255] Tigecycline does not undergo extensive metabolism (<10%).[247] The predominant elimination route is biliary excretion of unchanged tigecycline and its metabolites (biliary/fecal excretion 59%), and glucuronidation and renal excretion of unchanged tigecycline represent secondary routes.[247] In healthy volunteers, $AUC_{0–12h}$ in alveolar cells and in the ELF was 78-fold and 32% higher than $AUC_{0–12h}$ in alveolar cells and ELF, respectively.[247] CSF penetration of tigecycline is low.[256,257] A PK study reported that after a single 100-mg IV dose of tigecycline, the concentrations in tissue/fluid were significantly higher compared with serum (expressed as $AUC_{0–4h}$ ratio): in bile (×537), gallbladder (×23), colon (×2.6), and lungs (×2), whereas they were lower in bone (×0.41), synovial fluid (×0.31), and CSF (×0.11).[257] Tigecycline has in vitro time-dependent activity with extended PAE, and the best PD predictor is $AUC_{0–24h}$/MIC.[258]

Clinical efficacy. The efficacy of tigecycline for the indications of cIAIs, cSSSIs, and CAP has been demonstrated in several phase III and IV RCTs.[259–265]. Nevertheless, efficacy for nosocomial pneumonia and

diabetic foot infections has not been established.[266–268] Moreover, in a pooled analysis of 13 clinical trials, an increase in all-cause mortality in tigecycline arms versus the comparators was found (mortality 4.0% versus 3.0%), without the cause of this increase having been clearly established.[247,269] Particularly, in patients with VAP, the arm that received tigecycline had lower cure rates (47.9% versus 70.1% for tigecycline and comparator, respectively) and higher mortality (19.1% versus 12.3% for tigecycline and comparator, respectively), whereas VAP with baseline bacteremia had the highest risk of clinical failure and mortality.[270] Another meta-analysis of 10 clinical trials (including trials after tigecycline's approval) conducted for FDA-approved uses only, also demonstrated increased mortality compared with other drugs (2.5% versus 1.8%, respectively).[247,269] Based on these data, a combination of tigecycline with other antimicrobial agents has been suggested, especially for critically ill patients, such as combinations with colistin, polymyxin B, rifampicin, or meropenem.[271] Also, higher doses (200 mg followed by 100 mg/12 hours instead of the approved dose of 100 mg followed by 50 mg/12 hours) have been used off-label for the treatment of MDR infections and in HAP/VAP.[245] A recent meta-analysis of 10 studies that assessed the effectiveness and safety of high-dose tigecycline compared with the standard dose or other non-tigecycline-containing regimens, reported that the high-dose regimen had lower all-cause mortality, a higher cure rate, and a higher microbiologic eradication rate for the treatment of severe infections. Nonetheless, it was emphasized that the included studies were mostly observational, with a high risk of bias, a fact that represents an important limitation for the generalization of the results, and further studies are needed.[272]

Dosage. For dosages, see Table 107.1. It should be highlighted that an off-label higher dose has been suggested, especially for the treatment of HAP/VAP, *A. baumannii,* CRE, and bacteremic infections (i.e., 100 mg every 12 hours after 200-mg loading dose).[272] The recommended duration of treatment is 5–14 days for SSSIs and cUTIs and 7–14 days for CAP guided by the severity, infection site, and bacteriologic progress.[247]

Adverse events. Nausea, vomiting, diarrhea, abdominal pain, headache, and serum glutamate pyruvate transaminase (SGPT) increase are the most common adverse events with an incidence >5%.[245,247] A higher dose of tigecycline has been related to an augmented risk of gastrointestinal tract adverse events and coagulopathy, usually reversible with tigecycline discontinuation, manifested by a decrease in fibrinogen levels and prolongation of prothrombin time and activated partial thromboplastin time.[245,273–275] Anaphylaxis/anaphylactoid reactions (including life threatening), hepatic dysfunction/liver failure, and pancreatitis, including fatalities, and *C. difficile*–associated diarrhea have been reported.[247] As with the other tetracyclines, tigecycline may cause fetal harm if administered during pregnancy and permanent discoloration of teeth if administered during tooth development.[247]

Eravacycline

Eravacycline is a novel fluorocycline of the tetracycline class of antimicrobial agents, with broad-spectrum antibacterial activity.[101] In 2018 eravacycline was approved by both the FDA and the EMA for the indication of adult cIAIs.[276,277]

Mode of Action, Spectrum of Activity, and Resistance Mechanisms. Eravacycline is a bacterial protein synthesis inhibitor, like the other tetracyclines. It is a synthetic tigecycline analogue with a pair of modifications to the D-ring core at C-7 and C-8; these modifications widen the activity of eravacycline against gram-positive and gram-negative bacteria that have acquired certain mechanisms of resistance against tetracyclines, such as efflux pumps and ribosomal protection mechanisms.[101,278,279] The in vitro ribosomal-binding affinity of eravacycline is 10 times higher than other tetracyclines and inhibits bacterial protein translation at concentrations four times lower.[278,280,281]

The antimicrobial spectrum of eravacycline, as demonstrated by vitro studies, is broad, covering a wide range of microorganisms, including MDR GNBs and MDR gram-positive microorganisms, such as MRSA and VRE.[106,282] Generally, eravacycline is bacteriostatic like the other tetracyclines; however, it is bactericidal against strains of *A. baumannii, E. coli,* and *K. pneumoniae*. Moreover, it should be noted that its activity includes CRAB strains, ESBL-*Enterobacteriaceae,* and some CRE strains, and it is also active against biofilms formed by uropathogenic *E. coli.* [281,283] It should be highlighted, though, that it is not active against *P. aeruginosa* and *Burkholderia cenocepacia.*[281]

PK/PD. The V_d of eravacycline at steady state is approximately 321 L, protein binding is 79%–100% and it increases with increasing plasma concentration, and it has a long half-life of approximately 20 hours. It is mainly metabolized via oxidation by CYP3A4 and FMO; concomitant administration with strong CYP3A4 inducers, such as rifampicin, phenobarbital, carbamazepine, and phenytoin, leads to a clinically significant increase of eravacycline's metabolism.[276,280] After a single IV dose, 34% and 47% of the dose is excreted in the urine and feces, respectively, as unchanged eravacycline and metabolites.[276] Regarding eravacycline's PD, the best predictors of activity are $fAUC_{0–24}$/MIC ratios.[276]

Clinical efficacy. Eravacycline showed noninferiority in phase III RCTs in patients with cIAIs compared with ertapenem (NCT01844856; IGNITE1) and compared with meropenem (NCT02784704; IGNITE4).[284] However, because of poor PK in the urinary tract, eravacycline failed to show noninferiority in two phase III RCTs in patients with cUTIs compared with levofloxacin (NCT01978938; IGNITE 2) and compared with ertapenem (NCT03032510; IGNITE3).[285,286] It is noteworthy that eravacycline is not indicated for cUTIs.[276]

Dosage. For dosages, see Table 107.1.[276] The recommended treatment duration is 4–14 days.[276]

Adverse events. Eravacycline's most common adverse reactions observed in clinical trials (incidence ≥3%) include infusion site reactions (7.7%), nausea (6.5%), and vomiting (3.7%).[276] As it has a similar structure to the tetracycline class of antimicrobial agents, it might have similar adverse reactions, and there are warnings about life-threatening hypersensitivity (anaphylactic) reactions; inhibition of bone growth and tooth discoloration (yellow-gray-brown)/enamel hypoplasia if used during tooth development (last half of pregnancy, infancy, and childhood to 8 years); reversible inhibition of bone growth (if administered from the second trimester of pregnancy to 8 years); and *C. difficile*–associated diarrhea.[276]

Omadacycline

Omadacycline is a novel antibacterial agent from the class of tetracyclines.[1,287,288] In 2018 the FDA approved omadacycline for the treatment of ABSSSIs and CABP.[288]

Mode of Action, Spectrum of Activity, and Resistance Mechanisms. Omadacycline is the first-in-class aminomethylcycline. Similar to the other members of the class, it blocks protein synthesis by binding to the 30S ribosomal subunit.[289] It is active against a broad spectrum of gram-positive microorganisms, including VRE and MRSA, and gram-negative microorganisms, some ESBL-producing *Enterobacteriaceae,* some strains of CRE (KPCs, NDM, OXA-48), *S. maltophilia, A. baumannii* (including some CRAB strains), atypicals, and anaerobes. Notably, it is not active against *P. aeruginosa, Proteus mirabilis, Providencia* spp., and *Morganella morganii.*[1,290] Although it is generally considered bacteriostatic, it showed bactericidal activity against strains of *S. pneumoniae* and *Haemophilus influenzae.*[288]

Similar to eravacycline, the unique structure enables omadacycline to overcome several resistance mechanisms that inactivate tetracyclines, such as efflux pumps and target site protection, and does not seem to have cross-resistance with other antibiotic classes.[288,291]

PK/PD. Omadacycline is the first 9-aminomethylcycline with IV and oral formulations. The V_d of omadacycline at steady state in healthy individuals is 168–288 L, and protein binding was 21%.[287,292] Omadacycline is excreted unchanged in the feces (81.1%) and urine (14.4%), and its potential for drug-drug interactions is low. As with older tetracyclines and eravacycline, the PD parameter that best correlates with activity is the $fAUC_{0-24}$/MIC ratios.[287,292] Omadacycline has PAE that is in general similar to tigecycline.[287,292]

Clinical efficacy. The noninferiority of omadacycline as effective monotherapy for ABSSSI and CABP in inpatient (not ICU patients) and outpatient settings has been established by three phase III RCTs: OASIS-1 (NCT02378480) and OASIS 2 (NCT02877927) studies in patients with ABSSI with linezolid as a comparator and OPTIC (NCT02531438) in patients with CABP with moxifloxacin as a comparator.[291,293,294] The role of omadacycline in the treatment of infections caused by MDR GNBs is still unclear, and clinical trials are needed to evaluate its role against pathogens such as CRE and *A. baumannii.*[1,287]

Dosage. There are formulations of omadacycline for both oral and IV use. For dosages, see Table 107.1.[288] The suggested duration of treatment is 7–14 days.[288]

Adverse events. The most common adverse reactions, with incidence ≥2%, include nausea, vomiting, infusion site reactions, alanine aminotransferase increase, aspartate aminotransferase increase, gamma-glutamyl transferase increase, hypertension, headache, diarrhea, insomnia, and constipation.[288,295] There is a warning for mortality imbalance in bacterial CAP (2% versus 1% for the moxifloxacin arm) but without a clearly established cause for the increased mortality, and caution is advised, especially for CAP patients with higher severity.[288] Moreover, as it belongs to the tetracycline class, there are warnings regarding administration during tooth development (it may cause discoloration and enamel hypoplasia), during bone development (it may cause reversible hypoplasia), and about the possibility of *C. difficile*–associated diarrhea.[288]

POLYMYXINS

Polymyxins are an "old" class of cationic antimicrobial agents that became available in the 1950s, including five different chemical compounds (polymyxin A–E); in clinical practice, polymyxin E (colistin) and polymyxin B have been mainly used. With the exponential increase of MDR GNB worldwide, polymyxins have been "rediscovered" and have become a last-line defense against infections by MDR/XDR (extensively drug resistant) GNBs that are otherwise untreatable.[296] Colistin and polymyxin E, although having almost identical in vitro microbiologic activity, differ in the form administered parenterally to patients, with clinical implications; when both are available, the choice should be carefully considered in each case based on the relative merits.[297]

Mode of Action, Spectrum of Activity, and Resistance Mechanisms

Polymyxins are bactericidal agents that exert their action by disrupting the bacterial membranes.[298] They interact with the lipid A component of lipopolysaccharide (LPS) through anionic displacement of LPS stabilizing magnesium and calcium, resulting in loss of integrity and increased permeability of outer membranes, leakage of cell contents, and eventually, cellular death.[298] This unique mechanism of action, apart from providing rapid bactericidal activity, may also increase the activity of other antibiotic classes.[298]

Polymyxins are active against a wide spectrum of GNBs, including *A. baumanni, P. aeruginosa,* and *K. pneumoniae.* It should be noted, however, that they have poor activity against *Proteus* spp. (most species present high resistance to polymyxins) and against *Providencia* spp., *Serratia* spp., *Moraxella* spp., *Morganella* spp., *Burkholderia* spp., *Aeromonas* spp., *Vibrio* spp., *Helicobacter* spp., *Vibrio* spp., and *Edwardsiella* spp. Polymyxins are not active against gram-positive microorganisms, gram-negative cocci, and anaerobes.[299]

Resistance of gram-negative bacteria to colistin seems to be related to an LPS modification that stops the initial interaction between the positively charged peptides of polymyxins and LPS.[300] A plasmid-mediated resistance mechanism (MCR-1) and resistance conferred by bacterial capsule polysaccharide mutations have been also described.[301,302] It should be highlighted that cross-resistance between polymyxins is complete.[297] Although resistance to polymyxins is still relatively rare, it has been increasingly reported in several countries worldwide, especially for *A. baumanni, P. aeruginosa,* and *K. pneumoniae,* and is in parallel with its increased use in human and animals.[303–305] Regrowth after polymyxin administration, rapid for *A. baumannii* and delayed for *P. aeruginosa,* has been described, attributed in part to the presence of heteroresistance, and therefore the combined use of polymyxins with another active agent has been suggested (with the dose of the other agent to be administered without a long interval from the dose of polymyxin).

PK/PD–Synergy

Polymyxins are rapidly bactericidal antimicrobial agents in a "concentration-dependent" manner, with a PAE for *P. aeruginosa* but not for *A. baumannii.*[8,296]

PK/PD of colistin (*polymyxin E*). Colistin is administered as an inactive prodrug, colistimethate (CMS), also known as colistin methanesulfonate, that is slowly hydrolyzed to active colistin; two forms of colistin are commercially available: for parenteral (IV, intrathecal, intraventricular) or aerosol use and for topical or oral use (not absorbed when given orally).[296,306] Colistin is mainly distributed within the extracellular space, so its V_d is low and can be altered in critically ill patients, as can its clearance.[306] The half-life of CMS is 2 hours, and the half-life of colistin hydrolyzed by CMS is 4 hours. Protein binding is concentration-dependent, reportedly 59%–74%.[307] Two-thirds of CMS is renally cleared within 24 hours, although the active colistin is not renally eliminated. The $fAUC_{0-24}$/MIC ratio is the best predictor of the activity of colistin; $fAUC_{0-24}$/MIC ratios of 10.9–13.7 and 3.5–9.0 are reported as optimal for bactericidal activity against *P. aeruginosa* and *A. baumannii,* respectively.[8,308] Colistin achieves adequate concentration in the liver, kidney, heart, and muscle, but the distribution in the bones, joint fluid, CSF, biliary tract, lung parenchyma, and pleural fluid is poor.[309] After inhalation, serum levels of colistin are very low.[310]

PK/PD of polymyxin B. Polymyxin B is administered in its active form. The profile of polymyxin B is similar to that of colistin, with the AUC_{0-24}/MIC ($fAUC_{0-24}$/MIC) ratio best predicting its activity.[8] The serum half-life of polymyxin B is 9–11.5 hours.[311] Protein binding is high, but presents great variability (58%–98.4%).[8] Contrary to colistin, polymyxin B is eliminated mainly by nonrenal pathways, with <1% recovered unchanged in the urine, and its clearance seems to be relatively unaffected by renal function.[8,312]

Combination of polymyxins with other antimicrobial agents. Colistin and polymyxin B have assumed an important role as salvage therapy for otherwise untreatable gram-negative infections, most notably MDR and XDR strains of *P. aeruginosa, A. baumannii,* and *Enterobacteriaceae.*[313] The increasing reports related to the emergence of polymyxin

resistance with monotherapy lend theoretical support to a possible benefit of a combination with other active antimicrobial agents to achieve enhanced bacterial killing and a suppression of resistant subpopulations.[314] However, the role of such combinations has been debated, and the evidence is quite controversial.[314] Polymyxins have been combined with other antimicrobial agents in vitro for synergy against MDR GNBs, such as imipenem, meropenem, piperacillin, ciprofloxacin, moxifloxacin, amikacin, gentamycin, minocycline aztreonam, cefotaxime, levofloxacin, fosfomycin, ceftolozane/tazobactam, and rifampicin, with maximum synergy having been observed with rifampicin.[314,315] A meta-analysis of RCT and observational studies comparing polymyxin monotherapy and polymyxin-based combination therapy for infections caused by carbapenem-resistant or carbapenemase-producing GNBs reported an increased mortality in cases of monotherapy; however, because of the low quality of evidence, it cannot be taken as proof of positive impact of the combination.[316] Moreover, regarding *A. baumannii* infections, three RCTs did not demonstrate any decrease in mortality with the use of rifampicin/colistin or fosfomycin/colistin.[316] The international guidelines on polymyxin use, although acknowledging and emphasizing the lack of strong evidence, recommend the use of combination therapy for infections caused by CRE, CRPA, and CRA.[296] Specifically, for CRE, CRPA, and CRA, colistin or polymyxin B is recommended to be used combined with one or more antimicrobial agents to which the pathogen displays a susceptible MIC.[296] In case of unavailability of another agent with susceptible MIC for the infecting CRE or CRPA, the combination with a second and/or third nonsusceptible agent (such as carbapenem) is recommended, with priority given to nonsusceptible agents with the lowest MIC relative to the respective susceptibility breakpoint.[296] For infections caused by CRAB, if no additional antimicrobial agent with a susceptible MIC is available, monotherapy with polymyxin B or colistin is recommended.[296]

Dosing and Monitoring

Because of different conventions used to describe dosing of the polymyxins, especially colistin, with several CMS commercial preparations, outdated product information, and other uncertainties regarding polymyxin's use that could lead to dose confusion, international guidelines were published for the optimal use of polymyxins.[296,317–319]

Colistin (polymyxin E) dosing. The international guidelines recommended, for clarity and harmonization, doses to be prescribed as milligrams of the chemical CMA; 1 million internal units (IU) corresponds to ~33 mg colistin base activity (CBA) and also corresponds to ~80 mg of the chemical CMS. For critically ill patients a loading dosing of colistin is recommended because of the expected increased V_d: initiation of IV therapy with a CMS loading dose of 300 mg CBA (~9 million IU) infused over 0.5–1 hours and after 12–24 hours, administration of the first maintenance dose.[8,296,306,307,319,320] The recommended maintenance daily dose is 300–360 mg CBA (~9–10.9 million IU), divided into 12-hour intervals (0.5- to 1-hour infusions). [8,296,319] In cases of renal impairment, the loading dose and the maintenance dose should be adapted to renal function that should be monitored daily (see Table 107.1). Colistin's TDM has an inherent difficulty because of ex vivo conversion of CMS to colistin.[296] The international guidelines recommend that TDM and adaptive feedback control (AFC) be used for colistin whenever available, although they emphasize that the optimal approach for TDM implementation needs to be researched further.[296,321] An $AUC_{ss,24\ hr}$ of ~50 mg·hour/L that is equivalent to a target average steady state plasma concentration ($C_{ss,avg}$) of ~2 mg/L for total drug is required, and this is considered the maximum tolerable target, as higher concentrations have been associated with increased incidence and severity of nephrotoxicity.[296] The *C*ss avg 2 mg/L target is expected to achieve an $fAUC_{0–24}$/MIC ratio of ~12 for pathogens with an MIC of ≤2 mg/L, which is the European Committee on Antimicrobial Susceptibility Testing (EUCAST) breakpoint for susceptibility to colistin for *P. aeruginosa, A. baumannii,* and *Enterobacteriaciae*.[8] The recent position paper on TDM neither recommends nor discourages routine TDM for colistin.[8] It suggests, however, that if TDM is used, as colistin's therapeutic index is remarkably narrow, the sampling and handling should be appropriate, that is, sampling should be done in a way that minimizes ex vivo conversion of CMS to colistin (sampling just before the next dose when both CSM concentrations and conversion are at the lowest), and the samples should be processed immediately.[8] It should be pointed out that colistin concentrations fluctuate only a little at steady state; thus the *C*ss average target can be applied for Cmin monitoring as well.[8]

Polymyxin B dosing. A loading dose of 2.0–2.5 mg/kg for polymyxin B, based on total body weight (equivalent to 20,000–25,000 IU/kg) administered IV over 1 hour, is recommended for patients with severe infections, and the maintenance dose is 1.25–1.5 mg/kg (equivalent to 12,500–15,000 IU/kg) every 12 hours as a 1-hour IV infusion. Adjustment of the loading or the maintenance dose of colistin B is not recommended for renal impairment; nonetheless, additional research is warranted for the definition of the optimal maintenance doses in terms of efficacy and safety.[296,321] Unnecessary renal dose adjustments may lead to underexposure and clinical failure.[296] The international guidelines on polymyxins recommend TDM and AFC to be used if there is availability, with the dosing guidance for polymyxin B having a similar target as for colistin (i.e., $C_{ss,avg}$ of 2 mg/L, seems appropriate). Nevertheless, emerging data suggest that polymyxin B might have a different toxicodynamic profile than colistin, and a $C_{ss,avg}$ of 2–4 mg/L ($AUC_{ss,24\ hr}$50–100 mg·hour/L) may be acceptable in terms of toxicity.[296] The recent position paper on TDM, on the other hand, neither recommends nor encourages monitoring for polymyxin B.[8]

Adverse Events

Dose-related, usually reversible, nephrotoxicity risk and neurotoxicity risk are the major dose-limiting adverse events of polymyxin use.[322,323] Neurotoxicity may manifest as paresthesias and peripheral neuropathy, but the most severe form is neuromuscular blockade resulting in muscle weakness and even apnea with need for ventilatory support until the effect of polymyxin wears off. Curariform drugs potentiate neurotoxicity, whereas IV administration of calcium may contribute to apnea reversal. Overdose of polymyxins, presence of renal impairment, and concurrent use of aminoglycoside increase the risk of nephrotoxicity.[323–326]

FOSFONIC ACID DERIVATIVES: FOSFOMYCIN

Fosfomycin is another "old" antibiotic, discovered in the 1960s, with its use almost abandoned until the mid-2000s, when it again attracted the interest of clinicians and was reintroduced into clinical practice as alternative/salvage treatment for infections by XDR and pandrug-resistant (PDR) GNBs, especially in the critical care setting.[327–338] IV fosfomycin has been approved in several countries, including European ones, encouraging salvage use in the labeling information.[327] In the United States, only the oral formulation is approved, whereas the IV formulation has been granted Qualified Infectious Disease Product and Fast Track designation by the FDA.[327,339]

Mode of Action

Fosfomycin represents an antimicrobial class of its own, without any structural relevance with other currently clinically approved class.[336] It is a bactericidal antibiotic and exerts its action by a unique mechanism of irreversible inhibition of peptidoglycan synthesis, one of the initial

steps of prokaryote wall synthesis, acting in an earlier step than beta-lactams and glycopeptides.[327,328,336] This inhibition eventually leads to cell lysis and death.[327,328,336] This unique mechanism of action makes cross-resistance with other antimicrobial agents most unlikely, and in addition, it allows for synergistic action with other antibiotics, such as beta-lactams, aminoglycosides, and fluoroquinolones.[327,331–333,336]

Spectrum of Activity

Fosfomycin is active against both gram-negative and gram-positive microorganisms, such as *Enterobacteriaceae*, including ESBL- and carbapenemase-producing ones; *S. aureus,* including MRSA, enterococci, including vancomycin-resistant strains; *L. monocytogenes*, and *Neisseria gonorrhoeae.*[327] The sensitivity of streptococcal species is variable, whereas *Staphylococcus capitis* and *Staphylococcus saprophyticus* are intrinsically resistant to fosfomycin.[327,336] The activity against *P. aeruginosa* is moderate with variable MICs, whereas *A. baumannii, B. cepacia,* and *M. morganii* are resistant to fosfomycin, and its use should only be considered as part of a combination regimen.[333,336] It should be noted that the susceptibility testing of fosfomycin is problematic.[327] Regarding resistance to fosfomycin, it can be inherent or acquired, chromosomal or plasmid-mediated, and the main mechanisms include reduced permeability, binding site modification, and enzymatic inactivation; more than one mechanism may coexist.[331,332] Whereas in vitro resistance development is fast, in vivo development is slower.[331,332]

PK/PD

Fosfomycin is a hydrophilic antimicrobial agent with V_d comparable to that of beta-lactams and aminoglycosides, and it has negligible protein binding.[328,336] It is not metabolized, it is almost entirely renally excreted by glomerular filtration unchanged to the urine, and its half-life is 2.3–7.4 hours.[328,333,336] It has good penetration into many tissue types, lungs, CSF, and abscess fluid.[327,336] However, the PK/PD of fosfomycin may be altered in critically ill patients and is not well-studied in the critical care setting.[327,328] A significant PK variability of fosfomycin that could only partially be explained by difference in renal function was reported in a population PK study in critically ill patients.[329] To date, the most appropriate parameter for the PK/PD profile of the drug has not been established, and no well-defined parameters exist to safely predict drug efficacy or resistance development.[327]

Clinical Efficacy

A meta-analysis of RCTs and comparative observational trials about IV fosfomycin reported that it was mostly used for sepsis/bacteremia and infections of the respiratory tract, bone/joint, and CNS and that there were no differences in clinical or microbiologic efficacy.[337] The main use of fosfomycin currently is for MDR, XDR, and PDR pathogens. Studies have shown good efficacy for MRSA infections (even as monotherapy) and against ESBL-producing *E. coli,* carbapenem-resistant *K. pneumoniae* (in combination regimens), and MDR *P. aeruginosa* (in combination regimens).[327,336]

Because of reports of fast resistance development during monotherapy, especially for GNBs, fosfomycin should be used in combination with other active antimicrobial agents, but no specific agent can be recommended, as the available data regarding possible synergies are inconsistent.[327] Some in vitro data suggest a benefit when fosfomycin is coadministered with carbapenems, aminoglycosides, fluoroquinolones, and colistin.[327,336] Also, time-kill experiments have reported promising results against MBL-producing *K. pneumoniae* with triple combinations of fosfomycin with antimicrobials such as colistin, meropenem, rifampin, vancomycin, telavancin, and daptomycin.[336]

Further studies are warranted to establish the correct dose/dosing intervals of IV fosfomycin and the most appropriate companion antimicrobial agents in order to optimize efficacy against difficult-to-treat GNBs.[327]

Dosage

Oral and IV formulations of fosfomycin are available.[327,333] IV doses of fosfomycin up to 24 g daily have been used for severe infections by MDR pathogens (see Table 107.1).[327,335] However, the individual minimum and maximum doses, the infusion duration, and the optimal dosing intervals for fosfomycin administration need to be further established.[327] The limited PK data in critically ill patients prevent accurate dosing guidance, and further studies are needed.[327]

Adverse events. Fosfomycin has a favorable safety profile with unremarkable toxicity and mild adverse events, with diarrhea being the most frequent.[327,336–338] The most significant adverse events are reversible hypokalemia and sodium overload (0.32 g [14 mEq] of sodium in 1 g of disodium fosfomycin), but both are closely monitored and can be corrected in the intensive care setting.[327] Nonetheless, it should be noted, however, that for high doses of fosfomycin (exceeding 16 g/day), further data on safety are needed.

KEY POINTS

- Concerns regarding the rapid spread of antimicrobial resistance against clinically important gram-negative bacteria are ever increasing at a worldwide level, with treatment choices for MDR strains being limited, especially for strains that produce extended-spectrum beta-lactamases and carbapenemases. Carbapenemases particularly inactivate the potent class of carbapenems along with all beta-lactams.
- During the last decade new antimicrobial agents or combinations of beta-lactam with beta-lactamase inhibitors have been approved, reinforcing our armamentarium against gram-negative bacteria, namely ceftolozane/tazobactam, ceftazidime/avibactam, meropenem/vaborbactam, imipenem/cilastatin/relebactam, plazomicin, eravacycline, omadacycline, and delafloxacin. However, the options against carbapenem-resistant *A. baumannii* and MBL-producing strains are still limited. Moreover, resistance against novel anti–gram-negative agents has already started to emerge; implementation of antimicrobial stewardship is essential for the preservation of their activity and the extension of their self-life.
- Older antibiotics, such as polymyxins and fosfomycin, have been "rediscovered" and used as "salvage" treatment for infections caused by MDR gram-negative bacteria.
- The potential for synergy of antibiotic combinations and the impact on outcome improvement are still controversial. However, although there is no definitive evidence yet about the impact of combination therapy on clinical outcomes, it is recommended in patients with difficult-to-treat MDR gram-negative bacteria in order to increase efficacy and limit resistance development. The potential of combinations of the novel antibiotics with the older ones needs to be explored.
- Apart from discovering novel antimicrobial agents, dosing optimization of the current antimicrobial agents, taking into consideration their PK/PD characteristics along with the physiologic changes of critically ill patients, is of utmost importance. TDM allows dosage individualization at the bedside and is expected to significantly contribute to outcome improvement, decrease potential toxicity, and curb resistance development.

Abdul-Aziz MH, Alffenaar JWC, Bassetti M, et al. Antimicrobial therapeutic drug monitoring in critically ill adult patients: A position paper. *Intensive Care Med.* 2020;46(6):1127–1153.

A position paper endorsed by the European Society of Intensive Care Medicine (ESICM), Pharmacokinetic/Pharmacodynamic and Critically Ill Patient Study Groups of European Society of Clinical Microbiology and Infectious Diseases (ESCMID), International Association for Therapeutic Drug Monitoring and Clinical Toxicology (IATDMCT), and International Society of Antimicrobial Chemotherapy (ISAC). Available data on TDM of antibacterials, antifungals, and antivirals in critically ill adult patients in the ICU were reviewed and discussed, and a practical guide on how TDM can be applied in routine clinical practice in order to improve outcomes was provided. For critically ill patients, routine TDM was recommended for aminoglycosides, beta-lactam antibiotics, linezolid, teicoplanin, vancomycin, and voriconazole.

A comprehensive review that critically summarizes the novel approved antibiotics for gram-negative bacterial infections, presents promising agents in the pipeline currently in clinical trials (phase III, II, or I), and introduces new alternative avenues with potential to combat multidrug-resistant gram-negative bacteria in the future.

Leone M, Roberts JA, Bassetti M, et al. Update in antibiotic therapy in intensive care unit report from the 2019 Nimes International Symposium. *Anaesth Crit Care Pain Med.* 2019;38(6):647–656.

The 2019 Nîmes International Symposium in Antibiotic Therapy Optimisation aimed at determining the best approaches of a number of the antibiotic management strategies for critically ill patients. A panel of experts, aiming to determine the best antibiotic management strategies in the critical care setting, reviewed the relevant latest literature and presented the available evidence and key messages for the following topics: requirements of optimal antibiotic stewardship program, risks of subtherapeutic dosing of antibiotics in critically ill patients, persisting issues about efficiency of combination therapy and the value of de-escalation, new perspectives of pharmacokinetics, drug toxicities including collateral damages associated with antibiotics, the place of nebulization of antibiotics, management of patients receiving extracorporeal therapies, and the place of new antibiotics.

Roger C, Louart B, Elotmani L, et al. An international survey on aminoglycoside practices in critically ill patients: The AMINO III study. *Ann Intensive Care.* 2021;11(1):49.

A prospective, multicenter, observational cohort study conducted in 59 ICUs in five countries that enrolled 931 consecutive patients receiving aminoglycosides (AG) for septic shock. The 84% of the patients received AG empirically; amikacin was the most frequently used AG, followed by gentamicin (33%), the median (IQR) duration of therapy was 2 (1–3) days, the median dose was 25 ± 6, 6 ± 2, and 6 ± 2 mg/kg for amikacin, gentamicin, and tobramycin, respectively, and the median dosing interval was 26 (23.5–43.5) hours. TDM of C_{max} and C_{min} was performed in 47% and 57% of the patients, respectively. After the first dose 68% of patients achieved a C_{max}/MIC >8, suggesting that efforts to optimize the first AG dose are warranted, and 71% of the patients had C_{min} above the recommended thresholds.

Tsuji BT, Pogue JM, Zavascki AP, et al. International consensus guidelines for the optimal use of the polymyxins: Endorsed by the American College of Clinical Pharmacy (ACCP), European Society of Clinical Microbiology and Infectious Diseases (ESCMID), Infectious Diseases Society of America (IDSA), International Society for Anti-infective Pharmacology (ISAP), Society of Critical Care Medicine (SCCM), and Society of Infectious Diseases Pharmacists (SIDP). *Pharmacotherapy*. 2019;39(1):10–39.

The first ever consensus therapeutic guidelines for optimal therapeutic use of polymyxins, colistin (polymyxin E), and polymyxin B in adult patients endorsed by the IDSA, ISAP, SCCM, and SIDP. Also endorsed by ESCMID as a consensus statement and the overall document conclusions endorsed by the European Committee on Antimicrobial Susceptibility Testing (EUCAST). The document was developed based on evidence by a diverse international expert panel aiming to make therapeutic recommendations regarding PK/PD properties and PK targets of polymyxins, polymyxin agent selection, dosing, dosage adjustment, TDM, polymyxin-based combination therapy, intrathecal therapy, inhalation therapy, toxicity, and prevention of renal failure.

Antimicrobial Agents With Primary Activity Against Gram-Positive Bacteria

Kelli A. Cole and Diane M. Cappelletty

Nosocomial infections continue to pose a significant burden on the healthcare system. The most recent summary of data reported to the National Healthcare Safety Network (NHSN) showed that gram-positive organisms remained a leading cause of healthcare–associated infections (HAIs) between 2015 and 2017.[1] Similarly, the EPIC II study in 2007 demonstrated that gram-positive organisms were associated with 47% of infections in the intensive care unit (ICU).[2] *Staphylococcus aureus* and coagulase-negative staphylococci were the most commonly isolated pathogen in nosocomial bacteremia, and the former was responsible for the greatest proportion of ventilator-associated pneumonia and surgical site infections in hospital ICUs. Along with the increase in prevalence of gram-positive cocci in the ICU, staphylococci are becoming multidrug resistant. This chapter addresses gram-positive organisms and resistance issues associated with each of the antimicrobials with activity against these pathogens.

VANCOMYCIN

Vancomycin was discovered in 1956 and marketed in 1958. Early preparations of the drug contained pyrogens and impurities that produced a brownish, muddy appearance that provided vancomycin's nickname, "Mississippi mud." In addition, these pyrogens and impurities caused high fevers, hypotension, severe phlebitis, and possibly nephrotoxicity.[3]

Mechanisms of Action and Resistance

Vancomycin is a glycopeptide that inhibits synthesis of the cell wall by binding to the D-alanyl-D-alanine terminus of cell wall precursor units and is bactericidal against most gram-positive organisms. In the mid-2000s, the Clinical and Laboratory Standards Institute (CLSI) and the U.S. Food and Drug Administration (FDA) changed the vancomycin breakpoints against *S. aureus* from less than or equal to 4 μg/mL to less than or equal to 2 μg/mL for susceptible strains. Intermediate susceptibility is now 4–8 μg/mL, and resistance to vancomycin is greater than or equal to 16 μg/mL.[4] The European Committee on Antimicrobial Susceptibility Testing (EUCAST) changed their vancomycin interpretations against *S. aureus* to less than or equal to 2 μg/mL as susceptible and greater than 2 μg/mL as resistant. These changes in breakpoints will alter how literature is interpreted with respect to the frequency or prevalence of vancomycin-intermediate or vancomycin-resistant *S. aureus* over the past 30 years.

Vancomycin-intermediate *S. aureus* (VISA), defined using the previous breakpoints of minimum inhibitory concentration (MIC) 8–16 μg/mL, was first reported from Japan in 1996; by June 2002, eight cases were confirmed in the United States.[5] A precursor to VISA, known as *heteroresistant vancomycin-intermediate S. aureus* (hVISA), was described around the same time.[6] A systematic review and meta-analysis from 2015 found that both phenotypes are increasing in prevalence.[7] In June 2002, the first case of vancomycin-resistant *S. aureus* (VRSA) with an MIC greater than 32 μg/mL was identified in Michigan, and to date, 14 clinical isolates have been reported.[5,8,9] Although the exact mechanism leading to reduced susceptibility in VISA isolates has yet to be determined, many agree that a common element involves thickening of the cell wall, whereas all VRSA strains possessed the VanA gene.

Nine types of resistance for vancomycin have been isolated from enterococci: VanA, VanB, VanC, VanD, VanE, VanG, VanL, VanM, and VanN. The VanA phenotype, inducible by vancomycin, confers high-level resistance to both teicoplanin (MICs: 16–512 μg/mL) and vancomycin (MICs: 64 to greater than 1000 μg/mL), whereas VanB confers low-level resistance primarily to vancomycin. Both have been identified in *Enterococcus faecium* and *Enterococcus faecalis*. VanA, B, D, and E are all transferable to other organisms. In contrast, the VanC phenotypes are endogenous (constitutively produced) and are components of *Enterococcus gallinarum, Enterococcus casseliflavus,* and *Enterococcus flavescens* and confer resistance to vancomycin alone.

Spectrum of Activity

Vancomycin is active primarily against aerobic gram-positive cocci, including streptococci and staphylococci. Although it is considered the drug of choice for most methicillin-resistant *S. aureus* (MRSA) infections, it has been shown to be inferior to nafcillin or oxacillin for the treatment of methicillin-susceptible *S. aureus* (MSSA), and similarly should be considered an agent of last resort against streptococci.[10,11] It has reliable activity against *Corynebacterium* spp. and is also considered first-line for such infections. The activity of vancomycin against enterococci varies greatly with the species. *E. faecium* is the most resistant, with approximately 80% of strains demonstrating resistance compared with only ~10% of *E. faecalis* strains.[1]

Vancomycin is active against anaerobic gram-positive organisms such as *Peptostreptococcus* spp., *Propionibacterium* spp., *Eubacterium* spp., *Bifidobacterium* spp., and most *Clostridium* spp., including *C. difficile*.[12]

Pharmacokinetics and Pharmacodynamics

Vancomycin is administered orally and parenterally. The drug is poorly absorbed after oral administration, and although the majority of the drug is excreted unchanged in feces, inflammation of the gastrointestinal tract may result in increased absorption.[13] Intramuscular injections are extremely painful and should not be used. Intraperitoneal, intrathecal, or intraventricular administration may be needed in certain circumstances. Vancomycin is approximately 55% bound to plasma proteins. The volume of distribution (V_d) corrected for weight ranges is 0.4–0.9 L/kg.[14–17] Vancomycin does not penetrate well into aqueous humor or noninflamed meninges; however, penetration ranges from 1% to 37% of serum concentrations in the setting of meningeal inflammation.[18–20] Penetration is greater than 75% serum concentrations into ascitic,

pericardial, and synovial fluids; approximately 50% into pleural fluid; and 30%–50% into bile.[16] Elimination of vancomycin is 80%–90% unchanged drug in the urine via glomerular filtration and the remaining via nonrenal elimination (up to 40 mL/min in healthy individuals).[21] The half-life of the drug increases with decreased renal function; in patients with creatinine clearances (CrCl) greater than 80 mL/min, the half-life is 4–6 hours. The pharmacodynamic target predicting efficacy has received much attention and is suggested to be an area under the concentration time curve to MIC (AUC/MIC) ratio of 400.[22]

Dosage Regimens and Therapeutic Monitoring

Therapeutic Drug Monitoring

Routine monitoring of vancomycin serum concentrations has become a highly debated issue over the years. Those who advocate routine monitoring cite the need to ensure therapeutic concentrations and to minimize toxicities.

Studies have shown that peak concentrations of vancomycin are not associated with safety or clinical efficacy. Therefore monitoring peak serum concentrations has largely fallen out of favor. On the other hand, vancomycin troughs have been heavily studied for their correlation with efficacy and toxicity. And although a few publications found improved outcomes when targeting vancomycin troughs of 15–20 μg/mL for serious MRSA infections, mounting evidence suggests that vancomycin troughs of this magnitude (greater than or equal to 15 μg/mL) are associated with an increased risk of nephrotoxicity.[23–25] Because of this, greater attention has been given to AUC-based dosing strategies, with recent literature finding that an AUC/MIC target ratio of ≥400 was associated with decreased mortality and clinical failure while at the same time lower rates of nephrotoxicity and overall vancomycin exposure.[26–29] Unfortunately, AUC monitoring is not routinely performed in clinical practice, and most critically ill patients are inappropriate for AUC-based dosing. Thus it still remains prudent to measure serum trough concentrations until more definitive guidance is provided to address these patient populations.[30]

Intravenous Administration in Adults

In nonobese adults with normal renal function, the usual dose of vancomycin is 1 g (~15 mg/kg actual body weight) intravenously (IV) every 12 hours. For severe MRSA infections, 15–20 mg/kg every 8–12 hours has been recommended to achieve serum trough concentrations of 15–20 μg/mL, and loading doses of 25–30 mg/kg are proposed for critically ill patients in order to achieve higher concentrations sooner (both grade IIIB recommendations).[30] Several dosing nomograms using body weight and CrCl have been developed to accurately and easily dose vancomycin; however, significant interpatient variability exists in both volume of distribution and renal clearance estimation in the critically ill population, so use of these nomograms is limited.[31–34] Similarly, use of continuous infusion has been proposed, but with limited data on its benefit over intermittent infusion.[35,36] Table 108.1 lists dosing regimens for the antimicrobials discussed in this chapter.

Dosing in the Setting of Obesity

Morbidly obese, critically ill patients are difficult to dose given the lack of pharmacokinetic studies. Although actual body weight and CrCl continue to be the best correlate to volume of distribution and vancomycin clearance in the obese population, use of traditional weight-based dosing has led to overexposure and toxicity.[37] This has prompted various alternative dosing strategies, including AUC-targeted nomograms, but these have yet to be studied in the combined critically ill and obese cohort.[38–40] Because of this, therapeutic drug monitoring (TDM) remains a key tool in managing vancomycin dosing in this population.[41,42]

Dosing in Renal Failure/Dialysis

Dose reduction is recommended for patients with renal dysfunction.[15] In patients receiving intermittent hemodialysis, vancomycin pharmacokinetics vary depending on the patient's actual body weight, timing of administration, residual renal function, and type of dialysis membrane used. With older, low-flux membranes, less frequent and lower postdialysis supplemental doses are required.[43] With high-flux membranes, as much as 50% of vancomycin is removed.[44–49] In these situations, common practice involves administration of a weight-based loading dose followed by maintenance doses given during the last hour of each dialysis session.[50] Use of trough levels before each dialysis session may further guide dosing.

When continuous renal replacement therapy (CRRT) is being used, vancomycin dosing again depends on patient- and dialysis modality–related factors. Continuous venovenous hemodialysis (CVVHD) and continuous venovenous hemodiafiltration (CVVHDF) result in a greater total body clearance of vancomycin than does continuous venovenous hemofiltration (CVVH); therefore dosing every 12–24 hours and every 24–48 hours has been proposed for each modality, respectively.[21,51–53] For patients receiving sustained low-efficiency dialysis (SLED), a newer modality combining intermittent hemodialysis and CRRT, it appears that an initial weight-based loading dose followed by maintenance doses coupled with TDM may be appropriate.[54] Overall, a review of several pharmacokinetic studies in patients receiving various forms of CRRT showed an association between effluent flow rate and vancomycin clearance. However, these findings require additional validation.[55] Based on the variability in clearances achieved with each of these methods depending on blood flow rate, ultrafiltration rate, and the membranes used, TDM remains an effective method of ensuring appropriate vancomycin dosing when CRRT is used.

Dosing in Cardiopulmonary Bypass/Extracorporeal Membrane Oxygenation

Cardiopulmonary bypass (CPB) was found to significantly affect the pharmacokinetic parameters of vancomycin in several small studies over the past 20 years. For example, Ortega and colleagues observed an immediate decrease in vancomycin serum concentration by 7 μg/mL after initiation of CBP, followed by gradual and steady decreases over the next 30 minutes.[56] However, a recent prospective, comparative evaluation of vancomycin pharmacokinetics found no difference in maximum plasma concentration (C_{max}), area under the curve ($AUC_{0–8}$), V_d, and clearance (Cl) between patients undergoing cardiac surgery with and without CBP.[57]

Three studies in adult patients receiving extracorporeal membrane oxygenation (ECMO) found no significant differences in pharmacokinetic parameters compared with matched controls, reflecting vancomycin's relative stability in ECMO circuits.[58]

Oral Administration

Oral administration of vancomycin is only for treating *C. difficile* colitis. The dose is 125–500 mg orally every 6 hours depending on severity and is not adjusted for renal dysfunction. Two oral formulations (capsules or liquid) can be used, or the IV solution can be administered orally to treat *C. difficile*. In cases of ileus or toxic megacolon, administration via rectal tube (as a retention enema) or ileostomy can be considered.

Adverse Effects

The most notable adverse effects associated with vancomycin include nephrotoxicity, ototoxicity, and infusion-related reactions.

Initial reports of nephrotoxicity were thought to be related to impurities in the early formulations.[3] After improved purification methods,

TABLE 108.1 Dosages for Agents With Primary Activity Against Gram-Positive Bacteria

Drug	Dosage	Adverse Effects	Considerations
Vancomycin	Oral (PO) and intravenous (IV) administration Dose based on actual body weight (ABW) PO: 125–500 mg q6h IV: 1 g (~15 mg/kg) q12h for average-weight adult or 15 mg/kg loading dose followed by 30 mg/kg/day continuous infusion IV: For morbidly obese adult, dose on ABW ~15 mg/kg/dose	Red man syndrome: erythema, pruritus, flushing of upper torso Thrombophlebitis Ototoxicity: rare Nephrotoxicity: rare Maculopapular or erythematous rashes	Intramuscular injections painful Poorly absorbed orally Half-life of drug increases with decreased renal function Optimal target to be determined For obese patients and patients on dialysis, consider therapeutic drug monitoring
Teicoplanin	PO and IV administration PO: 200 mg BID (*Clostridium difficile*–associated diarrhea) Moderate infections: 400 mg (6 mg/kg) once followed by maintenance dose 200 mg (3 mg/kg) q24h Severe infections: 400–800 mg (6–12 mg/kg) q12h for 2–3 doses, followed by 400–800 mg q24h	Nephrotoxicity: rare Ototoxicity: rare Hypersensitivity	Special dosage considerations for patients with renal failure, patients on dialysis Compassionate use only in the United States (not FDA approved)
Telavancin	IV: 10 mg/kg once daily	Nausea and vomiting Taste perversion Foamy urine Renal impairment	Teratogenic in animal models, further information needed in humans Interferes with common anticoagulation and urine protein dipstick testing
Daptomycin	IV: 4 mg/kg q24h for average-weight adult for skin and skin structure infection 6 mg/kg q24h for bacteremia/endocarditis	Transient muscle weakness Myalgia CPK elevations	Contraindicated in pneumonia 8–12 mg/kg considered for serious infections
Linezolid	Bioequivalence between PO and IV formulations Moderate infections: 600 mg twice daily Uncomplicated infections: 400 mg twice daily	Reversible myelosuppression Anemia Neutropenia Thrombocytopenia Monoamine oxidase interactions Peripheral and optic neuropathy	Oral formulation is bioequivalent to IV formulation Caution with prolonged use and in patients on selective serotonin reuptake inhibitors (SSRIs)
Tedizolid	Bioequivalence between PO and IV formulations 200 mg daily for acute bacterial skin and skin structure infections	Nausea, vomiting, diarrhea Headache Dizziness	Less myelosuppressive and risk for monoamine oxidase interaction
Quinupristin/dalfopristin	IV: 7.5 mg/kg q8–12h infused over 1 hr	Arthralgia Myalgia Infusion-related Nausea, vomiting, diarrhea, rash	Last-line agent because of significant toxicities

the rate is generally accepted to be between 5% and 10% when vancomycin is not administered with other nephrotoxic agents and trough concentrations are less than 10 μg/mL.[59–61] Factors that may increase the risk of nephrotoxicity include trough concentrations >15 μg/mL, higher total daily doses (≥4 g/day), larger patient weight, prolonged durations (>7 days), and concomitant nephrotoxins (i.e., aminoglycosides).[23,61–67] Recently, piperacillin-tazobactam in combination with vancomycin has also been associated with increased risk of acute kidney injury when compared with either agent alone and when compared with combinations of vancomycin with other beta-lactams.[68,69] On the other hand, use of continuous infusion appears to lower these risks.[35] Although vancomycin-associated nephrotoxicity is usually reversible, it can lead to increased hospital length of stay, healthcare costs, and even mortality.[62]

Ototoxicity is rare and ranges from vertigo and tinnitus to hearing loss.[3,59] Correlation between vancomycin exposure and risk of ototoxicity is lacking, suggesting that early reports of toxicity may have been caused by either another drug or the combination of another drug with vancomycin.[59,70] In the majority of cases, ototoxicity symptoms disappear within a month of discontinuing vancomycin.

Red man syndrome comprises erythema, pruritus, and flushing of the upper torso and is often associated with too rapid an infusion of the drug. In general, the infusion rate should not exceed 1 g/hr. Less frequently, hypotension and angioedema can occur. It is thought that increased histamine release is the cause of this syndrome, and the effects can be relieved by antihistamines.[3,59,71–74]

Other toxicities associated with vancomycin include maculopapular or erythematous rashes (2%–8%)[17,75,76] and anecdotal reports of neutropenia and thrombocytopenia.[75,77]

TEICOPLANIN

Teicoplanin is a glycopeptide antibiotic and is not approved for use in the United States. It is available for use in Europe, some Asian countries,

Mexico, New Zealand, and Australia. It has a more favorable adverse effect profile than vancomycin; however, there is concern over teicoplanin's clinical efficacy in the treatment of severe gram-positive infections.

Mechanisms of Action and Resistance

Teicoplanin, like other glycopeptide antibiotics, inhibits synthesis of the cell wall by binding to the d-alanyl-d-alanine terminus of cell wall precursor units. Resistance has been reported in both staphylococci and enterococci. The VanA phenotype confers high-level resistance to both teicoplanin (MIC: 16–512 μg/mL) and vancomycin (MIC: 64 to >1000 μg/mL). The VanB phenotype has also been identified in both *E. faecium* and *E. faecalis* and usually confers low-level resistance to vancomycin but not to teicoplanin. This resistance may limit the utility of teicoplanin for some vancomycin-resistant enterococcal infections. Several reports of *S. aureus* resistance developing during therapy with teicoplanin have been reported.[78–81] The mechanism of the resistance was determined in one patient to be constitutive and non–plasmid-mediated.[79] Most phenotypes of hVISA and VISA demonstrate cross-resistance to teicoplanin.[82]

Spectrum of Activity

Teicoplanin is only active against gram-positive organisms. Activity against MSSA and MRSA is comparable to that of vancomycin. Coagulase-negative staphylococci have a varied pattern of susceptibility to teicoplanin. *Staphylococcus haemolyticus* is the most resistant species to teicoplanin (30%).[76] For methicillin-resistant coagulase-negative staphylococci, 39% of isolates have teicoplanin MICs greater than 8 μg/mL compared with 1% with vancomycin.[76,83] Teicoplanin is active against other aerobic and anaerobic gram-positive organisms such as *Corynebacterium* spp.; *Clostridium* spp., including *C. difficile* and *C. perfringens; Peptostreptococcus* spp.; and *Propionibacterium acnes*.

Pharmacokinetics and Pharmacodynamics

Teicoplanin is administered orally and intravenously. The drug is poorly absorbed after oral administration, and approximately 40% of the drug is excreted unchanged in feces. IV administration of 400 mg (6 mg/kg) should provide a peak serum concentration of 20–50 μg/mL attained 1 hour after administration.[84] The volume of distribution is large, at 0.9–1.41 L/kg, and teicoplanin is 90%–95% protein bound.[84] Tissue distribution is variable; most notably, penetration is poor into noninflamed meninges and fat but good into myocardium and pericardium.[85] Teicoplanin is primarily eliminated via glomerular filtration, and only 3% is metabolized.[84] The half-life is approximately 150 hours in patients with normal renal function.[84] In patients with mild to moderate renal dysfunction, the half-life was found to be 157–567 hours.[85,86]

Dosage Regimens and Therapeutic Monitoring

Despite the long half-life in patients with normal renal function, teicoplanin should be administered daily, and the dose is dependent on the severity of infection. For less serious infections involving the urinary tract, skin, soft tissue, and lower respiratory tract, a loading dose of 400 mg (6 mg/kg) × 1 is administered, followed by a maintenance dose of 200 mg (3 mg/kg) every 24 hours. For severe infections such as septicemia, endocarditis, and osteomyelitis, 400 mg of teicoplanin is administered every 12 hours for 3 doses, followed by 400 mg every 24 hours. For specific clinical scenarios such as *S. aureus* endocarditis, levels between 20 and 30 mg/L have been recommended. Therefore higher doses (up to 12 mg/kg) are suggested.[84,87]

Dosing in Renal Failure/Dialysis

Teicoplanin is not removed by hemodialysis or continuous ambulatory peritoneal dialysis (CAPD).[88,89] The amount removed by high-flux membranes such as CVVH, CVVHD, and CVVHDF can be significant.[90–92] For renal dysfunction, several dosing regimens exist, with doses even as high as 600–1800 mg/day during CVVH.[91] Even with such high doses, therapeutic drug monitoring is still recommended, given the variability in protein binding and ultrafiltration rates when using CRRT.

Dosing in Venoarterial Extracorporeal Membrane Oxygenation

Limited data are available on the use of teicoplanin in patients receiving venoarterial extracorporeal membrane oxygenation (VA-ECMO). Eleven patients received a median loading dose of 11.6 mg/kg every 12 hours × 3 then a fourth dose 24 hours after the third dose. The range of trough concentrations was 14.85–44.84 μg/mL.[93]

Adverse Effects

Nephrotoxicity associated with teicoplanin is much lower than with vancomycin. The incidence from published and unpublished studies found the nephrotoxic rate to be 4%.[71] Ototoxic rates with teicoplanin are similar to those with vancomycin.[71] Hypersensitivity reactions are the most common adverse reaction to teicoplanin (2%–15%).[71]

TELAVANCIN

Mechanisms of Action and Resistance

Telavancin is a lipoglycopeptide derivative of vancomycin that has a dual mechanism of action. It binds to the d-alanyl-d-alanine terminus of the cell wall precursors, as does vancomycin, but additionally binds to bacterial membranes, resulting in depolarization and increased permeability of the membrane.[94,95] This dual mode of action, in addition to structural differences, allows for enhanced activity against MRSA and some enterococci.[96] The acquired VanA phenotype in enterococci confers resistance to telavancin. However, susceptibility is retained with the VanB phenotype.[97] Van-mediated resistance in *S. aureus* leads to reduced telavancin activity but not as great as for vancomycin. In vitro studies have shown a low rate of de novo resistance development in both staphylococci and enterococci, even with previous vancomycin exposure, and currently only one case of elevated telavancin MIC has been reported with clinical use.[98–104]

Spectrum of Activity

Telavancin is active against MSSA, MRSA, coagulase-negative staphylococci, vancomycin-susceptible enterococci, *Streptococcus pyogenes, Streptococcus agalactiae,* and *Streptococcus anginosus*. The MIC_{90} against both MSSA and MRSA is 0.06 μg/mL, and despite higher MICs, telavancin does have activity against vancomycin-intermediate and vancomycin-resistant strains (MIC ranges of 0.03–0.25 μg/mL, 0.06–0.5 μg/mL, and 0.25–8 μg/mL against hVISA, VISA, and VRSA, respectively).[105–110] Against *Enterococcus* spp., telavancin is slightly less potent, and greater activity is seen against vancomycin-resistant strains, with VanB over those with VanA.[97,105–110] Telavancin is active against most anaerobic gram-positive organisms, including *C. difficile* and *C. perfringens*.[111]

Pharmacokinetics and Pharmacodynamics

Telavancin is administered IV and demonstrates linear pharmacokinetics over doses of 7.5–15 mg/kg. In healthy subjects, doses of 7.5 and 15 mg/kg at steady state resulted in mean C_{max} serum concentrations of 88 and 186 μg/mL and trough concentrations of 6 and 16 μg/mL, respectively.[112] Approximately 70% of telavancin is renally eliminated, and the half-life was dose dependent and ranged from 6 to 7.5 hours.[112] Telavancin is 90% protein bound to albumin and has a volume of distribution of approximately 0.14 L/kg.[113] Telavancin penetrates lung epithelial lining fluid and alveolar macrophages well, and concentrations

exceeded 0.5 μg/mL during the entire dosing interval.[114] Penetration into blister fluid is approximately 40% of serum concentrations but only 1%–2% into inflamed meninges.[115,116]

Telavancin exhibits rapid concentration-dependent killing. The pharmacodynamic parameter identified in animal models as the best predictor of efficacy is the AUC/MIC ratio, with a target of 219 resulting in optimal killing.[117,118]

Dosage Regimens and Therapeutic Monitoring

For both complicated skin and skin structure infections and hospital-acquired/ventilator-associated pneumonia, telavancin is dosed 10 mg/kg IV every 24 hours when CrCl is over 50 mL/min.

Dosing in Renal Failure/Dialysis

Because of the high urinary elimination of telavancin, dosage reductions are required when the patient's CrCl falls below 50 mL/min. If CrCl is 30–50 mL/min, the dose of telavancin is 7.5 mg/kg every 24 hours; when less than 30 mL/min, the dose is further reduced to 10 mg/kg every 48 hours.[113,118] Hemodialysis does not have a significant impact on telavancin removal.[119] In vitro studies evaluated the effect of CRRT on telavancin elimination and found high ultrafiltrate or dialysate rates can remove a significant amount of telavancin, which could require supplemental dosing.[120]

Dosing in the Setting of Obesity

A linear relationship is seen between body weight and clearance, thus supporting the milligram per kilogram dosing strategy; however, further investigation is warranted, given the potential overestimation of CrCl using total body weight.[121,122]

Adverse Effects

Little information is available about the safety of telavancin in pregnant women. In three animal species, telavancin was found to have fetal effects including decreased birth weight and increased digit and limb malformations. A serum pregnancy test should be performed in women of childbearing age before starting telavancin. A pregnancy exposure registry is available should there be a need to use telavancin in a pregnant woman.[113]

The most common adverse effects associated with telavancin are nausea, vomiting, diarrhea, taste disturbance, foamy urine, and renal impairment.[113,123–126] Telavancin interferes with urine protein qualitative dipstick tests and several anticoagulation tests, including prothrombin time (PT), activated partial thromboplastin time (APTT), international normalized ratio (INR), activated clotting time (ACT), and factor X activity assays.[113] For this reason, concomitant use with unfractionated heparin is contraindicated.[113,127] When measuring anticoagulation, these tests should be performed as close as possible before a patient's next dose or alternative monitoring methods considered.[113]

DAPTOMYCIN

Daptomycin is a lipopeptide that was first discovered in the 1980s and was approved in 2003 by the FDA for complicated skin and skin structure infections and in 2006 for *S. aureus* bloodstream infections, including right-sided endocarditis.

Mechanisms of Action and Resistance

Daptomycin has a unique mechanism of action targeting the cell membrane in the presence of calcium.[128,129] To date, there have been several case series and case reports describing daptomycin resistance in patients with *S. aureus*.[130] The mechanism appears to be multifactorial, with cell membrane changes being largely implicated. Development of resistance in enterococcus has been observed as well.[131] However, in contrast to *S. aureus,* genetic pathways appear to be the key alterations explaining this phenomenon. Clinically, the development of resistance has led to treatment failures and the need for salvage therapy.

Spectrum of Activity

Daptomycin's rapid, concentration-dependent antibacterial activity encompasses most gram-positive bacteria (staphylococci, pneumococci, and enterococci), including vancomycin-resistant and penicillin-resistant strains. Because of the calcium-dependent nature of daptomycin activity, all in vitro testing must be supplemented with physiologic concentrations of calcium.[132] The breakpoint for susceptibility is less than or equal to 1 μg/mL for staphylococci and beta-hemolytic streptococci. Isolates with higher MICs are considered nonsusceptible. Although rare, 0.03% and 0.06% of *S. aureus* strains were found to be nonsusceptible in the United States and Europe, respectively.[133] Daptomycin initially appeared active against vancomycin-intermediate and vancomycin-resistant strains of *S. aureus*. However, a recent analysis of 33 VISA isolates found 70% resistance to daptomycin.[134] Interestingly, 100% of VRSA isolates were susceptible, possibly because of the difference in resistance mechanisms. The FDA breakpoint for susceptibility against enterococci is less than or equal to 4 μg/mL, whereas EUCAST is currently reviewing and CLSI has recently established new cutoffs.[135,136] This includes a definition of susceptible dose-dependent (MIC ≤ 4 μg/mL), warranting higher doses of 8–12 mg/kg, or resistant (≥8 μg/mL) for all *E. faecium* isolates. On the contrary, ≤2 μg/mL is considered susceptible, 4 μg/mL intermediate, and ≥8 μg/mL resistant for all other *Enterococcus* spp. Daptomycin resistance is more common in enterococci compared with staphylococci and is higher among *E. faecium* than *E. faecalis*.[133]

Pharmacokinetics and Pharmacodynamics

Daptomycin given as either a 30- or 2-minute infusion demonstrates linear kinetics at dosing from 4 to 12 mg/kg.[136,137] The drug is 90%–95% protein bound and has a lower affinity for tissue proteins, leading to a small volume of distribution and relatively low rate of central nervous system (CNS) penetration.[136] Although it does distribute to lung parenchyma, it is inactivated by pulmonary surfactant, rendering it ineffective in bronchoalveolar pneumonia. It is primarily eliminated by the renal route, and the half-life is 7–9 hours in patients with normal renal function.[136] In patients with CrCl less than 30 mL/min, end-stage renal disease, hemodialysis, or peritoneal dialysis, a 4 mg/kg dose should provide peak serum concentrations around 25–30 μg/mL and a half-life of about 30 hours.[136]

Daptomycin is rapidly bactericidal and exhibits concentration-dependent killing against gram-positive organisms, including enterococci.[128,129] Daptomycin also exhibits a postantibiotic effect that allows for once-daily dosing.[138]

Dosage Regimens and Therapeutic Monitoring

Intravenous Administration in Adults

For complicated skin and skin structure infections, dosing of daptomycin is 4 mg/kg every 24 hours. Dosing for *S. aureus* bacteremia or right-sided endocarditis is 6 mg/kg every 24 hours.[136] Limited clinical evidence suggests consideration of higher doses (8–12 mg/kg) in specific scenarios such as MRSA bacteremia or deep-seated enterococcal infections.[139,140]

Dosing in the Setting of Obesity

Daptomycin exposure is greater in obese patients, but does not exceed safety thresholds.[141,142] Based on this, recommendations have been to base daptomycin dosage on total body weight. However, recent data

demonstrate greater risk for toxicities in this population, such as creatine phosphokinase (CPK) elevations, and some may advocate for alternative dosing strategies.[143–147] Despite this, there is currently insufficient evidence to routinely use other weight measurements, such as ideal body weight or adjusted body weight, when determining daptomycin dosage, especially in critically ill obese patients.

Dosing in Renal Failure/Dialysis

In patients with CrCl less than 30 mL/min or undergoing hemodialysis or chronic peritoneal dialysis, the dose should be reduced and given every 48 hours according to the underlying infection.[136] In patients undergoing CRRT, the amount of daptomycin removed is dependent on the type of filter and the flow rates.[148] Dosing recommendations for patients undergoing CRRT are 4–6 mg/kg every 48 hours, although there is some speculation that doses may need to be increased to 8–10 mg/kg every 48 hours or 4–6 mg/kg every 24 hours.[52,149–154] Similarly, a dose of 6 mg/kg every 24 hours has been proposed for patients receiving extended daily dialysis (EDD).[155] Despite this, until more data are obtained, the use of higher doses should be balanced with the risk of adverse effects.

Dosing in Cardiopulmonary Bypass/Extracorporeal Membrane Oxygenation

Daptomycin administered at a dose of 8 mg/kg to patients undergoing cardiopulmonary artery bypass grafting requiring CPB produced mean concentrations greater than 30 μg/mL throughout the procedure and until sternum closure.[156] In a single ex vivo study examining daptomycin concentrations after passage through pediatric and adult ECMO circuits, no significant daptomycin loss was observed at 24 hours.[157]

Dosing in Burn Patients

One study evaluated single-dose pharmacokinetics (4 mg/kg) in burn patients and found the C_{max} was 44% lower, with 47% lower AUC and an increase in volume of distribution and clearance.[158] The authors suggest a dose of 10–12 mg/kg in burn patients should provide the same drug exposure as 6 mg/kg in healthy volunteers.

Adverse Effects

CPK concentrations increased in 2.8% of patients treated with daptomycin in the complicated skin and skin structure infection studies and 9.2% in the bacteremia/endocarditis trial.[129,136] Elevations in CPK can occur 2–3 days before clinical signs or symptoms of myopathy present but generally return to normal upon discontinuation of the drug.[138] Daptomycin minimal concentrations (C_{min}) above 24.3 mg/L and concomitant statin therapy have been associated with increased risk of this adverse effect.[144,159]

LINEZOLID

Linezolid was approved in 2000 by the FDA for several indications involving susceptible gram-positive organisms, including skin and skin structure infections, community-acquired and nosocomial pneumonia, and vancomycin-resistant *E. faecium* infections (including those with concomitant bacteremia).

Mechanisms of Action and Resistance

Linezolid is an oxazolidinone antibiotic, a newer class of synthetic agents. Linezolid binds to the 50S ribosome and inhibits the binding of messenger RNA (mRNA), thereby preventing protein synthesis.[160] Clinical isolates of *S. aureus, E. faecium,* and *E. faecalis* resistant to linezolid have been identified, but rates are low (≤1.5%) and have remained relatively stable.[161] The most common mechanism of resistance is chromosomal alteration of the 23S ribosomal RNA (rRNA).[161] Other emerging mechanisms involve acquisition of the natural resistance gene, *cfr,* and a newly identified gene, *optrA,* both of which have been increasing in linezolid nonsusceptible isolates in recent years.[162–165] This finding is worrisome because the *cfr* gene confers resistance to other antimicrobial classes, including chloramphenicol and clindamycin, and both genes are transmissible.[163] These resistance issues, although rare, do raise concern and emphasize the importance of appropriate use of linezolid.

Spectrum of Activity

The FDA and CLSI breakpoint for susceptibility to linezolid is less than or equal to 4 μg/mL for staphylococci and less than or equal to 2 μg/mL for enterococci and streptococci. EUCAST breakpoints are less than or equal to 4 μg/mL for staphylococci and enterococci and less than or equal to 2 μg/mL for streptococci. It is active against both MSSA and MRSA and VISA and VRSA.[134,161,166,167] Linezolid is equally active against both vancomycin-susceptible and vancomycin-resistant enterococci and both penicillin-susceptible and penicillin-resistant *S. pneumoniae*.[161,168] Linezolid is also active against a variety of other organisms, including *Pasteurella multocida, Peptostreptococcus* spp., *Fusobacterium* spp., and *Prevotella* spp.

Pharmacokinetics and Pharmacodynamics

Linezolid is available in both oral and IV formulations. Oral absorption is over 90%, making the oral formulation bioequivalent to the IV formulation. The peak serum concentration and half-life at steady state after 600 mg twice daily are 14–18 μg/mL and 5–6 hours.[169–171] Linezolid is approximately 30% protein bound and penetrates quickly into bone, fat, and muscle, achieving 50%–60% of serum concentrations in bone and 90%–95% in muscle.[172] Cerebrospinal penetration has been documented in patients with meningitis at a fluid/plasma ratio around 1, and pulmonary distribution is excellent.[173–177] Elimination of linezolid is 30% renal and 70% metabolized to inactive metabolites, with essentially no linezolid eliminated in feces as unchanged drug.[171] Linezolid is not an inducer of the cytochrome P-450 enzyme system.

Linezolid is bacteriostatic against staphylococci and enterococci and is bactericidal against streptococci. It demonstrates time-dependent pharmacodynamics, and the parameters that best model the killing activity are an AUC/MIC ratio >100 and %T > MIC of ≥85%.[178]

Dosage Regimens and Therapeutic Monitoring

Intravenous Administration in Adults

The usual dose of linezolid is 600 mg twice daily, and for uncomplicated skin and skin structure infections, the dose is 400 mg twice daily. In critically ill patients, linezolid pharmacokinetics have been found to vary significantly and may lead to insufficient levels in those receiving standard dosing.[179–183] For this reason, alternative dosing strategies (i.e., continuous infusion, increased frequency, higher doses) coupled with TDM have been proposed; however, further studies are needed to assess the efficacy and safety of this.[179,184]

Dosing in the Setting of Obesity

Body weight has been associated with alterations in linezolid kinetics; however, no concrete dose adjustments have been recommended for critically ill, obese patients.[178,185,186]

Dosing in Renal Failure/Dialysis

Hemodialysis removes approximately 30% of linezolid during a 3- to 4-hour session, and limited data exist on peritoneal dialysis removal. However, no dosage adjustment is needed in patients with

renal dysfunction or end-stage renal disease. During different modalities of CRRT, linezolid removal is variable and has the potential to lead to subtherapeutic levels; however, further studies are warranted to determine the optimal dosing regimen when CRRT is used.[187,188]

Dosing in Burn Patients

In a small study of severe burn patients, the volume of distribution and renal clearance were similar to healthy controls; however, total clearance was higher, likely the result of increased nonrenal clearance in those with thermal injuries (323 + 191 vs. 80.4 + 27.5 mL/min, $P = 0.063$).[189]

Adverse Effects

Reversible myelosuppression is the most significant adverse effect associated with linezolid therapy. Anemia, neutropenia, and thrombocytopenia have all been reported, and the incidence increases with durations of therapy exceeding 14 days.[190,191] Renal dysfunction and elevated linezolid concentrations have also been associated with this toxicity.[192] Complete blood cell counts should be monitored weekly, especially in patients in whom the duration of therapy is likely to exceed 2 weeks.

Linezolid is a reversible, nonselective inhibitor of monoamine oxidase; therefore the potential for interaction with adrenergic and serotonergic agents exists. Several case reports of serotonin syndrome (fever, agitation, tremors, and mental status changes) secondary to an interaction between linezolid and selective serotonin reuptake inhibitors (SSRIs) have been identified.[193]

Serious reactions, including optic or peripheral neuropathy, have been increasingly reported and are generally seen after longer durations of linezolid therapy.[193] Optic neuropathy tends to be reversible upon discontinuation of linezolid, but peripheral neuropathy tends to be permanent.[193] The mechanism underlying this neuropathy is thought to involve the inhibition of mitochondrial protein synthesis.[193,194] Lactic acidosis, another potentially fatal effect, is also thought to be caused by prolonged therapy and mitochondrial disruption.[195]

TEDIZOLID

FDA-approved in 2014 and European Medicines Agency (EMA)–approved in 2015, tedizolid is currently indicated only for the treatment of acute bacterial skin and skin structure infections.

Mechanisms of Action and Resistance

Tedizolid phosphate, the prodrug of the active moiety tedizolid, is a second-generation oxazolidinone. It acts via a mechanism similar to linezolid in preventing protein synthesis by binding to the 50S ribosome.[196] Owing to the incorporation of a D-ring substituent and a hydroxymethyl group, however, tedizolid exhibits fourfold to eightfold greater potency against staphylococcal, streptococcal, and enterococcal isolates.[197,198] These structural changes are also responsible for tedizolid's ability to maintain activity against some oxazolidinone-resistant organisms expressing the *cfr* gene.[199,200] Cross-resistance to tedizolid can occur, however, and is likely mediated by a combination of alterations at the ribosomal binding site or acquisition of the *otprA* gene.[165,200,201] Overall, the spontaneous development of resistance to tedizolid is low.[202]

Spectrum of Activity

The FDA breakpoint for susceptibility to tedizolid is less than or equal to 0.25 μg/mL for streptococci in the *S. anginosus* group and less than or equal to 0.5 μg/mL for *S. pyogenes, S. agalactiae, E. faecalis,* and *S. aureus* (including both methicillin-resistant and methicillin-susceptible isolates).[203] Against hVISA, VISA, and daptomycin-nonsusceptible (DNS) *S. aureus,* tedizolid demonstrates activity with an MIC_{90} value of 0.5 μg/mL against all pathogens.[166] Higher MICs were seen when tedizolid was tested against linezolid-resistant isolates of *S. aureus* (range: 1–8 μg/mL), albeit much lower than the MICs to linezolid (range: 8–64 μg/mL).[204] Tedizolid is equally active against both vancomycin-susceptible and vancomycin-resistant enterococci with an MIC_{90} of 0.5 μg/mL, and against linezolid-resistant enterococci, the MIC ranged from 1 to 4 μg/mL.[203,204] Tedizolid exhibited similar potency against penicillin-susceptible and penicillin-resistant *S. pneumoniae* with an MIC_{90} of 0.25 μg/mL.[203]

Pharmacokinetics and Pharmacodynamics

Tedizolid is available in both oral and IV formulations as tedizolid phosphate, a prodrug that is rapidly converted by serum phosphatases to the active tedizolid compound. Oral absorption is approximately 90%.[205,206] The mean maximum plasma concentration ranged from 1.8 to 2.4 μg/mL at 2–3 hours after oral administration, with a mean half-life of approximately 11 hours.[205] Tedizolid is 90% protein bound and is widely distributed into soft tissues (V_d = 108 L), including significant accumulation in epithelial lining fluid (ELF).[207,208] Elimination of tedizolid is 20% renal and 80% via the liver as an inactive sulfate conjugate.[209,210] Tedizolid has low affinity for cytochrome P-450 enzymes, and weak, reversible inhibition of monoamine oxidase (MAO) was seen in vitro.[196,211]

Tedizolid is bacteriostatic, and early models suggest that the AUC/MIC ratio is the pharmacodynamic parameter most reflective of tedizolid killing of staphylococci.[212–215]

Dosage Regimens and Therapeutic Monitoring

The usual dose of tedizolid is 200 mg once daily for the treatment of acute bacterial skin and skin structure infections and is not affected by obesity.[216] At this time, there have been no completed studies exclusively in critically ill patients. However, a phase III study is currently ongoing comparing tedizolid with linezolid for the treatment of hospital-acquired bacterial pneumonia (HABP) and ventilated nosocomial pneumonia (VNP).[217]

A study of patients with extensive renal and hepatic impairment suggested that no adjustment of tedizolid dosage is required for these populations.[210] Additionally, neither hemodialysis nor CRRT significantly removes the drug.[210,218]

Adverse Effects

The potential for myelosuppression, similar to that observed with linezolid, exists with tedizolid; however, it was not observed in healthy adults receiving 200 mg of tedizolid daily for 21 days.[219] Similarly, a pooled analysis of two phase III trials found a lower incidence of thrombocytopenia compared with those receiving linezolid.[220] These results suggest that tedizolid may have less harmful hematologic effects than linezolid.

MAO inhibition by tedizolid was also evaluated in human and animal studies, yet no significant rise in blood pressure or serotonergic effect was seen.[211] Similarly, no evidence of optic or peripheral neuropathy was found after a 21-day course of tedizolid in healthy adults.[221] Despite these findings, the true impact of these untoward reactions remains to be seen as more widespread use of tedizolid takes place.

QUINUPRISTIN/DALFOPRISTIN

Mechanisms of Action and Resistance

Quinupristin/dalfopristin is a streptogramin antibiotic and is a mix of two different streptogramin components from groups A and B. The individual components are bacteriostatic, but the combination is often

bactericidal except against *E. faecium*. Each component binds to different sites on the 50S subunit of the ribosome, inhibiting translation of mRNA at the elongation step, thereby inhibiting protein synthesis.[222]

Streptogramins share similar sites of action with macrolide and lincomycin antibiotics. As a result, mechanisms of resistance are also shared. The most common type of resistance to streptogramins involves the erythromycin resistance methylase *(erm)* genes, termed MLS_B.[223] These genes decrease the binding of antibiotics such as streptogramins group B, erythromycin, and clindamycin by dimethylating a residue on the 23S ribosome. Group A streptogramins are not affected, and the combination often retains its synergistic activity.[223] Enzymatic modification of both components is another mechanism of resistance to the drug.[224,225] The third mechanism involves efflux pumps: one that pumps out both macrolides and streptogramins and one specific for streptogramins.[224,226,227]

Spectrum of Activity

Quinupristin/dalfopristin is active against a wide variety of gram-positive organisms in addition to many anaerobes and oral flora organisms. An MIC of 2 μg/mL or less indicates susceptibility. Against vancomycin-intermediate and vancomycin-resistant *S. aureus,* the drug is active with MICs of 0.25–1 μg/mL.[228,229] Both vancomycin-susceptible and vancomycin-resistant *E. faecium* are susceptible to quinupristin/dalfopristin (MIC_{90}: 1–4 μg/mL); however, *E. faecalis* is resistant to quinupristin/dalfopristin (MIC_{90}: 4–32 μg/mL).[229–231]

Pharmacokinetics and Pharmacodynamics

In healthy volunteers and in patients undergoing CAPD, the mean peak serum concentration of quinupristin was 2.6 and 2.9 μg/mL, respectively, and for dalfopristin it was 7.1 and 8.5 μg/mL, respectively, after a single 7.5-mg/kg dose.[232] Quinupristin/dalfopristin is hepatically metabolized to several active metabolites, and both the parent components and the metabolites are primarily eliminated via bile into feces.[233] Urinary excretion of quinupristin/dalfopristin and metabolites is 15%–19%. The mean half-life ranges from 1.2 to 1.5 hours. The drug is 90% protein bound.[234]

Dosage Regimens and Therapeutic Monitoring

The dose of quinupristin/dalfopristin is 7.5 mg/kg every 8–12 hours and infused over 1 hour. Dosage reduction is likely required in patients with severe liver dysfunction, although specific recommendations are not available.

Dosing in Renal Failure/Dialysis

Neither hemodialysis nor peritoneal dialysis removes any appreciable amount of quinupristin/dalfopristin.[232,235] Penetration into the peritoneal cavity is negligible in CAPD patients. No dosage adjustment is needed in patients with renal insufficiency or on dialysis.

Adverse Effects

Myalgias (6%–7%) and arthralgias (9%–9.5%) are the most severe adverse effects and are often the reason for discontinuation of the drug.[236,237] Elevations in direct and conjugated bilirubin and gamma-glutamyl transferase are common. Infusion-related adverse effects occur in 30%–45% of patients with peripheral lines used for the infusion.[236] The reactions include pain, burning, inflammation, and thrombophlebitis. Other toxicities include nausea, diarrhea, vomiting, and rash.

KEY POINTS

- Vancomycin is a first-line agent for most gram-positive infections, including those caused by staphylococci, streptococci, and enterococci. Resistance to vancomycin in *S. aureus* is rare but much more common in *Enterococcus* spp.
- Significant attention has been drawn to the challenge of dosing vancomycin, especially in the critically ill population. TDM is recommended, and the optimal target for safety and efficacy is a continued source of debate.
- Red man syndrome, nephrotoxicity, and, rarely, ototoxicity are the most common adverse effects associated with vancomycin use.
- Telavancin can be used as an alternative for skin and skin structure infections or nosocomial pneumonia; however, use of this agent is plagued by teratogenicity and interference with anticoagulation tests.
- Daptomycin is a lipopeptide with gram-positive activity, including several vancomycin-resistant strains. It is approved for bacteremia, right-sided endocarditis, and complicated skin and skin structure infections.
- Dosing concerns exist with critically ill patients, and traditional weight-based dosing has led to subtherapeutic and supratherapeutic concentrations in different populations. Alternative dosing strategies need to balance efficacy with the risk of toxicity, most commonly manifested as myopathy and CPK elevations.
- Linezolid is an oxazolidinone used both intravenously and orally for skin and skin structure infections and for pneumonia. The most common side effects include myelosuppression, MAO interactions, and peripheral and optic neuropathy.

Antimicrobial Agents Active Against Anaerobic Bacteria

Itzhak Brook

Infections caused by anaerobic bacteria are common and may be serious and life-threatening. Anaerobes are predominant components of the bacterial flora of the normal human skin and mucous membranes[1] and are a common cause of endogenous bacterial infections. Because of their fastidious nature, they are difficult to isolate and are often overlooked. Their isolation requires appropriate methods of collection, transportation, and cultivation.[2–5] Treatment of anaerobic bacterial infections is complicated by the relatively slow growth of these organisms, frequent polymicrobial nature, and growing resistance to antimicrobials.

Antimicrobial resistance among anaerobes has increased in the past three decades, and their susceptibility has become less predictable.[6–14] The most commonly isolated antibiotic-resistant anaerobes are those that belong to the *Bacteroides fragilis* group.[15] This increase makes the choice of appropriate empiric therapy more difficult. Resistance patterns have been monitored through national and local surveys, but susceptibility testing of anaerobic bacteria at individual hospitals is rarely done.[10,11] This chapter describes the antimicrobials effective against anaerobic bacteria and the resistance of these organisms against them.

ANTIMICROBIAL AGENTS EFFECTIVE AGAINST ANAEROBIC BACTERIA

Table 109.1 illustrates the antimicrobials effective against anaerobic bacteria and their efficacy against both aerobic and anaerobic bacteria. Table 109.2 illustrates the resistance of bacteria from the *B. fragilis* group and other anaerobes to antimicrobials.

Beta-Lactam Antibiotics

Penicillin G is the classical drug of choice when the infecting strains are susceptible. Most *Clostridium* strains (except some *C. ramosum, C. clostridioforme,* and *C. innocuum*) and *Peptostreptococcus* spp. remain susceptible to penicillin. Most *B. fragilis* groups are resistant to penicillin. Other strains that may show resistance are growing numbers of anaerobic gram-negative bacilli (AGNB), such as pigmented *Prevotella* and *Porphyromonas* spp., *Prevotella oralis, P. bivia, B. disiens*, strains of *Clostridia, Fusobacterium* spp. (*F. varium* and *F. mortiferum*), and microaerophilic streptococci. Some of these strains show minimum inhibitory concentration (MIC) of 8–32 units/mL of penicillin G. In these instances, administration of very high dosages of penicillin G (for non–beta-lactamase producers) may eradicate the infection.

Ampicillin, amoxicillin, and penicillin are generally equal in activity to penicillin G, but the semisynthetic penicillins are less active. **Methicillin, nafcillin,** and the isoxazolyl penicillins (**oxacillin, cloxacillin,** and **dicloxacillin**) are ineffective against the *B. fragilis* group, have unpredictable activity, and are frequently inferior to penicillin G against anaerobes.[16]

Penicillin and ampicillin/amoxicillin are of limited utility because of the production of beta-lactamases by many oral and most intraabdominal anaerobes. Clavulanate, sulbactam, and tazobactam irreversibly inhibit beta-lactamase enzymes produced by beta-lactamase–producing *Fusobacterium* spp. and AGNB.[16–18] When used in combination with a beta-lactam antibiotic (e.g., **ampicillin-sulbactam, amoxicillin-clavulanate,** and **piperacillin-tazobactam**), they are effective in treating anaerobic infections caused by beta-lactamase–producing bacteria (BLPB).

Beta-lactam/beta-lactamase inhibitor combinations (BL-BLICs) are appropriate choices for mixed aerobic-anaerobic infections. They have maintained good activity against most anaerobes. Whereas 89% of *B. fragilis* are susceptible to ampicillin-sulbactam, 98% are susceptible to piperacillin-tazobactam[8] compared with 86% and 92%, respectively, for *B. thetaiotaomicron* isolates. Recently, the Infectious Diseases Society of America (IDSA) removed ampicillin-sulbactam from the recommended list of drugs for intraabdominal infections because of increased *Escherichia coli* resistance.[19] Amoxicillin-clavulanate remains the agent of choice for human and animal bite wound infections,[20] especially when anaerobes may be involved. Piperacillin-tazobactam is also a frequently and appropriately prescribed agent for serious intraabdominal infections. It has also maintained good activity against most anaerobes.[8]

The semisynthetic penicillins, the carboxy-penicillins (**carbenicillin** and **ticarcillin**) and ureidopenicillins (**piperacillin, azlocillin,** and **mezlocillin**), generally are administered in large quantities to achieve high serum concentration. These drugs are effective against Enterobacteriaceae and have good activity against most anaerobes at these concentrations. However, up to 30% of the bacteria in the *B. fragilis* group is resistant.[21]

Many anaerobes possess cephalosporinases, and therefore cephalosporins have limited utility.[22] The activity of **cephalosporins** against the beta-lactamase–producing AGNB varies. The antimicrobial spectrum of the first-generation cephalosporins against anaerobes is similar to penicillin G, although on a weight basis, they are less active. Most strains of the *B. fragilis* group and many *Prevotella, Porphyromonas,* and *Fusobacterium* spp. are resistant to these agents.[23] Cephalosporinases have little or no hydrolytic activity against the second-generation **cefoxitin** (a cephamycin), which is the most effective cephalosporin against the *B. fragilis* group. However, susceptibility may vary by geographic location and is generally directly related to its clinical use. Cefoxitin is relatively inactive against most species of *Clostridium,* including *C. difficile,* with the exception of *C. perfringens*.[23–25]

Cefoxitin is often used for surgical prophylaxis at most body sites that involve mucous membranes. With the exception of moxalactam, the third-generation cephalosporins are not as active against *B. fragilis*.

Currently, approximately 85% of *B. fragilis* isolates are susceptible to cefoxitin, but the other *B. fragilis* group species are more resistant.[8]

TABLE 109.1 Antimicrobial Agents Effective Against Mixed Infections

	ANAEROBIC BACTERIA		AEROBIC BACTERIA	
Antimicrobial Agent	Beta-Lactamase–Producing AGNB	Other Anaerobes	Gram-Positive Cocci	Enterobacteriaceae
Penicillin[a]	0	+ + +	+	0
Chloramphenicol[a]	+ + +	+ + +	+	+
Cephalothin	0	+	+ +	±
Cefoxitin	+ +	+ + +	+ +	+ +
Carbapenems	+ + +	+ + +	+ + +	+ + +
Clindamycin[a]	++	+ + +	+ + +	0
Ticarcillin	+	+ + +	+	+ +
Amoxicillin + clavulanate[a]	+ + +	+ + +	+ +	+ +
Piperacillin + tazobactam	+ + +	+ + +	+ +	+ +
Metronidazole[a]	+ + +	+ + +	0	0
Moxifloxacin	++	++	++	+++
Tigecycline	++	+++	+++	++

AGNB, Anaerobic gram-negative bacilli.
Degrees of activity: 0 to + + +.
[a]Available also in oral form.

TABLE 109.2 Percent Resistance of *Bacteroides fragilis* Group and Other Anaerobes to Antimicrobial Agents (Includes Intermediate-Resistant Strains)

Cefotetan is less effective than cefoxitin against *B. fragilis* and other members of the *B. fragilis* group. Recently, the IDSA removed cefotetan from the recommended list of drugs against intraabdominal infections because of poor *B. fragilis* group activity and resultant clinical failures.[26–28]

The carbapenems (imipenem, meropenem, doripenem, and ertapenem) have excellent activity against anaerobes.[29] **Imipenem,** a thienamycin, is a beta-lactam antibiotic that is effective against a wide variety of aerobic and anaerobic gram-positive and gram-negative organisms, including *B. fragilis*.[30,31] It is also effective against most Enterobacteriaceae, with about 5%–15% of *Pseudomonas* spp. resistance.[32] To overcome the problem of renal metabolism of imipenem, it is combined at a 1:1 ratio with an inhibitor of the renal dipeptidase, cilastatin. This agent is an effective single agent for the treatment of mixed aerobic-anaerobic infections. Recarbrio (imipenem, cilastatin, and the beta-lactamase inhibitor relebactam) has been approved by the Food and Drug Administration (FDA) for the treatment of complicated intraabdominal infections. Relebactam is active against both class A and class C beta-lactamases and restores imipenem susceptibility to many imipenem-resistant isolates of AmpC-producing *Pseudomonas aeruginosa* and Enterobacteriaceae expressing *Klebsiella pneumoniae* carbapenemases (KPC) or combinations of impermeability and extended-spectrum beta-lactamases (ESBLs)/AmpCs.[33]

Meropenem antibacterial activity is similar to imipenem. However, it is less active against staphylococci and enterococci and provides better coverage of aerobic and facultative gram-negative bacteria.[34] Meropenem has been effective in abdominal infections, meningitis in children and adults, community-acquired and nosocomial pneumonia, and neutropenic fever.[35]

Ertapenem, a newer 1-beta-methyl carbapenem, is stable to dehydropeptidase and has a broad antibacterial spectrum for aerobic and anaerobic bacteria, including *C. perfringens, Fusobacterium* spp., *Peptostreptococcus* spp., and AGNB.[36] Compared with other available carbapenems, ertapenem has a long half-life of 4.5 hours and is given as a single daily dose. It is not active against *P. aeruginosa, Enterococcus* spp., and *Acinetobacter* spp.

Doripenem, a synthetic 1-beta-methyl carbapenem, possesses a similar antimicrobial spectrum to meropenem and imipenem.[31] It has significant in vitro activity against aerobic and anaerobic bacteria, including the *B. fragilis* group. In vitro, resistant *P. aeruginosa* mutants appear to be harder to select with doripenem than with other carbapenems.

Carbapenems are generally employed in more serious anaerobic infections such as intraabdominal and skin and soft tissue infections.[26–28] Recent reports have noted the development of some carbapenem resistance among anaerobes,[13] ranging from 1.1% to 2.5% in a multicenter US survey but higher in a small number of isolates from Taiwan.[37]

Resistance to Beta-Lactam Antibiotics

Anaerobes manifest three major resistance mechanisms to beta-lactam antibiotics: inactivating enzymes, mainly beta-lactamases (BLAs), which include penicillinases and cephalosporinases; low-affinity penicillin binding proteins (PBPs); and decreased permeability through alterations in the porin channel.[38] The production of BLAs is the most common mechanism of resistance to beta-lactam antibiotics in anaerobes, especially among the *B. fragilis* group and *Prevotella* spp.[39] Typically, the cephalosporinases belong to the 2e class type and can be inhibited by three beta-lactamase inhibitors: clavulanic acid, sulbactam, and tazobactam. Each individual cephalosporin may have either a class or specific inhibitor enzyme that is able to inactivate it.

Carbapenemases are active against the carbapenems and all beta-lactam antibiotics. Carbapenem resistance occurs in <1% of US isolates, and up to 3% of *Bacteroides* strains harbor one of the genes that is expressed at a very low level.

With a few exceptions among some *Clostridium* spp., strains of *Clostridium, Porphyromonas,* and *Fusobacterium* have also been found to express resistance by one or more of the BLAs. BLA-producing *Fusobacterium* and *Clostridium* spp. express enzymes that are generally inhibited by clavulanic acid.[40] Resistance to beta-lactam antibiotics through changes in the OMP/porin channels, decreased PBP affinity, and efflux pumps[41] is less well studied. The bacteria in the *B. fragilis* group are generally resistant to penicillins (average 90%), piperacillin (25%), cefoxitin (25%), cefotetan (30%–85%), and third-generation cephalosporins.[42,43] The combinations of BL-BLICs inhibitors and carbapenems have maintained their excellent antibacterial activity. The combination of ampicillin-sulbactam, amoxicillin-clavulanate, ticarcillin-clavulanate, and piperacillin-tazobactam is generally very active against members of the *B. fragilis* group.[42] However, species-to-species variation in susceptibility occurs.[44] Resistance to co-amoxiclav (8%) was reported in Slovania.[45] *B[6]. fragilis* group resistance rates for piperacillin-tazobactam is generally <1%.[42] However, resistance of *Parabacteroides distasonis* to ampicillin-sulbactam has risen to 20% in 2002–2004 but continued to be low for the other *B. fragilis* group species.

The carbapenems (imipenem, meropenem, doripenem, and ertapenem) are very effective against all members of the *B. fragilis* group, and resistance is rare at <0.1%.[41,44,46] Geometric mean MICs for imipenem and meropenem for *P. distasonis, B. thetaiotaomicron,* and *B. ovatus* have been reported to be onefold dilution lower than those for ertapenem[42] in 2004. The non–*B. fragilis* group (including *B. intestinalis, B. nordii, B. pyogenes, B. stercoris, B. salyersiae,* and *B. cellulosilyticus*) was found resistant to meropenem (14%) between 2014 and 2016 in Korea.[47] Imipenem resistance was found in a quarter of metronidazole-resistant isolates.[48]

Beta-lactams are generally effective against non–*B. fragilis* group species, and resistance to them is generally low, except that more than half of *Prevotella* spp. may also produce BLAs. A multicenter survey[30] found penicillin resistance for *Fusobacterium* spp., *Porphyromonas* spp., and *Peptostreptococcus* spp. at 9%, 21%, and 6%, respectively. No resistance was found to cefoxitin, cefotetan, beta-lactam/BLA inhibitor combinations, and carbapenems in that survey, with the exception of *Peptostreptococcus* spp. and *Porphyromonas* spp. (4% and 5% resistance to ampicillin-sulbactam, respectively). BLAs were identified in several *Prevotella* and *Porphyromonas* spp. recovered from pediatric intraabdominal infections.

Chloramphenicol

Chloramphenicol, a bacteriostatic agent, is active against most anaerobic bacteria but is rarely used in the United States.[3,23] Resistance is rare. Although several failures to eradicate anaerobic infections with chloramphenicol have been reported,[49] this agent has been used for over 65 years for treatment of anaerobic infections. In the past, it was the drug of choice for the treatment of serious anaerobic infections, including the central nervous system (CNS). However, the drug has potential significant toxicity. The risk of fatal aplastic anemia with chloramphenicol is estimated to be approximately 1 per 25,000–40,000 patients treated. This serious complication is unrelated to the reversible, dosage-dependent leukopenia. Other side effects include the production of the potentially fatal "gray baby syndrome" when given to neonates, hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, and optic neuritis in those who take the drug for a prolonged time.[50]

Chloramphenicol has a unique property of lipid solubility to permit penetration across lipid barriers. Levels in the cerebrospinal fluid, with or without meningitis, usually are one-third to three-fourths the serum concentrations. Levels in brain tissue may be substantially higher than serum levels.[51]

Macrolides: Erythromycin, Azithromycin, and Clarithromycin

The macrolides, which possess low human or animal toxicity, have moderate to good in vitro activity against anaerobic bacteria other than the *B. fragilis* group and *Fusobacterium*.[23] Macrolides are active against pigmented *Prevotella* and *Porphyromonas* and microaerophilic streptococci, gram-positive non–spore-forming anaerobic bacilli, and certain clostridia. They are less effective against *Fusobacterium* and *Peptostreptococcus* spp.[52] They show relatively good activity against *C. perfringens* and poor or inconsistent activity against AGNB.

Clarithromycin is the most active of the macrolides against gram-positive oral cavity anaerobes, including *Actinomyces* spp., *Propionibacterium* spp., *Lactobacillus* spp., and *Bifidobacterium dentium*. Azithromycin is slightly less active than erythromycin against these species.[52] Azithromycin is the most active macrolide against AGNB: *Fusobacterium* spp., *Bacteroides* spp., *Wolinella* spp., and *Actinobacillus actinomycetemcomitans,* including those resistant to erythromycin. Clarithromycin showed similar activity to erythromycin against most AGNBs.[53]

Erythromycin resistance during therapy can occur.[54,55] Erythromycin is effective in the treatment of mild to moderately severe anaerobic soft tissue and pleuropulmonary infections when combined with adequate débridement or drainage of infected tissue. Phlebitis is reported

to develop in one-third of the patients receiving intravenous erythromycin, but the oral preparation is well tolerated.

Clindamycin

Clindamycin has a broad range of activity against anaerobes. It is used to treat dental infections, especially in patients allergic to penicillin, and to treat aspiration pneumonia. Clindamycin hydrochloride is rapidly absorbed from the gastrointestinal tract.[56–58] It rapidly penetrates into body tissues and fluids, including saliva, sputum, respiratory tissue, pleural fluid, soft tissues, prostate, semen, bones, and joints,[59] and into fetal blood and tissues. Clindamycin does not efficiently cross the blood-brain barrier or eye and should not be administered in CNS infections.

The side effect of most concern is *C. difficile*–associated colitis.[60,61] Colitis has also been associated with a number of other antimicrobials, such as ampicillin, cephalosporins, and quinolones, and occasionally also in the absence of previous antimicrobial therapy.

Because *B. fragilis* resistance to clindamycin is increasing, it is no longer recommended as an empiric therapy for intraabdominal infecti ons.[13,42,46,62] Clindamycin resistance was found in 31.6% of *B. fragilis* group isolates among isolates recovered from 2013 to 2015 in a study done in South India.[63] High rates of resistance were reported to clindamycin, in particular among isolates of the *Bacteroides fragilis* group (22.1%–48.1%) and *Prevotella* spp. (10.9%–32.2%) in a study of nine European countries between 2010 and 2016.[64] Clindamycin resistance was found in 54% of *Finegoldia* genera, 49% of *Bacteroides* spp., and 40% of *Prevotella* spp. recovered in Spain in 2018.[65] An 8-year study revealed that 19.3% of 2721 *B. fragilis* group isolates, 29.6% of *P. distasonis,* 33.4% of *B. ovatus,* 33.3% of *B. thetaiotaomicron,* and 35.6% of *Bacteroides vulgatus* strains were clindamycin resistant. This is a significant increase compared with only 3% clindamycin resistance in 1987.[43]

Clindamycin resistance was detected in 46.6% of *B. fragilis* and 17.6% of *Propionibacterium acnes* isolates recovered from pulmonary empyema.[66] Resistance has also increased for many non-*Bacteroides* anaerobes. Up to 10% resistance was noted in *Prevotella* spp., *Fusobacterium* spp., *Porphyromonas* spp., and *Peptostreptococcus* spp., with higher rates for some *Clostridium* spp. (especially *C. difficile*).[30] *P. acnes* isolates have also become more resistant to clindamycin, and this has been associated with prior therapy for acne.[67]

Clindamycin has lost some of its activity against anaerobic gram-positive cocci (*Finegoldia magna*, 30% resistant; *Peptoniphilus* spp.; etc.) and *Prevotella* spp. (*P. bivia,* 70% resistant; *P. oralis* and *P. melaninogenica*, both 40% resistant), although its activity against *Fusobacterium* and *Porphyromonas* spp. remains good.[68]

Among the other resistant anaerobes are various species of *Clostridium,* especially *C. difficile*. Approximately 20% of *C. ramosum* are resistant to clindamycin, as are a smaller number of *C. perfringens.*

Metronidazole and Tinidazole

Metronidazole and tinidazole have excellent in vitro activity against most obligate anaerobic bacteria, such as the *B. fragilis* group, other species of *Bacteroides, Fusobacterium*, and *Clostridium*.[36] Only six strains of the *B. fragilis* group were ever reported to be clinically resistant and associated with therapeutic failure.[2]

Resistance of anaerobic gram-positive cocci is rare, and nonsporulating bacilli are common. Microaerophilic streptococci, *P. acnes,* and *Actinomyces* spp. are almost uniformly resistant.[69] Aerobic and facultative anaerobes are usually highly resistant. Because of its lack of activity against aerobic bacteria, an antimicrobial effective against these organisms (e.g., a cephalosporin, a fluoroquinolone) needs to be added when treating a polymicrobial infection.

Adverse reactions to metronidazole are rare and include CNS toxicity, ataxia, vertigo, headaches, convulsions, and peripheral neuropathy. Peripheral neuropathy is associated with prolonged metronidazole use. Gastrointestinal side effects are common and include nausea, vomiting, metallic taste, anorexia, and diarrhea. Other adverse reactions include reversible neutropenia, phlebitis at intravenous infusion sites, and drug fever.

Some studies in mice[70,71] have shown possible mutagenic activity associated with administration of large doses of metronidazole. Other experiments[71] in rats and hamsters did not show any pathology. In addition, no evidence of mutagenicity was found in humans.[72]

Metronidazole is effective in the treatment of anaerobic infections, including those of the CNS.[73,74] Valid data on the safety of metronidazole in pregnancy are still needed. The nonteratogenicity of metronidazole is difficult to prove, but the existing data indicate no major risks.[75]

Resistance to metronidazole among the *B. fragilis* group is rare.[35,76] Half of the resistant *B. fragilis* group isolates carry one of nine known *nim* genes (nim A–I) on either a chromosome or a mobilizable plasmid. This gene encodes a nitroimidazole reductase that converts 4- or 5-nitroimidazole to 4- or 5-aminoimidazole, preventing the formation of toxic nitroso residues necessary for the agent's activity. Resistance among gram-positive organisms that are not strict anaerobes is frequent, especially for *P. acnes* and *Actinomyces* spp. A significant increase in metronidazole resistance of *Bacteroides* spp., from 12.3% in 2010–2011 to 17.5% in 2017, was found in a study done in Pakistan.[48]

Tetracyclines

Tetracycline is of limited use because of the development of resistance to it by most anaerobes. Resistance to *P. acnes* has been related to previous use.[67] Only about 45% of all *B. fragilis* strains presently are susceptible to this drug.[23] The tetracycline analogues, doxycycline and minocycline, are more active than the parent compound. Because of significant resistance to these drugs, they are useful only when susceptibility tests can be performed or in less severe infections in which a therapeutic trial is feasible. The use of tetracycline is not recommended before 8 years of age because of its adverse effect on teeth.

Tigecycline is a glycylcycline, a direct analog of minocycline with a 9-glycylamide moiety. It has activity against both aerobic gram-negative and gram-positive bacteria, anaerobes,[77,78] and certain drug-resistant pathogens.[79] It is active against the ***Streptococcus anginosus*** group (which includes *S. anginosus*, *S. intermedius*, and *S. constellatus*), *B. fragilis*, *B. thetaiotaomicron*, *B. uniformis*, *B. vulgatus*, *C. perfringens*, *C. difficile*, and *Parvimonas micra* (*Peptostreptococcus micros*).[77] Resistance of tigecycline for members of the *B. fragilis* group varied from 3.3% to 7.2%.[13,42]

Omadacycline (OMC), a broad-spectrum aminomethylcycline, has shown clinical efficacy in anaerobic acute bacterial skin and skin structure infections and in animal models of intraabdominal anaerobic infections. The in vitro activity of OMC against anaerobes was similar to that of tigecycline.[80]

Eravacycline is fully synthetic fluorocycline antibiotic of the tetracycline class with in vitro activity against clinically important gram-positive and gram-negative aerobic and anaerobic bacteria, including most of those resistant to cephalosporins, fluoroquinolones, beta-lactam/beta-lactamase inhibitors, multidrug-resistant strains and carbapenem-resistant Enterobacteriaceae, and most anaerobic pathogens.[81] It has been approved by the FDA for the treatment of complicated intraabdominal infections.

Fluoroquinolones

Quinolones with low activity against anaerobes include ciprofloxacin, ofloxacin, levofloxacin, fleroxacin, pefloxacin, enoxacin, and lomefloxacin. Compounds with intermediate antianaerobic activity include sparfloxacin and grepafloxacin.[82] **Trovafloxacin, gatifloxacin,** and

moxifloxacin yield low MICs against most groups of anaerobes.[83] The use of trovafloxacin has been limited because of hepatotoxicity. Quinolones with the greatest in vitro activity against anaerobes include clinafloxacin and sitafloxacin.[84]

Moxifloxacin has been studied as monotherapy in intraabdominal infections in adults[26,62] and has shown activity against intraabdominal anaerobic isolates.[85,86] However, the increasing fluoroquinolone resistance in both the *E. coli* and *B. fragilis* groups has reduced its use in intraabdominal infections.[9,13,62,86]

The use of quinolones is restricted in growing children because of their possible adverse effects on cartilage. The major concerns with the use of fluoroquinolones to treat anaerobic infections have been the increasing resistance in the *B. fragilis* group and anaerobic gram-positive cocci and the impact of these antibiotics on the growing incidence of *C. difficile*–associated disease.[84]

Bacteroides spp. resistance to fluoroquinolone has been attributed to either an alteration in efflux of the antibiotic or a mutation in the quinolone resistance determining region (QRDR) of the gyrase A gene *(gyrA)* from either single or multiple mutations.[87] High-level resistance can be caused by both mechanisms.

Other Agents

Bacitracin was active in vitro against pigmented *Prevotella* and *Porphyromonas* spp. but is inactive against *B. fragilis* and *Fusobacterium nucleatum*.[23] Vancomycin and daptomycin are effective against all gram-positive anaerobes but are inactive against AGNB.[88] Quinupristin/dalfopristin shows antibacterial activity against some anaerobic organisms that were tested, including *C. perfringens, Lactobacillus* spp., and *Peptostreptococcus* spp.[89] Linezolid is active against *Fusobacterium nucleatum* and other *Fusobacterium* spp., and *Porphyromonas* spp., *Prevotella* spp., and *Peptostreptococcus* spp.[53] Little clinical experience has, however, been gained in the treatment of anaerobic infections using these agents.

GENERAL CONSIDERATION OF ANTIMICROBIAL SELECTION

Because anaerobic infection is often polymicrobial, antimicrobials effective against both aerobic and anaerobic components of the infection should be administered. When such therapy is not given, the infection may persist, and serious complications may occur.[2,3,90] A number of factors should be considered when choosing appropriate antimicrobial agents: they should be effective against all target organisms, induce little or no resistance, achieve sufficient levels in the infected site, have minimal toxicity, and have maximum stability and longevity.

When selecting antimicrobials for the therapy of mixed infections, their antibacterial spectrum and their availability in oral or parenteral form should be considered (see Table 109.1). Some antimicrobials have a limited range of activity. For example, metronidazole is only active against anaerobes and therefore cannot be administered as a single agent for the therapy of mixed infections. Other antimicrobials, such as carbapenems, tigecycline, and BL-BLICs, possess a broader spectrum of activity against aerobic and anaerobic bacteria.

Selecting antimicrobials is simplified when a reliable culture result is available. However, this may be particularly difficult in anaerobic infections because of the difficulties in obtaining appropriate specimens. For this reason, many patients are treated empirically on the basis of suspected, rather than established, pathogens. Fortunately, the types of anaerobes involved in many anaerobic infections and their antimicrobial susceptibility patterns tend to be predictable.[2,3] However, some anaerobes have become resistant to antimicrobials, and many can develop resistance during therapy.[41,91]

Aside from susceptibility patterns, other factors influencing the choice of antimicrobial therapy include the pharmacologic characteristics of the various drugs, their toxicity, their effect on the normal flora, and bactericidal activity.[2,3] Although identification of the infecting organisms and their antimicrobial susceptibility may be needed for selection of optimal therapy, the clinical setting and Gram stain preparation of the specimen may indicate the types of anaerobes present in the infection and the nature of the infectious process.

Typically, antimicrobial therapy for anaerobic infections should be given for prolonged periods because of their tendency to relapse. This may range from 3 weeks to 3 months, depending on the site and severity of the infection.

RESULTS/DISCUSSION

Hastey and colleagues,[92] who reported the changes in the antibiotic susceptibility of anaerobic bacteria in the United States from 2007–2009 to 2010–2012, illustrated the importance of the annual generation of an institutional-specific antibiogram of anaerobic bacteria for tracking of resistance trends over time. The authors illustrated that increased resistance led to most of the significant changes noted between the two periods. Significant increases in antimicrobial resistance was seen overall with anaerobic gram-positive cocci to ampicillin/sulbactam, cefoxitin, and moxifloxacin. Small increases in resistance rates were noted for meropenem against the *B. fragilis* group without *B. fragilis* and for metronidazole against the *B. fragilis* group, whereas moderate increases in resistance rates were seen in both for ampicillin-sulbactam and piperacillin-tazobactam. For organisms other than *B. fragilis,* there was a similar pattern of moderate increases in resistance to ampicillin-sulbactam and ertapenem but smaller increases in metronidazole resistance rates. In contrast, the resistance rate decreased in the *B. fragilis* group without *B. fragilis* for cefoxitin. Moxifloxacin resistance rates were also lower for some *B. fragilis* group isolates and for certain other anaerobes such as *Prevotella* spp.

KEY POINTS

- Because anaerobic infection is often polymicrobial, antimicrobials effective against both aerobic and anaerobic components of the infection should be administered. When such therapy is not given, the infection may persist, and serious complications may occur.
- Anaerobes are often involved in mixed infections, which present unique situations for antimicrobial use. The interactions between the different bacteria and the various antibiotics can be difficult to distinguish and/or predict.
- Selecting antimicrobials is simplified when a reliable culture result is available. However, this may be particularly difficult in anaerobic infections because of the difficulties in obtaining appropriate specimens.
- Susceptibility patterns of anaerobes have been changing over the years, and susceptibility to metronidazole cannot be assumed. Although susceptibility testing of anaerobes is difficult, clinicians must realize the importance of performing and analyzing the susceptibility tests.
- Several beta-lactam antibiotics, fluoroquinolones, clindamycin, and tigecycline possess activity against anaerobic organisms. However, resistance is a concern with all of these classes of antibiotics. A few investigational agents have the potential for use in anaerobic infections, but clinical data are needed.

Selective Decontamination of the Digestive Tract

Evelien A.N. Oostdijk, Jeroen A. Schouten, and Anne Marie G.A. de Smet

Infections acquired in the intensive care unit (ICU) often occur during the treatment of critically ill patients, increasing their morbidity, mortality, and healthcare costs.[1,2] Several studies suggest that the use of prophylactic antibiotic regimens such as selective decontamination of the digestive tract (SDD)[3–6] and selective oropharyngeal decontamination (SOD) can reduce the incidence of nosocomial infections and mortality in ICU patients.[5,7,8] The SDD approach[9,10] is directed toward the following: prevention of secondary colonization with gram-negative bacteria, *Staphylococcus aureus,* and yeasts through application of nonabsorbable antimicrobial agents in the oropharynx and gastrointestinal tract; preemptive treatment of possible infections caused by commensal respiratory tract bacteria through systemic administration of cephalosporins during the patient's first 4 days in the ICU; and maintenance of anaerobic intestinal flora through selective use of antibiotics (administered both topically and systemically) without antianaerobic activity.[10]

BACKGROUND

The intestinal flora is highly diverse and consists primarily of anaerobic bacteria. Intact anaerobic flora is considered an important defense mechanism against intestinal colonization by potentially pathogenic microorganisms. The commensal flora of the oropharynx consists of hundreds of bacterial species, including enterococci and anaerobic bacteria, which are replaced by gram-negative bacteria during the first week of hospitalization in the ICU. Gastric acidity usually prevents bacterial overgrowth in the stomach. Yet in ICU patients, reduced acid production caused by underlying diseases, use of acid-modifying medication (stress ulcer prophylaxis), and intragastric administration of enteral nutrition (with a pH of 6) leads to a gastric environment that favors bacterial growth, especially of gram-negative bacteria.

Anaerobic bacteria grow well on the mucosa of the gut and actively line the epithelium.[11] Disruption of this layer by antibiotics that destroy the anaerobic flora may create a portal of entry for pathogenic microorganisms.

Combinations of nonabsorbable antibiotics have been used to selectively decontaminate the digestive tract and reduce the load of pathogenic aerobic microorganisms while maintaining the anaerobic flora. This concept was first investigated in mice[9] and later developed into an infection prevention strategy for neutropenic leukemia patients, which the investigators called *selective decontamination of the digestive tract,* or SDD.[12,13]

From Concept to Practice in the ICU

The earlier experience with SDD in leukemia patients suggested that some infections in ICU patients might have an endogenous source and could be prevented in the same way. After a 2-year observational microbiologic study of trauma patients, an infection classification was proposed (Table 110.1) that included definitions for colonization and the use of SDD for infection prevention in trauma patients in the ICU.[10,14,15] These studies resulted in the establishment of an SDD regimen consisting of the application of nonabsorbable antimicrobial agents in the oropharynx and gastrointestinal tract to prevent acquired colonization with gram-negative bacteria, *S. aureus,* and yeasts, in combination with 4 days of intravenous administration of a third-generation cephalosporin to preemptively treat incubating respiratory tract infections with gram-positive and gram-negative bacteria. Topical and systemic antibiotics were selected based on their antibacterial spectrum and presumed absence of activity on the anaerobic intestinal flora.[14,15]

CLINICAL RESULTS

Earlier Studies

The first study of SDD in ICU patients was performed in 63 trauma patients, using a historical control group of 59 trauma patients.[10] Because of its design and use of a historical control group, this study not only triggered many critical comments and editorials but also led to additional studies in more heterogeneous ICU patient populations, with different combinations of absorbable and nonabsorbable antibiotics, with or without parenteral antibiotics.[3,16–18] The conflicting results of these clinical trials led to the conclusion that there was insufficient scientific evidence to recommend SDD as a routine infection control measure in ICU patients.[19]

SDD was also used early as a prophylactic strategy in major gastrointestinal surgery and showed a decreased rate of postoperative infections and anastomotic leakage.[20] SDD has been reported to reduce gram-negative colonization and to decrease postoperative infection rates after esophagectomy.[21] This study included a very limited patient group from a single center, and the surgical technique, perioperative care, and SDD protocols have changed over time.

Randomized ICU Studies

A Dutch single-center, prospective, controlled, randomized, unblinded study in 2003 reported significantly lower ICU and hospital mortality rates (35% and 22%, respectively), shorter length of stay, and lower incidence of antibiotic resistance in patients with an expected duration of mechanical ventilation of ≥2 days and/or expected length of stay in the ICU of ≥3 days and receiving SDD.[4,22] A subsequent multicenter, controlled, crossover study using cluster randomization and identical inclusion criteria that compared SDD with SOD was performed in the Netherlands. SOD was included because of the hypothesis that the main

TABLE 110.1 Definitions

Colonization resistance	The strong protective effect of the endogenous anaerobic fraction of the intestinal microflora in resisting colonization by aerobe microorganisms along the alimentary canal. Suppression of the anaerobic flora increases the risk of overgrowth by gram-negative bacteria.
PPM	Potentially pathogenic microorganisms
SDD	*Selective decontamination of the digestive tract* is the selective elimination of PPM from the oral and intestinal flora by topical, nonabsorbable antibiotics.
SOD	*Selective oropharyngeal decontamination* is the selective elimination of PPM from the oral flora by topical, nonabsorbable antibiotics.
Primary endogenous infections	Caused by PPM with which the oropharynx and/or digestive tract of the patient was colonized at admission. These PPM are part of the "normal" flora of the patient.
Secondary endogenous infections	Caused by PPM with which the oropharynx and/or digestive tract of the patient was not colonized at admission but acquired during ICU stay.
Exogenous infections	Caused by PPM not present at admission and developing without preceding colonization.
Colonization	Presence of the same species of PPM in an organ system for more than 3 days (≥2 positive cultures) without signs of infection.

ICU, Intensive care unit.

effect of SDD—a reduction in the incidence of ventilator-associated pneumonia (VAP)—could be achieved by oropharyngeal decontamination only, without intestinal decontamination and without the routine prophylactic use of systemic antibiotics during the first 4 days of ventilation.[7,8] The results of this first Dutch multicenter trial (DMT-I) with almost 6000 patients showed that SDD and SOD groups were associated with a reduction in mortality at day 28 of 13% and 11% relative to controls, respectively, corresponding to an absolute reduction of 3.5% and 2.9%.[5] There were several noteworthy limitations to this study; in particular, as with most SDD studies, it was not blinded, so all physicians were aware of the treatment patient participants would receive. Because inclusion was based on several criteria, this created the possibility of selection bias. To minimize the occurrence of selection bias, patient eligibility and inclusion rates were monitored frequently and immediately followed by feedback to the participating investigators. Yet despite the use of these measures next to the objective inclusion criteria, there were baseline differences between the control and the two intervention groups. Patients in the intervention groups (SDD and SOD) were more frequently intubated, were less likely to be surgical patients, and had a higher baseline APACHE score. Further, SDD patients were older compared with SOD and control patients.[5]

A second Dutch open cluster, randomized, crossover, multicenter trial (DMT-II: 11,997 patients) compared 12 months of SDD with 12 months of SOD. Again, there was a baseline difference, with SDD patients being more severely ill. Mortality at day 28 was significantly higher in the SOD group (25.7% compared with 23.8%, respectively, with corresponding adjusted odds ratios (ORs) of 0.85 (95% confidence interval [CI] 0.77–0.93).[23]

Various meta-analyses were published. In 2009 a Cochrane meta-analysis was published on the effects of topical antibiotics (with or without systemic antibiotics) and their effects on mortality and the incidence of respiratory tract infections (RTIs).[6] This meta-analysis included 36 trials, with a total of 6914 patients (without DMT-I and DMT-II). They concluded that a combination of topical and systemic antibiotics as compared with controls resulted in a significant reduction in both RTIs (16 studies; OR, 0.28; 95% CI 0.20–0.38) and mortality (17 studies; OR, 0.75; 95% CI, 0.65–0.87).

Topical antibiotics alone as compared with controls or comparing topical plus systemic with systemic alone resulted in a significant reduction in RTIs (17 studies; OR, 0.44; 95% CI, 0.31–0.63) but not in mortality (19 studies; OR, 0.97; 95% CI, 0.82–1.16).

Another systemic review and meta-analysis published in 2014 compared SDD, SOD, and oropharyngeal chlorhexidine for the prevention of death and concluded that SDD had a favorable effect on mortality with a less certain effect of SOD. Both were superior to chlorhexidine, with a remark that chlorhexidine might be associated with increased mortality.[24] In 2018 an individual patient data meta-analysis was published. It included all patients of six randomized controlled studies (including DMT-I and DMT-II) and found significantly lower hospital mortality during SDD and SOD as compared with control, with an OR of 0.82 (95% CI 0.72–0.93) and 0.84 (95% CI 0.73–0.97), respectively. In a head-to-head comparison, in-hospital mortality was lower during SDD than during SOD (adjusted odds ratio [aOR], 0.90; 95% CI, 0.82–0.97).[25]

It has been a consistent critique that no large randomized controlled trials (RCTs) had been performed in countries with higher levels of antibiotic resistance. All Dutch trials were carried out in ICUs with low levels of antibiotic resistance. Wittekamp and colleagues performed a cluster randomized trial in a diversity of European countries in settings with moderate to high levels of antibiotic resistance.[26] In 13 European, non-Dutch or Scandinavian ICUs, SDD, SOD, or a chlorhexidine mouthwash were used for 6-month periods. Only ICUs with an extended-spectrum beta-lactamase prevalence of at least 5% among Enterobacteriaceae-causing bloodstream infections were eligible. The order of interventions was randomized.

The difference with the trials performed in the Netherlands was the use of the chlorhexidine and omitting the standard systemic prophylaxis (4 days of intravenous [IV] cephalosporin) during SDD. Another difference with the Dutch randomized studies is that there were no protocol modifications for patients with tracheostomy, jejunostomy, or colostomy or for those with persistent respiratory tract colonization with yeasts or gram-negative bacteria. In total 8665 patients were included. No significant differences were found in the incidence of ICU-acquired bacteremias with multidrug-resistant, gram-negative bacteria and for mortality at day 28 between the three groups.

The "what, when, and why" of the different parts of the SDD regimen as it is used in the two Dutch randomized studies are shown in Table 110.2.

TABLE 110.2 Selective Decontamination of the Digestive Tract Regimen

What	When	Why
BASELINE		
Oropharyngeal application of 0.5 g of a paste containing polymyxin E, tobramycin, and amphotericin B, each in a 2% concentration*	Four times daily until ICU discharge	Selective decontamination of the oropharynx
Administration of 10 mL of a suspension containing 100 mg polymyxin E, 80 mg tobramycin, and 500 mg amphotericin B via the nasogastric tube	Four times daily until ICU discharge	Selective decontamination of the gut from stomach to rectum
Cefotaxime 1 g intravenously during the first 4 days of study (or other third-generation cephalosporins)	Four times daily during the first 4 days	Preemptive treatment of primary endogenous infections
Avoidance of systemic antibiotics that might impair the colonization resistance (i.e., antibiotics with antianaerobic activity)	During treatment with SDD, until ICU discharge	Avoidance of penicillins, carbapenems, etc. No addition of antibiotics for patients with colonization without clinical signs suggestive of infection
Cultures of endotracheal* aspirates, oropharyngeal* and rectal swabs	On admission and surveillance cultures twice weekly	Determination of colonization pattern at admission and during treatment, including monitoring of effectiveness of SDD Detection of infection
Oropharyngeal care*	Four times daily using sterile water or chlorhexidine† mouthwash, preceding application of oropharyngeal paste; includes brushing of teeth twice daily. Clean visually contaminated oropharyngeal cavity with swab moistened with 1.5% hydrogen peroxide	Cleansing of mouth and teeth Removing residue of paste Preparing mouth for (next) application of paste
Use of normal hygiene guidelines*	Always	Preventing transmission of pathogens in the patient Prevention of (exogenous) cross-contamination and infections from and to other patients Control of outbreak
MODIFICATIONS FOR PATIENTS WITH		
Tracheostomy*	0.5 g of paste applied around the tracheostomy 4 times daily	Selective decontamination of the oropharynx
Duodenal tube or jejunostomy	Divide the 10 mL of suspension into 5 mL suspension via the gastric tube and 5 mL via the duodenal tube or jejunostomy	Selective decontamination of the gut from stomach to rectum
Colostomy or ileostomy	SDD suppositories (containing 100 mg polymyxin E, 40 mg tobramycin, and 500 mg amphotericin B) twice daily in the distal part of the gut	Selective decontamination of the gut from stomach to rectum
Documented cephalosporin allergy	Cefotaxime can be replaced by ciprofloxacin (twice daily 400 mg)	Avoidance of allergic reaction
MODIFICATIONS FOR PATIENTS WITH PERSISTENT RESPIRATORY TRACT COLONIZATION WITH YEASTS OR GRAM-NEGATIVE BACTERIA		
If a surveillance culture (>48 h after admission culture) of the throat yields yeasts and/or gram-negative bacteria*	Increase application of oropharyngeal paste to 8 times daily until two surveillance cultures are negative	Decolonization
If a sputum surveillance (>48 h after admission culture) culture yields yeasts*	Nebulize 5 mL (5 mg) amphotericin B 4 times daily until two sputum cultures are negative	Decolonization
If a sputum surveillance culture (>48 h after admission culture) yields gram-negative bacteria*	Nebulize 5 mL (80 mg) polymyxin E 4 times daily until two sputum cultures are negative	Decolonization

ICU, Intensive care unit; *SDD*, selective decontamination of the digestive tract.
*The SOD regimen from de Smet AM, Kluytmans JA, Cooper BS, et al. Decontamination of the digestive tract and oropharynx in intensive care patients. *N Engl J Med.* 2009;360:20–31.

MICROBIOLOGIC EFFECTS OF SELECTIVE DECONTAMINATION

Decontaminating Effect

The DMT-I showed that the proportion of SDD patients colonized with gram-negative bacteria isolated from rectal swabs decreased from 56% at day 3 to 25% at day 8 and 15% at day 14. Oropharyngeal colonization rates with gram-negative bacteria decreased from 18% at day 2 to 4% at day 8 among SDD patients. The same trial showed a comparable decrease in oropharyngeal colonization rates with gram-negative bacteria in SOD patients from 20% at day 2 to 7% at day 8.[5] These results are comparable to those reported in other studies.[10,27,28] Further, it was

shown that SDD could eradicate cephalosporin-resistant Enterobacteriaceae from the intestinal tract.[29]

The positive effects of SDD and SOD on respiratory tract colonization and infection have been described extensively.[4,6–8] The DMT-I showed significantly a lower incidence of ICU-acquired bacteremia during SOD and SDD for *S. aureus* gram-negative rods as *Pseudomonas aeruginosa* and other nonfermenters and Enterobacteriaceae as compared with controls. The incidence of ICU-acquired candidemia was lower in the SDD group compared with either SOD or control groups.[5] Patients receiving SDD had a lower incidence of ICU-acquired bacteremia with Enterobacteriaceae than those receiving SOD,[5,30] a result that was confirmed in the DMT-II.[23]

Emergence and Selection of Antibiotic Resistance in Gram-Negative and Gram-Positive Microorganisms During Selective Decontamination

Enhanced selection of antibiotic-resistant microorganisms has been suggested to occur as a result of the application of SDD and SOD and as such is considered an important threat to SDD and SOD.[31] Consistent use of surveillance cultures as part of SDD and SOD protocols makes it possible to assess the efficacy of enteral decontamination and to detect the emergence of antibiotic-resistant pathogens early.

Gram-Negative Microorganisms

To the contrary of what has been suggested, several studies showed an overall decrease in antibiotic-resistant, gram-negative microorganisms in patients during the episode when they were receiving SDD, including a significantly beneficial effect on colonization with resistant gram-negative bacteria, such as *P. aeruginosa* resistant to ceftazidime, imipenem, and ciprofloxacin and other aerobic gram-negatives resistant to imipenem, ciprofloxacin, and tobramycin.[4,18,32] One prospective Dutch study determined the effect of SDD on colonization with antibiotic-resistant gram-negative bacteria (ARGNB) after ICU discharge (T = 0) on day 3, 6 and 10. They found lower ARGNB rates at ICU discharge during SDD as compared with SOD and in addition the risk to acquire ARGNB after ICU discharge was found to be lower as well (hazard ratio, 0.61; 95% CI, 0.40–0.91; $P = .02$).[33] Patients receiving SDD during the DMT-I had a lower incidence of ICU-acquired candidemia and a lower incidence of bacteremia with Enterobacteriaceae and with highly resistant microorganisms (HRMOs; as defined in Dutch guidelines[34]) than those receiving SOD. Apart from candidemia, this was all confirmed in the DMT-II.[35]

Analysis of the rates of colistin resistance during SDD and SOD in DMT-I showed that during persistent intestinal carriage of gram-negative bacteria and during intestinal colonization with tobramycin-resistant gram-negative bacteria, the risk of acquisition of colistin-resistant gram-negative bacteria and conversion rates to colistin resistance increased. The overall risk of acquisition of colistin-resistant gram-negative bacteria and conversion rates to colistin resistance were, however, low.[36] This finding was confirmed by a Dutch study analyzing colistin-resistant *Enterobacter cloacae* in two ICUs during SDD using detailed microbiologic techniques, including whole-genome sequencing. They found low acquisition rates for colistin-resistant *E. cloacae* and no trend in time during their 5-year study period. Conversion from colistin susceptibility to colistin resistance occurred, yet the main route of acquisition of colistin-resistant *E. cloacae* was via clonal transmission, stressing the need for detailed microbiologic surveillance during SDD.[37]

A post hoc analysis in five Dutch ICUs using SDD or SOD over 7 years showed no increase in the prevalence of resistance against colistin or tobramycin.[38] A Dutch single-center study determined the ecologic effects of SDD over a 21-year period. SDD was used throughout the whole 21 years. No increase was observed in incidence rates of ICU-acquired antibiotic-resistant bacteria.[39] On the other hand, an increase in colistin resistance in extended-spectrum beta-lactamase (ESBL)–producing *Klebsiella pneumoniae* was reported when SDD was used to control an outbreak.[40]

The incidence of candidemia and bacteremia caused by HRMO was low in both the DMT-I and DMT-II, so whether the difference between SDD and SOD will translate into a difference in clinical outcome depends on the overall incidence of candidemia and HRMO bacteremia, the appropriateness of empiric antimicrobial therapy in such patients, and the attributable effects of such events on the outcome and length of stay.

All these findings do not support the concern that the use of topical antibiotics, with or without systemic prophylaxis with third-generation cephalosporins, increases the prevalence levels of antibiotic resistance in gram-negative bacteria. This conclusion is further supported by two 5-year prospective studies and a recent meta-analysis.[31,41,42]

Finally, a post hoc analysis of the European SDD (without systemic antibiotics)-SOD-chlorhexidine study on the eradication and acquisition of third-generation cephalosporin and carbapenem-resistant gram-negative bacteria showed in mechanically ventilated patients that SDD was associated with less acquisition and more eradication of both the cephalosporin- and carbapenem-resistant bacteria in the rectum compared with the SOD and chlorhexidine group. Both SDD and SOD were associated with less acquisition and more eradication of cephalosporin- and carbapenem-resistant bacteria in the respiratory tract compared with the chlorhexidine group.[43]

Gram-Positive Microorganisms

Methicillin-resistant *S. aureus* (MRSA) and vancomycin-resistant *Enterococcus* (VRE) are highly prevalent in ICUs in many countries, unlike the Netherlands, where the last three major studies were carried out. The use of topical antibiotics for SDD or SOD is generally considered to be contraindicated in such settings, as such regimens may increase colonization and infection rates with these bacteria. The effects of SDD and SOD are studied in settings with high levels of MRSA.[41] In one study, a shift toward gram-positive organisms was detected after the introduction of SDD in trauma patients, including an outbreak and increased carriage rates with MRSA 2 years after the introduction of SDD.[44,45] This shift was successfully addressed by implementation of control measures.[44] To prevent infections with MRSA, some investigators add vancomycin to the SOD or SDD regimen.[7,46] When applied topically, vancomycin is not absorbed and reaches high concentrations in the intestinal tract. In a Spanish burn unit, SDD with topical vancomycin was associated with improved patient outcome and lower colonization rates with MRSA.[46]

The results of the DMT-I and DMT-II indicate that both SDD and SOD are associated with higher rates of acquired respiratory tract colonization (DMT-I), but not with higher rates of bacteremia caused by enterococci or rectal colonization with VRE (DMT-I and DMT-II). In ICU patients, enterococci will colonize all body sites (especially the skin) and contaminate the inanimate environment. Enterococci are now among the most frequent causes of hospital-acquired infections worldwide, and the proportion of infections caused by ampicillin-resistant enterococci (ARE) has increased substantially in Western countries, including the Netherlands.[47] In the United States, approximately 35% of all ICU-acquired enterococcal bacteremias are caused by VRE. The clinical relevance of ARE and VRE infections is unclear.

Widespread use of topical vancomycin in units with high levels of MRSA will increase the selective pressure for VRE. This factor should be carefully balanced against the benefits of applying SDD or SOD with

vancomycin added to oral paste and/or suspension. In the United States, ICUs with high levels of MRSA frequently also have high endemic levels of VRE. In such settings, the addition of oropharyngeal chlorhexidine oral washings and/or chlorhexidine body washings may help to control spread and bloodstream infections caused by VRE and MRSA.[48,49]

Ecologic Effects

During the DMT-I, surveillance cultures from the respiratory and intestinal tract were obtained each month on a fixed day from all patients present in the ICU, regardless of whether they were included in the study.[5] These 18 point-prevalence studies in 13 ICUs allowed analysis of the effects of SDD and SOD on the bacterial ecology in these ICUs together. The effect of SDD (over a 6-month period) and SDD/SOD (combined over a 12-month period) on intestinal and respiratory tract carriage with gram-negative bacteria was determined by comparing results from consecutive point-prevalence surveys using intervention to consecutive point-prevalence data in the preintervention and intervention periods.[50] The average proportion of patients colonized with ceftazidime-, tobramycin-, or ciprofloxacin-resistant gram-negative bacteria in the intestinal tract decreased during the use of SDD in the ICU and increased again after discontinuation. During combined SDD/SOD, resistance levels in the respiratory tract were low (≤6%) for all three antibiotics but seemed to increase gradually, with a significant increase only for ceftazidime resistance ($P < .05$). After discontinuation of SDD/SOD, the resistance levels increased to 10% or higher. Clearly, both SDD and SOD have marked ecologic effects that are supported by the results of a 4-year ecologic study published in 2014.[51] According to the DMT-II, SDD showed significantly lower rectal carriage of ARGNB than did SOD.[23] Further, a gradual increase in tobramycin resistance was observed during both the SOD and SDD periods, but more clearly during SDD; however, the incidence of acquired bacteremia with aminoglycoside-resistant GNB was lower in the SDD group than in the SOD group.[23] Of note, some of these patients were in the ICU only briefly and not receiving SOD or SDD, and the incidence of resistance in other hospital wards was unknown. An increasing incidence of resistance in the participating hospitals might have influenced these results.

Overall, the ecologic effects (i.e., lowest resistance levels during interventions) corroborate the positive effects of SOD and even more of SDD on antibiotic resistance in individual patients. One might regard this effect as a herd effect of the use of SDD or SOD.[4,31]

Other Issues

Effectiveness of SDD in Specific Patient Groups

Evidence suggests that SDD might not be equally effective in all ICU patient groups. In one meta-analysis, increased SDD efficacy was observed in surgical patients.[17] Further, studies on the preoperative use of SDD suspension and other oral antibiotics in patients undergoing gastrointestinal surgery report lower rates of surgical site infections (SSIs) and anastomotic leakage.[20,52,53] In 2019 a Dutch multicenter RCT was published that included patients with colorectal cancer who electively underwent curative surgery with a primary anastomosis. Both the control and SDD group patients received perioperative IV cefazolin and metronidazole. The SDD group received standard SDD (i.e., tobramycin, colistin, and amphotericin B). SDD was started 3 days before surgery and continued until patients had normal bowel motion with a minimum of 3 days after surgery. Four hundred and fifty-five patients were included, and no significant differences were found for the incidence of anastomotic leakage (6.1% during SDD versus 9.7% in the control group). Yet infectious complications were less frequent during SDD as compared with control (14.9% versus 26.9%, respectively).[54] The individual patient data meta-analysis did show comparable treatment effects for SOD and SDD in surgical versus nonsurgical patients.[25]

Hospital-Acquired Infections After Treatment With SOD and SDD

In the SDD study by De Jonge and colleagues, the relative risk reduction in ICU mortality of 35% decreased to 22% at hospital discharge.[4] Triggered by these findings, it was hypothesized that this reduction in survival benefit after ICU discharge might be related to an increased incidence of hospital-acquired infections (HAIs) in patients who had received SDD in the ICU. Nested within the DMT-I, the incidence of HAI was prospectively monitored during the first 14 days after ICU discharge in all patients transferred to regular wards in two university hospitals.[55] Most HAIs were in the respiratory tract, with a similar incidence and duration of infection in all three posttreatment study groups. The incidence of bloodstream infections was also similar in the three posttreatment groups, but the time until infection tended to be longer in the post-SOD and post-SDD groups compared with the post-control group. On the other hand, the incidence of SSIs increased in the postintervention groups. The low rates of HAI, the overall low mortality rates after ICU discharge, and the low prevalence of infections among those who succumbed after ICU discharge refute the hypothesis that discontinuation of SDD and SOD post-ICU increases the infection rate and thus affects clinical outcomes.[55]

Antibiotic Use and Cost-Effectiveness

De Jonge and colleagues determined that the total cost of antibiotics, topical and systemic, was 11% lower in the SDD group than in the control group. This difference was primarily attributed to the decrease in the use of antibiotics such as ciprofloxacin, ceftazidime, imipenem, and antifungal treatment.[4] These results were confirmed by the DMT-I, with a decrease of 12% and 10% in the use of daily defined doses (DDDs) of systemic antibiotics in the SDD and SOD groups, respectively, as compared with controls.[5] Although the increase in the use of third-generation cephalosporins in SDD patients was obvious, DMT-1 showed a remarkable decrease in more broad-spectrum antimicrobial use such as ciprofloxacin, ceftazidime, and imipenem and in antifungal treatment. As such, SDD may be considered a potentially powerful intervention in antimicrobial stewardship programs. It may be hypothesized that the lack of an effect on antimicrobial resistance (AMR) by SOD/SDD is caused by a decrease in the Defined Daily Dose (DDD) of broad-spectrum antibiotics used in these same patients.

A cost-effectiveness individual patient data meta-analysis included DMT-I and DMT-II. It reported significantly lower hospital mortality during SDD as compared with SOD, with no difference in costs.[56]

Adverse Events

Three patients are reported to have suffered large clots from accumulation of the buccally applied oral SDD/SOD paste, causing obstruction of the esophagus or jejunum. This complication can be prevented by regular and appropriate oral care.[57]

Toxic serum concentrations of tobramycin caused by enteral absorption has been reported as an adverse event of prolonged use of SDD. As tobramycin is renally eliminated, patients with kidney failure are most at risk for toxic levels. A prospective study in 19 SDD patients treated with renal replacement therapy could detect serum tobramycin concentrations in 63% of the patients.[58] They reported a toxic concentration (≥2.0 mg/L) in one patient (5%). The highest concentrations of tobramycin were found in patients with bowel ischemia. It is hypothesized that ischemia may lead to decreased intestinal barrier function, in turn leading to detectable serum tobramycin concentrations.

The use of chlorhexidine 2% mouthwash has been associated with the development of oral mucosal lesions, including ulcerations and bleeding mucosa.[59] Replacement with 1% mouthwash resulted in reported intolerance in less than 1% of the patients.

KEY POINTS

- SOD and SDD improve survival in ICU patients.
- Both SDD and SOD lower the incidence of ICU-acquired bacteremia, RTIs, and the use of systemic (broad-spectrum) antibiotics. SDD reduces the incidence of ICU-acquired bacteremia compared with SOD. Only SDD lowers the incidence of candidemia compared with controls.
- No evidence supports the concern that the use of topical antibiotics with or without systemic prophylaxis increases the prevalence of antibiotic resistance to gram-negative bacteria. In particular, SDD decreases the rate of antibiotic resistance to gram-negative bacteria.
- Both SDD and SOD are cost-effective.
- More studies are needed to determine the long-term effects of SOD and SDD on antibiotic resistance, with special attention to the changes in antibiotic resistance among gram-negative bacteria in surroundings with high antibiotic resistance levels.
- During the use of SDD, strict surveillance should be carried out to monitor effectiveness and to detect colonization with resistant bacteria.

Intravascular Catheter-Related Infections

Niccolò Buetti and Jean-François Timsit

INTRODUCTION

Intravascular catheters are essential in the care of critically ill patients in order to allow safe intravenous administration of medications, help in the monitoring of hemodynamic parameters, and aid in the intravenous administration of fluid resuscitation. In European intensive care units (ICUs), the central venous catheter (CVC) utilization rate was, on average, 71 CVC days per 100 patient days.[1] Moreover, bloodstream infections (BSIs) were catheter-related in 42.6% of cases,[1] and rates of catheter-related BSIs (CR-BSI) ranged to levels as high as 1–6.2 per 1000 catheter days.[1] In the United States, 15 million CVC days are estimated to occur each year in ICU patients, in addition to about 40,000 CVC-related BSIs, leading to a rate of more than 2 per 1000 CVC days.[2] However, peripherally inserted central venous catheters (PICCs) are less frequently placed for central access in critically ill patients, and their use in the ICU setting remains debated.[3]

CR-BSIs are associated with a significantly increased mortality.[4] However, recent studies describe a nonincreased risk of mortality in a cohort of patients where catheters were systematically removed.[5] The excess of ICU length of stay is estimated at 9–12 days.[6,7] Early adequate antimicrobial therapy and catheter removal are key components of therapy in the case of CR-BSI with severe sepsis or shock. Data on duration of antimicrobial therapy are scarce and will be discussed.

In contrast to other hospital-acquired infections, the majority of the risk factors for intravascular catheter infection are linked to the device itself and can be prevented efficiently.[8,9] Healthcare worker education and training and continuous unit–based improvement programs are therefore instrumental.[9,10] We will discuss the potential interests of new technical developments and put them into perspective according to the available recommendations. Our focus will be mostly on short-term CVC use in critically ill patients, though other catheters are also mentioned.

PICCs, arterial, and short-term dialysis catheters will be discussed separately in the electronic supplemental material.

PATHOPHYSIOLOGY AND MICROBIOLOGY

The colonization of the catheter can occur by two main pathways: the extraluminal route or the intraluminal route. Colonization of the catheter from its dermal surface is the predominant route of colonization for short-term CVCs (<15–30 days), whereas colonization via the intraluminal route resulting from hub contamination predominates for long-term CVCs.[11] These main differences should be kept in mind when choosing between different diagnostic options and preventive strategies.

The occurrence of bacteremia caused by common skin organisms (e.g., coagulase-negative staphylococci [CoNS] or *Staphylococcus aureus*) is a major criterion for the diagnosis of CR-BSI, although Enterobacteriaceae and *Pseudomonas aeruginosa* are increasingly observed these last years,[12] especially in case of femoral site of insertion.[13,14]

DEFINITIONS

Definitions that are currently accepted are displayed in Table 111.1 and apply to all types of vascular catheters. Having them in mind is important to better interpret clinical evidence. Two major definitions are used to define BSIs caused by vascular catheters: central line associated–BSI (CLA-BSI) and catheter-related BSI (CR-BSI). The CLA-BSI definition requires a single positive blood culture for a typical pathogen (or two positive blood cultures for a skin commensal) without positive tip culture or positive peripheral blood cultures. Although this definition is accepted for surveillance, it overestimates the true incidence of catheter infections and remains subjective in assigning the source of infection.[2,15] A recent meta-analysis illustrated that the consistency between CLA-BSI and CR-BSI definitions was rather poor.[16] Indeed, the CR-BSI definition is a more specific clinical definition that requires specialized microbiologic data (e.g., differential time to positivity [DTP], catheter tip culture) and positive peripheral blood cultures.[17]

DIAGNOSIS OF CATHETER INFECTIONS

Clinical Diagnosis

An old study showed that inflammation signs (e.g., erythema or redness) at the exit site are nonspecific and are rarely present in case of CR-BSI.[20] However, an analysis including four randomized controlled trials (RCTs) with more recent data illustrated that local signs at removal were significantly associated with CR-BSI and were highly predictive for catheter infection, especially in the first 7 catheter days.[21] Usually, when CR-BSI is suspected, the common practice in the ICU is to remove the CVC and replace it at a new site. However, only about 15%–25% of CVCs so removed indeed proved infected upon quantitative tip culture.[22–24]

Diagnosis of CR-BSI After Catheter Removal

Cultures at catheter removal should only be performed if an intravascular catheter infection is suspected (see Table 111.1).[18] Although the qualitative broth tip culture has a high sensitivity, its specificity is very low, and contamination cannot be discriminated from infection; it should therefore be abandoned. Quantitative culture techniques have been developed and explore either the extraluminal part of the catheter (semiquantitative Maki technique) or the extraluminal and intraluminal parts via vortex wash or sonication.[25–28] The semiquantitative culture techniques appear to be as accurate as the quantitative methods for diagnosis of catheter-related infections.[29] Of note, the sensitivity of the

TABLE 111.1 Proposed Definitions

	Definition	Comments
Catheter tip colonization	Positive culture of the catheter tip that grew to ≥15 cfu/mL (semiquantitative), 10^2 cfu/mL (quantitative sonication), or 10^3 cfu/mL (quantitative vortexing).	Qualitative culture should no longer be used.
Exit site infection	Tenderness, erythema, or induration > 0.5 cm at the exit site. It may be associated with other signs and symptoms (e.g., fever or purulent drainage).	Positive culture of exudate confirms the exit site infection microbiologically.
Catheter-related bloodstream infection (CR-BSI)	One positive blood culture obtained from peripheral vein and clinical manifestation of infection and (1) a catheter tip colonization or (2) a differential time to positivity of more than 120 min and no obvious source of bacteremia except the catheter or (3) simultaneous quantitative cultures of blood with a ratio of >3:1 cfu/mL of blood (catheter vs. peripheral blood).	Simultaneous quantitative culture from a peripheral vein and the catheter of 3–5: 1 ratio is rarely used.
Central line associated–bloodstream infection (CLA-BSI)	One positive blood culture and clinical manifestation of infection in a patient with a catheter in place with no other source of bacteremia except the catheter.	Easy to use for surveillance purposes. However, this definition can lead to an overestimation of the BSI incidence caused by catheter infection, especially in ICU and in onco-hematologic patients.
Catheter-related clinical sepsis	Clinical manifestation of infection that disappears within 48 hours of catheter removal and a positive catheter tip culture and no other obvious treated source of infection.	Represent 30%–50% of catheter-related infections with general manifestation. Not easy to collect routinely, but may need antimicrobial treatment.
Suspected intravascular catheter infection	The presence of one of the following signs: elevation of inflammatory signs (fever or organ dysfunction) after catheter placement without other infectious or noninfectious explanations; exit site infection signs (purulent discharge, redness, or cellulitis >0.5 cm diameter, abscess); positive blood culture without identification of infectious focus.	This definition is based on expert opinion.[18] The exclusion of other sources of infection can lead to important variability in the final classification in ICU patients. The purulence of the exit site of the catheter is a strong argument to impute the catheter as the source of infection.
Clinical/laboratory signs or risk factors for complicated catheter infection	• Hemodynamic instability. • Neutropenia (<500/mm^3) or immunosuppression (including organ transplantation). • Local exit site signs (purulent discharge or redness/cellulitis >0.5 cm diameter).	This definition is based on exclusion criteria used in a study investigating a watchful waiting strategy versus immediate catheter removal in ICU patients with suspected catheter-related infection.[19]
Noncomplicated intravascular catheter infection	• Favorable clinical course without persistence of fever and negative blood cultures after 72 hours of adequate treatment. • No septic metastasis, endocarditis, or septic thrombophlebitis. • Without other intravascular devices or immunosuppression.	In contrast, a persistent CR-BSI is defined as the presence of positive blood cultures after 72 hours of adequate antimicrobial therapy.
Catheter-related thrombophlebitis	Clinical definition: induration or erythema, warmth, and pain or tenderness along the tract of a catheterized or recently catheterized vein. Alternatively, imaging evidence of vascular thrombosis and clinical manifestations concordant with location of a catheterized or recently catheterized vein.	

BSI, Bloodstream infection; *cfu*, colony-forming unit; *CoNS*, coagulase-negative staphylococci; *ICU*, intensive care unit.
Adapted from Timsit JF, Rupp M, Bouza E, et al. A state of the art review on optimal practices to prevent, recognize, and manage complications associated with intravascular devices in the critically ill. *Intensive Care Med*. 2018;44(6):742–759; and Buetti N, Timsit JF. Management and prevention of central venous catheter-related infections in the ICU. *Semin Respir Crit Care Med*. 2019;40(4):508–523.

catheter culture may be decreased in case of prior use of antimicrobials.[30,30a] This point should be kept in mind when interpreting negative or borderline culture results. Therefore the need to perform diagnostic tests (blood and catheter cultures) before starting any new antimicrobials should be always emphasized.

Diagnosis of CR-BSI With Catheter in Place

In the case of severe sepsis or shock, the catheter should be promptly removed.[17,31] However, most of the suspected catheter infections are not life-threatening, and diagnostic techniques allowing an accurate diagnosis while keeping the catheter in place are an attractive option[19] (see "Management of Catheter-Related Infections").

Quantitative Culture of the Catheter Exit Site

A negative culture of the catheter exit site in case of suspicion of infection may rule out the diagnosis of CR-BSI or colonization but their role remains debated in the literature.[32,32a] Alternatively, the combination of skin and flushed needleless connectors culture (i.e., connectors closing catheter hubs requiring a less invasive microbiologic diagnostic) may be a valuable option for ruling out catheter colonization,[33] thus avoiding any unnecessary catheter replacement.

Differential Time to Positivity

Simultaneous blood cultures, drawn through the catheter and a peripheral vein without removal or exchange of the catheter, are accurate

means for predicting CR-BSI. The time to positivity (TTP) of a blood culture is related to the magnitude of the bacterial inoculum: if a catheter is the source of bacteremia, blood cultures sampled through this catheter will likely have an increased inoculum than peripheral samples and should yield bacterial growth more quickly.[34] Therefore the *differential* time to positivity (DTP) of hub-drawn blood cultures as compared with peripherally drawn blood cultures has been proposed as a means to diagnose CR-BSI[35] (i.e., the difference in the time to positivity between hub blood and peripheral blood cultures). If a cutoff of 120 minutes is used, sensitivity and specificity are greater than 90%[35]; moreover, for short-term catheters, a meta-analysis documented a sensitivity of 89% and specificity of 87%.[27] Theoretically, this technique only explores the intraluminal route of infection, but other authors showed that it can be used for both short-term and long-term CR-BSI diagnosis,[36,37] thus indirectly suggesting a good yield for the extraluminal route diagnosis. However, aspiration of blood cultures drawn through the catheter lumen is technically impossible in one case out of four.[38] Furthermore, each lumen may represent a source of infection. It has been shown that the sampling of one out of three lumens of triple-lumen catheters misses 37% of the CR-BSI cases.[39] Moreover, the role of DTP for the diagnosis of several specific microorganism CR-BSIs remains debated. For diagnosis of *Candida* CR-BSI, one retrospective study showed good sensitivity (85%) and specificity (82%),[40] whereas other investigators reported a specificity of only 40%.[41] Similar controversies are observed for the diagnosis of *S. aureus,* CoNS, or non-AmpC Enterobacteriaceae CR-BSI with DTP.[42–45]

Paired Quantitative Blood Cultures

A diagnosis of CR-BSI can be made if the microorganism colony count is higher in blood cultures obtained from the CVC versus percutaneously obtained peripheral blood.[17] Although it is an accurate method to diagnose CR-BSI,[27] this technique is limited by the lack of standardized cutoff points. In addition, most laboratories rarely perform quantitative blood cultures.[17,27]

PREVENTION

The only sure way to prevent CR-BSI, in addition to other catheter-related complications, is to avoid unnecessary intravascular catheters.[46,47] An increasing body of studies indicates the safety of peripheral intravenous lines for administration of low-dose vasoactive medication.[48,49] Therefore a minimization of catheter use or the use of alternatives are important tools for CR-BSI prevention. The need for CVCs should be assessed daily, and unnecessary CVCs should be removed.[15]

Guidelines on CR-BSI prevention have been recently updated.[8,9,18,31,50,50a] They belong to two categories: studies applying multimodule programs to improve general infection control measures when using catheters, such as surveillance, education, and quality management strategies, and studies that have tested new biomaterials, antiseptic dressings, and catheter locks. Their key points are illustrated in Figs. 111.1, 111.2, and 111.3.

Catheter Insertion

Sterile Barrier Precautions

Full barrier precautions using sterile gloves, long-sleeved sterile gown, procedure mask, cap, and large sterile sheath drape during catheter insertion are essential for the prevention of CR-BSI and should represent the standard during CVC and pulmonary catheter insertion.[51,52] Only one prospective randomized study in surgical patients did not show any additional benefit for full sterile barrier precautions.[53] Nevertheless, most available evidence suggests risk reduction with this intervention. A bedside checklist should be used to improve the compliance with appropriate insertion procedures.[54]

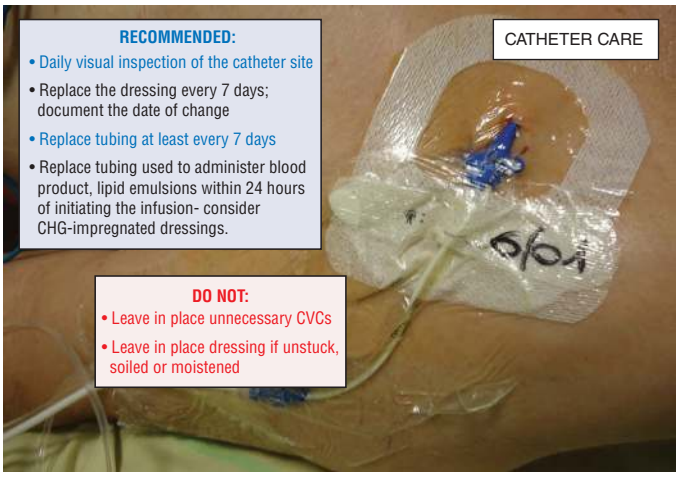

Fig. 111.3 Catheter Care. Strongly recommended preventive measures are written in **bold**. *CVC,* Central venous catheter.

Skin Antisepsis

Skin antisepsis is one of the most important preventive measures. An old in vitro study postulated that antiseptic detergent before application of an antiseptic solution may decrease the amount of bacteria and (potentially antiseptic-inhibiting) protein-rich biomaterials on the skin.[55] However, an RCT demonstrated that cleansing of the skin with a detergent is unnecessary; therefore this measure should be abandoned unless the skin is obviously contaminated.[24]

Adequate skin decontamination requires correct application technique, including the dose for the skin surface area and allowing adequate drying time. The optimal modality of antiseptic application remains controversial.[56] The application of the antiseptic either using applicators or sterile gauze handled with a pincer may increase antiseptic diffusion into the deeper layers of the skin while keeping the hands of the operator away to reduce the risk of contamination.[31] Single-use vials containing sterilized antiseptic further reduce the risk of contaminated solutions from multiuse bottles but may increase costs.[31]

Numerous studies have been conducted to identify the best antiseptic solution for skin decontamination. In patients without contraindications (e.g., chlorhexidine allergy), a sterile 2% (w/v) chlorhexidine gluconate (CHG) solution should be used to decontaminate the skin before the insertion of a vascular catheter, and neither aqueous nor alcoholic povidone-iodine (PVI) should be used as a first-line agent for skin decontamination.[24,57–59] The CHG superiority is probably because of its rapid bactericidal activity. The majority of these studies were conducted using 2% alcoholic CHG. Interestingly, one prospective cohort study found no difference in catheter colonization by CR-BSI between 0.5% alcoholic chlorhexidine and 2% aqueous chlorhexidine.[60] In contrast, another observational study found a similar risk for catheter-related infections between alcoholic CHG <1% and alcoholic PVI, suggesting less benefit using lower concentrations of CHG.[59] The potential benefit of the 2% alcoholic CHG compared with 0.5% alcoholic CHG has been demonstrated in vitro[61] and suggested by one before-and-after study evaluating *S. aureus* bacteremia in patients receiving hemodialysis.[62] Given the widespread use of CHG in medicine, the development of CHG resistance, and especially cross-resistance, to clinically relevant antibiotics has raised concerns.[63] For example, gram-negative bacteria can exhibit a high level of intrinsic resistance to CHG (e.g., *P. aeruginosa, Proteus* spp., and *Providencia stuartii*).[63,64] Moreover, efflux pumps' gene-resistance mechanisms are present in both gram-positive (e.g., *Enterococcus* spp.) and gram-negative microorganisms (e.g., *Acinetobacter* spp. or *Klebsiella pneumoniae*), thus raising the concern that the resistance to CHG with widespread clinical use may simultaneously increase the antibiotic resistance.[63,65] Moreover, CHG tolerance has been associated with methicillin-resistant *S. aureus* (MRSA) decolonization protocol failure.[66] However, the clinical impact of this is uncertain, and a possible cross-resistance between CHG and antibiotics remains controversial.[65] Ubiquitous use of CHG, including patient bathing, oral care, and decontamination of medical devices, however, warrants closer monitoring for emergence of resistant strains to CHG and cross-resistance to antibiotics.[31,63,65] CHG is probably the most effective disinfectant; however, it is associated with more cutaneous skin reactions,[24,67] and rarely, severe anaphylaxis has been reported.[68] *Sequential* use of PVI-containing and CHG cutaneous antiseptics may be beneficial, particularly for high-risk cases, but prospective, multicentered RCTs should be conducted to more rigorously address the utility of this approach to preventing intravascular catheter-related infections.[69]

Chlorhexidine Patient Bathing

Important RCTs have found that routine patient washing with CHG or universal decolonization protocols result in significant CLA-BSI reduction.[70–72] However, in a meta-analysis, the effect was evident in the gram-positive subgroup and became nonsignificant after removal of a high-risk-of-bias study.[73] The impact on gram-negative BSI was not significant.[73] The last cluster-RCT conducted in more than 70 German ICUs showed no benefit of chlorhexidine bathing on CLABSI.[73a] Considering the existing concerns about the risk of emergence of CHG resistance and antibiotic cross-resistance,[65] the implementation of universal skin decolonization with CHG warrants caution and further evaluation.[74]

Catheter Insertion Site

Selection of the insertion site should be based on both the benefits and the risks of the procedure. These include infection, thrombosis, and mechanical complications. The subclavian site is the preferred insertion site for reducing infectious complications.[75,76] An old RCT demonstrated that the subclavian site was associated with lower risk of infectious and thrombotic complications than femoral catheterization in ICU patients.[73] The three-site multicentric RCT confirmed the superiority of the subclavian site compared with the femoral site, and based on results of the per-protocol analysis, a decreased risk for the subclavian site was observed compared with the jugular site.[72] Of note, the impact of systematic ultrasound-guided catheter insertion has not been routinely considered in the previously mentioned analyses.

Several meta-analyses compared the differences in the infectious risk between femoral and jugular sites.[77–80] Two of them showed a superiority for the jugular insertion site. However, when considering RCTs only, the femoral and internal jugular accesses were associated with similar risk of infection.[78,79,81] Two studies using individual data of RCTs suggested that catheter colonization and infection were higher for the femoral site in females, in patients with elevated body mass index (>28.4),[81] or if the catheter dwell time was ≥5 days.[80]

Catheter Fixation

Application of sutures disrupts the skin at the insertion site and may serve as a nidus for microbial growth. An innovative approach using a suture-free system has been proposed by Karpanen and colleagues.[82] This securement system performed similarly in terms of CVC migration and unplanned removal of CVC; however, to date, its effect on CR-BSI reduction has not been demonstrated.

Ultrasound-Guided Placement

The use of ultrasound compared with anatomic landmarks is associated with greater procedural success, lower number of attempts, shorter time of catheterization, and a reduction of mechanical complication, especially for internal jugular and subclavian veins.[83,84] Moreover, this technique may allow prompt recognition of complications (e.g., pneumothorax).[85] However, the impact of ultrasound on the rate of catheter infections is uncertain. Only a few studies have assessed the infectious risk associated with ultrasound guidance, and a prospective study did not show any effect of ultrasound guidance on CVC-associated BSIs or mortality.[86] A recent large post-hoc analysis including data until 2014 showed that ultrasound guidance may be associated with an increased risk of infection. In hospitals where ultrasound equipment is available and the physician has a sufficient training level, combining the anatomic landmarks with ultrasound catheter insertion procedures should be considered to reduce the risk of mechanical complications.

Thrombosis and Infection

Some clinical data suggested a close relationship between catheter thrombosis and infection.[87] A fibrin sheath surrounding the catheter enhances catheter colonization,[88] and therefore the diagnosis of catheter thrombosis should increase the suspicion for catheter infection. Anticoagulant and antithrombotic agents have been used to prevent and manage complications of CVCs. However, the role of heparin in

preventing CR-BSI remained controversial: a recent meta-analysis showed that heparin saline is not superior to regular saline in reducing CR-BSI.[89] Data supporting the specific use of systemic anticoagulant therapy to prevent catheter-related thrombosis in ICU patients are scarce. In selected patient populations (e.g., cancer patients) with CVCs, anticoagulation administration should balance the possible benefit of reduced thromboembolic complications with the possible harms of anticoagulants.[31,90] To date, routine use of systemic anticoagulation cannot be recommended.

Few data exist regarding the use of heparin-bonded catheters in adult patients in the ICU. A meta-analysis including two studies performed in pediatric patients concluded that heparin-bonded catheters did not reduce the rate of catheter-related thrombosis.[91] One study reported a reduction in the rate of CR-BSI and colonization after the use of heparin-bonded catheters.[91] Another study including patients with hemato-oncologic disease illustrated that the use of heparin-coated catheters can be a safe and effective approach for prevention of CR-BSI.[92] However, the potential interest of heparin-coated catheters might be balanced by the risk of heparin-induced thrombocytopenia.

Catheter Care

Replacement

Repeated catheterizations of the same vein are associated with an increased risk of catheter infection.[22] However, the scheduled replacement of catheters as a preventive strategy has not lowered catheter infection rates in many trials in the 1980s to 1990s.[93,94] These findings argue in favor of avoiding any routine replacement of CVCs for catheters that are functioning and have no evidence of local or systemic complications.[95] Importantly, such a statement might not hold true for arterial catheters, whose daily risk of colonization might increase with duration of catheter maintenance.[96]

Dressing

Semipermeable transparent dressings are widely used; they allow continuous observation of the skin insertion site and reduce the risk of extrinsic colonization. Gauze dressing is preferred if blood is oozing from the catheter insertion site. Catheter dressings should be changed immediately if the dressing becomes damp, loosened, or soiled. The risk of CR-BSI increases by more than threefold after the second dressing disruption and by more than tenfold if the final dressing is disrupted.[97] The optimal frequency of routine changes of a CVC dressing is not well-established. However, an RCT demonstrated that the interval of scheduled dressing changes could be safely increased to 7 days in the ICU, provided the dressings are closely monitored.[98] New dressings combining high adhesiveness and permeability and good skin tolerance were not able to decrease the risk of catheter infection and overall catheter complications in a large monocentric RCT.[99] The application of a new acrylic terpolymer skin-protective barrier film around the catheter insertion site resulted in fewer dressing disruptions and skin integrity issues. However, the effect on CR-BSI was not demonstrated, and this technology was tested only in CHG-impregnated dressing.[100]

Both CHG-impregnated sponges and CHG-gel dressings were associated in two RCTs with a 60% decrease in the risk of catheter infections, including CR-BSIs.[98,101] The limitations of these studies included the use of skin antisepsis with PVI at insertion and when changing dressings (first study) and the lack of a double-blind design and a manufacturer's financial participation (second study). Moreover, CHG-impregnated sponges and CHG-gel dressings triggered contact dermatitis at a low rate, <10/10,000 catheters in adult patients. Two meta-analyses confirmed that CHG-impregnated dressings were beneficial in preventing catheter colonization and CR-BSI.[102,103] In light of these considerations, CHG-impregnated dressings should probably be used to decrease CR-BSI in adults.

Administration Set Replacement (Tubing)

Administration sets that do not convey lipids, blood, or blood products may be left in place for intervals of up to 96 hours without increasing the risk of infection.[104] A large RCT conducted in several ICUs in Australia showed that infusion set use can be safely extended to seven days.[105,105a] Nevertheless, tubing used to administer blood, blood products, or lipid emulsions (including propofol infusions) should probably be replaced at least every 24 hours.[106,107]

Catheter Hubs and Needleless Connectors

Any excessive manipulation of CVCs increases the risk for subsequent bacterial ingress into the catheter lumen, and therefore CR-BSI, and must be avoided.[10] Any intravascular access point with a surface open to the environment requires disinfection before use, as it acts as the immediate portal of entry.[108] Before accessing catheter hubs or needleless connectors, an appropriate antiseptic (alcoholic CHG, 70% alcohol) should be used.[8,15,108] Applying mechanical friction for at least 5 seconds was associated with reduced contamination[109,110] and should therefore be implemented. However, it is unclear whether this minimum scrub time can be generalized to needleless connectors.[109] Although some needleless systems appear to be associated with a greater risk of BSI, probably related to their features (i.e., transparency, displacement, flow dynamic, fluid pathway, difficulty of cleaning),[15,111–114] needleless intravascular connector valves may be introduced into clinical practice to minimize the risk of needlestick injury during intermittent use.

The catheter hub should be appropriately disinfected to prevent catheter infections; however, the compliance with this time-consuming manual disinfection process is low. New antiseptic barrier caps have been developed that clean the catheter hub by continuous passive disinfection and may be associated with a lower CLA-BSI incidence.[115]

Antimicrobial-Coated or -Impregnated Catheters

The efficacy of catheters impregnated with CHG and silver sulfadiazine was tested in many RCT studies in the 1990s. A meta-analysis including 57 studies and 11 types of impregnations showed that catheter impregnation significantly reduced CR-BSI and colonization.[116] However, catheter impregnation did not significantly influence the rates of clinically diagnosed sepsis, all-cause mortality, and catheter-related local infections.[116] In terms of microbiologic outcomes (e.g., catheter colonization) minocycline-rifampicin impregnation appeared to be superior to chlorhexidine–silver sulfadiazine impregnation, which was in turn superior to silver impregnation.[116] However, many of the studies were performed in the era before infection preventive bundles became routinely used; whether impregnated catheters are still cost-effective in such settings is uncertain.[31,116] Although the emergence of antimicrobial resistance is of concern, particularly with the minocycline-rifampin–coated catheter, the available data suggest that the long-term use of antimicrobial-coated CVCs is not associated with increased resistance against staphylococcal species.[117] However, no clear conclusion could be drawn regarding the impact of the use of rifampin-minocycline–impregnated catheters on the development of antimicrobial resistance or on the selection of resistant flora and *Candida* spp.[118,119] Therefore the use of such catheters should be limited to hospital units with an infection rate above the institutional goals despite their compliance with basic catheter infection prevention practices.[8,15] Other catheters impregnated with silver

zeolite, oligon, platinum, and carbon have been tested but have not proven their efficacy.[120]

Systemic Antibiotic or Antiseptic Lock Solutions

The prophylactic use of systemic antibiotics at the time of catheter insertion has not proven to be effective in reducing CR-BSI. However, only a few studies investigated the role of systemic antibiotic prophylaxis in short-term catheters. A meta-analysis including three relatively small studies demonstrated that the routine use of prophylactic systemic antibiotics in newborns during the full period of CVC maintenance reduced the rate of "proven" or "suspected" septicemia and of clinical sepsis without any effect on mortality.[121] Only a few studies investigated the role of systemic antibiotic prophylaxis in adults. Concurrent systemic antibiotics at catheter insertion and intravascular catheter-related infection in the ICU: a post hoc analysis using individual data from five large RCTs.[123,123a] The prophylactic use of systemic antibiotics at catheter insertion has not proven to be effective in reducing the incidence of CR-BSI and is therefore discouraged.

Antimicrobial lock therapy (ALT) consists of instilling a supratherapeutic concentration of an antimicrobial solution into a catheter lumen and leaving it in place until the catheter hub is reaccessed. ALT is intended for catheters not used continuously and targets endoluminal catheter infections. Importantly, most available data evaluating this strategy are derived from long-term catheters.[31] In a meta-analysis, the use of antimicrobial lock solutions led to a reduction of CLA-BSI rate and a decrease of exit-site infections compared with the use of heparin.[124] However, this meta-analysis identified a significant publication bias.[124] Moreover, lock solutions may lead to the emergence of antibiotic-resistant organisms[125] and could lead to systemic toxicity caused by lock solution spillage from catheters.[31] Some fibrinolytics reduced the rate of catheter infection and dysfunction in tunneled dialysis catheters[126]; however, the extrapolation of these studies to short-term catheters inserted in ICU patients is debatable because of differences in catheter type, use, and accessibility for ALT.[31] To date, the use of prophylactic ALT for short-term catheters cannot be recommended.

Role of Nursing Care

The intravenous catheter care bundle includes a checklist for catheter insertion, appropriate postinsertion catheter care, and prompt removal of the catheter when no longer required.[8,50] Nursing staff and any personnel involved with the care of intravascular catheters have an essential role during these processes.[31] The checklist is a tool to assure that the catheter insertion procedure is followed correctly, and it empowers healthcare workers to challenge and stop the procedure if this is not executed appropriately.[8,31] Finally, it is essential to assure an appropriate nurse-to-patient ratio and limit the use of float nurses in ICUs.[8,127]

Bundles of Care

Several insertion and maintenance prevention measures can be combined to create a bundle. Implementation of such bundles has been demonstrated to reduce the median incidence of CLA-BSI from 6.4 per 1000 catheter days to 2.5 per 1000 catheter days after their implementation.[128]

Proposed bundles should result from available recommendations and be adapted locally.[129] The key components include (1) improvement of hand hygiene compliance; (2) use of maximal barrier precautions during the insertion; (3) preferential use of subclavian access; (4) use of alcoholic 2% CHG for skin antisepsis and catheter care; (5) daily inspection of the insertion site; (6) immediate change of unstuck, soiled, or moistened catheter dressings; and (7) removal of the catheters as soon as no longer requested. Although nearly 50% of US ICUs reported having a CLA-BSI prevention bundle policy, only 38% of institutions that monitored bundle implementation reported full bundle compliance.[130] Therefore hospitals must target improving bundle implementation and compliance as opposed to simply instituting policies.[130] Several success stories were published using these recommendations, most of which were observed in ICUs.[47,131–134]

Knowledge, Education, and Behavioral Interventions

Practice change was one of the most important interventions that reduced the incidence of CLA-BSI.[128] In particular, the implementation of central-line bundles has the potential to reduce the incidence of CLA-BSI.[128] Knowledge, education, and training are the cornerstones of any behavior change strategy. Individual experience is instrumental in explaining behavior compared with the evidence base or formal education.[135] Therefore isolated knowledge delivery by ex cathedra teaching or handing out of written protocols is not sufficient to change behavior.[31] In this context, a systematic review on organization and structure of infection control identified three essential components addressing knowledge, education, and behavioral interventions: (1) guidelines should be used in combination with practical education and training; (2) education and training should involve frontline staff and should be team- and task-oriented; and (3) implementation should follow a multimodal strategy, including tools such as checklists and bundles, developed by multidisciplinary teams, taking into account local conditions.[124,125,136–138]

MANAGEMENT OF CATHETER-RELATED INFECTIONS

Catheter Removal or a More Conservative Attitude?

When CR-BSI is suspected, in the case of hemodynamic instability, immunosuppression, or if local signs of infection are observed, the catheter should be removed[31] (see Table 111.1 and Fig. 111.4). Otherwise, the decision of catheter removal should take into account the ease of a new catheter insertion and the severity of the comorbidities of the patient. In this context, there are few relevant data, especially from RCTs. Moreover, cautious decisions about catheter removal and type and length of antibiotic therapy should be made after each case is examined in light of these variables. An RCT including a relatively low number of hemodynamically stable critically ill patients without proven bacteremia and without local signs of CR-BSI illustrated that a *watchful waiting strategy* (versus immediate catheter removal) permitted a substantial decrease in the number of unnecessarily removed CVCs without increasing morbidity.[19] Another strategy for patients with limited venous access (e.g., patients with a hemodialysis catheter) is the *change of catheter over a guidewire* (GWX).[139] An old systematic review comparing GWX with new site replacement showed a trend toward fewer mechanical complications but increased infections using GWX.[140]

When conservative strategies have been initiated, the catheter should be removed depending on microorganisms recovered and on the clinical course within the first 72 hours (see Table 111.1).

Catheter removal is strongly recommended in patients with CR-BSI caused by *S. aureus,* gram-negative bacilli, enterococci, fungi, or multidrug-resistant (MDR) bacteria.[17,141–145] If CoNS are identified and if blood culture contamination is ruled out, the catheter should also be removed: CVC retention does not have any impact on the resolution of CoNS bacteremia but is a significant risk factor for recurrence.[146] For CR-BSI (i.e., *bacteremic* intravascular catheter infection) in the ICU, the catheter removal is usually preferable, as it allows a complete removal of the source of infection. Overall, conservative strategies are associated with an increased risk, and critically ill patients have to be cautiously monitored. Of note, if GWX is performed in the setting of a catheter infection, the newly

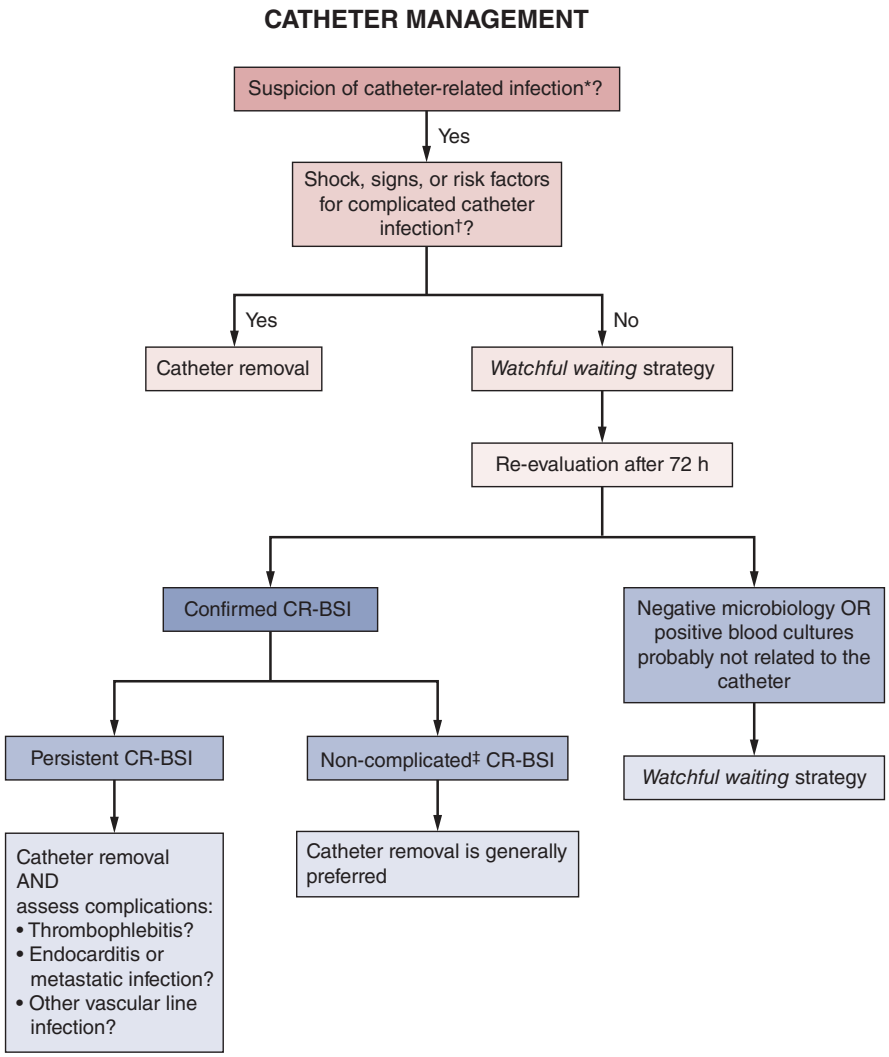

Fig. 111.4 Algorithm for the Management of Suspected Catheter-Related Infections. *Elevation of inflammatory signs after catheter placement without other infectious or noninfectious explanations, or exit site infection signs (purulent discharge, redness/cellulitis >0.5 cm diameter, abscess), or positive blood culture without identification of infectious focus. †Hemodynamic instability; or neutropenia (<500/mm^3) or immunosuppression (including organ transplantation); or local exit site signs (purulent discharge or redness/cellulitis >0.5 cm diameter). ‡Favorable clinical course without persistence of fever and negative blood cultures after 72 hours of adequate treatment; and no septic metastasis, endocarditis, or septic thrombophlebitis; and no other intravascular devices or immunosuppression. *CR-BSI*, Catheter-related bloodstream infection.

placed catheter should be removed. The optimal timing of antimicrobial therapy administration in this specific case has not been evaluated.

Positive Catheter Tip Culture With No Positive Blood Cultures

The Infectious Diseases Society of America (IDSA) guidelines recommend that catheter cultures be performed each time a catheter is removed for suspected CR-BSI.[17] However, in the ICU, at the time of any catheter removal, the body temperature is abnormal in more than half of the patients, and two of the four systemic inflammatory response syndrome (SIRS) criteria are present in about 90% of patients.[98,101] Thus most catheter tips would end up by being cultured on the sole basis of these criteria. There are limited data on the clinical significance of positive tip culture without concomitant bacteremia or fungemia.[147] Considering all microorganisms, the prevalence of *subsequent BSI* (i.e., delayed BSI with the same microorganism as the one recovered from the catheter tip) ranges from 1.3% to 4.1%.[147–151] However, a comparison between studies is difficult because of the lack of a generally accepted definition of subsequent BSI.[150] Therefore the management of a positive catheter culture without positive blood cultures in a patient without specific symptoms is a challenge at bedside. The decision of whether antibiotic treatment should be administered depends on the identified microorganism. Overall, the risk of subsequent BSI is the highest for *S. aureus*, followed by gram-negative microorganisms, whereas it is low for *Enterococcus* spp. and CoNS.

In patients with suspicion of infection and positive catheter tip culture with *S. aureus* though without demonstrated bacteremia within 24 hours after intravascular catheter removal, the risk of subsequent *S. aureus* bacteremia is 24% if they do not receive immediate antistaphylococcal antibiotics.[152] Interestingly, a treatment within

24 hours after intravascular catheter removal led to a reduction in the incidence of subsequent bacteremia,[152] and therefore the majority of authors supported the role of antibiotics for *S. aureus*.[153–156] An important percentage of subsequent BSI has also been found for *P. aeruginosa,*[157] extensively resistant *Acinetobacter baumannii,*[158] *Serratia marcescens,*[150] and more generally for gram-negative microorganisms.[159] The risk is probably lower for CoNS and enterococci.[151] Little is known about the significance of a fungal colonization of a catheter tip (i.e., candidemia). Whereas some authors found a low risk of developing subsequent fungemia,[160,161] other studies hypothesized an increased risk of developing a delayed fungal infection.[162] These findings are supported by two other studies investigating subsequent fungemia and bacteremia.[147,151] All these retrospective studies suffer from important methodologic flaws and did not demonstrate that subsequent BSI was directly related to the positive catheter tip culture. It makes sense to treat critically ill patients with sepsis whose catheter tip reveals a significant growth of *S. aureus, P. aeruginosa, A. baumannii,* or *Candida* spp., especially if they are immunocompromised or if a thrombosis of the catheterized vein was observed at removal.[87] For these microorganisms, follow-up blood cultures should be drawn, and an ultrasound examination may be considered.[31] When the catheter tip culture yields CoNS, *Enterococcus* spp. or Enterobacteriaceae, management without any antimicrobial treatment may be considered. The duration of therapy is not known: a maximum of 3–5 days is generally accepted[18] (Table 111.2).

Empiric Treatment

Empiric therapy should be individualized to the patient's characteristics, clinical stability, risk factors, and local epidemiology (Fig. 111.5). Once an intravascular catheter infection is suspected and associated with clinical or laboratory signs for complicated infection (see Table 111.1), empiric antimicrobial therapy should be administered immediately after appropriate samples are drawn for culture.

CR-BSI are frequently caused by gram-positive microorganisms and, accordingly, intravenous vancomycin (or daptomycin in patients with acute renal failure or when organisms have reduced susceptibility to vancomycin) is recommended in healthcare settings with a high prevalence of MRSA.[22] Empiric therapy for gram-negative pathogens, particularly *P. aeruginosa,* should be based on clinical (e.g., severity of disease, neutropenia, immunosuppression, or hematologic malignancy) and epidemiologic factors (e.g., known colonization or exposure to high-prevalence healthcare settings).[17,31] It is usually recommended to use a fourth-generation cephalosporin, beta-lactam/beta-lactamase inhibitor combination, or carbapenem.[15] Moreover, having had a previous MDR gram-negative infection, sharing a room with a known MDR carrier, critical illness, neutropenia and immunosuppression, and prior antibiotic therapy are recognized risk factors for MDR gram-negative infections.[163,164] Especially in patients with documented recent colonization with MDR gram-negative bacilli, a combination therapy with two different classes of antimicrobials against MDR gram-negative bacilli is indicated.[15] Empiric coverage for fungal infections should be considered only in a limited subpopulation of septic *and* severely ill immunocompromised patients (e.g., bone marrow or organ transplants, hematologic malignancy, or other immunosuppression) and if multiple sites are colonized with *Candida* spp., or for patients with total parenteral nutrition or prolonged administration of broad-spectrum antibiotics.[17,31,165] Empiric treatment consists mainly of an echinocandin, whereas fluconazole may represent an option in patients without risk of azole-resistant fungal infections (i.e., without previous identification of *C. glabrata* or *C. krusei* or without exposure to fluconazole in the previous 3 months).[31,165] Among other critically ill patients with ICU-acquired sepsis (e.g., nonsevere immunocompromised with risk factors for invasive *Candida* infections), an empirical treatment with echinocandin did not improve the fungal infection–free survival at day 28 and is therefore discouraged.[166]

TABLE 111.2 Proposed Targeted Therapy After Catheter Removal for Suspected Infection and Positive Catheter Tip Culture

Microbiologic Findings	Duration of Antimicrobial Therapy
Staphylococcus Aureus, Candida spp.	
Negative blood cultures	3–5 days
Positive blood cultures, without complications*	14 days
Positive blood cultures, with complications*	4–6 weeks
***Enterococcus spp., CoNS,*[a] Enterobacteriaceae[b]**	
Negative blood cultures	No therapy[b]
Positive blood cultures, without complications*	5–7 days
Positive blood cultures, with complications*	4–6 weeks
Pseudomonas Aeruginosa, Acinetobacter Baumannii	
Negative blood cultures	3–5 days
Positive blood cultures, without complications*	7 days
Positive blood cultures, with complications*	4–6 weeks

*See Table 111.1 for complications.
[a]Withholding antimicrobial therapy for CoNS may be considered.
[b]In the case of positive catheter tip with *Serratia* spp. without concurrent positive blood cultures a short course of antimicrobial therapy should be considered.
CoNS, Coagulase-negative staphylococci.

Targeted Antimicrobial Treatment According to the Specific Pathogen Isolated

Once the antimicrobial susceptibility patterns are available, a de-escalation to the most appropriate therapy with the narrowest possible spectrum is recommended. The targeted treatment depends on the causative pathogen, presence of complications, catheter management, and host factors.[15,165] In general, in noncomplicated intravascular catheter infections (for definition, see Table 111.1), a short course of antimicrobial treatment should be administered.[15,165,165a] The therapy duration may range from 5–7 days to 6 weeks[165] (see Table 111.2). Recommendations on duration of treatment for CR-BSI are often extrapolated from hospital-acquired bacteremia literature. A systematic review that included bacteremic critically ill patients showed no significant differences in clinical cure, microbiologic cure, and survival among bacteremic patients receiving shorter (5–7 days) versus longer duration (7–21 days) antibiotic therapy.[167] To date, the results from a large Canadian multicentric RCT in critically ill patients with bacteremia (BALANCE Trial) are not available.[168]

S. aureus is frequently responsible for CR-BSI. Standard therapy for methicillin-susceptible *S. aureus* (MSSA) consists of an antistaphylococcal penicillin or first-generation cephalosporin.[169] The addition of an aminoglycoside is not recommended, as it does not offer clinically significant benefit and increases the risk for renal impairment.[170] For MRSA, and based on long-term clinical experience and trial results, vancomycin (with trough levels of 15–20 μg/mL) or daptomycin are the agents of choice.[171] For uncomplicated *S. aureus* infection (i.e., not associated with endocarditis or metastatic infection, negative follow-up

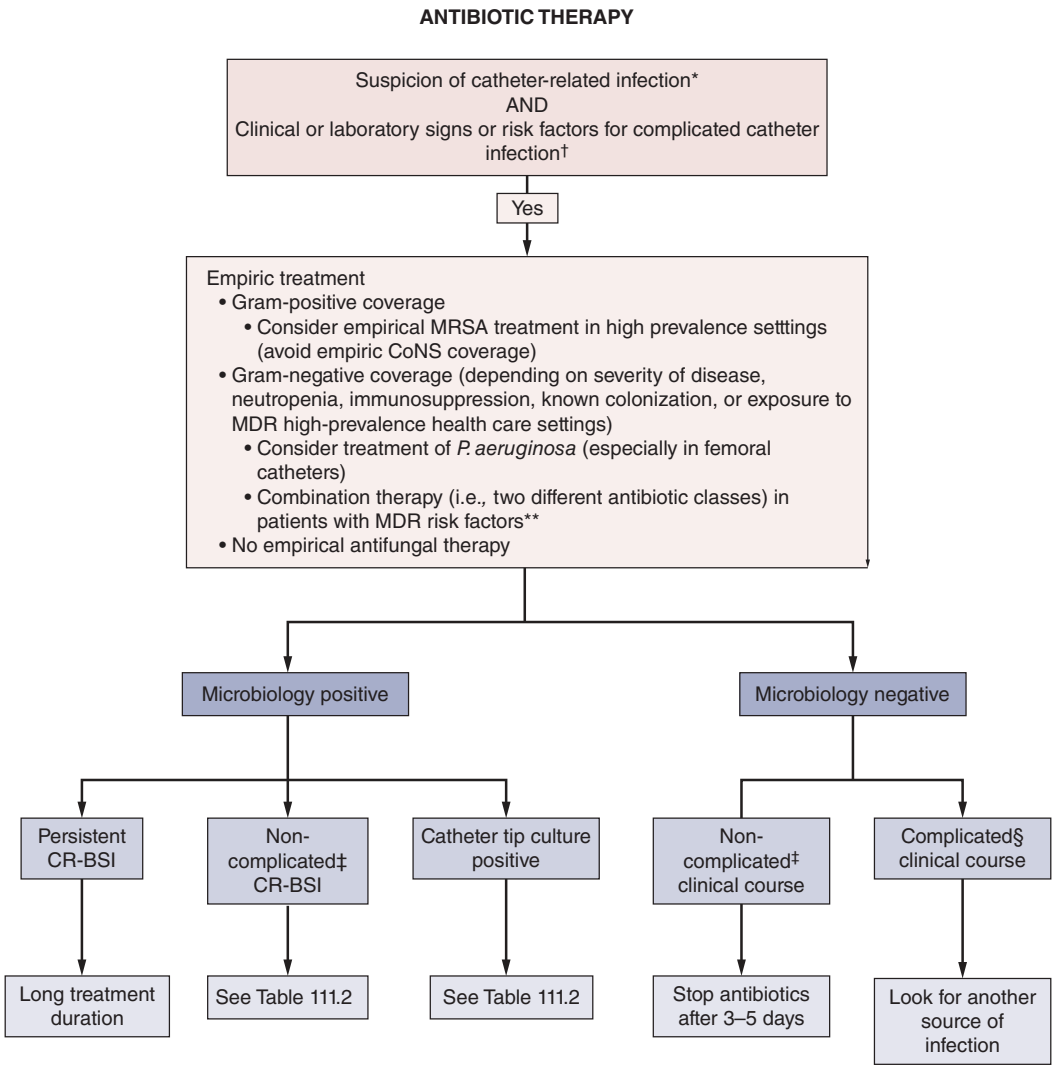

Fig. 111.5 Algorithm for Antibiotic Therapy in Suspected Catheter-Related Infections. *Elevation of inflammatory signs after catheter placement without other infectious or noninfectious explanations; or exit site infection signs (purulent discharge, redness/cellulitis >0.5 cm diameter, abscess); or positive blood culture without identification of infectious focus. †Hemodynamic instability; or neutropenia (<500/mm^3) or immunosuppression (including organ transplantation); or local exit site signs (purulent discharge or redness/cellulitis >0.5 cm diameter). **Previous multidrug-resistant (MDR) gram-negative infection or colonization, sharing a room with a known MDR carrier (e.g., neutropenic and immunosuppressed patients). ‡Favorable clinical course without persistence of fever and negative blood cultures after 72 hours of adequate treatment; and no septic metastasis, endocarditis, or septic thrombophlebitis; and without other intravascular devices or immunosuppression. §Persistence of fever or inflammatory signs after 72 hours or septic metastasis, endocarditis, or septic thrombophlebitis. *CoNS,* Coagulase-negative staphylococci; *CR-BSI,* catheter-related bloodstream infection; *MRSA.* methicillin-resistant *Staphylococcus aureus.*

blood cultures, prompt response to institution of therapy, no indwelling intravascular devices), 14-day therapy may be administered.[171] Otherwise, 4–6 weeks of antibiotic treatment should be given.

The optimal treatment for CoNS has not been addressed in clinical trials. A recent retrospective study that included a large number of ICU patients after catheter removal showed that withholding antimicrobial therapy in CoNS-CR-BSI was not associated with either short-term complications or long-term recurrences.[172] However, other experts advocate short antibiotic treatment courses (5–7 days).[17] Of note, *Staphylococcus lugdunensis* should be treated similarly to *S. aureus.*[173]

For enterococcal CR-BSI, ampicillin is the first choice for ampicillin-susceptible strains, vancomycin for those that are ampicillin-resistant, and daptomycin or linezolid for vancomycin-resistant enterococci (VRE) strains.[174] The role of combination therapy for treating enterococcal CR-BSI without endocarditis is unresolved, especially for VRE.[175] A 7-day course of therapy is recommended for uncomplicated enterococcal CR-BSI if the catheter is removed.[18]

Most of the recommendations for the management of CR-BSI caused by gram-negative bacilli have been limited by their small numbers of cases. Among gram-negative bacteria infections, the risk for metastatic complications is lower compared with *S. aureus* infections.

The antibiotic therapeutic course should be administered for at least 7 days with a single agent if the catheter is removed.[18,31]

Among *Candida* CR-BSI, echinocandins have the advantage of their fungicidal activity and their activity against yeasts in biofilm.[176] Fluconazole is an alternative for patients who are stable, have had no prior azole exposure,[176] and whose catheter is removed. Lipid formulation of amphotericin B and voriconazole are alternatives that may be considered, especially if *C. krusei* is identified.[176] The recommended minimal duration of therapy for candidemia without metastatic complications is 14 days after documented clearance of *Candida* from the bloodstream.[176,177]

In exceptional circumstances, catheter salvage therapy might be proposed in the ICU, especially for long-term catheter inserted before the ICU stay. This treatment should only be discussed in the absence of severe sepsis and when fungi, *S. aureus, Pseudomonas* spp., *A. baumannii,* or MDR bacteria are not involved. Compared with parenteral therapy alone, therapy including antibiotic lock was significantly more likely efficient for catheter salvage.

Complicated Courses

Persistent fever or bacteremia after catheter removal and despite an adequate antimicrobial therapy (i.e., *persistent* CR-BSI; see Table 111.1) may reflect a persisting infection focus. This must trigger an active search for another vascular line infection, metastatic abscess, septic thrombophlebitis (e.g., with ultrasound examination), or endocarditis (e.g., with transesophageal echocardiography).[17,31] A prolonged antibiotic course combined with adequate management of the complication may be required (4–6 weeks of therapy).

Failure resulting from the poor pharmacokinetic-pharmacodynamic properties of the antimicrobial are mainly encountered when treating MRSA with glycopeptides. The volume of distribution of hydrophilic antimicrobials is always increased in case of septic shock and might explain the failure of treatment with beta-lactams or vancomycin.[178] Therefore therapeutic drug monitoring for the pharmacokinetic optimization of antimicrobial doses, particularly vancomycin, is strongly recommended.[179] A trough level of vancomycin between 15 and 20 mg/L should be reached. Daptomycin might be an alternative,[180] particularly when the minimum inhibitory concentration (MIC) to vancomycin reaches 1.5 mg/mL.[181]

An infected intravascular thrombus after catheter removal may explain the persistence of severe sepsis despite adequate antibiotic therapy. The most common causal microorganism is *S. aureus,* whereas *Candida* spp. and gram-negative bacilli are less frequently observed. The optimal choice and duration of therapy are based on retrospective studies and expert recommendations. A 4- to 6-week course of antibiotic treatment is usually administered. In addition, the available literature suggests that early administration of heparin should be considered in the management of patients with septic thrombophlebitis.[182,183]

CONCLUSION

Intravascular catheter-related infections remain a leading cause of nosocomial infections, particularly in ICUs. They are the most frequent cause of hospital-acquired bacteremia and can be prevented if rigorous policies are implemented. They should be one of the main targets of a quality improvement program. The management of CR-BSI requires catheter removal in most critically ill patients. In noncomplicated intravascular catheter infections, a short course of antimicrobial treatment is usually appropriate.

KEY POINTS

- Catheters are the leading source of bloodstream infections in critically ill patients.
- Comprehensive, unit-based improvement programs are effective in decreasing the rate of CR-BSI.
- A locally adapted checklist of preventive measures should include hand hygiene, cutaneous antisepsis with 2% alcoholic CHG preparation, maximal barrier precautions, preferential use of a subclavian venous insertion site, a strict policy of catheter maintenance, and prompt ablation of useless catheters.
- A conservative approach might be attempted in mild infections, whereas the catheter should always be removed in cases of severe sepsis or septic shock.
- In case of persistence of fever or positive blood culture after 3 days despite adequate antimicrobial therapy and catheter removal, endocarditis or thrombophlebitis should be ruled out.

This is an excellent review of all the current management strategies for catheter-related bloodstream infections.

Safdar N, Maki DG. The pathogenesis of catheter-related bloodstream infection with non-cuffed short-term central venous catheter. *Intensive Care Med.* 2004;30:62–67.
This article provides a concise review of the four mechanisms of CR-BSI pathogenesis.

Timsit JF, Rupp M, Bouza E, et al. A state of the art review on optimal practices to prevent, recognize, and manage complications associated with intravascular devices in the critically ill. *Intensive Care Med.* 2018;44(6):742–759.
This excellent review article covers management, prevention, and diagnostic techniques for catheter-related infections, with a special focus on critically ill patients.

PERIPHERALLY INSERTED CENTRAL CATHETERS

The use of PICCs has increased in ICU patients.[184,185] Compared with CVCs, PICCs exhibit several advantages, including (1) a convenient placement procedure via the upper extremity without pleural-pulmonary damage; (2) low cost; (3) placement performed by nurse-led vascular access teams; and (4) clinical advantages in specific patient populations (e.g., with coagulopathies, morbid obesity).[186–188] A systematic review found no significant difference in rates of CR-BSI between PICCs and CVCs in hospitalized patients (including ICU patients).[189] However, PICCs are associated with several risks, particularly in critically ill patients. Probably because of their insertion in smaller veins, PICCs are prone to venous stasis; a systematic review showed that PICCs were associated with a higher risk of deep vein thrombosis than are CVCs, especially in critically ill patients.[3] Moreover, because of their small diameter and length, PICCs appear to be more prone to catheter tip malpositioning, catheter dysfunction, and thrombophlebitis than CVCs.[190] In general, PICC infections were strongly associated with multilumen catheters,[189,191] which are frequently used in the ICU setting. Moreover, PICCs placed at the bedside in the ICU setting are associated with higher complication rates (e.g., infectious complications) than those placed by interventional radiology in non-ICU patients.[192] For all these reasons, PICCs cannot be strongly recommended for short-term (<15–20 days) catheterization in the ICU.[193] Exceptions may be made in patients with severe obesity or with an elevated hemorrhagic risk.

ARTERIAL CATHETERS

Arterial catheters (ACs) are essential in the care of critically ill patients to facilitate hemodynamic monitoring and frequent blood sampling. Frequent complications of ACs include transient vascular occlusion, hemorrhage, hematoma, iatrogenic pseudoaneurysm, air embolism, and neurologic injury.[194] The risk of mechanical complication is decreased by ultrasound-guided access.[195–197]

To date, the duration of catheter maintenance of ACs is similar to CVCs, thus increasing the infection risk among ACs.[198] The infection risk associated with ACs is similar to that observed for CVCs.[99,199,200] However, a nationwide survey showed that clinicians significantly underestimated the infection risk associated with ACs.[201] In contrast to CVCs, the daily colonization risk appeared to increase during catheter maintenance.[96] The infection risk is lower for radial as compared with femoral ACs[200]; therefore radial access should be preferred. The microorganisms responsible for colonization and infection of ACs appeared similar to those identified in CVCs.[14,202] Reducing the duration of AC insertion may also limit the risk of arterial thrombi and infection occurrence.

SHORT-TERM HEMODIALYSIS CATHETERS

About one-third of critically ill patients have acute kidney injury (AKI), of whom approximately 20% receive renal replacement therapy (RRT).[203] In the ICU, vascular access for RRT for AKI management is usually granted by means of a large-bore, short-term dual-lumen catheter (DC) inserted in a central vein.[204] On one hand, extrapolating the DC data regarding catheter-related infections from long-term dialysis patients is debatable, as procedures applied in dialysis centers and in the ICU differ in terms of catheter types, patient populations, modalities, and catheter duration.[204] On the other hand, data on the epidemiology of standard CVCs cannot be extrapolated to DCs, as the latter differ substantially from CVCs in design and use (e.g., different use with frequent hub disconnections, other insertion sites, and different lumens).[204] For example, the subclavian site is discouraged to preserve the vascular network. The most information and recommendations on DC are based on data on the use of CVCs in the ICU.[205,206] A recent post hoc analysis of four RCTs showed that the infection risk was higher for DCs than for CVCs within the first 7 catheter days and appeared to be similar to CVCs later on. These findings suggest that targeted prevention strategies for DCs should focus on the period after catheter insertion.[207] The risk of DC colonization was demonstrated to remain stable over time for intermittent hemodialysis but to increase after 10 days for continuous RRT.[208] There is no difference in CR-BSI between the jugular and the femoral insertion sites; however, the risk of colonization is higher at the femoral site in obese patients.[81] An old small RCT showed that minocycline-rifampicin–coated DCs failed to decrease the rate of colonization but reduced CR-BSIs.[209] Studies conducted in chronic dialysis patients have suggested that locks might be associated with lower rates of thrombotic and infective complications, particularly if associated with antimicrobial solutions.[210] However, only a few studies were conducted in critically ill patients.[23,211,212] Souweine and colleagues demonstrated that a 2-minute 60% ethanol lock was not able to decrease the rate of intravascular catheter infections in short-term hemodialysis catheters of ICU patients.[23] A large study comparing interdialytic lock with unfractionated heparin and citrate as a catheter locking solution for nontunneled central venous hemodialysis catheters showed no significant difference in catheter-related infections between the two groups.[213] To date, the use of prophylactic ALT for short-term DC cannot be recommended. Skin antisepsis before catheter insertion should be performed with 2% CHG for DC,[24] but the impact of CHG dressings on DC catheter infections was not evaluated. However, in light of recent published data, the introduction of CHG dressing in the first 7 days for DC may be of value.[207] Empirical treatment therapies for DCs did not differ from CVCs: new data suggested that microorganisms associated with CR-BSI were similar between CVCs and DCs.[14] The risk of catheter colonization for DCs replaced because of dysfunction did not differ between DCs inserted by new puncture or exchanged over a guidewire.[214]

Septic Shock

Jean-Louis Vincent

INCIDENCE

Septic shock is a form of acute circulatory shock that occurs secondary to severe infection. The incidence of septic shock may be rising, partly related to medical progress that allows individuals to survive longer, resulting in increased numbers of older, debilitated, or immunocompromised patients passing through the intensive care unit (ICU). Some 15% of ICU patients develop septic shock at one time or another, and the mortality rate is 40%–50%.[1,2] Somewhat lower mortality rates have been reported in some trials evaluating the effects of new therapeutic interventions, but such studies include a number of exclusion criteria that are often associated with high mortality rates—cirrhosis, immunosuppression, and "do-not-resuscitate orders," for example—so it is perhaps not surprising that mortality rates are lower in these therapeutic trials than in "real life."

ETIOLOGY OF SEPTIC SHOCK

Septic shock is most often bacterial, but it can also be caused by a fungal, parasitic, or viral[3] infection. In one-third of patients, no infectious agent is identified.[1] About half of the infections are nosocomial in origin. Although an infection can originate anywhere, the lung is the most common source of infection (40%), followed by the abdomen (20%), indwelling venous and arterial catheters and primary bacteremias (15%), and the urinary tract (10%).[1]

PATHOPHYSIOLOGY OF SEPTIC SHOCK

The pathophysiology of septic shock is complex. Essentially, the systemic sepsis response starts with the body's recognition of an invading organism or its toxins. Among the bacterial factors, one of the best known toxins is lipopolysaccharide, which is part of the outer gram-negative bacterial membrane, but other bacteria-derived factors include lipoteichoic acid and peptidoglycan. In certain cases, especially infections involving *Staphylococcus aureus* or beta-hemolytic group A streptococcus, the formation of superantigens results in toxic shock syndrome.

The early humoral response involves the complement and contact (kinin-kallikrein) systems. Immune cells, principally monocytes/macrophages and polymorphonuclear neutrophils (PMNs), are not only able to recognize pathogenic agents and their products so they can phagocytose and destroy them but also to release a series of mediators that can activate other cells. Among cell membrane receptors implicated in the recognition of pathogenic agents are the Toll-like receptors. In response to cellular stimulation, intracellular signaling is activated, resulting largely in the activation of transcriptional factors, including nuclear factor kappa B, which in turn are responsible for the initiation of proinflammatory reactions. A number of cytokines that interact synergistically are released by macrophages and other cells. Two of the key players are tumor necrosis factor alpha (TNF-α) and interleukin (IL)-1. TNF-α and IL-1 are particularly important proinflammatory cytokines whose administration in animals can reproduce all features of septic shock, including hypotension and development of multiple organ failure. A host of secondary mediators, including lipid mediators, oxygen free radicals, proteases, and arachidonic acid metabolites, are also released by macrophages, PMNs, and other cells. Vasodilator substances such as nitric oxide (NO) and prostaglandins are released by endothelial cells and are responsible for the early hemodynamic changes of sepsis. NO, in particular, acts as a powerful vasodilator on vascular smooth muscle. Increased NO production is essentially the result of the induction of inducible NO synthase by proinflammatory cytokines. The formation of large quantities of NO can also have secondary toxic effects on cells. It is important to note that the inflammatory response also causes release of vasoconstrictor substances, including thromboxane and endothelins.

Other effects of the inflammatory reaction that accompanies septic shock include expression of adhesion molecules on vascular endothelium and circulating cells (platelets, PMNs, and monocytes), allowing adhesion of activated leukocytes and their migration to subendothelial tissues. Alterations in intercellular endothelial junctions result in increased capillary permeability and generalized edema. Alterations in coagulation and fibrinolysis complete the picture, with proinflammatory mediators creating a procoagulant state. In addition, sepsis causes a significant reduction in plasma levels of natural anticoagulants such as protein C, protein S, and antithrombin by reducing their synthesis and increasing their consumption and clearance. Thrombolysis is also stimulated with an increase in the levels of plasminogen activator inhibitor-1. The net result is a balance that favors procoagulant processes, often leading to disseminated intravascular coagulation and contributing to the microcirculatory disorder that leads to multiple organ failure and death in many patients with sepsis. Antiinflammatory mediators including IL-4 and IL-10 are also released, which limit the effects of proinflammatory mediators and can lead to a state of relative immunosuppression sometimes called *immunoparalysis*.[4] Many patients are already immunosuppressed when sepsis is diagnosed.[5]

CLASSIFICATION

Patients with septic shock may be classified according to the letters *PIRO*[6]:

P = Predisposing Factors

Each patient has specific characteristics. For example, an individual receiving long-term immunosuppressant therapy requires a different

approach than someone who was previously healthy. Factors associated with lifestyle, such as alcoholism, may influence the course of septic shock.[7] Patient age and gender may also be important. Increasingly, genetics is being considered, and studies are discovering the genetic factors that can influence the development of and survival from sepsis.[8–10] Improved understanding of these aspects should help better direct therapeutic strategies.

I = Infectious Insult

This refers to the specific characteristics of the infection, that is, the agent or pathogen involved (e.g., gram-positive vs. gram-negative, bacteria vs. virus or fungus), the source of sepsis (e.g., urinary tract vs. respiratory tract), and the degree of extension of the infection (e.g., pneumonia confined to one lobe of one lung vs. generalized bilateral lung involvement, appendicitis vs. generalized peritonitis). All of these factors can influence the severity of sepsis response and the patient's likely response to therapy.

R = Host Response

This refers to factors involved in the inflammatory response of the host to the infection and is assessed largely by the presence or absence of the signs and symptoms of sepsis (e.g., degree of elevation of white blood cell count, C-reactive protein [CRP], or procalcitonin). Each patient mounts a different response dependent on various factors, including those previously discussed, and a patient's response will vary with his or her clinical course and treatment.

O = Organ Dysfunction

This refers to the degree of organ dysfunction related to sepsis and can be evaluated using the Sequential Organ Failure Assessment (SOFA) score,[11] which uses objective, readily available measures to quantify the dysfunction of six organ systems (Table 112.1). Dysfunction of each organ is rated according to a scale (0 [normal function] to 4 [organ failure]), and individual scores can then be summed to provide a total. Individual organ function and a composite score can thus be followed during the course of the disease and treatment.

CLINICAL PRESENTATION

It has been suggested that sepsis progresses in a continuum through to septic shock, but in the clinical situation, such a progression is not always so clear-cut or constant, and it is difficult to predict which patients are going to develop septic shock and when. Septic shock can develop very abruptly, without evidence of signs of sepsis in the preceding hours.

Septic shock is characterized by the persistence of severe arterial hypotension requiring vasopressor support, despite adequate fluid resuscitation, and the presence of perfusion abnormalities manifested by oliguria, reduced peripheral perfusion, and altered mental status. Septic shock is typically associated with hyperlactatemia (blood lactate concentrations greater than 2 mEq/L).[12]

One may anticipate that patients with septic shock will have fever, leukocytosis, and other typical features of sepsis, but this is not always true. Fever may be an important clue, but moderate fever can be found in other types of shock as well. More importantly, fever is often absent in patients with septic shock; in fact, hypothermia may be present in 10%–15% of cases, and this feature is associated with higher mortality rates.[13] Tachycardia can be the result of circulatory alterations associated with any type of shock. Leukocytosis is also nonspecific and can be found in other types of circulatory failure; moreover, acute leukopenia may occur in sepsis because of peripheral trapping of activated leukocytes and is also associated with a worse prognosis. Lactic acidosis, a hallmark of all types of circulatory failure, is usually compensated for by hyperventilation, so tachypnea is not specific for septic shock.

A more typical characteristic of septic shock is the hyperkinetic pattern characterized by high cardiac output. Although such a hemodynamic pattern is not entirely specific—it can be found in other inflammatory states such as polytrauma, pancreatitis, or even anaphylactic

TABLE 112.1 The Sequential Organ Failure Assessment Score

SOFA Score	0	1	2	3	4
Respiration PaO_2/FiO_2, mm Hg	>400	≤400	≤300	≤200 with respiratory support	≤100 with respiratory support
Coagulation Platelets × $10^3/mm^3$	>150	≤150	≤100	≤50	≤20
Liver Bilirubin, mg/dL (μmol/L)	<1.2 (<20)	1.2–1.9 (20–32)	2.0–5.9 (33–101)	6.0–11.9 (102–204)	>12.0 (>204)
Cardiovascular Hypotension	No hypotension	MAP <70 mm Hg	Dopamine ≤5 *or* dobutamine (any dose)*	Dopamine >5 *or* epinephrine ≤0.1 *or* norepinephrine ≤0.1*	Dopamine >15 *or* epinephrine >0.1 *or* norepinephrine >0.1*
Central Nervous System Glasgow Coma Score	15	13–14	10–12	6–9	<6
Renal Creatinine, mg/dL (μmol/L) *or* urine output	<1.2 (<110)	1.2–1.9 (110–170)	2.0–3.4 (171–299)	3.5–4.9 (300–440) *or* <500 mL/d	>5.0 (>440) *or* <200 mL/d

From Vincent JL, de Mendonca A, Cantraine F, et al. Use of the SOFA score to assess the incidence of organ dysfunction/failure in intensive care units. Results of a multicenter, prospective study. *Crit Care Med.* 1988;26:1793–1800.
*Adrenergic agents administered for at least 1 hour (doses given are in μg/kg/min).

shock—it should alert the attending physician to a likely diagnosis of septic shock.

HEMODYNAMIC CHANGES

The inflammatory reaction causes intense vasodilation that increases vascular capacity and results in a fall in arterial blood pressure. Hypovolemia caused by fluid loss (e.g., diarrhea, vomiting, or sweating) and alterations in capillary permeability contribute to hypotension, and reduced myocardial contractility can further aggravate the hemodynamic situation, although it is completely reversible when the septic shock resolves. The pathophysiology of reduced myocardial contractility includes alterations in endothelial function, beta-adrenergic receptors, and myocardial calcium metabolism. These effects are caused largely by sepsis mediators such as TNF-α and IL-1, oxygen free radicals, platelet activating factor, and NO, which all have negative inotropic effects.

After vascular filling as a result of volume resuscitation, the hemodynamic status in septic shock is characterized by reduced vascular tone associated with reduced systemic vascular resistance and a raised cardiac output. In addition, impaired myocardial contractility causes a fall in the ventricular ejection fraction. Ejection volume and cardiac output may be maintained by an increase in diastolic volumes. Hence, there is myocardial depression or dysfunction without any true cardiac failure (which would be associated with reduced cardiac output).

MONITORING

Any patient with septic shock requires monitoring with an arterial catheter to enable reliable and continuous assessment of arterial pressure. Changes in systolic and pulse pressures in mechanically ventilated patients during the respiratory cycle may also indicate a greater likelihood of response to a fluid challenge; however, this sign is not reliable when the patient triggers the ventilator.[14] The arterial catheter also facilitates blood sampling, notably for blood gas analysis.

Invasive Versus Less Invasive Monitoring

The use of the pulmonary artery catheter (PAC) has decreased substantially in recent years, primarily because of the development of less invasive techniques, especially echocardiography. Echocardiography can provide useful additional information, largely to visualize the degree of ventricular filling and ejection volume. However, echocardiography provides no information on the adequacy of cardiac output for the patient's needs and is difficult to perform continuously, so information is usually intermittent. Other less invasive methods of monitoring cardiac output include PiCCO, LidCO, transesophageal Doppler techniques, and even bioimpedance or bioreactance techniques.[15,16] However, measurement of cardiac output in isolation is not very helpful in most critically ill patients.

Blood Lactate Levels

The blood lactate level is an important biologic variable for determining the adequacy of perfusion and oxygenation. The normal blood lactate level is around 1 mEq/L, and hyperlactatemia becomes clearly pathologic above a level of 2 mEq/L. Although hyperlactatemia is the result of cellular hypoxia in other forms of circulatory shock, in septic shock, additional mechanisms may play an important role in raising blood lactate levels. In sepsis, blood lactate levels may be raised by an increase in cellular metabolism, inhibition of pyruvate dehydrogenase, and reduced clearance. Repeated measurements enable one to assess the efficacy of treatment[17] and have a predictive value superior to derived oxygenation parameters. The evolution of blood lactate levels enables a global evaluation of the state of shock in response to treatment, although in view of the relatively slow rate of change, blood lactate levels cannot be used to guide resuscitation.

Peripheral Perfusion Parameters

Measurements of the gastric intramucosal pH or its derivatives (mucosal PCO_2 or the difference between the mucosal and arterial PCO_2 [the PCO_2 gap]) reflect splanchnic perfusion and hence provide an idea of the adequacy of regional oxygenation. However, these techniques may be influenced by technical considerations, including the influence of gastric acid and enteral nutrition, and are not used clinically.

Other techniques for monitoring peripheral perfusion have been developed. Although the sublingual tissue is not a region that would immediately seem to be of most interest, it is easily accessible. Using techniques of orthogonal polarization spectral or side stream darkfield imaging, the heterogeneity of microcirculatory flow and the proportion of perfused vessels can be observed (Fig. 112.1) and quantified in patients with sepsis.[18] Moreover, the impact of therapeutic interventions on such vessels can be monitored,[19,20] opening the possibility that monitoring the microcirculation could be used to guide treatment.

Near-infrared spectroscopy is a technique that uses the differential absorption properties of oxygenated and deoxygenated hemoglobin to evaluate tissue oxygenation (StO_2). Analysis of changes in StO_2 during a circulatory stress test, such as a brief episode of forearm ischemia (venous or arterial occlusion), may be more useful to quantify sepsis-induced microvascular dysfunction than an isolated StO_2 value.[21] The

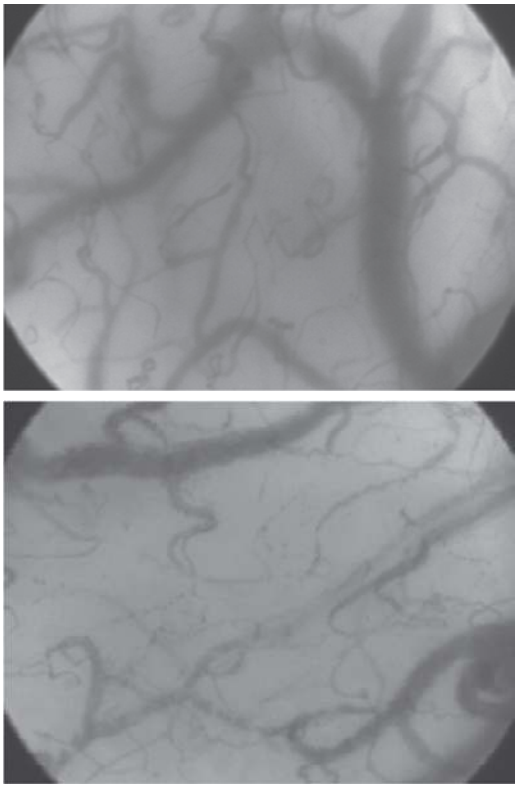

Fig. 112.1 Representative examples of sublingual microvasculature in a healthy volunteer *(top panel)* and in a patient with septic shock *(lower panel)*. Note decrease in density of small vessels in sepsis. (From De Backer D, Creteur J, Preiser JC, et al. Microvascular blood flow is altered in patients with sepsis. *Am J Respir Crit Care Med.* 2002;166:98–104, with permission.)

cutaneous perfusion can also be assessed objectively using Doppler techniques.[22]

Although all these techniques have demonstrated clearly the presence of an altered microcirculation in patients with sepsis, findings which are associated with prognosis,[23] further research is needed to fully evaluate the relevance of these values to the early resuscitation and care of critically ill patients.

MANAGEMENT

Septic shock, which both causes and reflects dysfunction of vital organs, is a serious condition, and patients must be stabilized as a matter of urgency. Management of the patient with septic shock involves three inseparable components: treatment of the infection, cardiovascular resuscitation, and modulation of the host response (Fig. 112.2).[24]

Treatment of Infection

Infection must be treated effectively and rapidly. Antibiotic therapy should be started as early as "reasonably possible." In all cases, sampling of blood and other material for culture is very important. In severe cases, including septic shock, antibiotic administration is urgent. In less severe cases, a bit more time could be taken to further evaluate the patient and sometimes in complex cases to consult with infectious disease specialists to determine the optimal agents. The choice of antibiotics may depend on local microbiologic flora and resistance patterns. Often, however, the microorganisms responsible for sepsis in an individual patient are not known for sure, and empiric broad-spectrum antibiotics must be given to ensure adequate coverage. Such empiric therapy must then be modified as soon as microbiology culture results become available.

In addition to antibiotic treatment, any focus of infection must be removed or drained without delay. If no source is identified, a systematic search should be made based on the "big five": lungs, abdomen, urine, wounds, and catheters.

Cardiovascular Resuscitation

The VIP rule proposed by Weil and Shubin[25] should be followed. Each patient is, in fact, a VIP, but the letters refer here to *Ventilation, Infusion,* and *Pump*.

V = Ventilation

All patients with septic shock must be generously oxygenated, with the aim of correcting any hypoxemia, regardless of whether it is caused by inadequate cardiac output, pulmonary edema, or pulmonary disease.

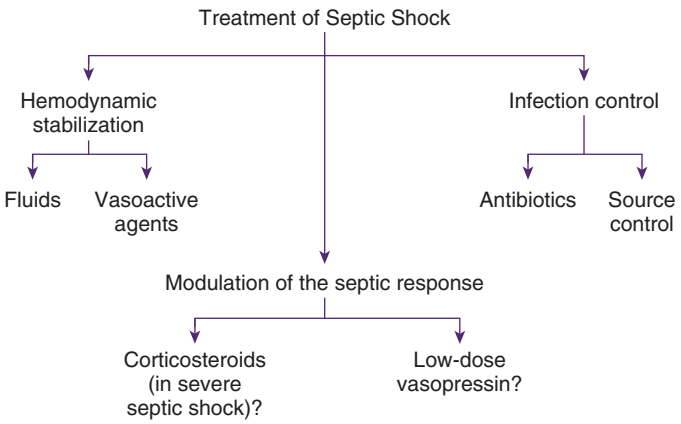

Fig. 112.2 The three aspects of the treatment of septic shock.

Severe cases require endotracheal intubation and mechanical ventilation. Noninvasive ventilation is not recommended in such hemodynamically unstable patients. Even though it may represent a temporary support rather than a treatment per se, mechanical ventilation allows not only an improvement in gaseous exchange but also has beneficial hemodynamic effects, notably by reducing the oxygen requirement of the respiratory muscles. As soon as the situation becomes more stable, hyperoxemia should be avoided. A reasonable rule is to target an SpO_2 of around 94%–97%.

I = Infusion

Septic shock is accompanied by absolute and relative hypovolemia, the result of various mechanisms:

- External losses, which may be obvious, such as vomiting and diarrhea, or less apparent, such as sweating
- Internal losses via an increase in capillary permeability with development of edema and sometimes liquid effusions (peritoneal, pleural effusion)
- Increase in plasma volume associated with arterial and venous dilatation

Hypovolemia needs to be corrected rapidly, as it causes hemodynamic instability both at the level of cardiac output and in terms of peripheral perfusion.

Assessment of an adequate volume state is essentially clinical: restoration of arterial pressure, improvement of cutaneous perfusion, improved urine output, and improved mental state. The central venous pressure (CVP) can be a useful guide, but it is not possible to define in advance the CVP that should be reached in any individual patient. Measurements of cardiac filling are primarily used as a limit to fluid administration in order to minimize the risk of pulmonary edema. In fluid replacement, it is preferable to use a fluid challenge technique, in which filling pressures are measured at regular intervals during fluid administration (Table 112.2).[26] If cardiac output is monitored, one should ensure that it increases with fluid boluses, and such fluid administration should be stopped when cardiac output reaches a plateau. The passive leg raising test represents a form of mini-fluid challenge without giving fluids. Raising the legs sounds easy, but there are limitations. Importantly, the test should not trigger a stress response in the patient, which would result in an increase in cardiac output, arterial pressure, and heart rate in any individual. In any case, it is not the blood pressure that counts, but the transient increase in stroke volume associated with the maneuver that must be assessed properly.[27]

There has been considerable debate as to which fluid should be used in sepsis, but it is the quantity of fluid rather than the type of fluid per se that is of greatest importance. Because of their propensity for leakage into the extravascular space, greater volumes of crystalloids are needed to achieve the same effect as colloids,[28] thus potentially increasing the risk of edema, but colloids are more expensive and carry their own risks. Although this is still controversial, the current evidence

TABLE 112.2 The Fluid Challenge Technique (With the TROL Mnemonic)

Define	Example
Type of fluid	Ringer's lactate
Rate of infusion	200 mL in 10 min
Objective	Mean arterial pressure >75 mm Hg
Limits	Central venous pressure 16 mm Hg

supports the administration of some albumin in septic patients with significant hypoalbuminemia and risks of multiple organ failure.

P = Pump (Vasoactive Agents)

If fluid administration alone is unable to restore an adequate perfusion pressure, vasoactive agents are required. Catecholamines are preferred for their rapid action and efficacy and their short half-lives. Adrenergic agents stimulate beta-1 (positive inotropes), beta-2 (essentially vasodilators and bronchodilators), and alpha- (essentially vasoconstrictors) receptors to varying degrees. Dopamine also stimulates dopaminergic receptors, causing vasodilation primarily in the splanchnic and renal regions, but the clinical relevance of this effect is doubtful.

A randomized controlled study showed that dopamine use is associated with increased adverse effects, notably arrhythmias, in patients with shock,[29] and a meta-analysis indicated that dopamine administration is associated with higher mortality rates than norepinephrine in septic shock.[28] Norepinephrine is therefore the preferred first-line vasopressor in patients with septic shock. Epinephrine should not be used as a first-line vasopressor in patients with septic shock; it can have deleterious effects on splanchnic circulation and increase cellular metabolism. Dobutamine is often added to vasopressor therapy, particularly when using norepinephrine, to increase cardiac output by its positive inotropic effects.

Angiotensin II has strong vasopressor activity. Initially proposed (also called "hypertensin") in the early 1960s,[30] therapeutic interest was revived with the commercial development of a new preparation (angiotensin II).[31] The beneficial effects need to be better defined before generalized use can be recommended.

The place of vasopressin derivatives is also not well defined. Patients with septic shock usually have a degree of relative vasopressin deficiency so that vasopressin supplementation may be warranted. The primary risk is that of excessive vasoconstriction, with reduced blood flow to the splanchnic and coronary circulation. Therefore vasopressin should never be administered when cardiac output is low. Doses should not exceed 0.03 U/min, and cardiac output should be monitored. Vasopressin may be involved in endothelial protection so that its early administration may limit edema formation.[32] This hypothesis, however, requires confirmation by further study.

Maintaining oxygen delivery (DO_2), and therefore cardiac output, is fundamental, because septic shock is typically a hyperkinetic state. Mixed venous oxygen saturation (SvO_2) is typically normal or high. Attempts to maintain central venous oxygen saturation ($ScvO_2$) at least at 70% may be beneficial, although taking this approach should not be routine.[33] In patients who do not improve with initial resuscitation, $ScvO_2$ should be checked.[33] A low $ScvO_2$ should prompt the administration of more fluids and possibly dobutamine. A transfusion may be useful.[34] Decreasing oxygen demand by administering sedatives has its own problems because sedatives can decrease DO_2 and alter the microcirculation.

Immunomodulation

Clinical trials assessing drugs that limit the effects of proinflammatory cytokines such as TNF-α (anti-TNF antibodies, TNF receptors) and IL-1 (IL-1 receptor antagonist inhibitors) have not given convincing results regarding the beneficial effects of these agents on outcome, probably largely because such cytokines have multiple effects, beneficial and harmful. Administration of activated protein C (drotrecogin alfa [activated]) early in septic shock reduced mortality and morbidity in initial studies,[35] but the drug was withdrawn from the market after negative results were obtained in a placebo-controlled study.[36] A trial of thrombomodulin in patients with sepsis-associated coagulopathy[37] gave promising results[38] but further study is needed to confirm this effect.

The administration of large doses of corticosteroids for patients with septic shock was proposed many years ago and not shown to be beneficial. More recently, the concept of relative adrenal insufficiency has emerged, and administration of moderate doses of corticosteroids (200 mg hydrocortisone in 24 hours) in patients with septic shock may be effective.[39]

The treatment of fever is controversial. Increased body temperature increases oxygen requirements, but the increased cellular metabolism may form part of the body's natural defense. Animal studies have suggested that control of fever is detrimental[40] and that the release of heat shock proteins in fever may have important cell-protective effects.[41] A multicenter study of acetaminophen in febrile ICU patients with suspected infection showed that the drug was well tolerated but did not reduce mortality.[42]

High-flow hemofiltration techniques can remove a range of bacterial products and mediators. These techniques appear to improve hemodynamic status and decrease vasopressor requirements. However, clinical studies have provided conflicting data regarding the effects of these techniques on outcomes.[43]

Nutritional Support

Malnutrition can prolong the course of sepsis and increase the risk of complications. When considering nutritional support in patients with septic shock, several factors should be remembered:

- There is no urgency to start nutritional support unless the patient is malnourished.
- The enteral route is preferable to the parenteral route.
- Enteral nutrition should not be started during the initial phase of resuscitation. Although studies are limited, increasing the oxygen requirements of the gut is probably unwise in circulatory shock. However, as soon as the patient has achieved a degree of hemodynamic stability (after a maximum of 24–48 hours), enteral nutrition should be started.
- There is no urgency to start parenteral nutrition. Waiting a few days is acceptable.
- Careful control of blood glucose levels is recommended. It is suggested that the glucose concentration be kept below 180 mg/dL or, even better, below 150 mg/dL.[44] This can be achieved quite easily with modern equipment. Variability in glucose levels should also be avoided.[45]

Organ Support

Organ dysfunction can involve any organ and can be quantified using the SOFA score (see Table 112.1). Techniques for individual organ support are covered in separate chapters, but an overview is given here.

Respiratory Alterations

Respiratory failure is a common complication of sepsis and is usually characterized by hypoxemia. The diagnosis of acute respiratory distress syndrome (ARDS) is made when the PaO_2/FiO_2 ratio is less than 300 mm Hg in the presence of bilateral infiltrates on a chest radiograph, with no evidence of left heart failure.[46] There is no specific therapy for ARDS, and treatment relies on respiratory support and management of the underlying cause (e.g., sepsis).[47]

When starting a patient on mechanical ventilation, several factors need particular attention:

- Worsening of arterial hypotension when starting mechanical ventilation suggests the presence of hypovolemia because of a reduction in venous return (and hence in cardiac output) when intrathoracic pressures are increased.
- As in all mechanically ventilated patients, the use of large tidal volumes and high inflation pressures must be avoided not only for

hemodynamic reasons but also to avoid a major inflammatory reaction from ventilator-induced lung injury (VILI).

- Sedation must be avoided whenever possible. Administration of effective analgesia can help reduce sedative needs, which in turn can improve patient comfort and shorten the duration of mechanical ventilation and ICU stay.[48] This approach can be summarized in the mnemonic, eCASH: early Comfort using Analgesia, minimal Sedatives and maximal Humane care.[49]

Renal Alterations

Sepsis is the leading cause of acute renal failure in the ICU.[50] Renal function can worsen as a result of combined circulatory changes and inflammation. In addition, management of septic patients may involve administration of nephrotoxic agents, such as aminoglycosides or contrast material used for radiologic examinations.

Unfortunately, there is no prophylactic approach to renal failure other than to try to maintain adequate renal perfusion and overall volume state. Administration of dopaminergic agents is ineffective at preventing renal failure,[51] and the indiscriminate use of diuretics may be harmful.[52]

Renal replacement therapy is frequently necessary in septic patients. In septic shock, continuous venovenous hemofiltration techniques, with or without dialysis, are generally preferred over intermittent techniques to facilitate control of fluid balance.

Coagulation Alterations

Coagulopathy is common in septic shock. A low platelet count is common and may be associated with a prolonged prothrombin time and an activated partial thromboplastin time. Treatment of these alterations revolves primarily around the cause, and there is no indication for heparin administration other than for thromboembolism prophylaxis. In severe cases associated with significant bleeding, administration of fresh frozen plasma or platelet infusions may be indicated.

Hepatic Alterations

Circulatory shock of any cause frequently results in the elevation of liver-associated enzyme levels, but the contribution of various organs (e.g., muscles) to increased enzyme levels is difficult to quantify. Often there is a rise in bilirubin levels after several days, without evidence of hemolysis, major hematomas, or biliary pathology. Supplementary examinations such as ultrasound may be indicated to exclude any associated biliary pathology.

Cerebral Function Alterations

Circulatory shock is typically accompanied by an alteration in cognitive function, initially manifested as confusion without coma. Cerebral alterations can be prolonged, and the patient is then said to have septic encephalopathy. The exact cause of the encephalopathy is unclear, although various mediators of sepsis have been implicated. Sedative agents, especially benzodiazepines, can contribute to delirium. Investigations are of little use except to exclude other causes. The electroencephalogram generally shows a diffuse slowing,[53] whereas cerebral computed tomography and cerebrospinal fluid examination are normal. These alterations are usually fully reversible with the resolution of shock.

CONCLUSION

Optimal treatment of a patient with septic shock requires a rapid and effective management plan with the assistance of the full ICU team. Infection control and achieving hemodynamic stability must be tackled simultaneously. Other interventions are currently undergoing clinical trials, with the hope that they will improve the microcirculatory changes of sepsis or beneficially modulate the host response. A better characterization of patients with septic shock—for example, by using the PIRO system—is necessary to appropriately titrate therapeutic interventions to individual patients.

KEY POINTS

- Septic shock affects about 15% of ICU patients and has a mortality rate of close to 40%–50%.
- Septic shock is most commonly caused by a bacterial infection, although fungi, viruses, and parasites can all be implicated. The most common source of such serious infection is the lung, followed by the abdomen.
- Patients with sepsis can be classified according to their predisposing factors, the nature of the infection, degree of immune response, and associated organ dysfunction.
- Septic shock is defined as sepsis with organ dysfunction with persistent arterial hypotension requiring vasopressor administration despite adequate fluid resuscitation in the presence of perfusion abnormalities manifested by oliguria, reduced peripheral perfusion, and/or altered mental status.
- Blood lactate levels are typically raised in septic shock, and persistently raised levels are a poor prognostic sign.
- Management of septic shock includes infection control, hemodynamic stabilization, and modulation of the host response.

Infections of the Urogenital Tract

Florian M.E. Wagenlehner, Adrian Pilatz, and Kurt G. Naber

Infections in the intensive care unit (ICU) contribute significantly to patient morbidity. Depending on the type of ICU, nosocomial infections may account for 70% of infections.[1] Nosocomial infections of the urogenital tract are frequent and sometimes underestimated in the ICU.[2]

DEFINITION

Urinary tract infection (UTI) can be the primary cause for admission to the ICU or can be acquired after intensive care procedures. Because patients are frequently sedated in the ICU, clinical diagnosis of UTI is often difficult. Nevertheless, UTI is an important cause of morbidity and antibiotic resistance in the ICU. Complicated UTI is a highly heterogeneous entity, with a common pattern of the following factors[3,4]:

- Anatomic, structural, or functional alterations of the urinary tract, which significantly impede urodynamic properties (e.g., stents, urine transport disturbances, instrumentation of the urinary tract, stones, tumors, or neurologic disorders)
- Impaired renal function caused by parenchymal diseases or prerenal, intrarenal, or postrenal nephropathies (e.g., acute and chronic renal insufficiencies, cardiac insufficiency)
- Accompanying diseases impairing the patient's immune status (e.g., diabetes mellitus, liver insufficiency, use of immunosuppressive agents such as corticosteroids, acquired immunodeficiency syndrome [AIDS], hypothermia)

ETIOLOGY

Causative pathogens of UTI are almost exclusively bacteria and yeast. Viral pathogens are only found in patients with severe immunosuppression, such as after bone marrow transplantation. High antibiotic pressure and special circumstances in the ICU modulate the microbial spectrum. *Escherichia coli* is the most frequent pathogen but occurs less frequently in nosocomial UTI than in uncomplicated community-acquired UTI. Other Enterobacteriaceae may also be uropathogenic (e.g., *Klebsiella, Proteus*, *Enterobacter*, *Serratia*, *Citrobacter,* or *Morganella* species). Nonfermenters such as *Pseudomonas aeruginosa,* gram-positive cocci such as staphylococci and enterococci, and *Candida* species may also play an important role. The microbial spectrum is likely to differ over time and from one institution to the other. To follow the spectrum and development of antibiotic resistance, each ICU has to update its own surveillance analyses (Table 113.1, Fig. 113.1).

EPIDEMIOLOGY

The Extended Prevalence of Infection in Intensive Care (EPIC II) study[1] revealed that 51% of patients were infected on the study day and that 71% of all patients were receiving antibiotics. The most frequent types of ICU-acquired infections with their total occurrence were respiratory tract infections, 63.5%; abdominal infections, 19.6%; bloodstream infections, 15.1%; and renal or UTIs, 14.3%.[1] The true incidence of UTI, however, may be even higher if more meticulously looked for. In a prospective study specifically evaluating nosocomial UTI, nosocomial UTIs accounted for 28% of nosocomial infections, lower respiratory tract infections for 21%, pneumonia for 12%, and bloodstream infections for 11%. The rates of urinary catheter–associated UTIs varied between 4.2% (symptomatic UTI) and 14.0% (asymptomatic UTI), which shows that asymptomatic bacteriuria is frequent in ICU patients, although symptoms of UTIs in intensive care patients are frequently difficult to assess.[2] In the global one-day point prevalence study in urologic hospitalized patients (GPIU study), asymptomatic bacteriuria accounted for 27% of healthcare–associated (HA) UTIs (HAUTIs), followed by cystitis (26%), pyelonephritis (20%), urosepsis (11%), and other urogenital infections (16%),[7] showing that HAUTI is present in high frequency in certain patient groups. In a recent infection control program HAUTI caused by indwelling urinary catheters (CAUTI) rates were assessed in ICUs in order to prevent CAUTI by educational means. Before the intervention, the CAUTI rate in ICU patients was 2.48 CAUTIs/1000 catheter days. In non-ICUs the CAUTI rate was 2.28/1000 catheter days.[8]

UTIs in the ICU are divided into two groups:

1. UTIs with nonurologic complicating causes: diabetes mellitus, renal insufficiency, immunodeficiency, infectious foci contiguous to the urogenital tract, or trauma patients
2. UTIs with urologic complicating causes: renal transplantation, neurogenic bladder dysfunction, procedures in the urogenital tract, urinary stones or foreign bodies in the urogenital tract (e.g., CAUTI)

In UTIs with primary nonurologic complicating causes, antimicrobial therapy is generally sufficient. However, in UTIs with primary urologic causes, the complicating factors must be identified and treated. In such cases, antimicrobial therapy is only one component of the treatment.

Urinary Tract Infections With Nonurologic Complicating Causes

Individuals with diabetes are at higher risk of UTIs.[9,10] Increased susceptibility in patients with diabetes is positively associated with the increased duration and severity of diabetes as a result of impaired granulocyte function, decreased excretion of the Tamm-Horsfall protein, low levels of interleukin (IL)-6 and IL-8 in the urine that lead to lower "cidality" of the urine, and altered microflora in the genital region. Furthermore, diabetic cystopathy and nephropathy may be complicating factors in the urinary tract. In addition to antibiotics, treatment must address the metabolic situation. In pyelonephritis, usually a switch to insulin or insulin-analogous therapy is necessary.

TABLE 113.1 Bacterial Spectrum of Healthcare–Associated Uropathogens (≥2%) From Distinct Surveillance Studies

Name of Study	SENTRY[5]	SENTRY[5]	SENTRY[5]	ESGNI-003[6]	GPIU-Study[7]
Regions of the world	North America	Latin America	Europe	Europe	Global
Year of surveillance	2000	2000	2000	2000	2003–2010
Type of surveillance	Longitudinal	Longitudinal	Longitudinal	Cross-section	Cross-section
Origin of samples	Microbiology laboratories	Microbiology laboratories	Microbiology laboratories	Different departments in the hospital	Urology departments
Number of pathogens	*n* = 1466	*n* = 531	*n* = 783	*n* = 607	*n* = 1371
SPECIES, %					
Escherichia coli	43%	60%	46%	36%	40%
Klebsiella spp.	12%	12%	9%	8%	11%
Pseudomonas spp.	7%	6%	9%	7%	11%
Proteus spp.	6%	7%	10%	8%	6%
Enterobacter spp.	3%	4%	4%	4%	5%

The place of immunosuppression per se in the development of UTI remains unresolved.[11] Patients with end-stage renal failure are generally not particularly susceptible to the usual gram-negative urinary pathogens, although they may acquire unusual and granulomatous infections. Patients have evidence of reduced cellular and humoral immunity. However, the situation is a little clearer in male patients with human immunodeficiency virus (HIV) and AIDS, where there is a close relationship between CD4 counts and the risk of bacteriuria, particularly in those whose counts are less than 200 cells/mL.[12]

Pathogens may be translocated into the urinary tract from contiguous infectious foci (e.g., appendicitis, sigmoid diverticulitis, or translocation by ileus). Symptoms and localization of pain can be misleading and may delay the diagnosis. Operations or trauma may cause hypothermia, tissue hypoxia, and hemodynamic alterations that result in kidney dysfunction and impaired mucosal perfusion. The use of latex catheters in these critical situations (e.g., operations with heart-lung machine) can also lead to urethral strictures. Silicone catheters or suprapubic catheters are recommended in these patients.[13] Suprapubic catheters cannot prevent UTIs. They can, however, lower the rate of UTIs from 40% to 18%.[14]

Urinary Tract Infections With Urologic Complicating Causes

Patients show a high risk of developing bacteriuria after renal transplantation, threatening clinical outcomes for both the patient and transplant. Early infections (up to 3 months after transplantation) are differentiated from late infections (more than 3 months after transplantation). Early infections may present with no symptoms. In this phase, occult bacteremia (60% of bacteremias after renal transplantation originate from the urinary tract), allograft dysfunction, and recurrent UTIs after antibiotic therapy are frequently seen.[4] Sometimes, it can be quite difficult to distinguish rejection from infection. Patients must also be investigated for surgical complications.

UTIs caused by *Candida* species are frequently asymptomatic. There is, however, a risk of obstructive fungal balls leading to candidemia or invasion of the anastomosis in renal transplant recipients. Asymptomatic candiduria should therefore be treated in these patients.[4] Urine transport disturbances (e.g., from an obstructive ureteral stone) require specific urologic therapy such as percutaneous nephrostomy or stenting. In case of bladder obstruction, an indwelling urinary catheter (suprapubic or transurethral) will be the primary therapy in the ICU. Long-term indwelling catheters (more than 30 days) are associated with a selected microbial spectrum of difficult-to-treat uropathogens (e.g., *Providencia* spp., *Proteus* spp., or *Pseudomonas* spp.).[15] After initiation of antimicrobial therapy, the catheter should be replaced to remove the biofilm material.[4]

PATHOPHYSIOLOGY

UTIs generally occur from organisms invading the urinary tract via the urethra. Pathogens originate from endogenous or exogenous nosocomial flora. Hematogenous spread to the urinary tract is rare.

In uncomplicated UTIs, pathogens need to have specific virulence factors enabling them to initiate an infection after invasion of the urinary tract. The medical conditions of an ICU patient may weaken physiologic barriers and defenses, thus facilitating the entry of pathogens. In addition, the nosocomial environment in the ICU, including antibiotic pressure and decreased supply of oxygen or nutrients (e.g., iron) to tissues, can select pathogens with specific resistance patterns. A general adaptation strategy is the formation of hypermutator strains, which show 100- to 1000-fold increased mutation frequencies, enabling the pathogens to rapidly adapt to challenging environments and thus develop effective mechanisms for antibiotic resistance.[16,17]

An important mechanism contributing to UTI is the formation of biofilms, which are associated with the increased number of biomaterials used in medical practice. Biofilm infections develop not only around foreign bodies such as urinary catheters or stents but also in urinary stones, scarred or necrotic tissue, obstructive uropathies, or even chronic bacterial prostatitis. A biofilm has been defined as an accumulation of microorganisms and their extracellular products forming a structured community on a surface. The formation of a biofilm generally consists of three steps:

1. Deposition of a host conditioning film
2. Attachment of microorganisms followed by microbial adhesion and anchorage to the surface by exopolymer production
3. Growth, multiplication, and dissemination of the organisms

The basic structural unit of a biofilm is a microcolony—that is, a discrete matrix-enclosed community consisting of bacteria of one or more species. The biofilm is usually built up of three layers[13,14]:

1. Linking film that attaches to the surface of a tissue or biomaterial
2. Base film of compact microorganisms
3. Surface film as an outer layer, where planktonic organisms can be released to float freely and spread on the surface

Bacteria within biofilms differ both in behavior and phenotypic form from the planktonic, free-floating bacteria. The failure of antimicrobial agents to treat biofilms has been attributed to a variety of mechanisms:

- Organisms encapsulated in biofilms grow more slowly than planktonic ones, probably because encapsulated bacteria have a decreased nutrient and oxygen supply, leading to a decreased metabolic rate and antimicrobial susceptibility. This may select a less susceptible genotype, forming a resistant population. Furthermore, antimicrobial binding proteins are poorly expressed in these slow-growing bacteria.
- The biofilm matrix delays or impedes the diffusion of antibiotic molecules into the deeper layer of the film (extrinsic resistance).
- Bacteria within the biofilm are phenotypically so different from their planktonic counterparts that antimicrobial agents fail to eradicate them. Bacteria within a biofilm activate many genes that alter the cell envelope and molecular targets by altering the susceptibility to antimicrobial agents (intrinsic resistance). These phenotypic changes are likely to play a more important role in the development of antimicrobial resistance than external resistance (biofilm matrix, glycocalyx).
- Bacteria within a biofilm can sense the external environment, communicate with each other, and transfer genetic information and plasmids within biofilms.
- Bacteria in biofilms can usually survive antibacterial concentrations 100–150 times higher than those needed to kill planktonic bacteria of the same species.[18–20]

Antimicrobial treatment can be effective in only "young" biofilms (<24 hours). At present, combination therapy with fluoroquinolones and macrolides or fosfomycin seems to be most effective against biofilm infections. During an acute febrile phase of biofilm infection, antimicrobial therapy is essential and can be effective because the planktonic bacteria are responsible for the febrile reactions and not the bacteria covered in the biofilm. However, to eradicate pathogens from the biofilm, the biofilm itself has to be removed (e.g., catheter change or extraction of infectious stones).

DIAGNOSIS

Medical History and Physical Examination

Sedated intubated patients are often difficult to evaluate regarding their signs and symptoms of UTIs. The patient or a family member should be asked about previous episodes of UTIs and urologic diseases (e.g., stones or tumors) or operations.

The physical examination should include inspection and palpation of the costophrenic area, lower abdomen, pubic region, inguinal lymph nodes, and genitals and a digital transvaginal or transrectal examination. Ultrasound is an important diagnostic device, and its use should be frequently considered because of the close proximity of the urogenital organs to the intestine, spleen, liver, pancreas, gallbladder, ovary, or uterus.

Urinary Examinations

Urine specimens in ICU patients are almost exclusively collected from catheters. Because urine from catheters has to be collected into a closed system, the urine specimen should be taken from the puncture site at the catheter after disinfection, without opening the closed system. There are different complementary methods for laboratory examination of the urine specimen.

Dipstick Test

The dipstick test is performed with undiluted urine and investigates the following infection-related parameters[21]:

- pH: An alkaline urine (pH >8.0) points to urease-producing organisms such as *Proteus* or *Providencia* spp. and is associated with magnesium-ammonium-phosphate stones.
- Nitrate: Most Enterobacteriaceae harbor a nitrate reductase that reduces nitrate to nitrite. Some common uropathogens such as *Enterococcus* and *Staphylococcus* lack nitrate reductase and will therefore not be detected using this parameter, independent of their urinary concentration. The positive detection of nitrate requires its inclusion in the patient's diet.
- Leukocytes (positive leukocyte esterase): Granulocytes are the most frequently detected leukocytes in the urine of UTI patients. Macrophages appear fairly often in patients with UTIs, but their significance remains unknown.
- Erythrocytes (positive hemoglobin): Hematuria remains a major sign of urinary tract and renal disease.
- Specific gravity/osmolality (degree of urine dilution).
- Protein: Total protein in urine is a mixture of high- and low-molecular-weight plasma proteins from the kidney and urinary tract or bacteria.
- Glucose (metabolic condition of the patient).

Microscopy

There are two possibilities of a microscopic evaluation[21]:

1. Chamber counting of uncentrifuged urine (standard values for urine are shown in Table 113.2).
2. Urinary sediment findings; at least 10 fields of vision at 400× magnification are counted, and the mean value of particles is registered. However, centrifugation methods are never quantitative in counting erythrocytes and leukocytes because of variable loss during centrifugation.

Urine Flow Cytometry

Flow cytometry usually combines impedance method detection with the identification and quantification of urinary particles, such as leukocytes and bacterial cells, available for real-time assessment. Urine flow cytometry has not been specifically evaluated in critical care patients. However, existing data suggest that flow cytometry is beneficial in real-time assessment of uropathogens and leukocytes.[22]

Microbiology

To differentiate contamination in urine from significant bacteriuria, quantitative microbiology is needed. The microbial count has to be interpreted in relation to the urinary dilution.

Clinical Diagnosis

To survey and compare infection rates in different institutions, UTIs should be classified according to widely accepted definitions, such as the definitions of the US Centers for Disease Control and Prevention (CDC). The CDC/National Healthcare Safety Network definitions[23] stratify HAUTIs into symptomatic, asymptomatic, and other infections of the urinary tract. To be of value in determining a nosocomial infection, urine specimens must be obtained aseptically using an appropriate technique such as clean catch collection, bladder catheterization, or suprapubic aspiration.

THERAPY

General Principles

Not all bacteriuric patients in the ICU need to be treated. In general, asymptomatic bacteriuria does not have to be treated.[24] Therapy should only be started in patients with significant symptoms and morbidity and in whom asymptomatic bacteriuria may be deleterious (e.g., before traumatizing intervention of the urinary tract and in pregnant women). In the ICU, indications for treatment of asymptomatic UTIs might include some other circumstances such as renal transplant, severe diabetes mellitus, or severe immunosuppression. In complicated UTIs, antibiotic therapy can only be successful when complicating factors can be eliminated or urodynamic functions restored. Treatment of complicated UTIs therefore comprises adequate antibiotic treatment and successful urologic intervention.

Antibiotic Therapy

For therapy of complicated UTI, antibiotics must possess appropriate pharmacodynamic and pharmacokinetic prerequisites: high renal unmetabolized clearance with good antibacterial activity, both in acidic and alkaline urine. Moreover, microbial resistance patterns must be considered in the choice of antibiotics. Increasing antibiotic resistance, especially among Enterobacteriaceae, makes prudent antibiotic therapy increasingly difficult. The increasing appearance of quinolone-resistant and extended-spectrum beta-lactamase (ESBL)–forming enterobacteria will inevitably lead to the increased use of carbapenems in empiric therapy, thus increasing antibiotic pressure on these highly potent antibiotics. To diminish the selection pressure for resistant pathogens, antibiotics from different classes should be used. Multiple antimicrobial agents are available for therapy for complicated UTIs (see Table 113.2): second- or third-generation cephalosporins, broad-spectrum penicillins with beta-lactamase inhibitors, cephalosporins with beta-lactamase inhibitors, carbapenems, carbapenems with beta-lactamase inhibitors, monobactams, fluoroquinolones, and aminoglycosides. For empiric therapy of severe UTIs, broad-spectrum antibiotics should be used (e.g., broad-spectrum penicillins with beta-lactamase inhibitors, third-generation cephalosporins with or without beta-lactamase inhibitors, fluoroquinolones, or carbapenems). Aminoglycosides as monotherapy have recently been shown to be noninferior to carbapenems or colistin and in severe infections.[25,26] Synergism with aminoglycosides, which inhibit protein synthesis and thus block the formation of toxins or virulence factors, might also be useful for initial therapy, but side effects have to be considered.

Candiduria is a common problem in ICUs. It may represent harmless colonization, but it can also be an early sign of systemic candidosis.[27] A second urine culture after replacing the urethral catheter can rule out contamination. In critically ill patients, systemic therapy for *Candida* species should be started according to susceptibility testing or species differentiation (see Table 113.2). Complicating factors such as diabetes mellitus or urologic abnormalities should be treated concomitantly. Systemic antimycotic therapy is preferred to local instillation therapy because of the potentially systemic nature of candiduria in ICU patients.

TABLE 113.2 Division and Dosage of Distinct Antibiotics Recommended for Treatment of Urinary Tract Infections

		DOSAGE	
Antibiotic Group	**Substance**	**Oral**	**IV**
Aminopenicillin + BLI	Ampicillin/sulbactam	0.750 g twice daily	0.75–3 g 3 times daily
	Amoxicillin/clavulanic acid	1 g twice daily *or* 0.625 g 3 times daily	1.2–2.2 g 3 times daily
Acylureidopenicillin + BLI	Piperacillin/tazobactam	—	2.5–4.5 g 3 times daily
	Piperacillin/sulbactam	—	5 g 3 times daily
Cephalosporin Gr. 1	Cephalexin	Prophylaxis only	—
Cephalosporin Gr. 2	Cefuroxime axetil	500 mg twice daily	—
	Cefuroxime	—	0.75–1.5 g 3 times daily
	Cefotiam	—	1–2 g 2–3 times daily
Cephalosporin Gr. 3	Cefpodoxime proxetil	200 mg twice daily	—
	Ceftibuten	200–400 mg daily	—
Cephalosporin Gr. 3a	Cefotaxime	—	1–2 g 2–3 times daily
	Ceftriaxone	—	1–2 g daily
Cephalosporin Gr. 3b	Ceftazidime	—	1–2 g 2–3 times daily
Cephalosporin Gr. 4	Cefepime	—	2 g twice daily
Cephalosporin + BLI	Ceftolozane/tazobactam	—	Ceftolozane/tazobactam 1.5 g 3 times daily
	Ceftazidime/avibactam	—	Ceftazidime/avibactam 2.5 g 3 times daily
Carbapenem Gr. 1	Imipenem	—	0.5–1 g q6–8h
	Meropenem	—	0.5–1 g 3 times daily
	Doripenem		0.5 g 3 times daily
Carbapenem Gr. 2	Ertapenem	—	1 g daily
Fluoroquinolone Gr. 2	Ciprofloxacin	500–750 mg twice daily	400 mg twice daily
	Ciprofloxacin XR	1000 mg daily	—
Fluoroquinolone Gr. 3	Levofloxacin	500–750 mg daily	500–750 mg
Aminoglycoside	Plazomicin	—	15 mg/kg/body weight once daily
Antimycotic Group			
Azole derivatives	Fluconazole	400–800 mg daily	400–800 mg daily
	Voriconazole	4–6 mg/kg BW daily	4–6 mg/kg BW daily
Pyrimidine analog	Flucytosine		100–150 mg/kg BW 4 times daily
Echinocandin	Caspofungin		50–70 mg daily

BLI, Beta-lactamase inhibitor; *BW,* body weight, *IV,* intravenous.
Data adapted from Grabe M, Bartoletti R, Bjerklund-Johansen TE, et al. *Guidelines on Urological Infections. European Association of Urology Guidelines, Arnhem.* The Netherlands: European Association of Urology; 2015.

Urologic Therapy

Urologic interventional therapy of complicated UTIs is divided into acute therapy and control of the infectious focus with delayed definitive therapy. The primary aim of acute therapy is early focus control, with minimal tissue necrosis. In primary therapy, catheters, stents, or drains are frequently used. Delayed definitive therapy of the urinary tract (e.g., lithotomy, prostatic resection, or ureter reimplantation) is frequently performed after days or weeks of stabilization.

Prophylaxis of Catheter-Associated Urinary Tract Infections

Some 80%–90% of nosocomial UTIs are associated with urinary catheters or instrumentation of the urinary tract. The best prophylaxis is to avoid a catheter or, if catheterization is necessary, to minimize catheter duration. Unfortunately, prevention programs with the aim of reducing CAUTIs by educational activities were not able to reduce CAUTI rates in ICUs compared with non-ICUs.[8] Various techniques have been used to avoid catheter-related infections.

Silver coating of catheters may exert a bactericidal effect, but the concentration of free silver ions must be high, whereas the exposure to albumin and chloride ions has to be low because silver-chloride complexes can precipitate.[28] A multicenter randomized controlled trial using silver alloy– or nitrofural-coated catheters in adults requiring short-term catheterization in the hospital could not demonstrate a sufficiently high reduction in symptomatic UTIs to recommend routine use of antimicrobial-impregnated catheters.[29] Suprapubic catheterization can initially decrease the rate of UTIs from 40% to 18% because proximity to the anal region and irritation of the urethral mucosa with ensuing mucopurulent discharge are avoided.[14] Urinary drainage should be performed with a closed system that should not be opened either for emptying or for urinary sampling. The sites used for urinary sampling must be adequately sterilized. General hygienic procedures such as aseptic catheter insertion, wearing of disposable gloves, and hygienic hand disinfection to prevent cross-contamination or cross-infection are mandatory. International consensus recommendations for the use of urinary catheters to prevent HA infections have been described.[30]

Recommended Evidence-Based Measurements for Preventing Catheter-Associated Urinary Tract Infections

The primary methodologies for preventing CAUTIs[30] include:

- Limiting unnecessary catheterization and discontinuing use of the catheter as early as possible.
- Policies and procedures for recommended catheter insertion indications, insertion and maintenance techniques, discontinuation strategies, and replacement indications should be developed and closely followed.
- Alternatives to indwelling urethral catheterization should be considered, such as condom catheterization, intermittent catheterization, or suprapubic catheterization, although data are insufficient to recommend one alternative over another.
- Closed catheter drainage systems should be used.
- Most other measures for the prevention of CAUTIs, such as prophylaxis with systemic antimicrobials, methenamine salts, cranberry products, enhanced meatal care, and catheter irrigation with either antimicrobials or saline, are not recommended.[30]
- It is also unclear whether routine catheter changes reduce the risk of catheter-associated bacteriuria or UTIs.

SPECIAL CLINICAL ISSUES

Infections of the Upper Urinary Tract and Contiguous Organs

Pyelonephritis

The high osmolality of the renal medulla has a negative effect on leukocyte function. For this reason, the interstitium of the renal medulla is more affected in pyelonephritis than the cortex. Clinical symptoms are unilateral or bilateral flank pain, painful micturition, dysuria, and fever (>38°C). Focal nephritis is limited to one or more renal lobules, which is comparable to that in lobular pneumonia. Ultrasonographic findings are circumscribed lesions with interrupted echoes that break through the normal cortex/medulla organization. A computed tomography (CT) scan with contrast medium shows typical oval-shaped, poorly limited areas of diminished contrast perfusion. As differential diagnoses, renal abscess, tumor, and renal infarction must be taken into account. Emphysematous pyelonephritis characteristically shows gas formation in the renal parenchyma and perirenal space. Diabetes mellitus or obstructive renal disease is the predisposing factor. The most frequently isolated organisms are *E. coli*, *Klebsiella pneumoniae,* and *Enterobacter cloacae*. Fermentation of glucose in Enterobacteriaceae occurs via two different metabolic pathways: mixed acid fermentation and the butylene glycol pathway. Organisms of the *Klebsiella-Enterobacter-Hafnia-Serratia* group and, to a lesser extent, *E. coli* use the butylene glycol pathway and produce copious amounts of CO_2, which appears clinically as gas formation.[31] Aggravated by diminished tissue perfusion, the contralateral side is often affected as well.

Renal and Perirenal Abscess

Clinical symptoms are rigor, fever, back or abdominal pain, flank tenderness, mass lesion and redness of the flank, and tenderness of the upper lumbar and paraspinal muscles. Respiratory insufficiency, hemodynamic instability, or reflectory paralytic ileus occurs frequently. Frequent signs of renal abscess formation are fever and leukocytosis for more than 72 hours, despite antibiotic therapy. The urinary culture may be negative in 14%–20% of cases.[32] Frequently isolated organisms are *E. coli*, *K. pneumoniae, Proteus* spp., and *Staphylococcus aureus* from hematogenous spread. The fascial limitations are open toward the pelvis, and the perirenal fat is in close contact with the pelvic fat tissue. A perinephritic abscess may therefore point to the groin or perivesical tissue or to the contralateral side, thus penetrating the peritoneum. Inflammation of the flank, thigh, back, buttocks, and lower abdomen may occur. Because of the late diagnosis, the mortality can be as high as 57%. Blood cultures are positive in 10%–40% of cases, and urinary cultures are positive in 50%–80%.[33]

Infections of the Lower Urinary Tract and Contiguous Organs

Cystitis

Cystitis is frequently limited to the bladder mucosa and hence shows no systemic signs or symptoms. An ascending infection can, however, clinically result. Cystitis in the ICU is almost exclusively catheter-associated and can cause hematuria. Spontaneous elimination is frequently found after removal of the indwelling catheter but is less frequent in elderly patients.[4]

Epididymitis/Orchitis

Epididymitis in the ICU is usually an ascending infection and can also involve the testis. Possible causes are subvesical obstruction, transurethral resection of the prostate, or an indwelling transurethral urinary catheter, in which case the pathogens are identical with the pathogens in the urine. Of note, epididymitis is frequently involved in urogenital tuberculosis. Orchitis with the formation of a sterile hydrocele can appear during the course of polyserositis or cardiac failure and may point to a generalized systemic disease.

Cavernitis

Cavernitis of the penis is a rare phlegmonous infection of the cavernous bodies. Possible causes are indwelling transurethral urinary catheters, penile operations, autoinjection for erectile dysfunction, pelvic operations, or trauma. Pathogens may represent skin flora or uropathogens. Treatment consists of suprapubic catheterization, broad-spectrum antibiotic therapy, and, if needed, operative débridement.

Acute Prostatitis and Prostatic Abscess

Acute prostatitis and prostatic abscess are bacterial infections of the prostate gland. Prostate biopsy is currently one of the most frequent causes for development of acute bacterial prostatitis. The bacterial spectrum consists of 53%–80% *E. coli* and other enterobacteria, 19% gram-positive bacteria, and 17% anaerobic bacteria.[34] In regions with a high incidence of *Neisseria gonorrhoeae*, the prostate may be involved. Symptoms are high fever, rigor, dysuria, urinary retention, and perineal pain. Rectal palpation reveals an enlarged, tender prostate. Prostate massage is contraindicated. In acute prostatitis, the pathogens are usually detected in the urine. However, the urine may be sterile in prostatic abscess formation. Therapy consists of a combination of antibiotic therapy with broad-spectrum antibiotics and the insertion of a suprapubic catheter. In case of a prostatic abscess, urologic drainage is necessary.[34]

Fournier Gangrene

Fournier gangrene is a necrotizing fasciitis of the dartos and Colles fascias. It is mainly seen in men in the fourth to seventh decades but also occurs in women or newborns. Causes are operations or trauma in the genital or perineal region, including microlesions, or infectious processes from the rectal or urethral areas. Important predisposing factors are diabetes mellitus, liver insufficiency, chronic alcoholism, hematologic diseases, or malnutrition. Patient-related predictors of mortality are increasing age; increased Charlson comorbidity index; preexisting conditions such as congestive heart failure, renal failure, or coagulopathy; and hospital admission via transfer.[35] Fatality rates were

7.5% in one large study.[36] The infectious process follows anatomically preformed spaces. The superficial perineal fascia is fixed dorsally at the transverse deep perineal muscle and laterally at the iliac bone and merges ventrally in the superficial abdominal fascia. Hence, a ventrally open and craniodorsally and laterally closed space is formed (Colles space), which facilitates the spread of infection. In contrast to gas gangrene, the fascial borders are respected in Fournier gangrene. A mixed bacterial flora is seen, consisting of gram-positive cocci, enterobacteria, and anaerobic bacteria. The released toxins facilitate platelet aggregation and complement activation, which, in conjunction with the release of heparinase by anaerobic bacteria, lead to small vessel thrombosis and tissue necrosis. The destruction of tissue enhances the potential of acute renal failure. Fournier gangrene is a rapidly progressing infection that leads to septic shock if not treated in time.

Therapy for Fournier gangrene consists of immediate operative débridement, followed by subsequent operations until the infectious process has been controlled. A suprapubic catheter is advisable, and colostomy may have to be performed in cases where fecal contamination of the wound is inevitable. A combination of antibiotic therapy with broad-spectrum beta-lactam antibiotics, fluoroquinolones, and clindamycin is recommended.

Urosepsis

In 20%–30% of all septic patients, the initial infectious focus is in the urogenital tract. The most frequent causes of urosepsis are obstructive diseases of the urinary tract such as ureteral stones, anomalies, stenosis, or tumor. Early relief from the obstruction controls the infectious focus and improves organ perfusion. This is one reason why mortality in urosepsis is usually lower than that in other septic forms (Fig. 113.2).[37]

Biomarkers such as procalcitonin and/or midregional proadrenomedullin, in addition to lactate, should be included into the early diagnostic work-up. The initial levels of procalcitonin or midregional proadrenomedullin are positively correlated with signs of severity, such as bacteremia or length of hospital stay, but do not predict treatment outcome in urosepsis.[38] C-reactive protein is not discriminatory at all.

Immediately after microbiologic sampling of urine and blood, empiric broad-spectrum antibiotic therapy should be started parenterally. Adequate initial (e.g., in the first hour) antibiotic therapy ensures improved outcome in septic shock.[39,40] Inappropriate antimicrobial therapy in severe UTIs is linked to a higher mortality rate.[41] Empiric antibiotic therapy is based upon the expected bacterial spectrum, institution-specific resistance rates, specific pharmacokinetic and pharmacodynamic factors in UTIs, and individual patient characteristics.

The bacterial spectrum in urosepsis predominantly consists of Enterobacteriaceae such as *E. coli*, *Proteus* spp., *Enterobacter* and *Klebsiella* spp., nonfermenting organisms such as *P. aeruginosa*, and gram-positive organisms.[42,43] *Candida* spp. and *Pseudomonas* spp. occur as causative agents in urosepsis mainly if the host defense is impaired. Patients with candiduria show frequently invasive candidiasis and candidemia.[44,45] Candiduria at any time in an ICU is associated with higher mortality rates (odds ratio [OR], 2.86).[45] Viruses are not common causes of urosepsis.

Although urosepsis is a systemic disease, the activity of an antibiotic at the site of the infection is critical. A variety of studies have shown that inflammatory mediators such as IL-6, CXC chemokines, endotoxin, or HMGB1 are produced and released in the urinary tract.[46–48] Therefore predominantly antimicrobial substances with high activities in the urogenital tract are recommended.[49,50]

The increasing antibiotic resistance rates of pathogens causing urosepsis significantly diminish the choice of antibiotics available for adequate empiric initial therapy in urosepsis. In particular, the increasing rates of Enterobacteriaceae producing ESBL pose clinically relevant problems.[5,51–53] Other recent developments of concern include increased rates of fluoroquinolone-resistant enterobacteria and vancomycin-resistant enterococci.[54,55] Currently, there are no specific pharmacokinetic/pharmacodynamic parameters available for the treatment of patients with urosepsis.

Correct dosing in urosepsis has to consider the altered systemic and especially renal pathophysiology that exists in patients with urosepsis. Sepsis and the treatment thereof result in higher clearances of antibacterial drugs.[56] The increased volume of distribution as a result of peripheral edema in sepsis will lead to underexposure, especially of hydrophilic antimicrobials such as beta-lactams and aminoglycosides, which exhibit a volume of distribution mainly restricted to the extracellular space.[57] Increased dosing is therefore necessary. On the other hand, urosepsis may also cause multiple organ dysfunction such as hepatic or renal dysfunction, resulting in decreased clearance of antibacterial drugs. In such a case, dosing adjustment has to be considered. As beta-lactams are time-dependent antibacterials, optimal administration would be by continuous infusion. Fluoroquinolones, on the other hand, display largely concentration-dependent activity. The volume of distribution of fluoroquinolones in sepsis is not greatly influenced by fluid shifts, and therefore no alterations of standard doses are necessary, unless renal dysfunction occurs.[56,57] Antimicrobial resistance in patients with UTI and urosepsis is generally higher than antimicrobial resistance in patients with nonseptic UTI.[58] Depending on local susceptibility patterns, a third-generation cephalosporin with or

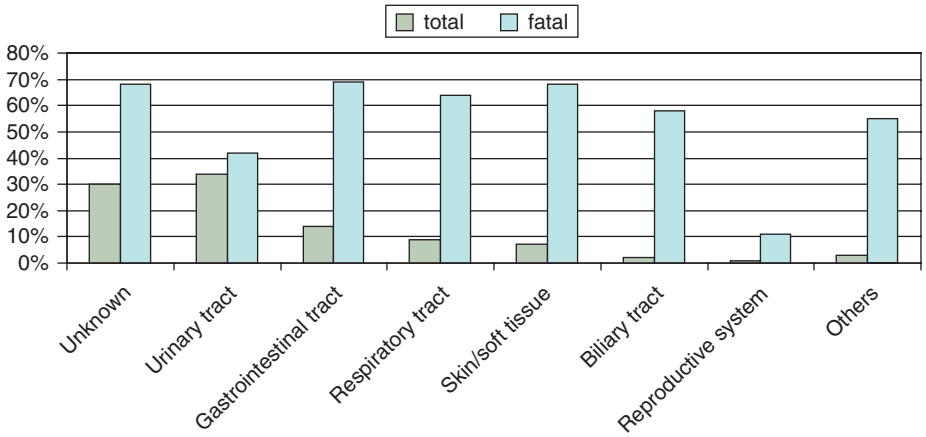

Fig. 113.2 Six Hundred and Twelve Episodes of Gram-Negative Bacteremia 1965–1974.[3]

without a beta-lactamase inhibitor, piperacillin, in combination with a beta-lactamase inhibitor or a carbapenem may be appropriate for empiric therapy.[4,59–62] In areas with a high (>10%) rate of Enterobacteriaceae producing ESBL, initial treatment with a carbapenem might be advisable.[59–63] Aminoglycosides as monotherapy might be an alternative.[26] In case of candiduria with signs of sepsis, antifungal treatment is recommended.[44,45]

KEY POINTS

- Complicated UTI is a highly heterogeneous entity with a common pattern of complicating factors.
- The bacterial spectrum of complicated UTIs is much broader than that of uncomplicated UTIs, comprising a variety of gram-negative and gram-positive pathogens and, among these, frequently multiresistant pathogens. Patients with urosepsis have higher antimicrobial resistance rates than patients with nonseptic UTI.
- UTIs are frequent in ICUs. It would be pragmatic to stratify UTIs into those with nonurologic complicating causes, in which antimicrobial therapy is the primary therapy, and those with urologic complicating causes, in which the complicating urologic anomaly has to be effectively treated as well.
- Pathogens of nosocomial complicated UTIs may be characterized by certain properties such as adaptation strategies to changing environments (i.e., hypermutator strains) or propensity to biofilm formation.
- The diagnosis of UTIs is based on medical history and a thorough physical examination, including bedside ultrasound and investigations of urine (dipstick test, microscopy, and microbiology). For clinical diagnosis, general accepted criteria should be employed. Symptomatic UTIs in ICU patients are especially difficult to evaluate.
- Not all bacteriuric patients in ICUs need to be treated. Therapy should, however, be started early in those with significant symptoms and morbidity. Management of complicated UTIs comprises adequate antibiotic therapy and successful treatment of complicating factors.
- Prophylaxis of UTIs is important. However, the percentage of infections that can be prevented is not known. Important points in prophylaxis encompass training of staff, hygiene measures, type of catheter and drainage, and patient care.
- Special clinical pictures of UTIs and infections of contiguous organs are seen in the ICU. UTIs of the upper urinary tract are distinguished from those of the lower urinary tract and infections of the male adnexal glands and fasciitis of the perineum and scrotum. All these pictures can potentially merge into urosepsis if the UTI is not treated adequately. The urogenital tract is the source of sepsis in 20%–30% of cases.

An experimental setup to study the antibiotic susceptibility of pathogens in biofilm. Fluoroquinolones, and perhaps macrolides, have advantageous effects in the treatment of biofilm infections.

Bonkat G, Bartoletti RR, Bruyère F, et al. *Guidelines on Urological Infections. European Association of Urology Guidelines, Arnhem*. The Netherlands: European Association of Urology; 2022.
This is the extensive version of the guidelines on urologic infections elaborated by the corresponding guidelines panel of the European Association of Urology (ESIU). The topics include classification, diagnosis, treatment, and follow-up of uncomplicated UTI; UTI in children; UTI in diabetes mellitus, renal insufficiency, renal transplant recipients, and immunosuppression; complicated UTI caused by urologic disorders, sepsis syndrome, urosepsis, urethritis, prostatitis, epididymitis, and orchitis; and principles of perioperative prophylaxis in urology.

Hooton TM, Bradley SF, Cardenas DD, et al. Diagnosis, prevention, and treatment of catheter-associated urinary tract infection in adults: 2009 International Clinical Practice Guidelines from the Infectious Diseases Society of America. *Clin Infect Dis.* 2010;50:625–663.
These international guidelines deal with diagnosis, prevention, and treatment of catheter-associated urinary tract infection in adults, the most frequent cause for UTI in the intensive care units.

Oliver A, Cantón R, Campo P, et al. High frequency of hypermutable *Pseudomonas aeruginosa* in cystic fibrosis lung infection. *Science.* 2000;288:1251–1254.
This study elucidates an excellent model for the special propensities of nosocomial pathogens. There were 36.7% of patients with cystic fibrosis who harbored P. aeruginosa *isolates with 100- to 1000-fold increased mutation rates, thus enabling them to rapidly adapt to changing environmental needs.*

Vincent JL, Rello J, Marshall J, et al. International study of the prevalence and outcomes of infection in intensive care units. *JAMA.* 2009;302:2323–2329.
This multicenter 1-day prevalence study on 1265 ICUs in 75 countries investigated 14,414 patients; 51% were infected on the study day. The ICU mortality rate of infected patients was more than twice that of noninfected patients. Therefore infection control in critically ill patients is important.

Central Nervous System Infections

Michael J. Bradshaw and Karen C. Bloch

Central nervous system (CNS) infections represent life-threatening conditions that require emergent evaluation and frequently treatment in a critical care unit.[1] These infections may be challenging to identify, as numerous noninfectious conditions mimic CNS infections. Even when an infectious syndrome is suspected, it may take several days before a specific microorganism is identified, necessitating the use of broad empiric therapy directed against the most likely causative pathogens based on clinical, epidemiologic, and demographic clues. Pharmacologic considerations in selecting appropriate antimicrobials include the ability of the agent to cross the blood-brain barrier and achieve bactericidal levels at the site of infection. Clinical outcomes associated with CNS infections are directly related to the rapidity with which appropriate medical or surgical interventions can be provided, adding urgency to the diagnostic and therapeutic evaluation.[2]

CNS infections may be caused by bacteria, fungi, viruses, protozoa, and prions. The risk of infection with these pathogens varies based on the host immune status (e.g., human immunodeficiency virus [HIV] infection, immunosuppression), epidemiology (e.g., time of year, travel to endemic regions), and acquisition site (e.g., community acquired vs. healthcare acquired). The microbiology and pathophysiology of CNS infections differ based on the specific anatomic site of infection. The major CNS syndromes covered in this chapter include meningitis, brain abscess, encephalitis, and myelitis. These syndromes may occur in isolation or may be found as overlapping conditions (e.g., meningoencephalitis or encephalomyelitis). Localizing the site of infection is often the first step in guiding the diagnostic evaluation and initiating empiric therapy. An interdisciplinary approach with colleagues from critical care, infectious disease, and neurology is important in addressing diagnostic and treatment considerations and potential complications.

MENINGITIS

Infections of the meninges can be subclassified by the acuity of onset of symptoms. Bacterial infections cause an acute meningitis syndrome, characterized by rapid (<48 hours) progression of fever, headache, and neck stiffness or meningismus. In contrast, subacute meningitis syndrome, caused by viruses, fungi, or mycobacteria, is more slowly evolving, with symptoms developing over several days to weeks (Box 114.1). The following sections outline approaches to acute and subacute meningitis. These approaches prioritize the competing needs of obtaining a precise microbiologic diagnosis versus instituting early antimicrobial therapy.

Anatomy

Bacterial meningitis is a pyogenic infection of the meninges and subarachnoid space, with bacteria usually confined to the nutrient-rich cerebrospinal fluid (CSF), although brain and spinal cord parenchyma can be involved, given their anatomic proximity. In adults, CSF is produced at a rate of approximately 500 mL/day, yet the CSF space averages only 140 mL in volume; therefore there is rapid production and reabsorption. CSF is formed in the choroid plexus of the ventricles, flows into the subarachnoid space at the cisterna magna and around the cerebral hemispheres, and is reabsorbed by the arachnoid villi (Fig. 114.1). The cerebral and spinal subarachnoid spaces connect at the cisterna magna, and the flow of CSF through the spinal subarachnoid space is of variable velocity and direction.

There are numerous potential and actual spaces among the layers of the meninges (see Fig. 114.1). Meningitis involves the actual space (i.e., the subarachnoid space), which consists of multiple interconnected compartments. The small size of the foramina of Luschka and Magendie allows for a unidirectional caudal flow toward the cisterna magna, where the CSF then moves into the spinal canal. This compartmentalization has implications in therapy because the movement of medications and infectious agents is influenced by the rate and direction of CSF flow. Obstruction of CSF flow can produce hydrocephalus and may restrict the entry of antibiotics into sites of ongoing infection.

Infectious agents can invade the CSF by at least three routes (Box 114.2). First, the vascular structures of the choroid plexus and pia and the vessels that traverse the subarachnoid space may serve as conduits during bacteremia.[3] A second less common route is by direct invasion across the protective meninges. Physical disruption of the dura by trauma or surgery allows for the direct invasion of the subarachnoid space and should be considered in patients with a history of CSF leakage or clear, watery rhinorrhea, in addition to those who have undergone recent neurosurgical interventions. Emissary veins provide another pathway for bacteria to spread from contiguous foci into the subarachnoid space. These veins traverse the skull and dura, directly connecting the soft tissues of the head and neck with the venous system of the brain and meninges, including the arachnoid villi. Although blood in the emissary veins usually flows away from the brain, the CNS veins and dural sinuses do not contain valves, and retrograde flow of bacteria is possible. Rarely, organisms may reach the ventricles or subarachnoid space from within the neural tissue; for example, rupture of a brain abscess into the ventricles may have disastrous effects. Until 2015, it was thought that the brain has no lymphatic drainage, and these recently identified vessels may prove to be another route of infectious contamination of the CNS.[4,5]

Pathophysiology

Despite complex host-cellular and anatomic defense mechanisms, including immune surveillance of the CSF,[6,7] microorganisms have evolved a number of virulence factors that contribute to the development of

BOX 114.1 Causes of Acute and Subacute Central Nervous System Infection Syndromes

Acute Meningitis Syndrome

Rapid onset (<24–48 h) of fever, headache, or meningismus, with early cognitive impairment

Common

Pyogenic meningitis (pneumococcal, meningococcal, *Listeria,* other)

Uncommon

Viral encephalitis (especially herpes simplex), subarachnoid bleed, brain abscess (with rupture)

Rare

Viral meningitis, granulomatous meningitis (cryptococcal, mycobacterial), carcinomatous meningitis, brain tumor

Subacute Central Nervous System Infection Syndrome

Subacute onset (>24–48 h) of fever, headache, or meningismus, with no or gradual cognitive impairment

Common

Viral meningitis, viral encephalitis, rickettsial infection

Uncommon

Brain abscess, brain tumor, granulomatous meningitis

Rare

Cerebrovascular accident, carcinomatous meningitis

bacterial meningitis. Meningeal inflammation causes vasospasm or vasculitis with occlusion of cerebral arteries/arterioles, cerebral venous thrombosis, damage to nerve roots that traverse the subarachnoid space, and impaired CSF flow (see Fig. 114.1). The activation of leukocytes leads to an inflammatory cascade, with the release of cytokines, oxidants, and proteolytic enzymes, which contribute to the damage caused by the infection. This can lead to increased intracranial pressure and a risk of herniation, especially when there is focal parenchymal edema.[8]

Epidemiology

The epidemiology of bacterial meningitis in the United States has changed in the past 20 years because of the widespread use of vaccines active against *Haemophilus influenzae* type B, *Neisseria meningitidis,* and *Streptococcus pneumoniae.*[9] Simultaneously, the incidence of nosocomial bacterial meningitis caused by increasingly resistant strains of Enterobacteriaceae, *Pseudomonas aeruginosa,* and *Staphylococcus aureus* is increasing.[10]

Meningococcal meningitis presents unique public health and infection control challenges. This diagnosis is suggested by the presence of a petechial or purpuric rash; however, this finding is neither sensitive nor specific.[11] To prevent secondary cases among healthcare workers, all patients with presumed bacterial meningitis should initially be placed on droplet precautions to prevent the spread of infection by inhalation. This can be discontinued after an alternative pathogen is identified or after 24 hours of antibiotics effective against this organism.

Before the availability of antibiotics, bacterial meningitis was universally fatal. However, even with administration of effective antimicrobial

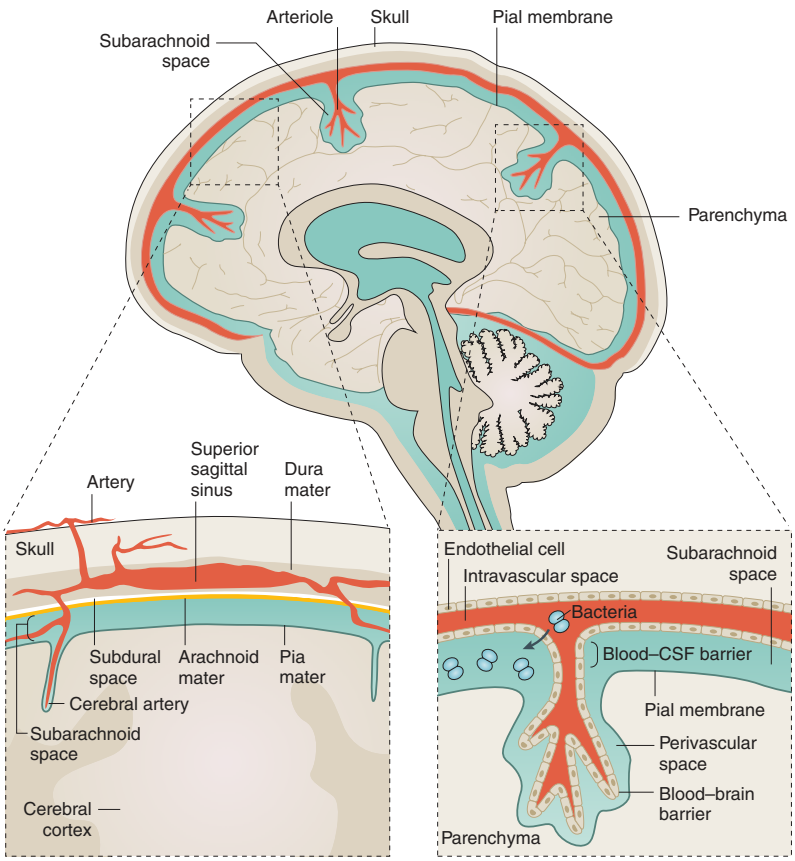

Fig. 114.1 Anatomic Considerations in the Pathophysiology of Bacterial Meningitis. (From van de Beek D, Brouwer M, Hasbun R, et al. Community-acquired bacterial meningitis. *Nat Rev Dis Primers.* 2016;2:16074.)

BOX 114.2 Routes by Which Bacteria May Enter the Subarachnoid Space

Vascular (Blood-Brain Barrier)
- Mostly likely pathogens: pneumococci, meningococci, *Listeria, Escherichia coli* (neonates), group B streptococci (neonates), *Haemophilus influenzae*
- Choroid plexus: may be common site of invasion for *H. influenzae*
- Meningeal blood vessels: throughout the subarachnoid space; may be usual route for pneumococci
- Arachnoid villi: possible route of invasion, located between the sagittal sinus and subarachnoid space

Transdural
- Most likely pathogens: pneumococci, gram-negative enteric bacilli, staphylococci (including coagulase-negative), *H. influenzae*
- Surgery: including ventriculoatrial or ventriculoperitoneal shunts
- Trauma: especially when cribriform plate or petrous bone is fractured
- Parameningeal infective focus: including sinusitis, mastoiditis, otitis, or osteomyelitis; emissary veins may serve as conduit
- Congenital defects: including myelomeningocele and spinal dermal sinus

Transparenchymal
- Mostly likely pathogens: anaerobic bacteria, enteric gram-negative bacilli
- Occurs when brain abscess ruptures directly into ventricles or subarachnoid space

therapy, the case fatality of bacterial meningitis remains significant, with a high incidence of neurologic sequelae among survivors. The fatality rate of pneumococcal meningitis ranges from 16% to 37% in developed countries. Neurologic sequelae, including hearing loss, epilepsy, focal neurologic deficits, and cognitive dysfunction, develop in 30%–52% of survivors.[7,12]

Clinical Manifestations

Bacterial Meningitis

Bacterial meningitis is a medical emergency, and patients with complications such as seizures or decreased level of consciousness are best managed in the intensive care setting.[13] The initial manifestations may be subtle, with a low-grade headache, nausea, and fever. However, once meningeal signs and symptoms (vomiting, severe headache, and stiff neck) develop, clinical decompensation is often rapid. The classic clinical triad associated with bacterial meningitis (fever, neck stiffness, and altered mental status) is present in only 44% of cases.[14] Signs of meningeal inflammation, including nuchal rigidity, Kernig sign, or Brudzinski sign, are neither sensitive nor specific for bacterial meningitis.[15] However, 95% of patients present with at least two of four of the most common symptoms of meningitis: i.e., headache, fever, neck stiffness, and altered mental status.[14] A petechial or purpuric skin eruption suggests meningococcal or pneumococcal meningitis, but skin lesions may be absent at the time of presentation, and other infections such as Rocky Mountain spotted fever encephalitis can also produce a rash.[11,16] Bacterial meningitis may present atypically in the elderly or immunocompromised patients, with minimal focal findings.[17–19] In addition, these populations have a higher incidence of noninfectious conditions that may mimic acute meningitis (e.g., subarachnoid bleeding and malignancies involving the CNS), complicating the initial evaluation.

The diagnosis of meningitis is confirmed through the evaluation of CSF, assuming there is no contraindication to lumbar puncture (see later). Prompt transportation and processing of CSF are important to maximize specimen integrity, as concentrations of neutrophils degrade by up to 50% after an hour post lumbar puncture.[20] Opening pressure is often elevated to the range of 20–50 cm H_2O. Other CSF findings in bacterial meningitis include moderate to high pleocytosis (hundreds to thousands of cells/uL) with a neutrophil predominance, hypoglycorrhachia (low glucose), and elevated protein levels (often >100 mg/dL). The CSF lactate level is a useful adjunct for differentiating bacterial meningitis from viral meningitis, but may be elevated in other CNS diseases that cause meningeal inflammation.[21,22] A positive Gram stain is diagnostic of bacterial meningitis, with a specificity of more than 99%, although the sensitivity varies based on concentration of bacteria in the CSF and the antecedent use of antibiotics.[23,24]

TABLE 114.1 Pathogens Included in the BioFire FilmArray Meningoencephalitis Panel

Bacteria	Viruses	Fungi
Escherichia coli K1	Cytomegalovirus (CMV)	*Cryptococcus neoformans/gattii*
Haemophilus influenzae	Enteroviruses	
Listeria monocytogenes	Herpes simplex virus 1 and 2 (HSV-1 and HSV-2)	
Neisseria meningitidis	Human herpesvirus 6 (HHV-6)	
Streptococcus agalactiae	Human parechovirus	
Streptococcus pneumoniae	Varicella-zoster virus (VZV)	

Molecular microarray panels for the diagnosis of meningoencephalitis are increasingly available and offer the advantage of rapid diagnosis and directed antibiotic therapy. Currently, the only commercially available product tests for 14 common CNS pathogens, including *Escherichia coli* K1, *H. influenzae*, *Listeria monocytogenes*, *N. meningitidis*, *S. pneumoniae,* and *Streptococcus agalactiae* (group B streptococcus) (Table 114.1). In a large retrospective multicenter trial, molecular testing performed comparably to conventional culture for detection of bacterial meningitis.[25] However, questions remain about the sensitivity of this assay after antibiotic treatment, and false positives may be seen because of the potential for contamination.

Management

Delay in antibiotic therapy increases the risk of an adverse outcome or death, particularly when progressive neurologic impairment occurs before receiving therapy.[26,27] For this reason, guidelines recommend the expedited administration of empiric antibiotics to patients with a presumptive diagnosis of bacterial meningitis.[28,29] Even in patients with profoundly abnormal Glasgow Coma Scale scores at presentation, complete recovery may be seen with directed therapy and intensive supportive care.[30]

Coupled with the need for emergent treatment is the need for microbial diagnosis. Identification of a pathogen allows a clinician to narrow the antibiotic regimen based on susceptibility patterns and has prognostic and therapeutic implications. However, in some cases, lumbar puncture is unavoidably delayed. When this is the case, antibiotics should be given immediately after peripheral blood cultures are obtained. The yield of CSF culture decreases within as little as 15 minutes after the administration of antibiotics.[31] Despite the inhibitory effect of prior antibiotics on bacterial culture and Gram stain, the absolute neutrophil count and differential are not initially affected by antibiotics and remain suggestive of bacterial meningitis.[32,33] A full course of empiric therapy should be completed if CSF parameters and the clinical presentation are consistent with this diagnosis.

Historically, neuroimaging has been recommended before lumbar puncture to exclude the presence of a mass lesion or any other risk factor for brain herniation. Studies have challenged this practice, citing the potential deleterious effect of computed tomography (CT) scan–related delays in the initiation of therapy or the sterilizing effect of antecedent antibiotics on CSF cultures.[26,27,31,34] Even among patients with an abnormal CT scan, only a minority of patients have radiographic findings precluding lumbar puncture.[35] For this reason, neuroimaging before lumbar puncture should be reserved for patients with compromised immune systems (e.g., HIV infection, use of immunosuppressive medications, or organ transplantation), new-onset seizures, severely altered mental status (defined as Glasgow Coma Scale of <10), or focal neurologic deficits/optic disc edema.[36] Signs of impending herniation such as deteriorating level of consciousness (particularly with Glasgow Coma Scale ≤11), brainstem signs, or very recent seizure are also important to identify.[37] In the absence of these features, it is generally safe to proceed directly to lumbar puncture, followed by immediate administration of empiric antibiotics.[28]

Antibiotics

The choice of empiric antibiotics is based on the assessment of the most likely causative agents. Recommendations for empiric therapy are listed in Table 114.2, with dosages commonly used for the treatment of CNS infections listed in Table 114.3.[28,29,38]

Empiric therapy should be directed against the most common causes of bacterial meningitis. In immunocompetent adults younger than 50 years,[10,39] *S. pneumoniae* and *N. meningitidis* are the most common causes of community-acquired bacterial meningitis, and therefore initial therapy should include a third-generation cephalosporin such as cefotaxime or ceftriaxone in combination with vancomycin. Strains of *S. pneumoniae* that are increasingly resistant to penicillin have emerged as important pathogens; however, most isolates remain sensitive to third-generation cephalosporins, and all are susceptible to vancomycin.[40]

Empiric therapy for *L. monocytogenes* should be included for adults aged 50 years or older, patients with T-cell immunocompromise (e.g., on chronic steroid therapy), pregnant women, or patients with significant use of alcohol.[28,39] If the CSF Gram stain shows gram-positive rods suggestive of *Listeria,* high-dose ampicillin plus intravenous (IV) gentamicin should be given. For patients with immediate sensitivity reaction to penicillin, meropenem or parenteral trimethoprim-sulfamethoxazole are acceptable alternatives.

In contrast to community-acquired meningitis, organisms causing nosocomial meningitis reflect the highly resistant strains endemic to the hospital.[29] Empiric therapy for patients suspected to have healthcare–associated meningitis should be directed against staphylococcal species (both coagulase-positive and -negative strains) and multidrug-resistant strains of gram-negative bacilli, including *P. aeruginosa* and *Acinetobacter baumannii*. Empiric therapy in this population includes vancomycin in addition to an antipseudomonal cephalosporin (ceftazidime or cefepime) or an antipseudomonal carbapenem. Imipenem is active against *Pseudomonas* and achieves therapeutic levels in the CSF; however, because this agent lowers the seizure threshold, it is relatively contraindicated for meningitis. Meropenem, a related carbapenem, is less epileptogenic and is therefore preferred for this indication.[38]

Initial antibiotic choices can be refined when sensitivity patterns become available, typically in 2–3 days. The duration of therapy varies based on the pathogen and clinical response. Although there have been few randomized studies evaluating the optimal duration of therapy, 7 days of treatment for *H. influenzae* and *N. meningitidis* meningitis is typically sufficient,[41] whereas *S. pneumoniae* requires 10–14 days of therapy.[28,42] Adults with pneumococcal meningitis may have predisposing infections, including pneumonia, sinusitis, otitis, or rarely, endocarditis, in which case prolonged therapy with bactericidal antibiotics is indicated.

Abnormalities of the CSF (e.g., pleocytosis and elevated protein) may persist for days to weeks after the eradication of infection. The resolution of infectious signs and symptoms (e.g., fever, meningismus, and leukocytosis) should serve as adequate evidence of successful therapy. In a patient who fails to respond to 48–72 hours of empiric therapy, lumbar puncture may be repeated, and head imaging, preferably magnetic resonance imaging (MRI) with and without contrast, is indicated. A repeat lumbar puncture is particularly important for detecting clearance of bacteria from the CSF in patients with cephalosporin-resistant pneumococcal meningitis who demonstrate a slow clinical response.[43] Patients with culture-negative pyogenic meningitis and suboptimal clinical response should also have repeat lumbar puncture to ensure response to empiric antibiotics. Worsening CSF parameters suggest infection with resistant bacteria, with a pathogen more typically associated with a subacute meningitis syndrome, or a noninfectious condition (see Box 114.1).

TABLE 114.2 Empiric Antimicrobial Therapy for Adult Patients With Presumed Bacterial Meningitis

Site of Acquisition	Predisposition	Organisms	Antimicrobial Agents
Community	Age 16–50 years	*Streptococcus pneumoniae*	Vancomycin plus third-generation cephalosporin*
		Neisseria meningitidis	
	T-cell deficiency	*S. pneumoniae, N. meningitidis*	Vancomycin plus third-generation cephalosporin*
		Listeria monocytogenes	*plus* ampicillin
	Age >50 years	*S. pneumoniae, N. meningitidis*	Vancomycin plus third-generation cephalosporin*
		L. monocytogenes	*plus* ampicillin
Nosocomial		Staphylococcal species	Vancomycin plus fourth-generation cephalosporin†
		Gram-negative bacilli (including *Pseudomonas aeruginosa*)	*or* meropenem

*Ceftriaxone or cefotaxime.
†Cefepime, ceftazidime.

TABLE 114.3 Antimicrobial Dosages for Central Nervous System Infections*

Drug	Dosage (by Total Body Weight)	Usual Dosage (for 70-kg Adult)
Acyclovir	10 mg/kg IV q8h	700 mg IV q8h
Ampicillin	30 mg/kg IV q4h	2 g IV q4h
Ceftazidime	30 mg/kg IV q8h	2 g IV q8h
Cefepime	30 mg/kg IV q8h	2 g IV q8h
Ceftriaxone	30 mg/kg IV q12h	2 g IV q12h
Meropenem	40 mg/kg IV q8h*	2 g IV q8h
Metronidazole	7.5 mg/kg IV/po q6h	500 mg IV q6h
Nafcillin	30 mg/kg IV q4h	2 g IV q4h
Penicillin G	60,000–70,000 units/kg IV q4h	4 million units IV q4h
Tobramycin or gentamicin	2-mg/kg IV load, then 1.7 mg/kg q8h‡	140 mg IV load, then 120 mg IV q8h‡
Intraventricular		4–8 mg/day
Trimethoprim-sulfamethoxazole	5 mg/kg IV q6h	350 mg IV q6h§
Vancomycin	15 mg/kg IV q6h	500 mg IV q6h‡ or 1 g IV q12h
Intraventricular dosing of vancomycin		5-20 mg/day

*These doses are for patients with normal renal function and modifications may be necessary for patients with reduced creatinine clearance.
‡Adjust dosage based on serum levels, with goal trough 15–20. For both gentamicin and tobramycin, the target peak is 8-10 mcg/mL and target trough <1-2 mcg/mL
§Dosage indicates trimethoprim component.

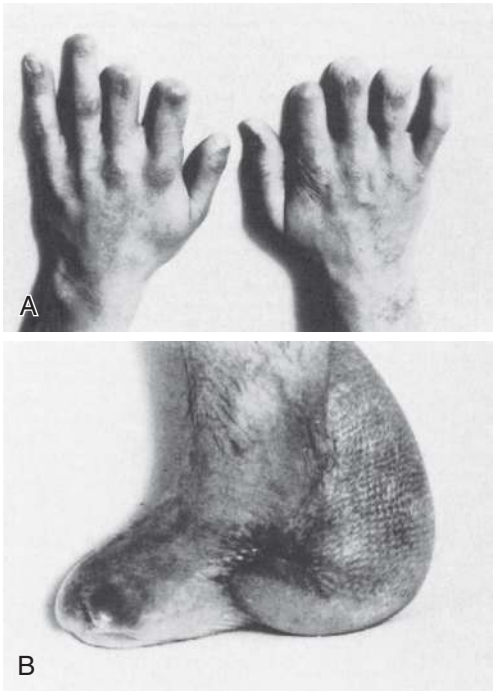

Fig. 114.2 Extremities—hands **(A)** and foot **(B)**—of a 14-year-old boy observed by two physicians as his petechial rash progressed to "bruises" (purpura fulminans). Purpura were not recognized as the hallmarks of *Neisseria meningitides*–induced sepsis. In addition to the loss of extremities from the necrotizing vasculitis of meningococcemia, the patient rapidly developed signs and symptoms characteristic of the acute meningitis syndrome.

Corticosteroids

Much of the morbidity from bacterial meningitis is caused by the host inflammatory response. Corticosteroids decrease inflammation, and animal studies have shown an improvement in outcome when corticosteroids are given as adjuvant therapy with antibiotics. A Cochrane Database review from 2013 evaluated 25 randomized controlled clinical studies on the effect of adjuvant corticosteroids for bacterial meningitis.[44] There was no reduction in overall mortality; however, there was a significant decrease in mortality among the subgroup of patients infected with *S. pneumoniae* meningitis. Administration of steroids was associated with a lower incidence of hearing loss and neurologic sequelae as well. US treatment guidelines recommend adjuvant dexamethasone (0.15 mg/kg IV every 6 hours for 2–4 days) given concomitantly with the first dose of antibiotics for adult patients with suspected or proven pneumococcal meningitis.[28] More recent guidelines by the European Society of Clinical Microbiology and Infectious Diseases suggests that adjuvant corticosteroids be started within 4 hours of antibiotic initiation for all patients with presumed bacterial meningitis beyond the neonatal age.[36]

Complications

Complications specific to meningococcal meningitis include purpura fulminans and necrotizing vasculitis leading to skin necrosis and digital gangrene (Fig. 114.2). Nonspecific complications associated with meningococcal and other forms of meningitis include adrenal insufficiency caused by infarction (Waterhouse-Friderichsen syndrome), renal failure (caused by acute tubular necrosis in the setting of hypotension), deafness, hydrocephalus, seizures, and cognitive impairment.

Other Causes of Meningitis

Other organisms, including viruses, fastidious bacteria (e.g., *Rickettsia rickettsii*, *Treponema pallidum*), fungi (e.g., *Cryptococcus*), or mycobacteria may also infect the meninges (see Box 114.1). These organisms are often classified as causes of aseptic meningitis to differentiate them from the more fulminant syndrome of bacterial meningitis. In contrast to acute bacterial meningitis, patients with aseptic meningitis are less likely to require admission to the intensive care unit (ICU), and in the case of viral meningitis, usually improve spontaneously without antimicrobial therapy.

Differentiating bacterial and nonbacterial etiologies of meningitis may be challenging at the time of presentation, and laboratory data play an important role in making this distinction. Peripheral blood leukocytosis (>10,000/mm^3), CSF white blood cell counts over 1000/mm^3, CSF protein concentration over 100 mg/dL, and CSF glucose concentrations below 40 mg/dL favor a bacterial cause. Patients with these findings should be given empiric antibiotics until a specific diagnosis is made or bacterial cultures return negative. A lymphocytic predominance in the CSF, particularly in the absence of prior antibiotic therapy, argues against a bacterial etiology. Several models incorporating these variables have been developed to predict the likelihood of bacterial meningitis, although these have been best studied in pediatric patients.[15] The measurement of CSF lactate levels has been shown to discriminate bacterial and aseptic meningitis; however, the sensitivity is decreased with prior receipt of antibiotics.[21,22,45] Clinical judgment supersedes results from prediction models or biomarkers, particularly given the possibility of a fatal outcome when antibiotic therapy is deferred.

Viruses are the most common cause of aseptic meningitis, with enteroviruses predominating.[42,46] Other viral causes of meningitis include arboviruses (including West Nile virus), herpesviruses (especially herpes simplex virus [HSV] type 2, which when recurrent is often referred to as *Mollaret meningitis*), acute HIV infection, and lymphocytic choriomeningitis virus. Viral meningitis is typically a self-limited syndrome and does not require treatment. Laboratory testing may be useful if there is diagnostic uncertainty or to aid in epidemiologic evaluations. Commercially available meningoencephalitis molecular array panels include testing for a number of viral pathogens, allowing rapid, point-of-care diagnosis.

Other causes of culture-negative meningitis may be more aggressive or require directed therapy. These include tickborne infections (such as with *Borrelia, Ehrlichia,* or *Rickettsia*), secondary syphilis, mycobacterial or fungal infections, irritation from a parameningeal focus (such as an epidural abscess), or partially treated bacterial infections. In these cases, additional diagnostic studies are indicated but should be individualized based on epidemiologic risk factors and clinical findings. Despite intensive diagnostic testing, a pathogen is identified in only two-thirds of patients with subacute meningitis syndrome.[42]

BRAIN ABSCESS

A pyogenic brain abscess is a localized suppurative infection of the brain parenchymal tissue and may be caused by infection with bacteria, fungi, mycobacteria, or parasites. In immunocompetent adults, 95% of brain abscesses are the result of bacterial pathogens.[47] Differentiating a brain abscess from other CNS infections or brain tumors may be challenging, as there is significant overlap in the clinical and radiologic presentations (Table 114.4). Optimal treatment often requires biopsy to identify the causative organism and obtain susceptibility testing. Even with a combined medical and surgical approach, mortality is significant. Rapid progression of symptoms and impaired mental status at presentation are predictors of an adverse outcome, with rupture of the abscess into the ventricles associated with significant mortality.[48]

Pathophysiology

A brain abscess begins as a localized area of parenchymal infection (cerebritis) that evolves to necrosis and frank suppuration. As cerebritis progresses, a capsule-like hyperemic zone surrounding the area of inflammation develops. In time, liquefactive necrosis leads to abscess formation, with the capsule typically appearing as a ring-enhancing lesion on contrast MRI. In relatively avascular areas such as the cerebral white matter of the brain, capsule formation is delayed, and these sites have higher rates of spontaneous rupture.

Brain abscesses arise thorough several different mechanisms. The most frequent cause is the extension of infection from a contiguous focus (middle ear, mastoids, or sinuses). In approximately one-third of cases, seeding arises through hematogenous spread, and microabscesses typically develop in the distribution of the middle cerebral artery.[49] Filtration of bacteria by the pulmonary vasculature provides some protection for the brain from hematogenous seeding. Therefore when cardiac shunts or pulmonary arteriovenous fistulae are present, as is the case with hereditary hemorrhagic telangiectasia, the risk of brain abscess is increased. Finally, direct inoculation may occur after neurosurgery or intracranial trauma.[50] In approximately 20% of patients, no obvious source of infection is identified.[51,52]

The pathogens causing brain abscesses differ according to the route of infection. Abscesses that arise from contiguous sites are frequently polymicrobial. In contrast, brain abscesses associated with hematogenous spread are usually caused by a single pathogen. Infections after neurosurgery reflect nosocomial flora and often include multidrug-resistant organisms such as methicillin-resistant *S. aureus* (MRSA), enteric bacteria, or *Acinetobacter*. The bacteria most often isolated from brain abscesses include Enterobacteriaceae, streptococci, staphylococci, and pneumococci.[49] Fastidious bacteria such as *Nocardia,* fungi such as *Aspergillus,* and even protozoa such as *Toxoplasma* can also be etiologic agents, particularly in immunosuppressed patients.

Clinical Manifestations

The signs and symptoms of a brain abscess relate to the anatomic location, size, and rapidity of development. At one extreme, the course may span weeks, with few constitutional symptoms. In this setting, signs and symptoms of a space-occupying lesion predominate. In contrast, a previously asymptomatic brain abscess may rupture into the subarachnoid space, causing death within hours. The differential diagnosis in this setting includes an acute cerebrovascular event and pyogenic meningitis. However, brain abscesses usually progress subacutely over 7–14 days,

TABLE 114.4 Differential Diagnosis of CNS Infection and Tumor

	Brain Abscess	Bacterial Meningitis	Herpetic Encephalitis	Brain Tumor
HISTORY				
Headache	Severe, often focal	Severe, generalized	Mild to severe	Absent to severe
Focal defect	Often	Occasional	Occasional	Often

*May be negative or nonspecific during first 48 hours of illness.
†Development of abscess wall may be delayed by steroid therapy.

which is temporally atypical for malignancy and inconsistent with stroke. The most common symptom is headache, present in approximately 70% of cases. Other signs and symptoms include fever (53%), focal neurologic deficits (48%), nausea or vomiting (47%), altered mentation (43%), papilledema (35%), nuchal rigidity (32%) and seizures (25%), and focal neurologic signs (48%).[51,52] The classic clinical triad of fever, headache, and focal neurologic deficit is present in only 20% of patients.[47] CSF findings are often nonspecific and may be normal in approximately 15% of cases. Lumbar puncture is contraindicated if there is clinical or radiographic evidence of increased intracranial pressure, given the risk of herniation.

Imaging

Neuroimaging plays an important role in diagnosis and in monitoring response to therapy. Maturation of a brain abscess is associated with encapsulation, and this is visualized as ring enhancement on CT or MRI.[53] MRI is superior to CT in assessing brain abscesses, as the latter may miss small lesions or those localized to the brainstem or cerebellum. Misinterpretation can occur, particularly when the abscess is in the white matter, where decreased vascularity may result in delayed encapsulation with minimal ring enhancement. Similarly, steroid therapy may decrease local inflammation, resulting in resolution of the ring enhancement. Ring enhancement is not specific for bacterial abscesses and may be seen with other infections or brain tumors. Diffusion-weighted imaging is useful for differentiation of a brain abscess from other cystic brain lesions.[54] Ring-enhancing neoplasms often exhibit facilitated diffusion in the central, nonenhancing area, whereas abscesses typically demonstrate diffusion restriction.[53] When differentiating abscess from other pathologies, diffusion-weighted imaging has a sensitivity of 72%–95% and a reported specificity of 96%–100%.[55,56]

Management

In general, a combination approach of antimicrobials coupled with surgical drainage remains the standard approach for the management of pyogenic brain abscesses. The choice of antimicrobials should be guided by culture results, given the diversity of potential pathogens and the need for prolonged therapy (e.g., 6–8 weeks). Because of the difficulty in achieving therapeutic concentrations of antibiotics across the blood-brain barrier, CNS penetration should be considered when selecting an agent. Empiric therapy should be guided by the most likely microbiology based on origin of the infection. In cases in which the source is unknown or a metastatic spread from a distant focus is likely, empiric therapy with vancomycin, metronidazole, and a third-generation cephalosporin is suggested.[52] An antipseudomonal cephalosporin should be substituted for postneurosurgical infections or for an abscess arising from an otogenic site. Meropenem may be substituted for cephalosporins and metronidazole when there is a contraindication to one of these agents.

Neurosurgical aspiration is invaluable in identifying specific pathogens, and sensitivity testing is crucial for narrowing therapy. Use of stereotactic biopsy allows minimally invasive drainage for both diagnostic and therapeutic purposes. Bacterial, fungal, and mycobacterial cultures should be obtained on all aspirates. Positive cultures from blood or extra-CNS suppurative foci can occasionally establish a presumptive etiologic agent. Ancillary testing for a culture-negative brain abscess includes HIV serology, serum cryptococcal antigen, and *Toxoplasma* titers.

Medical management without drainage may be necessary when the lesion is inaccessible or surgical intervention poses unacceptable risks. However, open or stereotactic drainage is indicated when deterioration from increased intracranial pressure occurs or there is no improvement on medical therapy.[52] Patients treated without drainage may require a longer duration (e.g., 12 weeks) of parenteral antibiotics and should be followed closely for clinical and radiographic improvement. Steroids should be reserved for cases in which significant edema is present.

ENCEPHALITIS

Encephalitis is inflammation of the brain parenchyma accompanied by neurologic dysfunction.[57] Clinical findings include altered mental status (such as disorientation, confusion, and behavioral/cognitive changes), seizures, fever, and focal neurologic dysfunction. The worldwide incidence of encephalitis is estimated at 0.07–12.6 cases/100,000 persons,[58] with mortality in the range of 7%–18% and severe disability reported in approximately half of all survivors.[59–61]

Encephalitis presents a diagnostic challenge to the clinician, and a specific etiology is only identified in approximately 50% of all cases.[62] A myriad of noninfectious etiologies can cause or mimic encephalitis, including direct parenchymal infection, postinfectious autoimmune reactions including acute disseminated encephalomyelitis (ADEM), other immune-mediated etiologies such as autoimmune encephalitis related to neuronal cell surface/synaptic autoimmunity (most commonly anti-*N*-methyl-D-aspartate receptor [NMDAR] autoantibody encephalitis), multiple sclerosis, neuromyelitis optica spectrum disorders, neuro-Behçet, neurosarcoidosis, and others.[1,63]

Infection is the most common cause of encephalitis and constitutes approximately 50% of identifiable etiologies.[63] HSV-1 is the single most common cause of sporadic encephalitis worldwide; this pathogen is of particular importance, as specific treatment is available.[64] Varicella-zoster virus (VZV) is another important cause of encephalitis that is associated with high mortality and treated with parenteral acyclovir, similar to HSV. In the United States, West Nile virus neuroinvasive disease is the leading cause of epidemic encephalitis during the summer and early fall.

Recent epidemiologic studies suggest that the incidence and prevalence of autoimmune encephalitides are comparable with infectious encephalitis.[65]

Infectious Encephalitides

Pathophysiology

The blood-brain and brain-CSF barriers help protect the CNS from the free diffusion of potentially harmful biological and chemical agents.[66] Most vascular endothelial cells in the CNS are sealed by tight junctions and are unfenestrated. These contribute to the protection afforded by the basement membrane, which functions as an acellular barrier to CNS penetration. Within the CNS, astrocytic foot processes form a dense basal lamina surrounding the brain and spinal cord that contributes to the blood-brain barrier.[67] Juxtavascular microglial cells and perivascular macrophages within the brain parenchyma surveil the perivascular spaces. In the choroid plexus, endothelial cells are fenestrated but supported by a second layer of epithelial cells.

Inhaled viruses such as VZV or measles and ingested viruses such as enteroviruses penetrate mucosal membranes and establish infection in the local lymphoid tissue. Viruses that are inoculated into subcutaneous tissue (e.g., arboviruses) are transported by Langerhans cells to the draining lymph nodes. From the secondary lymphoid tissues, the viruses are shed into the bloodstream and thereby disseminate. Many viruses (including West Nile virus, human T-lymphotropic virus type-1 [HTLV-1]), and some bacteria such as *R. rickettsii,* have been shown to directly infect microvascular endothelial cells in vitro.[68,69] Some viruses are capable of entering vascular endothelial cells by binding to endothelial cell-expressed molecules—for example, HTLV-1 can use glucose transporter 1 in order to enter the endothelial cell.[68] Once within the endothelial cell, some agents can alter cellular physiology

(e.g., promoting chemokine expression and altering expression of adhesion molecules), leading to increased vascular permeability and allowing the agent to bypass the first layer of CNS protection.[67]

Although the brain is protected by both the blood-brain and brain-CSF barriers, many neurotropic infectious agents have developed mechanisms for gaining entry into the CNS.[70] Infection of host leukocytes, which are capable of entering the CNS, can serve as a "Trojan horse" neuroinvasive mechanism for viruses such as HIV.[71] Another means of entry is direct neuronal invasion through peripheral nerves.[72] Rabies virus and some enteroviruses, such as poliovirus, are examples of agents that reach the CNS through this mechanism. Poliovirus initially infects mucosal epithelial cells before gaining access to the CNS via retrograde transport in motor neurons,[73] and rabies infects epithelial cells and myocytes at the site of inoculation before gaining access to the nervous system. Once in the motor neurons, rabies virus is transported to the CNS by retrograde axonal transport and through synapses until it reaches the CNS.[74] HSV-1 infects keratinocytes before entering peripheral sensory nerves and may also gain access to the CNS through olfactory sensory neurons (as may several other viruses).[75]

Individual infectious agents demonstrate variable affinities for different anatomic areas of the CNS. Those with a tropism for the meninges cause meningitis, whereas those capable of infecting the brain parenchyma can cause meningoencephalitis or encephalitis. Many agents can affect the spinal cord, causing myelitis (discussed later) as well. In older children and adults, HSV-1 characteristically causes temporal lobe encephalitis, whereas HSV-2 more typically causes meningitis or a lumbosacral radiculomyelitis (Elsberg syndrome).[76] A number of infectious agents have a tropism for the brainstem and can cause a syndrome of brainstem encephalitis. Findings of brainstem encephalitis include cranial nerve palsies, crossed hemiparesis (ipsilesional face/contralesional body from corticospinal tract lesions) or sensory changes (medial lemniscus or spinothalamic tracts), ataxia (cerebellum/cerebellar peduncles), decreased alertness (ascending arousal system), and unusual symptoms such as recalcitrant nausea/vomiting and hiccoughs (area postrema). Infectious etiologies that have been associated with brainstem encephalitis include *L. monocytogenes*,[77] tuberculosis, Whipple disease,[78] herpes group viruses,[79,80] enteroviruses (particularly enterovirus 71), and flaviviruses (especially Japanese encephalitis virus and West Nile virus). There are a number of immune-mediated causes of brainstem encephalitis as well, such as multiple sclerosis, neuromyelitis optica spectrum disorders, neuro-Behçet, neurosarcoidosis, chronic lymphocytic inflammation with pontine perivascular enhancement responsive to steroids (CLIPPERS), Fisher-Bickerstaff encephalitis, and others.[1,81–83]

Clinical Manifestations

In the approach to assessing a patient with possible encephalitis, it is important to first distinguish between encephalitis and encephalopathy without brain inflammation. Encephalopathy without inflammation can result from metabolic derangements (hypoglycemia, hypoxia, electrolyte disturbances, renal or liver disease) or toxin exposure (alcohol, illicit drugs, prescription medications, and environmental contaminants). A clinical case definition for encephalitis that has been proposed by an international working group[57] includes a major criterion of altered mental status for longer than 24 hours and at least two of the following: fever, seizures not attributable to a previously identified seizure disorder, new focal neurologic findings, CSF white cell count more than 5/mm^3, and abnormalities on neuroimaging or electroencephalogram (EEG) suggesting inflammation. This definition was designed for research and epidemiologic purposes but also provides a standardized case definition for clinicians. Notably, this definition may fail to identify patients with focal encephalitis, which may not produce altered mentation.

Management

The history and physical examination are critically important in the diagnostic evaluation of the patient with suspected encephalitis. Particular attention should be given to recent infectious symptoms, risk factors for tuberculosis or other infectious agents, unusual insect or toxin exposures, travel, rash, a history of autoimmunity, and neuropsychiatric manifestations. Full neurologic and general examinations are important in guiding the diagnostic approach. Given the broad differential diagnosis, a diagnostic algorithm has been proposed that emphasizes the most common causes, those that benefit from targeted therapies, and those that pose a particular public health threat.[57,84] Once a clinical diagnosis of encephalitis is suspected, empiric therapy with appropriate antimicrobial agents should be initiated while the diagnostic evaluation is under way.

Routine testing for adults with encephalitis includes complete blood count (CBC) with differential, measures of renal and liver function, blood cultures, HIV testing, and treponemal testing. In addition, *Mycoplasma pneumoniae* antibodies and Epstein-Barr virus (EBV) serologies (VCA immunoglobulin G [IgG] and immunoglobulin M [IgM] and EBNA IgG) should be obtained in children with encephalitis. Serum should be reserved from presentation, and convalescent serum collected 10–14 days later for paired antibody testing as indicated. CSF analysis should be pursued in all patients with encephalitis with routine testing, including opening pressure; cell count and differential; protein; glucose; oligoclonal bands; IgG index; Gram stain; bacterial cultures; HSV-1/2 polymerase chain reaction (PCR); VZV PCR; and if available, VZV IgG and IgM, enterovirus PCR, cryptococcal antigen, and Venereal Disease Research Laboratory (VDRL). In the last several years, molecular multiplex panels targeting the most common causes of community-acquired meningoencephalitis have become commercially available, allowing targeted testing for multiple pathogens, with results available within hours. Autoimmune antibody panels from the serum and CSF should be considered depending on the presentation.

Neuroimaging, preferably MRI with and without contrast, should be obtained in all patients and may reveal meningeal and/or parenchymal contrast enhancement, limbic edema, or other important diagnostic clues. EEG should be obtained in all patients with encephalitis, and when available, continuous EEG monitoring should be considered, as nonconvulsive status epilepticus is a common mimic and complication of encephalitis.[85]

Patients with depressed consciousness, increased intracranial pressure, or seizures are best managed in an intensive care setting. All patients with encephalitis should be treated with IV acyclovir pending CSF PCR result for HSV. Empiric antibiotics should be given if there is concern for meningoencephalitis or a bacterial etiology such as *Listeria* brainstem encephalitis. Anticonvulsant therapy should be initiated in patients with clinical or subclinical seizures but not prophylactically. With the exception of encephalitis caused by herpes group viruses and a few other agents (see later), the management of most viral encephalitides is focused on supportive care.[86]

Herpesvirus Encephalitis

Herpes Simplex Virus Encephalitis

HSV-1 and -2 are two of eight human herpesviruses (HHVs), which also include VZV (HHV-3), EBV (HHV-4), cytomegalovirus (CMV; HHV-5), HHV-6, HHV-7, and HHV-8. HSV-1 and -2 infections are common; HSV-1 seropositivity among adults is 80%–90% worldwide.[87] HSV-1 is the most common cause of sporadic encephalitis in the United States, responsible for approximately 90%

of HSV encephalitis in adults and children (with HSV-2 responsible for the remainder).[64] The mortality caused by untreated HSV-1 encephalitis is roughly 70%, and neurologic sequelae are almost universal in the absence of treatment.[64] Recent epidemiologic studies indicate mortality in the range of 6.2%–18.7% (higher numbers are seen for those admitted to the ICU) in the United States, with significant health and economic impact among survivors.[88,89] Early administration of acyclovir has been shown to significantly improve survival and outcomes.[90,91]

HSV-1 encephalitis may be caused by reactivation of the dormant virus or may occur in the setting of primary infection.[92] The virus has a tropism for the orbitofrontal and temporal lobes; however, no combination of clinical, laboratory, or radiographic findings is sufficiently sensitive to confirm the diagnosis, and empiric acyclovir therapy should be given to all patients with possible HSV-1 encephalitis until all definitive diagnostic studies are completed.[86]

Signs and symptoms typical of HSV-1 encephalitis reflect viral replication and inflammation in the mesial temporal and orbitofrontal lobes and include personality change, confusion, memory loss, hallucinations, aphasia, and seizures; fever is almost universally present.[1,64] Progressive temporal lobe edema can lead to uncal herniation with mydriasis (usually ipsilateral), which can progress to complete third nerve palsy, herniation, and death. When HSV-2 affects the CNS, it primarily causes meningitis, which may be recurrent (Mollaret meningitis) but may rarely cause encephalitis as well. In addition, HSV-2 can cause a triad of brainstem encephalitis, myelitis, and radiculomyelitis (Elsberg syndrome).[76]

The MRI is abnormal in most cases of HSV-1 encephalitis and may disclose unilateral or bilateral abnormalities within the mesial temporal and orbitofrontal lobes, the two most commonly affected structures, and the insular cortex.[93] Diffusion-weighted imaging may be more sensitive for HSV-1 encephalitis, particularly early in the course of the illness.[93] EEG is significantly more likely to demonstrate periodic discharges or focal slowing in frontotemporal leads in patients with HSV-1 encephalitis compared with those with encephalitis from other causes.[94]

The CSF exhibits lymphocytic pleocytosis in over 90% of patients but may appear normal early in the course and is nonspecific. The CSF protein is usually elevated, and glucose level is generally normal. CSF PCR for HSV-1 and -2 remains the diagnostic test of choice with a high sensitivity (96%) and specificity (99%).[95,96] Empiric acyclovir therapy can usually be discontinued if the PCR result is negative, although there have been reports of false-negative results early in the course of the disease; therefore if the clinical suspicion for HSV encephalitis is high, repeat lumbar puncture and PCR for HSV should be performed >3 days after the initial negative test, with continuation of empiric acyclovir.[97]

IV acyclovir 10 mg/kg every 8 hours is the treatment of choice for HSV-1 and -2 encephalitis and should be continued for a minimum of 14–21 days.[98] Dose adjustment is necessary with renal impairment. The safety and efficacy of adjunctive corticosteroids have not been rigorously investigated, and these are typically reserved for use in patients with significant edema.[99] Cognitive deficits and seizures are significant sequelae among survivors. A recent trial of long-term valacyclovir after standard treatment for HSV encephalitis, although well tolerated, did not improve outcomes.[100]

Although HSV-1 encephalitis is typically monophasic, roughly 27% of patients will suffer a secondary autoimmune encephalitis days to months after the initial presentation that can mimic a relapse of the HSV encephalitis.[101] Clinical features of the autoimmune relapse are age dependent. Children generally present with encephalopathy and movement disorders such as choreoathetosis, whereas adults typically present with neuropsychiatric manifestations.[101–103] HSV has been associated with a number of autoantibodies, including those targeting the NMDA receptor, and a number of other antibodies targeting identified or unidentified neuronal antigens.[101,104,105] Patients with clinical relapse after viral encephalitis should be evaluated for autoimmune antibodies and consideration given to empiric immunosuppression after infectious etiologies have been excluded.

Varicella-Zoster Virus Encephalitis

VZV is an important cause of encephalitis and was responsible for 5% of cases in one recent study, with a high case-fatality rate.[59] VZV can also cause brainstem encephalitis, meningitis, myelitis, and vasculopathy that may lead to multifocal ischemic strokes, which may be recurrent. The diagnosis is confirmed by demonstrating VZV PCR positivity or elevated VZV IgM or IgG in the CSF in the appropriate clinical context. Treatment is similar to that for HSV encephalitis and consists of IV acyclovir for 10–14 days. With VZV vasculopathy, concomitant steroid therapy may be indicated. Cutaneous zoster in the setting of encephalitis warrants empiric therapy while diagnostic evaluation is under way, although rash may not be present (zoster sine herpete).

Immune-Mediated Encephalitides

Although viral infections have historically been the most common identifiable etiologic category of encephalitis, a 2018 epidemiologic study from Olmstead County found that the incidence and prevalence of autoimmune encephalitis (AIE) were comparable to infectious encephalitis,[65] and it is increasingly recognized that immune-mediated encephalitis accounts for a substantial burden of disease.[106,107] In one large-scale study, NMDAR encephalitis was the most commonly identified cause of encephalitis in patients who were 30 years or younger.[108]

In 2005 six patients with encephalitis were reported, all of whom had unidentified neural cell surface antibodies and improved with immunotherapy and/or tumor removal.[109] Together with previous studies on paraneoplastic neurologic disorders, this small case series ushered in the characterization of a number of autoimmune encephalitides, a growing area of interest that has had a significant impact in the fields of medicine, neurology, and psychiatry. Since the discovery of NMDAR encephalitis in 2007,[110] roughly one to two novel autoantibody syndromes have been identified yearly. Among these, NMDAR encephalitis is the most common, followed by LGI-1 encephalitis.[106]

Pathophysiology

The AIEs associated with neuronal antibodies can be divided roughly into two categories: those with antibodies targeting cell surface/synaptic antigens and those with antibodies targeting intracellular antigens.[106] Broadly speaking (and with some exceptions), AIE associated with antibodies targeting *cell surface/synaptic antigens* may or may not be paraneoplastic, generally develop in younger patients, and tend to respond to immunotherapy, whereas AIE with antibodies targeting *intracellular antigens* are more often paraneoplastic, more common in older adults, and are less likely to respond to immunotherapy. In addition, whereas IgG antibodies targeting cell surface/synaptic antigens are often directly pathogenic, those targeting intracellular antigens generally are not directly pathogenic and are considered a marker of autoimmunity primarily affected by T cells. This paradigm is useful and has implications for the treatment of AIE, as discussed later.

Binding of autoantibodies to their target extracellular epitopes on neural cell surface or synaptic proteins can lead to alteration of the structure or function of the target antigen.[111] NMDAR encephalitis is the best studied of the autoimmune encephalitides. The NMDAR is localized to the postsynaptic membrane and clustered at the postsynaptic density. In cultured neurons, the binding of patient IgG antibodies to the GluN1

subunit of the NMDAR leads to selective cross-linking and internalization of the NMDAR in a titer-dependent, reversible manner.[112,113] GABAbR and AMPAR antibodies have also been shown to cause selective internalization of their respective receptors in cultured neurons.[114,115] Planaguma and colleagues demonstrated in vivo pathogenicity of NMDAR antibodies by continuously infusing CSF from patients with NMDAR encephalitis into the ventricles of mice, which caused memory and behavioral deficits.[116] Hippocampal analysis demonstrated accumulation of bound antibodies over time with a decrease in the number of synaptic NMDARs. Both the clinical and pathologic consequences improved with the cessation of antibody infusion.

Clinical Manifestations

The importance of the clinical history and examination cannot be overstated, and there has been a tendency to be overreliant on antibody testing in AIE. A 2016 position paper from experts in the field outlines a clinical approach to AIE.[117] The criteria for possible AIE include subacute, progressive deficits in memory, altered mental status or psychiatric symptoms with new focal CNS findings, unexplained seizures, CSF pleocytosis, or MRI suggesting encephalitis in patients in whom reasonable alternative causes have been excluded. Here we will briefly discuss NMDAR encephalitis, but interested readers are referred to several recently published reviews of immune-mediated encephalitides from several different institutions.[106,107,118–120]

NMDAR encephalitis most commonly occurs in young females, with a median age of 21 years (0.6–85 years) although all ages and both genders can be affected. The syndrome develops over stages, with approximately 70% experiencing a viral prodrome consisting of headaches, fevers, vomiting, diarrhea, and/or upper respiratory tract symptoms.[121,122] Within 2 weeks, behavioral and neuropsychiatric manifestations develop and can easily be misinterpreted as evidence of a primary psychiatric condition. This is followed by a depressed level of consciousness that may alternate with episodes of agitation and catatonia. Dissociative responses such as passive resistance to eyelid opening and no reaction to noxious stimulation may be observed, similar to findings in pharmacologic NMDAR antagonism such as ketamine.[123] In this stage, patients develop a variety of abnormal movements (dystonias, dyskinesias, etc.) and autonomic dysfunction that may lead to respiratory failure requiring mechanical ventilation.

Seizures are common throughout the illness, and EEG is abnormal in most patients. The extreme delta brush pattern, which consists of 1- to 3-Hz delta activity with superimposed 20- to 30-Hz beta activity, may be observed in 33% of patients and is relatively unique to NMDAR encephalitis.[124] Brain MRI is abnormal in only 23%–50% of patients and may reveal nonspecific T2 hyperintense lesions in the frontal, parietal, medial temporal, or posterior fossa and occasionally the basal ganglia.[125] A positron emission tomography (PET) scan may demonstrate frontotemporal hypermetabolism with occipital hypometabolism.[126] The detection of anti-NMDAR antibodies confirms the diagnosis, and autoantibodies should be sought in both the serum and CSF, as 6%–13% of patients will only have autoantibodies detectable in the CSF, depending on the method used for antibody detection.[127] There is also a risk of false-positive results if testing is limited to the serum.[128] When AIE is suspected or confirmed, search for an underlying malignancy should be aggressively pursued. Up to half of patients with NMDAR encephalitis have an underlying tumor; although neoplasia is less common in males and younger patients, appropriate diagnostic evaluation should still be pursued.[129,130]

Management

Management includes immunotherapy and the removal of any underlying tumor. With treatment, 70%–80% of patients with anti-NMDAR encephalitis will attain complete or near-complete recovery, and signs and symptoms of the disease generally abate in reverse order.[131] Any tumor should be promptly removed, particularly ovarian or testicular masses. A retrospective analysis of 501 patients treated for anti-NMDAR encephalitis provides the most comprehensive data regarding outcomes.[130] Treatment varied among patients and included first-line regimens consisting of tumor removal (when present), corticosteroids, IV immunoglobulin (IVIg), or plasmapheresis and second-line treatment with rituximab (anti-CD20 monoclonal antibody) and/or cyclophosphamide. For patients who received first-line therapy, 53% improved within 4 weeks. Among patients who did not respond to first-line therapy, 57% were given second-line therapy, which was associated with improved outcomes compared with those who were continued on first-line therapy alone. Patients may require hospitalization for months while undergoing evaluation and treatment.

Although no data have demonstrated the superiority of one regimen over another, one approach is to combine 1g IV methylprednisolone (IVMP) daily for 5–7 days with plasma exchange (1 volume every other day for five sessions) as first-line treatment. IVIg (0.4 g/kg/day for 5 days) can be used after plasma exchange if needed, but should not precede plasma exchange. IVIg antibodies are removed by plasma exchange, potentially decreasing the efficacy of this costly treatment. If improvement is not noted within 10 days, rituximab or cyclophosphamide can be considered. We prefer rituximab for patients with antibodies targeting cell surface/synaptic antigens and generally reserve cyclophosphamide for patients with intracellularly targeted antibodies (wherein the antibody is generally a marker of autoimmunity but not directly pathogenic). Once substantial clinical improvement is noted, treatment can be discontinued in most patients; however, 20%–25% of patients (usually those without a teratoma) may relapse, and longer immunosuppression should be considered in these patients.

Acute Disseminated Encephalomyelitis

ADEM is an immune-mediated inflammatory demyelinating disease of the CNS that is generally monophasic and can be difficult to prospectively distinguish from other causes of encephalitis. ADEM most often affects children, with an annual incidence of 0.07–0.6/100,000 people.[132–134] ADEM generally presents within 2–4 weeks of an infectious illness or, occasionally, vaccination, but antecedent exposure may be absent in 26% of patients.[135] This observation, combined with data from an animal model of demyelination (experimental AIE), suggests that the pathogenesis is related to molecular mimicry in which antigenic epitopes are shared between pathogens or vaccines and host myelin. Alternatively, CNS infection with the subsequent inflammatory cascade may lead to disruption of the blood-brain barrier, exposing CNS antigens to the host immune system, which may lead to breakdown of tolerance.

The syndrome clinically presents with fever, encephalopathy (42%–83%), headache with or without vomiting (15%–37%), meningeal signs (13%–43%), seizures (4%–48%), focal weakness (17%–77%), ataxia (10%–52%), cranial nerve palsies (11%–48%), and/or visual impairment (7%–23%).[136–138] CSF analysis may disclose a variable degree of lymphocytic pleocytosis with mildly to moderately elevated protein levels, normal glucose levels, normal Gram stain with sterile cultures, and transient oligoclonal bands in up to 29%.[137]

The MRI findings in ADEM typically include multiple large (>1–2 cm) asymmetric T2 and fluid-attenuated inversion recovery (FLAIR) hyperintense lesions randomly distributed in the cerebral hemispheres, cerebellum, brainstem, and spinal cord.[139–141] Lesions classically involve the white matter but commonly develop in the deep gray matter as well, particularly the thalamus and basal ganglia, where they tend to be more symmetric.[135] The frequency and patterns of gadolinium

enhancement are highly variable in ADEM (8%–100%), depending on the stage of inflammation, although all lesions tend to be at the same stage at the same time (in contrast to the lesions seen with multiple sclerosis). ADEM is classically a monophasic illness, and signs and symptoms generally resolve over time; however, "multiphasic ADEM" has been reported. There is no standard treatment for ADEM, and the current suggested therapy is based on level IV evidence. After infectious and other causes of encephalitis have been excluded, most authors suggest high-dose IVMP (20–30 mg/kg/day to maximum of 1 g/day) for 3–5 days followed by oral prednisone tapered over 4–6 weeks.[137,140,142,143] For patients who are not responding to steroids, IVIg has been reported to be successful in several case studies and can be considered. A reasonable regimen is 2 g/kg IV divided into doses given daily over 2–5 days (e.g., 0.4 mg/kg given daily for 5 days). In cases of fulminant ADEM unresponsive to steroids, plasma exchange can be considered and has been shown to be effective in aggressive CNS demyelination.[144]

MYELITIS AND MYELOPATHY

Myelopathy refers to any pathology of the spinal cord with associated neurologic dysfunction and includes noninflammatory etiologies such as nutritional deficiency and malignancy. Myelitis is an inflammatory cause of myelopathy and may occur in isolation (e.g., poliovirus myelitis or herpesvirus myelitis) or coexist with encephalitis as an overlap syndrome (e.g., acute flaccid paralysis associated with West Nile virus [WNV] encephalomyelitis, progressive encephalomyelitis with rigidity and myoclonus, or ADEM). The differential diagnosis of myelitis includes infectious and immune-mediated etiologies in addition to noninflammatory causes of myelopathy such as vitamin or mineral deficiencies (e.g., vitamin B_{12}, copper), vascular myelopathies, and neurodegenerative conditions.[1]

The differential diagnosis for myelitis is shown in Box 114.3. Some causes, such as ADEM and other postinfectious myelitides, are monophasic, whereas others, such as multiple sclerosis, neuromyelitis optica, lupus myelitis (now recognized to be often associated with neuromyelitis optica), and neurosarcoidosis, can be progressive and/or relapsing.

A thorough history and neurologic examination are critical for defining the temporal profile and localization. Back or neck pain (especially funicular pain), bowel or bladder dysfunction, saddle anesthesia, and bilateral upper or lower extremity weakness are historic features that suggest a spinal localization. The temporal profile is helpful in determining etiologic probabilities. For example, a hyperacute presentation is suggestive of a vascular or traumatic etiology, whereas an acute-subacute temporal profile suggests inflammatory or infectious etiologies, and a subacute-chronic course implies nutritional deficiency or malignancy.

Identifying a spinal level is a key step in localizing a lesion to the spinal cord, and the pattern of localization may assist in determining the etiology (e.g., weakness and loss of pain/temperature with preserved vibration and proprioception in cases of anterior spinal artery occlusion or loss of vibration and proprioception with preserved pain/temperature and motor function in tertiary syphilis). In the acute setting, patients may present with hyporeflexia that can mimic Guillain-Barré syndrome, a finding that can mislead the diagnostician to a peripheral localization. Although a localization can usually be identified, none of the features on the examination or history is sufficiently sensitive or specific to differentiate between inflammatory, vascular, or compressive causes. Therefore all patients with myelitis should be managed as true emergencies using a standardized approach.

The first step in the diagnostic approach to possible myelitis is to exclude extrinsic cord compression that might warrant surgical intervention.[145] Emergent imaging is indicated if cord compression is suspected, as early decompression dramatically improves functional outcomes. The preferred modality is spinal MRI with and without contrast, although CT myelography is a reasonable alternative if MRI is contraindicated. Once compression is excluded, lumbar puncture with cell count and differential, total protein, glucose, Gram stain/cultures, IgG index, and oligoclonal bands should be obtained, with an extra sample reserved for future studies. In addition, antiaquaporin-4 autoantibodies, Sjögren syndrome A antibodies/ Sjögren syndrome B antibodies (SSA/SSB), antinuclear antibodies (ANA), anticardiolipin antibodies, copper, vitamin B_{12}, treponemal antibody, CSF varicella-zoster PCR and IgG, and enterovirus PCR should be considered. Inflammation of the spinal cord is supported by contrast enhancement on MRI, CSF pleocytosis, or elevated CSF IgG index.

There are four key steps in the management of myelitis: (1) recognizing the syndrome, (2) extinguishing acute inflammation, (3) determining the etiology, and (4) providing long-term management. While the diagnostic evaluation is under way, high-dose steroids (typically with 1 g IVMP daily for 3–7 days) should be given in order to decrease the acute inflammation.[146]

BOX 114.3 Differential Diagnosis of Myelitis

Viral
- HIV
- HSV-1 and -2
- VZV
- CMV
- EBV
- WNV
- HTLV

Bacterial
- *Mycoplasma pneumoniae*
- *Borrelia burgdorferi*
- *Treponema pallidum*
- Pyogenic bacteria
- *Mycobacterium tuberculosis*

Fungal
- *Coccidioides immitis*
- *Actinomyces*
- *Aspergillus*
- *Blastomyces dermatitidis*
- Histoplasmosis

Immune-Mediated
- Multiple sclerosis
- Neuromyelitis optica
- Connective tissue disorders (neuro-lupus, neuro-Sjögren)
- Neurosarcoidosis
- Paraneoplastic

Noninflammatory Myelopathies
- Vitamin B_{12} deficiency
- Folic acid deficiency
- Copper deficiency
- Vitamin E deficiency
- Nitrous oxide toxicity
- Heroin
- Radiation myelopathy
- Traumatic/compressive myelopathy
- Vascular myelopathy

When infectious etiologies are suspected or confirmed, appropriate antimicrobial agents should be given. Patients with longitudinally extensive myelitis associated with lupus may benefit from the addition of cyclophosphamide to corticosteroids and plasma exchange.[147,148] Those with myelitis as a result of neuromyelitis optica should be treated with steroids and plasma exchange, a regimen associated with improved outcomes.[149,150] When neurosarcoidosis presents with myelitis, corticosteroids are usually effective,[151] and severe or refractory cases generally respond to tumor necrosis factor-alpha (TNF-α) antagonism (such as with infliximab).[152] No specific regimen for infliximab in this setting has been validated, as only small case series exist, but doses range from 3 to 5 mg/kg, including induction with doses at 0, 2, and 6 weeks and maintenance dosing every 4–6 weeks thereafter. Notably, TNF-α antagonism can worsen multiple sclerosis and is contraindicated in these patients.[153] In managing patients with severe myelitis of unknown etiology, consideration should be given to concomitant steroids and plasma exchange, which were associated with improved outcomes in at least one retrospective review.[148]

Myelopathy from vitamin B_{12} deficiency should be treated with 1000 μg intramuscular vitamin B_{12} daily for a week, weekly for a month, and then monthly thereafter. Depending on the cause of deficiency, some patients can eventually be treated with oral vitamin B_{12}.[154] Hypocupremic myeloneuropathy should be treated with oral elemental copper 8 mg by mouth daily for a week, then 6 mg daily for a week, then 4 mg daily for a week, followed by 2 mg daily thereafter.[150,155,156] The underlying cause of deficiency should be identified (often associated with excessive zinc consumption, gastrointestinal surgeries, or malabsorption syndromes). Nitrous oxide toxicity may present with subacute-acute myelopathy and has been reported after a single exposure.[157] Nitrous oxide inactivates vitamin B_{12} by oxidizing the cobalt center of the molecule; therefore treatment is with vitamin B_{12}. Heroin use may cause an acute myelopathy, the treatment of which is supportive.

Ischemic myelopathy secondary to spinal cord infarction is managed with lumbar drainage and hemodynamic augmentation with vasopressors in order to increase perfusion of the spinal cord.[158] Guidelines from the Congress of Neurological Surgeons in 2013 recommended against the use of steroids in acute spinal cord infarction,[159] unless caused by vasculitis. Physical and occupational therapy are important interventions in the care of all patients with myelopathy. Long-term medical management is contingent upon the etiology of the myelitis.

CENTRAL NERVOUS SYSTEM INFECTION AND THE ACQUIRED IMMUNODEFICIENCY SYNDROME PATIENT

Patients with HIV/AIDS are susceptible to an array of opportunistic infections in addition to the more common causes of CNS infection. Differentiating neurocognitive dysfunction associated with HIV from neurologic dysfunction related to malignancy or opportunistic infections requires a thoughtful and systematic diagnostic approach to allow rapid and appropriate treatment of what are frequently life-threatening infections.

Pathophysiology

Opportunistic infections of the CNS are common in patients with advanced HIV, including cryptococcus, toxoplasmosis, and progressive multifocal leukoencephalopathy (PML). Advanced HIV infection is associated with *HIV-associated neurocognitive disorders* (HANDs), which comprise a spectrum of disease, with HIV-associated dementia (HAD) reserved for the most severe cases of cognitive dysfunction.[160] Before the availability of highly active antiretroviral therapy (HAART), it was estimated that 20%–30% of patients with uncontrolled HIV suffered from HAD.[161] The prevalence of HAD has decreased to 2%–8% in patients treated with HAART.[162] Over 40% of patients with HIV will present with neurologic manifestations, either related to the direct involvement of HIV itself or related to opportunistic infections over the course of their lives.[163] The neuropathogenesis of HIV has recently been reviewed, to which interested readers are referred.[164] Here we focus on opportunistic infections associated with HIV.

Clinical Manifestations

The most important factor in assessing a patient with HIV and neurocognitive changes is the degree of immunosuppression.[165] This framework can be used to establish the most likely etiologies in the differential diagnosis. Patients with CD4 counts higher than 500/μL are more likely to present with noninfectious conditions or infections common to immunocompetent patients. The exception is tuberculous meningitis, which can occur at any CD4 count. Those with CD4 counts between 200 and 500/μL are more likely to present with HIV-associated cognitive and motor disorders, whereas patients with CD4 counts lower than 200/μL are more likely to have CNS mass lesions, HIV-associated malignancy (such as CNS lymphoma), and opportunistic infections.

Management

In the evaluation of the patient with HIV and neurologic manifestations, a systematic approach is important. Imaging should be performed before lumbar puncture, given the increased risk of mass lesion such as toxoplasmosis or lymphoma in this population. A brain MRI with and without gadolinium contrast is the preferred method and can assist in securing the diagnosis.[166] In addition to the standard diagnostic studies, CSF analysis in HIV/AIDS patients should include cytology, cryptococcal antigen testing, VDRL (for syphilis), and, when indicated, PCR for herpesviruses, JC virus, and *Mycobacterium tuberculosis*.[167] The clinical manifestations and management of several of the most common CNS infections in patients with HIV are briefly reviewed next.

Toxoplasmosis

An obligate intracellular protozoan, *Toxoplasma gondii* is the most common HIV-associated opportunistic infection of the CNS.[168] It is found in cat feces and undercooked meat, and in immunocompetent patients, results in an acute but self-limited, nonspecific febrile illness. Seroprevalence studies suggest infection rates in the United States between 15% and 25%.[169] In patients with CD4 counts lower than 100/μL, CNS reactivation of prior toxoplasmosis infection may occur, and patients present with acute to subacute encephalitis.[170] Brain MRI with and without gadolinium contrast is more sensitive than CT.[166,171] MRI findings suggestive of *Toxoplasma* encephalitis include multiple nodular or ring-enhancing lesions, usually with extensive surrounding vasogenic edema, with a predilection for the basal ganglia and corticomedullary junction.[172] On noncontrast images, the appearance of lesions is highly variable; they may be isointense or hypointense on T1-weighted images and hypointense, isointense, or hyperintense on T2-weighted sequences. The "eccentric target sign" is an infrequent, but highly specific (95%), finding.[173] Most patients with *Toxoplasma* encephalitis have positive serologies for toxoplasmosis, but their absence does not exclude the infection. PCR of the CSF for toxoplasmosis is highly specific but insensitive and is not universally available. Treatment consists of sulfadiazine, pyrimethamine, and leucovorin (given to prevent pyrimethamine-induced hematologic toxicity). Patients who are unable to take sulfadiazine can substitute clindamycin. Maintenance therapy should be given to prevent further episodes of infectious reactivation. Corticosteroids

should be reserved for patients with a significant mass effect. Surgical intervention is typically reserved for patients with signs of impending herniation or lack of radiographic response after 2 weeks of empiric therapy for toxoplasmosis, in which case a biopsy to exclude an alternative cause, such as CNS lymphoma, is indicated.

Cryptococcus

Cryptococcus neoformans, an encapsulated budding yeast, is commonly found in soil contaminated by bird feces. Cryptococcal meningitis is the second most common CNS infection in patients with HIV. Cryptococcus typically presents as subacute (1–2 weeks) meningitis, but can rarely present with fulminant disease progressing to death over several days. A high index of suspicion is warranted in patients with low CD4 counts (especially <100/μL). Neuroimaging findings are highly variable and are often normal. Involvement of the basal ganglia may be present. Some features that suggest cryptococcal meningoencephalitis include dilated Virchow-Robin spaces, pseudocystic and cystic masses, meningitis, or hydrocephalus.[166] Many patients present with evidence of elevated intracranial pressure (>20 cm H_2O) that is characterized by decreased consciousness, papilledema, and sixth nerve palsy. The CSF classically reveals a low white blood cell count (<50/μL), with a mononuclear predominance, elevated protein, and low glucose levels but is normal in up to 30% of infected patients.[174,175] The CSF should be tested for the presence of cryptococcal antigen.[176] Commercially available molecular diagnostic panels include testing for *Cryptococcus,* but importantly, the sensitivity of PCR is only 52%.[177]

Opening pressure should be checked in all patients undergoing lumbar puncture, as elevated pressure is a poor prognostic sign. Patients with elevated intracranial pressure should be treated with repeated lumbar puncture or lumbar drain placement for decompression.[178] Patients with moderately elevated intracranial pressure present with an opening pressure of less than 20 cm H_2O. When symptomatic patients have an extremely high pressure, the pressure target should generally be 50% of the initial value. Daily lumbar puncture may be necessary until normalization/stabilization of pressures. Antifungal therapy includes an induction phase with liposomal amphotericin B (amphotericin B deoxycholate is an alternative if the liposomal form is unavailable) and flucytosine for at least 2 weeks, followed by prolonged consolidation therapy with fluconazole.[179,180]

Herpesviruses

Immunocompromised patients with herpetic infections of the CNS present a diagnostic challenge, and the index of suspicion should be high in order to avoid missing the diagnosis. Immunocompromised patients with herpes encephalitis are less likely to present with prodromal symptoms or focal neurologic deficits, have more extensive radiographic involvement (often distributed outside the temporal lobes), and have CSF pleocytosis.[181] Even with modern treatment and supportive care, mortality among the immunocompromised is significantly higher than among the immunocompetent, with reported mortalities of 35.7% and 6.7%, respectively. As in immunocompetent patients, acyclovir is the preferred agent.

CMV is another herpesvirus that is latent in the majority of the population but may reactivate in immunocompromised persons. CMV can cause encephalitis, retinitis, myelitis, polyradiculopathy, and peripheral neuropathy and is most likely to manifest when the CD4 count is less than 50/μL. Findings on MRI are neither sensitive nor specific. MRI may reveal diffuse or focal T2 hyperintense lesions predominantly involving the periventricular white matter and possibly evidence of ventriculoencephalitis, characterized by T2 hyperintense lesions along the ependymal lining of the lateral ventricles that may enhance with the administration of gadolinium.[182] Analysis of the CSF may reveal neutrophilic pleocytosis (unusual for viral infection) and elevated protein and low glucose levels, though these findings are variably present.[182] CMV PCR should be obtained from the CSF, and high levels of viral DNA in the proper clinical context confirm the diagnosis, although low levels may be difficult to interpret. Several treatment regimens are in use for neurologic infections with CMV. Most clinicians use a combination of ganciclovir and foscarnet for patients with CNS infection, but patients who are unable to tolerate combination therapy can be treated with either agent alone.

Progressive Multifocal Leukoencephalopathy

PML is a life-threatening demyelinating disease of the CNS that results from reactivation of JC virus.[183] Primary infection usually occurs in childhood, with up to 86% of adults seropositive for the virus.[184] In most patients, the virus remains latent in the kidneys and the lymphoid organs, but in an immunocompromised individual, reactivation may occur with secondary spread to the CNS, where it causes a lytic infection of oligodendrocytes. PML usually manifests with subacute, progressive neurologic deficits, including personality change, altered mental status, and focal neurologic deficits referable to the localization of the infection. Seizures may occur in up to 18% of patients and are likely related to cortical or juxtacortical involvement.[185] Most patients with HIV who present with PML have CD4 counts of less than 100 μL, but PML has been associated with immunosuppression related to a number of medications, including mycophenolate mofetil,[186] rituximab,[187,188] and natalizumab.[189,190] PML classically affects the white matter, manifesting on MRI as symmetric or asymmetric T1-hypointense/T2-hyperintense lesions that may become confluent.[166] In patients with a profound immunocompromised status,[191] there may be minimal or no enhancement with gadolinium, but in the setting of PML-immune reconstitution inflammatory syndrome or with medications such as natalizumab, contrast enhancement is more common.[192] JC virus PCR from the CSF should be obtained when PML is suspected and is highly specific. However, the sensitivity may be decreased because of low viral burden with HAART.[177,193] Consequently, in rare cases, brain biopsy may be required to establish the diagnosis. There remains no specific treatment for PML; therefore therapy is aimed at restoring immune function. In patients with HIV, initiation or optimization of antiretroviral therapy is the best option and can prolong survival.[194,195] As the serotonin receptor 5HT2A can serve as a receptor for the virus, the addition of mirtazapine may be beneficial, but evidence is limited to case reports.[196–198] PML is associated with a bleak prognosis and is almost uniformly fatal in patients with AIDS.[199,200]

Central Nervous System Lymphoma

Patients infected with HIV are predisposed to several malignancies, including primary CNS lymphoma (PCL),[201] which are strongly linked to EBV infection.[202] PCL can mimic an opportunistic infection, and MRI may be helpful in differentiating the etiology of mass lesions in patients with AIDS. AIDS-related PCL is often associated with a high degree of contrast enhancement, which is typically irregular and inhomogeneous.[203,204] Lesions that involve the corpus callosum and periventricular or periependymal areas are more likely to represent PCL, whereas PCL involves the posterior fossa in less than 10% of cases in this population.[203,205] Among the conditions discussed here, PCL and toxoplasmosis are most likely to cause a mass effect.[206] As there is clinical and radiologic overlap with opportunistic infections, these should be thoroughly evaluated as outlined earlier with the inclusion of CSF EBV PCR, cytology, and flow cytometry. In the absence of a pathologic diagnosis, empiric corticosteroids should be used with caution, as these may decrease the diagnostic yield for CNS lymphoma.

EXTRACRANIAL INFECTIONS

Paradural Abscess

The epidural space is between the dura and the bony structures of the skull and vertebral column; the subdural space is between the subarachnoid membrane and the dura (see Fig. 114.1). Unlike the subarachnoid space, the paradural tissues are only potential spaces, with the arachnoid membrane and the dura limiting the spread of infection across their surfaces. Although subdural abscesses are more common within the cranium and epidural abscesses are more common within the vertebral column, the microbiology, pathophysiology, and treatment are similar. These abscesses usually develop from a contiguous infection, surgery, or trauma.

Cranial Paradural Abscess

In the skull, the epidural tissues are dense and abscess formation is unusual. The subarachnoid membrane is less adherent to the dura, making the subdural space the more likely site of infection. Intracranial paradural abscesses tend to evolve rapidly, often producing irreversible damage to underlying intracranial tissue. Antibiotics alone are inadequate, and neurosurgical drainage remains the mainstay of therapy. MRI has greatly aided in the rapid identification and management of intracranial paradural abscesses.

Cranial epidural abscesses most commonly occur adjacent to the frontal sinus, but if left untreated, infection can spread into the subdural space or even brain parenchyma. Infection may be the result of trauma or surgery, but, most commonly, is a complication of sinusitis, which is reflected in the microbiology of cranial epidural abscesses.[207] Treatment requires emergent surgical drainage followed by antibiotics tailored against the bacteria cultured intraoperatively.

Cranial subdural empyema may be clinically indistinguishable from meningitis or a brain abscess, with the triad of fever, headache, and altered consciousness seen at presentation in approximately 50% of patients.[208] A subdural abscess is most commonly a complication of a prior neurosurgical procedure but can also occur after infection of the paranasal sinuses and, less commonly, the ears or mastoids.[209] Rarely, spontaneous development of a subdural abscess after bacteremia has been reported. The microbiology of these infections reflects the pathophysiology. Infections after a neurosurgical procedure are typically caused by either skin flora such as *Staphylococcus,* or healthcare–associated organisms such as *Pseudomonas* or Enterobacteriaceae. Infections that occur as a complication of upper respiratory tract infections are usually caused by streptococci, pneumococci, *Haemophilus,* anaerobes, and staphylococci. Gram-negative enteric bacilli or *P. aeruginosa* may be associated with middle ear and mastoid infections. As with cranial epidural abscess, surgical drainage is crucial for treatment, followed by prolonged administration of antibiotics.[207]

Spinal Paradural Abscess

The incidence of spinal epidural abscess has increased in the past two decades, which is likely related to improved diagnostics with MRI and increases in comorbidities predisposing to infection. Risk factors for spinal epidural abscess include prior spinal surgery or trauma, injection drug use, diabetes, and end-stage renal dysfunction.[210] Patients typically present with localized spinal pain, with fever present in less than 50% of cases.[211,212] In the absence of treatment, symptoms usually progress through four clinical phases: spinal ache, nerve root pain, radicular weakness, and paralysis. The triad of back pain, fever, and progressive neurologic deficits strongly suggests this syndrome; however, the presence of any of these signs or symptoms should raise concern for the diagnosis.

Diagnosis hinges on visualization of a collection in the epidural space (Fig. 114.3). The diagnostic study of choice is MRI with contrast, which defines cord compression and the presence and extent of abscess, identifies drainable paraspinal fluid collections, and detects concomitant vertebral osteomyelitis. Other procedures such as myelography and CT scan may be used if MRI cannot be performed.

S. aureus accounts for more than two-thirds of cases of epidural abscess.[211,213] Although most cases are community acquired, an increasing number are caused by spinal instrumentation (surgery or nerve block), and nosocomial flora, including *Pseudomonas,* may be causative in this population. Other risk factors for spinal epidural abscess include IV drug use, diabetes mellitus, trauma, and comorbid conditions such as malignancy or alcohol use.[211] *Candida* infections are increasingly reported as causes of spinal epidural abscess.[214] Empiric therapy is directed against the most likely organisms and typically includes vancomycin and an antipseudomonal agent such as cefepime, but when possible, should be delayed until surgical cultures are obtained. Therapy should be refined once cultures confirm a causative pathogen.

Emergency neurosurgical intervention is considered mandatory for a spinal paradural abscess when there is neurologic compromise. A retrospective study found that 41% of patients with a spinal epidural abscess failed medical therapy and that neurologic outcomes were improved for patients with immediate rather than delayed neurosurgical decompression.[215] Progressive weakness mandates the need for immediate MRI and neurosurgical consultation because decompression within 24 hours offers the best chance of neurologic recovery.[213]

SEPSIS SYNDROME WITH CENTRAL NERVOUS SYSTEM INVOLVEMENT

In sepsis syndrome, an acutely ill patient develops CNS dysfunction, often associated with multiorgan system failure. Altered mental status, attributable to hypotension and hypoperfusion, ranges from confusion to obtundation. Seizures may occur as a result of metabolic abnormalities, ischemia, or hemorrhage. In treating such patients, general supportive measures take precedence over CNS concerns. After a brief assessment, general life support measures should correct hypotension, hypoxia, and anuria. After blood culture, broad-spectrum antimicrobials should be administered. A careful history and physical examination may identify a primary source for infection. When findings suggest a focal infection of the CNS, directed evaluation through neuroimaging and lumbar puncture is warranted.

CONCLUSION

Acute infection of the CNS requires rapid therapeutic intervention. The major syndromes of CNS infection (acute meningitis syndrome, subacute CNS infection syndrome that includes brain abscess, viral meningitis and encephalitis, and spinal epidural abscess) differ with respect to signs and symptoms and in the approach to definitive diagnosis and therapy. Moreover, diverse infectious and noninfectious causes may produce similar CNS syndromes. For therapy to be maximally effective, it must be instituted rapidly after the initial evaluation. Thus in the practice of critical care medicine involving CNS disease, the goal remains the rapid institution of empiric therapy for treatable infectious syndromes while efficiently working to identify the specific disease process.

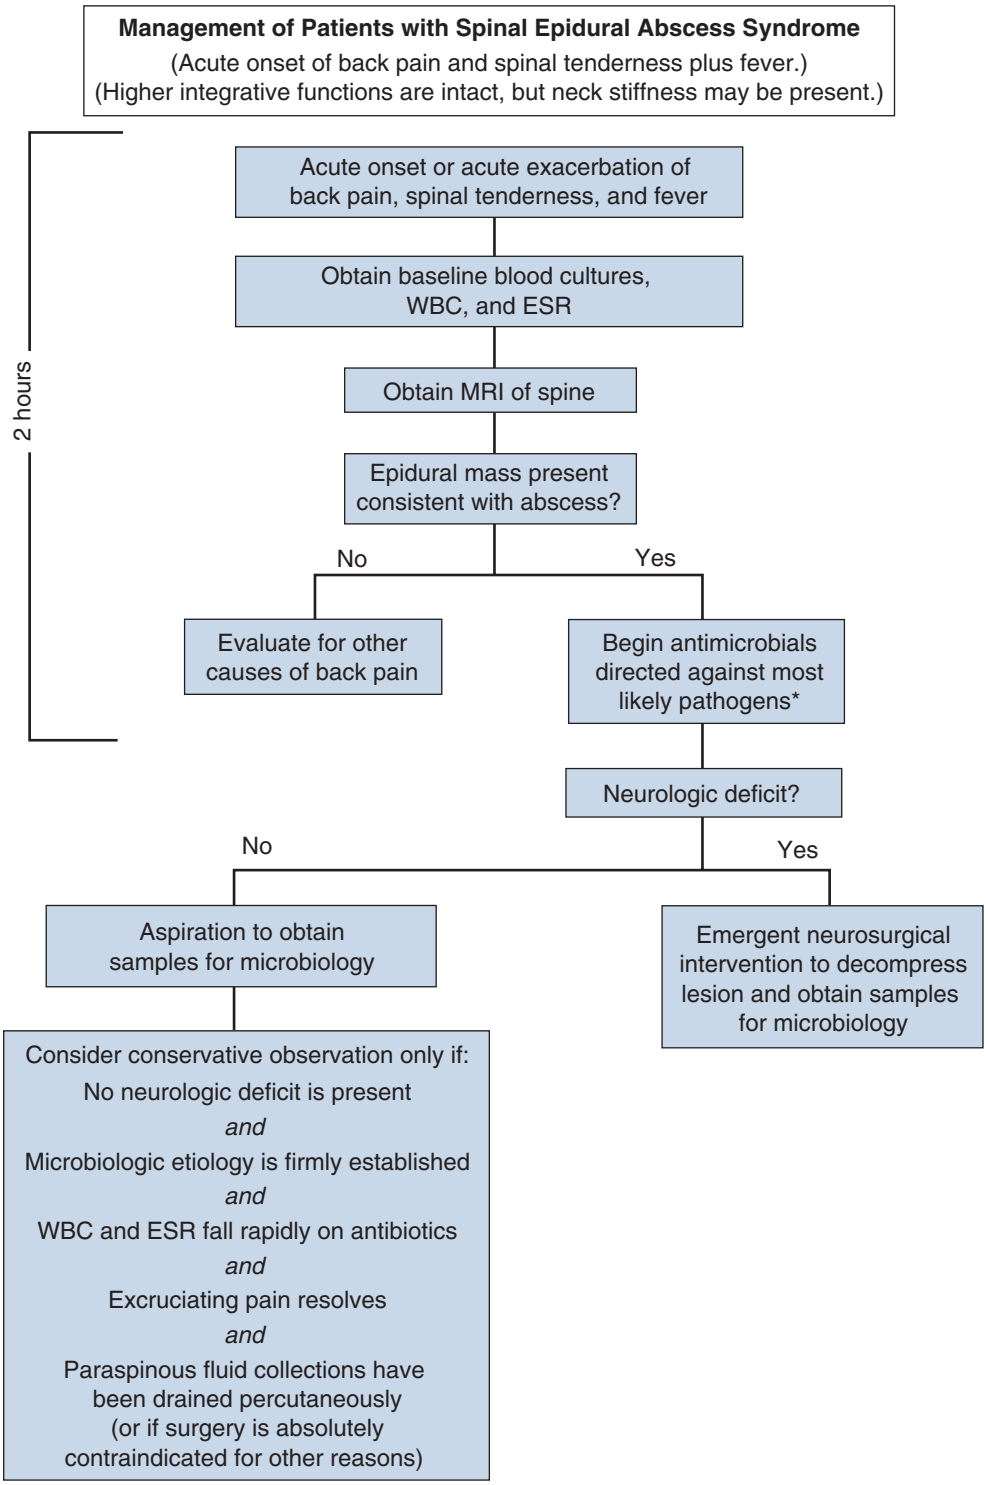

Fig. 114.3 Algorithm for the Management of Patients with Spinal Epidural Abscess Syndrome. If magnetic resonance imaging (*MRI*) cannot be performed, myelography, high-contrast computed tomography (CT), or CT myelography may be an acceptable alternative to localize an epidural abscess. *If abscess drainage can be performed promptly, antimicrobial drugs may be withheld until specimens for microbial analysis are obtained. *ESR,* Erythrocyte sedimentation rate; *WBC,* white blood cell.

KEY POINTS

Bacterial Meningitis

- For patients with bacterial meningitis, neuroimaging before lumbar puncture is associated with treatment delays and decreased yield of cultures and should be limited to patients with focal findings on neurologic examination, immunocompromise (HIV infection, malignancy, or transplant), new-onset seizures in the week prior to presentation, or coma.
- Empiric antibiotic therapy for bacterial meningitis includes vancomycin; a third-generation cephalosporin; and for patients at risk for *Listeria*, ampicillin and should begin as soon as possible after appropriate cultures have been obtained; these can be modified later based on results of CSF Gram stain and culture.
- Patients with negative microbiologic evaluation and limited clinical response after 48 hours of empiric therapy should undergo repeat lumbar puncture MRI scan.
- Adjuvant dexamethasone given within 4 hours of initiating antibiotics should be given to all non-neonatal patients with presumed bacterial meningitis and should be continued for patients with pneumococcal meningitis.

Brain Abscess

- Microbiology of brain abscesses is dependent on the route of infection; abscesses spreading from a contiguous focus (sinusitis, otitis) are frequently polymicrobial, and empiric therapy includes vancomycin, a third- or fourth-generation cephalosporin, and metronidazole.
- Treatment of brain abscesses typically requires neurosurgical drainage and prolonged administration of parenteral antibiotics tailored to culture results.

Encephalitis

- Although an infectious cause of encephalitis is found in less than 50% of cases, diagnostic evaluation to include HSV as either a stand-alone PCR or as part of a molecular diagnostic panel should be performed; other diagnostic testing should be guided by epidemiologic and clinical features.
- Autoimmune syndromes such as NMDAR encephalitis may mimic infectious etiologies but are treated with removal of the antigenic stimulus (i.e., surgical excision of a teratoma) and immunotherapy.

Central Nervous System Infection in HIV-Infected Patients

- HIV-infected patients may develop neurocognitive deficits related to HIV or from secondary infections, with the risk for opportunistic infections increasing inversely with declines in the CD4 count.
- Ring-enhancing lesions seen on neuroimaging are most frequently caused by either toxoplasmosis or lymphoma. In patients with positive *Toxoplasma* serology, empiric therapy for 2 weeks is indicated; brain biopsy should be performed in patients with lack of radiographic improvement.

Epidural Abscess

- Surgical drainage is imperative in patients with spinal epidural abscess and impaired neurologic function; there is little chance of recovery if symptoms have been present for more than 24 hours before decompression.

ANNOTATED REFERENCES

Brouwer MC, McIntyre P, Prasad K, et al. Corticosteroids for acute bacterial meningitis. *Cochrane Database Syst Rev*. 2013;6:CD004405.
This meta-analysis of 25 studies involving more than 4000 patients examined outcomes in patients with bacterial meningitis treated with corticosteroids in addition to antibiotics. There was no significant difference in mortality, hearing loss, or neurologic sequelae in patients treated with steroids. On subgroup analysis, adjuvant use of corticosteroids reduced mortality associated with S. pneumoniae *meningitis and hearing loss in children with* H. influenzae *meningitis. When the study was stratified by site, coadministration of corticosteroids in high-income (developed) countries was associated with statistically significant reduction in hearing loss and neurologic morbidity. There was no beneficial effect of corticosteroids in patients with bacterial meningitis in low-income countries.*

This comprehensive review provides updated information regarding the pathogenesis, epidemiology, clinical presentation, microbiology, and optimal treatment of brain abscesses. The authors emphasize the role of surgical management and highlight the increasing use of stereotactic biopsy as a less invasive means of identifying the causative organisms and providing therapeutic drainage.

Graus F, Titulaer MJ, Balu R, et al. A clinical approach to diagnosis of autoimmune encephalitis. *Lancet Neurol*. 2016;15(4):391–404.
In the past decade autoimmune disorders have been increasingly recognized as leading causes of encephalitis. These inflammatory etiologies may mimic infectious causes, but the treatment involves immunosuppressive medications rather than antimicrobial agents. This consensus statement by experts in the field of neuroimmunology provides an evidence-based strategy to guide diagnostic testing and identify a subset of patients most likely to benefit from empiric immunotherapy.

Kim SD, Melikian R, Ju KL, et al. Independent predictors of failure of nonoperative management of spinal epidural abscesses. *Spine J*. 2014;14(8):1673–1679.
This retrospective, case-control study compared outcomes among adult patients with nonsurgical spinal epidural abscess treated medically compared with those who underwent surgical decompression in addition to antibiotic therapy. Patients with neurologic compromise, age more than 65 years, diabetes mellitus, or infection caused by methicillin-resistant Staphylococcus aureus *had significantly higher rates of failure with solely medical management, and consideration of early surgical intervention in these populations is warranted.*

Thigpen MC, Whitney CG, Messonnier NE, et al. Bacterial meningitis in the United States, 1998-2007. *N Engl J Med*. 2011;364(21):2016–2025.
This paper summarized the results of a large population-based laboratory surveillance program for bacterial meningitis performed in selected areas in the United States between 1998 and 2007. During this period, there was a 31% overall decrease in the incidence of bacterial meningitis caused by declining rates of pediatric meningitis from S. pneumoniae *and* H. influenzae *as a result of vaccination. The median age of patients increased from 30.3 years to 41.9 years, with an aggregate case fatality rate of 14.8%.* S. pneumoniae *remained the leading cause of bacterial meningitis, accounting for 58% of cases.*

Venkatesan A, Tunkel AR, Bloch KC, et al. Case definitions, diagnostic algorithms, and priorities in encephalitis: Consensus statement of the international encephalitis consortium. *Clin Infect Dis*. 2013;57(8):1114–1128.
The authors provide expert consensus recommendations on a working case definition for encephalitis and outline diagnostic algorithms for both pediatric and adult patients with encephalitis. These protocols were developed to include the most prevalent pathogens and to optimize empiric therapy of treatment etiologies. Clinicians are encouraged to pursue additional diagnostic testing based on local epidemiology, seasonality, specific exposures, or clinical characteristics.

Infections of Skin, Muscle, and Necrotizing Soft Tissue Infections

Rebecca Maine and Eileen M. Bulger

Infections are a leading cause of admission to intensive care units (ICUs). Skin and soft tissue infections (SSTIs) are both the primary cause of admission to the ICU and a complication that develops for patients with other critical illnesses.[1] A large database review in the United Kingdom found that skin infections comprised less than 1% of all ICU admissions.[2] Prompt recognition, diagnosis, and treatment of SSTIs are lifesaving, especially for patients with necrotizing soft tissue infections (NSTIs).[3,4] Appropriate care for SSTIs in the critically ill often requires intensivists to collaborate with surgeons and/or interventional radiologists to achieve source control for the infection. The most common types of SSTIs routinely treated by intensivists include cellulitis, NSTIs, infected wounds including burn wounds and decubitus ulcers, and, more rarely, myositis. Severe infections of the head and neck are also common in critically ill patients but are discussed in greater depth in Chapter 116. This chapter reviews the epidemiology and diagnostic and management recommendations for these infections commonly encountered in the ICU.

CELLULITIS

Cellulitis, a common bacterial infection, occurs at a rate of more than 4 per 100 people per year in the United States.[3] Many episodes of cellulitis are minor, caused by *Staphylococcus* or *Streptococcus* spp., and arise from breakdown of the skin barrier in the interdigit space or after trauma.[5,6] Cellulitis accounts for up to 10% of hospital admissions,[6] but many fewer ICU admissions.[1] Cellulitis was the primary source of sepsis in <1% of patients in a Dutch study of ICU admissions for sepsis, and only 2.5% of all patients hospitalized for cellulitis typically require ICU admission.[1] Skin was the source of approximately 4% of infections that developed 48 hours after ICU admission; however, 0.07% of the patients who remained in the ICU for more than 48 hours developed a skin infection.[7] Predisposing factors for the development of cellulitis include obesity, diabetes mellitus, alcoholism, immunosuppression, and venous insufficiency.[6] Poor hygiene and fragile skin barrier can increase the risk of introducing bacterial pathogens.[6]

Diagnosis

Cellulitis is primarily a clinical diagnosis. Inflammation of the reticular dermis and hypodermis results in the typical findings: heat, pain, swelling, and redness in the affected region.[6] The lower extremities are most commonly affected: 70%–80% of cases.[6] Additional clinical markers include leukocytosis and elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), though the absence of inflammatory markers does not exclude a diagnosis of cellulitis.[6] Cellulitis can be associated with abscesses.[6] When possible, purulent material should be cultured to guide antibiotic therapy, but initiation of antimicrobials targeted at common gram-positive organisms or broad-spectrum antibiotics if the patient is in a high-risk group (see later) need not be delayed for culture results. Imaging is not necessary for all patients with cellulitis. However, ultrasonography, computed tomography (CT), and/or magnetic resonance imaging (MRI) may identify organized collections that require surgical intervention. In 606 episodes of cellulitis, just under half had imaging (46%), and of those 60 (22%) had purulent collection that was not detected on physical examination.[8] Blood cultures are not recommended for all patients with cellulitis, but are indicated for those with signs of systemic inflammation, sepsis, and for neutropenic and immunocompromised patients.[5]

Microbiology

The most common organisms responsible for cellulitis include *Streptococcus pyogenes* and *Staphylococcus aureus,* which cause approximately three-quarters of the infections in which a causative organism is identified.[8] Different causative organisms can be seen, however, in different patient populations (Table 115.1). Purulent cellulitis is most commonly associated with staphylococcal infections, with high rates of rates of methicillin-resistant *S. aureus* (MRSA), even in community-acquired infections in many areas.[6]

Treatment

The cornerstone to cellulitis treatment includes early and appropriate initiation of antibiotic therapy and identification and surgical drainage of any purulent collections. Although some studies suggest that simple cellulitis is cured in over 90% of patients without MRSA coverage, even in areas with high MRSA prevalence,[5] patients with severe cellulitis with associated signs of systemic infection should have empiric antibiotic coverage for MRSA. This is especially true for patients with evidence of prior MRSA colonization or positive nasal swab, purulent drainage, a history of injection drug use, or recent penetrating trauma.[5] If the patient is in a high-risk group, as outlined in Table 115.1, broad-spectrum antibiotic therapy is appropriate while awaiting culture results.[5] Local community and hospital resistance profiles are also important in guiding initial therapy selection. The addition of empiric gram-negative and/or anaerobic therapy is appropriate in certain patient populations, including patients with severe infections, neutropenia, on chemotherapy, cell-mediated immunodeficiency, immersion injuries and/or animal bites, diabetes, and pelvic lymph node dissections, patients who are immunocompromised, or in children.[5,6]

The duration of antibiotics depends on patient factors and the severity of systemic infection. For the patients treated by intensivists, intravenous antibiotic therapy for at least 5 days is appropriate; however, patients whose symptoms fail to resolve should receive a longer duration, with up to 14 days of treatment reported in several studies.[5,8] Failure of initial antibiotic therapy or relapse of cellulitis occurs in up to 8%–20% of lower extremity infections.[5]

TABLE 115.1 Common Infectious Organisms in Specific Patient Populations

Patient Population	Organism
Diabetics with chronic ulcers[1]	Anaerobes; gram negatives
Post–pelvic lymph node dissection[1]	*Streptococcus agalactiae*
Immunocompromised*[1]	Gram negatives, including *Vibrio vulnificus*[2] in endemic areas, *Streptococcus pneumoniae,* and *Cryptococcus neoformans*
Chronic liver disease[1]	
Nephrotic syndrome[1]	
Rheumatologic disease[1]	
After dog/cat bite[1]	*Capnocytophaga canimorsus, Pasteurella multocida*
After human bite[1]	*Eikenella corrodens*
Tropical region with exposure to shellfish[1]	*Vibrio vulnificus*
Fresh water or contact with leeches[1]	*Aeromonas* spp.
Exposure to raw meat or fish[1]	*Erysipelothrix rhusiopathiae*

Surgical incision and drainage of purulent collections and/or aspiration and placement of drains into large fluid collections is necessary for purulent cellulitis.[5] Although the majority of collections are noted on examination (65%), some deeper collections may require imaging. If a patient does not respond to initial therapy, the intensivist should consider the presence of a deeper abscess and proceed with imaging. Aspiration and/or serial evaluation may be appropriate for abscesses that are small (<1.5 cm) or associated with high morbidity with open surgical drainage. However, in a study of cutaneous abscesses without surrounding cellulitis, aspiration alone only resolved 25% of a patient's symptoms, regardless of size.[5,9]

Outcome

Mortality and outcomes after cellulitis vary greatly and are driven by the severity of infection and the patient's comorbidities. In a large series of patients admitted to Spanish hospitals with cellulitis, 3% of patients died, but only 28% of the deaths were related to cellulitis.[8] A recent meta-analysis of hospitalized patients with cellulitis estimated the overall in-hospital mortality rate to be 1%.[10] In patients with severe cellulitis without a necrotizing component, however, mortality rates approach 20%–40%.[1] Recurrence of infections occurs in up to one in five patients with lower extremity cellulitis.[5]

NECROTIZING SOFT TISSUE INFECTIONS

Though rare, the incidence of NSTIs appears to be increasing.[11,12] Previous estimates in the United States suggested the rate to be 4 per 100,000 persons/year; however, a study published in 2020 reported 8.7–10 per 100,000/year.[3,13,14] This is much higher than the rates reported in France at 3.6 per 100,000/year[15] and in New Zealand at 0.3 per 100,000/person/year.[16] Given the lack of consistent data collection, information regarding trends in national incidence rates is not available in most countries. In some studies, the rates of infection and mortality are higher among certain ethnic groups,[16–18] though this has not been extensively evaluated. Whereas historical mortality was as high as 70% in some series, modern mortality approaches 10%–20%, likely because of an emphasis on early surgical débridement, broad-spectrum antibiotic therapy, and advances in critical care.[17,19–21] Especially for patients with systemic symptoms, a high index of suspicion for NSTI is needed to facilitate early surgical consultation and débridement and potential transfer to a tertiary care facility.

NSTIs are most frequently classified by their causative organisms. Type I are polymicrobial, which included anaerobes in up to one-third of patients.[22] Type II infections are monomicrobial, typically caused by group A streptococcus (GAS) (30%),[22] *Clostridia* spp., or MRSA.[4,19,23–25] Different definitions of type III are in the literature. Most commonly, type III infections refer to gram-negative infections associated with aquatic organisms such as *Aeromonas* or *Vibrio* spp.[13,19,26]; however, some authors use this term to include monomicrobial gram-negative infections[11] and clostridial gas-forming infections.[27] Type IV infections are rare and caused by yeast, typically *Candida* spp.[19,27]

Diagnosis

Early diagnosis of NSTI is essential, as initial débridement is required within hours of seeking care to decrease the risk of mortality.[3,25,27–29] Distinguishing severe cellulitis from NSTI is challenging.[13] Misdiagnoses occur in up to 75% of NSTIs,[30] and in some large series diagnoses were delayed in 100% of patients.[31] Patients presenting early in their disease process may have skin findings that are consistent with simple cellulitis because the cutaneous manifestations of the underlying fascial necrosis have not yet manifested or may be very subtle (Fig. 115.1).[27,32] In patients with chronic wounds, distinguishing the progression of NSTI is even more challenging.[27,33] Although NSTI usually presents in one anatomic location, there have been reports of multifocal NSTI.[34,35]

Given the challenge in diagnosis, several studies have tried to determine which clinical features can distinguish severe cellulitis from NSTI. Crepitus from gas-producing organisms is a concerning finding for NSTI, but it will be present in only 10% of NSTI patients.[22] The most common signs of NSTI in a 2014 systematic review of 1463 patients were swelling (81%) and pain (79%).[30] In other studies, however, swelling was only 70% sensitive and 5% specific to distinguish NSTI from cellulitis.[3] Additional skin findings that should raise concern for NSTI include woody induration of the skin, skin sloughing or blistering, and cutaneous gangrene (Fig. 115.2). Pain out of proportion to examination should also be a very concerning sign for necrotizing infection.[3,31,36] Laboratory values have also been evaluated to distinguish patients with a necrotizing component. An ICU-based sepsis study found no difference in admission CRP, white blood cell (WBC) count, creatinine, or lactate between 23 patients with severe cellulitis and 31 NSTI patients, though the NSTI group had higher rates of organ dysfunction and sepsis.[1] Other groups have found erythrocyte counts, fibrinogen levels, pain on examination, and clinical evidence of renal failure helped to distinguish between cellulitis and NSTI.[31]

Several authors have developed scoring systems to distinguish cellulitis from an NSTI by combining different symptoms, signs, and laboratory values. Wong and colleagues' Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score based on WBC, creatinine, sodium, hemoglobin, glucose and CRP,[37] has been the most studied, with the predictive values of scores of ≥6 (high risk) or ≥8 (very high risk) that range in sensitivity (42%–92%) and specificity (63%–78%).[32,37–41] Given this range of performance, other scores have been developed. Cribb and colleagues developed the SIARI score. This score combines six data derived variables: (1) **s**ite other than lower limb (2) **i**mmunosuppression, (3) **a**ge ≤ 60 years, (4) **r**enal impairment and (5/6) **i**nflammatory markers (i.e. WBC, CRP).[39] In their recent 300-patient cohort, their SIARI score outperformed the LRINEC score in both sensitivity (81% vs. 59%) and specificity (73% vs. 64%).[39] Alayed and colleagues considered several factors, including clinical findings (hemorrhagic bullae, pain out of proportion, necrotic skin, progressive erythema, and fluctuance), markers of

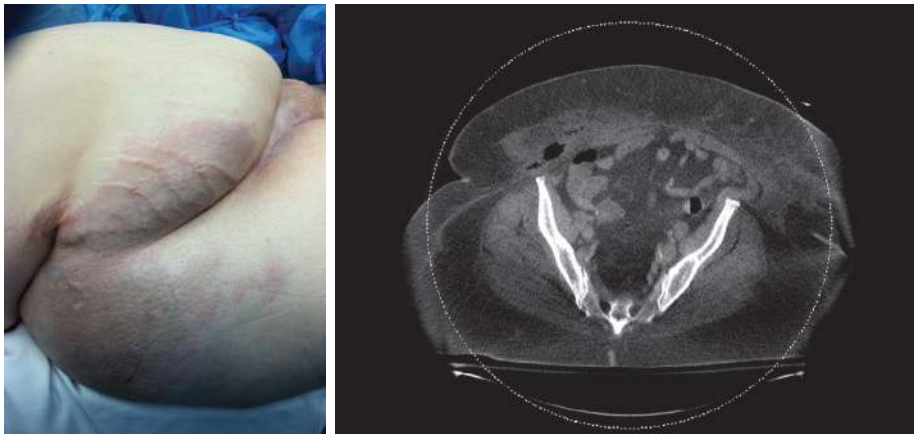

Fig. 115.1 A 45-year-old woman with a history of diabetes presents with diabetic ketoacidosis, pain in the right flank, and mild discoloration of the skin. She developed worsening septic shock over the next 24 hours, and an abdominal computed tomography (CT) scan showed gas in the deep tissues of the abdominal wall. The patient went on to extensive débridement for necrotizing soft tissue infection. This case illustrates the subtle nature of the early skin findings that often result in delays in diagnosis.

Fig. 115.2 Images from two patients with NSTI showing skin manifestations, including skin sloughing/blistering and cutaneous gangrene.

sepsis (hypotension and altered sensorium), history of surgery in the prior 90 days, and recent diarrhea. They found that patients with at least three of these findings were virtually guaranteed to have an NSTI.[3] Although scoring systems may be helpful to raise the index of suspicion, there should be a low threshold for surgical evaluation of underlying tissue if NSTI is considered possible.

Imaging

The role of imaging (e.g., ultrasound, MRI, CT, and plain x-ray) in diagnosing NSTIs has been evaluated in many studies.[30,42–45] MRI is likely the most precise,[22] and MRI findings combined with LRINEC have improved the ability to predict an NSTI.[41] However, when there is a concern for NSTI, MRI and other imaging modalities should not delay early surgical exploration and débridement, especially for patients with symptoms of sepsis.[3,5,13,46]

Imaging showing gas in the soft tissues (see Fig. 115.1), much like crepitus on examination, conveys a high likelihood of NSTI, but its absence does not rule out NSTI.[3,42] Other CT scan findings associated with NSTI are lack of contrast enhancement of tissue, multiple fluid collections, and subfascial inflammation.[28] Fluid collections deeper than 2–4 mm have had an increased association with NSTI.[43] Other ultrasound findings can include thickening of the fascia and emphysema in the tissues.[43] Imaging may also be considered in truncal NSTI to evaluate for an underlying source of intraabdominal infection presenting as an NSTI.

Operative Exploration

Those evaluating severe SSTIs should maintain a high index of suspicion for NSTI, especially when the severity of illness is not consistent with the physical examination findings, and ensure early surgical consultation. Early surgical consultation facilitates wound exploration to confirm the diagnosis and to debride affected tissue as quickly as possible.[3,4,19,30] At the time of exploration, clinical findings that are associated with an NSTI include thin, foul-smelling dishwasher fluid; fascial sliding; purulence; thrombosed vessels; failure of the muscle to respond to electric stimulation; and necrotic tissue at any layer, including skin, subcutaneous, fascia, or muscle.[13,19,30,47] Tissue cultures and samples of any purulent collections should be sent at the time of initial débridement to guide subsequent narrowing of antimicrobial therapy, but sampling error can lead to false negatives on pathologic evaluation and should not be the only diagnostic consideration.[13]

Bacteriology

Both monomicrobial (type II) and polymicrobial (type I) infections are seen in NSTI. Classically, type II NSTI infections are *Clostridium* and *Streptococcus,* causing gas gangrene and toxic shock syndrome,

respectively.[22] Toxic shock syndrome is reported in up to half of GAS-related NSTIs, but can also be seen in NSTI caused by *S. aureus* infections.[13,19] In certain regions, MRSA and marine organisms, like *Vibrio* spp., *Aeromonas* spp., and *Shewanella* spp., contribute to monomicrobial NSTI as well.[19,30] However, several different organisms have been associated with NSTI, especially in type I infections.[19,30,48] Bacteremia occurs in up to 27% of patients,[48] and in some studies was associated with increased mortality.[23] Failure of cultures to identify an organism is also common in NSTI; in some studies no organisms are identified on cultures in up to one-third of patients.[30,36,49] These negative cultures are likely the result of both initiation of antibiotics before débridement and difficulty in culturing anaerobic organisms.

Treatment

There are two cornerstones to treatment of NSTIs: early, appropriate antibiotic therapy and early complete surgical débridement,[5,13,19,30,48,50] in addition to supportive care for physiologic derangements from shock.[19,29,48] For NSTI, intravenous broad-spectrum antibiotic therapy should be initiated as quickly as possible to cover the range of causative organisms, which includes gram-positive cocci, gram-negative rods, and anaerobes.[19,48] An empiric drug regimen should include penicillin for GAS, clindamycin to cover both GAS and *Clostridium* spp., MRSA coverage, and gram-negative coverage (Table 115.2).[48] In the United States, both clindamycin and penicillin are recommended to address local resistance patterns in GAS and for the beneficial effect of clindamycin on reducing toxin production.[13,31,34] Therapy should be narrowed based on the results of intraoperative cultures once the patient is improving (Table 115.3),[13,31,48] though these may not be positive for up to one-third of patients,[30,48] especially if only culture swab material is processed, rather than tissue samples.[19] Empiric coverage with antifungal agents is not generally indicated, though it should be added if fungal elements are present in tissue or blood cultures.[13] Although erythromycin resistance in GAS has been described for decades, recent clindamycin resistance has emerged as well in up to 35% of isolates in some settings.[25] Clindamycin resistance is also emerging in clostridial species.[25] Studies in mouse models support the use of oxazolidinones (linezolid and tedizolid) as first-line treatment of severe GAS infections in the setting of increased resistance, as they provide similar RNA inhibition to reduce toxin production as clindamycin.[51] The optimal duration of antibiotic therapy has not been defined, and courses of antibiotic therapy in different studies range from 5 to 16 days or more.[19,20,34,48] Antimicrobial therapy should continue until there is no further need for surgical débridement, systemic symptoms have resolved, and infectious markers are improving.[19]

TABLE 115.2 Empiric Antibiotic Regimens for NSTI Before Culture Results

NSTI Type	Antibiotics
Unspecified NSTI	Penicillin, clindamycin*, vancomycin, and levofloxacin
Fournier gangrene or diabetic foot	Piperacillin/tazobactam, clindamycin, and vancomycin
NSTI with penicillin allergy	Aztreonam, clindamycin, ciprofloxacin, and vancomycin
Suspected *Vibrio vulnificus* or *Aeromonas* spp.	Add doxycycline

GAS, Group A streptococcus; *NSTI*, necrotizing soft tissue infection.
*If high rates of clindamycin resistance are observed with GAS, consider linezolid.

TABLE 115.3 Antibiotic Regimen for NSTI Based on Culture Results

Streptococcus pyogenes	Penicillin and clindamycin*
Clostridial species	Penicillin and clindamycin
Vibrio vulnificus	Doxycycline and ceftazidime
Aeromonas hydrophila	Doxycycline and ciprofloxacin
Methicillin-resistant *Staphylococcus aureus*	Vancomycin
Polymicrobial	Vancomycin and piperacillin/tazobactam

NSTI, Necrotizing soft tissue infection.
*If high rates of clindamycin resistance are observed with GAS, consider linezolid.

Operative Débridement and the Skin-Sparing Approach

Early débridement has been recognized as a key factor in the treatment of NSTI and has been associated with decreased rates of mortality from NSTI in modern times.[4,15,20,48] Initial débridement of all necrotic tissue should occur as soon as possible; guidelines recommend within 6–12 hours of presentation.[4,52] Although débridement as quickly as possible is essential, studies conflict about whether or not débridement must occur before transfer from the presenting facility.[53] Study results vary regarding whether débridement before transfer improves survival[15,36] and likely depends on the rapidity of transfer and available resources within the transferring and receiving hospitals. Physicians referring patients to tertiary centers should communicate directly with the receiving surgeon and intensivist to determine the optimal location of débridement, with pretransfer débridement strongly recommended for patients with severe sepsis and/or prolonged transport time.

The initial approach to débridement, wherever it occurs, must remove all infected and necrotic tissue, and the traditional wide débridement included the skin overlying deeper infected tissue, even if the skin was not necrotic.[52,54] This can result in large soft tissue defects. However, for many patients with NSTI, the skin is not as extensively involved as the deeper tissues and does not need to be completely resected to clear infected tissues.[52,54] Recent studies have described success treating patients with skin-sparing approaches that employ perforator-sparing incisions and the elevation of skin flaps, with complete débridement of underlying infected tissues.[54–57] This approach was found to decrease the need for wound grafting without increasing mortality at one high-volume center.[57] Although healthy flaps should be preserved if possible, all necrotic skin should be debrided, and surgeons should also not hesitate to perform amputations as necessary to achieve source control in patients with severe physiologic derangements and/or rapidly progressive extremity infections. Amputation rates range from 10% to 30%.[15,17,20,35,58,59]

Postoperative Care

The complex care needs of patients with NSTIs often involves postoperative critical care, extensive wound care, multiple reoperations, reconstruction, and rehabilitation. Thus transfer to tertiary facilities is frequently appropriate and comprises up to 81% of NSTI patients in some centers.[20,36,60] Treatment at a high-volume center, especially those with capacity for rapid surgical débridement and ongoing complex wound care, has been associated with improved survival in some studies.[15] Given a high frequency of systemic symptoms (76%),[31] sepsis (21.1%–69%),[30,31] and septic shock (32.9%)[49] in patients with NSTI, intensive care is frequently needed.[29,47,49] The percentage of patients who require intensive care varies globally, with rates at some centers as low as 43% and others as high as 98%.[3,12,15,17,49,59,61] Endothelial damage, intravascular hemolysis, and cardiomyopathy can develop as a result of both toxins from infectious bacterial like *Streptococcus* and *Clostridium* and the host inflammatory response to infection.[25]

Comorbidities are common in NSTI patients and occur in up to 92% of patients.[20] Type 1 and 2 diabetes is common in NSTI, with prevalence in studies ranging from 24% to 55%.[12,15,20,22,29,30,32,35,48–50,59,62–65] Alcohol and drug abuse, tobacco use, obesity, cardiovascular disease, liver disease, and respiratory diseases are also common.[12,17,20,22,48–50,65] Intensivists must be aware of the high rates of comorbidities and their increased risk for mortality to adjust management and counsel patients and families.

Most NSTI patients will require wound care, often for extensive soft tissue defects, in addition to critical care, both areas of expertise for burn centers. Regionalization of care, especially for large-area débridement, to burn centers has been associated with successful reconstructions and rehabilitation and reduced costs.[66] An analysis of administrative data regarding NSTI treatment at burn versus nonburn centers demonstrated a higher rate of mortality at burn centers, but likely because sicker patients are transferred to these centers for care.[67] More work is needed to define the optimal definitive treatment location for NSTI patients.

Initial postoperative dressings should facilitate frequent bedside wound assessments to determine if early re-débridement is needed. Gauze soaked in either saline or quarter-strength Dakin's solution is preferred to early wound vac therapy, which can hinder frequent wound assessments and may increase the risk of undetected progression of necrosis. At a minimum, early planned re-exploration after initial débridement within 12–24 hours is recommended.[58] Once no significant débridement is required at serial exploration, wound vac therapy can be initiated to decrease the frequency of dressing changes, and therefore reduced pain for patients, while helping prepare the wound bed for closure by stimulating granulation tissue.

Adjuvant Therapies

Several adjuvant therapies have been evaluated especially for patients with severe systemic illness or a failure to respond to initial therapy. These include hyperbaric oxygen therapy, intravenous immunoglobin G (IVIg), and a novel peptide that mediates CD28 receptor activation by superantigens (Reltecimod, aka AB103).[13,47,64] Few randomized controlled trials have evaluated these therapies, limited in part by the rarity of NSTI.[34]

Hyperbaric oxygen therapy is proposed to be beneficial by increasing tissue oxygen levels to kill anaerobic organisms, which are responsible for 7%–18% of NSTIs.[34] A recent discharge database study found hyperbaric oxygen was used in less than 1% of patients with NSTI.[68] Although in some small case series and retrospective analyses hyperbaric oxygen therapy was associated with decreased mortality,[61,68,69] others have found no difference in mortality.[70,71] Currently, no randomized controlled trials have evaluated the impact of hyperbaric oxygen therapy on NSTI outcomes, and hyperbaric oxygen therapy is not recommended as an essential intervention in current guidelines.[52]

Pooled IVIg infusions have been suggested for patients with severe systemic symptoms or persistent inflammatory response, as they could potentially bind toxins associated with severe GAS and *Staphylococcus* infections.[19,72–74] Although observational trials suggested benefit, randomized controlled trials and propensity-adjusted analysis did not confirm a mortality benefit.[34,72–74] However, for patients with toxic shock syndrome, IVIg infusions for 3 days did shorten the duration of organ failure.[74] Consideration of IVIg for patients with GAS infections causing NSTI is included in recent guidelines, which note that there is no clear mortality benefit.[52]

In 2014 investigators published the results of a phase IIa safety trial of a novel peptide (AB103) that targets the superantigen binding site, CD28, on T cells. They found the drug decreased Modified Sequential Organ Failure Assessment (mSOFA) scores at 2 weeks compared with placebo and was associated with lower levels of most tested cytokines.[64] In the recently completed phase III multicenter randomized controlled trial, the composite outcome (alive at 28 days, no amputation after first operation, <3 débridements by day 14, mSOFA ≤1 at day 14, mSOFA with reduction of ≥3 points) was achieved by 54.3% of patients who received the medication compared with 40.3% of patients in the placebo in the per protocol analysis, and patients receiving reltecimod had significant reductions in prolonged organ dysfunction and a more favorable discharge disposition.[75] This experimental drug is currently under review by the US Food and Drug Administration.

Outcomes

Although historical mortality in a series of patients with NSTI was as high as 70%,[65] in most recent series, the mortality rate for hospitalized patients with NSTI is 10%–20%,[20,23,48,67] though in critically ill patients mortality may be as high as 50%.[15]

Several authors have evaluated predictors of mortality in NSTI patients.[15,48,50,58,62,65,76,77] Although a primary driver of mortality appears to be related to underlying physiology, patient factors, management factors, and infection characteristics have been studied. Several measures of physiologic derangement have been associated with mortality after NSTI, including APACHE scores, SOFA scores, sepsis or septic shock, or need for ICU admission.[15,47,49,61,62,78] Patient factors associated with mortality include older age[15,50,58,65,76,77]; increasing number of comorbidities,[65] including poor renal function or underlying renal disease,[47,58,76,77] liver disease, cardiovascular diseases like heart failure or peripheral vascular disease,[78] cancer or other immunosuppression; and intravenous drug use[21,30,35,58–60] A mortality calculator recently developed using an NSTI cohort in the National Surgical Quality Improvement Program (NSQIP) includes age, prehospital functional status, need for dialysis, high American Society of Anesthesiologists (ASA) class, thrombocytopenia, emergency operation, and septic shock, with an area under the curve (AUC) of 0.83.[21] Infection characteristics associated with NSTI mortality include bacteremia,[48] gram-negative infections including *Vibrio* spp.,[26,49] elevated lactate levels,[48,59] and clostridial infection.[77] Delays in débridement have also been associated with increased mortality. Patients treated for NSTI remain at increased risk of mortality from all causes, including infectious causes, for several years after their NSTI treatment.[65]

Morbidity after NSTI can be quite high.[15] Initial mSOFA scores ≥2 were associated with several worse clinical outcomes in one prospective, multicenter trial, including fewer ventilator-free and ICU-free days and more débridements.[47] Given the need for significant soft tissue débridement, including amputation, these factors can have a significant impact on daily function, including sexual function.[15,78–80] Quality-of-life measures are often decreased after NSTI as well.[78,80–82] When compared with a reference population, German patients after NSTI had significantly decreased physical function and health and high rates of sexual dysfunction (65%), and many required ongoing pain treatment and assistive devices.[80] Studies of long-term outcomes after NSTI are limited, and more work is needed to develop strategies to improve recovery.

PYOMYOSITIS

Pyomyositis can present as a severe progression of cellulitis or as a component of NSTI; however, some patients present with severe chronic infections associated with the muscle without evidence of necrosis and rapid progression.[83,84] Infectious myositis caused by infection with fungus, bacteria, or parasites can be acute, subacute, or chronic.[84] It is a disease more frequently described in the tropics and in children.[84] It can have a multifocal appearance, especially when caused by bacteria.[84] By definition, in pyomyositis, the muscle infection arises from hematogenous spread of the organism. Myositis is rare because

muscles are resistant to infection, with <0.5% of cases of bacteremia developing myositis. Risk factors include trauma, ischemia, or other immunosuppressive condition that increase host susceptibility.[84] Intramuscular hematomas and tissue damage from trauma can create a substrate for the development of bacterial myositis.[84] It is postulated that to develop myositis, muscle injury, whether from trauma or overuse, must be paired with an integumentary break to allow transient bacteremia.[84]

Diagnosis

Infectious myositis typically presents with a leukocytosis and left shift and without an elevation in creatine kinase, except for the approximately one-fifth of patients with pyomyositis who are immunosuppressed from human immunodeficiency virus (HIV).[84] The most common location is in the large muscles of the lower extremities; however, in 10%–20% of cases there is diffuse rather than isolated muscle involvement.[84] Blood cultures are positive in only 5%–35% of patients.[84]

Imaging plays an important role in pyomyositis. Although plain x-rays may suggest muscle edema, CT, ultrasound, and MRI are more sensitive, with MRI being the most precise and thus recommended modality for diagnosis.[5,84] The Infectious Diseases Society of America (IDSA) recommends MRI to establish the diagnosis of pyomyositis.[5] If the muscle infection is diagnosed before developing a purulent collection, antibiotic therapy alone will suffice. Once a collection has developed, open or closed surgical drainage is needed in addition to antimicrobial therapy.[5] Blood and tissue cultures to identify causative organisms should be sent in patients with pyomyositis to narrow antibiotic therapy.[5,84]

Bacteriology

The primary mechanism underlying pyomyositis is the hematogenous spread of bacteria, often from transient bacteremia, to an area at risk in a muscle.[83] Hematogenous spread usually arises from staphylococcal infections, whereas pyomyositis after puncture wounds is typically polymicrobial in nature.[83,84] Typical bacteria in myositis include *S. aureus, Streptococcus* (A, B, C, and G), Enterobacteriaceae, *Yersinia enterocolitica, Pseudomonas, Aeromonas, Clostridium, Peptostreptococcus,* and *Bacteroides* spp.[85] In tropical areas, *S. aureus* causes approximately 95% of pyomyositis infections, whereas it causes about 70% of cases of myositis in high-income countries.[83,84] Immunosuppressed patients are at increased risk of infection with gram-negative organisms and/or polymicrobial infections. In some regions, amoebic infections, with associated eosinophilia, are also common.[83]

Treatment

Intravenous antibiotics are used initially, often for the first week, with a course of 2–6 additional weeks of oral antibiotics after adequate drainage and fever resolution.[5,83,84] Antimicrobial therapy should be accompanied by early surgical evacuation of purulent material.[5] Vancomycin is recommended for empiric coverage, with the addition of gram-negative coverage for patients who are immunocompromised or have had recent trauma that resulted in the pyomyositis.[5] When methicillin-sensitive *S. aureus* (MSSA) infection is confirmed from cultures, cefazolin or anti-staphylococcus penicillins (i.e., oxacillin or nafcillin) are the most appropriate antibiotic choice.[5] For patients with associated muscle necrosis, the addition of clindamycin is appropriate (see earlier for a discussion of NSTIs).

The identification of fluid collections on imaging should prompt surgical consultation to determine whether open or closed drainage of the fluid collections is most appropriate. Loculated fluid collections and deep multifocal collections can pose particular challenges.[84] When there is minimal systemic illness, a conservative and serial approach to drainage may be appropriate.

BURN WOUNDS

Epidemiology and Diagnosis

Given the severity of illness and inflammatory response that can accompany a large body surface area burn, the management of burn patients is frequently led by intensivists. With large areas of disrupted skin and local ischemia, burn patients are at high risk for infections and colonization of their wounds.[86] Distinguishing between active infection and colonization and determining when additional antibiotic therapy may be appropriate is a challenge for the burn physician. Infection and sepsis are the leading causes of mortality (~55%) for patients with burn injuries, with sepsis affecting 3%–30% of patients with a burn that affects ≥20% of their total body surface area (TBSA).[86] In a comparison of guidelines to diagnose sepsis in the background of an inflammatory response, the Sepsis-3 criteria outperformed burn-specific guidelines from the American Burn Association and markers proposed by Mann-Salinas in 2013.[86]

Burn wounds and eschar are frequently colonized with bacteria, making the discrimination between colonization and infection challenging. Wound biopsies, especially in the setting of wound purulence and loss of graft material, with bacterial counts 10^5 are consistent with burn wound infections, and systemic antimicrobial therapy is appropriate.[87] Systemic therapy must be accompanied by aggressive débridement and excision.[87]

Bacteria

Gram-positive bacteria colonize burn wounds early after injury, with gram-negative organisms becoming more common over time.[86]

Treatment

Although wound cultures should be used to guide the ultimate antibiotic selection, coverage of *Streptococcus* and *Staphylococcus* for early infections after burns, with the addition of third-generation cephalosporins for gram-negative coverage, including coverage of resistant *Staphylococcus* and *Pseudomonas,* should start 5 days after injury.[86] Although many topical agents used for initial burn wound care have antimicrobial properties, including silver sulfadine and silver nitrate dressings, there is no role for systemic antibiotics in burn care in the absence of a wound infection.[86] Controversy exists over the role of selective gut decontamination for thermally injured patients.[86] Whereas some studies reported decreased mortality in patients with >20% TBSA, others have shown no benefit in decreasing inflammatory response.[86]

PRESSURE ULCERS

Pressure ulcers are a frequent complication of ICU care, especially for elderly, malnourished patients whose mobility is restricted in the setting of chronic and/or critical illness. Hospital prevalence rates range from 3% to 11%.[88] Although infections and the presence of necrotic tissue in these wounds are not uncommon, severe infections are rare.[89] A large prospective observational study identified only 1.7 episodes of pressure ulcer–associated bacteremia per 10,000 hospital discharges.[88]

As in burn wounds, the diagnosis of serious infection such as sepsis or NSTI is challenging.[89] Studies that have evaluated different signs and symptoms have not identified characteristics with high sensitivity and/or specificity for infections in pressure ulcers. Pain and tenderness in the wound increases the likelihood of active infection.[33] Many

patients who develop NSTI in their pressure ulcers do not have an elevated LRINEC score.[89]

Bacteria

The most common pathogens associated with pressure ulcer infections include mixed gram-positive and gram-negative bacteria.[88,89] Both aerobic and anaerobic species are common. *S. aureus, Enterococcus faecalis, Corynebacterium,* group B streptococcus, *Bacteroides,* and *Peptostreptococcus* were the most commonly recovered organisms from deep tissue cultures in one series.[89] In a series of patients who developed bacteremia associated with pressure ulcers, *S. aureus, Proteus* spp., *Bacteroides, and Escherichia coli* were the most common organisms present in both the blood and wound cultures, with *Pseudomonas* spp. and *Enterococcus* also frequently cultured from wounds.[88] For patients who develop pressure ulcer–associated bacteremia, one-quarter of all blood cultures are positive for multiple organisms,[88] whereas wound cultures are polymicrobial in 73.2% of patients. *S. aureus* grows from 35.7% of wound cultures (30.4% of blood cultures that were positive), and *Proteus* is isolated from 46.4% of wounds.[88]

Treatment

As with other soft tissue infections described, effective therapy combines appropriate antimicrobials with surgical débridement to achieve source control. Broad-spectrum polymicrobial coverage should be initiated, with therapy directed toward organisms isolated on wound cultures, if infection is suspected. Given the depth of many pressure ulcers, treatment for osteomyelitis with longer antibiotic courses may be warranted.[88] In the setting of deep wounds, progressive infections that track along deeper tissue planes that are not visible on the wound surface should be suspected and either visually assessed in operative exploration or at least imaged to look for concerning signs of deep infection.[89] Overall, the diagnosis of severe infection related to pressures ulcers is challenging, but prompt recognition is key to appropriate treatment, especially given that the patients who typically get pressure ulcers have poor physiologic reserve and malnutrition.

CONCLUSION

SSTIs are frequently encountered by the intensivist, but the diagnosis is not always straightforward. Early surgical consultation to facilitate débridement and drainage for source control is essential for many severe SSTIs. Broad-spectrum antibiotics should be initiated and subsequently tailored to cultured organisms. Prompt initiation of treatment can help reduce mortality and improve functional outcomes.

KEY POINTS

- The diagnosis of NSTI is challenging. Any patient for whom the clinician has a high index of suspicion from a combination of physiology, laboratory investigations, and clinical examination should have rapid surgical consultation and operative exploration.
- Severe SSTIs can be complicated by organ dysfunction, requiring rapid resuscitation and initiation of appropriate antibiotics. The intensivist must be aware that growing resistance in common organisms causes SSTI and prescribe initial broad-spectrum antibiotics accordingly,
- The physiologic response to burn injury can mimic signs of sepsis, and burn wounds are frequently colonized with bacteria. Sepsis-3 criteria are the most sensitive to identifying sepsis in burn patients. There is no role for prophylactic systemic antibiotics—only topical—in the burned patient.

This study reviewed all admissions in France for necrotizing fasciitis from 2007 to 2012 (n = 1537) and identified some patient factors (older age, female sex, and ICU admission) that increased 28-day mortality, whereas certain hospital factors (public, teaching hospitals and larger NSTI volumes) were associated with lower 28-day mortality.

Cranendonk DR, van Vught LA, Wiewel MA, et al. Clinical characteristics and outcomes of patients with cellulitis requiring intensive care. *JAMA Dermatol.* 2017;153(6):578–582.
This prospective study compared outcomes and features of 54 patients with sepsis from severe cellulitis admitted to one of two ICUs with patients with NSTIs. Patients with severe cellulitis had more cormorbidities and lower illness severity on ICU admission; however, mortality was similar for patients with severe cellulitis and NSTI.

Crum-Cianflone NF. Bacterial, fungal, parasitic, and viral myositis. *Clin Microbiol Rev.* 2008;21(3):473–494.
This article provides a comprehensive review of infectious myositis and its underlying causes and management strategies. Although rare, the incidence in nontropical climates has been increasing, with myositis developing in patients who have a break in skin integrity often coupled with immunosuppression or preceding trauma.

Gelbard RB, Ferrada P, Yeh DD, et al. Optimal timing of initial debridement for necrotizing soft tissue infection: A Practice Management Guideline from the Eastern Association for the Surgery of Trauma. *J Trauma Acute Care Surg.* 2018;85(1):208–214.
This article presents guidelines for the timing of débridement for necrotizing soft tissue infections from the Eastern Association for the Surgery of Trauma. They recommend initial débridement within 12 hours of diagnosis.

Goh T, Goh LG, Ang CH, et al. Early diagnosis of necrotizing fasciitis. *Br J Surg.* 2014;101(1):e119–e125.
A systematic review of nine studies that included 1463 patients to identify clinical features and other investigations to aid in the early diagnosis of necrotizing fasciitis. Although high white blood cell count (>5); diabetes; and a physical examination with erythema, edema, and pain out of proportion to examination were commonly associated with NSTI, skin necrosis, bullae, and gas in the soft tissue on imaging are either late findings or uncommon.

Sartelli M, Guirao X, Hardcastle TC, et al. 2018 WSES/SIS-E consensus conference: recommendations for the management of skin and soft-tissue infections. *World J Emerg Surg.* 2018;13:58.
Guidelines published by the World Society of Emergency Surgery and the Surgical Infection Society of Europe reviewing the diagnosis and management of skin and soft tissue infections from simple cellulitis to necrotizing infections and surgical site infections.

Stanojcic M, Vinaik R, Jeschke MG. Status and challenges of predicting and diagnosing sepsis in burn patients. *Surg Infect (Larchmt).* 2018;19(2):168–175.
This literature review addresses the challenge of diagnosing infections in burn patients—the leading cause of mortality in this population—because of the similar physiologic response to burns and infections. The authors highlighted that compared with two most commonly used definitions to identify sepsis in burn patients, the Sepsis-3 definition had the highest sensitivity (85%).

Head and Neck Infections

Jeremy D. Gradon

Infections of the head and neck range in severity from minor to life threatening. A scoring system reflecting the need for hospitalization of such patients has been proposed.[1] The intensivist is called upon to manage such patients either when they are critically ill or when airway compromise has occurred or is imminent. Besides airway management and control of sepsis, the intensivist must also be aware of the local anatomy and relevant microbiology. This knowledge will help guide the choice of antimicrobial agents and allow the clinician to anticipate the potential for spread of infection to related anatomic spaces and subsequent complications.

NORMAL HEAD AND NECK FLORA

Huge numbers of bacteria reside in the oral cavity in health, with the bacterial load exceeding 10^{11}/mL in the gingival crevices of patients with teeth.[2] The main bacterial species are anaerobes, including *Bacteroides, Fusobacterium, Prevotella,* and *Peptostreptococcus*. Other common oral inhabitants include *Streptococcus mutans, Staphylococcus aureus, Actinomyces* spp., and *Eikenella corrodens*. Pharyngeal colonization and subsequent infection with organisms such as *Streptococcus pneumoniae, Neisseria meningitidis,* and *Streptococcus pyogenes* may also occur.

In acute illness, an additional modifying factor is the decreased production of oral mucosal fibronectin. This is of relevance to the clinician because fibronectin in normal physiologic amounts will preferentially bind gram-positive bacteria (such as *S. mutans*); however, when the production of fibronectin is decreased, there is rapid colonization of the oral cavity with gram-negative organisms, including species such as *Pseudomonas aeruginosa*.[2] These gram-negative organisms may then participate in head and neck infections of oral or odontogenic origin, necessitating broad nosocomial-type, gram-negative antibiotic coverage when the patient has been recently hospitalized or acquired the infection in the intensive care unit (ICU).

SITES OF DEEP HEAD AND NECK INFECTION

Knowledge of the local anatomy is critical to the understanding and management of these infections. This has recently been reviewed.[3] Serious infection of the head and neck can involve the following general anatomic areas:

- Sinus
- Pharynx
- Epiglottis
- Retropharyngeal space
- Submandibular space (Ludwig angina)
- Lateral pharyngeal space (anterior and posterior)
- Internal jugular vein (Lemierre syndrome)

Some of these anatomic areas are connected via actual (e.g., retropharyngeal) or potential (e.g., danger) spaces. Thus infection beginning in one space may spread rapidly to involve others, with potential resultant damage or destruction of vital structures. Such connections are discussed in the following sections, and differentiating features are highlighted in Table 116.1.

Predisposing factors for the development of deep neck infection include uncontrolled dental infection, spread of infection from other local structures (tonsils, vertebrae), local intravenous (IV) catheter placement or injection drug use, diabetes, human immunodeficiency virus (HIV) infection, and local trauma (e.g., the use of laryngeal mask anesthesia).[4,5] The use of cetuximab in combination with either radiation or chemotherapy for locally advanced head and neck cancer is associated with increased risk of local infection, as is the use of rituximab.[6] A poor level of education and living far from a tertiary care center have also been shown to increase the risk of development of severe deep neck space infection.[7]

CLINICAL SYNDROMES

Sinusitis

Acute bacterial sinusitis accounts for a high proportion of physician visits in the primary care setting.[8] In the ICU, patients who are critically ill with nasogastric, endotracheal, or nasotracheal tubes in place, may develop acute sinusitis caused by resistant nosocomial organisms (e.g., methicillin-resistant *S. aureus* [MRSA], *P. aeruginosa*) and anaerobes.[9] Treatment involves the use of broad-spectrum antimicrobial agents (Table 116.2) and close collaboration with an otolaryngologist to determine if drainage is needed. In addition, application of topical vasoconstrictors and inhaled topical steroids to the nasal mucosa is often recommended to help the sinus secretions drain.

Complications of nosocomial sinusitis are related to the local anatomy. Spread via the diploic veins can result in meningitis, brain abscess, contiguous osteomyelitis, or cavernous sinus thrombosis. Spread from the ethmoid sinuses can result in frontal lobe brain abscesses, whereas sphenoid sinus infection can spread to involve the surrounding pituitary gland, optic chiasm, internal carotid artery, cavernous sinus, or temporal lobe of the brain.[3]

In patients with diabetic ketoacidosis, high-dose steroid treatment, severe neutropenia, or history of desferrioxamine treatment, rhinocerebral mucormycosis (most commonly *Rhizopus* spp.) or aspergillosis can develop. This infection can be rapidly fatal if the underlying problem cannot be corrected. The general teaching has been that high-dose antifungal therapy (see Table 116.2) plus extensive surgery are always required for any hope of survival. However, the need for major surgery in all cases has come into question recently.[10] Close collaboration with appropriate surgeons and infectious disease colleagues is required in such cases.

TABLE 116.1 Differentiating Features of Deep Neck Infections

Space	Clinical Features*
Submandibular space (Ludwig angina)	Woody submental induration, protruding swollen/necrotic tongue, no trismus, rotted lower molars commonly present
Lateral pharyngeal space (anterior)	Fever, toxicity, trismus, neck swelling
Lateral pharyngeal space (posterior)	No trismus, no swelling (unless ipsilateral parotid is involved), cranial nerve IX–XII palsies, Horner syndrome, carotid artery erosion
Retropharyngeal space (retropharynx)	Neck stiffness, decreased neck range of motion, soft tissue bulging of posterior pharyngeal wall, sore throat, dysphagia, dyspnea
Retropharyngeal space ("danger space")	Mediastinal or pleural involvement
Retropharyngeal space (prevertebral)	Neck stiffness, decreased neck range of motion, cervical instability, possible spread along length of vertebral column
Jugular vein septic thrombophlebitis (Lemierre syndrome)	Sore throat, swollen tender neck, dyspnea, chest pain, septic arthritis

*Fever and signs of systemic toxicity are common to all.

Pharyngeal Infections

Life-threatening pharyngeal infections include acute anaerobic pharyngitis (Vincent angina) caused by a combination of oral anaerobes and spirochetes. The clinical manifestations of this entity in the critically ill host include acute ulcerations and necrosis of the oral mucosa and gums. Secondary bacteremia with sepsis can complicate matters. Treatment involves adequate oral debridement and administration of antibiotics with both aerobic and anaerobic activity (see Table 116.2).

Quinsy (peritonsillar abscess) can complicate previous tonsillitis and is most common among young adults. In a recent case series from India, quinsy accounted for 12% of deep head and neck infections.[11] Presenting symptoms include fever, pharyngeal pain, and unilateral pharyngeal swelling. If not adequately drained, the infection can spread into the lateral pharyngeal space, which was the most common cause of quinsy-related mortality in preantibiotic days. Infection with anaerobes can result in a higher rate of recurrence of quinsy.[8] *Fusobacterium necrophorum* is currently the most commonly encountered organism in peritonsillar abscesses in Denmark.[12]

Recurrent bouts of tonsillitis (five or more) in patients aged under 30 years have been noted to be a risk factor for the development of peritonsillar abscess.[13]

Diphtheria is now rare thanks to mass vaccination. It presents as a sharply demarcated, adherent, dark gray nasal or pharyngeal membrane. Clinical illness is caused by the release of a bacterial toxin that inhibits translocase (via inhibition of elongation factor 2). Myocardial dysfunction and central nervous system toxin-mediated injury may occur late, but fulminant infections can be complicated by death from acute respiratory obstruction or circulatory failure (bull-neck diphtheria). Culture of the organism *(Corynebacterium diphtheriae)* requires the use of a specific Loeffler medium.

Epiglottitis

Acute epiglottitis is primarily a disease of children who have not received the *Haemophilus influenzae* type b (Hib) vaccine and is thus rare at present.[14] Acute epiglottitis presents as an acute febrile illness usually of less than 12 hours' duration, with the child characteristically sitting forward, drooling saliva, and taking shallow and apprehensive breaths (deeper breathing draws the epiglottis over the airway and produces obstruction). The diagnosis is made clinically, although lateral neck radiography (if the child is stable enough to go for x-ray) characteristically shows enlargement of the epiglottis 30%–57% of the time. Attempts to visualize the classically described edematous cherry-red epiglottis directly may precipitate acute airway obstruction and should not be attempted unless the ability to secure an airway immediately is certain. Blood and epiglottis

TABLE 116.2 Therapeutic Options for Sinusitis, Pharyngitis, and Epiglottitis

Syndrome	Likely Flora	Antibiotic Options*
Sinusitis (community acquired)	*Haemophilus influenzae, Streptococcus pneumoniae, Staphylococcus aureus*	Ampicillin-sulbactam (3 g IV q6h) Ceftriaxone (1–2 g IV q24h)
		Levofloxacin (500 mg IV q24h) *plus* clindamycin (300–900 mg IV q8h) *or* moxifloxacin (400 mg IV q24h)
Sinusitis (ICU acquired)	*Pseudomonas aeruginosa, Escherichia coli* and related coliforms, methicillin-resistant *S. aureus* (MRSA)	Ceftazidime (2 g IV q8h) *or* piperacillin-tazobactam (3.375 g IV q4h) *plus* an aminoglycoside, *plus* vancomycin (1 g IV q12h)
Sinusitis (fungal)	*Aspergillus* spp. *Mucorales* spp.	Amphotericin B (1–1.5 mg/kg/day IV)
		Liposomal amphotericin B (5–10 mg/kg/day IV)
		Voriconazole (6 mg/kg q12h × 2 doses, then 4 mg/kg q12h)
		Itraconazole (200 mg IV q12h × 4 doses, then 200 mg/day IV)
Pharyngitis	*Corynebacterium diphtheriae*	IV penicillin or erythromycin *plus* diphtheria antitoxin
	Epstein-Barr virus (with airway compromise)	No antiviral therapy effective IV steroids
Epiglottitis	*H. influenzae* type b	Ceftriaxone (1–2 g IV q24h)
	Streptococcus pyogenes (group A strep)	Ampicillin-sulbactam (3 g IV q6h)
		Rifampin prophylaxis (600 mg orally q24h) for close contacts for 4 days

*Antibiotic choices listed are examples, because for most infections, multiple different antibiotics are effective; individual choice will be influenced by patient factors (e.g., allergies), local hospital bacterial resistance rates, and microbiologic culture results.

cultures usually grow *H. influenzae* type b. However, since the introduction of mass vaccination against *H. influenzae* type b, the incidence of infection with non–type b strains is increasing.[14]

Antibiotic options for epiglottitis are outlined in Table 116.2. There is no clear consensus on the role of exogenous corticosteroids to decrease epiglottic edema. Rifampin prophylaxis should be administered for 4 days to close household and hospital contacts of patients (especially those younger than 4 years) with invasive *H. influenzae* type b disease.

Retropharyngeal Infections

The area situated between the pharynx anteriorly and the vertebrae posteriorly constitutes the retropharyngeal space, which begins behind the pharynx and ends at the junction of the cervical and T1–T2 thoracic vertebrae (see Table 116.1). The space is subdivided into several distinct anatomic spaces (retropharyngeal, prevertebral, "danger space"), some of which may provide the means of spread of infection from the initial retropharyngeal area to distant sites.[15]

Located between the prevertebral space posteriorly and the retropharyngeal space anteriorly is a potential space called the "danger space," which connects the base of the skull with the posterior mediastinum and diaphragm. Infection may spread unimpeded within this space. In addition, infection occurring between the vertebrae and the prevertebral fascia may spread along the length of the vertebral column.

Infections of the retropharynx occur as:

- Primary infections
- Secondary to extension posteriorly from the pharynx or anteriorly from infected cervical vertebrae
- Via hematogenous spread

Clinically, retropharyngeal infections present with acute fever, systemic toxicity, sore throat, neck stiffness, dysphagia, and dyspnea. Airway obstruction may occur as a consequence of anterior bulging of the pharyngeal wall with supraglottic compression.

Prevertebral infections usually involve the cervical vertebrae and present with neck pain and stiffness and prevertebral soft tissue swelling. Rarely, instability or destruction of the cervical vertebrae may develop, with death the result of acute spinal cord compression.

Danger-space infection is suspected when pleural or mediastinal infection or pain complicates a retropharyngeal infection.[15] Mediastinitis secondary to danger-space infection is generally fulminant, with pleural extension and a high mortality rate. Rarely, mediastinal infections, such as may occur after coronary artery bypass graft surgery, may spread upward through the danger space and present in the retropharynx.

The bacteriology of retropharyngeal infections is that of mixed aerobic/anaerobic oral bacteria. In the critically ill host with nosocomial infection, colonization of the oropharynx with resistant pathogens will necessitate modification of antimicrobial coverage. The imaging techniques needed include plain lateral neck x-rays that will show loss of normal cervical lordosis in addition to thickening of the retrotracheal area (usually <22 mm) or of the prevertebral fascia (usually <7 mm). Bedside ultrasonography may provide information regarding the presence or absence of drainable collections, but if the patient is stable enough to go to the radiology suite, computed tomography (CT) or magnetic resonance imaging (MRI) scans provide the best definition studies.[16] The presence of a hypodense mass with rim irregularity on a contrast-enhanced CT scan is highly suggestive. Close collaboration with appropriate surgical colleagues is necessary for successful management.[15] Therapy is outlined in Table 116.3. On occasion, nonbacterial processes such as Kawasaki disease can mimic retropharyngeal abscesses.

It should be noted that involvement of multiple deep neck spaces can occur simultaneously.[17]

Submandibular Space Infection (Ludwig Angina)

The submandibular space is contained between the mucous membranes of the floor of the mouth superiorly and the muscle and fascia attachments of the hyoid bone inferiorly. The most common route of infection into this space is via infected lower molar teeth, and infection is more common in persons with underlying diabetes, neutropenia, or systemic lupus erythematosus. In a recent case series, 37% of deep infections were caused by submandibular space infection.[11]

Clinical presentation of submandibular space infection is that of an acutely ill patient with mouth pain, dysphagia, drooling of saliva, stiff

TABLE 116.3 Therapeutic Options for Deep Neck Infections

Syndrome	Likely Flora	Therapeutic Options*
Submandibular space infection (community acquired)	Anaerobes, streptococci, *Staphylococcus aureus*	Ampicillin-sulbactam (3 g IV q6h)
		Ceftriaxone (1–2 g IV q24h) *plus* clindamycin (300–900 mg IV q8h) *or* metronidazole (500 mg IV q8h)
		Ertapenem (1 g IV q day)
Submandibular space infection (hospital/ICU acquired)	*Pseudomonas aeruginosa,* methicillin-resistant *S. aureus* (MRSA), anaerobes	Imipenem (500 mg IV q6h) *or* piperacillin-tazobactam (3.375–4.5 g IV q6–8h by continuous infusion) *plus* vancomycin (1 g IV q12h)[18]
Retropharyngeal space infection	Anaerobes, streptococci, *S. aureus*	Ampicillin-sulbactam (3 g IV q6h)
		Ceftriaxone (1–2 g IV q24h) *plus* clindamycin (300–900 mg IV q8h) *or* metronidazole (500 mg IV q8h)
		Ertapenem (1 g IV q day)
Lateral pharyngeal space infection	Anaerobes, streptococci, *S. aureus*	Ampicillin-sulbactam (3 g IV q6h)
		Ceftriaxone (1–2 g IV q24h) *plus* clindamycin (300–900 mg IV q8h) *or* metronidazole (500 mg IV q8h)
		Ertapenem (1 g IV q day)
Internal jugular vein septic thrombophlebitis	*Fusobacterium necrophorum*	Metronidazole (500 mg IV q8h)
		Clindamycin (300–900 mg IV q8h)
		Ampicillin-sulbactam (3 g IV q6h)

*Antibiotic choices listed are examples, because for most infections, multiple different antibiotics are effective; individual choice will be influenced by patient factors (e.g., allergies, concurrent medications), local hospital bacterial resistance rates, and microbiologic culture results.

neck, and fever. The submandibular tissues are "woody," not fluctuant, and true drainable collections are uncommon. The tongue may be swollen and displaced upward against the palate and also protrude out of the mouth. Trismus is not present; however, if the infection spreads to the lateral pharyngeal space, trismus may occur. Unrecognized lateral pharyngeal space involvement may be complicated by subsequent spread to the retropharyngeal space. Late complications of Ludwig angina include death from airway obstruction, aspiration pneumonia, carotid artery erosion, and tongue necrosis.[18]

Lateral neck x-rays will demonstrate edema of the submandibular soft tissues. Pockets of gas may be seen if gas-forming organisms are involved. CT scanning is most helpful diagnostically. However, attention must be paid to having qualified staff accompany the patient to the CT scanner in case acute airway obstruction develops. Should airway protection be needed, tracheotomy or cricothyroidotomy is advocated because of the risk of inducing acute airway obstruction with routine "blind" nasal or oral intubation. The infection is commonly polymicrobial, and appropriate antibiotic therapy options are described in Table 116.3. In approximately 50% of cases, surgical drainage is required. In addition, causative rotted molar teeth (if present) should be removed.[19]

Lateral Pharyngeal Space Infections

Infection of the lateral pharyngeal space is one of the most common deep neck infections encountered. In a review of 110 deep neck infections in adults seen at an academic medical center over a 10-year period, infections of the lateral pharyngeal space accounted for 55%.[19] In contrast, such infections are rare in children, with peritonsillar infection (quinsy) being the most common deep neck infection.

The lateral pharyngeal space is cone shaped, extending from the sphenoid bone down to the hyoid bone. Posteriorly, it is bound by the prevertebral fascia (which separates it from the retropharyngeal space) and anteriorly by the buccinator and superior constrictor muscles. The parotid gland communicates with this space. The styloid process divides the space into an anterior compartment (containing fat, lymph nodes, and muscle) and a posterior compartment (containing the carotid artery, cranial nerves IX–XII, and the cervical sympathetic trunk).

Common precipitating causes of lateral pharyngeal space infection include dental disease (33%), injection drug use (inserting needles directly into the space) (20%), local trauma (9%), and tonsillitis (4%). Patients frequently have underlying diabetes or HIV infection.

Clinically, anterior lateral pharyngeal space infections present with fever, pain, trismus, and systemic toxicity. Turning the head to the opposite side causes increased pain because of stretching of the ipsilateral sternocleidomastoid muscle.

Infection of the posterior lateral pharyngeal space presents differently from infections involving the anterior pharyngeal space. Common symptoms include fever, systemic toxicity, and parotid swelling. Trismus and external swelling do not occur. Involvement of local vital structures can occur, including carotid artery erosion or clot, septic thrombophlebitis of the internal jugular vein, cranial nerve IX–XII palsies, or Horner syndrome.

Therapy involves urgent surgical intervention to drain purulent material and prevent spread of infection to the retropharyngeal space or erosion of the carotid artery. The choice of antibiotics for this frequently polymicrobial infection is shown in Table 116.3.

Descending Necrotizing Mediastinitis

Rapid downward spread of deep neck infections can result in the development of necrotizing soft tissue infections of the chest wall and mediastinum. A recent study of 45 such cases collected over a 12-year period demonstrated that they tended to develop as a complication of dental or deep neck polymicrobial infections, affecting persons aged 40–60 years most commonly. Mixed aerobic/anaerobic flora was the rule, and risk factors included neutropenia, alcoholism, and diabetes mellitus. Mortality was around 15%–20%. Death may be sudden because of medical complications of the infectious process.[20]

Internal Jugular Vein Septic Thrombophlebitis (Lemierre Syndrome)

Septic thrombophlebitis of the internal jugular vein is known as *Lemierre syndrome*. This relatively rare entity is usually caused by infection with the anaerobe *F. necrophorum,* a normal inhabitant of the human gingival crevice. Latest theories on the pathogenesis of this infection indicate that the first stage of infection is pharyngitis in approximately 87% of cases. Recent data suggest that *F. necrophorum* causes pharyngitis in young adults aged 15–24 years as frequently as *S. pyogenes*.[12] This infection is then followed by invasion of the lateral pharyngeal space, with development of septic thrombophlebitis of the internal jugular vein.[21,22] Subsequently, bloodborne infection develops, with the classic findings of septic pulmonary emboli or cavitating pneumonia and septic arthritis. Other precipitating factors include mastoiditis, lateral pharyngeal space infection, and trauma to the internal jugular vein. Lemierre syndrome is the most common identified source of *F. necrophorum* bacteremia.

Clinically, Lemierre syndrome begins with fever and sore throat. When internal jugular vein involvement develops, patients complain of a swollen and/or tender neck, which is thus a warning sign of danger in a patient with recent pharyngitis. Dyspnea and pleuritic chest pain indicate pulmonary involvement.

Early diagnosis is critical to minimize the risk of infectious metastatic complications requiring surgical intervention or drainage. Blood cultures should be promptly obtained and empirical antianaerobic bacterial coverage begun. Radiologic diagnosis is made most reliably by CT scanning, although bedside ultrasound examination of the internal jugular vein can be useful in the critically ill patient who cannot leave the ICU. If the infection occurs secondary to mastoiditis, it is necessary to rule out intracerebral vein thrombosis by MRI scanning. The patient may also develop secondary complications such as carotid artery thrombosis or parotid gland infection with abscess formation.[23]

Antibiotic choices are outlined in Table 116.3. There are no firm data to support or refute the use of anticoagulants in Lemierre syndrome.[22] In addition, surgical ligation or excision of the internal jugular vein for uncontrollable sepsis was necessary in approximately 8% of cases in a recently published series of cases.[23] MRSA has been shown to cause Lemierre syndrome, especially in injection drug users or patients, with the infection developing as a complication of venous cannulation.[24]

CONCLUSION

The intensivist will frequently be asked to assist in the care of patients with serious deep neck infections. Critical issues encountered include protection of the airway, sepsis management, and the potential for erosion of the infection into surrounding vital structures in the neck. Such infections are frequently polymicrobial in nature; thus broad-spectrum antibiotics with both aerobic and anaerobic coverage should be chosen.

Common issues to be decided for each patient individually include the following:

- The safety of performing an intraoral examination, given the risk of precipitating acute airway obstruction.
- The safety of sending a patient out of the ICU for studies such as CT scanning. Although patients may appear stable initially, they are at risk for sudden development of acute airway obstruction and thus should always be accompanied by a team capable of securing an airway when they travel out of the ICU for tests or procedures.

- The need for and timing of possible surgical intervention. Early close collaboration with otolaryngologists, head and neck surgeons, neurosurgeons, or vascular surgeons is critical for successful management of these complex and frequently critically ill patients.

KEY POINTS

- Deep infections of the head and neck are frequently polymicrobial, including both aerobic and anaerobic bacteria.
- Deep infection can threaten the airway, deep vascular structures, and mediastinum by means of local spread along complex deep anatomic planes.
- Intraoral inspection or attempts to palpate the posterior pharynx in such patients can precipitate acute airway occlusion. They should only be undertaken if an emergency airway can be immediately secured.
- Septic internal jugular vein thrombophlebitis is frequently anaerobic in etiology *(F. necrophorum)* and can be associated with metastatic spread of infection to the lungs, joints, and other organs.

A masterful overview of this complex and frequently fatal infection, with updates and guidance for the implementation of all available diagnostic and therapeutic options.

Ridder GJ, Maier W, Kinser S, et al. Descending necrotizing mediastinitis. Contemporary trends in etiology, diagnosis, management and outcome. *Ann Surg.* 2010;251:528–534.
A review of 45 patients with necrotizing chest and mediastinal infections seen over 12 years in one medical center. The source of infection was usually pharyngeal, dental, or deep neck infection. With aggressive diagnostic efforts and multidisciplinary management, a survival rate of 85% was achieved.

Rybak M, Lomaestro B, Rotschafer JC, et al. Therapeutic monitoring of vancomycin in adult patients: a consensus review of the American Society of Health-System Pharmacists, the Infectious Diseases Society of America and the Society of Infectious Diseases Pharmacists. *Am J Health Syst Pharm.* 2009;66:82–98.
A consensus statement suggesting that vancomycin is a concentration-independent killer of gram-positive organisms. The trough-level target concentration is suggested to be 15–20 μg/mL. The authors suggest that if the minimum inhibitory concentration (MIC) of S. aureus *to vancomycin is >2 μg/mL, an alternative agent other than vancomycin should be used for MRSA coverage for theoretical pharmacologic reasons.*

Infectious Endocarditis

Anastasia Antoniadou and Helen Giamarellou

INFECTIOUS ENDOCARDITIS: GENERAL INFORMATION

Infectious endocarditis (IE) is a rare disease with a yearly crude incidence of 1.5–11.6 episodes per 100,000 persons (3–9/100,00 in developed countries), increasing dramatically with advanced age and male sex and with varying epidemiology between high- and low-income countries.[1,2] Despite advances in early diagnosis and treatment, mortality of IE at 1 year has not improved over the last decades, being ≈30%. In low-income countries rheumatic heart disease remains the main risk factor for IE, but in high-income countries the epidemiologic profile has changed. Patients with IE are old, frail, with comorbidities and risk factors including diabetes, cancer, immunosuppression (including human immunodeficiency virus [HIV]), hemodialysis, prosthetic valve replacement, presence of cardiac implantable electronic devices, central venous catheters, intravenous drug use, and degenerative or congenital heart disease.[2–5]

IE is presently classified by the setting and source of infection into healthcare-associated infectious endocarditis (HAIE) and community-acquired infectious endocarditis (CAIE) and as native valve endocarditis (NVE) and prosthetic valve endocarditis (PVE). HAIE includes patients hospitalized for more than 48 hours before the symptoms of IE develop or patients with extensive healthcare contact defined as (1) home-based nursing or intravenous (IV) therapy, hemodialysis, or IV chemotherapy less than 30 days before onset of IE symptoms; (2) hospitalization less than 90 days before onset of IE; (3) residency in a nursing home or a long-term care facility; or (4) history of any interventional procedure during the previous 4–8 weeks.[3,6] The definition of HAIE applies both to NVE and PVE. Early PVE (now defined as presenting <1 year postsurgery) has a portion included in the HAIE definition (those presenting 60 days postsurgery).[2,3] IE in high-income countries is >25% healthcare associated, carrying a significant in-hospital mortality rate of 15%–20%, with a 1-year mortality rate approaching 40%.[7]

Gram-positive cocci (staphylococci, streptococci, and enterococci) comprise 80%–90% of the microbial etiology of IE, whereas rare (<5%) causes include HACEK species (*Haemophilus* spp., *Aggregatibacter* [formerly *Actinobacillus*] spp., *Cardiobacterium* spp., *Eikenella corrodens,* and *Kingella* spp.); aerobic gram-negative bacilli; fungi (*Candida* spp. and *Aspergillus* spp.); *Bartonella* spp.; *Brucella* spp.; *Coxiella burnettii;* and *Tropheryma whipplei*. In 10% of cases, IE is culture negative, and serology or polymerase chain reaction (PCR) assays in blood or on surgically removed heart valves/vegetations may contribute to the diagnosis. *Staphylococcus aureus* is responsible for 35%–40% of NVE and 50% of HAIE, replacing streptococci as the most common pathogen in developed countries, and streptococci are the cause of 30%–40% of CAIE (both NVE and PVE). Group D streptococci (e.g., *Streptococcus gallolyticus,* formerly *Streptococcus bovis*) are isolated in 15% and should be notable for causing IE associated with an underlying colonic tumor (usually undiagnosed). Enterococci (mostly *faecalis*) are implicated in 10% of IE, being more common in HAIE and transcatheter aortic valve replacement (TAVR) IE. Coagulase-negative staphylococci predominate (>60%) in IE in the presence of prosthetic valves, cardiac implanted electronic device (CIED), or venous catheters except for *Staphylococcus lugdunensis,* which can also be the cause of community-acquired NVE.[2–5]

Rapid and accurate diagnosis of IE remains a challenge and affects disease outcome. Fever is present up to 90%, a heart murmur up to 85%, and an embolic event up to 25% at the time of diagnosis. Other signs are less common: hematuria, splenomegaly, splinter hemorrhages, Janeway lesions, Roth spots, conjunctival hemorrhage, sepsis, meningitis, unexplained heart failure, septic pulmonary emboli, stroke, acute peripheral arterial occlusion, and renal failure.[2–5] Cerebral complications are severe and frequent in IE, occurring symptomatically in 15%–30% of patients, and there is evidence that additional clinically silent cerebral embolism may occur in 35%–60%.[2,5] Diagnosis of IE relies on clinical, microbiologic (blood cultures), and imaging findings (the first-line modality is transthoracic echocardiography [TTE] and transesophageal echocardiography [TEE]), incorporated in the modified Duke diagnostic criteria, which have an overall 80% sensitivity and specificity, which decrease in PVE and cardiac device–related IE. A definite diagnosis requires two major, one major with three minor, or five minor criteria[2,3] (Table 117.1 and Fig. 117.1).

Treatment of IE aiming at microbial eradication necessitates the use of bactericidal combination regimens for prolonged periods. In the 2015 guidelines (1) aminoglycosides are no longer indicated in staphylococcal NVE; (2) when used in streptococcal, enterococcal IE, or staphylococcal PVE, they should be given in a single daily dose to reduce nephrotoxicity; (3) rifampin should be used in IE with foreign material in place (PVE) after 3–5 days of effective antibiotic therapy (to prevent an antagonistic effect against planktonic/replicating bacteria) and after bacteremia has been cleared; (4) daptomycin used in methicillin-resistant *S. aureus* (MRSA) IE should be used in high doses (≥10 mg/kg per day) and in combination with a second antibiotic to increase activity and prevent emergence of resistance; (5) in methicillin-sensitive *S. aureus* (MSSA) IE treatment with beta-lactams is preferred (vancomycin is inferior to beta-lactams); and (6) treatment duration is evaluated from day 1 of effective treatment (i.e., negative blood cultures in case of previously positive ones). In the case of new prosthetic valve implantation in the course of IE, if the removed valve is culture positive, a new full treatment course starts postsurgery.[2,3] Indications for cardiac surgery during the course of IE are heart failure (severe regurgitation or obstruction of the affected valve), evidence of uncontrolled infection (persisting bacteremia despite treatment and

TABLE 117.1 Modified Duke Criteria for the Clinical Diagnosis of Infectious Endocarditis

Major Criteria

1. Blood Cultures Positive for IE
   - a. Typical microorganisms consistent with IE from two separate blood cultures:
     - Viridans streptococci, *Streptococcus gallolyticus (Streptococcus bovis),* HACEK group, *Staphylococcus aureus;* or
     - Community-acquired enterococci, in the absence of a primary focus; or
   - b. Microorganisms consistent with IE from persistently positive blood cultures:
     - ≥2 positive blood cultures of blood samples drawn >12 h apart; or
     - All of 3 or a majority of ≥4 separate cultures of blood (with and last samples drawn ≥1 h apart); or
   - c. Single positive blood culture for *Coxiella burnetii* or phase I IgG antibody titer >1:800
2. Imaging Positive for IE
   - a. Echocardiogram positive for IE:
     - Vegetation
     - Abscess, pseudoaneurysm, intracardiac
     - Valvular perforation or aneurysm
     - New partial dehiscence of prosthetic valve
   - b. Abnormal activity around the site of prosthetic valve implantation detected by ^{18}F-FDG-PET/CT (only if the prosthesis was implanted for >3 months) or radiolabeled leukocytes SPECT/CT.
   - c. Definite paravalvular lesions by cardiac CT.

Minor Criteria

1. Predisposition such as predisposing heart condition or injection drug use.
2. Fever as temperature >38°C.
3. Vascular phenomena (including those detected by imaging only): major arterial emboli, septic pulmonary infarcts, infectious (mycotic) aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions.
4. Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor.
5. Microbiologic evidence: positive blood culture but does not meet a major criterion as noted earlier or serologic evidence of active infection with an organism consistent with IE.

Definite IE
- Two major criteria; or
- One major criterion and three minor criteria; or
- Five minor criteria

Possible IE
- One major criterion and one minor criterion; or
- Three minor criteria

Rejected IE
- Firm alternative diagnosis; or
- Resolution of symptoms suggesting IE with antibiotic therapy for ≤4 days; or
- No pathologic evidence of IE at surgery or autopsy, with antibiotic therapy for ≤4 days; or
- Does not meet criteria for possible IE, as noted earlier

CT, Computed tomography; *^{18}F-FDG-PET/CT*, ^{18}F-Fluorodeoxyglucose-positron emission tomography/computed tomography; *IE*, infective endocarditis; *SPECT*, single-photon emission computed tomography.

From Task Force for the Management of Infective Endocarditis of the European Society of Cardiology (ESC): 2015 ESC Guidelines for the management of infective endocarditis. *Eur Heart J.* 2015;36(44):3075–3128.

control of metastatic foci, abscess or fistula formation, infection by fungi or multiresistant organisms), and prevention of embolism (vegetation size, mobility, and embolic events).[2] A summary of antibiotic treatment recommendations is shown in Table 117.2.

HEALTHCARE–ASSOCIATED NATIVE VALVE ENDOCARDITIS

Data emerging from the International Collaboration on Endocarditis Prospective Cohort Study (ICE-PCS) recognize that 34% of NVE is healthcare–associated (HANVE), consistent with the contemporary high incidence of healthcare–associated infection.[8,9] Almost 50% were acquired outside of the hospital, and compared with CAIE, patients with HANVE more often have comorbid conditions (e.g., diabetes mellitus, cancer, or long-term immunosuppressive therapy). Fever is the most common presenting feature, but physical signs of IE present more rarely in HANVE, suggesting a more acute course. Non-nosocomial acquisition of HANVE is most often dependent on hemodialysis or an intravascular catheter (54%), whereas patients with nosocomial acquisition more often have a preexisting valvular disease or undergo a nondental invasive medical procedure. The mitral valve is most frequently involved, followed by the tricuspid and aortic valve.[8] Staphylococci represent the major pathogens in HAIE. *S. aureus* is responsible in >50% of cases, 91% in the presence of an intravascular device.[6] In the ICE-PCS study, *S. aureus* was methicillin-resistant (MRSA) in 47%.[8] The second most common bacteria were enterococci (15%), followed by coagulase-negative strains of staphylococci (13%). MRSA is more prevalent in infections acquired during hospitalization (57% vs. 41%).[8] Among coagulase-negative strains, *S. lugdunensis* deserves attention because it behaves like *S. aureus* with high virulence, has a 50% probability of complicated infection when isolated in blood, and has an aggressive course when it is the cause of IE.[10]

Gram-negative bacilli are rare causes of HANVE despite the fact that they cause lethal bacteremias in hospitals, probably as a result of their decreased ability to adhere to heart valves and susceptibility to bactericidal action of serum.[6,11] Recently, cases of IE caused by multidrug-resistant MDR and extensively drug-resistant (XDR) gram-negatives (e.g., *Pseudomonas, Acinetobacter, Escherichia coli,* and *Burkholderia cepacia*) have been published with poor outcomes despite aggressive management because of a lack of effective treatment options.[12]

Fungal IE is a rare infection, comprising <2% of IE cases, with a mortality rate exceeding 30%. An increasing frequency of fungal endocarditis has been observed in recent years, attributed to the extensive use of vascular lines, noncardiac surgery, and increased numbers of immunocompromised patients.[13,14] Fungi most commonly associated with IE are *Candida* (*albicans* and non-*albicans,* 50%–80%) and *Aspergillus* spp. (20%–25%). In contradistinction to *Candida* spp., in which blood cultures in cases of IE are positive in 83%–95% of cases, blood cultures are positive in only 11% or less of patients with *Aspergillus* spp. In cases of fungal endocarditis, prolonged symptoms before hospitalization and the embolization of major arteries are classic findings. However, the diagnosis is delayed or missed in 82% of patients. For early diagnosis of fungal endocarditis, it should be considered in the differential diagnosis and echocardiography performed, which demonstrates large, bulky vegetations. Peripheral blood cultures should be obtained and accessible embolic specimens subjected to histologic examination.[13,14]

HANVE has higher mortality compared with community-acquired NVIE (25% versus 13%), and factors independently associated with increased risk of death are increased age (>60 years old), diabetes,

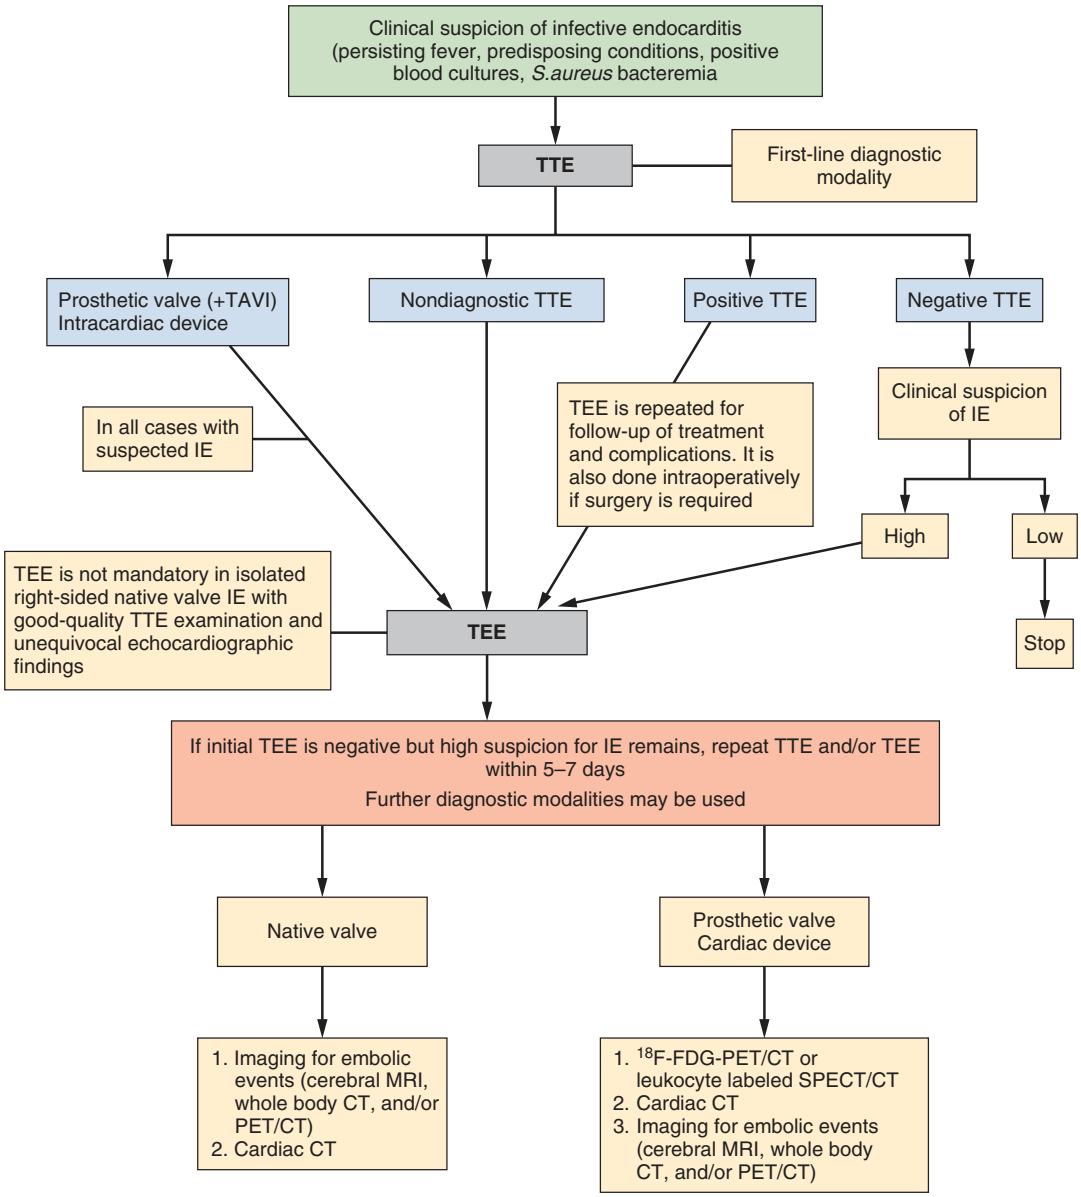

Fig. 117.1 Algorithm of Diagnostic Imaging Modalities in Suspected Infective Endocarditis. *CT,* Computed tomography: ^{18}F-FDG-PET/CT, ^{18}F-Fluorodeoxyglucose-positron emission tomography/computed tomography; *IE,* Infective endocarditis; *MRI,* magnetic resonance imaging; *SPECT,* single photon emission computed tomography; *TAVI,* transcatheter valve implantation. *TEE,* transesophageal echocardiography; *TTE,* transthoracic echocardiography. (Adapted from Habib G, Lancellotti P, Antunes MJ, et al. 2015 ESC Guidelines for the management of infective endocarditis: the Task Force for the Management of Infective Endocarditis of the European Society of Cardiology [ESC]. Endorsed by: European Association for Cardio-Thoracic Surgery [EACTS], the European Association of Nuclear Medicine [EANM]. *Eur Heart J.* 2015;36[44]:3075–3128, Figure 1.)

S. aureus infection, paravalvular abscess, stroke, heart failure, and new conduction abnormality. Cardiac surgery during the IE episode is found to be associated with a lower mortality,[8] and therefore early surgical intervention is often mandatory. In fungal endocarditis, the removal of the infected valve is indicated, and postsurgery suppressive therapy for 2 or more years along with close follow-up are required to detect relapses.[13,14]

Special consideration should be given to chronic hemodialysis (HD) patients, in whom IE is significantly more common (16–18 times) and causes greater morbidity and mortality. In this group of patients, IE is the second leading cause of death after cardiovascular disease, and it has been proposed to be added as a special category in classification by acquisition.[15,16] In the ICE-PCS study, 63% of HANVE cases were HD patients.[8] *S. aureus* was the pathogen in 75%–80% of cases, half of which were MRSA. Fever may not be present, and blood cultures may less often be positive, complicating a diagnosis by the Duke criteria. Mortality remains high: 30% during the first month, about 65% during the first year, and reaching more than 70% if cardiac surgery is indicated. Age older than 65, diabetes as the cause of renal failure, mitral involvement, large vegetations, septic emboli, and infections caused by MRSA or vancomycin-resistant enterococci (VRE) have been identified as risk factors for mortality.[15]

For MSSA, anti-staphylococcal penicillins should be the treatment of choice, whereas in cases of MRSA with minimum inhibitory

TABLE 117.2 Summary of Treatment Recommendations for IE and the Most Common Pathogens

Microorganism	Treatment Regimen	Duration	Comments
Penicillin-susceptible streptococci (MIC ≤0.125 mg/L)	Penicillin G 12–18 million U/day IV in 4–6 doses or continuously or Amoxycillin or ampicillin 100–200 mg/kg/day IV in 4–6 doses or Ceftriaxone 2 g/day IV or IM in 1 dose plus Gentamicin 3 mg/kg/day IV or IM in 1 dose or netilmicin 4–5 mg/kg/day IV in 1 dose	2 weeks	Short-duration treatment only in normal renal function and with monitoring of aminoglycoside levels In PVE 6-week duration is recommended
	Penicillin G 12–18 million U/day IV in 4–6 doses or continuously or Amoxycillin or ampicillin 100–200 mg/kg/day IV in 4–6 doses or Ceftriaxone 2 g/day IV or IM in 1 dose	4 weeks	
	If beta-lactam allergy present: Vancomycin 30 mg/kg/day IV in 2 doses	4 weeks	Vancomycin levels should be monitored
Relatively resistant to penicillin streptococci (MIC 0.250–2.0 mg/L)	Penicillin G 24 million U/day IV in 4–6 doses or continuously or Amoxycillin or ampicillin 200 mg/kg/day IV in 4–6 doses or Ceftriaxone 2 g/day IV or IM in 1 dose Plus Gentamicin 3 mg/kg/day IV or IM in 1 dose	4 weeks 2 weeks	In PVE 6-week duration is recommended If beta-lactam allergy, change beta-lactam to vancomycin
Enterococci and streptococci with penicillin MIC>2 mg/L	Amoxycillin or ampicillin 200 mg/kg/day IV in 4–6 doses Plus Gentamicin 3 mg/kg/day IV or IM in 1 dose	6 weeks 2–6 weeks 6 weeks	
If high-level resistance to gentamicin	Ampicillin 200 mg/kg/day IV in 4–6 doses plus ceftriaxone 4 g/day IV or IM in 2 doses	6 weeks	
If allergy or resistance to beta-lactams (*Enterococcus faecium*)	Vancomycin 30 mg/kg/day IV in 2 doses plus gentamicin 3 mg/kg/day IV or IM in 1 dose	6 weeks	Consultation with ID physician recommended
If resistance to beta-lactams, vancomycin and gentamicin	Daptomycin 10 mg/kg/day IV plus ampicillin 200 mg/kg/day IV in 4–6 doses or ertapenem linezolid 600 mg BID IV	8 weeks	
MSSA NVE PVE	Flucloxacillin or oxacillin 12 g/day IV in 4–6 doses Flucloxacillin or oxacillin 12 g/day IV in 4–6 doses with rifampin 900–1200 mg/day IV or PO in 2–3 doses plus Gentamicin 3 mg/kg/day IV or IM in 1 dose	4–6 weeks ≥6 weeks 2 weeks	Rifampin has been suggested to start 3–5 later
MRSA or beta-lactam allergy NVE PVE	Vancomycin 30–60 mg/kg/day IV in 2–3 doses or Daptomycin 10 mg/kg/day IV once daily Vancomycin 30–60 mg/kg/day IV in 2–3 doses with rifampin 900–1200 mg/day IV or PO in 2–3 doses plus Gentamicin 3 mg/kg/day IV or IM in 1 dose	4–6 weeks 4–6 weeks ≥6 weeks 2 weeks	Daptomycin is superior to vancomycin for MSSA and MRSA bacteremia with vancomycin MIC >1 mg/L. Some experts recommend combination of daptomycin with fosfomycin or cloxacillin.
HACEK	Ceftriaxone 2 g/day IV in 1 dose or ampicillin plus gentamicin if beta-lactamases are not produced	NVE: 4 weeks PVE: 6 weeks	Ciprofloxacin is a not well-validated alternative

[1]For MSSA and MRSA NVE, an alternative regimen is also the combination of sulfamethoxazole 4800 mg/day and trimethoprim 960 mg/day IV in 4–6 doses plus clindamycin 1800 mg/day IV in 3 doses.
[2]For multiresistant or fungal pathogens, ID consultation is recommended.
[3]When vancomycin or aminoglycosides are used, monitoring of drug levels is recommended. Target levels for gentamicin 1 mg/L for trough and 10–12 mg/L 1-hour post-dose levels. For vancomycin trough levels of 15–20 mg/L and 35–40 mg/L 1-hour postinfusion.
IE, Infective endocarditis; *MIC*, minimal inhibitory concentration; *MRSA*, methicillin-resistant *Staphylococcus aureus*; *MSSA*, methicillin-sensitive *S. aureus*; *NVE*, native valve endocarditis; *PVE*, prosthetic valve endocarditis.
Adapted from 2015 ESC Guidelines for the management of infective endocarditis. *Eur Heart J*. 2015;36:3075–3128.

concentration (MIC) >1 mg/L to vancomycin, antimicrobial choices include high-dose daptomycin in combination with another antibiotic.[2] If vancomycin is indicated, drug levels should be followed, with trough levels of 25–30 mg/L required for efficacy.[17]

HEALTHCARE–ASSOCIATED PROSTHETIC VALVE ENDOCARDITIS

PVE accounts for 10%–30% of all cases of IE,[18] with mortality rates ranging between 25% and 60%.[19] It occurs in 3%–4% of patients within 5 years after surgery (0.3–1.2 per patient-year). More than one-third is healthcare acquired. Contamination of prosthetic valves during this early period occurs either directly at the time of implantation by a break in sterile surgical techniques or via transient episodes of bacteremia, emanating mostly from infected intravascular catheters and wound or skin infections during hospitalization, therefore representing a real nosocomial infection.[19] Early PVE (<1 year) presents mostly during the first 2–3 months after surgery.

PVE may manifest as an indolent illness with low-grade fever and immune-mediated manifestations or as a fulminant acute febrile disease with hypotension. When early PVE is caused by *S. aureus,* the clinical picture is accompanied in more than 40% of cases by central nervous system (CNS) and intracardiac complications, with a subsequent mortality ranging from 42% to 85%. Staphylococci prevail in the microbiology of PVE. In the ICE-PCS study, 36.5% of PVE were healthcare associated and 70% were acquired in the hospital.[19] Of PVE cases, 71% were early, the majority diagnosed on day 60 (median on day 84). In 43% of HAPVE, an intravascular device was in place. *S. aureus* was the most common pathogen, with a higher MRSA incidence in cases with healthcare–acquired PVE (HAPVE) (34% and 13.3%), followed by coagulase-negative staphylococci.[19]

Recent progress in TEE, applying a high-resolution biplane or multiplane transducer, has enhanced the diagnostic approach to PVE. Sensitivity and specificity of TEE in the diagnosis of PVE exceeds 90% versus a sensitivity of 40%–70% with transthoracic echocardiography (TTE).[20] New diagnostic modalities are currently used and recommended for the diagnosis of PVE, including multislice cardiac computed tomography (CT), ^{18}F-Fluorodeoxyglucose (FDG) positron emission tomography (PET), and radiolabeled leukocyte single-photon emission computed tomography (SPECT), when suspicion for the presence of PVE is high and the TEE is not diagnostic (see Fig. 117.1). These new methods have been incorporated in the modified Duke criteria (see Table 117.1) in the last update of the European guidelines of IE, which are effectively used to confirm the diagnosis of PVE.[20,21] Mortality in PVE is still substantial, being higher in early PVE (77% vs. 42% in late PVE). Leading causes of death in early PVE are septic shock (36%), congestive heart failure (29%), and renal failure (21%).[6,22,23] In the ICE-PCS study, overall mortality for PVE was 22.8% (for HAPVE it was 30.5%). Other factors related to increased risk of death are older age; diabetes; early PVE; *S. aureus* or fungi as the pathogen; and complications such as heart failure, stroke, intracardiac abscess, and persistent bacteremia.[21] The survival rate with medical therapy alone in cases of moderate to severe chronic cardiac failure caused by prosthesis dysfunction is almost nil. However, valve replacement in this group plus antimicrobial therapy will achieve a survival rate of 44%–64%.[24] It is noteworthy that PVE recurs in only 6%–15% of patients who are operated on with active bacterial invasive infection. Treatment duration for PVE is longer, at least 6 weeks.[2]

Transcatheter valve replacement or implantation (TAVI or TAVR) has transformed the management of severe aortic stenosis in patients with prohibitive or high operative risk and an otherwise grave prognosis. IE after TAVI shares clinical, diagnostic, and management characteristics with PVE and similar incidence (0.3–2.1 per 100 person-years). It occurs early postprocedure, with >75% during the first year, and 18%–60% are healthcare associated. *Enterococcus* is frequently isolated (19%–34%), a pathogen frequently neglected in periprocedural prophylaxis (in 48%, the isolated pathogen was not covered by prophylaxis, which should be tailored according to local epidemiology of resistance). Complications are common (65%–87% rendering indication for surgical care), and mortality is extremely high (in-hospital 11%–64%, 1-year 22%–75%).[25]

CIEDs include permanent pacemakers, implantable cardioverter defibrillators, and cardiac resynchronization therapy devices, and the incidence of infection is overall 1–10/1000 device-years, with staphylococci implicated in the etiology in 60%–80%. CIED-related IE may involve the leads, the endocardium surface, or a valve (most often the tricuspid) and arise either from pocket infection or bacteremia. In CIED-related IE, complete removal of the system is indicated because of increased risk of recurrence and mortality, along with prolonged (4–6 weeks) antibiotic treatment. If a new device is essential, implantation is performed after 72 hours with sterile cultures. If there is evidence for remnant valvular infection, implantation is delayed for 14 days.[2,26]

INFECTIVE ENDOCARDITIS IN THE ICU

Five studies have focused on patients with IE admitted to the intensive care unit (ICU) in the past decade.[27–31] Patients with IE are admitted because of complications (e.g., severe sepsis or septic shock, heart failure with hemodynamic instability, embolic phenomena especially from the CNS, multiorgan failure, or after acute surgery for IE). They usually need prolonged hospitalization, and more than 50% undergo cardiac surgery, which is a protective factor for mortality. A total of 15%–20% of IE patients admitted to the ICU are healthcare associated, 15%–36% involve a prosthetic valve, and one-third are accompanied by embolic phenomena most commonly from the CNS. Pathogens recorded are usually *S. aureus* and streptococci. Mortality rates are 30%–45% among studies for the first 30 days, with risk factors for mortality in recent years being high values of severity scores at admission (SAPS II, SOFA) and multiorgan failure. Long-term mortality has been recently studied by Mirabel and colleagues,[31] and it was found to be 69% for the subsequent 5 years, with risk factors for mortality being a high Sequential Organ Failure Assessment (SOFA) score at admission, the presence of a prosthetic valve, and the size of the vegetation (>15 mm). IE may also be acquired in the ICU, usually as a result of bacteremia related to a medical procedure, and *S. aureus* is the most common pathogen.[32] The expected classic clinical features of IE are often absent in ICU patients. For instance, CNS signs resulting from sedation may be blunted, and manifestations of renal failure are usually attributed to septic multiple organ dysfunction syndrome.

Because the risk of HAIE is proportionally increased with the duration of hospitalization, the diagnosis of IE should always be suspected in the presence of a fever of unknown origin with positive blood cultures after a prolonged stay in the ICU. The latter suspicion is strengthened in patients with prosthetic valves or CIEDs, in those undergoing procedures that may damage the right side of the heart, and whenever bacteremia lasts for more than 72 hours after catheter removal and/or positive blood cultures that persist 3 days after starting appropriate antimicrobials, especially if the microorganism isolated in blood is *S. aureus.*[33]

The diagnostic value of echocardiography in the diagnosis of IE and particularly of the transesophageal view has been established. In a patient with *S. aureus* bacteremia, a TTE should always be performed. If bacteremia persists beyond 48–72 hours and/or the patient has an implantable cardiac device or a prosthetic valve, then a TEE should also be performed because the risk of IE is high.[34,35] In the case of a negative TEE, if clinical suspicion continues to be high, a second examination should be advocated (a multislice CT for native valves and

^{18}F-FDG PET/CT, in addition to radiolabeled leukocyte SPECT/CT for prosthetic valves or CIED).[2] HAIE in the ICU requires the prompt initiation of antimicrobial therapy and cardiosurgical evaluation, keeping in mind that mortality increases sharply with *S. aureus* as a pathogen, with age, and with the origin of the infection (i.e., ICU acquired vs. community acquired). Of note, the treatment duration of catheter-related staphylococcal *(S. aureus)* bacteremia aiming to treat successfully any seeded valve (as occurs in 23% of the cases) should never be shorter than 2 weeks, and echocardiography should be performed before treatment discontinuation. Otherwise, a treatment duration of 4 weeks is recommended.[36]

Prophylaxis of HAIE, especially in ICU patients, mandates (1) intravenous (IV) access and intravascular procedures to be performed with aseptic care; (2) IV and intraarterial catheters to remain in place for as brief a duration as possible; and (3) tunnelization, although a controversial issue, to be considered either as an immediate approach for temporary dialysis catheters or as a systemic procedure if the catheter has been or will be in place for more than 4 days.[37,38] Antimicrobial prophylaxis is not justified before performing TEE.[2]

THE ENDOCARDITIS TEAM[39]

The latest European Society of Cardiology (ESC) guidelines support the management of patients by a multidisciplinary team (incorporating cardiac surgeons, cardiologists, ID specialists, microbiologists, anesthesiologists, and imaging specialists) in reference centers, especially when complications or an indication for cardiac surgery is present. A multidisciplinary approach can substantially reduce the still unacceptably high morbidity and mortality in patients with IE, as it allows early diagnosis and appropriate comprehensive management and follow-up during hospitalization and postdischarge. Decision making within the endocarditis team must follow a standard protocol that is based on current clinical guidelines, and if surgery is indicated, it is best to be performed early.

KEY POINTS

- IE remains a rare disease with high morbidity and mortality and a changing epidemiologic profile in developed countries.
- IE currently is affecting aging populations with comorbidities and is often healthcare associated or related to intracardiac devices or foreign material (prosthetic valves, catheters, CIED).
- Major pathogens (90%) include gram-positive cocci, with *S. aureus* (with increasing rates of MRSA) being the most common pathogen and *Enterococcus* spp. increasing in incidence, both reflecting the extended healthcare–associated profile of IE in the new era.
- Mortality of HAIE is higher in the elderly, in patients with *S. aureus* and fungal endocarditis, and in patients with complications (e.g., heart failure, stroke, intracardiac abscess, persistent bacteremia). Early surgical intervention is mandatory and may improve the in-hospital outcome.
- TEE has enhanced our diagnostic approach in HAIE (NVE or PVE), especially when the Duke diagnostic clinical criteria are effectively used, and it must always be performed in patients with persisting *S. aureus* bacteremia and prosthetic valves or CIED.
- New diagnostic imaging modalities (^{18}FDG-PET/CT, radiolabeled leukocyte SPECT/CT, cardiac CT, MRI) are supporting the still challenging early diagnosis of IE, especially in the presence of cardiac devices or intracardiac foreign material.
- ICU-IE shares overlapping characteristics with HAIE and is either acquired in the ICU or is an emergency necessitating critical care, involving native or prosthetic valves.
- A multidisciplinary approach for the management of IE is recommended by the "endocarditis team" consisting of many specialties in reference centers.

Fungal Infections

Philipp Koehler, Paul O. Gubbins, and Oliver A. Cornely

Medical advances continue to improve the prognosis of patients with cancer and other immunodeficiencies. In the past 50 years, the field of transplantation has greatly affected the management of patients with cancer and renal, cardiac, and liver diseases. Moreover, advances in neonatology continue to increase the survival of premature infants. These advances have benefited society greatly, but they have also fueled the emergence of invasive fungal infections. *Candida* species first appeared as significant nosocomial pathogens approximately 40 years ago.[1] For two decades, infections caused by these pathogens increased dramatically.

Fungal infections among critically ill patients are primarily caused by *Candida* spp. However, infections caused by other opportunistic fungal pathogens, including *Aspergillus, Fusarium,* Mucorales, and *Cryptococcus neoformans,* also occur in critically ill populations (e.g., solid-organ transplant [SOT], hematopoietic stem cell recipients, influenza, and acquired immunodeficiency syndrome [AIDS] patients). Moreover, primary or endemic mycosis caused by *Blastomyces dermatitidis, Coccidioides immitis,* and *Histoplasma capsulatum* can cause severe disseminated infection in immunocompetent or compromised hosts.

Fungal infections are generally more prevalent in intensive care units (ICUs) than on the general medical wards.[2] The importance of effective preventive measures against invasive fungal infection is widely appreciated in leukemia or hematopoietic stem cell transplant (HSCT) recipients. As our understanding of these infections continues to improve, so too does the ability to institute appropriate preventive measures. In the past decade, the development of agents possessing either a different mode or broader spectrum of activity, less toxicity, or a reduced propensity to interact with other drugs has increased the number of available systematically active antifungal agents. Consequently, clinicians can now tailor antifungal therapy to specific patients. Moreover, our understanding of antifungal pharmacodynamics is developing, and methods to measure antifungal susceptibility are improving.

FUNGAL INFECTIONS IN THE CRITICALLY ILL

Candida Infections in the ICU

Epidemiology

Candida spp. remain among the 10 most common pathogens of healthcare–associated infections, but are the most common cause of nosocomial bloodstream infections (BSIs).[3] *Candida* spp. have consistently caused a substantial disease burden for more than a decade.[4–7] However, over the past decade, population-based studies have noted a decline in overall incidence, which likely reflects improvements in healthcare delivery.[8] Worldwide, *Candida* spp. are the third most frequent cause of infection in ICUs.[9] Traditionally, ICUs have a higher incidence of *Candida* BSIs than medical and surgical wards, although recent data suggest an increasing prevalence of such infections in non-ICU patients.[2,10–12] Although prior data had suggested the frequency of *Candida* BSIs among ICU patients had declined, estimates from national secondary databases and population-based studies suggest the disease burden may be shifting from the ICU to the general hospital population.[1,11]

Globally, *C. albicans* remains the most common invasive *Candida* spp.[13] However, decreasing trends in the isolation of this species over time have been observed in the ICU and non-ICU setting.[11,13,14] The isolation of *C. albicans* and *C. parapsilosis* among neonatal ICU patients and the prevalence of *C. glabrata* infections among adults have been widely appreciated.[1,13–16] *C. albicans* is responsible for approximately 45% of episodes of candidemia.[11,17] The incidence of infection caused by a particular *Candida* spp. varies considerably by the clinical service on which the patient is hospitalized. However, in general, *C. albicans* is the primary fungal pathogen in the ICU setting and is followed by *C. glabrata, C. parapsilosis, C. tropicalis, C. krusei,* and other *Candida* spp. (i.e., *C. guilliermondii, C. lusitaniae*).[11,17] This rank order varies little across infection site, but it may vary with age, underlying disease, or local epidemiology.[1,13,14,17] Surveillance data have noted that candidemia in neonatal ICUs is predominantly the result of *C. albicans* and *C. parapsilosis* and rarely the result of *C. glabrata* or other *Candida* spp.[1,13,14,17] Surveillance studies have demonstrated that BSI caused by *C. albicans* occurs less frequently with increasing age.[1,13,14,17] In contrast, *C. glabrata* is rarely isolated among infants and children but is more frequently found with increasing patient age.[1,13,14,17]

In 2009 a new multidrug-resistant species, *Candida auris,* first emerged and subsequently, infections caused by this species have spread across the globe.[18–20] Compared with other known non-*albicans* species, the emergence of *C. auris* has fostered significant concern because of its rapid global spread and its multidrug-resistance profile. Genomic sequencing has identified at least four major phylogenetically distinct populations (clades), each of which geographically cluster. Widespread genetic variation exists between each clade, but within each population, there is minimal genetic diversity.[21] Interclade genetic variation leads to differences in pathogenicity, biochemical characteristics, and antifungal susceptibility. For example, strains comprising the East Asian clade are associated with noninvasive infections and appear to be more susceptible to antifungal therapy than isolates of the other three clades.[22] *C. auris* is phenotypically similar to other *Candida* spp., but phylogenetically it is most closely related to *Candida haemulonii*.[23] Historically, *C. auris* has often been misidentified by commercial assays, so prevalence estimates for this pathogen and the frequency with which it causes infections in the ICU are difficult to ascertain.[24] Nonetheless, before its emergence in 2009, it appears the prevalence of *C. auris* was exceedingly rare.[21,25] *C. auris* infections occur in ICUs

among critically ill patients of all ages, those undergoing invasive procedures, or those with serious underlying conditions that affect their host defenses.[26,27]

C. albicans is part of one's microbiota. Infections, including BSIs caused by most *Candida* spp., particularly *C. albicans*, arise endogenously from the gastrointestinal mucosa, skin, and urinary tract.[28] Invasive *Candida* infections occur when alteration of the patient's microbiota leads to overgrowth of yeast which, in the presence compromised skin or gastrointestinal mucosa integrity, translocates from its commensal environment to the bloodstream.[28] *Candida* spp., including *C. albicans,* may also be transmitted exogenously in ICU settings.[29,30] Exogenous transmission of non-*albicans Candida* spp. through indirect contact with the ICU environment occurs commonly.[29] For example, *C. parapsilosis* is known for its ability to form biofilms on catheters and inert devices, which enables it to persist in the nosocomial environment.[31] Moreover, it is spread throughout the hospital through hand carriage by healthcare workers.[31] Infections caused by *C. auris* can arise from colonization, travel to endemic regions, and making contact with the hospital environment. *C. auris* frequently colonizes the axilla and groin, but it can also be isolated from a variety of body sites.[32] Some *C. auris* isolates demonstrate the capacity to form biofilms and can survive on inert surfaces. Estimates suggest that acquisition from a contaminated environment or colonized patient can occur in as little as 4 hours, and invasive infections can reportedly develop within a couple days to weeks of admission to an ICU.[21,33,34]

Detection and Isolation

Candida BSIs are often difficult to detect. Symptomatically, BSIs caused by *Candida* spp. are indistinguishable from BSIs of bacterial etiology. Isolating *Candida* spp. from blood is challenging because they are cleared rapidly from the circulation by several organs, particularly the liver. Blood and deep-seated tissue cultures yield positive results approximately 50% of the time, have slow turnaround, and may not manifest until late in the disease course.[35–37] Deep-seated tissue cultures also must often be collected by invasive techniques, which depending on comorbidities, may not be possible.[37] Despite these limitations, these culture-based methods remain the "gold standard" in the diagnosis of candidemia and other forms of invasive candidiasis. Moreover, the ability of automated blood culture systems to recover *Candida* spp. has continued to improve, and nonculture methods are available that, when used in with culture-based methods, can identify more infected patients earlier.[38]

The biochemical characteristics associated with *C. auris* are difficult to distinguish from other species and can vary across clades. Consequently, routinely used, commercially available identification methods based on phenotypic assimilation/fermentation tests often misidentified *C. auris* as a variety of other *Candida* spp. Much of the problem has been related to the lack of representative isolates, or clade diversity, in the databases of most commercially available biochemical identification systems. This gap should close over time, with system database updates as information and experience with this emerging pathogen continue to grow. Molecular methods have some advantages over biochemical methods, but such systems are still reliant upon accurate and up-to-date databases for comparison to the analyzed sample. Still, molecular diagnostic methods developed to enable accurate and timely diagnosis should be employed as needed to complement biochemical methods.

Mortality

Estimating the mortality caused by *Candida* infections is challenging, particularly in critically ill patients, and is dependent on the underlying conditions and specific patient population. Nonetheless, earlier studies continually demonstrated *Candida* BSIs carry a relatively poor prognosis. *Candida* spp. isolated from the blood have been identified as an independent predictor of mortality.[39–41] Whether expressed as part of all-cause mortality or as crude mortality estimates, *Candida* BSIs are associated with high rates of death. Estimates for mortality rates associated with *Candida* BSIs hospital-wide and in the ICU range from 30% to 40%, with rates as high as 72% in certain countries.[7,41–46] Reported mortality rates associated with the emerging pathogen *C. auris* have varied substantially; whether species-related differences in mortality rates exist is difficult to quantify. With more reporting, it is likely that mortality rates associated with invasive infections caused by *C. auris* will be similar to that reported with other *Candida* spp.

Mortality rates associated with candidemia and other forms of invasive candidiasis hospital-wide and in the ICU, though variable, remain quite high despite the advent of potent and safer anti-*Candida* antifungal therapy.[43,45,47,48] Inadequate treatment may be a reason why mortality has not improved despite the availability of potent and safe antifungal therapy. Inadequate therapy resulting from delays in administration, treatment with an agent to which the organism is resistant, inadequate dosing or treatment duration, or failure to recognize and treat candidemia all contribute to the mortality associated with *Candida* BSI.[49–55] Delaying initiation of adequate antifungal therapy even 12–48 hours is independently associated with mortality in candidemia patients.[50,51,53,56–58]

Candidemia produces significant morbidity and increases the length of hospital stay.[1,28] Given the severity of illness associated with this infection, the added length of stay uses significant healthcare resources.[4–6]

Risk Factors

Among critically ill patients, risk factors for *Candida* infections are well known.[10,59–63] Broad-spectrum antimicrobial use, colonization, indwelling vascular catheters, extremes of age, and hemodialysis have been consistently identified as independent risk factors for *Candida* BSIs.[10,41] Many of these diverse risk factors are commonly present and unavoidable in ICUs. The ICU itself provides an ideal environment for transmission of *Candida* spp., including *C. auris,* among patients; thus it is not surprising that prolonged ICU stay has been identified as an independent risk factor.[33,64] For these reasons, combined with the high mortality rates associated with candidemia and invasive candidiasis, a variety of predictive models to identify patients most at risk for infection have been developed using clinical and/or microbiologic variables. Early efforts using only microbiologic data gained through surveillance cultures focused on the relationship between colonization and infection and sought to quantify it through a so-called "colonization index." The use of resource-intensive surveillance cultures and a lack robust validation studies limit the usefulness of such approaches.[65] Predictive models based solely on clinical variables generally demonstrate poor positive predictive values, and consequently have high negative predictive values (i.e., they are better at identifying those who are unlikely to benefit from antifungal therapy).[65] A model designed using microbiologic data and clinical variables in non-neutropenic patients colonized with *Candida spp.* with a minimum length of ICU stay of 7 days. Performed slightly better at identifying at-risk patients and may be useful for recognizing the need for prompt initiation of antifungal therapy.[66] Although these models may have some utility in curbing inappropriate antifungal therapy, they are somewhat complicated to apply, and certain components of individual prediction rules may be impractical to collect or determine.[60,67] Given the diversity of risks associated with developing infection, caution should be used when employing predictive models for candidemia and invasive candi-

diasis in critically ill patients. Clinicians should also be aware of the patient population and the clinical conditions used to derive a given predictive model and understand it may not be generalizable to their patient.[65]

Opportunistic Fungal Infections in Immunocompromised Critically Ill Patients

Invasive Aspergillosis in Critically Ill Patients With Hematologic Malignancies

In contrast to *Candida* spp., the burden of infection caused by *Aspergillus* spp. is small.[1,28] *Aspergillus* spp. cause infection in critically ill populations immunocompromised by burns, cytotoxic chemotherapy, prolonged corticosteroid therapy, malignancy, leukemia, SOT or HSCT, and other congenital or acquired immunodeficiencies. *Aspergillus* spp. are ubiquitous environmental molds. Although several hundred species of *Aspergillus* have been described, relatively few are known to cause disease in humans. Most *Aspergillus* infections are acquired exogenously via inhalation. In the absence of an effective immune response, airborne conidia invade sinus or lung vasculature. Although the lung is the most common site of invasive aspergillosis, *Aspergillus* spp. also demonstrate tropism for cutaneous, central nervous system (CNS), bone, and cardiac vasculature.[68]

The incidence of invasive aspergillosis in immunocompromised patients varies among specific populations. Among patients with hematologic malignancies, those with acute myelogenous leukemia have the highest incidence of invasive aspergillosis.[69–72] Patients in ICUs are at increased risk, and susceptibility in general depends on the use of immunosuppressants, structural lung damage, and genetic predisposition.[73–80] Like patients with leukemia, patients undergoing HSCT are at high risk for invasive aspergillosis. The incidence of invasive aspergillosis varies depending on transplant type but not the type of conditioning regimen (myeloablative vs. nonmyeloablative). The incidence is higher among allogeneic HSCT recipients than among autologous HSCT recipients. In the HSCT population, whether the incidence of invasive aspergillosis is truly increasing or decreasing is difficult to ascertain, because the rate of autopsy continues to decline. The incidence of invasive aspergillosis among SOT is highest among lung transplant recipients and lowest among renal transplant recipients. Patients receiving HSCT or SOT can develop invasive aspergillosis shortly (within 40 days) after transplantation, but typically it occurs late post-HSCT (>40–100 days) or SOT (>90 days).[81–86]

In patients with acute leukemia or in HSCT recipients, prolonged neutropenia after cytotoxic chemotherapy or HSCT is the primary risk for early invasive aspergillosis. Risk factors associated with invasive aspergillosis in HSCT and SOT recipients vary with time after the transplant. However, in general, risks early in the transplant process are associated with transplant-related factors (underlying disease, neutropenia, type of transplant), biologic factors (hyperglycemia, iron overload), and extrinsic factors (excluding spores from the environment, air filtration). In contrast, risks for invasive aspergillosis occurring later in the transplant process include transplant complications (acute graft-versus-host disease [GVHD] [grade ≥3] and high-dose corticosteroid therapy).[85]

Lesions associated with invasive pulmonary aspergillosis evolve over a period of weeks. Computed tomography (CT) findings, especially nodular infiltrates with "halo sign," are strongly suggestive of invasive aspergillosis and infection from other angioinvasive fungi in immunocompromised patients. Moreover, this finding is associated with significantly improved response and survival if antifungal therapy is initiated shortly upon detection of this sign of infection.[87]

Recent diagnostic efforts have focused on detecting non–culture-based serum markers (e.g., galactomannan test, 1,3-β-D-glucan, polymerase chain reaction [PCR]). Galactomannan is a cell wall constituent of *Aspergillus* spp. that can be detected in the serum during invasive infection. The test is specific for invasive aspergillosis and is commercially available as a sandwich enzyme immunoassay (enzyme-linked immunosorbent assay [ELISA]) that detects circulating galactomannan. The values from this test have been shown to strongly correlate with the clinical outcome of patients with invasive aspergillosis.[88–90] Because 1,3-β-D-glucan is a cell wall component of many fungal pathogens, it can be detected by colorimetric detection assays. Although the test is highly sensitive, the presence of 1,3-β-D-glucan in the serum is not specific for any fungi. Using both of these non–culture-based serum markers may improve the ability to diagnose invasive aspergillosis in high-risk populations and could lead to earlier diagnosis or improved monitoring of the success of antifungal therapy.[91,92] CT-guided biopsy has a high diagnostic yield, and samples should undergo both histopathologic and cultural evaluation.[93] The combination of radiologic, serologic, cultural, histopathologic, and clinical data may ultimately improve the diagnosis of invasive aspergillosis and speed up initiation of appropriate antifungal therapy.[94]

Miscellaneous Pathogens in Critically Ill Patients With Hematologic Malignancies

Candida and *Aspergillus* spp. are the primary fungal pathogens in critically ill patients with hematologic malignancies. However, other pathogens such as Mucorales, *Fusarium, Lomentospora, Scedosporium,* and other orphan but emerging mold diseases are increasing in frequency.[28] Each of these less common organisms has clinical characteristics or tissue tropism. In addition, they are often less susceptible than *Aspergillus* spp. to systemic antifungal agents. Consequently, infections caused by these pathogens are associated with high mortality. Of these, the Mucorales are the most common among critically ill patients. These angioinvasive pathogens are acquired through inhalation and produce a necrotic infection with the highest morbidity and mortality.[95] Rhinocerebral, paranasal, pulmonary with or without transdiaphragmatic extension, cutaneous, and gastrointestinal infections are common manifestations of mucormycosis.[96] Common risks are diabetic ketoacidosis, immunosuppression, organ transplantation, traumatic skin damage, and a prolonged ICU stay.[95,97] Pulmonary and disseminated infection mostly affects patients with hematologic malignancy; rhinocerebral and paranasal mucormycosis is predominant in patients with uncontrolled diabetes.[98,99] The "reversed halo" sign in CT is indicative of pulmonary mucormycosis; however, diagnosis should be enforced by cultural and histopathologic work-up of biopsies.[100–102] Management of mucormycosis, including the important role of surgical debridement, is detailed in the global guideline for the diagnosis and management of mucormycosis.[103]

Influenza-Associated Pulmonary Aspergillosis

Within the last years, increasing numbers of influenza-associated pulmonary aspergillosis (IAPA), especially in critically ill patients, were described. Most importantly is that immunocompetent patients also are at risk to develop invasive aspergillosis after influenza infection.[104–106]

Patients with lower respiratory symptoms and respiratory insufficiency need a thorough clinical work-up in addition to bronchoalveolar lavage with lower respiratory tract samples for galactomannan assay; direct microscopy; culture; and bacterial, fungal, and viral PCR. If *Aspergillus* species are recovered either by culture or via PCR testing, chest CT should be performed.

Cryptococcosis, Histoplasmosis, Blastomycosis, and Coccidioidomycosis in Critically Ill Patients

Cryptococcus neoformans, Cryptococcus deneoformans, Histoplasma capsulatum var. *capsulatum, Blastomyces dermatitidis,* and *Coccidioides immitis* are not common pathogens in the ICU setting. These organisms can cause infection in patients with intact immune function. However, with the exception of *B. dermatitidis,* severe infections caused by these pathogens are more common among critically ill immunocompromised populations, particularly those with AIDS and SOT recipients. Cryptococcosis is the third most common invasive fungal infection among SOT recipients.[28,107]

C. neoformans is a ubiquitous encapsulated yeast isolated from diverse environmental sources (i.e., soil, trees and plant material, and droppings from pigeons). This pathogen is primarily acquired by inhalation.[108] In the lung, the organism elicits a cell-mediated response involving neutrophils, monocytes, and macrophages. The cryptococcal polysaccharide capsule, an important virulence factor, facilitates laboratory identification and recognition by host cell-mediated immune response and possesses immunosuppressive properties. The advent of AIDS significantly altered the incidence of cryptococcosis. Before the AIDS epidemic, cryptococcosis was an uncommon disease in the United States, but since then, the majority of cases have been associated with human immunodeficiency virus (HIV) infection.[109,110] The prevalence of cryptococcosis in HIV in the United States has declined with the widespread use of fluconazole and highly active antiretroviral therapy to treat HIV infection. Cryptococcosis still produces significant acute mortality, but overall long-term outcomes have improved dramatically in the past two decades.[111] Mortality among HIV-infected patients and SOT recipients is similar and is estimated to be approximately 15%–20%.[111–113]

Among critically ill immunosuppressed populations, cryptococcal infections typically involve the CNS.[107] However, HIV-negative patients may have only extra-CNS (i.e., skin, soft tissue, or osteoarticular) manifestations. The onset of this infection may be acute or gradual, and patients often present with nonspecific complaints.[114] When the disease manifests as subacute meningitis or meningoencephalitis, classic meningeal findings such as photophobia or nuchal rigidity may be absent.

In cases of cryptococcal meningitis, characteristic cerebrospinal fluid (CSF) findings may be present; however, CSF leukocyte count can be low, and CSF protein and glucose values may be normal. Therefore CSF analysis for cryptococcal antigen and culture of the organism are required to diagnose cryptococcal meningitis. Detection of the organism by India ink stain is highly specific but associated with low sensitivity. Determination of serum cryptococcal antigen using latex agglutination is a highly sensitive and specific test, and therefore it is an important component of the diagnosis of cryptococcal disease. In patients with cryptococcal meningitis, particularly those with AIDS, the serum cryptococcal antigen is usually positive, and usually titers are very high. Detection of antigen in the CSF strongly suggests infection, but in HIV-infected patients, false-negative results can occur in up to 10%, even in the presence of positive cultures. The definitive diagnosis of cryptococcal infection requires a positive culture for *C. neoformans.*

Histoplasmosis (caused by *H. capsulatum* var. *capsulatum*), blastomycosis *(B. dermatitidis),* and coccidioidomycosis *(C. immitis)* are the major endemic mycoses found in North America. Infections by these pathogens are reported primarily in distinct geographic areas, but owing to population mobility, they can be reported throughout the United States. Diagnosis is established via antigen and antibody detection from urine or serum, respectively.[115,116] *H. capsulatum* is endemically distributed primarily in the Mississippi and Ohio River valleys; *B. dermatitidis* is found primarily in the south central United States, the Mississippi and Ohio River valleys, and in certain regions of Illinois and Wisconsin. *C. immitis* is found primarily in the arid southwest regions of the United States. Infection with all these pathogens is acquired via inhalation. Overall, hospitalization is required in an estimated 4.6 and 28.7 cases per million children and adults, respectively.[117] Nationwide, endemic mycoses require substantial healthcare resources to manage and produce significant crude mortality rates in children and adults (5% and 7%, respectively).[117] The severity of histoplasmosis depends on host immune function and the extent of exposure, particularly in the immunocompetent host. Hematogenous dissemination from the lungs occurs in all infected patients, but in immunocompetent hosts, it is controlled by the reticular endothelial system. However, among elderly hosts or those with cell-mediated immune disorders (e.g., HIV infection), progressive disseminated infection readily occurs. After inhalation, *B. dermatitidis* can disseminate from the lungs to other organs as the yeast form. The primary pneumonia is often undetected and resolves without sequelae. Endogenous reactivation in the lungs, skin, or bones is often the first sign of infection.

C. immitis requires the inhalation of only a few arthroconidia to produce primary coccidioidomycosis. Like the other endemic mycoses, in the majority of patients, primary coccidioidomycosis typically manifests as an asymptomatic pulmonary disease.[118] However, it can also manifest as an acute respiratory illness, chronic progressive pneumonia, pulmonary nodules and cavities, extrapulmonary nonmeningeal disease, and meningitis.[119,120]

Among critically ill patients, histoplasmosis manifests as either chronic pulmonary histoplasmosis or progressive disseminated (extrapulmonary) histoplasmosis. Chronic or cavitary pulmonary histoplasmosis occurs in middle-aged and elderly patients with underlying lung disease that compromises the ability of nonspecific host defenses to effectively clear the organism.

Progressive disseminated histoplasmosis occurs in healthy or critically ill immunocompromised hosts, but it is more common and severe in the latter population (i.e., patients with malignancies or HIV infection). The infection can disseminate to a variety of organs, including the reticuloendothelial system, oropharyngeal and gastrointestinal mucosa, skin, adrenal glands, and kidneys.[118]

Clinical manifestations of blastomycosis can mimic many other diseases, such as tuberculosis (TB) and cancer, but typically occurs as an asymptomatic infection, acute or chronic pneumonia, or disseminated (extrapulmonary) disease.[121] Extrapulmonary blastomycosis typically afflicts the skin, bones, and genitourinary system.[121] Cutaneous lesions are the most common skin manifestations of this disease.[121] Extrapulmonary (disseminated) coccidioidomycosis afflicts 1%–5% of all patients infected with *C. immitis* and is deadly if not treated properly. Even with appropriate treatment, chronic infection is common.[119]

SYSTEMIC ANTIFUNGAL AGENTS

Amphotericin B Formulations

Amphotericin B Deoxycholate

Amphotericin B deoxycholate (AmB-d), a polyene antifungal agent, disrupts biologic membranes, thereby increasing their permeability. AmB-d also stimulates the release of cytokines, which causes arteriolar vasoconstriction in the renal vasculature.[121,122]

Pharmacology and pharmacokinetics. The majority (70%) of an administered AmB-d dose is recovered from the urine and feces over a 7-day period; approximately 30% of the administered dose remains in the body a week after dosing.[123]

Overview of toxicity. AmB-d infusion-related reactions, including hypotension, fever, rigors, and chills, occur in approximately 70% of patients.[124–128] These reactions occur early in therapy and often subside

with time. Pretreatment regimens consisting of diphenhydramine, acetaminophen, meperidine, and hydrocortisone may be used to prevent infusion-related reactions. The efficacy of these regimens is unclear, so their routine use is discouraged until the reactions occur, after which pretreatment regimens should be employed with subsequent dosing.[124] Although common and noxious, infusion-related reactions rarely cause early termination of AmB-d therapy or interfere with the use of other medications.

AmB-d also produces dose-related toxicities, including nephrotoxicity, azotemia, renal tubular acidosis, electrolyte imbalance, cardiac arrhythmias, and anemia.[122,125] AmB-d–induced nephrotoxicity is the most common dose-related toxicity.[129] In the ICU this toxicity often limits the use of AmB-d or interferes with the ability to use other medicines. Saline hydration before dosing can reduce the incidence of AmB-d–induced nephrotoxicity, but in the ICU setting, the utility of saline hydration may be limited by fluid restriction employed to manage the fluid status of critically ill patients. Use of the deoxycholate formulation of amphotericin B is discouraged in most, if not all, indications.[130]

Lipid Amphotericin B Formulations

Amphotericin B lipid complex (ABLC) and liposomal amphotericin B (LAmB) are lipid AmB formulations that in many centers have supplanted the use of AmB-d. They retain the activity of AmB-d but have significantly less associated nephrotoxicity than the parent drug.[129,130]

Pharmacokinetic comparisons of lipid amphotericin B formulations. The lipid AmB formulations differ in physicochemical properties and composition. These differences produce subtle differences in their pharmacokinetic behavior that may ultimately prove to be clinically significant. The disposition and activity of these formulations in human tissue is poorly characterized. However, animal data indicate that high serum concentrations may influence the delivery of lipid AmB formulations to certain infection sites such as the CNS and lungs.[131]

Toxicity comparisons of lipid amphotericin B formulations. Compared with AmB-d, the lipid formulations have significantly less associated nephrotoxicity.[129] The formulations differ in the incidence of infusion-related reactions and other adverse events associated with AmB-d infusion.[127,132] These reactions typically do not result in early termination of therapy.[132,133] Observational safety comparisons between ABLC and LAmB suggest the two formulations have a similar nephrotoxicity profile, but prospective comparative data suggest LAmB is less nephrotoxic than ABLC.[129,134] There are few data comparing the safety of lipid AmB formulations to the triazole antifungal agents in critically ill patients.

Azole Antifungal Agents

Fluconazole, Itraconazole, Isavuconazole, Posaconazole, and Voriconazole

The systemic azoles exert a fungistatic effect by dose-dependent inhibition of cytochrome P-450 (CYP)–dependent 14α-demethylase, the enzyme necessary for the conversion of lanosterol to ergosterol, leading to the depletion of ergosterol, the essential sterol of the fungal cell wall, an event that ultimately compromises cell wall integrity. The degree of inhibition varies among the different azole agents, which accounts for differences in the spectrum of activity.

Pharmacology and pharmacokinetics. The triazoles differ in chemical properties, which form the basis of the pharmacokinetic differences between the agents and the propensity of this class to interact with other medications.

Fluconazole pharmacokinetics in critically ill patients are well established.[135–137] In surgical ICU patients, fluconazole clearance correlates with creatinine clearance (CrCl), and its volume of distribution correlates with body weight.[135] In addition, fluconazole volume of distribution is greater in this population than in healthy volunteers.[135] The fluconazole half-life is markedly prolonged in surgical ICU patients.[135] In patients with severe renal dysfunction (CrCl <30 mL/min), some recommend dosage reductions of 50%, but such reductions should be made cautiously and take into account the infecting pathogen in patients receiving fluconazole via enteral feeding tubes.[135,137] Data suggest that the systemic availability of fluconazole is relatively unaffected by administration via enteral feeding tubes.[137] However, serum concentrations obtained with standard doses administered via an enteral feeding tube may not be adequate to treat *C. glabrata* infections, for example.[136] Moreover, in critically ill abdominal trauma patients with and without abdominal wall closure, intravenous (IV) fluconazole may be warranted because the bioavailability of enterally dosed fluconazole in these patients is highly variable.[135]

Itraconazole is a highly lipophilic weak base and practically insoluble in water. It is available as a capsule and as an oral solution formulated in hydroxypropyl-β-cyclodextrin (HP-βCD). The IV solution was removed from the US market in 2008; however, this dosage form may be available in other countries. Slow and erratic absorption of the capsule formulation precludes its use in critically ill ICU patients. HP-βCD enhances itraconazole solubility and improves its oral systemic availability. HP-βCD is poorly absorbed from the gastrointestinal tract, stimulates gastrointestinal secretion and propulsion, and causes diarrhea.

Under fasting conditions in healthy adults, itraconazole is rapidly absorbed from the oral solution, and compared with the capsule, there is less interpatient and intrapatient variability in serum concentrations.[138] After IV administration, renal elimination of itraconazole is negligible, but HP-βCD is renally eliminated (80%–90%). IV itraconazole was contraindicated in cases of significant renal impairment (CrCl ≤30 mL/min) because of concerns over the renal accumulation of HP-βCD. Itraconazole is extensively metabolized by CYP3A4 to produce several metabolites, including one that is bioactive.[139] Rare cases of congestive heart failure are documented in the literature.[140]

Isavuconazole has been available as an IV formulation and capsules since March 2015. It shows a prolonged half-life of 100–130 hours, long persisting tissue levels enabling once-daily dosing after a 1-day loading dose, and independence of oral food intake.[141–143] Isavuconazole clearance is dependent on hepatic CYP3A4/5 metabolism and subsequently modification by uridine diphosphate glucuronosyltransferase (UGT) to be secreted in the feces and bile.[144,145]

Posaconazole is available as an oral suspension, delayed-release tablet, and IV formulation. It exhibits linear pharmacokinetics with dosages between 50 and 800 mg/day.[146] However, absorption of the oral suspension is saturated at doses exceeding 800 mg/day.[146] Posaconazole oral suspension absorption is influenced by gastric pH and is optimal under acidic conditions. Posaconazole absorption and exposure are maximized by dividing the total daily dose four times daily rather than administering it as a single dose for the liquid solution.[147,148] Posaconazole absorption and exposure are also enhanced by administration with or shortly after a meal.[147] In the ICU, it is often impractical to give posaconazole with or shortly after a meal, but absorption and exposure are also enhanced by administering the drug with a liquid nutritional supplement. With the introduction of posaconazole tablet formulation, the issue of pH- and meal-dependent absorption is overcome.[149] In critically ill patients (e.g., because of severe mucositis or mechanical ventilation), the IV formulation is preferred.[150] Although posaconazole binds extensively (>95%) to plasma proteins, its large estimated volume of distribution suggests that it distributes widely throughout the body, but there are few data describing its penetration into the CSF.

Posaconazole is primarily eliminated in feces and urine as unchanged drug. Less than 20% of a dose is metabolized, most of which occurs by UGT pathways and very little by CYP3A4.[151,152]

Voriconazole is a derivative of fluconazole with limited aqueous solubility and improved antifungal activity. It is available in IV and oral formulations. IV voriconazole contains sulfobutyl ether β-cyclodextrin (SBECD) as a solubilizing agent. There are few data on how critically ill patients handle voriconazole. In healthy volunteers, voriconazole exhibits good oral availability and wide tissue distribution, with hepatic metabolism and renal excretion of metabolites. In patients with moderate to severe renal function, SBECD accumulates, and it is recommended that oral dosing be used in patients with a CrCl less than 50 mL/min.[153] Oral dosing in critically ill patients is often not possible; therefore how SBECD is handled in critically patients on dialysis has been examined. A small study observed accumulation of SBECD in three patients during hemodialysis. No toxicity resulting from accumulation of SBECD was observed, and the accumulated dose values were lower but comparable with those used in previous toxicity studies with animals. Nonetheless, if possible, use of IV voriconazole in patients on hemodialysis should be avoided. Data demonstrate that voriconazole achieves adequate CSF concentrations.[153,154]

For all azoles therapeutic drug monitoring is generally indicated, as pharmacokinetic variability is extensive and levels may be unpredictable.[155]

Overview of toxicity. The azoles are a relatively safe class of drugs and are associated with few serious adverse effects. The advent of fluconazole and subsequent agents greatly improved the safety of this class. All the azoles are associated with gastrointestinal intolerance, transient transaminitis, hepatic toxicity, rashes, and dizziness. Nausea, vomiting, and diarrhea commonly occur with all agents in this class, particularly with oral itraconazole solution. These effects are usually observed with high doses of the azoles, but rarely are they severe enough to warrant discontinuation of therapy. All azoles may produce significant elevations in transaminases. Patients experiencing azole-associated transaminase abnormalities are asymptomatic, but these increases, on rare occasions, can evolve into fatal drug-induced hepatitis. The azoles can also produce allergic skin rashes that are generally mild and subside with discontinuation of the drug.

Fluconazole is perhaps the safest azole, and doses four to five times in excess of the recommended daily dose have been well tolerated. For isavuconazole, reported adverse effects are gastrointestinal disturbances, transaminase abnormalities, and hypersensitivity reactions.[143,145] Whether isavuconazole leads to QTc prolongation or decrease of QTc time is not yet understood.[143,156,157] The common adverse effects associated with posaconazole use have been similar to those observed with the other agents in the class (i.e., gastrointestinal, transient transaminase abnormalities); however, the tolerability in comparison to previous azoles has improved.[158] During the phase II and III clinical trials, a QTc prolongation was described in 4% of patients.[159] In addition to the adverse effects seen with other azoles, voriconazole produces transient visual disturbances in approximately 30% of patients, which rarely lead to discontinuation of therapy. These visual disturbances are acute and include changes in color discrimination, blurred vision, photophobia, and the appearance of bright spots.

Azole drug interactions. Drug interactions occur primarily in the intestine, liver, and kidneys by a variety of mechanisms. In the intestine they can occur as a result of changes in pH, complex formation with ions, or interference with transport and enzymatic processes involved in gut wall (i.e., presystemic) drug metabolism. In the liver, drug interactions can occur because of interference with transport proteins and drug-metabolizing enzymes. Drug interactions in the kidney can occur through interference with glomerular filtration, through active tubular excretion, or by other mechanisms. The azoles are one of the few drug classes that can cause or be involved in drug interactions at all of these anatomic sites by one or more of the mentioned mechanisms. Drug interactions involving the azoles have been extensively reviewed.[160–162] Several of the drug–drug interactions involving the azoles occur class-wide. Therefore when using the azoles, the clinician must be aware of the many drug–drug interactions, both real and potential, associated with this class.

Interactions involving the azoles result because of their physicochemical properties. All azoles are somewhat lipophilic and thus undergo CYP-mediated metabolism.[163] The azoles all inhibit one or more CYP enzymes. Itraconazole, posaconazole, and isavuconazole also inhibit ABC transporters such as P-glycoprotein (P-gp), which is a transport protein involved in drug distribution.[164] Fluconazole is not affected by agents that increase gastric pH, but its potential to cause CYP-mediated interactions is more than that suggested by in vitro studies. CYP-mediated interactions involving fluconazole are often dose dependent and can involve drugs metabolized by CYP3A4 (e.g., midazolam, rifampin, phenytoin) and CYP2C9 (e.g., warfarin).[160–162] Because of its linear and predictable pharmacokinetic properties, these interactions may sometimes be avoided or managed by using the lowest effective fluconazole dose. In patients with SOT or bone marrow transplantation, cyclophosphamide, tacrolimus, and sirolimus levels are increased if fluconazole treatment is concomitantly administered.[165–168]

Itraconazole is subject to pH-based interactions and interactions involving CYP3A4 and P-gp. Drugs that can interact with itraconazole include agents that increase gastric pH (e.g., protonics) and lipophilic CYP3A4 (e.g., HMG-CoA reductase inhibitors, benzodiazepines, immunosuppressive agents), and/or P-gp substrates (e.g., digoxin) with poor oral availability.[160–162] Agents that increase gastric pH do not affect the absorption of voriconazole. However, CYP-mediated interactions involving voriconazole can involve drugs metabolized by CYP3A4/5 (e.g., midazolam, rifampin, phenytoin, tacrolimus), CYP2C9 (e.g., warfarin), or CYP2C19 (e.g., omeprazole).[160–162,169] Significant pharmacogenomics considerations exist for drug–drug interactions with voriconazole because it interacts with several polymorphic CYP enzymes, most notably CYP3A4/5, CYP2C9, and CYP2C19. Such considerations are most relevant in interactions involving tacrolimus, midazolam, and warfarin.[162] Although posaconazole is minimally metabolized by CYP, it inhibits hepatic CYP3A4.[160,161] Like the other azoles, the most clinically significant interactions associated with posaconazole involve benzodiazepines (oral midazolam), calcineurin inhibitors (cyclosporine, tacrolimus), other immunosuppressive agents (sirolimus), and phenytoin.[160,161]

Isavuconazole acts as a CYP3A4 inhibitor, and its clearance is highly dependent on CYP3A4/5 metabolism.[145]

Drug interactions involving the azoles that are relevant to the ICU setting are summarized in Table 118.1.

Emergence of resistance and the selective pressure of azoles. Azole resistance in *Candida* has been widely observed for fluconazole and *C. albicans*; however, resistance to other azoles among other *Candida* spp. has been reported and studied. *Aspergillus fumigatus*–resistant isolates were detected with a substitution of leucine with histidine in the cyp51A gene in combination with a 34 base-pair tandem sequence in the promotor gene (TR/L98H) in patients and environmental isolates.[170–172] Both, resistant *Candida* and *Aspergillus* raised concerns about frequency and clinical relevance for patients at high risk of invasive fungal infection.

Echinocandin Antifungal Agents

Caspofungin, Micafungin, and Anidulafungin

Pharmacology and pharmacokinetics. The echinocandins are generally fungicidal and disrupt cell wall synthesis by inhibiting 1,3-β-D-glucan synthase. The echinocandins are active against *Aspergillus* and *Candida*

TABLE 118.1 Drug Interactions Involving Azoles in the ICU Setting

	Fluconazole	Itraconazole	Voriconazole	Posaconazole	Isavuconazole	Comments
CYP Inducers						
Carbamazepine	X	+	X	X	X	Avoid combination – significantly ↓s azole concentration
Phenobarbital	X	+	X	X	X	Avoid combination – significantly ↓s azole concentration
Phenytoin	+	+	+	+	X	Avoid combination – significantly ↓s azole concentration
Rifampin	+	+	+	+	X	Avoid combination – significantly ↓s azole concentration
CYP Inhibitors						
Amiodarone	X	X	X	X	X	Decreases the metabolism of CYP3A4 substrates
Aprepitant	X	X	X	X	X	Avoid combination
Clarithromycin	X	X	X	X	X	Avoid combination – may ↑ azole concentration
Diltiazem	X	X	X	X	X	Monitor therapy
Dronedarone	X	X	X	X	X	Monitor therapy
HAART	X	X	X	X	X	Avoid combination – may ↑ azole concentration
Idelalisib	X	X	X	X	X	Avoid combination – may ↑ azole concentration
Nilotinib	X	X	X	X	X	Monitor therapy
Verapamil	X	X	X	X	X	Monitor therapy
Benzodiazepines and Anxiolytics						
Diazepam	+	+	+	X	X	Effect of midazolam ↑'d by triazoles
Midazolam	+	+	+	+	X	Effect of midazolam ↑'d by triazoles
Triazolam	+	+	X	X	X	Effect of midazolam ↑'d by triazoles
Immunosuppressants						
Cyclosporine	+	+	+	+	X	Triazoles ↑ calcineurin exposure, troughs
Sirolimus	+	+	+	+	X	Triazoles ↑calcineurin exposure, troughs
Tacrolimus	+	+	+	+	+	Triazoles ↑ calcineurin exposure, troughs
Gastric pH Modifiers						
Antacids	X	+	X	–	X	Significantly ↓s itraconazole concentration
H_2 antagonists	–	+	X	X	X	Significantly ↓s itraconazole concentration
PPIs	X	+	X	+	X	Significantly ↓s itraconazole and posaconazole concentration

+, Interaction documented by clinical study or case series; –, no interaction documented by clinical study; X, no published data. *PPIs*, Proton pump inhibitors.

spp. In addition, their spectrum of activity extends to *Pneumocystis carinii*. These agents have little or no activity against *H. capsulatum, B. dermatitidis,* or *C. neoformans.* The echinocandins are large, poorly absorbed lipopeptide compounds and thus are not formulated for oral dosing. The individual echinocandins all demonstrate linear pharmacokinetic behavior. However, each agent differs slightly in how it distributes throughout the body and how it is metabolized or degraded. These differences, though, are not clinically significant. The echinocandins are not appreciably metabolized by the cytochrome P-450 enzyme system, but their interactions with drug transport proteins remain to be elucidated.

Caspofungin binds extensively to plasma proteins (primarily albumin). Caspofungin distribution is multiphasic; initially it distributes to plasma and extracellular fluid before being actively transported slowly into the liver and other tissues via organic anion transport proteins.[173,174] The prolonged elimination half-life (8–13 hours) of caspofungin is caused in part by this slow multiphasic distribution.[173,174]

Caspofungin is slowly metabolized in the liver via *N*-acetylation and peptide hydrolysis to inactive metabolites, which are then excreted in bile and feces.[175] Compared with healthy subjects, caspofungin average serum concentrations 24 hours after administration vary greatly and are elevated in surgical ICU patients.[176,177] Body weight and hypoalbuminemia were found to be prognostic factors responsible for these increased caspofungin concentrations.[176] The clinical significance of such findings is unclear. Dosage adjustment is not required in patients with impaired renal function, but the dose should be reduced by 50% in patients with significant hepatic impairment.[178,179] Micafungin distribution and metabolism are not fully understood. After IV administration, micafungin binds extensively to albumin and, to a lesser extent, alpha-1-acid glycoprotein.[180,181] In addition, the hepatic uptake of micafungin involves transport proteins.[180,181] Micafungin is hepatically metabolized to several metabolites, and it is predominately eliminated as parent drug and metabolites in feces, and the pharmacokinetics are unaltered in a state of renal dysfunction.[182] Micafungin is a weak CYP 3A4 inhibitor.[183]

Of all the other echinocandins, anidulafungin binds the least to plasma proteins, has a larger volume of distribution, and achieves lower peak (C_{max}) serum concentrations.[184–186] Anidulafungin is not hepatically metabolized, but rather in the plasma, it undergoes slow nonenzymatic chemical degradation to an inactive peptide breakdown product, which likely undergoes further enzymatic degradation and is excreted in feces and bile.[185,186] The majority of an anidulafungin dose is excreted in feces or urine as unchanged drug.[185,186]

Toxicity and drug interactions. In general, echinocandins are well tolerated but are associated with nonspecific (i.e., fever, headache, nausea, phlebitis, rash, elevated hepatic enzymes) adverse effects, which are generally mild and rarely cause early discontinuation of therapy. Similarly, echinocandins have low potential to interact with other drugs.

Pyrimidine Antifungal Agents

5-Fluorocytosine (5-FU; flucytosine)

Pharmacokinetics and toxicity. 5-Fluorocytosine (5-FC) is a fluorinated pyrimidine related to 5-fluorouracil, and it is the only agent in this therapeutic class. This antimycotic possesses a narrow spectrum of activity and is often associated with significant toxicity. Moreover, when used as monotherapy, resistance develops rapidly. Orally, 5-FC is nearly completely absorbed and distributes to total body water. Hepatic metabolism and protein binding of 5-FC are negligible. Nearly all of a dose is renally excreted as unchanged drug, and renal clearance is highly correlated with CrCl. Reductions in CrCl prolong the half-life of 5-FC.

Myelosuppression is the primary toxicity associated with 5-FC. In addition, 5-FC can cause significant rash, nausea, vomiting, diarrhea, and liver dysfunction. Flucytosine toxicity is associated with elevated drug concentrations and often occurs in the presence of renal dysfunction. Because 5-FC is primarily used in combination with AmB, the effects of renal dysfunction on 5-FC pharmacokinetics and the subsequent risk of toxicity cannot be ignored.

Dosing and Therapeutic Drug Monitoring

Therapeutic drug monitoring for 5-FC is beneficial. Ideally, 5-FC serum concentrations should be maintained between 25 and 100 μg/mL to minimize toxicity and avoid the emergence of resistance. There are several nomograms for dosing 5-FC based on CrCl in patients with renal dysfunction. However, the nomograms are based on serum creatinine measurements; thus they should be used only with chronic renal dysfunction. In addition, the nomographs should be used cautiously in elderly patients. During therapy, any necessary dosage adjustments should be made on the basis of plasma concentrations. Use of lower 5-FC doses (75–100 mg/kg/day) to minimize toxicity has been advocated. In vitro data suggest antifungal efficacy would not be compromised by such dosing.

IN VITRO SUSCEPTIBILITY TESTING OF SYSTEMIC ANTIFUNGAL AGENTS

In vitro susceptibility testing of *Candida* spp. is widely accepted. Standardized broth microdilution and disk diffusion methods developed by the Clinical and Laboratory Standards Institute (CLSI) and European Committee on Antimicrobial Susceptibility Testing (EUCAST) for in vitro susceptibility testing of *Candida* spp. are reproducible and accurate. Interpretative breakpoints for *Candida* spp. exist for fluconazole, itraconazole, voriconazole, 5-FC, echinocandins, and posaconazole. For antifungal breakpoints, either CLSI or EUCAST provide data categorizing isolates into susceptible, resistant, and intermediate isolates.[187–193] In contrast to *Candida* spp., in vitro susceptibility testing of *C. neoformans* is not routinely performed because primary resistance to first-line antifungal drugs (5-FC, AmB, fluconazole) is not currently a significant clinical problem, and the susceptibility testing methods and interpretive breakpoints for *Cryptococcus* spp. against any antifungal are not validated.[194] Validated broth microdilution methods for in vitro susceptibility testing methods of *Aspergillus* spp. for the azoles and AmB have been developed, but interpretive breakpoints for these agents have not been established.[195] Validated agar-based disk diffusion methods and commercial kits (Etest) are available and may be reliable methods for determining susceptibilities for *Aspergillus* spp.[195] Although broth microdilution methods for susceptibility testing for *Aspergillus* spp. for the echinocandins exist, the minimum inhibitory concentration (MIC) is not the ideal measure of drug activity for this class of agents.[195] The European Committee on Antimicrobial Susceptibility Testing Subcommittee on Antifungal Susceptibility Testing (EUCAST-AFST) determined breakpoints based on pharmacokinetic and pharmacodynamic data, epidemiologic cutoff values, and clinical experience.[188]

TREATMENT OF FUNGAL INFECTIONS IN THE CRITICALLY ILL

Candidiasis in the ICU

There are many options for empirical therapy of fungal infections in the ICU. For many years, the poor prognosis associated with invasive candidiasis has fueled widespread use of antifungal agents, particularly fluconazole, in ICU patients with or without an established source of fungal infection.

The paradigms of preventive antimycotic therapy are prophylaxis and empirical or "preemptive therapy." Prophylaxis is generally initiated in a population in anticipation of certain risk factors, regardless of whether they ever manifest. There are few data to justify the use of this paradigm in the ICU setting,[196,197] where concerns regarding selection of resistant fungal pathogens with indiscriminate antifungal use persist.[198] Moreover, the risk for invasive candidiasis is not the same for all ICU patients, and some risk factors evolve during an ICU stay. Therefore universal institution of antifungal prophylaxis in the general ICU population is generally discouraged in favor of a more targeted approach selectively directed toward those patients at the highest risk.[196,198] *Empiric treatment,* or fever-driven approach, describes the situation of a patient at risk for invasive candidiasis with persistent fever but no other symptom or microbiologic evidence present.

Preemptive therapy is the administration of antifungal treatment before the occurrence of a septic syndrome in patients with several risk factors for infection and evidence of significant *Candida* colonization.[198]

Historically, AmB-d was the sole option for prevention or treatment of candidiasis in the ICU setting. However, the risk of nephrotoxicity and the advent of safe and effective alternatives such as the echinocandins have diminished its use in the ICU.

Prophylaxis

Most studies of prophylactic antifungal use in the ICU setting have evaluated fluconazole. A placebo-controlled study for the prevention of intraabdominal *Candida* infections in a selected group of high-risk abdominal surgical patients showed that daily fluconazole (400 mg) significantly reduced the incidence of invasive candidiasis.[199] This study included patients who had recurrent gastrointestinal perforations or anastomotic leakages; therefore they were at very high risk of developing intraabdominal candidiasis. The patients in this study had moderate acuity (APACHE II score 13), but prophylactic fluconazole prevented *Candida* colonization and dissemination of *Candida* spp. Similar to experiences with HSCT recipients, this study illustrates that when the prophylactic paradigm is selectively applied, it may benefit specific patient populations. This has also been shown in the HSCT population.[199,200] Similar results were obtained in critically ill surgical patients staying in the ICU longer than 3 days.[136,137] However, these results should be interpreted cautiously. This was a single-center study, and true to the paradigm, patient selection was somewhat subjective and based on an anticipated ICU stay of 3 or more days and the clinician's experience. Therefore the results may not be widely generalizable. Others have also prospectively studied prophylactic fluconazole and shown an advantage for low-dose IV fluconazole (100 mg/day) in reducing *Candida* colonization and candidemia, with no effect on either invasive candidiasis or overall mortality.[201] In this double-blind, randomized, placebo-controlled study, all patients received selective digestive decontamination. The incidence of *Candida* infections, particularly candidemia, was significantly less in the fluconazole-treated patients.

Using these three studies and others that included ketoconazole or nonabsorbable antifungal agents, three meta-analyses have attempted to provide further insight into the role of antifungal prophylaxis in critically ill patients, but with disparate results. One analysis concluded that prophylactic fluconazole administration to prevent mycoses in surgical ICU patients successfully decreased the rate of fungal infections, but it did not improve survival.[202] Conversely, a second analysis demonstrated that antifungal prophylaxis indeed reduced the risk of candidemia and resulted in a reduction of overall mortality and attributable mortality (31% and 79%, respectively).[203] The third and perhaps most rigorous meta-analysis demonstrated that antifungal prophylaxis in non-neutropenic critically ill patients reduces proven invasive fungal infections by approximately half and total mortality by approximately one-quarter.[196] Although the analyses had slightly differing results, all concluded that if antifungal prophylaxis is employed, it should be done selectively and targeted toward those patients at high risk of developing infection.[196,202,203] Thus what the prophylactic studies have highlighted is the need to identify high-risk patients for empiric or preemptive therapy.

Empiric Therapy

Empiric therapy is defined as a fever-driven approach in a persistently febrile patient at risk for invasive candidiasis without microbiologic proof of infection. Early treatment of presumed candidemia is favorable, as it is associated with higher survival rates. However, current clinical trials could not show statistically significant prevention of invasive candidiasis.[36,204,205] The optimal time to start empiric antifungal therapy remains unclear. The choice of the antifungal administered should be based on local epidemiology and currently administered drugs (interactions).

Preemptive Therapy (Diagnosis-Driven Approach)

There are few randomized prospective data addressing preemptive therapy. Nonetheless, in the absence of mechanisms to identify patients who would most benefit by preemptive antifungal therapies, this strategy shares similar drawbacks to the prophylactic strategy. However, a growing body of data clearly demonstrates the importance of early institution of antifungal therapy in the adult ICU.[50,52,53,56,57,206] There are a number of predictive rules of varying complexity described in the literature. All of the studies have produced different predictive algorithms; few have been prospectively validated.[67] Although the methods are improving, published methods have yet to be widely applied in ICU patients as part of routine practice. Moreover, there are few data describing the outcomes associated with preemptive therapy instituted based on a predictive rule. One small study assessed the use of a scoring system to identify high-risk patients and demonstrated that fluconazole significantly decreased the incidence of invasive candidiasis in patients with a corrected colonization index (CCI) of $\geq$0.5.[207] Another prospective study to assess whether preemptive antifungal therapy in high-risk ICU patients (CCI $\geq$0.4) would reduce invasive candidiasis demonstrated a significant decrease in the incidence of surgical ICU–acquired invasive candidiasis with preemptive therapy compared with historical controls.[208] However, to generate the CCI, required weekly surveillance cultures at multiple anatomic sites in all ICU patients is necessary. This method is not practical for most ICUs, and it is doubtful that the CCI could be used with similar success without routine surveillance cultures.[60] The serologic detection of 1,3-β-D-glucan, which is not specific for *Candida* spp., is a useful tool for ruling out invasive fungal infection.[35]

With the exception of fluconazole, there are few prospective data assessing the efficacy of other antifungal agents as preemptive therapy in the ICU. Administering itraconazole capsules through feeding and nasogastric tubes, as used in ICU patients, is difficult. Although the oral solution solves this problem, there are few data assessing its effectiveness in preventing or treating invasive candidiasis. Furthermore, the use of itraconazole in critically ill patients is also limited by a significant drug–drug interaction profile with agents commonly used in the ICU.

In case of invasive candidiasis caused by multiresistant *C. auris,* expert consultation at national or international reference centers with regard to susceptibility testing and tailored treatment should be sought. The newly developed EQUAL Candida Score (a European Confederation of Medical Mycology [ECMM] score derived from current guidelines to measure the QUAlity of Clinical Candidaemia Management) aids in guideline-conforming diagnosis and treatment.[209,210]

The recommended antifungal therapy for candidiasis in the ICU setting is summarized in Table 118.2.

Invasive Aspergillosis, Mucormycosis, and Other Opportunistic Mycoses in Bone Marrow Transplantation

Fever and neutropenia are common among critically ill immunocompromised individuals with hematologic malignancies. Although fever can be the result of many causes, these patients, and particularly leukemia and HSCT recipients, are at risk of developing invasive fungal infections caused by *Candida, Aspergillus* spp., or Mucorales. Owing to the difficulty in diagnosing infections caused by these pathogens, antifungal prophylaxis is standard in HSCT patients. Fluconazole has been shown to decrease the incidence of invasive infections with *Candida* spp. and is widely used in the prophylactic paradigm.[199] As stated previously, invasive aspergillosis occurs relatively late after transplantation. Therefore persistently febrile HSCT recipients should be treated empirically with antifungal agents with activity against molds, particularly *Aspergillus* spp.

TABLE 118.2 Summary of Recommended Antifungal Therapy for Aspergillosis, Candidiasis, and Mucormycosis in the ICU Setting

Infection	Recommended Treatment	Alternative Treatment
Invasive Aspergillosis		
Targeted therapy	VCZ, 6 mg/kg IV q12h for 1 day, followed by 4 mg/kg q12h; oral dose is 200 mg q12h if already administered IV; if not, loading is needed *or* ISA, 200 mg TID IV for 2 days, followed by 200 mg/d IV thereafter. Oral dose is 200 mg/d if already administered IV; if not, loading is needed.	Consider if prior azole exposure, L-AmB, 3 mg/kg/d IV Caspofungin 70 mg IV on day 1 and 50 mg/d IV thereafter. If body weight >80 kg, consider continuation with 70 mg/d IV.
Empirical therapy (fever-driven approach)	Caspofungin 70 mg IV on day 1 and 50 mg/d IV thereafter. If body weight >80 kg, consider continuation with 70 mg/d IV.	
Prophylaxis invasive aspergillosis	PCZ tablet 300 mg BID PO on day 1 and 300 mg/d PO thereafter. PCZ 300 mg BID IV on day 1 and 300 mg/d IV thereafter in patients unable to swallow.	
Invasive Candidiasis (Candidemia)*		
Treatment (non-neutropenic) Alphabetic order	Echinocandin – Anidulafungin 200 mg IV on day 1 and 100 mg/d IV thereafter *or* caspofungin 70 mg IV on day 1 and 50 mg/d IV thereafter (if body weight >80 kg, consider continuation with 70 mg/d IV) *or* micafungin 100 mg/d IV – Consider local epidemiology (*C. parapsilosis*, *C. krusei*) and susceptibility testing – if *C. parapsilosis* switch to FCZ 400 mg/d IV.	L-AmB 3 mg/kg/d *or* VCZ 6 mg/kg IV q12h for 1 day, followed by 4 mg/kg q12h; oral dose is 200 mg q12h.
Treatment (neutropenic)	Caspofungin 70 mg IV on day 1 and 50 mg/d IV thereafter (if body weight >80 kg, consider continuation with 70 mg/d IV) *or* micafungin 100 mg/d IV.	Anidulafungin 200 mg IV on day 1 and 100 mg/d IV thereafter *or* L-AmB 3 mg/kg/d. FCZ 400 mg/d IV should be used as step-down only.
Suspected candidiasis treated with empirical antifungal therapy (non-neutropenic patients)	Early treatment for suspected candidiasis is associated with higher survival. However, because of lack of data, no specific drug can be recommended. Choose according to local epidemiology, administered drugs (interactions) from antifungals recommended for candidemia.	
Suspected candidiasis treated with empiric antifungal therapy (neutropenic patients)	L-AmB 3 mg/kg/d *or* caspofungin 70 mg IV on day 1 and 50 mg/d IV thereafter (if body weight >80 kg, consider continuation with 70 mg/d IV).	Micafungin 100 mg/d IV *or* VCZ 6 mg/kg IV q12h for 1 day, followed by 4 mg/kg q12h; oral dose is 200 mg q12h.
Prophylaxis	FCZ 400 mg/d while patients are at high risk.	Micafungin 50 mg/d IV, caspofungin 70 mg IV on day 1 and 50 mg/d IV thereafter (if body weight >80 kg, consider continuation with 70 mg/d IV).
Mucormycosis		
Targeted therapy	L-AmB 5–10 mg/kg/d IV.	ISA 200 mg TID IV for 2 days, followed by 200 mg/d IV thereafter. PCZ 300 mg BID IV on day 1 and 300 mg/d IV thereafter.
Prophylaxis	PCZ tablet 300 mg BID PO on day 1 and 300 mg/d PO thereafter.	

*In case of invasive candidiasis caused by multiresistant *C. auris,* expert consultation at national or international reference centers with regard to susceptibility testing and tailored treatment should be sought. First-line therapy remains an echinocandin, provided that specific susceptibility testing follows as soon as possible.

BID, Twice daily; *FCZ,* fluconazole; *ISA,* isavuconazole; *ITZ,* itraconazole; *IV,* intravenous; *L-AmB,* liposomal amphotericin B; *PCZ,* posaconazole; *PO,* per os; *TID,* three times a day; *VCZ,* voriconazole.

For many years "high-dose" AmB-d was employed as standard empirical therapy of invasive aspergillosis, but within the last decade, based upon data from a randomized trial that compared voriconazole with AmB and suggested superiority with the azole, voriconazole has been considered the gold-standard therapy of documented and suspected aspergillosis.[211] Although voriconazole is considered an initial option for prophylactic therapy, the choice of therapy may vary based upon the individual's organ function. Voriconazole may not be ideal in cases where liver disease is present or if the patient is being treated with concomitant medicines that interact with this azole. Similarly, the presence of reduced renal function may preclude the use of lipid AmB formulations. Fluconazole lacks activity against molds. Itraconazole has activity against *Aspergillus* spp., but as discussed previously, the capsule dosage form is not suitable for many critically ill patients and produces erratic blood levels. The oral solution of itraconazole is not well tolerated and is commonly associated with diarrhea. If available, IV itraconazole solution suffers the same drawback as lipid AmB formulations in patients with diminished renal function. With the new tablet and IV formulations, posaconazole can be administered to critically ill patients independent of food intake or oral application.

The latest development and clinical data on isavuconazole show noninferiority in comparison with voriconazole for the treatment of invasive aspergillosis, but improved tolerability.[156] With their lack of toxicity and low propensity for drug–drug interactions, the echinocandins are promising agents for empirical therapy of invasive aspergillosis in critically ill patients.

For influenza-associated pulmonary aspergillosis pneumonia, neuraminidase inhibitors are first-line therapy. Antifungals are combined as described earlier (mainly voriconazole or isavuconazole). Vaccination is most important to decrease influenza-related illness, especially in patients with comorbidities.[104] The newly developed EQUAL Aspergillosis Score aids in guideline-conforming diagnosis and treatment.[212]

Patients with profound immunosuppression are at risk for mucormycosis, and targeted treatment differs considerably from therapy of Invasive Aspergillosis (IA). With surgery being an integral part of therapy, as it decreases mortality, initiation of high-dosage liposomal amphotericin B or isavuconazole appears warranted.[101,103,156,157,213] A combination of isavuconazole or posaconazole with high-dose L-AmB may be needed in patients with extensive disease.[101,103] The newly developed EQUAL Mucormycosis Score aids in guideline-conforming diagnosis and treatment.[214]

Recommended antifungal therapy for the treatment of invasive aspergillosis and mucormycosis in the ICU setting is summarized in Table 118.2.

Cryptococcosis, Histoplasmosis, and Blastomycosis

Although cryptococcosis, histoplasmosis, blastomycosis, and coccidioidomycosis are not considered nosocomial mycoses, patients with severe infections may require intensive care. The treatment of cryptococcosis, and particularly that in the CNS, evolved from a series of classic clinical trials. Current guidelines base their recommendations on the best data available to address unresolved questions surrounding treatment of this infection.[215] Recommended antifungal therapy for treatment of cryptococcosis in the ICU setting is summarized in Table 118.3.

Management of Increased ICP in CNS Cryptococcosis

Elevations in intracranial pressure (ICP) occur in more than half of patients with cryptococcal meningitis and contribute significantly to the morbidity and mortality associated with this infection.[215] There are much less data on treatment of HIV-negative patients with acute elevated ICP with regard to recommendations of pressure control. Therefore ICP management may be underused in the management of non–HIV-infected patients with CNS cryptococcosis. Persistent elevations in ICP should be managed by sequential lumbar punctures.[215] If necessary, more invasive procedures, including insertion of a lumbar drain or placement of a ventriculoperitoneal shunt, should be performed.[215] The frequency with which sequential lumbar punctures are performed depends on the initial opening pressure and symptoms. For patients with elevated baseline opening pressure, lumbar puncture should be done to reduce the pressure 50% and performed daily to maintain the ICP in the normal range.[215]

Serum and CSF antigen titers are important in establishing the presumptive diagnosis and assessing the prognosis of CNS infection. The test measures cryptococcal polysaccharide capsule antigens but does not differentiate viable from nonviable organisms. Therefore once therapy is started, treatment decisions should not be based on antigen test results.[215] A reduction in antigen titers during therapy is desired, but treatment decisions should be based on culture results. The newly developed EQUAL Cryptococcosis Score aids in guideline-conforming diagnosis and treatment.[216]

Treatment of Histoplasmosis in Critically Ill Patients

Although there are no comparative studies, the efficacy of individual antimycotics for therapy of chronic and disseminated histoplasmosis has been well documented. AmB-d and itraconazole have proven efficacy. The efficacy of 6 weeks to 4 months of AmB-d therapy for chronic infection is approximately 75%; however, relapse is common. The efficacy of itraconazole ranges from 75% to 85%, but, as is the case for AmB-d, relapse may be common. In vitro susceptibility of *H. capsulatum* to fluconazole is poor, and generally it is not used to treat this infection. Voriconazole and posaconazole are likely effective in the treatment of histoplasmosis, but data assessing their safety or efficacy as treatment for this infection are lacking.

The efficacy of AmB-d for therapy for disseminated histoplasmosis among immunocompetent patients is 70% to 90%. Therefore AmB-d is recommended initially in severely ill patients. In a small study, all patients responded to itraconazole 200 to 400 mg daily.[217] Once an adequate response is noted to AmB-d, therapy can be switched to itraconazole.[217] Few data exist concerning the efficacy of the lipid AmB formulations as therapy for disseminated histoplasmosis in immunocompetent patients. Recommended antifungal therapy for treatment of histoplasmosis in the ICU setting is summarized in Table 118.3.

Treatment of Disseminated (Extrapulmonary) Blastomycosis in the Critically Ill

Disseminated blastomycosis and diffuse pulmonary infection are both associated with significant mortality. Treatment of these infections produces cure rates ranging from 85% to 90%, and the effective agents cause little associated toxicity.[119] The optimal duration of therapy for the treatment of blastomycosis with existing antifungal agents is unknown and has been empirically derived from noncomparative studies and clinical experience. In cases of life-threatening infections or extrapulmonary disease and in patients who are severely immunocompromised or have already failed therapy with an azole, the risk of relapse is high.[119] Therefore the duration of therapy is lengthy to prevent relapse. Patients can be switched to safer azole therapy when significant improvement is observed.[119] Pharmacologic treatment of blastomycosis in the ICU setting is summarized in Table 118.3.

TABLE 118.3 Summary of Recommended Antifungal Therapy for Cryptococcosis and Endemic Mycoses in the ICU Setting

Infection	Recommended Treatment(s)	Alternative Treatment
Cryptococcosis		
CNS infection (HIV infected) – Antiretroviral therapy should be delayed to avoid immune reconstitution syndrome	Induction: AmB-d 0.7–1 mg/kg/d IV + 5-FC 100 mg/kg/d PO *or* L-AmB 3–6 mg/kg/d IV *or* ABLC 5 mg/kg/d IV + 5–FC 100 mg/kg/d PO for 4–6 wk, Consolidation: FCZ or ITZ 400 mg/d PO for 8 wk, followed by maintenance with FCZ 200 mg/d PO if disease free and CD4 count >200 μ/L	AmB-d 0.7–1 mg/kg/d IV + FCZ 800 mg/d PO FCZ ≥800–1200 mg/d PO favorable + 5-FC 100 mg/kg/d PO
CNS infection (transplant recipient)	Induction therapy: L-AmB 3–6 mg/kg/d IV *or* ABLC 5 mg/kg/d IV + 5-FC 100 mg/kg/d PO for at least 2 wk Consolidation therapy: FCZ 400–800 mg/d PO for 8 wk Maintenance therapy: FCZ 200–400 mg/d PO for 6 mo to 1 yr	L-AmB 6 mg/kg/d *or* ABLC 5 mg/kg/d for 4–6 wk
CNS infection (non-HIV, nontransplant recipient)	Induction: AmB-d 0.7–1 mg/kg/d IV + 5-FC 100 mg/kg/d PO for at least 4 wk *or* AmB-d 0.7–1 mg/kg/d IV for ≥6 wk *or* L-AmB 3–6 mg/kg/d IV *or* ABLC 5 mg/kg/d IV + 5-FC 100 mg/kg/d PO, if possible ≥4 wk *or* AmB-d 0.7 mg/kg/d IV + 5-FC, 100 mg/kg/d PO for 2 wk Consolidation therapy: FCZ 400–800 mg/d PO for 8 wk Maintenance therapy: FCZ 200 mg/d PO for 6 mo to 1 yr	
Histoplasmosis		
Acute pulmonary (moderately severe to severe)	L-AmB 3–5 mg/kg/d IV; *or* AmB 0.7–1 mg/kg/d IV for 1–2 wk ± corticosteroids, then ITZ 200 mg PO BID for 12 wk	
Progressive disseminated histoplasmosis (moderately severe to severe)	L-AmB 3–5 mg/kg/d IV *or* ABLC 5 mg/kg/d IV; *or* AmB-d 0.7–1 mg/kg/d IV for 1–2 wk; followed by ITZ 200 mg PO BID for at least 1 yr	
Blastomycosis		
Pulmonary (moderately severe to severe)	L-AmB 3–5 mg/kg/d IV; *or* AmB-d 0.7–1 mg/kg/d IV until clinical improvement; followed by ITZ 200 mg PO BID for 6–12 mo	
Extrapulmonary (Disseminated)		
CNS	L-AmB 5 mg/kg/d IV until clinical improvement; followed by an oral azole for at least 1 yr (e.g., FCZ 400–800 mg/d PO *or* ITZ 200 mg PO BID)	
Non-CNS (moderately severe to severe)	L-AmB 3–5 mg/kg/d IV; *or* AmB-d 0.7–1 mg/kg/d IV for 1–2 wk; followed by ITZ 200 mg PO BID for 12 mo	

5-FU, 5-Fluorouracil; *ABLC*, amphotericin B lipid complex; *BID*, Twice daily; *CNS*, central nervous system; *FCZ*, fluconazole; *HIV*, human immunodeficiency virus; *ITZ*, itraconazole; *IV*, intravenous; *L-AmB*, liposomal amphotericin B; *PO*, per os; *VCZ*, voriconazole.

CONCLUSIONS

Invasive fungal infections are widespread in critically ill patients. Specifically in the ICU setting, *Candida* spp. are a common cause of nosocomial BSIs. Many risks are associated with the ICU environment or the patients' underlying disease states that predispose them to infections with these pathogens. In addition, historically, because of the high mortality associated with BSIs caused by *C. albicans*, this species has been the primary fungal pathogen of concern. Although the epidemiology of *Candida* isolates in the ICU continues to shift, whether the changing epidemiology is a consequence of injudicious antifungal use is a matter of speculation and debate. Nonetheless, the steady increase in BSIs caused by *C. glabrata*, a species with reduced susceptibility to antifungal therapy, is concerning. Furthermore, select populations of critically ill patients are at risk of developing life-threatening infections resulting from *Aspergillus* spp., *Fusarium* spp., and the Mucorales. These pathogens are angioinvasive and often respond poorly to antifungal therapy. The endemic mycoses (e.g., histoplasmosis, blastomycosis, and coccidioidomycosis) are not typically a concern in the ICU setting, but patients with severe infections caused by *B. dermatitidis*, *H. capsulatum*, or *C. immitis* will often require intensive care.

Methods to perform antifungal susceptibility tests on a variety of pathogens, particularly *Candida* spp., are becoming routine in clinical practice. There is improved understanding of antifungal resistance and the pharmacodynamic actions of antifungal drugs. This understanding may ultimately lead to more rational use of antifungal agents and improved outcomes in infected patients. The advent of additional safer agents means that the available drugs differ sufficiently in terms of toxicity and potential for drug–drug interactions and that clinicians have the luxury of choice when tailoring antifungal therapy to a specific patient.

KEY POINTS

Overview

- Generally, fungal infections are more prevalent in ICUs than on the general medical wards. Although *Candida* spp. are the most commonly isolated fungi in critically ill patients, infections caused by other opportunistic fungal pathogens (i.e., *Aspergillus, Cryptococcus neoformans, Fusarium,* and Mucorales) are also a concern in selected critically ill populations.
- New antifungal agents differ in mode and spectrum of activity, toxicity, and propensity to interact with other drugs. Antifungal therapy has to be tailored to the specific fungal pathogen and the needs of the patient.

Fungal Infections in the Critically Ill

- *Candida albicans* is the primary fungal pathogen in the ICU setting, but the prevalence of a given species may vary with age. For example, candidemia among neonates is predominantly the result of *C. albicans* and *C. parapsilosis* and rarely because of *C. glabrata* or other *Candida* spp. In adults, *C. glabrata* and *C. albicans* predominate.
- Age differences in the isolation of specific species may have important repercussions for infection control, dosing, and selection of antifungal agents in older critically ill patients.
- BSIs caused by *C. glabrata* have continually become more prevalent.
- In the ICU, *Candida* BSIs are common and difficult to detect, and consequently they carry a relatively poor prognosis. Although isolation techniques have improved, the attributable mortality rate associated with *Candida* BSIs is 35%, and *Candida* spp. are the only BSI pathogens that are an independent predictor of mortality. In surviving patients, candidemia adds approximately 1 month to the length of hospital stay.
- Critically ill patients with hematologic malignancies are at high risk for infections caused by *Candida, Aspergillus* spp., and Mucorales. Infections resulting from these pathogens are associated with high mortality. Influenza-associated pulmonary aspergillosis does not need underlying hematologic malignancy or immunosuppression as a prerequisite and shows high morbidity in critically ill patients.

Systemic Antifungal Agents

- AmB-d possesses a broad spectrum of activity and a long history of use with little acquired resistance, but its toxicity is significant, and it is potentially costly. In low doses for short courses, this agent is tolerable.
- Lipid AmB formulations are safer than AmB-d, but their cost may limit their use.
- Triazoles (azoles) possess a broad spectrum of activity and are relatively safe, but they interact with a vast array of drugs that are commonly used in ICU populations.
- Echinocandins are safe and interact with few drugs, but their spectrum of activity is limited to primarily *Candida* and *Aspergillus* spp.

Treatment of Fungal Infections in the Critically Ill

- The paradigms of preventive antifungal therapy are prophylaxis, empirical, and preemptive therapy. There are few data to support these three approaches. *Empirical therapy* is the administration of antifungals to patients with persistent fever as the only symptom of a potential fungal infection. *Preemptive therapy* is the administration of antifungal treatment before the appearance of sepsis syndrome in patients with risk factors for infection and evidence of significant *Candida* colonization.
- The treatment of CNS cryptococcosis evolved from a series of classic clinical trials. Elevations in ICP occur in more than 50% of patients and contribute significantly to the morbidity and mortality of this infection. Therefore in addition to antifungal therapy, elevations in ICP should be managed by sequential lumbar punctures. Serum and CSF antigen titers aid in the presumptive diagnosis and assessing the prognosis of infection. A reduction in antigen titers during therapy is desired, but treatment decisions should be based on culture results.

ANNOTATED REFERENCES

Garey KW, Rege M, Pai MP, et al. Time to initiation of fluconazole therapy impacts mortality in patients with candidemia: a multi-institutional study. *Clin Infect Dis.* 2006;43:25–31.
Inadequate antimicrobial treatment is an independent determinant of hospital mortality, and in companion publications, this group demonstrated the most common causes of inappropriate therapy for fungal BSIs are omission of initial empirical therapy and incorrect dosing of fluconazole. In this work, the authors link inadequate therapy to mortality. They demonstrate that delays in initiation of therapy of more than 24 hours were independently associated with mortality in candidemia patients. The rate of development of newer and more potent antifungal agents is tailing off. Thus this work, which has been subsequently corroborated, illustrated that current antifungal agents, if used properly, can perhaps help reduce mortality more than realized to date. In addition, it calls attention to the need to focus on early appropriate therapy as a strategy to reduce the significant mortality associated with candidemia.

Golan Y, Wolf MP, Pauker SG, et al. Empirical anti-*Candida* therapy among selected patients in the intensive care unit: a cost-effectiveness analysis. *Ann Intern Med.* 2005;143:857–869.
*Few studies have prospectively evaluated antifungal prophylaxis, and meta-analyses of these studies all produce slightly different conclusions. However, the meta-analyses all agree that in the ICU, targeted empirical therapy directed at targeted high-risk ICU patients is probably a better strategy than general prophylaxis. However, even fewer studies have prospectively evaluated empirical therapy directed at targeted high-risk ICU patients. This study provides a decision analytic model to evaluate the cost-effectiveness of empirical anti-*Candida *therapy given to high-risk patients in the ICU, defined as those with altered temperature (fever or hypothermia) or unexplained hypotension despite 3 days of antibacterial therapy in the ICU. In doing so, they identify that although empirical caspofungin is the most effective strategy, it does not reduce mortality at an acceptable cost. On the other hand, empirical amphotericin B, regardless of formulation, was the least effective strategy, owing to drug toxicity. Thus the most effective strategy was empirical fluconazole, because it reduced mortality at an acceptable cost.*

Maertens JA, Raad II, Marr KA, et al. Isavuconazole versus voriconazole for primary treatment of invasive mould disease caused by *Aspergillus* and other filamentous fungi (SECURE): *a* phase 3, randomised-controlled, non-inferiority trial. *Lancet. 2016;387*(10020):760–769.
This was a phase 3, double-blind, multicenter, comparative-group study. Patients with suspected invasive mold disease were randomized in a 1:1 ratio to receive isavuconazonium sulfate or voriconazole. Isavuconazole was noninferior to voriconazole for the primary treatment of suspected invasive mold disease and was well tolerated, with fewer study drug-related adverse events.

Pittet D, Li N, Woolson RF, et al. Microbiological factors influencing the outcome of nosocomial bloodstream infections: a 6-year validated, population-based model. *Clin Infect Dis.* 1997;24:1068–1078.
This article provides compelling data concerning the importance of Candida *spp. as bloodstream pathogens, in addition to data regarding the crude and attributable mortality rates of* Candida *BSIs in the hospital. The study demonstrates that of all the microbial causes of BSIs, only* Candida *spp. are an independent predictor of mortality resulting from BSI.*

Schauwvlieghe A, Rijnders BJA, Philips N, et al. Invasive aspergillosis in patients admitted to the intensive care unit with severe influenza: *a* retrospective cohort study. *Lancet Respir Med. 2018;*6(10):782–792.
This is the first major study reporting the incidence of invasive pulmonary aspergillosis over several seasons in patients with influenza pneumonia in the ICU. Influenza was identified as an independent risk factor for invasive pulmonary aspergillosis showing high mortality.

Wey SB, Mori M, Pfaller MA, et al. Risk factors for hospital-acquired candidemia: a matched case-control study. *Arch Intern Med.* 1989;149:2349–2353.
This study was one of the first rigorous epidemiologic assessments of the risk factors that predispose patients to candidemia. Established risk factors have been borne out on subsequent analyses.

Influenza and Acute Viral Syndromes

Sylvain A. Lother, Anand Kumar, and Steven M. Opal

Acute viral infections can produce a variety of clinical manifestations and differing degrees of severity. The vast majority of viral infections range from asymptomatic to mild, occur in the community, and are self-limited. Rarely, acute viral infections cause severe disease, which necessitates critical care management. Common viral upper respiratory tract infections can cause serious acute exacerbations of underlying lung disease. Certain viral agents can become life-threatening when they infect vulnerable hosts or if novel pathogens emerge with an absence of immunologic experience in humans. Systemic viral infections, particularly seasonal and pandemic influenza, will be covered in this chapter. However, the increasing availability of rapid genomic diagnostics, immunotherapies, and antiviral chemotherapies now necessitates that intensive care unit (ICU) clinicians maintain some working familiarity with other viral pathogens that can cause serious illness. A summary of clinical presentations, major pathologies, mechanisms of spread, and treatment strategies for a variety of human viral pathogens will be reviewed.

INFLUENZA

Influenza is an acute febrile respiratory illness of varying severity causing seasonal epidemics during the winter months in temperate climates and year-round endemic infections in tropical climates. This viral zoonosis is indigenous to migratory wild birds, with periodic introduction into domesticated poultry, swine, marine mammals, and humans. The consequences of viral pathogen transfer from the avian reservoir or animal vectors to humans can be devastating, with substantial mortality rates, rapid transmission, and potential for global pandemics. The fate of influenza virus infection in human populations depends on the viral virulence properties, antigenic differences from previous influenza outbreaks, fitness of viral replication, dissemination within humans, and status of the host immune defenses.[1]

For seasonal cases, severe disease may occur in individuals with vulnerabilities in host defenses, including the very young, the very old, and those with immunodeficiency or chronic cardiopulmonary disease. However, healthy and young individuals can be seriously affected, particularly in pandemic years when novel viruses emerge. The incidence rates of epidemics depend on yearly variation in viral transmissibility, infectivity, and host susceptibility. Influenza pandemics typically have much higher incidence rates as the virus circulates throughout the entire susceptible global population. In 2009 the H1N1 pandemic swept through a huge number of patients susceptible to the novel swine influenza A (H1N1)pdm09.[2] Other historic pandemics included the Spanish flu of 1918 (H1N1), the Asian flu of 1957 (H2N2), and the Hong Kong flu of 1968 (H3N2). The Spanish flu was particularly catastrophic, infecting a third of the world's population and killing an estimated 50–100 million people.[3]

Even in a typical nonpandemic year, influenza accounts for hundreds of thousands of deaths worldwide and exacts billions of dollars in terms of morbidity and lost productivity. Estimates from the United States indicate that each year, at least 610,660 life-years are lost, with between 9 and 45 million illnesses, up to 31.4 million outpatient visits, 12,000–61,000 deaths, and ~$10.4 billion in direct medical costs from influenza alone.[4,5] The staggering amount expended for influenza care is $16.3 billion in projected lost earnings and an estimated total cost burden (including lost life-years) amounting to $87.1 billion.[4] The estimated global mortality varies from 291,000 to 645,000 deaths per year,[6] and global costs during a pandemic year such as 2009 have been estimated to be upwards of 374 billion dollars.[7] The costs of intensive care services required for managing the most severely ill influenza victims alone are enormous.[2]

Pathogenicity of Influenza Viruses

Influenza viruses are single-stranded RNA viruses of the family Orthomyxoviridae that are classified by their matrix protein composition.[1,8] Three influenza types can infect humans: influenza A, influenza B, and influenza C. The influenza A virus is divided into specific subtypes based upon two major antigenic proteins on its surface: hemagglutinin (HA) and neuraminidase (NA). Influenza A can replicate in the gastrointestinal (GI) tract of some avian species without causing symptoms, but infection and symptoms may occur in other bird species, mammals, and humans. It is the only subtype with pandemic potential. Influenza B almost exclusively infects humans. The lack of animal reservoir leads to less genetic variability, making pandemics with influenza B not possible. However smaller-scale mutations cause seasonal epidemics with potential serious repercussions. Influenza C affects humans, dogs, and pigs but seldom causes severe illness or epidemics in humans.[9]

Influenza virus has a particular predilection for respiratory epithelial cells. Infected cells undergo abrupt cessation of protein synthesis and subsequent apoptosis. Viral particles are released infecting nearby cells. Local immune cells are also infected, causing measurable deficiencies in immune function, increasing the likelihood of secondary complications. Lung histopathology of fatally infected patients reveals a diffuse alveolar filling process, with early hyaline membrane formation, and occasionally focal areas of hemorrhage.[10] The alveolar lining is thickened, with lymphocytic infiltrates and, occasionally, early fibrosis. A typical lung tissue section is seen in Fig. 119.1.

Influenza A Epidemics and Pandemic Potential

The genome of influenza A viruses consists of eight separate single-stranded RNA segments, each encoding a major viral protein. RNA replication provides a high background mutation rate resulting in antigenic "drift"—point mutations that change the major surface

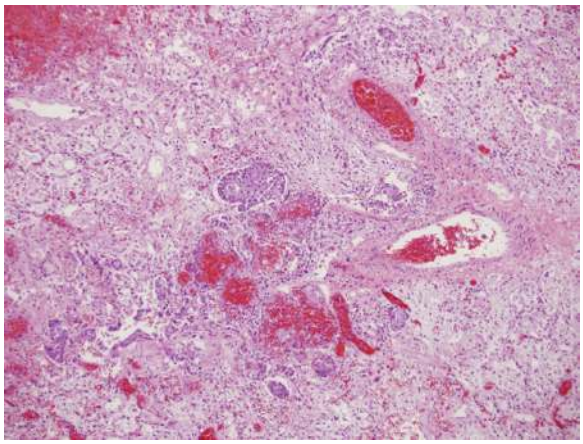

Fig. 119.1 Lung pathology of fatal case of primary influenza pneumonia in a previously healthy 20-year-old woman. Note diffuse alveolar filling, squamous metaplasia, lymphocytic infiltrates, and focal hemorrhage. *(Figure courtesy of David Horn, MD.)*

antigens. The resulting variation is sufficient to evade host immune responses and cause seasonal epidemics. However, influenza pandemics typically occur after an antigenic "shift"—when animal vectors are coinfected simultaneously by more than one influenza A subtype, large-scale reassortment of viral genome segments can occur, resulting in entirely new hybrid viruses with new antigenic constituents. As an example, the swine-origin influenza A/Mexico City/4/2009 (H1N1) pandemic strain was a quadruple-reassorted virus derived from gene segments originating from ducks, Eurasian swine, North American swine, and human-adapted influenza viruses.[11]

Avian-origin influenza viruses can occasionally be transmitted to mammals, causing outbreaks in animals and potentially giving rise to human pandemics. Swine are important "mixing vessels" in shuttling avian influenza viruses to humans.[1] Their mucous membranes express a diversity of sialic acid–coated glycopeptides in a favorable conformation to bind both avian and human viruses via the HA glycoprotein. Avian species primarily express α2,3-linked sialic acids, human upper airways primarily express α2,6-linked sialic acids, and swine express both receptors. This biochemical arrangement in swine facilitates simultaneous dual infections with avian- and human-adapted viruses and the attendant risk of hybrid viruses.[1,11,12]

Seasonal influenza strains in humans bind readily to α2,6 linkages found in the upper airways. This usually leads to high transmission frequency by airborne droplets deposited upon the upper airways, but a relatively low risk of primary influenza pneumonia.[13] However, the lower airways and alveolar pneumocytes of humans express α2,3-linked sialic acids, and avian viruses that bind efficiently to α2,3 linkages can cause severe lower tract disease if deposited into the distal airways. The avian strain of H5N1 preferentially binds to α2,3 linkages in the distal airways, and therefore is poorly transmissible but can cause severe pneumonia. Poultry workers, particularly those in close proximity to infected livestock, can receive large enough inoculums into the distal airways to cause severe pneumonia, with mortality rates ranging from 50%–70%.[13,14]

Notably, the Spanish flu of 1918 (subtype of H1N1) expressed an HA that could bind with high affinity to both α2,6- and α2,3-linked sialic acids.[15,16] This resulted in high transmissibility and spread within the upper airways in addition to severe pneumonia. Disturbingly, the recent 2009 pandemic subtype of H1N1 also bound with high affinity to both α2,6- and α2,3- linkages, resulting in potential for high transmissibility and severe devastation. However, much lower case-fatality rates were seen (<0.1%), likely attributed to fewer viral virulence factors (Table 119.1). Other mitigating factors included infection control strategies, large-scale vaccination, improved supportive care, and effective antivirals. Additionally, populations born before the early 1950s

TABLE 119.1 Pathogenicity Traits and Virulence Factors of Influenza Viruses

Viral Trait	Mechanism of Virulence	Comments
HA and NA – epitope variations	Immune escape from recognition by preexisting antibodies within the population from previous virus exposure	Antigenic drift (point mutations) leads to epidemics; antigenic shift (reassorted genomes) leads to pandemics
HA – cleavability	HA undergoes proteolysis by host-derived proteases before receptor binding	Readily cleaved HA is associated with avid binding and disease severity
HA – binding preference	α2,3-linked sialic acid receptor in alveoli; α2,6 linkage in upper airways	Viruses that bind to the α2,3 linkage or both α2,3 and α2,6 are more virulent; cause lower tract disease and increased transmissibility
HA:NA ratio	NA cleaves sialic acid glycopeptides on host epithelium (binding site for HA)	Optimal ratio of NA and HA activity needed for high replication and viral shedding
NS-1	This viral nonstructural protein inhibits host innate and adaptive immune response; inhibits IFN expression; blocks T-cell activation	Some subtypes have truncated variants of NS-1, associated with lower virulence
PB1-F2	This viral peptide targets host mitochondria, induces apoptosis in CD8 T cells and alveolar macrophages, increases severity of viral pneumonia, increases risk of secondary bacterial infection	Many subtypes do not encode full-length PB1-F2; truncated forms of PB1-F2 are associated with lower virulence; absence of full-length PB1-F2 in 2009 H1N1 pandemic strain led to lower pathogenicity
NA inhibitor resistance	H275Y mutation in the viral NA gene, alters NA inhibitor binding site, leads to oseltamivir resistance	Previously common mutation in seasonal H1N1, but rarely seen in the 2009 H1N1 pandemic strain and in circulating subtypes since then
M2 inhibitor resistance	S31N mutation in viral M2 gene, alters M2 inhibitor binding site, leads to amantadine and rimantadine resistance	Common in both H3N2 and H1N1 circulating subtypes
PB2 temperature range	Viral polymerase preferentially replicates at lower temperatures in mammalian respiratory tract and at higher temperatures in avian GI tract	Mutant polymerases can effectively replicate at broad temperature range, aiding transfer from birds to humans

GI, Gastrointestinal; *H275Y,* histidine substitution for tyrosine at amino acid at position 275; *HA,* hemagglutinin; *IFN,* interferon; *M,* matrix protein; *NA,* neuraminidase; *NS-1,* nonstructural protein; *PB,* polymerase basic; *Pol,* polymerase; *S31N,* serine substitution for asparagine at amino position 31.

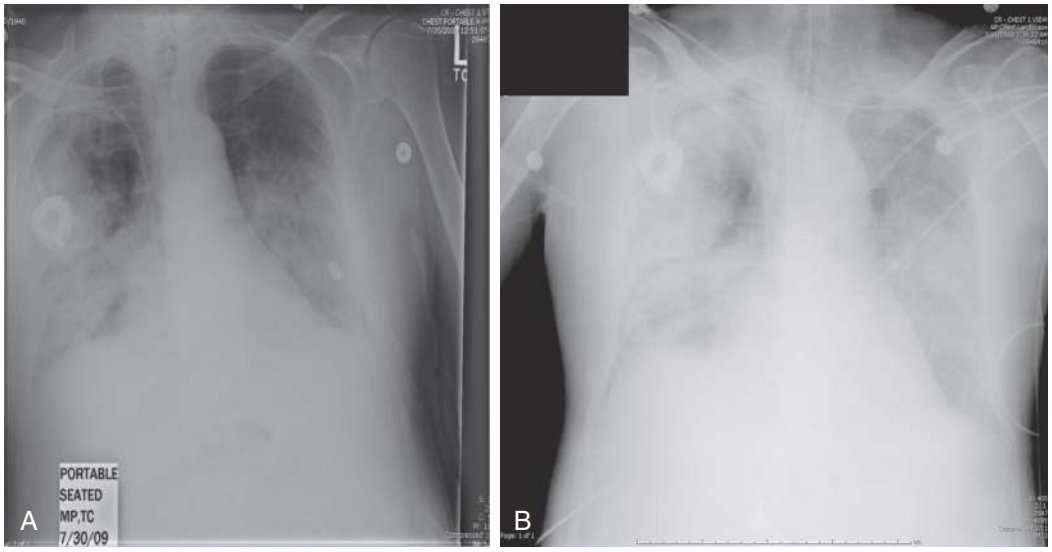

Fig. 119.2 A, Chest radiograph of a 70-year-old male with B-cell lymphoma and hypogammaglobulinemia in the ICU with primary influenza pneumonia. Note Port-a-Cath in right anterior chest wall and diffuse pulmonary infiltrates, most prominently seen in both lower lung fields. **B,** Chest radiograph of same patient 3 days later; note diffuse alveolar filling process associated with profound hypoxemia. The patient expired secondary to severe hypotension and acute kidney injury despite oseltamivir and intensive supportive care.

had a degree of clinical protection from preexisting immunity induced by historical circulation of other H1N1 viruses that evolved from the 1918 H1N1 pandemic virus.[17]

The major subtypes of influenza A currently circulating in humans include several distinct clades of H1N1 and H3N2.[18] The avian flu (H5N1) continues to cause sporadic disease in humans and circulate in birds. Although this is often cited as the most recent pandemic threat, it has yet to demonstrate sustained person-to-person or community-level transmission.[19] Other avian influenza subtypes (H7N2, H7N3, H7N7) cause sporadic outbreaks of mild severity, but more alarming was a novel avian flu (H7N9) that emerged in China in 2013, causing severe pneumonia. Thankfully, inefficient person-to-person transmission has limited spread of this serious subtype.[20] Several other influenza A subtypes are circulating sporadically in humans and animals, but of the 198 possible subtype combinations, only 131 have been detected in nature.[21] The rapid and dramatic evolution of influenza viruses in animals and humans continues to impose a threat to our global population of potential catastrophic proportions. For current updated information on local influenza activity and subtype distribution, the reader is directed to http://www.cdc.gov/flu.

Clinical Manifestations and Pulmonary Complications of Influenza

Classical seasonal influenza in adults is typified by a 4- to 5-day period of sudden-onset fever, chills, upper respiratory tract symptoms, headache, muscle pain, and weakness. High fever is characteristic and correlates with severity of initial symptoms. Fevers typically last for 3 days but may persist for up to 8 days. Diarrhea is more common with influenza than with most other viral upper respiratory tract infections. Other distinguishing features include the predominance of systemic symptoms, often overshadowing the respiratory symptoms (dry cough, pharyngeal pain, nasal discharge and obstruction).

Primary influenza pneumonia is the most common serious complication and occurs in up to 29% of patients hospitalized for influenza.[22] Early symptoms are indistinguishable from typical influenza aside from a rapid and fulminant progression of hypoxemia and widespread bilateral interstitial pneumonitis on chest radiograph (Fig. 119.2). These patients generally present to the hospital within 4 days of symptom onset with shortness of breath and require ICU admission within <1 day of hospital presentation. Influenza pneumonitis frequently progresses to hypoxemic respiratory failure, with over 80% of patients requiring mechanical ventilation. Very few patients can successfully be managed with noninvasive ventilation strategies alone.[22] The mean admission PaO_2/FiO_2 in the ICU is <150 mm Hg, and advanced ventilatory/oxygenation strategies are often needed for refractory cases.[23–27]

Secondary bacterial pneumonia and influenza-bacterial coinfection are frequently severe, and also common, affecting between 11% and 35% of hospitalized cases.[28–30] Secondary bacterial pneumonia is generally attributable to damaged airways and poor mucociliary clearance after severe influenza pneumonia.[31] Patients frequently experience a period of improvement after the classical influenza illness before recrudescence of fever, cough, purulent sputum, and consolidation on chest radiograph. Influenza-bacterial coinfection is more complex, with bacterial and viral synergism. Viral PB1-F2 proteins induce pneumocyte apoptosis, which facilitates *Streptococcus pneumoniae* growth in lung tissue.[32] Sialic acids that have been cleaved by NA allow more efficient *S. pneumoniae* binding to epithelial surfaces and increase lethality in experimental models.[33,34]

The most common pathogens involved in secondary bacterial pneumonia and influenza-bacterial coinfection include *S. pneumoniae* (up to 35%) and *Staphylococcus aureus* (up to 28%),[30] but others may be implicated, including *Streptococcus pyogenes, Haemophilus influenzae, Moraxella catarrhalis,* and gram-negative bacilli.[25,35–37] Given the frequency of secondary bacterial infection, clinicians should have a low threshold for considering antibacterial agents against these commonly observed pathogens.

In children with severe influenza infection, the median age of hospitalized patients is 5.0 years (range 1 month to 17 years).[25,28,29,38] One or more chronic comorbid illnesses are typically observed (70.2%): lung disease (44%), neurologic diseases (19%), immune suppression or immunodeficiency (16%), history of prematurity (9%), and congenital

heart disease (7%). Mechanical ventilation is used in approximately 68% of children admitted to the ICU, and the median duration of ventilation is 6 days (range 0–67).[25]

Extrapulmonary Complications of Influenza

Influenza may cause serious or life-threatening complications in other organ systems, including cardiac, renal, hepatic, and neurologic disease.[8,29] Myocarditis is a common complication of influenza illness and may occur in up to 10% of hospitalized patients.[39] The diagnosis is made on the basis of presenting symptoms, elevated cardiac enzymes, and echocardiographic findings. Importantly, myocarditis may be present with or without serious pulmonary involvement. Occasionally, myocarditis leads to serious complications in the ICU, including atrial and ventricular arrythmias, atrioventricular (AV) conduction block, pericardial effusions with or without tamponade, acute myocardial infarctions, and reduced ejection fraction with heart failure.[39,40] Reduced ejection fraction may occur in up to 80% of patients with influenza myocarditis, leading to serious repercussions in patients with critical illness and shock.[40]

Septic shock may occur in up to 15%–30% of critically ill patients with influenza and is more common in the setting of bacterial coinfection.[41] In addition to the effects of myocarditis, a severe surge of cytokines and capillary leak causes reduced systemic vascular resistance, reduced perfusion pressure, microcirculatory coagulopathy, reduced end-organ perfusion, and cellular toxicity. The presence of shock is associated with approximately 30% mortality, and studies have shown that *S. aureus* coinfection is an independent predictor for mortality.[41] Acute kidney injury (AKI) may ensue as a result of prerenal and tubular injury secondary to sepsis and/or rhabdomyolysis. Many patients also receive nonsteroidal antiinflammatory drugs (NSAIDs) because of myalgias and other systemic symptoms, adding potential nephrotoxicity.

Neurologic complications often accompany severe influenza infection, including encephalitis, encephalopathy, and seizures. Computed tomography (CT) and magnetic resonance imaging (MRI) studies of the brain are often abnormal, but findings are nonspecific. Guillain-Barré syndrome (GBS) incidence increases in the months during and after seasonal influenza. It has been suggested that influenza may trigger this serious neurologic complication.[42]

Risk Factors and Prognosis With Influenza Critical Illness
