Pneumothorax

Sharad Chandrika and David Feller-Kopman

INTRODUCTION

The term *pneumothorax* was first coined by Itard in 1803.[1] Pneumothorax is defined as the presence of air in the pleural space. Traditionally, pneumothorax has been categorized into primary, secondary, traumatic, and iatrogenic. Spontaneous pneumothorax is considered "primary" when there is no obvious underlying lung disease and "secondary" when there is a known underlying lung disease such as emphysema or cystic lung disease. As thoracic imaging has evolved, subtle cystic/fibrotic disease is more easily visualized, and the categorization of primary vs. secondary has been called into question.[2] Traumatic pneumothorax is secondary to penetrating or blunt thoracic trauma, which is further categorized as iatrogenic or noniatrogenic. The clinical implications of pneumothorax are dependent on the degree of lung collapse of the lung on the affected side and the patient's underlying cardiopulmonary reserve. A simple pneumothorax may rapidly progress to a life-threatening "tension pneumothorax" with resultant hypoxia and/or hypotension or cardiogenic shock, especially if the patient is receiving positive-pressure ventilation. Therefore it is imperative that healthcare workers in the intensive care unit (ICU) be able to rapidly diagnose and treat a patient with pneumothorax.

PATHOPHYSIOLOGY

Pleural membranes line the surface of the lung and the lining of the chest wall. Under normal physiologic conditions, the lungs are inflated secondary to airway pressure being higher than the pleural pressure.[3] Pneumothorax most commonly results from a breach in the visceral pleura, but air may also enter the pleural space from the atmosphere (trauma/iatrogenic) or via gas-producing organisms in the setting of empyema.[4] Primary spontaneous pneumothorax (PSP) typically occurs in tall, thin males with an "ectomorph" body habitus, and is thought to be the result of increasing pleural porosity or rupture of previously unseen subpleural blebs.[5] Although height and male sex are risk factors for primary spontaneous pneumothorax, smoking has been identified as the most important risk factor contributing to the development of the disease.[6] The relative risk of pneumothorax increases from 7 to 100 times higher in light to heavy smokers.[6] Smoking cessation is associated with a significant reduction in the risk of recurrence[7] (Table 66.1). Several inherited disorders such as Marfan syndrome, Birt-Hogg-Dubé syndrome, other mutations of the folliculin gene (FLCN), alpha-1-antitrypsin deficiency,[1] and homocystinuria also predispose to pneumothorax. Traumatic pneumothorax is the second most common clinical finding after chest trauma, following broken ribs. Iatrogenic pneumothorax in the ICU most often occurs after central venous access, thoracentesis, transbronchial lung biopsy, and positive-pressure ventilation.[8]

The progression from a simple pneumothorax to tension pneumothorax relies on the continued escape of gas into a closed pleural space. This leads to increasing pleural pressure, with resultant atelectasis and hypoxemia. As the pleural pressure continues to elevate, venous return is limited, resulting in a fall in cardiac output and shock. Animal studies have investigated the pathophysiology of tension pneumothorax.[9–12] Proposed mechanisms contributing to tension physiology include hypoxia caused by shunting of blood through the atelectatic lung, hypoventilation resulting from increased transpleural pressure causing reduced diaphragmatic excursion, and decreased preload from increases in intrathoracic pressure. The traditionally taught mechanism of vena cava mechanical obstruction likely plays less of a role.[9] Major clinical findings may differ depending on whether the patient is spontaneously breathing or on positive-pressure ventilation. Hypoxia is usually the main finding in spontaneously breathing patients. Patients with impaired respiratory drive (needed to decrease intrathoracic pressure and increase venous return) or hypovolemia, however, may have reductions in cardiac output.

Patients on mechanical ventilation pose the highest risk for hemodynamic instability. The rate of increase in volume in the pleural space depends on the volume and pressure being delivered and degree of pleural injury. With an increasing volume of gas entering the pleural space, a critical point is reached, resulting in decreased venous return and eventual equalization of pressure within the cardiac chambers, in turn leading to a decrease in cardiac output and, ultimately, cardiac arrest.[13]

DIAGNOSIS AND EVALUATION

The diagnosis of pneumothorax in critically ill patients can sometimes be made with information from the history and physical examination, noting acute onset of dyspnea or chest pain, tachycardia, hypotension, decreased breath sounds, pulsus paradoxus, and contralateral tracheal deviation. Tension pneumothorax should be suspected if severe tachycardia, hypotension, hypoxia, or cyanosis have developed. Although clinical features can be used to diagnose the presence of a pneumothorax, it should be noted that many of these findings are nonspecific and have not been a reliable indicator of pneumothorax size, especially in the case of secondary spontaneous pneumothorax (SSP) where severe symptoms of dyspnea can be out of proportion to the size of the pneumothorax, and underlying emphysema can cause diminished breath sounds. Acute changes in ventilatory parameters, such as a reduction in tidal volume or increase in airway pressures resulting from reduced respiratory system compliance, may be associated with pneumothorax but can also be found in other disease states and therefore have the potential to be misinterpreted under different clinical scenarios.

TABLE 66.1 A Possible Alternative Classification System to Categorize Pneumothorax

	Management Issues
Iatrogenic pneumothorax	Likely benign course in which conservative management may be appropriate
Traumatic pneumothorax	Management of coincident trauma or parenchymal injury
Pneumothorax associated with endometriosis	Potential role for hormone treatment; high risk of recurrence
Pneumothorax with a genetic predisposition (e.g., Marfan syndrome, Birt-Hogg-Dubé syndrome)	Related multisystem pathology; familial screening
Idiopathic pneumothorax	Likely low risk of recurrence; conservative or ambulatory management may be appropriate
Pneumothorax with previously unrecognized abnormal parenchyma (e.g., respiratory bronchiolitis or bullous disease)	Smoking cessation; consideration of early surgical intervention in selected cases
Pneumothorax associated with infection or immunocompromise	Identification of underlying immunocompromise; targeted antimicrobial treatment
Pneumothorax with abnormal parenchyma in context of known lung disease (e.g., COPD, cystic fibrosis, lung cancer, interstitial lung disease)	High risk of ongoing air leak and recurrence; suitability for surgical intervention; optimizing management of existing lung disease

COPD, Chronic obstructive pulmonary disease.

From Bintcliffe OJ, Hallifax RJ, Edey A, et al. Spontaneous pneumothorax: time to rethink management? *Lancet Respir Med.* 2015;3(7):578.

Because of the lack of specificity of the clinical examination, radiologic imaging remains the gold standard for the diagnosis of pneumothorax.[14] It should be understood, however, that therapeutic intervention (i.e., needle decompression or chest tube placement) may be required in unstable patients based on a clinical diagnosis before radiographic confirmation[15] (Fig. 66.1).

Portable chest radiographs traditionally have been the initial diagnostic test in the ICU to diagnose a pneumothorax. Most of these radiographs have the patient in the supine or semirecumbent position rather than an erect position.[16] However, caution should be exercised when interpreting supine radiographs, as the most nondependent part of the chest (where air will collect) is in the costophrenic recess, known as the *deep sulcus sign*.[17] A skin fold on chest radiograph may resemble a pneumothorax by mimicking a sharp lung edge but, in fact, represents a normal finding.[18] Skin folds may be seen in elderly or obese patients and can be confirmed by a repeat radiograph in a different position.

Because of the limitations of chest radiography, it is important to treat the patient and not the radiograph. In the right clinical situation with concern for tension pneumothorax, clinicians should proceed with immediate pleural evacuation to avoid further clinical decompensation. If there is doubt in regard to the findings on a chest radiograph and the patient is stable, it is advised to seek the expert opinion of the radiologist and/or further imaging with ultrasound or chest computed tomography (CT).[19]

CT is the gold standard test for confirming the diagnosis and size of the pneumothorax. CT also allows for assessment of underlying lung parenchyma and pleural-based lesions and can differentiate bullous disease from pneumothorax, potentially avoiding inappropriate drainage and creation of a parenchymal-pleural fistula.[20] With the widespread use of CT scanning, the diagnosis of occult pneumothoraces has become more common. The occult pneumothorax is defined as a pneumothorax detected via CT that was not clinically suspected or recognized on standard chest radiography.[21] This may be more common with the increased availability of CT scans. The overall incidence of occult pneumothorax in trauma patients ranges from 2% to 15% and can be as high as 64% in multitrauma patients.[22] There is controversy on how to treat patients with an occult pneumothorax on mechanical ventilation because of the potential escalation to tension pneumothorax. A multicenter randomized study in a trauma population on mechanical ventilation did not show a difference in respiratory distress between observation vs. prophylactic chest tube insertion (relative risk: 0.71; 95% confidence interval: 0.40–1.27).[23] Ultimately, 31% of the observed patients had subsequent chest tube placement nonurgently for worsening pneumothorax on imaging without an increase in morbidity. Although this single study lends support for the observation of occult pneumothoraces in mechanically ventilated trauma patients, further studies are needed to guide management in different populations and situations. Expert consensus remains that clinical judgment is used to determine if drainage is needed.[24]

Thoracic ultrasound has become an increasingly accessible tool in the ICU for the diagnosis of pneumothorax. There are several advantages of ultrasound over chest radiograph and CT, including availability at the bedside, absence of radiation, real-time imaging, and the ability to easily perform dynamic and repeat evaluations. A recent meta-analysis has shown that ultrasound is more sensitive and specific than a standard chest radiograph for detecting pneumothorax and can be used to assess lung re-expansion after tube thoracostomy.[25] The major pitfall in ultrasound is in acquiring the skills of image acquisition and interpretation for the nonradiologist.[26] Another limitation is that severe subcutaneous emphysema will limit ultrasound waves penetrating into the thoracic cavity and also create an "E-line" artifact. A study comparing ultrasound with CT/chest radiographs for the diagnosis of occult pneumothorax showed that the use of ultrasound detected 92% of occult pneumothoraces diagnosed with CT.[27] Ultrasound is extremely useful in ruling out pneumothorax after pleural procedures and central line placement, negating the need and time delay for a portable radiograph.[28,29]

Normal movement of the underlying lung with respiration produces a "sliding" or "gliding" sign, and this dynamic movement identifies the visceral pleura and lung parenchyma. Examination of the lung with ultrasound commonly shows A-lines and B-lines. A-lines are horizontal, hyperechoic lines that represent reverberation artifacts of the visceral-parietal pleural interface. B-lines, also known as *comet tail artifacts,* are caused by echo reverberations of the air-filled lung and appear as narrow, hyperechoic, raylike opacities extending from the pleural line to the edge of the ultrasound screen without the fading that moves with lung sliding. As pleural air would block the visualization of the underlying lung, the presence of B-lines and lung sliding rule out a pneumothorax, with a negative predictive value of 100% in the location of the chest probe.[30] It is important to examine several locations on the thorax, especially the superior anterior and lateral

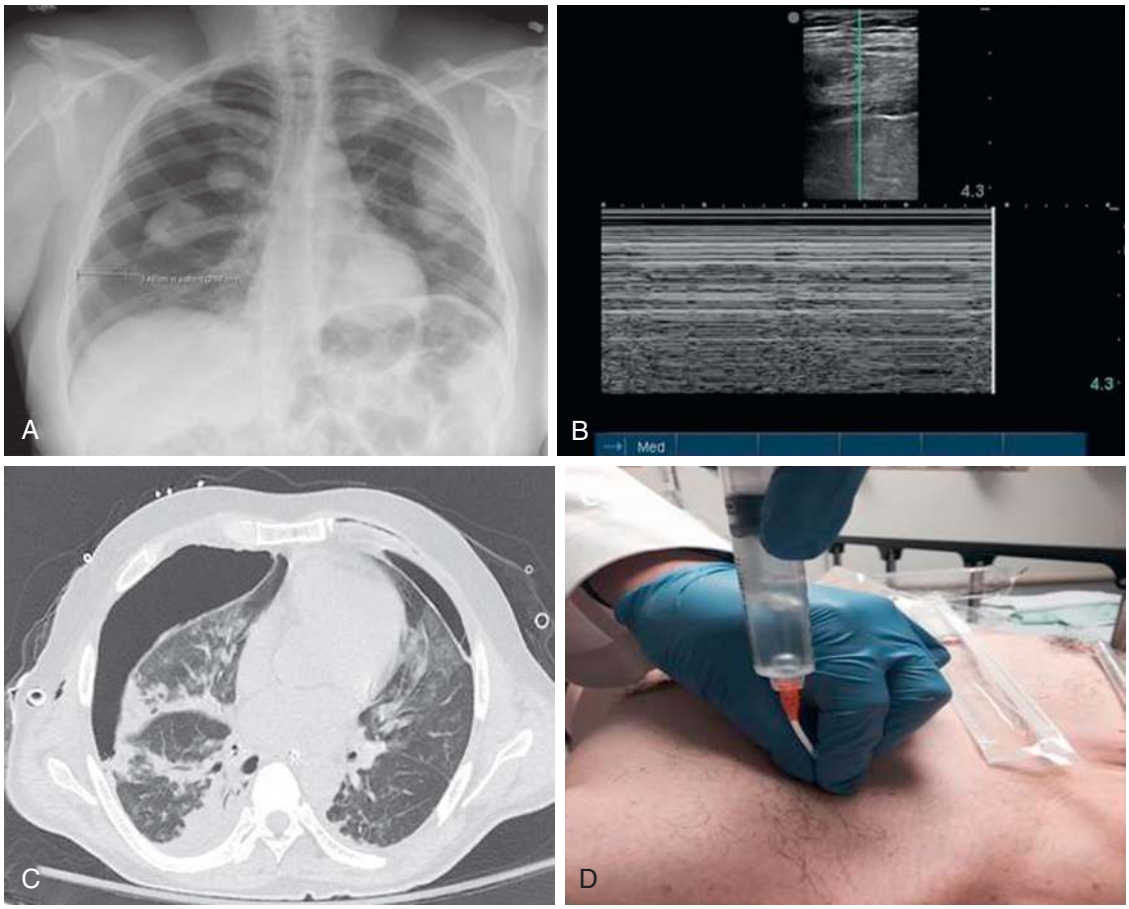

Fig. 66.1 Different Modalities for Diagnosing Pneumothorax. **A,** Chest x-ray. **B,** US M-mode. **C,** CT scan. **D,** Needle aspiration. *CT,* Computed tomography; *US,* ultrasound.

chest wall, where air would normally accumulate. One can also fail to see lung sliding when there is contralateral mainstem intubation, pleural-parenchymal adhesions, endobronchial obstruction, or diaphragmatic paralysis. Therefore the main utility of ultrasound for the assessment of pneumothorax lies in its ability to rule out a pneumothorax. Lung ultrasound, however, can also be used to rule in pneumothorax by identifying the point where the lung separates from the chest wall. This is seen as an area where normal lung sliding meets an area where no lung sliding is seen and has been termed the *lung point*. The lung point can be visualized with both B-mode and M-mode ultrasound and, when seen, has 100% specificity for pneumothorax.[31] The sensitivity of the lung point for pneumothorax is inversely proportional to the size of the pneumothorax, as a large pneumothorax would prevent the parenchyma from opposing the chest wall. Ultrasound has recently been used to serially follow the lung point and determine if the pneumothorax is enlarging.

MANAGEMENT

Appropriate treatment of pneumothorax is dictated by the clinical assessment of symptoms, pneumothorax size, and etiology. The primary goal of the management of a pneumothorax is to restore normoxia and hemodynamic stability and evacuate air from the pleural space, allowing visceral and parietal pleural apposition.

There is no universal consensus regarding the management of PSP. The British Thoracic Society (BTS) and American College of Chest Physicians (ACCP)[32,33] recommend that select patients with small (defined as <2 cm at the hilum on standard chest x-ray [CXR] by the BTS and <3 cm at the apex by the ACCP) PSP without symptoms be managed with observation. In patients with PSP >2 cm and/or symptoms, BTS recommends simple aspiration, whereas the ACCP recommends chest tube drainage. Both BTS and ACCP recommend pneumothorax prevention in patients with recurrent pneumothorax. Pleurodesis as an alternative strategy is recommended by both BTS and ACCP guidelines where the patient may not be a surgical candidate or be unwilling to undergo surgery. Operative intervention is reserved for patients with recurrent pneumothorax or individuals who plan to engage in high-risk activities (such as flying or diving).

As patients with SSP have underlying lung disease with less cardiopulmonary reserve, they typically present more acutely than those with PSP and require more urgent drainage, and hospitalization is recommended.[34] The BTS and ACCP recommend the use of high-flow oxygen and observation in a hospitalized setting for patients with small/asymptomatic SSP and chest drainage for symptomatic or large SSP.

The majority of patients in the ICU with a pneumothorax require evacuation of pleural space.[35] Pneumothorax secondary to barotrauma, tension pneumothorax, and concurrent sepsis has been significantly and independently associated with an increased risk of death in the ICU.[36] The BTS recommends intercostal drainage for all pneumothoraces in patients on a mechanical ventilator and those exhibiting signs or suspicion of tension physiology, traumatic pneumothorax, or hemothorax and postsurgical pneumothoraces.[32] The role of needle decompression has not been well elucidated for patients on mechanical ventilation, and

there are data to suggest that the therapeutic effect of this intervention may be insufficient despite proper placement and positioning.[37,38] If needle decompression is performed, standard tube thoracostomy is usually subsequently required for definitive management.

The standard treatment for a mechanically ventilated patient with a pneumothorax or tension pneumothorax is tube thoracostomy.[39,40] Several studies have reported excellent success rates using small-bore catheters.[41] These tubes are associated with less pain and likely have reduced complications in patients with thrombocytopenia or coagulopathy. The risk of serious complications associated with small-bore catheters is small, with a frequency of organ injury of 0.2% and a malposition rate of 0.6%. The largest risk is drain blockage, with a rate of 8.1%, and it is easily preventable with scheduled sterile flushing to maintain patency.[42]

The use of ultrasound has decreased the rate of complications and should be routinely used, especially in the nonemergent placement of chest tubes.[15] If there is a high clinical suspicion of tension pneumothorax, chest tube insertion should not be delayed while awaiting radiographic confirmation; however, in this case, it may be prudent to perform open (surgical) thoracostomy as opposed to the modified Seldinger technique to avoid injury to the lung, heart, or other organs should pneumothorax not be present.[43]

PERSISTENT AIR LEAK

A persistent air leak (PAL) is defined as an air leak present for >5–7 days and may represent a more complex problem requiring additional treatment beyond chest tube insertion. Factors such as poor nutrition, the size of the pleural injury, mechanical ventilation, and medications (i.e., steroids) may hinder the resolution of pneumothorax. For most patients with PAL, conservative measures such as continued chest tube drainage are recommended. Many of these leaks will resolve spontaneously. Additionally, if the patient can clinically tolerate a water seal (even if the pneumothorax enlarges), the lack of an increased transpleural pressure gradient created by chest tube suction can expedite healing of the visceral pleura. Other supportive strategies include the optimization of nutrition and therapy for comorbidities. For select patients who fail conservative therapy, bronchoscopic therapy with endobronchial valve placement can be attempted. Bronchoscopic treatment implanting a unidirectional endobronchial valve to isolate and close the fistula has been described to be safe and effective and is approved for a humanitarian device exemption in the United States.[44] The valves are currently indicated for the treatment of prolonged air leaks or leaks that are likely to be prolonged (defined as >7 days) after lobectomy, segmentectomy, or surgical lung volume reduction. The procedure is performed by first identifying the "culprit" airway via sequential bronchoscopic balloon occlusion. When the airway leading to the alveolar-pleural fistula is occluded, the amount of air leak in the chest drainage system will stop or be significantly reduced. The valve is then sized and inserted through the working channel of the flexible bronchoscope. The visceral pleura defect is then allowed to heal, and the valve is removed 6 weeks later.

For patients who fail or are not candidates for bronchoscopic or surgical approaches, ambulatory drainage devices and nonsurgical pleural procedures are options (e.g., blood patch or chemical pleurodesis) that can be offered. Although no randomized studies have compared different chemical agents for pleurodesis, a recent large European prospective series showed that European-graded talc used for pleurodesis is effective and safe.[8,9] Nonsurgical pleural procedures are also considered complementary when surgical or bronchoscopic methods achieve a partial response only. Choosing among them should be individualized and depends on fistula size, local expertise, and patient preference. Except for patients with persistent air leaks, procedures to prevent the recurrence of a PSP should be reserved for the second pneumothorax occurrence, yet be considered after the first SSP.

KEY POINTS

- Pneumothorax is common in the ICU and may have various clinical presentations.
- Treatment of a highly suspected tension pneumothorax should not be delayed for radiographic confirmation.
- Occult pneumothorax on mechanical ventilation should be closely monitored if chest tube insertion is readily available.

Community-Acquired Pneumonia

Girish B. Nair and Michael S. Niederman

INTRODUCTION

Pneumonia is an infection of the gas-exchanging units of the lung and has a wide spectrum of clinical severity, ranging from mild outpatient illness to severe respiratory failure and sepsis. Pneumonia and influenza together are the eighth leading cause of death in the United States and the number-one cause of death from infectious diseases.[1,2] Pneumococcal pneumonia–related hospitalization has been projected to increase 96% by 2040 in the United States alone, with an estimated increase of $2.5 billion annually in healthcare expenditure.[3] Pneumonia in the community setting or occurring within 48 hours after hospital admission is termed *community-acquired pneumonia* (CAP). In an effort to streamline the use of appropriate antibiotics, the guidelines for managing CAP were recently updated by American Thoracic Society (ATS) and Infectious Diseases Society of America (IDSA), with significant departure from the 2007 recommendations.[4] Healthcare–associated pneumonia (HCAP) is no longer recognized as a separate entity, and caution is advised to use biomarkers such as procalcitonin (PCT) as a diagnostic test to identify bacterial pneumonia.[4] The pneumonia-related mortality rate increases to more than 10% in hospitalized patients and can exceed 30% in those requiring intensive care unit (ICU) level of care.[5–7] Pneumonia patients requiring mechanical ventilation (MV) or invasive vasopressor support (IVS) and those with pneumonia-related hypotension that is unresponsive to fluids alone are generally considered as having severe CAP (SCAP). However, there is no uniform definition for SCAP, and it often proves challenging to define severe pneumonia and the need for ICU care. Severity assessment scores may identify high-risk patients and help with decision on site of care. Delay in providing ICU level of care for patients with life-threatening pneumonia is associated with worse outcomes. Implementing a large, publicly funded pneumococcal vaccination strategy for infants and young children has led to a significant improvement in herd immunity and a decrease in age-adjusted pneumonia rates.[8]

INCIDENCE

The annual incidence of pneumonia ranges from 5 to 11 per 1000 population, and the majority of patients are treated out of the hospital.[1,9] However, the major portion of the total cost of treating patients with pneumonia is concentrated in hospitalized patients—particularly those admitted to critical care units. In addition, those with comorbid illness and those of advanced age make up a large proportion of the hospitalized, critically ill CAP patients. Although CAP can vary from being a relatively mild ailment to a severe illness, very few hospitalized patients are severely ill enough to require ICU admission.[10,11]

Time to ICU admission may have an impact on subsequent prognosis. Woodhead and colleagues found that earlier ICU admission (within 2 days of hospitalization) was associated with a lower mortality rate (46.3%) than later admission (>7 days in the hospital, 50.4% mortality rate).[12] Restrepo and colleagues also noted a higher mortality rate among CAP patients admitted to ICU after 48 hours as compared with direct admission or within 24 hours, even after adjustment for severity of illness (47.4% vs. 23.2%, $P = .02$).[13] Other studies have shown higher odds of short-term mortality (odds ratio [OR] = 2.6) for patients who were initially triaged to the general ward but later admitted to the ICU.[14,15]

The economic liability associated with CAP remains significant at >$17 billion annually in the United States.[16] Kaplan and colleagues evaluated the cost of care for 623,718 elderly patients with CAP in the United States and found two-thirds of the population had one or more underlying illnesses, with congestive heart failure, the most common comorbidity, present in 32%.[11] The overall mortality rate was 10.6%, but rose higher with advancing age, nursing home residence, and comorbid illness. The mean length of stay (LOS) was 7.6 days, with cost generally paralleling LOS and being disproportionately high for those needing MV. Kozma and colleagues, in a study of approximately 1.5 million CAP admissions, showed a potential economic benefit of $2300 per 1 less day per patient spent in the hospital.[17] Other studies of CAP have reported that costs are higher for patients with comorbid illness than those without, as might be expected. However, in those without comorbid illness, the cost for those who died was less than for those who survived, whereas the opposite was true when the entire CAP population was considered.[18]

RISK FACTORS FOR DEVELOPING SCAP

In all studies of CAP, patients who are admitted to the hospital or ICU commonly have a number of coexisting illnesses, suggesting that individuals who are chronically ill have an increased risk of developing severe illness (Table 67.1).[19] In studies of SCAP, serious coexisting illness is present in 46%–66% of all patients.[11,19,20] The common chronic illnesses in these patients are respiratory disease, cardiovascular disease, and diabetes mellitus.[1,6,21] The most common respiratory illness in CAP patients is chronic obstructive pulmonary disease (COPD), a finding that applies to those with either mild or severe forms of CAP.[6,10]

Cigarette smoking has been identified as a risk factor for bacteremic pneumococcal infection, especially in younger patients with fewer comorbid conditions, and "current smoking" status is associated with a higher mortality in CAP patients compared with nonsmokers or ex-smokers.[10,22,23] Other common illnesses associated with CAP include malignancy, neurologic illness (including seizures), and AIDS.[1,20] One study identified alcohol abuse as a risk factor, along with the failure to receive antibiotic therapy before hospital admission, a finding suggesting that a delay in therapy may convert milder forms of pneumonia into a more severe illness.[20] Genetic differences in the immune

response may predispose certain individuals to more severe forms of infection and adverse outcomes.[24] Also, use of inhaled corticosteroids is related to increased risk of developing serious pneumonia.[25]

PROGNOSTIC FACTORS

In recent years there has been a trend towards increased hospitalizations in patients with a diagnosis of CAP, especially in the elderly and those with comorbid diseases, who may also have higher mortality.[26,27] Various studies have pointed out a high inpatient mortality among CAP patients, ranging from 12.1% to 24.4%, but even higher in patients admitted to the ICU.[5–7] Investigators from the Community-Acquired Pneumonia Organization (CAPO) international cohort study reported mortality differences between patients hospitalized for CAP. A higher frequency of deaths occurred in Latin America (13.3%) compared with Europe (9.1%) and the United States (7.3%).[28] In a meta-analysis of 33,148 patients with CAP, the overall mortality rate (OR) was 13.7%, but in those admitted to the ICU, the mortality rate was 36.5% (Box 67.1).[7]

Metersky and colleagues evaluated factors predicting in-hospital versus postdischarge mortality in 21,223 Medicare patients, 65 years old or older, admitted with a diagnosis of pneumonia.[5] The authors noted a mortality rate of 12.1% within 30 days of admission (52.4% of the deaths occurred during the hospital stay), and the in-hospital rate of mortality was higher in patients requiring MV on admission, who had bacteremia, who had hypotension (systemic blood pressure <90 systolic), who had a respiratory rate >30 per minute, who had a pH <7.35, or who had renal failure. Of note, the timing of death (early versus late) was unrelated to baseline patient demographic factors or comorbidities, but in-hospital mortality related to the severity of illness.

In other studies, the clinical features that have predicted a poor outcome (Table 67.2) include advanced age (>65 years), preexisting chronic illness of any type, absence of fever on admission, respiratory rate exceeding 30 breaths/min, diastolic or systolic hypotension, elevated blood urea nitrogen (BUN >19.6 mg/dL), profound leukopenia or leukocytosis, inadequate antibiotic therapy, need for MV, hypoalbuminemia, and the presence of certain "high-risk" organisms (type III pneumococcus, *Staphylococcus aureus,* gram-negative bacilli, aspiration organisms, or postobstructive pneumonia).[1] One study of 3233 patients in Spain found that risk factors for all-cause mortality were a higher severity of illness on admission, need for ICU care, and the presence of multilobar infiltrates. However, late mortality rate (after at least 3 days)

TABLE 67.1 Risk Factors for Developing Severe Community-Acquired Pneumonia

Advanced age
Comorbid illness (e.g., chronic respiratory illness, cardiovascular disease, diabetes mellitus, neurologic illness, renal insufficiency, malignancy)
Cigarette smoking
Alcohol abuse
Absence of antibiotic therapy before hospitalization
Failure to contain infection to its initial site of entry
Immune suppression
Genetic polymorphisms in the immune response

BOX 67.1 Factors Related to Increased Mortality in Hospitalized CAP Patients[7]

1. Male sex (OR = 1.3)
2. Pleuritic chest pain (OR = 0.5)
3. Hypothermia (OR = 5.0)
4. Systolic hypotension (OR = 4.8)
5. Tachypnea (OR = 2.9)
6. Diabetes mellitus (OR = 1.3)
7. Neoplastic disease (OR = 2.8)
8. Neurologic disease (OR = 4.6)
9. Bacteremia (OR = 2.8)
10. Leukopenia (OR = 2.5)
11. Multilobar infiltrates (OR = 3.1)

OR, Odds ratio.

TABLE 67.2 Risk Factors for a Poor Outcome From Community-Acquired Pneumonia

Patient-Related Factors
Male sex
Absence of pleuritic chest pain
Nonclassic clinical presentation
Neoplastic illness
Neurologic illness
Age ≥65 years
Family history of severe pneumonia or death from sepsis
Abnormal Physical Findings
Respiratory rate ≥30 breaths/min on admission
Systolic (<90 mm Hg) or diastolic (≤60 mm Hg) hypotension
Tachycardia (>125 beats/min)
High fever (>40°C) or afebrile
Confusion
Laboratory Abnormalities
Blood urea nitrogen ≥19.6 mg/dL
Leukocytosis or leucopenia (<4000/mm^3)
Multilobar radiographic abnormalities
Rapidly progressive radiographic abnormalities during therapy
Bacteremia
Hyponatremia (<130 mmol/L)
Multiple organ failure
Respiratory failure
Hypoalbuminemia
Thrombocytopenia (<100,000/mm^3) or thrombocytosis (>400,000/mm^3)
Arterial pH <7.35
Pleural effusion
Pathogen-Related Factors
High-risk organisms: type III pneumococcus, *Staphylococcus aureus,* gram-negative bacilli (including *Pseudomonas aeruginosa*), aspiration organisms, severe acute respiratory syndrome (SARS)
Possibly high levels of penicillin resistance (minimal inhibitory concentration of at least 4 mg/L) in pneumococcus
Therapy-Related Factors
Delay in initial antibiotic therapy (more than 4 hours)
Initial therapy with inappropriate antibiotic therapy
Failure to have a clinical response to empiric therapy within 72 hours

was reduced if blood cultures were negative, antibiotic therapy was consistent with guidelines, and an etiologic agent was identified.[29]

In another prospective study of 1166 SCAP patients from 17 different countries, factors related to mortality at 28 days and at 6-month follow-up were higher Acute Physiology and Chronic Health Evaluation (APACHE) II scores, lower hematocrit, and need for MV. Lower pH on arterial blood gas analysis predicted early mortality.[6] Other studies have noted that an elevated red blood cell distribution width, either alone or in combination with elevated BUN ≥30 gm/dL, was related to increased 90-day mortality and a complicated hospital course in CAP patients, likely reflecting the inflammatory suppression of erythropoiesis in severe infection.[30,31] In general, severity of illness on admission most affected early mortality, whereas therapy-related, modifiable risk factors affected late mortality.

Prina and colleagues noted a biphasic relationship between platelet count and mortality in hospitalized CAP patients, with mortality rate increasing for values outside the range of 100,000 to 400,000/mm^3.[3,32] The authors noted more respiratory complications, such as empyema and pleural effusion, in patients with thrombocytosis (platelet count $\geq 4 \times 10^5$/mm^3) than in those without. On the other hand, those with thrombocytopenia (platelet count $\leq 10^5$/mm^3) had higher rates of severe sepsis, septic shock, invasive MV, and ICU admission than the remainder of the studied population. In another study, Laserna and associates observed a biphasic relationship when relating CAP mortality to arterial partial pressure of carbon dioxide ($PaCO_2$) on admission. Both hypocapnia ($PaCO_2$ <35 mm Hg) and hypercapnia ($PaCO_2$ >45 mm Hg) were risk factors for higher 30-day mortality and a greater need for ICU admission, compared with patients with a normal $PaCO_2$, even after excluding those patients with COPD.[33]

As with other acute severe infections, any delay in treatment or admission to the ICU in patients with SCAP can lead to higher rates of complications and increased risk of mortality.[13] Several studies have noted an increased mortality rate when CAP patients experience a delay in the initiation of appropriate antibiotic therapy, with most studies using an average of 6 hours elapsed since being first evaluated in the emergency room as the cutoff value.[1,10,20,34,35] Renaud and colleagues, in a study of 453 CAP patients, noted that the 28-day mortality rate was 11.7% for those who were directly admitted to the ICU with an obvious need for ICU care, a value significantly lower than the 23.4% mortality rate experienced among those initially without obvious need for ICU care whose admission to the ICU was delayed.[36] In their analysis, Hraiech and associates divided CAP patients into those requiring MV within 72 hours of the onset of CAP and those with progressive respiratory failure who required invasive MV 4 or more days after the onset of CAP.[37] There was a significant difference in mortality between the early respiratory failure group compared with late (28% vs. 51%, $P = .03$), suggesting that delay in identification of respiratory failure, delay of transfer to the ICU, or the development of progressive symptoms have deleterious effects on patient outcome.

Cardiac events, including acute myocardial infarction (AMI), are common in patients with SCAP. Ramirez and colleagues reported a 15% incidence in patients with severe CAP.[38] In another study including 55,276 patients, Carr and colleagues noted 8% of cardiac arrests occurred in pneumonia patients, and in this population, 62% of cardiac arrests occurred in patients admitted to the ICU. Approximately 50% were on vasopressors or required MV.[39] Cardiac arrests occurred earlier in the ICU than on the ward (at a median of 18.9 versus 28.4 hours) and were generally characterized by a "not shockable" rhythm (asystole or pulseless electrical activity). These findings suggest that patients with CAP in the hospital, or even the ICU, commonly have cardiac ischemia and that ischemic events may occur without warning. In another study, a restrictive red blood cell transfusion strategy (target hemoglobin level 7–9 g/dL in all patients except those with acute myocardial infarcts or unstable angina) was associated with better outcomes for CAP patients.[40]

Waterer and colleagues studied avoidable factors that contributed to CAP-specific short-term mortality from a large prospective study of acute respiratory infection with image confirmation across five hospitals in the United States.[41] The overall inpatient mortality was 2.2% (52/2320) but was higher among patients ≥65 years of age (4%, 33/832) and those with more than three severe comorbidities (Pneumonia Severity Index [PSI] risk classes IV and V). Investigators noted that only two patients who died had an identifiable lapse in quality of inpatient pneumonia care characterized by no administration of antibiotic within 1 hour in the presence of shock or the use of antibiotics not consistent with the IDSA/ATS 2007 CAP guidelines. These observations suggest that most CAP-related mortality is unavoidable and is determined by older age and comorbidities.

In a recent study evaluating the changes in pneumonia-related hospitalizations from 2001 to 2014, the average annual age-adjusted and pneumonia-associated hospitalization rate was 464.8 per 100,000 (95% confidence interval [CI] 452.5–467.1), with an inpatient mortality of 7.4%.[8] In this study, factors associated with increased mortality were male sex and having a colisting of immunocompromised state and lower income status.[8] There was a significant decrease in age-adjusted pneumonia-related hospitalizations over the study period, despite a significant increase in sepsis or respiratory failure. Age-adjusted hospitalizations were highest during the months of December to March; however, the inpatient mortality rate was highest in July (8.2%) and lowest in March, April, and May (7.1%).

When these findings are viewed together, they suggest some general principles. Mortality is more likely in CAP patients who have severe physiologic derangements, serious underlying illnesses, and delay in the initiation of appropriate antimicrobial therapy or MV and the presence of atypical clinical features. This last factor suggests that an unusual clinical presentation (low fever, nondistinct respiratory symptoms) is associated with mortality, which may be the result of its reflecting an inadequate inflammatory response to infection and because such a presentation can delay the recognition of pneumonia and the need to institute appropriate therapy.

PATHOGENESIS

Pneumonia results when host defenses are overwhelmed by an infectious pathogen. This may occur because the patient has an inadequate immune response, often as the result of underlying comorbid illness, anatomic abnormalities, acute illness-associated immune dysfunction, or therapy-induced dysfunction of the immune system. Pneumonia can also occur in patients who have an adequate immune system if the host defense system is overwhelmed by a large inoculum of microorganisms or if the patient encounters a particularly virulent organism to which he or she has no preexisting immunity or to which the patient has an inability to form an adequate acute immune response.[42,43]

Microaspiration of infected oropharyngeal secretions is the most common mechanism associated with pneumonia. Other routes of entry include inhalation (which applies primarily to viruses, *Legionella pneumophila, Mycobacterium tuberculosis*), hematogenous dissemination from extrapulmonary sites of infection (e.g., right-sided endocarditis), and direct extension from contiguous sites of infection (such as liver abscess). Thus previously healthy individuals develop infection with virulent pathogens such as viruses and *L. pneumophila, Mycoplasma pneumoniae, Chlamydia pneumoniae,* and *Streptococcus pneumoniae*. On the other hand, chronically ill patients can be infected by these organisms, and in addition by organisms that commonly colonize patients but only cause infection when immune responses are

inadequate. These organisms include enteric gram-negative bacteria (e.g., *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Acinetobacter* spp.) and fungi.

Studies evaluating the normal lung immune response to infection have shown that in most patients with unilateral CAP, the inflammatory response is limited to the site of infection.[43] In patients with localized pneumonia, tumor necrosis factor-alpha (TNF-α), interleukin (IL)-6, and IL-8 levels were increased in the pneumonic lung and generally not increased in the uninvolved lung or in the serum.[44,45] On the other hand, in patients with severe pneumonia, the immune response is characterized by a "spillover" of the immune response into the systemic circulation, reflected by increases in serum levels of TNF-α and IL-6.[46] It remains uncertain why localization does not occur in all individuals and why some patients develop diffuse lung injury (e.g., acute respiratory distress syndrome [ARDS]) or systemic sepsis as a consequence of pneumonia. These complications may result from an inability to develop a brisk lung immune response as a consequence of specific bacterial virulence factors, inadequate or delayed therapy, or genetic polymorphisms that affect the immune response.[47] There is a growing body of evidence suggesting polymorphonuclear neutrophils (PMNs) not only have defensive properties through phagocytosis of invading microorganisms or releasing reactive oxygen species, antimicrobial peptides, and neutrophil extracellular traps, but also they can modify the adaptive immune system, causing both T-cell suppression and activation, thereby influencing lung injury.[48]

CLINICAL FEATURES

Symptoms and Physical Findings

Patients with CAP and an intact immune system have a normal pulmonary response to infection and generally have respiratory symptoms such as cough, sputum production, and dyspnea, along with fever and other complaints. Cough is the most common finding and is present in up to 80% of all patients, but is less common in those who are elderly, those with serious comorbidity, or patients coming from nursing homes.[49] Pleuritic chest pain is also common in patients with CAP, and in one study its absence was identified as a poor prognostic finding.[50] The elderly generally have fewer respiratory symptoms than younger individuals, and, as mentioned, the absence of clear-cut respiratory symptoms and an afebrile status have themselves been predictors of an increased risk of death.[1,51] In elderly patients, pneumonia can have a nonrespiratory presentation with symptoms of confusion, falling, failure to thrive, altered functional capacity, or deterioration in a preexisting medical illness, such as congestive heart failure.[49,52,53]

Physical findings of pneumonia include tachypnea, crackles, rhonchi, and signs of consolidation (egophony, bronchial breath sounds, dullness to percussion). Patients should also be evaluated for signs of pleural effusion. In addition, extrapulmonary findings should be sought to rule out metastatic infection (arthritis, endocarditis, meningitis) or to add to the suspicion of an "atypical" pathogen, such as *M. pneumoniae* or *C. pneumoniae,* which can lead to complications such as bullous myringitis, rash, pericarditis, hepatitis, hemolytic anemia, or meningoencephalitis. In the elderly, an elevation of respiratory rate can be the initial presenting sign of pneumonia, preceding other clinical findings by as much as 1–2 days.[54] In fact, in one study, tachypnea was the most common finding in elderly patients with pneumonia, being present in over 60% of all patients and occurring more often in the elderly than in younger patients with pneumonia.[49]

RADIOGRAPHIC FEATURES

For most patients, CAP is defined by a combination of clinical symptoms and the presence of a new radiographic infiltrate, but not all patients with this illness will have such findings when first evaluated. Even when the radiograph is negative, if the patient has appropriate symptoms and focal physical findings, pneumonia may still be present. Some studies have suggested that febrile and dehydrated patients can have a normal chest radiograph when first admitted with pneumonia. The presence of alveolar densities (lobar or bronchopneumonic) has been associated with a high likelihood of a bacterial etiology, but it is extremely difficult to distinguish among specific pathogens by using patterns of radiographic abnormalities.[55] The chest radiograph may have prognostic value in patients with severe pneumonia. Multilobar infiltrates or rapid progression of infiltrates serve as poor prognostic signs, helping to identify patients who require intensive care.[1,10]

Chest computed tomography (CT) generally has a higher sensitivity in diagnosing occult pneumonia, with an initially negative chest radiograph.[56] Chest CT can also have value in the critically ill patient in situations when a noninfectious process is being considered or when complications such as pneumothorax, empyema, or abscess are suspected. CT can suggest certain alternative noninfectious diagnoses such as granulomatous vasculitis, acute eosinophilic pneumonia, and bronchiolitis obliterans with organizing pneumonia. Upchurch and associates compared "CT-only" pneumonia with a negative chest x-ray in hospitalized CAP patients (present in 3% of patients) with pneumonia diagnosed via chest x-ray (in 97% of patients) and noted similar pathogens (bacterial 12% and 13.6% and viruses 30.3% and 26.1%, respectively), and clinical outcomes, including disease severity, death, need for ICU admission, vasopressor use, and invasive MV.[57] A lower percentage of patients with "CT-only" pneumonia had received antibiotics within 6 hours, compared with those with overt pneumonia on chest x-ray (59% vs. 83%, $P < .01$). Thus in the right clinical setting, pneumonia may need to be treated even with a negative chest radiograph.

Although a variety of radiographic patterns can be seen in pneumonia, specific findings cannot generally be used to predict the microbial etiology in CAP; however, there are certain patterns to keep in mind. Focal consolidation can be seen with infections caused by pneumococcus, *Klebsiella* species, aspiration (especially if in the lower lobes or other dependent segments), *S. aureus, Haemophilus influenzae, M. pneumoniae,* and *C. pneumoniae*. Interstitial infiltrates should suggest viral pneumonia in addition to infection resulting from *M. pneumoniae, C. pneumoniae, Chlamydia psittaci,* and *Pneumocystis jirovecii*. Lymphadenopathy with an interstitial pattern should raise concerns about anthrax, *Francisella tularensis*, and *C. psittaci,* whereas adenopathy can be seen with focal infiltrates in tuberculosis, fungal pneumonia, anthrax, and bacterial pneumonia. Cavitation can be the result of an aspiration lung abscess, infection with *S. aureus* or aerobic gram-negatives (including *P. aeruginosa*), tuberculosis, fungal infection (*Aspergillus*), nocardiosis, and actinomycosis.

Lung ultrasound (LUS) has increasingly been adopted for diagnosing pleural and pulmonary diseases. Various patterns with B- and M-mode ultrasound techniques, including "tissue sign," "shred or fractal sign," and " dynamic air bronchograms," are seen with pulmonary consolidation, whereas the "sinusoidal sign" and "quad sign" are seen with even small pleural effusions.[58] In a prospective, multicenter study including 362 patients with suspected CAP, LUS had a sensitivity of 93.4% and specificity of 97.7% compared with chest x-ray and chest CT.[59] In that study, the combination of LUS and auscultation decreased the negative likelihood ratio to 0.04 (95% CI 0.02–0.09), but the technique is operator dependent, and about 8% of pneumonic lesions are not visualized by LUS. The noninvasive nature of the test and the rapidity with which it can be performed make this another tool in the armamentarium for critical care physicians. A meta-analysis of 10 studies with 1172 patients supports the use of LUS by skilled

practitioners.[60] A recent meta-analysis including 5108 emergency department patients showed a sensitivity of 92% and specificity of 93% for the diagnosis of CAP using LUS.[61] Another cluster-randomized study using the biomarker PCT and LUS as a combination for decision on antibiotic prescription in patients with CAP is underway and could provide more insight into LUS use in the primary care setting.[62]

SEVERITY SCORING IN CAP

Although there is no uniformly accepted definition for SCAP, this term generally refers to any patient who is admitted to the ICU because of CAP. Most of these patients have severe sepsis or "respiratory failure," defined by the presence of hypoxemia or hypercarbia, but not all such patients require MV. Some patients with CAP are treated in the ICU because the pneumonia has led to clinical instability of an underlying disease, but the pneumonia itself may not be severe. Bacteremia does not always correlate with more severe illness, and its presence alone is not always a predictor of a poor outcome, with most episodes of bacteremia being the result of pneumococcus. However, in the elderly with pneumococcal pneumonia, bacteremia is present in one-fourth of patients with CAP and is often associated with azotemia and multilobe involvement.[63] When an infection, such as pneumonia, is complicated by severe sepsis or septic shock (not just bacteremia), outcome is adversely affected, with increases in mortality, LOS, and costs for survivors.

One approach to evaluating CAP patients is to use a scoring system to define prognosis and predict the risk of death. The most widely used prognostic scoring systems are the PSI and a modification of the British Thoracic Society (BTS) scoring system, the CURB-65 score. Other prediction rules, such as the ATS/IDSA criteria for severe CAP, the Australian SMART-COP, the Japanese A-DROP scoring system, CAPPIRO, and the Spanish CURXO-80, have also been developed for risk prognostication and help with appropriate resource utilization.[1,64–66]

The investigators in the Pneumonia Outcomes Research Team (PORT) study have developed a mortality prediction rule that classifies all patients into one of five groups (PSI classes I to V), each with a different risk for death.[67] Patients in classes IV and V have a predicted mortality risk of 8.2%–9.3% and 27%–31.1%, respectively, whereas those in classes I and II have a mortality risk of 0.1%–0.4% and 0.6%–0.7%, respectively. To use this scoring system, patients have points calculated based on such factors as age, sex, the presence of comorbid medical disease, certain physical findings, and laboratory data.[67] Although the PORT scoring system has been shown to be accurate for predicting mortality and prognosis, it does not directly measure severity of illness, and there is poor correlation between mortality risk and the need for ICU admission.[68,69] In general, the PSI V patients who need the ICU tend to get more of their points from acute illness, whereas those not needing the ICU tend to score points because of chronic disease factors. In addition, in young patients without comorbid illness, the pneumonia must be particularly severe to place the patient in a high-mortality risk group, and certain vital sign thresholds must be exceeded to accumulate points toward a poor prognosis.

For the critical care physician, underestimating the severity of illness is a serious concern, and the use of the CURB-65 approach, modified from the BTS rule, is a simple and accurate way to address this issue. CURB-65, an acronym for the clinical features used to assess pneumonia severity and prognosis, assigns 1 point, on a 5-point scale, to confusion, BUN greater than 19 mg/dL, respiratory rate greater than or equal to 30 breaths/min, blood pressure of $<$90 mm Hg systolic or $\leq$60 mm Hg diastolic, and age greater than or equal to 65 years. In one study, when the score was 0–1, the mortality rate was 0%, whereas mortality was more than 20% for a score of 3 or higher, and those with a score of 2 had a mortality risk of 8.3%.[70] The use of the CURB-65 rules may be a problem in the elderly, reflecting the altered clinical presentations of pneumonia in this population. Interestingly, although the rule was not optimal in an elderly population and did not work as well as it did in other populations, it had a higher sensitivity for predicting mortality than the PSI, derived from the PORT study. Some studies have compared the PSI with CURB-65 and found them to be similar for identifying low-risk populations, but the CURB-65 may be more discriminating for identifying poor prognosis in those with severe illness, compared with the PSI.[71] An amended version of the CURB-65 without the use of laboratory measurement of BUN—CRB-65—has also been found to be similarly accurate.[72] Chalmers and colleagues in a meta-analysis including 40 studies reported CURB-65 and CRB-65 to be superior to PSI in identifying high-risk patients, whereas PSI was superior in identifying low-risk patients.[73] An expanded version of CURB-65 that includes the three additional variables: platelet count $<100 \times 10^9$/L, lactate dehydrogenase (LDH) levels $>$230 u/L, and albumin $<$3.5 g/dL, was recently shown to have improved accuracy in identifying higher mortality risk among hospitalized CAP patients.[74]

The A-DROP scoring system uses a 6-point scale that stratifies the severity of CAP, and it includes age (male 70 years, female 75 years); dehydration (BUN $\geq$21 mg/dL); respiratory failure (SaO_2 $<$90% or PaO_2 $<$60 mm Hg); orientation disturbance (confusion); and low blood pressure (systolic blood pressure $<$90 mm Hg).[75] Basically it is a modification of CURB-65 with the inclusion of hypoxemia as a variable in place of respiratory rate and with different gender-based thresholds for age in risk assessment. The sensitivity, specificity, and 30-day mortality predictive value of the A-DROP scoring tool is similar to CURB-65.[64] The CORB scoring system is a simple predictive tool that does not require invasive testing and removes bias regarding patient age.[76] The CORB tool does not use variables of age and BUN levels but does add oxygen saturation as a variable in the risk calculation. In both the derivation and validation cohorts, risks of mortality and/or requirement for ventilatory or inotropic support were systolic blood pressure $<$90 mm Hg (OR 3.49); acute confusion (OR 5.48); SaO_2 $\leq$90% (OR 3.49); and respiratory rate $\geq$30/min (OR 2.65). Dwyer and colleagues developed the "DS-CRB 65" criteria to improve the sensitivity and negative predictive value of CRB-65 by adding 1 point (D criterion) for the presence of any underlying disease according to the PSI rule and 1 point if SaO_2 was $<$90% (S criterion).[77]

The 2019 ATS/IDSA CAP guidelines endorse using a validated clinical prediction rule plus clinical judgment in decision making regarding outpatient vs. inpatient care in immunocompetent CAP patients.[4] The guideline supports PSI over CURB-65 based on the PSI's ability to identify a large proportion of patients at lower risk and increased precision for mortality decision making (strong recommendation with moderate-quality evidence).[4] In the new Sepsis-3 guidelines, the qSOFA score has been proposed to predict sepsis outcome. This score is similar to CURB but with the criteria being altered mental status, respiratory rate $>$22/min, and systolic blood pressure $<$100 mm Hg. In one study of 152 ICU patients, the qSOFA score was a good mortality predictor—in fact better than traditional systemic inflammatory response syndrome (SIRS) criteria.[78] In another study of 6574 CAP patients, the qSOFA score did not perform as well as CURB-65 to identify mortality risk.[79]

Other prognostic scoring systems have been developed to define the presence of severe pneumonia. Espana and associates estimated the need for ICU admission by the presence of one of two major criteria: arterial pH $<$7.30 or systolic blood pressure $<$90 mm Hg.[66] In the absence of these criteria, SCAP can also be identified by the presence of two of six minor criteria, which are confusion, BUN $>$30 mg/dL, respiratory rate $>$30/min, PaO_2/FiO_2 ratio $<$250, multilobar infiltrates, and

age of at least 80 years. When these criteria were met, the tool was 92% sensitive for identifying those with SCAP and was more accurate than the PSI or CURB-65 criteria, although not quite as specific as the CURB-65 rule.[66] Using this approach, some criteria (acidosis and systolic hypotension) are weighted more heavily than others, which contrasts with some of the other approaches to define SCAP.

A different method than assessing risk for death is to use scoring systems to define the need for ICU interventions, such as intensive respiratory and vasopressor support (IRVS). The SMART-COP tool was developed to predict the need for IRVS.[65] Using a multivariate model, eight clinical features were associated with the need for IRVS: systolic blood pressure <90 mm Hg, multilobar infiltrates, albumin <3.5 g/dL, respiratory rate elevation (>25 for those less than age 50, and >30 for those greater than age 50), tachycardia (>125/min), confusion, low oxygen (<70 mm Hg if less than age 50 or <60 mm Hg if greater than age 50), and arterial pH <7.35. The abnormalities in systolic blood pressure, oxygenation, and arterial pH each received 2 points, and the five other criteria received 1 point each, and, with this system, the need for IRVS was predicted by a SMART-COP score of at least 3 points. Using this cutoff, the sensitivity for need for IRVS was 92.3% and the specificity 62.3%, with a positive and negative predictive value of 22% and 98.6%, respectively. The PSI and CURB-65 did not perform as well overall for predicting the need for IRVS.

The 2007 IDSA/ATS guidelines for CAP suggested that ICU care be considered if the patient has one of two major criteria (need for MV or septic shock with the need for vasopressors), or three of nine minor criteria.[1] The minor criteria are respiratory rate ≥30 breaths/min, PaO_2/FiO_2 ratio ≤250, multilobar infiltrates, confusion/disorientation, uremia (BUN level ≥20 mg/dL), leukopenia (white blood cell [WBC] count <4000 cells/mm^3), thrombocytopenia (platelet count <100,000 cells/mm^3), hypothermia (core temperature <36°C), and hypotension requiring aggressive fluid resuscitation. Other factors to consider in the decision-making process are hypoglycemia (in a nondiabetic patient), hyponatremia, acute alcohol intoxication, cirrhosis, asplenia, and unexplained metabolic acidosis. The use of these minor criteria alone requires validation, with one study showing that patients who met only minor criteria for ICU admission did not have an increase in mortality, whereas in another study, use of four minor criteria instead of three improved the accuracy in defining the need for ICU admission.[80,81] Phua and colleagues showed that the ATS minor criteria had greater discriminatory power in the prediction of severity, ICU admission, and mortality than the PSI and CURB.[82] Brown and associates noted that both the positive and negative predictive value of minor criteria exceeded 80% if four criteria were used to define the need for ICU admission rather than just three criteria.[81] In another study, investigators simplified the ATS/IDSA criteria by excluding variables that occurred in <5% of cases—leukopenia, thrombocytopenia, and hypothermia—and noted similar predictive value for mortality and intensive care admission as compared with the original ATS/IDSA criteria.[83] In the same study, addition of another variable—acidosis (pH <7.35)—improved the prediction for mortality and for ICU admission.

Rello and associates evaluated the CAP-PIRO score calculated within 24 hours of ICU admission.[84] In this study, 1 point was assigned for each variable: comorbidities (COPD, immunocompromise), age greater than 70 years, multilobar opacities on chest radiograph, shock, severe hypoxemia, acute renal failure, bacteremia, and ARDS. Patients were stratified into four levels of risk: (a) low, 0–2 points; (b) mild, 3 points; (c) high, 4 points; and (d) very high, 5–8 points. The PIRO score performed well as a 28-day mortality prediction tool in patients with CAP requiring ICU admission, with a better performance than APACHE II and the IDSA/ATS criteria. CAP-PIRO can further stratify patients in PSI class V and differentiate patients requiring more intense care.

The Risk of Early Admission to ICU (REA-ICU) index was derived from a data set of nearly 5000 patients and is helpful as a tool on admission to identify patients who had no obvious indication for ICU management but subsequently required ICU care. It categorizes individuals into four risk groups based on 11 criteria independently associated with ICU admission: male gender, age younger than 80 years, comorbid conditions, respiratory rate of 30 breaths/min or higher, heart rate of 125 beats/min or higher, multilobar infiltrate or pleural effusion, WBC less than 3 or 20,000/L or above, hypoxemia (oxygen saturation <90% or PaO_2 <60 mm Hg), BUN of 11 mmol/L or higher, pH <7.35, and serum sodium concentration <130 mEq/L.[85] The mortality and likelihood of needing ICU care increased with each risk group, with the highest in class IV with a score ≥9. In a study including 850 CAP patients who had no obvious need for ICU care on admission, the REA-ICU index performed better than PSI but was similar to other tools (like SMART-COP, CURXO-80, the 2007 IDSA/ATS minor severity criteria, and CURB-65) at defining the need for early ICU admission.[86] The need for sensitive criteria to define severe illness in CAP patients is important because the benefit seems most certain if patients are admitted to the ICU early in the course of severe illness. The 2019 ATS/IDSA guidelines recommend direct admission to ICU for those who require IRVS, and for those who do not require it, using the 2007 ATS/IDSA minor criteria plus clinical judgment in making a decision on ICU care.[4]

ROLE OF BIOMARKERS IN SEVERE CAP

Measurement of serum levels of biomarkers such as C-reactive protein (CRP), midregional proadrenomedullin, midregional pro-atrial natriuretic peptide (MR-proANP), proarginine-vasopressin (copeptin), proendothelin-1, or PCT may be valuable in guiding management of antibiotics for CAP. PCT is an acute-phase reactant synthesized in the liver in response to bacterial, but not viral, infection. Studies in CAP have documented that serial measurement of levels of PCT can guide the duration of antibiotic therapy, allowing cessation of therapy once levels fall and leading to a marked reduction in the duration of therapy, compared with unaided clinical judgment.[87,88] In patients with SCAP, measurement of initial and serial levels can help to define those with a poor prognosis, and a low PCT value may distinguish which patients in PSI classes IV and V might be safely managed outside the ICU.[89] Kruger and colleagues reported nonsurvivors had significantly higher median PCT levels on admission than survivors (0.88 vs. 0.13 ng/mL; $P = .0001$).[90] Low PCT accurately predicted patients at very low risk of death, even in patients falling in a high prognostic scoring category by the CURB-65 evaluation. Given its high negative predictive potential (98.9% with PCT level of <0.228 ng/mL), patients with low initial PCT might be safely treated outside the ICU.[90] Huang and colleagues found that 23.1% (126/546) of high-risk patients defined by PSI had low PCT levels on the first hospital day, and this subgroup had very low mortality, similar to low-risk patients.[91]

Ramirez and associates, in a prospective study of 685 CAP patients, evaluated the relationship between biomarkers and ICU admission.[92] Inflammatory biomarkers helped identify patients needing intensive care monitoring, including those requiring delayed ICU admission. No patient with ≥3 ATS minor severity criteria and PCT levels below the cutoff (0.35 ng/mL) needed ICU admission compared with 14 (23%) with levels above the cutoff ($P = .032$).[92] In another study, the authors compared the levels of three biomarkers—N-terminal pro-B-type natriuretic peptide (NT-proBNP), MR-proANP, and B-type natriuretic peptide (BNP)—with the PSI and CURB-65 score for predicting short- and long-term mortality.[93] The levels of NT-proBNP, MR-proANP, and BNP increased with the severity of pneumonia, and patients who died

had a higher level of all three biomarkers. A combined assessment using categorical PSI score and NT-proBNP levels seemed beneficial over a single-marker approach for short- and long-term risk stratification. In a recent meta-analysis of seven studies including 1075 patients using a PCT-based regimen in patients with severe sepsis or septic shock, the 28-day mortality was not different between the PCT-based regimen and standard treatment groups, but the PCT-guided group had a shorter duration of antimicrobial therapy.[94] Using a PCT-based strategy led to more de-escalation and a shorter duration of antibiotic therapy, with no adverse impact on mortality.

In the EPIC study of CAP, 1770 patients had PCT measured on admission, and the results were combined with the ATS minor severity criteria to best identify patients needing ICU care.[95] Patients with three or more ATS minor severity criteria plus a PCT level ≥0.83 ng/mL were admitted to the ICU 41.1% of the time, whereas those in this group with a PCT <0.83 ng/mL needed the ICU only 14.6% of the time. In those with fewer than three minor criteria and a low PCT level, the ICU was used by only 3.5%.

In another study, Mendez and associates studied the time-related changes on systemic concentrations of inflammatory cytokines and biomarkers since onset of self-reported symptoms in two different prospective, longitudinal CAP cohorts (derivation $n = 541$ and validation $n = 398$).[96] Because bacterial growth is exponential within the first 48 hours, investigators divided the patient population as early presenters (<3 days) vs. not. They noted CRP levels were higher ≥3 days (18 vs. 13.2, $P = .005$ in derivation and 18.8 vs. 13.6, $P = .006$ in validation) in both groups, whereas the PCT levels were higher in early presenters (,5 vs. 0.3, $P = .023$ and 0.9 vs. 0.4, $P = .028$). This finding was not affected by prior antibiotic use. Taken together, the inflammatory responses of cytokines and biomarkers appear to depend on time since onset of symptoms. There is a risk of underestimating the inflammatory profile based on the cytokine tested for CAP clinical trials if the time since onset of symptoms is not taken into account.

Using biomarkers to adjudicate severity is best done in conjunction with clinical, microbiologic, and pathologic data. A combined approach that includes severity scores and biomarkers can aid clinicians in assessing severity of illness and the need for using antibiotics, and serial measurements can be used to assess treatment response. However, PCT or other biomarkers are not specific for pneumonia itself and can be elevated in other infectious or inflammatory conditions. Levels should be interpreted with particular caution in patients with cardiac and renal failure. Based on the reported sensitivity of PCT to detect bacterial infection that ranges from 38% to 91%, the ATS/IDSA 2019 guidelines do not recommend withholding empiric antibiotics, regardless of the initial PCT levels in suspected CAP patients.[4] In ICU patients, the decision to start antibiotics should never be guided by biomarkers, but biomarkers can be used along with other data to decide to stop or shorten the duration of antibiotic therapy. In a randomized Dutch study of over 1500 ICU patients, PCT guidance for antibiotic therapy duration was compared with standard care, and it led to reductions in antibiotic use, antibiotic duration, and 28-day mortality.[97]

ETIOLOGIC PATHOGENS

Even with extensive diagnostic testing, an etiologic agent is defined in only about half of all patients with CAP, pointing out the limited value of diagnostic testing and the possibility that we do not yet know all the organisms that may cause CAP.[1,98] In the past 4 decades, a variety of new pathogens for this illness have been identified, including *L. pneumophila, C. pneumoniae,* Middle East respiratory syndrome coronavirus (MERS-CoV), avian-origin influenza A – H7N9, novel H1N1, H3N2 influenza, hantavirus, and severe acute respiratory syndrome coronavirus (SARS-CoV-2). In addition, antibiotic-resistant variants of common pathogens, such as *S. pneumoniae,* have become increasingly common. However, recent data indicate that ICU mortality decreased for pneumococcal CAP between 2000 and 2013, probably as a reflection of appropriate identification of SCAP, early antibiotic prescription, and increased use of combination therapy.[99]

The likely pathogens for infection vary, depending on patient risk factors for specific microorganisms and the presence of certain comorbid illnesses, but for all patient groups, including those with SCAP, pneumococcus remains the most common pathogen.[1,100] Recent studies, however, have shown an increasing frequency of viral CAP, including among those admitted to the ICU. The incidence of antibiotic-resistant pneumococci has increased in recent years, and up to 40% of these organisms can have reduced sensitivity to penicillin or other antibiotics, although the clinical relevance of in vitro resistance is still uncertain.[1,101,102] Although *S. pneumoniae* is the most common bacterial organism causing CAP, the frequency of pneumococcal pneumonia has declined, probably because of effective vaccination practices and a decreased incidence of smoking in adults.[103] Identified risk factors for drug-resistant *S. pneumoniae* (DRSP) include beta-lactam therapy received in the past 3 months, alcoholism, age older than 65 years, immune suppression, multiple medical comorbidities, and contact with a child in daycare.[1,104,105] Other common infecting organisms in those with SCAP include viruses (e.g., influenza, respiratory syncytial virus [RSV], and various coronavirus illnesses), *L. pneumophila, M. pneumoniae, M. tuberculosis,* and *H. influenzae* (especially in smokers). In the setting of severe pneumonia, patients can be infected with *S. aureus* (including methicillin-resistant forms, or MRSA) or enteric gram-negatives and, rarely, anaerobes. In the elderly, including those with aspiration pneumonia and in those with underlying cardiopulmonary disease, enteric gram-negative organisms are frequently encountered.

Although aspiration has often been considered a risk factor for anaerobic infection, studies of SCAP in elderly patients with aspiration risk factors suggested that this population is very likely to have aerobic gram-negative infection.[106,107] Risk factors for gram-negative organisms causing CAP are probable aspiration, previous hospital admission within 30 days of admission, previous antibiotics within 30 days of admission, presence of pulmonary comorbidity, smoking, and hyponatremia.[108,109] In a study of 3272 episodes of CAP, Falguera and associates found that 2% were caused by enteric gram-negatives (most commonly *P. aeruginosa*) and the risk factors for these organisms were COPD, current use of corticosteroids, prior antibiotic therapy, tachypnea >30 breaths/min, and septic shock on admission.[110] Patients with these organisms needed ICU care more often and had a higher risk for mortality and extended LOS than those without these pathogens present. Changes in the airway microbiome with different illnesses may result in a change in the lung microbiota and could potentially impair pulmonary defenses. A macro aspiration event in those with reduced reflexes or impaired mentation could then overwhelm the homeostasis created by an altered microbiome, resulting in pneumonia.[111]

Primary pulmonary infection with atypical pathogens has been reported for patients with SCAP for many years. In fact, in one ICU in Spain, atypical pathogens were present in almost 25% of all patients, but the organisms responsible varied over time. *Legionella* was the most common atypical pathogen leading to SCAP in 14% of patients during one period, but in the same hospital a decade later, it was seen in only 2%, having been replaced by *Mycoplasma* and *Chlamydophila* infection. The latter were found in 17% of patients, compared with only 6% a decade earlier.[20] Several studies have shown that even if bacterial pathogens lead to CAP, they can be accompanied by atypical pathogens in the form of mixed infection.[112,113] Atypical pathogens can include *C. pneumoniae, M. pneumoniae,* and *L. pneumophila,* and some studies have

shown that these infections are common in patients of all ages, not just young and healthy individuals. These organisms have even been reported among the elderly in nursing homes.[1,112,114] When mixed infection is present, it may lead to a more complex course and a longer LOS than if a single pathogen were present, which may explain the increasing number of studies that show a reduction in CAP mortality, including those in the ICU, when initial therapy provides coverage for these organisms, compared with regimens that do not.[115,116] Mixed infections with bacteria and viruses may also increase mortality, and in one study of 117 SCAP patients, 15.4% had mixed viral and bacterial infection.[117] This group had a 14-fold higher mortality in multivariate analysis, compared with culture-negative patients, emphasizing that even with documented viral infection, empiric antibiotics are necessary in severely ill patients to address possible bacterial coinfection. Interestingly, multiple retrospective studies of pneumococcal bacteremia have shown a reduced mortality when dual therapy (usually involving a macrolide) rather than monotherapy is used, raising the possibility that even these patients have mixed infection with atypical pathogens.[118,119] The frequency of atypical pathogens can be as high as 60%, with as many as 40% of all CAP patients having mixed infection.[113] These high incidence numbers have been derived using serologic testing, which is of uncertain accuracy. Atypical organism pneumonia may not be a constant phenomenon, and the frequency of infection may vary over the course of time and with geographic location.

In the past, *S. aureus* was an uncommon but often life-threatening cause of CAP. In the past several years, a community-acquired strain of MRSA (CA-MRSA) has emerged as a cause of SCAP, particularly in patients without a history of previous hospitalization or chronic illness, often as a complication of influenza infection.[1,120,121] The organism can lead to a severe, bilateral, necrotizing pneumonia, often related to toxin production by the organism. This organism is distinct from the nosocomial strain of MRSA and is clonal in origin, usually due to the USA 300 strain. In a study including 3702 patients from the Global Initiative for MRSA Pneumonia (GLIMP) database collected from 54 countries worldwide, Aliberti and colleagues noted the prevalence of confirmed MRSA pneumonia was ~3.0%, varying among different countries.[122] The three risk factors associated with MRSA pneumonia were previous MRSA infection or colonization (OR = 6.21), recurrent skin infections (OR = 2.87), and severe pneumonia (OR = 2.39). The investigators also assessed the risk factors and characteristics of immunocompromised patients admitted with CAP from the GLIMP database.[123] *S. pneumoniae* was the most prevalent pathogen causing CAP, but immunocompromised patients had more frequent *P. aeruginosa,* RSV, pneumocystis, *Aspergillus fumigatus,* and *Nocardia* species compared with immunocompetent patients. Interestingly, multidrug-resistant (MDR) pathogens were similarly isolated from both groups and the rates of bacteremia between the groups were not different. Pathogens not covered by usual CAP therapy were more common in those with COPD and in patients with tracheostomy or severe pneumonia. Fungal infections were associated with AIDS and hematologic cancers, whereas viruses other than influenza were associated with hematologic cancer and severe pneumonia. Nontuberculous mycobacteria were associated with AIDS and malnutrition, and *M. tuberculosis* with malnutrition. As one in five hospitalized patients have an immunocompromised status, it would be prudent to assess both at the time of admission, and treatment should be tailored to avoid treatment failure.

RISK FACTORS FOR SPECIFIC PATHOGENS

Table 67.3 summarizes the common pathogens causing CAP in hospitalized patients, including those admitted to the ICU. The classification is based on the presence of clinical risk factors for specific pathogens, referred to as "modifying factors." In predicting the likely etiologic pathogens for those admitted to the ICU, patients are divided into a population at risk for pseudomonal infection and a population without this organism being likely. The risk factors for *P. aeruginosa* infection are structural lung disease, corticosteroid therapy (>10 mg prednisone/day), broad-spectrum antibiotic therapy for more than 7 days in the past month, and malnutrition.[1] From the GLIMP database, Restrepo and associates found the prevalence of *P. aeruginosa* and antibiotic-resistant *P. aeruginosa* CAP was 4.2% and 2.0%, respectively.[124] The risk factors associated with *P. aeruginosa* CAP were prior infection or colonization because of *P. aeruginosa* and one of the three chronic lung conditions: tracheostomy, bronchiectasis, and/or very severe COPD. In another study, Aliberti and colleagues showed patients with at least one risk factor for MDR pathogens had more severe pneumonia on admission and a higher prevalence of severe sepsis compared with those without (45% vs. 29%, P <.001; 31% vs. 21%, P = .001). Of all risk factors, hospitalization in the preceding 90 days (OR 4.87) and residence in a nursing home (OR 3.55) were the best independent predictors of infection with a resistant pathogen and mortality.[125] Table 67.4 shows that certain clinical conditions are associated with specific pathogens, and these associations should be considered in all patients when obtaining an intake history.[1]

TABLE 67.3 Common Pathogens Causing Community-Acquired Pneumonia

Inpatient, with no Cardiopulmonary Disease or Modifying Factors
Streptococcus pneumoniae, Haemophilus influenzae, Mycoplasma pneumoniae, Chlamydophila pneumoniae, mixed infection (bacteria plus atypical pathogen), viruses (including influenza), *Legionella* species, and others (*Mycobacterium tuberculosis,* endemic fungi, *Pneumocystis jirovecii*)
Inpatient, with Cardiopulmonary Disease and/or Modifying Factors
All of the ones listed earlier, but drug-resistant *S. pneumoniae* (DRSP) and enteric gram-negative organisms are more of a concern
Severe Community-Acquired Pneumonia, with no Risks for *Pseudomonas aeruginosa*
S. pneumoniae (including DRSP), *Legionella* species, *Haemophilus influenzae,* enteric gram-negative bacilli, *Staphylococcus aureus* (including MRSA), *M. pneumoniae,* respiratory viruses (including influenza), others (*C. pneumoniae, M. tuberculosis*, endemic fungi)
Severe CAP, with Risks for *P. aeruginosa*
All of the pathogens noted earlier plus *P. aeruginosa.*

CAP, Community-acquired pneumonia; *MRSA*, methicillin-resistant *Staphylococcus aureus*.

FEATURES OF SPECIFIC PATHOGENS

Streptococcus pneumoniae

The most common bacterial pathogen for CAP, this organism is a gram-positive, lancet-shaped diplococcus, of which there are 84 different serotypes, each with a distinct antigenic polysaccharide capsule. Eighty-five percent of all pneumococcal infections are caused by the 23 serotypes included in a polysaccharide vaccine. Infection is most common in the winter and early spring, which may relate to the finding that up to 70% of patients have a preceding viral illness. The organism spreads from person to person and commonly colonizes the oropharynx before it

TABLE 67.4 Clinical Associations With Specific Pathogens

Condition	Commonly Encountered Pathogens
Alcoholism	*Streptococcus pneumoniae* (including penicillin-resistant), anaerobes, gram-negative bacilli (possibly *Klebsiella pneumoniae*), tuberculosis
Chronic obstructive pulmonary disease/current or former smoker	*S. pneumoniae, Haemophilus influenzae, Moraxella catarrhalis*
Residence in nursing home	*S. pneumoniae*, gram-negative bacilli, *H. influenzae, Staphylococcus aureus, Chlamydia pneumoniae;* consider *Mycobacterium tuberculosis.* Consider anaerobes, but less common
Poor dental hygiene	Anaerobes
Bat exposure	*Histoplasma capsulatum*
Bird exposure	*Chlamydia psittaci, Cryptococcus neoformans, H. capsulatum*
Rabbit exposure	*Francisella tularensis*
Travel to southwestern USA	*Coccidioidomycosis;* hantavirus in selected areas
Exposure to farm animals or parturient cats	*Coxiella burnetii* (Q fever)
Postinfluenza pneumonia	*S. pneumoniae, S. aureus* (including CA-MRSA), *H. influenzae*
Structural disease of lung (e.g., bronchiectasis, cystic fibrosis)	*P. aeruginosa, P. cepacia,* or *Staphylococcus aureus*
Sickle cell disease, asplenia	Pneumococcus, *H. influenzae*
Suspected bioterrorism	Anthrax, tularemia, plague
Travel to Asia	Severe acute respiratory syndrome (SARS), tuberculosis, melioidosis

CA-MRSA, Community-acquired methicillin-resistant *Staphylococcus aureus*.

leads to pneumonia. Pneumonia develops when colonizing organisms are aspirated into a lung that is unable to contain the aspirated inoculum. Bacteremia is present in up to 20% of hospitalized patients, and extrapulmonary complications include meningitis, empyema, arthritis, endocarditis, and brain abscess. The burden of pneumococcal disease is often underestimated, because most studies report the incidence of bacteremic or invasive pneumococcal disease (IPD). In a systematic review and meta-analysis, Said and colleagues estimated the proportion of CAP attributable to pneumococcus at 27.3%, and using urine antigen testing helped diagnose an additional 11.4% of pneumococcal CAP beyond conventional techniques.[126] In that study, 24.8% of all cases were bacteremic. Bloodstream invasion was more common among those with severe illness, no prior antibiotics, and a positive HIV status. As mentioned elsewhere, in recent years there has been a trend towards improved survival of severe pneumococcal CAP in the ICU, perhaps owing in part to improved antibiotic prescription practices and a decrease in smoking.[99]

Since the mid 1990s, antibiotic resistance among pneumococci has become increasingly common, and penicillin resistance, along with resistance to other common antibiotics (macrolides, trimethoprim/sulfamethoxazole, selected cephalosporins), is present in over 40% of these organisms.[1,101,102,104,105] Fortunately, most penicillin resistance is of the "intermediate" type (penicillin minimal inhibitory concentration [MIC] of 0.1–1.0 mg/L) and not of the high-level type (penicillin MIC >2.0 mg/L). Although the clinical impact of in vitro resistance is uncertain, one large database indicated that only organisms with a penicillin MIC of more than 4 mg/L led to an increased risk of death.[101] The definitions of resistance have been changed for nonmeningeal infection, with sensitive being defined by a penicillin MIC ≤2 mg/L, intermediate as an MIC of 4 mg/L, and resistant as an MIC ≥8 mg/L.[127] The clinical impact of resistance on outcomes such as mortality has been difficult to show using older definitions. Nonetheless, although very few pathogens will be defined as resistant using the newer criteria, those that are so classified would logically seem likely to adversely affect outcome. Yet in a study including 118 patients that used the new definition for resistance, there was no apparent difference in 30-day mortality between penicillin-susceptible and -resistant groups.[128] The penicillin-resistant group had a higher frequency of having received antibiotics within the last 2 weeks, but, interestingly, it was the susceptible group who had a higher frequency of worse initial presentation, such as ICU admission and bacteremia. In this cohort both groups received equally broad-spectrum antibiotic regimens, such as extended-spectrum cephalosporins, vancomycin, and a carbapenem.

The relationship of prior antibiotic use to subsequent pneumococcal resistance is well-known, and prior therapy with macrolides, beta-lactams, and quinolones has been identified as a predisposing factor for subsequent resistance to the same class of antibiotic.[104,129–131] The risk appears no lower for therapy received in the preceding 6 months compared with therapy in the past 1 month.[131] Other studies have shown that quinolone therapy can predispose to subsequent pneumococcal resistance to this class of antibiotics.[129,130] Seok and colleagues report risk factors for levofloxacin-resistant pneumococcal pneumonia to be recent hospitalization, bronchopulmonary disease, cerebrovascular disease, and prior antibiotic use within 3 months.[132] In another study of patients with pneumococcal bacteremia, resistance to beta-lactams (penicillins and cephalosporins), macrolides, and quinolones was more likely if the patient had received the same agent in the preceding 3 months.[129] Although some studies have indicated that discordant therapy of drug-resistant pneumococcus can be a risk factor for mortality, one study suggested that discordant therapy was less likely if patients were treated with ceftriaxone or cefotaxime, compared with other therapies.[133] Thus in clinical practice, resistance is not highly likely to affect outcome, because current guidelines for SCAP recommend the use of these effective agents as empiric therapy. Macrolide-resistant pneumococci have also been described, and can be either low- or high-level resistant, depending on whether the mechanism of resistance is efflux or ribosomal alteration, respectively. Although high-level resistance may be clinically relevant, this is generally not an issue in the management of ICU CAP, because all patients who receive macrolide therapy do so in combination with a highly active beta-lactam effective against pneumococcus, even if macrolide resistance is present.

Legionella pneumophila

This small, weakly staining, gram-negative bacillus was first characterized after an epidemic in 1976 and can occur either sporadically or in epidemic form. Although multiple serogroups of the species *L. pneumophila* account for 90% of all cases of legionnaires' disease, serogroup 1 is responsible for most cases. The other species that commonly causes human illness is *L. micdadei*. The organism is water-borne and can emanate from air-conditioning equipment, drinking water, lakes and river banks, water faucets, and shower heads.[134] Infection is generally caused by inhalation of an infected aerosol generated by a contaminated water source. When a water system becomes infected in an institution, endemic outbreaks may occur. In its sporadic form, *Legionella* may account for 7%–15% of all cases of CAP, being a particular

concern in patients with severe forms of illness.[1,20,134] Recent studies show an increase in the reported cases of *Legionella,* especially in populous cities like New York, with a higher incidence in diabetic patients and in those from poor neighborhoods.[135]

The classic *Legionella* syndrome is characterized by high fever, chills, headache, myalgias, and leukocytosis.[134] The diagnosis is also suggested by the presence of pneumonia with preceding diarrhea, along with mental confusion, hyponatremia, relative bradycardia, and liver function abnormalities. Symptoms progress rapidly, and the patient may appear to be quite toxic. This classic syndrome is not always present, so the diagnosis should always be considered in patients admitted to the ICU with CAP and in those with rapidly progressive radiographic abnormalities. To establish this diagnosis serologically, it is necessary to collect both acute and convalescent titers. The urinary antigen test (UAT) is the single most accurate acute diagnostic test for *Legionella,* but is specific only for serogroup 1 infection. It does not detect other types of *Legionella,* so a negative result does not rule out infection from another sero-class. In recent years, most cases have been diagnosed with UAT and there has been less reliance on blood serology and culture.[136] With increased availability of UAT, the case fatality rate of *Legionella* has fallen, in part reflecting the diagnosis of less severe illness than in the past.[136]

Staphylococcus aureus

S. aureus leads to severe forms of CAP, which can cause necrotizing cavitary pneumonia and disseminate hematogenously to multiple extrapulmonary sites. The organism can also seed the lung hematogenously from valvular vegetations in patients with right-sided endocarditis or from septic venous thrombophlebitis (from central venous catheter or jugular vein infection). When a patient develops post–influenza pneumonia, *S. aureus* can lead to secondary bacterial infection and, in the United States, CA-MRSA strains have emerged. These primarily affect skin and soft tissues but also may cause SCAP. CA-MRSA is a clonal disease, emanating from the USA300 clone of *S. aureus* and is clinically and bacteriologically different from the strains of MRSA that cause nosocomial pneumonia.[120] In addition, it can infect previously healthy individuals, and the classic clinical presentation of this pathogen as CAP occurs as a complication of a preceding viral or influenza infection.

The illness is characterized by a severe, bilateral, necrotizing pneumonia, which may relate to staphylococcal virulence factors, such as the Panton–Valentine leukocidin (PVL). In a prospective study of 627 patients from 12 emergency departments across the United States during two influenza seasons, the authors isolated CA-MRSA from 2.4% of all patients and 5% of patients admitted to the ICU. The mortality rate was 14%, and all isolates were of the USA300 strain.[137] CA-MRSA patients had severe infections with multiple infiltrates or cavities on chest imaging, were intubated or required vasopressors, and compared with other patients were more likely to develop illness after nursing home admission within the previous year or after close contact in the previous month with someone with a skin infection. Because the pathogenesis of pneumonia resulting from this organism may be related to toxin production by the bacteria, therapy may need to involve both an antibacterial agent and an antitoxin-producing agent.[121] Sicot and associates, in a study of 133 patients with PVL-positive CAP, found similar mortality rates for patients who had MRSA and methicillin-susceptible *S. aureus* (MSSA). However, treatment with antibiotics having antitoxin effects (clindamycin, rifampin, and linezolid) was associated with a reduced mortality, compared with those who did not get antitoxin therapy (6.1% vs. 52.3%, P <.001). Notably, only about one-third of patients received this therapy.[138] The frequency of this illness is still relatively low, but it does occur sporadically, with certain geographic areas having a high occurrence frequency, especially during influenza season.

OTHER ORGANISMS

The incidence of viral pneumonia is difficult to define, but one careful study of over 300 nonimmunocompromised CAP patients looked for viral pneumonia by paired serologies and found that 18% had viral pneumonia, with about half being pure viral infection and the others being mixed with bacterial pneumonia.[139] Influenza (A more than B), parainfluenza, and adenovirus were the most commonly identified viral agents. The multicenter EPIC study of CAP found that viral infection was more common than bacterial infection, but among the 482 admitted to the ICU, 45% had an identified pathogen, with viral infection in 22% and bacterial infection alone in 19%, and 4% with mixed infection. The viral pathogens were rhinovirus (8%), influenza (6%), metapneumovirus, RSV, parainfluenza, coronavirus, and adenovirus.[140] Viral illnesses that can lead to respiratory failure in addition to influenza include RSV (which can affect the elderly), varicella (a particular concern in pregnant females with chickenpox), and hantavirus (endemic in the Four Corners area of New Mexico).[141] In a study of patients with severe pneumonia using polymerase chain reaction (PCR) techniques, the authors found viral infection to be common: 36.4% ($n = 72$) had positive viral markers and 9.1% ($n = 18$) had bacterial and viral coinfections.[142]

It is important to always consider the diagnosis of tuberculosis in patients with SCAP and to be aware of fungal infections with coccidioidomycosis and histoplasmosis in endemic areas, especially among HIV-infected persons. Several rickettsiae can also cause CAP, including Q fever (*Coxiella burnetii*), which occurs worldwide; Rocky Mountain spotted fever (RMSF); and scrub typhus (*Rickettsia tsutsugamushi*) in Asia and Australia. Transmission typically involves an intermediate vector, often ticks (Q fever, RMSF) or mites (scrub typhus), but also sheep, cows, and contaminated milk (Q fever). These infections have variable incubation periods, ranging from days to a few weeks, and are characterized by a febrile syndrome that may have a pneumonic component and a maculopapular rash (Q fever and RMSF).

INFLUENZA

Influenza should always be considered during epidemic periods and can lead to a primary viral pneumonia or to secondary bacterial infection with pneumococcus, *S. aureus,* or *H. influenzae*. In April 2009, an outbreak of H1N1 influenza infected approximately 61 million people worldwide, with as many as 13,000 deaths. H1N1 influenza, in contrast to seasonal flu, affected younger people more often than the elderly, and high-risk populations included pregnant women and those with obesity.[143] In one series, 12% of all hospitalized patients with H1N1 infection were mechanically ventilated and 6% of hospitalized patients died.[144] Antiviral therapy with zanamivir and oseltamivir may reduce the severity of these illnesses, particularly if given early, and the role of corticosteroids for patients with severe illness is controversial.[143,145] MacIntyre and colleagues report during the pandemic of influenza A(H1N1)pdm09, a mean prevalence of bacterial coinfection in 19% of patients admitted to the ICU and in 12% of hospitalized patients not requiring ICU care. *S. pneumoniae* was the most common cause in both groups.[146] Muscedere and associates evaluated the risk of coexistent or secondarily acquired bacterial respiratory tract or bloodstream-positive cultures in 681 patients with 2009 influenza A (H1N1) infection.[147] In that study, 38% of patients had at least a positive blood or respiratory culture during their ICU stay even though almost all patients had received antibiotics. Patients with any positive culture experienced higher

morbidity, with more days on the ventilator, longer ICU and hospital LOS, and higher hospital mortality compared with those with negative cultures. During the spring of 2013, infection with novel avian-origin influenza A (H7N9) emerged in China and was strongly related to exposure to live animals, including chickens (82%).[148] It was linked with a high incidence of respiratory failure and ICU admission, especially in those with comorbid conditions, and mortality ranged from 27% to 34% among ICU patients.[148,149] Use of steroids as an adjunctive treatment in influenza is controversial. Although the results of most studies have been prone to confounding by indication, recent evidence suggests that steroid use is associated with greater mortality risk in influenza patients with pneumonia.[150,151]

SEVERE ACUTE RESPIRATORY SYNDROME

In late 2003, a respiratory viral infection caused by a coronavirus emerged in parts of Asia and was termed *severe acute respiratory syndrome (SARS).* The illness affected people from a variety of endemic areas in Asia, but was encountered in North America when an outbreak occurred in Toronto, Canada, after exposure to an infected traveler returning from Asia. Importantly, worldwide as many as 20% of affected patients were healthcare workers, particularly those caring for patients admitted to the ICU. Although transmission risk was greatest during emergent intubation, it also occurred during noninvasive ventilation, making this latter modality of therapy contraindicated when SARS is suspected.[152] Infection control may be quite effective in preventing the spread of SARS to healthcare workers and includes the careful handling of respiratory secretions, ventilator circuits, the use of N-95 respirator masks, and careful gowning and gloving.[153] Even more elaborate infection control measures, including personal air exchange units, are needed for healthcare workers involved in high-risk procedures such as intubation. The mortality rate for ICU-admitted SARS patients was over 30%, and, when patients died, it was generally from multiple system organ failure and sepsis. A similar experience has accompanied the COVID-19 pandemic.

MIDDLE EAST RESPIRATORY SYNDROME CORONAVIRUS

A new coronavirus outbreak, subsequently named "Middle East respiratory syndrome coronavirus" (MERS-CoV), started September 2012 in the Arabian Peninsula.[154] Patients presented with severe acute pneumonia with hypoxemic respiratory and renal failure. MERS-CoV pneumonia can occur sporadically in the community in addition from healthcare–associated human-to-human transmission.[155] The infection was associated with a very high fatality rate (up to 60%), especially in patients with medical comorbidities. The majority of patients required invasive respiratory support and had extrapulmonary manifestations, mainly kidney failure.[156] The effectiveness of steroids, oseltamivir, ribavirin, and interferon for treatment of this illness has remained uncertain.

BIOTERRORISM CONSIDERATIONS

Certain airborne pathogens can cause pneumonia as the result of deliberate dissemination by the aerosol route, in the form of a biologic weapon, and present a clinical syndrome of CAP. The pathogens that are most likely to be used in this fashion and that can lead to severe pulmonary infection are *Bacillus anthracis* (anthrax), *Yersinia pestis* (plague), and *F. tularensis* (tularemia).[157–161] The Centers for Disease Control and Prevention (CDC) has classified these agents as category A pathogens because of their high mortality rate and their potential impact on public health.[157] Other pneumonic pathogens could also serve as agents of biologic warfare but are potentially less serious and are category B, and include *C. burnetii* and *Brucella* species. Certain emerging pathogens are category C agents and are not widely available as weapons but have the potential for high morbidity and mortality and include hantavirus and MDR tuberculosis. Some agents of bioterrorism can be spread via the aerosol route but do not generally present as pneumonia. These include smallpox and viral hemorrhagic fevers (Ebola, Marburg).

DIAGNOSTIC EVALUATION

As discussed, the diagnosis of CAP is suggested by the history and physical examination and confirmed by chest radiograph. The history may call to mind certain pathogens on the basis of epidemiologic considerations (see Table 67.4), but the clinical features and chest radiograph cannot nail down an exact etiologic diagnosis. In the patient with SCAP, diagnostic testing is done to define the presence of pneumonia, the severity of illness and its complications, and the etiologic pathogen. Although defining a specific etiologic diagnosis of CAP allows for focused antibiotic therapy, most patients never have a specific pathogen identified, and in many who do, the diagnosis may be made days or weeks later when the results of cultures or serologic testing become available. An etiologic diagnosis is best established if blood or pleural fluid cultures identify a pathogen, if bronchoscopic techniques demonstrate an organism in high concentrations, or if serologic testing confirms a fourfold rise in titers to specific pathogens (comparing acute and convalescent samples collected weeks apart).

For ICU-admitted patients, after a chest radiograph establishes the presence of pneumonia, testing should include an assessment of oxygenation (pulse oximetry or blood gas if retention of carbon dioxide is suspected), routine admission blood work, and two sets of blood cultures[1] (Table 67.5). Although blood cultures are positive in only 10%–20% of CAP patients, they can be helpful when they define a specific diagnosis and may indicate the presence of drug-resistant pneumococci.[1,101] Blood cultures are not routine for all admitted patients, but should be done in those with severe illness, especially if the patient has not received antibiotics before admission, because the incidence of a true positive result is higher in this population.[162] Current IDSA/ATS 2019 guidelines discourage obtaining blood cultures in outpatient and inpatient settings, unless the patient has severe CAP, is being empirically treated for or has a history of infection with MRSA or *P. aeruginosa,* or has a history of being hospitalized and has received parenteral antibiotics within the preceding 90 days of admission.[4] If the patient has a significantly large ipsilateral pleural effusion, this should be tapped and the fluid sent for culture and biochemical analysis.

The role of Gram stain of sputum to guide initial antibiotic therapy is controversial, but this test has its greatest value in guiding the interpretation of sputum culture and can be used to define the predominant organism present in the sample. Gram stain can be used to broaden initial empiric therapy by enhancing the suspicion for organisms that are not covered in routine empiric therapy (such as *S. aureus* being suggested by the presence of clusters of gram-positive cocci, especially during a period of epidemic influenza).[1] Sputum culture can help identify the presence of a drug-resistant or unusual pathogen and should be obtained from all critically ill patients who are intubated.[1] IDSA/ATS 2019 guidelines extend the same recommendation as with blood culture for Gram stain of sputum and culture to be done in patients with SCAP who are being empirically treated for or have a history of infection with MRSA or *P. aeruginosa* or have a history of being hospitalized and have received parenteral antibiotics within the preceding 90 days before admission.[4] UAT for pneumococcus or

TABLE 67.5 Diagnostic Testing for Community-Acquired Pneumonia

Test	Sensitivity	Specificity	Comment
Chest radiograph	65%–85%	85%–95%	Computed tomography is more sensitive to infiltrates. Recommended for all patients.
Computed tomography	Gold standard	Not infection specific	Should not be done routinely but helpful to identify cavitation and loculated pleural fluid. Recommended in the evaluation of nonresponding patients.
Blood cultures	10%–20%	High when positive	Usually shows pneumococcus (in 50%–80% of positive samples) and defines antibiotic susceptibility. Recommended in patients with severe CAP, particularly if not on antibiotic therapy at the time of testing.
Sputum Gram stain	40%–100% depending on criteria	0%–100% depending on criteria	Can correlate with sputum culture to define predominant organism and can use to identify unsuspected pathogens. Recommended if sputum culture obtained. May not be able to narrow empiric therapy choices.
Sputum culture			Use if suspect drug-resistant or unusual pathogen, but positive result cannot separate colonization from infection. Obtain via tracheal aspirate in all intubated patients
Oximetry or arterial blood gas			Both define severity of infection and need for oxygen; if hypercarbia is suspected, a blood gas sample is needed. Recommended in severe community-acquired pneumonia.
Serologic testing for *Legionella, Chlamydia pneumoniae, Mycoplasma pneumoniae*, viruses			Accurate, but usually requires acute and convalescent titers collected 4–6 weeks apart. Not routinely recommended.
Legionella urinary antigen	50%–80%		Specific to serogroup 1, but the best acute diagnostic test for *Legionella*
Pneumococcal urinary antigen	70%–100%	80%	False positives if recent pneumococcal infection. Can increase sensitivity with concentrated urine.
Serum procalcitonin			Not a routine test, but if done, should be measured with the highly sensitive KRYPTOR assay. May help guide duration of therapy and need for ICU admission.

CAP, Community-acquired pneumonia; *ICU*, intensive care unit.

Legionella has some potential value for providing a rapid diagnosis. *Legionella* urinary antigen is specific to serogroup 1 infection and is only positive in a little more than half of all infected patients, but it is the one test that is most likely to be positive in the setting of acute illness.[163] UAT is also available for detection of capsular polysaccharide of *S. pneumoniae* and has 77%–88% sensitivity in patients with bacteremic pneumococcal pneumonia, but is only 64% positive with nonbacteremic pneumococcal pneumonia.[103,164] The sensitivity of pneumococcal UAT increases if concentrated urine is examined, and it can be positive even in the presence of antibiotic therapy. False-positive tests can occur in patients who have had recent pneumococcal infection.[165] In a randomized study of 177 patients treated based on UAT for *Legionella* and *S. pneumoniae* compared with empiric guideline-directed treatments, there was no difference in mortality, need for ICU level of care, or hospital LOS. Nonetheless, targeted treatment was associated with a slightly higher overall cost and lower exposure to broad-spectrum antimicrobials.[166] IDSA/ATS 2019 guidelines discourage routine UAT testing in all adults with CAP, but recommend it for those with SCAP and for those with high-risk epidemiologic factors, such as recent travel or *Legionella* outbreak in the community.[4]

Routine serologic testing is not recommended.[1] Nucleic acid amplification tests and PCR assays provide rapid test results in CAP for atypical agents such as viruses, *Mycoplasma, Chlamydophila,* and *Legionella*. Cultureless, rapid diagnostic tests such as new nucleic acid amplification platforms, real-time computer-assisted microscopy, next-generation sequencing, and high-throughput mass spectrometry are being developed for early detection and pathogen-specific therapy.[167] The usefulness of these techniques in managing CAP has not yet been proven. The concern with using this method is that it is so sensitive that if a respiratory sample is positive, it cannot distinguish colonization from infection. However, the test may be valuable if negative, because the absence of a suspected pathogen by PCR may permit a more focused antibiotic therapy approach.

Bronchoscopy is not indicated as a routine diagnostic test and should be restricted to immunocompromised patients and to selected individuals with severe forms of CAP. Several studies[168,169] have not shown improvement in outcome when a specific etiologic diagnosis is made for patients with SCAP. Rather, outcome is improved if the initial empiric therapy is accurate and the patient has a prompt clinical improvement.[169] However, patients who have rapidly progressive lung infection in spite of therapy may benefit from invasive diagnostic testing. Again, however, a favorable impact of this testing on patient outcome has not been demonstrated. One population that should be considered for invasive testing is the corticosteroid-treated COPD patient who has a slowly responding or nonresponding pneumonia, because these individuals are at risk for infection with *Aspergillus,* and this organism usually can be recovered from a bronchoscopic lavage sample. In addition, bronchoscopy may have value for the nonresponding patient or other immunesuppressed individuals.[170]

In patients with SCAP, diagnostic testing may be valuable for guiding modifications of antibiotic therapy, rather than affecting the choice of initial therapy.[171] In one study, nearly 40% of patients had no pathogen identified. Pathogen-directed therapy had no overall impact on mortality or LOS, but led to fewer adverse events than empiric therapy and also was accompanied by a lower incidence of

mortality for patients admitted to the ICU.[172] In addition, studies have emphasized mortality benefit from prompt administration of effective antibiotic therapy.[173] Thus, therapy should never be delayed for the purpose of diagnostic testing, and the diagnostic workup should be streamlined, with all patients receiving empiric therapy based on algorithms as soon as possible.

TREATMENT

Initial antibiotic therapy for SCAP is necessarily empiric, with the goal of targeting the likely etiologic pathogens, based on the considerations listed in Tables 67.3 and Table 67.4, which categorize patients on the basis of severity of illness and risk factors for specific pathogens. The likelihood of organisms such as DRSP, enteric gram-negative organisms, and *P. aeruginosa* is determined by the presence of cardiopulmonary disease or "modifying factors."[1] A set of likely pathogens can be predicted for each patient (see Table 67.3), and this information can be used to guide initial empiric therapy. If diagnostic testing shows the presence of a specific pathogen, broad-coverage therapy can be narrowed and focused.

In choosing empiric therapy of CAP, certain principles and therapeutic approaches should be followed (Table 67.6).[1,174] All individuals should be treated for DRSP and atypical pathogens, but only those with appropriate risk factors (see earlier) should receive coverage for *P. aeruginosa*, and patients with bilateral necrotizing pneumonia occurring after influenza need coverage for CA-MRSA.[1] All patients admitted to the ICU require combination therapy, using a beta-lactam with either a macrolide or quinolone, with the addition of other agents, depending on the clinical setting.[1,4,175] The recommendation to avoid monotherapy is based on the fact that the efficacy (especially for meningitis complicating pneumonia), effective dosing, and safety of any single agent, including quinolone monotherapy, has not been established for ICU-admitted CAP patients. From the available data, it appears that adding either a macrolide or a quinolone to a beta-lactam leads to similar results. Some data in patients with bacteremic CAP, especially with pneumococcus, suggest that a macrolide may have particular advantages to adding a quinolone, possibly because of its antiinflammatory effects.[118,119,176,177]

In one study of 529 patients with ICU-admitted CAP, combination therapy with a beta-lactam plus either a macrolide or quinolone led to improved survival for the population with shock needing pressors (279 patients), compared with the use of monotherapy.[178] Another study of SCAP patients (not all pneumococcal) also confirmed the benefit of adding a macrolide as part of initial empiric therapy, but not a quinolone, for reducing mortality.[179] In a study comparing the impact of dual (beta-lactam plus macrolide or fluoroquinolone [$n = 394$]) versus monotherapy (beta-lactam alone [$n = 471$]) in immunocompetent SCAP, there was no difference in 60-day mortality between the two groups.[180] However, there was a survival advantage for patients who had initial adequate antibiotic therapy, and those who received dual therapy had a higher frequency of initial adequate antibiotics. In one study comparing high-dose levofloxacin with a beta-lactam/quinolone combination, the single-agent regimen was overall effective. However, patients in septic shock were excluded, and there was a trend to a worse outcome with monotherapy for individuals receiving MV.[175] In a meta-analysis of SCAP, the addition of a macrolide to a beta-lactam was associated with reduced mortality compared with other regimens.[181] In another systematic review that included 17 studies with 16,684 patients, no difference in outcomes was noted between combination beta-lactam plus macrolide versus beta-lactam plus fluoroquinolone.[182] If *Legionella* is suspected, then the use of a quinolone may be preferable, because these agents have been highly successful in treating pneumonia caused by this organism—possibly more effective than macrolides.[183] Also, IDSA/ATS 2019 guidelines do not recommend adding antibiotics for anaerobic coverage for suspected aspiration pneumonia in inpatient settings, except when lung

TABLE 67.6 Empiric Therapy Regimens for Severe Community-Acquired Pneumonia

No Pseudomonal Risk Factors

Selected beta-lactam (ampicillin + sulbactam 1.5–3 g every 6 h, cefotaxime 1–2 g every 8 h, ceftriaxone 1–2 g daily, or ceftaroline 600 mg every 12 h)
Plus
Intravenously administered macrolide (azithromycin 500 mg daily or clarithromycin 500 mg twice daily) *or* quinolone (levofloxacin 750 mg daily or moxifloxacin 400 mg daily)

Pseudomonal Risk Factors Present or Prior Pseudomonal Colonization or the Presence of Local Etiologic and Risk Factor Data

Selected antipseudomonal beta-lactam (piperacillin-tazobactam [4.5 g every 6 h], cefepime [2 g every 8 h], ceftazidime [2 g every 8 h], aztreonam [2 g every 8 h], meropenem [1 g every 8 h], or imipenem [500 mg every 6 h])
Plus
Intravenously administered antipseudomonal quinolone (ciprofloxacin or levofloxacin)
Or selected antipseudmomonal beta-lactam
Plus
Aminoglycoside
Plus
Antipneumonoccal quinolone or macrolide

MRSA Risk Factors Present or Prior Isolation of MRSA

Vancomycin (15 mg/kg every 12 h, adjust based on trough levels 15–20) or linezolid (600 mg every 12 h).
Note: Although routine MRSA coverage is NOT recommended for all cases of severe CAP, consider CA-MRSA, especially after influenza and with bilateral necrotizing pneumonia, and if toxin-mediated infection suspected, treat by adding either linezolid or the combination of vancomycin and clindamycin.

CAP, Community-acquired pneumonia; *CA-MRSA*, Community-acquired MRSA; *MRSA*, methicillin-resistant *Staphylococcus aureus*.

abscess or empyema is suspected, as the majority of these pneumonias are caused by gram-negative pathogens.[4]

Although they should not be used as monotherapy for ICU-admitted CAP patients, the antipneumococcal quinolones have assumed great importance because they can cover pneumococcus (including DRSP), nonpseudomonal gram-negative organisms, and atypical pathogens.[1] Quinolones penetrate well into respiratory secretions and are highly bioavailable, achieving similar serum levels with either oral or intravenous therapy and facilitating a rapid switch to oral therapy in responding patients. The available intravenous agents that are active against pneumococcus are moxifloxacin and levofloxacin.[184] Based on in vitro activity, the recommended doses for moxifloxacin are 400 mg daily and for levofloxacin 750 mg daily, with the need to adjust dosing of levofloxacin (but not moxifloxacin) in patients with renal insufficiency.

For patients with pseudomonal risk factors, effective therapy can be provided with a two-drug regimen, using an antipseudomonal beta-lactam (cefepime, imipenem, meropenem, piperacillin/tazobactam) plus ciprofloxacin (the most active antipseudomonal quinolone) or levofloxacin. Alternatively, a three-drug regimen can be used, combining an antipseudomonal beta-lactam plus an aminoglycoside plus either an intravenous antipneumocccal quinolone (moxifloxacin or levofloxacin) or a macrolide.[1] If CA-MRSA is suspected, effective therapy can be provided with either vancomycin or linezolid, although other agents might be effective, because this pathogen is not as antibiotic resistant as nosocomial MRSA. However, because CA-MRSA is in part a toxin-mediated illness, the use of an agent that inhibits toxin production along with an antibacterial effect is recommended by some.[121] To do this, linezolid can be used alone (because it acts to inhibit protein synthesis), or clindamycin can be added to vancomycin. IDSA/ATS 2019 guidelines recommend empiric coverage for *Pseudomonas* and MRSA based on locally validated epidemiologic risk factors for either pathogen to be present.[4] Guidelines do not recommend prior categorization of HCAP and empiric therapy with broad-spectrum antibiotics. Maruyama and colleagues applied a simple therapeutic algorithm for all pneumonia patients based on MDR risks in a prospective study of 1089 patients including 656 CAP patients and found that 30-day mortality was not associated with site of classification such as CAP, HCAP, hospital-acquired pneumonia (HAP), or ventilator-acquired pneumonia (VAP). Therapy was based on five risk factors—namely, advanced age, hematocrit <30%, malnutrition, dehydration, and chronic liver disease—in addition to shock or prior inappropriate therapy.[185] Using this algorithm, inappropriate empiric therapy was given in less than 5% of all patients.

Patients admitted with influenza should be treated with appropriate antiviral agents, regardless of the duration of illness before diagnosis.[4] There is a high incidence of postinfluenza bacterial pneumonia, with mortality rates approaching 10% with both seasonal and pandemic influenza.[186] In addition, antibiotics should be started, even in confirmed influenza, with a special focus on *S. aureus, S. pneumoniae, H. influenzae*, and group A streptococcus to account for the possibility of coinfection. However, the guidelines allow consideration for de-escalation of antibiotics in those with no evidence of bacterial superinfection and clinical stability after 48–72 hours of initiation of antibiotics.[4]

Several newer antibiotics are on the horizon for the treatment of CAP, including solithromycin, lefamulin, omadacycline, ceftobiprole, ceftazidime-avibactam, ceftolozane-tazobactam, and delafloxacin.[187] Solithromycin is a novel fourth-generation macrolide. In two recent double-blind, randomized controlled, noninferiority trials, its effectiveness was comparable to oral moxifloxacin in patients with mild to moderate CAP (PORT scores II–IV).[188,189] Lefamulin is a novel semi-synthetic antibiotic in the pleuromutilin class. In the phase 3 "LEAP 2" randomized clinical trial comparing early clinical responses in CAP patients with PORT risk class of II, III, or IV, 5 days of oral lefamulin was not inferior to 7-day oral treatment with moxifloxacin.[190] Omadacycline is an aminomethycycline, and in a recent randomized, double-blind trial conducted in CAP patients (PORT risk class of II, III, or IV), a comparison of omadacycline (100 mg intravenously every 12 hours for two doses, then 100 mg intravenously every 24 hours) with moxifloxacin (400 mg intravenously every 24 hours) demonstrated similar early clinical responses with both antibiotics.[191] Ceftobiprole is an extended-spectrum cephalosporin available in intravenous form. In a double-blind controlled trial with 706 hospitalized CAP patients, ceftobiprole medocaril was found noninferior to ceftriaxone with or without linezolid.[192] Nemonoxacin is a novel nonfluorinated quinolone. In a phase III study of CAP patients randomized to nemonoxacin ($n = 356$) or levofloxacin ($n = 171$) there was no difference in clinical or microbiologic cure rates between the groups at 7–10 days; adverse side effects were comparable.[193] Delafloxacin is another novel fluoroquinolone, and in a phase III study in CAP patients, there was 16-fold greater activity with delafloxacin compared with moxifloxacin for gram-positive and fastidious gram-negative pathogens. Retained activity was observed against resistant phenotypes found in S. *pneumoniae* (penicillin-resistant, macrolide-resistant, MDR), *Haemophilus* species (beta-lactamase producing, macrolide-nonsusceptible), and *S. aureus* (MRSA, fluoroquinolone-nonsusceptible MSSA).[194] Both ceftazidime-avibactam and ceftolozane-tazobactam are agents in development for treating nosocomial pneumonia, and both have excellent activity against *P. aeruginosa*. These agents will be important newer options over the next decade, given increasing concerns regarding drug resistance. But for now, the workhorse of CAP treatment in the critical care setting remains the beta-lactam plus macrolide or beta-lactam plus fluoroquinolone combinations.

TIMELINESS OF INITIAL THERAPY

For inpatients with CAP, timely and accurate therapy is essential to reduce mortality. In patients with SCAP, improved survival has been shown to occur if initial empiric therapy is accurate and if it leads to a rapid clinical response.[115,169,173] In one study, if initial therapy led to a clinical response within 72 hours, mortality of SCAP was approximately 10%, compared with a mortality rate of 60% in patients who received ineffective therapy initially.[169] For CAP in general, early therapy is associated with reduced mortality compared with therapy given later; if the patient has pneumonia with sepsis and hypotension, mortality rises by nearly 8% for every hour of delay in starting therapy.[195]

DURATION OF THERAPY

There is little information on the proper duration of therapy in patients with CAP, especially those with severe illness. Even in the presence of pneumococcal bacteremia, short durations of therapy may be possible, with a rapid switch from intravenous to oral therapy in those who respond.[196] Generally, *S. pneumoniae* can be treated for 5–7 days if the patient responds rapidly and has received the correct dose of an appropriate therapy. Initial PCT level may accurately predict a positive blood culture in pneumonia patients, and serial measurements help with antibiotic de-escalation and withdrawal in CAP patients.[197,198] In a randomized trial of antibiotic therapy in the ICU, PCT guidance reduced the duration of therapy compared with standard care in all patients, including those with SCAP.[199] A meta-analysis of 14 randomized trials favored a PCT-based treatment algorithm for

antibiotic de-escalation without an increase in either mortality or treatment failure.[200] In a recent meta-analysis of 19 randomized controlled trials of CAP including 4861 patients there were no differences in clinical cure rates between short-course treatment defined as ≤6 days and treatment for ≥7 days irrespective of patient setting or severity of pneumonia.[201] In that study, short-course treatment was associated with fewer serious adverse events (relative risk [RR] = 0.73; 95% CI 0.55–0.97) and potentially lower mortality than long-course treatment (RR = 0.52; 95% CI 0.33–0.82). The IDSA/ATS 2019 guideline recommends clinicians continue antibiotics until the patient achieves stability using a validated measure of clinical stability, including normalization of vital sign abnormalities, oxygen saturation, ability to eat, and normal mentation. The duration is not less than a total of 5 days.[4]

The presence of extrapulmonary infection (e.g., meningitis, empyema) and the identification of certain pathogens (such as bacteremic *S. aureus* and *P. aeruginosa*) may require a longer duration of therapy. Identification of *L. pneumophila* pneumonia may require at least 14 days of therapy, depending on severity of illness and host defense impairments, but shorter durations with quinolone therapy have been effective. Most therapy in the ICU will be given intravenously; however, recent studies, using a variety of antibiotics, have suggested that oral therapy may be instituted after as early as 2–3 days of parenteral therapy, assuming that the patient's condition has stabilized and the patient is afebrile.[1] The switch to oral therapy, even in severely ill patients, may be facilitated by the use of quinolones that are highly bioavailable and achieve similar serum levels with oral therapy as with intravenous therapy.

ADJUNCTIVE THERAPY MEASURES

In addition to antibiotic therapy, the patient with SCAP may require chest physiotherapy, especially if the patient has either an excessive volume of purulent sputum (>30 mL/day) or severe respiratory muscle weakness resulting in ineffective cough.[202] Aerosolized humidification has been used to reduce sputum viscosity, thereby enhancing clearance in patients who have generally ineffective cough, and nebulized hypertonic saline may promote cough and expectoration of sputum. However, it is likely that much of the generated water vapor is deposited in the upper airway, where it is likely to stimulate cough but unlikely to influence the rheologic properties of sputum. Bronchodilator therapy, which also enhances mucociliary clearance and ciliary beat frequency, is most likely to be of benefit in patients with pneumonia complicating COPD. A recent Cochrane review did not find convincing evidence supporting the role of chest physiotherapy in pneumonia patients.[203]

Previous studies looking into the use of adjunctive corticosteroids in patients with SCAP have shown mixed results.[204,205] Although the role of corticosteroids as routine therapy for CAP is not established, steroids may be beneficial in patients with sepsis and relative adrenal insufficiency, which occurs in a high proportion of patients with SCAP.[206] A recent meta-analysis of nine trials involving 1001 patients did not support routine use of corticosteroids in CAP patients, but may improve mortality in a subset with SCAP.[207] Another setting in which corticosteroids may have benefit is in pneumococcal pneumonia that is complicated by meningitis, where pretreatment with corticosteroids before antibiotic therapy may lead to more favorable neurologic outcomes.[208] In a randomized, prospective study, Torres and associates found that in patients with SCAP and elevated CRP >150 mg/L at admission, administration of intravenous methylprednisolone (bolus of 0.5 mg/kg every 12 hours) led to less treatment failure, compared with placebo.[209] In that study, there was no significant difference in hospital mortality between the two groups. The IDSA/ATS 2019 guideline gives a strong conditional recommendation against routine use of adjunctive steroids in patients treated for CAP.[4] Even if corticosteroids are given to selected SCAP patients, they should probably be withheld in those with documented influenza, unless there is another specific indication (e.g., adrenal insufficiency). Adjunctive immune therapy with granulocyte colony-stimulating factor (G-CSF) has also been used in SCAP, with no benefit in mortality or in the course of illness resolution.[210]

EVALUATION OF RESPONSE TO THERAPY

The majority of patients will respond rapidly to appropriate empiric therapy within 24–72 hours. Clinical response is defined as improvement in symptoms of cough, sputum production, and dyspnea, along with ability to take medications by mouth, declining WBC count, and an afebrile status on at least two occasions 8 hours apart.[1] In the critically ill patient, improvement in oxygenation may be one of the earliest signs of response to therapy, although few studies have examined mechanically ventilated patients.[1] Radiographic improvement lags behind clinical improvement, and in general, 50% of patients with pneumococcal pneumonia have radiographic clearing at 5 weeks, whereas the majority clear in 2–3 months. With bacteremic disease, 50% of patients have a clear chest radiograph at 9 weeks, and most are clear by 18 weeks.[211] Radiographic resolution is most influenced by the number of lobes involved and the age of the patient. Radiographic clearance of CAP decreases by 20% per decade after age 20, and patients with multilobar infiltrates take longer to clear than those with unilobar disease.[211]

If the patient fails to respond to appropriate therapy in the expected time interval, then it is necessary to consider infection with a drug-resistant or unusual pathogen (tuberculosis, *C. burnetii*, *Burkholderia pseudomallei*, *C. psittaci*, endemic fungi, or hantavirus); a pneumonic complication (lung abscess, endocarditis, empyema); or a noninfectious process that mimics pneumonia (bronchiolitis obliterans with organizing pneumonia, hypersensitivity pneumonitis, pulmonary vasculitis, bronchoalveolar cell carcinoma, lymphoma, pulmonary embolus).[1] The evaluation of the nonresponding patient should be individualized, but may include CT of the chest, pulmonary angiography, bronchoscopy, and, occasionally, open lung biopsy.

PREVENTION

Prevention of CAP is important for all groups within the population but especially for the elderly patient, who is at risk for both a higher frequency of infection and a more severe course of illness. Appropriate patients should be vaccinated with both pneumococcal and influenza vaccines, and cigarette smoking should be stopped in all at-risk patients. Even for the patient who is recovering from CAP, immunization while in the hospital is appropriate to prevent future episodes of infection, and the evaluation of all patients for vaccination need and the provision of information about smoking cessation have been performance standards used to evaluate the hospital care of CAP patients.[1]

PNEUMOCOCCAL VACCINE

Pneumococcal capsular polysaccharide vaccine can prevent pneumonia in otherwise healthy populations, as was initially demonstrated in South African gold miners and American military recruits.[1,212] The benefits in individuals of advanced age or with underlying conditions in nonepidemic environments are less clearly defined. Efficacy of the polysaccharide vaccine has ranged from 65% to 84% in patients with diabetes mellitus, coronary artery disease, congestive heart failure,

chronic pulmonary disease, and anatomic asplenia.[212] In immunocompetent patients over the age of 65, effectiveness has been documented to be 75%. In the immunocompromised patient, effectiveness has not been proven, and this includes patients with sickle cell disease, chronic renal failure, immunoglobulin deficiency, Hodgkin disease, lymphoma, leukemia, and multiple myeloma. A single revaccination is indicated in a person who is older than age 65 years who initially received the vaccine more than 5 years earlier and was younger than age 65 on first vaccination.[1,105] If the initial vaccination was given at age 65 or older, revaccination is indicated, and the second dose is given at least 5 years after the original dose.

The available polysaccharide pneumococcal vaccine is widely underutilized, especially as the 23-valent pneumococcal vaccine contains 23 pneumococcal serotypes that cause 85% of all infections resulting from pneumococcus. Two protein-conjugated pneumococcal vaccines have been licensed and are more immunogenic than the older vaccine, but contain only 7 and 13 serotypes.[1] However, the conjugate vaccine has had benefit for adults, even when given to only children, demonstrating a "herd immunity" effect.[213] In a recent study, investigators studied the influence of conjugate vaccine on pneumonia-related hospitalizations compared with nonpneumonia hospitalizations over five study intervals: prevaccine period, availability of PCV-7 for private purchase, public funding of PCV-7, replacement of PCV-7 with PCV-10, and replacement of PCV-10 with PCV-13 using a difference-in-differences approach.[214] They noted that although the hospitalization rates and costs for pneumonia were similar to nonpneumonia hospitalizations during the prevaccine period for all age groups, there was a drastic difference in the postvaccination period. The impact of indirect effects was seen also among those ineligible to receive vaccination, with statistically significant reductions in hospitalizations and related costs across all age groups.

The 13-valent pneumococcal conjugate vaccine (PCV-13) was approved by the Food and Drug Administration (FDA) in late 2011 for use among adults aged ≥50 years.[215] Based on the recent report from the randomized, placebo-controlled trial evaluating the efficacy of PCV-13 for preventing CAP among adults aged ≥65 years (CAPITA: Community Acquired Pneumonia Immunization Trial in Adults), the Advisory Committee on Immunization Practices has recommended routine use of PCV-13 among adults aged ≥65 years since August 2014.[215] PCV-13 should be administered in series with the 23-valent pneumococcal polysaccharide vaccine, giving PCV-13 first, if possible. More recent recommendations suggest that the decision to use PCV-13 in patients over age 65 be a shared decision with the patient and physician, because of a decline in pneumococcal infection rates as a result of current immunization practices.[216] PCV-13 and pneumococcal polysaccharide vaccine 23-valent vaccination are also recommended in patients with chronic pulmonary diseases on steroids or receiving immunomodulating therapy, or who have concurrent sickle cell disease or other hemoglobinopathies, primary immunodeficiency disorders, human immunodeficiency virus (HIV) infection/acquired immunodeficiency syndrome (AIDS), nephrotic syndrome, and hematologic or solid malignancies.[217]

Hospital-based immunization could be highly effective, because over 60% of all patients with CAP have been admitted to the hospital, for some indication, in the preceding 4 years, and hospitalization could be defined as an appropriate time for vaccination. Pneumococcal vaccine can be given simultaneously with other vaccines, such as influenza vaccine, but each should be given at a separate site. The vaccine can, and often should, be given before discharge in the patient admitted for CAP.

INFLUENZA VACCINATION

Influenza epidemics contribute to morbidity and mortality, both by causing direct infection and by leading to postinfluenza complications. The influenza vaccine preparations are revised annually to account for changes in the antigenic nature of the virus (antigenic drift) that is present each season. Three strains are represented in each vaccine preparation: two influenza A strains (H3N2 and H1N1) and one influenza B strain. Vaccination should be given to all patients older than age 65 and to those with chronic medical illness (including nursing home residents) and to those who provide health care to patients at risk for complicated influenza.[1] It is given yearly, usually between September and mid-November. Although the traditional influenza vaccine contains an inactivated virus, there is now an intranasal vaccine containing a live attenuated influenza virus. It is currently approved for individuals ages 5 to 49 years who are not immune suppressed or chronically ill and who do not have asthma. When the vaccine matches the circulating strain, it can prevent illness in 70%–90% of healthy persons younger than age 65.[1,218] For older persons with chronic illness, the efficacy is less, but the vaccine can still attenuate the influenza infection and lead to fewer lower respiratory tract infections and the associated morbidity and mortality that follow influenza. In many studies, the vaccine has been shown to be cost-effective and able to prevent severe illness and death and to reduce the occurrence of secondary pneumonia and hospitalization.[218] For those above 65 years of age a higher-dose influenza vaccine (60 μg of hemagglutinin per strain) has been shown to provide better protection.[219,220] In a randomized study including 31,989 participants, the high-dose vaccine induced significantly higher antibody responses and provided better protection against laboratory-confirmed influenza illness than standard vaccine.[219] In another study, Izurieta and colleagues examined a large Medicare database of patients aged ≥65 years and found that those who had received high-dose inactivated influenza vaccine during the 2012–13 influenza seasons were less likely to have influenza-related medical encounters and hospitalization than those who received the standard-dose vaccine.[221]

KEY POINTS

- CAP is a common illness, but only about 20% of all affected patients are admitted to the hospital, and only 10%–20% of admitted patients require ICU care.
- Risk factors for SCAP include smoking, alcohol abuse, serious comorbid medical illnesses, and advanced age.
- Risk factors for CAP mortality include severe physiologic abnormalities, delays in the initiation of appropriate antibiotic therapy, advanced age, genetic abnormalities in the immune response, rapid radiographic progression, the development of respiratory failure, and the presence of certain high-risk pathogens.
- Prognostic scoring systems are useful for predicting CAP mortality but are less accurate for identifying patients who require ICU care. ICU care is needed for patients with respiratory failure, multilobar infiltrates, severe hypoxemia (PaO_2/FIO_2 ratio <250), and systolic blood pressure less than 90 mm Hg. Early recognition of SCAP may allow the ICU to be used in a fashion that can reduce the mortality of this illness.
- The failure to localize infection to a single site in the lung, with excessive systemic and pulmonary inflammation, is a common feature in patients with severe forms of CAP.
- Clinical features of pneumonia cannot help to predict the microbial etiology, especially in older patients with impaired immune response, who commonly have less dramatic clinical findings than younger patients with a similar severity of illness.
- The most common pathogens causing SCAP include pneumococcus, atypical pathogens (*Legionella* spp., *M. pneumoniae,* and *C. pneumoniae*), enteric gram-negatives (including *P. aeruginosa*), *S. aureus* (including community-acquired methicillin-resistant strains), and *H. influenzae,* but infection can also be the result of viral illness (influenza, coronaviruses such as SARS), bioterrorism (anthrax), and other miscellaneous organisms.
- Antibiotic-resistant pneumococci are increasingly common and must be considered in the choice of initial antibiotic therapy for SCAP; however, the impact of resistance on the outcomes of patients is uncertain.
- It may be difficult to establish an exact etiologic diagnosis in patients with SCAP, but diagnostic testing should always include a chest radiograph, oxygenation assessment, blood cultures, and, in selected patients, sputum Gram stain and culture, bronchoscopic culture, and UAT for *Legionella* and pneumococcus.
- Therapy for SCAP must be done promptly and empirically, using multiple antibiotics directed against pneumococcus, atypical pathogens, enteric gram-negative organisms, and, in some patients, *P. aeruginosa* and CA-MRSA. This usually requires the combination of a specific beta-lactam with either a macrolide or a quinolone and sometimes the addition of other agents. Quinolone monotherapy is not recommended for the empiric management of SCAP. In patients with SCAP after influenza, CA-MRSA should be considered.
- On serial measurements, biomarkers like PCT can help with antibiotic de-escalation.
- Nonresponse in severe CAP can be recognized as early as 24–48 hours and requires consideration of unusual or drug-resistant pathogens, noninfectious diseases that mimic pneumonia, and pneumonia complications.
- Prevention of pneumonia can be accomplished by focusing on smoking cessation and immunization for pneumococcus and influenza, with consideration of a hospital-based immunization program. The 13-valent pneumococcal conjugate vaccine (PCV-13) was approved by the FDA in late 2011 for use among adults aged ≥50 years, and recent evidence suggests using PCV-13 in series with 23-valent pneumococcal polysaccharide vaccine among patients ≥65 years of age.

Nosocomial Pneumonia

Gianluigi Li Bassi, Miguel Ferrer, and Antoni Torres

DEFINITIONS

Nosocomial pneumonia is an infection of the pulmonary parenchyma caused by pathogens acquired in hospital settings.[1,2] Nosocomial pneumonia develops in patients admitted to the hospital for more than 48 hours, and the incubation period usually is no longer than 2 days. Among nosocomial pneumonias, ventilator-associated pneumonia (VAP), which is the main focus of this chapter, develops in intensive care unit (ICU) patients who have been mechanically ventilated for at least 48 hours. Recently, an additional subpopulation of patients with severe nosocomial pneumonia who ultimately require mechanical ventilation has been recognized and defined as those who ultimately require invasive mechanical ventilation (VHAP). Of note, causative pathogens and outcomes associated with VHAP more closely resemble VAP than nosocomial pneumonia.[1–4] Ventilator-associated tracheobronchitis (VAT) is characterized by signs of respiratory infection without new radiologic infiltrates.[5] American studies[6] have suggested that patients hospitalized for 2 days or more within the preceding 90 days; residents in a nursing home or extended care facility; or those undergoing home infusion therapy, chronic dialysis, home wound care, or have contact with subjects colonized by multidrug-resistant (MDR) pathogens may be at risk of acquiring healthcare–associated pneumonia (HCAP) caused by MDR microorganisms, similar to pathogens isolated in hospitalized patients or critically ill patients. European data[7] have also found substantial similarities in the etiology of HCAP and community-acquired pneumonia, challenging the definition of HCAP.

Nosocomial pneumonia is a classification based on the presence of microorganisms isolated from respiratory surveillance cultures and includes the following categories[8]:

1. Primary endogenous pneumonia: causative microorganisms are carried in the nasopharynx and upper airways and isolated in cultures taken on admission.
2. Secondary endogenous pneumonia: causative microorganisms are nosocomial pathogens not present on admission but colonize the patient during a hospital stay.
3. Exogenous pneumonia: caused by microorganisms not originally isolated from surveillance cultures; hence the patient is not a previous carrier.

The time of onset for nosocomial pneumonia reflects possible etiologies, empirical antimicrobial treatment, and outcomes. Previously, VAP has been categorized as either early or late onset.[9] In contrast, Trouillet and colleagues[10] demonstrated that three variables were significant for predicting infection with MDR: duration of mechanical ventilation (MV) ≥7 days (odds ratio [OR] = 6.0), prior antibiotic use (OR = 13.5), and prior use of broad-spectrum antimicrobial agents (OR = 4.1). Subsequent studies[11,12] challenged this classification and reported comparable microbial etiologies in patients with early- or late-onset VAP. This similarity may relate to the worldwide rise in MDR and emphasizes that the local ICU ecology is the most important determinant for acquiring MDR pathogens, irrespective of the duration of intubation.

EPIDEMIOLOGY

Incidence and Associated Burden

Nosocomial pneumonia is the second most common nosocomial infection and the leading cause of death from nosocomial infections among critically ill patients. Incidence ranges from 5 to more than 20 cases per 1000 hospital admissions,[1,2] with the highest rates in immunocompromised, surgical, and elderly patients. Approximately one-third of nosocomial pneumonias are acquired in the ICU, with VAP being the majority of these. Epidemiology studies from the United States report a VAP incidence density between 2 and 16 episodes per 1000 ventilator-days. In the last decade, according to the US Centers for Disease Control and Prevention's National Healthcare Safety Network (NHSN),[13] and before the 2019 SARS-CoV-2 pandemic, the incidence of VAP was consistently decreasing, down to 0.9 VAP cases per 1000 ventilator-days in medical ICUs. In surgical ICUs, the reported incidence declined from 5.2 to 2.0. These figures are not in line with international reports,[14] and as suggested by Metersky and colleagues,[15] optimistic percentages reported from NHSN diverge from the Medicare Patient Safety Monitoring System data, which suggest that the rate of VAP remained stable among ventilated patients between 2005 and 2013 (10.8% during 2005 to 2006 versus 9.7% during 2012 to 2013). Cook and colleagues[16] estimated that the risk of VAP is 3% during the first 5 days on MV, 2% from the fifth to the tenth days, and 1% for subsequent days. Nosocomial pneumonia, and particularly VAP, increases both healthcare costs and the duration of hospitalization. Worsened clinical outcomes associated with VAP have been consistently reported.[17,18] As a result, mean hospital charges per VAP patient have been estimated to increase by approximately US$40,000.

VAP in Coronavirus Disease 2019

In 2019 a novel coronavirus, namely SARS-CoV-2, was isolated from patients in China who presented with pneumonia of unknown cause.[19] The viral infection was found to cause a multisystemic condition named *coronavirus disease (COVID-19)*. Patients with COVID-19 are potentially at risk for concomitant pulmonary infections for several reasons.[20,21] First, SARS-CoV-2 causes substantial damage to respiratory ciliated cells, potentially impairing the mucociliary escalator and facilitating bacterial adhesion and colonization. Second, a significant proportion of hospitalized COVID-19 patients require prolonged MV[22,23] and, specifically during the early phase of the pandemic, have

been treated with a broad range of immunosuppressants. To date, there are still uncertainties on the exact risk of acquiring pulmonary infections in patients with COVID-19. In a few early small case series, a higher incidence of VAP in COVID-19 patients was noted,[24,25] but conflicting lower figures have been demonstrated in subsequent reports.[26–29] In addition, the stated impact of VAP on mortality is variable across these studies, and understanding has been limited by the competing high risk of mortality associated with COVID-19 itself, especially during the early phase of the pandemic. In a meta-analysis by Lansbury and collaborators that pooled data from more than 3800 COVID-19 hospitalized patients,[30] 7% had bacterial coinfection. Yet the incidence of bacterial coinfection increased to 14% in ICU patients. The most common bacteria were *Mycoplasma pneumoniae, Pseudomonas aeruginosa,* and *Haemophilus influenzae*. Finally, in an interesting small case study in COVID-19 patients on MV,[31] *Aspergillus* spp. were detected in up to 21.4% of the patients through galactomannan antigens assay in bronchoalveolar lavage (BAL) fluid. At the time this chapter is written, there is an urgent need for further appraisal of the incidence of concomitant pulmonary infections in the COVID-19 ventilated population and accurate assessment of the impact of VAP on major outcomes.

Mortality

One-third to one-half of all VAP-related deaths are the direct result of the infection, with a higher mortality rate in cases caused by *P. aeruginosa* and *Acinetobacter* spp., abetted by inappropriate or delayed antibiotic therapy.[32,33] Several other factors such as severity of illness and multilobar, cavitating, or rapidly progressive lung infection and comorbidities significantly affect mortality risk.[34–37] Attributable VAP mortality has been defined as the percentage of deaths that would not have occurred in the absence of the infection. The impact of VAP on mortality has required in-depth analysis, because many critically ill patients die from their underlying disease rather than VAP.[38–40] In particular, as mentioned earlier, the risk of VAP is time-dependent, possibly causing a significant time-dependent bias, because mortality and ICU discharge act as competing endpoints. Thus comprehensive analyses reported an attributable mortality associated with VAP of 10%,[38,39] with surgical patients and patients with mid-range severity of illness at the highest associated risk. Lisboa and collaborators proposed a useful tool to assess severity and predict mortality associated with VAP.[41] The authors included parameters to assess predisposition, insult, response, and organ dysfunction (PIRO), and they stratified mortality risk into mild, high, or very high. The hazard ratio for mortality in the very high-risk group was 4.63 (95% confidence interval [CI] 2.68–7.99), and the area under the receiver operating characteristic (ROC) curve (AUROC) corroborated mortality discrimination by the VAP PIRO score (AUROC = 0.81; 95% CI 0.77–0.85).

PATHOGENESIS

Extensive laboratory and clinical work has determined the key pathogenic mechanisms of VAP. Pathogens must first gain access to the airways to cause pneumonia, and intubated patients are at high risk for aspiration of colonized oropharyngeal secretions. In healthy, nonintubated patients, colonization by bacteria that gain access to the respiratory tract is prevented by defense mechanisms such as a cough, mucus clearance, and cellular and humoral immune responses. Critically ill and intubated patients are already at a high risk for infection because of underlying illness, comorbidities, malnutrition, and invasive devices or procedures. However, tracheal intubation is the *conditio sine qua non* for the development of VAP, because it facilitates aspiration of pathogens and hinders intrinsic respiratory defenses.

The Role of the Endotracheal Tube in the Pathogenesis of VAP

Pulmonary aspiration of the colonized oropharyngeal secretions across the endotracheal tube (ETT) cuff is the main pathogenic mechanism for the development of VAP. The most commonly used ETT for long-term mechanically ventilated patients comprises a high-volume, low-pressure (HVLP) cuff. HVLP cuffs were originally designed to prevent tracheal injury.[42] However, because the potential diameter of the HVLP cuff is two to three times greater than the tracheal diameter, folds invariably form along the inflated cuff surface, predisposing to aspiration of oropharyngeal secretions.[43]

Pathogens may also grow on the internal surface of the ETT, and these ultimately translocate into the lungs. Bacteria easily adhere to the ETT internal surface to form a structure called a *biofilm*[44] (Fig. 68.1). Biofilm is composed of sessile bacteria embedded within a self-produced exopolysaccharide matrix.[45] Biofilm on the internal surface of an ETT can be identified early after tracheal intubation.[46,47] Sessile bacteria undergo phenotypic differentiation from their planktonic counterparts to enable their survival. Indeed, sessile bacteria are difficult to eradicate by the host's immune response or antibiotics.[48] During MV, biofilm particles may dislodge into the airways as a result of the inspiratory airflow[49] and invasive medical interventions, such as tracheal aspiration.[50] Several studies[46,47,51] have confirmed that the ETT biofilm constitutes a persistent source of colonization.

Sources of Colonization

Patients are colonized exogenously by contaminated respiratory equipment, the ICU environment, and the hands of the ICU staff. Several reports have described ICU outbreaks caused by colonized bronchoscopes,[52,53] water supply,[54] respiratory equipment,[55] humidifiers,[56] ventilator temperature sensors,[57] respiratory nebulizers,[58] and the contaminated ICU environment.[59]

Endogenous colonization is the primary pathogenic mechanism for VAP development. In the critically ill patient, the oral flora shifts early to a predominance of aerobic gram-negative pathogens,[60] *P. aeruginosa*, and methicillin-resistant *Staphylococcus aureus* (MRSA). Pulmonary aspiration of oropharyngeal contents increases the risk for airway colonization and infection. After aspiration and colonization of the airways, the occurrence of VAP primarily depends on the size of the inoculum, functional status of the patient, and competency of host defenses. Controversy remains regarding the exact sequence of colonization and source of infection in the pathogenesis of VAP. Early studies by Feldman and colleagues[61] found that in patients undergoing MV, the oropharynx is the first site to be colonized by pathogens (36 hours), followed by the stomach (36–60 hours), the lower respiratory tract (60–84 hours), and the ETT thereafter (60–96 hours).

Oropharyngeal Colonization

In ICU patients, several oropharyngeal defense mechanisms are dramatically altered. First, comorbidities and inherent patient characteristics, such as alcohol abuse,[62] diabetes,[63] and chronic obstructive pulmonary disease (COPD),[64] are well-known risk factors for gram-negative oropharyngeal colonization. Elderly patients,[65] patients with disabilities,[66] and patients tracheally intubated for extended periods are at increased risk for overgrowth of oropharyngeal pathogens because of their inability to carry out effective oral care. Additionally, the extensive use of antibiotics in critical care settings promotes overgrowth of oropharyngeal pathogens.[67,68] Second, during critical illness, the antimicrobial effectiveness of saliva is highly impaired because of a dramatic reduction in the salivary flow,[69] decreased pH,[70] and increased amount of proteases released by host immune cells and periodontal bacteria.[71,72] Bacteria that colonize the oropharynx also

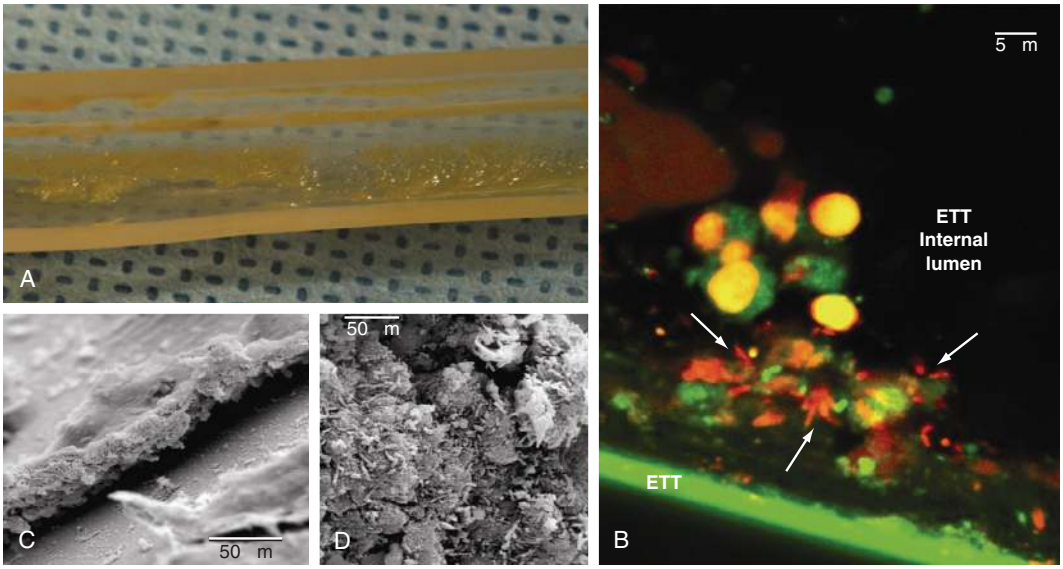

Fig. 68.1 Laboratory Studies to Assess Biofilm Formation on the Internal Surface of the Tracheal Tube After Oropharyngeal Challenge in Pigs of *Pseudomonas Aeruginosa* (Strain PAO1) and 72 Hours of Mechanical Ventilation. **A,** Internal surface of the tracheal tube at extubation, largely covered by respiratory secretions. **B,** Cross section of tracheal tube stained with LIVE/DEAD BacLight bacterial viability kit and imaged with confocal scanning laser microscopy. Bacterial biofilm adheres to internal endotracheal tube (*ETT*) surface. *White arrows* indicate bacteria embedded into biofilm matrix. **C,** Scanning electron microscopy of tracheal tube lumen. Note the presence of amorphous deposits on most of the surface. **D,** Higher magnification of tracheal tube lumen through scanning electron microscopy. *P. aeruginosa* sessile cells are clearly visible within biofilm extracellular polymeric substance.

produce a large variety of hydrolases that lead to increased expression of key receptors for bacterial adhesion.[73,74]

Fourrier and collaborators[75] found that prolonged ICU stay increased the risk for oropharyngeal colonization, which ultimately led to nosocomial pulmonary infection. Azarpazhooh and colleagues[76] found evidence of an association between pneumonia and poor oral health (OR = 1.2–9.6, depending on oral health indicators); improved oral hygiene reduced the occurrence of respiratory infection among high-risk elderly adults. Interestingly, in a study by Heo and colleagues,[77] oral respiratory pathogens were often genetically identical to pathogens recovered from the lower airways, and rapid changes of bacterial species occurred in both oral and pulmonary sites.

Sinuses

The association between sinusitis and VAP has long been debated.[78] Several studies have confirmed that orotracheal as compared with nasotracheal intubation is associated with a decreased incidence of sinusitis[79–81] and that the incidence of VAP is lower in patients who do not develop sinusitis.[82] A study by Holzapfel and colleagues[83] evaluated the incidence of nosocomial maxillary sinusitis and pneumonia in patients who underwent either nasotracheal or orotracheal intubation. The authors found that sinusitis increased the risk of nosocomial pneumonia by a factor of 3.8. Presently, only a small proportion of patients are nasotracheally intubated; hence the incidence of sinusitis in mechanically ventilated patients and associated risks of VAP may now be lessened.

Stomach

According to the gastropulmonary hypothesis of colonization, the stomach of ICU patients is colonized by pathogens because of gastric alkalinization associated with enteral nutrition and drugs for the prevention of gastrointestinal (GI) bleeding.[84] Gastroesophageal reflux facilitates translocation of microbes into the oropharynx, which is then aspirated across the ETT cuff. Early studies have shown that in tracheally intubated patients, gastric pH higher than 4 was consistently associated with gastric colonization.[85,86] However, the association between gastric colonization and VAP reported in very early studies[87,88] has been challenged.[89,90] Overall, this area remains highly controversial, and several studies have not found that bacteria causing VAP first originated in the stomach. Recently, in a large randomized clinical trial,[91] Krag and collaborators randomized 3298 ICU patients to daily pantoprazole versus placebo and found pneumonia rates identical between the groups.

Impairment of Respiratory Defense During Critical Illness and Tracheal Intubation

In healthy subjects, the anatomic laryngeal barrier prevents aspiration of pathogen-laden oropharyngeal contents. After intubation, the ETT completely bypasses these anatomic barriers. A cough is one of the most efficient mechanisms to prevent further translocation of pathogens that may have gained access to airways. Tracheal intubation prevents the closure of the glottis and sudden, high-velocity expulsions. Hence, it hinders cough[92]; moreover, intubated patients are often sedated and unable to generate high expiratory flows.

Mucociliary clearance is the primary innate airway defense mechanism to clear pathogens. In young, healthy nonsmokers, the mucociliary velocity ranges between 10 and 20 mm/min. Studies in animals have shown that inflation of the ETT cuff lowers mucociliary velocity by 50% after only 2 hours.[93] Clinical studies[94] in critically ill patients have found similar reductions of mucociliary velocity (0.8–1.4 mm/min) accompanied by higher risks for pulmonary complications.

As previously mentioned, the daily hazard rate for developing VAP is higher during the first days of MV.[16] Investigators have found that a temporary immunoparalysis can be found early in the course of the

critical illness and sepsis.[95,96] In particular, researchers have assessed human leukocyte antigen-DR (HLA-DR) expression on peripheral monocytes as a marker of immune function.[97] Low levels of HLA-DR expression have been found in patients who subsequently developed nosocomial pneumonia.[98]

Respiratory Dysbiosis and Nosocomial Pneumonia

The diverse and dynamic ecosystem of bacteria within the respiratory system has been highlighted by novel culture-independent technologies.[99] The respiratory system microbiome presents a higher level of complexity than previously thought, and it is continuously challenged by microaspiration of pharyngeal microbiota.[100] These potential invaders are ultimately cleared by effective coughing, mucociliary clearance, and the innate and adaptive host defenses. In recent years, investigators have focused on the dynamics of the respiratory microbiome during critical illness and nosocomial pneumonia and emphasized that the microbial burden, diversity, community composition, and host's response are variably impaired.[101] In particular, there is evidence regarding dysbiosis resulting from substantial changes of the predominant bacterial taxa before and after hospitalization. A progressive depletion of biodiversity toward dominant pathogens progressively increases their biomass, and in the context of altered respiratory immunity could ultimately lead to an infection.[102]

Etiology of Nosocomial Pneumonia

Nosocomial pneumonia may be caused by a variety of pathogens; also, in many patients, more than one pathogen may be isolated. Microorganisms responsible for nosocomial pneumonia differ according to the ICU population, the durations of hospital and ICU stays, and the specific diagnostic method(s) used. VAP is commonly caused by aerobic pathogens, often MDR, including *P. aeruginosa*, *Acinetobacter* species, carbapenemase-containing *Klebsiella pneumoniae*, and MRSA.[1,2] Data from 8135 patients with suspected or proven infections (60% with respiratory tract infection) have confirmed that *Klebsiella* species (27%), *Escherichia coli* (25%), *Pseudomonas* species (24%), and *Acinetobacter* species were the most commonly detected pathogens and *S. aureus* was isolated in 5% of the patients, predominantly in North America.[103]

Esperatti and colleagues[3] prospectively evaluated 315 ICU patients with hospital-acquired pneumonia (HAP) admitted to an ICU; among those, 52% were invasively ventilated, whereas 48% were either breathing spontaneously or receiving noninvasive ventilation (NIV). Interestingly, the proportion of causative pathogens was similar between groups, except for a higher proportion of *Streptococcus pneumoniae* in patients not invasively ventilated. In another report[104] that concerned 200 patients with HAP who were eventually admitted to the ICU and either received or did not receive invasive MV, MDR pathogens were identified in 41% and 39% of the isolates, respectively, emphasizing similar risks of harboring these pathogens between HAP and VHAP when critical care is required. Thus it seems that in ICU-acquired pneumonia, the overall frequency of MDR pathogens and MRSA is sufficiently high to warrant the use of broad empirical therapy.

The high rate of polymicrobial infection in VAP has been shown repeatedly. Combes and colleagues[105] studied 124 ICU patients, of whom 52% had monomicrobial VAP and 48% had polymicrobial VAP. In most patients, two different bacterial species were isolated (34%); however, up to four different bacterial species coexisted in seven patients (6%). Interestingly, no differences were detected in mortality rate at 30 days among patients with polymicrobial or monomicrobial infection. A study by Teixeira and colleagues[106] investigated risk factors for inadequate empirical antimicrobial therapy in 151 ICU patients and found that inadequate antimicrobial treatment was associated with polymicrobial VAP (OR = 3.67; 95% confidence interval [CI] = 1.21–11.12; $P = .02$) and higher mortality.

Underlying diseases may predispose patients to infection with specific organisms. Patients with COPD are at increased risk for *H. influenzae*, *Moraxella catarrhalis*, *P. aeruginosa*, and *S. pneumoniae* infections.[107,108] Patients with acute respiratory distress syndrome (ARDS) are at higher risk for developing VAP caused by *S. aureus*, *P. aeruginosa*, and *Acinetobacter baumannii*, and often in these patients, VAP is caused by multiple pathogens.[109,110] Finally, trauma and neurologic patients are at increased risk for *S. aureus*, *Haemophilus*, and *S. pneumoniae* infections.[111–113]

Causative pathogens of VAP that are potentially multiresistant are *P. aeruginosa*, MRSA, *Acinetobacter* spp., *Stenotrophomonas. maltophilia, Burkholderia cepacia*, and *K. pneumoniae.*[11,103] Conversely, *S. pneumoniae*, *H. influenzae*, methicillin-sensitive *S. aureus* (MSSA), and antibiotic-sensitive Enterobacteriaceae are not considered MDR pathogens. In the majority of cases, resistance to third- and fourth-generation cephalosporins in carbapenem-susceptible strains of *E. coli* and *K. pneumoniae* is caused by the acquisition of plasmidic Ambler class A extended-spectrum beta-lactamases or AmpC-like cephalosporinases.[114] Resistance to carbapenems in Enterobacteriaceae is caused by the acquisition of plasmidic carbapenemases, either of Ambler class A (mainly *K. pneumoniae* carbapenemase), B, or D.[114] Importantly, plasmids harboring extended-spectrum beta-lactamase (ESBL)–encoding and/or carbapenemase-encoding genes often carry other resistance genes, which ultimately confer pan-drug resistance. Conversely, carbapenem resistance in *P. aeruginosa* and *A. baumannii* may be caused by loss of outer membrane porins, hyperexpression of efflux pump systems, and carbapenemase production. In 2010 linezolid-resistant MRSA was reported,[115] caused by a plasmid harboring the chloramphenicol-florfenicol resistance gene.[116–118]

Patients at risk of being colonized by MDR pathogens often present with several comorbidities, and many have received antibiotics during their hospitalization. The incidence of MDR pathogens is also closely linked to local factors and varies widely from one institution to another.[119] Therefore clinicians must be aware of their ICU's local ecology and antibiotic susceptibility so as to avoid the administration of inadequate initial antimicrobial therapy.

Legionella pneumophila as the cause of nosocomial pneumonia should be considered, particularly in immunocompromised patients.[120] Often, the source of legionellosis outbreaks within the hospital is a water system that has become colonized by the microorganism.[121]

A primary mechanism for VAP development is through aspiration of oropharyngeal contents, and the oropharynx is highly colonized by anaerobes. Robert and colleagues[122] studied 26 mechanically ventilated patients and found that 15 patients became colonized with 28 different anaerobic strains. Similarly, Doré and colleagues[123] found anaerobic bacteria in 30 (23%) of 130 patients diagnosed with VAP but always in association with aerobic pathogens. Importantly, empirical antibiotic therapy active against anaerobic bacteria appears to improve short-term outcomes in patients with VAP. The role of anaerobes in VAP has been consistently controversial in the reported literature.[124] Yet more advanced molecular techniques to appraise lung microbiota during acute disease are corroborating the role of anaerobes in the development of VAP.[125]

Rarely, VAP is caused by fungi. *Candida* spp. and *Aspergillus fumigatus*[126] are the most commonly isolated fungi, predominantly in immunocompromised patients. *Candida* promotes the development of pneumonia by creating biofilms that facilitate bacterial colonization.[127] Moreover, *Candida* seems to reduce host immune response.[128] Thus clinical studies have shown that *Candida* colonization increases

the risk of VAP by *P. aeruginosa*.[129] Yet in a postmortem study of patients with evidence of pneumonia at autopsy and isolation of *Candida* from respiratory samples, no case of *Candida* pneumonia was found.[130] Interestingly, colonization by *Candida* has also been associated with longer MV, ICU and hospital stays, and rates of in-hospital mortality.[131–133] Some investigators argue that the presence of *Candida* is merely a marker of severity rather than a true etiologic factor for VAP.[134] The role of *Aspergillus* spp. in the pathogenesis of VAP has been recently reappraised.[31] In an interesting study by Loughlin and collaborators,[135] 24 out of the 194 mechanically ventilated patients (12.4%) met the definition of *Aspergillus* infection, corroborated by positive galactomannan in either BAL fluid or serum. These figures are in line with postmortem findings corroborating invasive pulmonary aspergillosis often clinically undiagnosed antemortem.[136]

Viruses may also cause VAP. Herpes simplex virus type-1 (HSV-1) nosocomial pneumonia is more frequently reported in immunocompromised patients and patients with ARDS,[137] major surgery,[138,139] or extensive burns.[140] Luyt and colleagues demonstrated in 201 patients with clinical suspicion of VAP that 21% had HSV-1 pneumonia.[141] Several studies[142–145] have reported a high incidence of active cytomegalovirus (CMV) infection in mechanically ventilated patients. Chiche and colleagues[144] studied 242 immunocompetent ICU patients and found active CMV infection in 39 (16%) individuals. At 28 days, only 15% of the patients with active CMV infection were weaned and alive, in comparison to 52% of patients free of CMV infection ($P < .001$).

PREVENTION

Nosocomial pneumonia is associated with high rates of morbidity and mortality and constitutes an important burden for the healthcare system. Therefore preventive strategies should be implemented to reduce the overall incidence of the disease (Box 68.1). The Institute for Healthcare Improvement recommends that approaches with proven efficacy in infection control be implemented together as a "bundle" because when combined, they are expected to result in better outcomes than when implemented individually. Designing a preventive bundle is just a first step that must be followed by a continuous assessment of healthcare personnel compliance and by improvements to implement interventions. An interesting report by Klompas and colleagues[146] that appraised the effects of certain components of various bundles found that the association of head-of-bed elevation, sedative infusion interruptions, spontaneous breathing trials, and thromboembolism prophylaxis were the most beneficial elements within bundles. Several reports[147–149] have found consistent reductions in the incidence of VAP after the implementation of VAP preventive bundles.

BOX 68.1 Preventive Strategies for Nosocomial Pneumonia

- Implementation, as a bundle, of nosocomial pneumonia preventive strategies that have proven efficacy in reducing morbidity and mortality
- Implementation of educational programs for caregivers and frequent performance feedbacks and compliance assessment
- Strict alcohol-based hand hygiene
- Avoidance of tracheal intubation and use of NIV when indicated
- Daily sedation vacation and implementation of liberation from mechanical ventilation protocols
- No ventilatory circuit tube changes unless the circuit is soiled or damaged
- Use of tracheal tube with cuff made of novel materials and shapes
- Use of silver-coated tracheal tube
- Application of low-level PEEP during tracheal intubation
- Aspiration of subglottic secretions
- Internal cuff pressure maintained within the recommended range and carefully controlled during transport of patients outside the ICU
- Oral care with chlorhexidine
- Avoid stress ulcer prophylaxis in very low-risk patients for gastrointestinal bleed, and consider use of sucralfate when indicated
- Semirecumbent patient positioning
- Continuous lateral rotation therapy
- Postpyloric feeding in patients who have impaired gastric emptying
- SDD for patients requiring >48 hours of mechanical ventilation

ICU, Intensive care unit; *NIV,* noninvasive ventilation; *PEEP,* positive end-expiratory pressure; *SDD,* selective digestive decontamination.

General Prophylactic Measures

Maintaining high levels of education among ICU personnel relating to VAP pathophysiology and preventive strategies can be effective in reducing its incidence.[150] Needleman and colleagues[151] studied administrative data from 799 hospitals in 11 states (covering 5,075,969 discharges of medical patients and 1,104,659 discharges of surgical patients) and found that a higher proportion of hours of care per day provided by registered nurses, compared with licensed practical nurses and nurses' aides, was associated with lower incidence of pneumonia.

Adherence to simple infection control measures, such as alcohol-based hand disinfection,[152,153] effectively reduces cross-transmission of pathogens and incidence of VAP. The World Health Organization has endorsed hand hygiene as the single most important element of strategies to prevent healthcare–associated infections.[154] Overall, most studies have demonstrated a temporal association between implementation of alcohol-based hand hygiene and reduction of nosocomial infections in ICU environments.[148,155]

Investigators have reported that transporting the patient outside the ICU was associated with increased risk for VAP.[156,157] Clinicians and nursing staff should carefully check the internal pressure of the ETT cuff before and during patient transport. Also, ventilator circuits should be carefully manipulated to prevent the aspiration of colonized fluids from within the circuit.

Daily interruption or lightening of sedation[158–160] and early mobilization,[161] in addition to avoidance of paralytic agents, are highly recommended to avoid impairment of respiratory defenses, prolonged tracheal intubation, and VAP.

There is evidence of shorter length of MV, reduced rates of failed extubation, and decreased incidence of VAP when protocol-driven liberation from the ventilator is implemented.[162,163] Marelich and colleagues[163] randomized 385 patients to receive either a protocol-driven weaning procedure or standard care and found that duration of MV was decreased from a median of 124 hours for the control group to 68 hours in the protocol-driven weaning group ($P = .0001$). Moreover, a trend toward less VAP was found in the treatment group ($P = .061$).

Noninvasive Ventilation

Tracheal intubation and MV are the main risks for nosocomial pneumonia and should therefore be avoided whenever possible. NIV is an attractive alternative for patients with acute exacerbations of COPD or mild to moderate acute hypoxemic respiratory failure and for some immunocompromised patients with pulmonary infiltrates and respiratory failure.[164–168] NIV can also be safely used to facilitate early extubation and curtail extended invasive weaning. A meta-analysis[169] confirmed that noninvasive weaning is associated with reduced mortality, VAP, and length of stay in the ICU and hospital. Other reports[170,171] have emphasized the role of NIV in preventing reintubation of recently extubated patients at risk for relapse and respiratory failure. Kohlenberg et al.[172] pooled data of 400 ICUs in Germany and found a mean

pneumonia incidence of 1.58 and 5.44 cases per 1000 ventilator days for NIV and invasive MV, respectively. Therefore when indicated, NIV should be attempted to avoid tracheal intubation and reduce the overall duration of tracheal intubation.

Tracheal Tube Cuff

In current critical care settings, patients are intubated with ETTs that are sealed by HVLP cuffs. Upon inflation, folds form along the cuff surface, and colonized oropharyngeal secretions may leak through these folds.[173] ETT cuffs made of polyurethane,[174] silicone,[175] and latex[176] have been developed and tested in the laboratory and clinical trials. In particular, the polyurethane cuff has a thickness of 5 to 10 μm, in comparison with 50 μm for polyvinyl chloride (PVC) cuffs. Hence, upon inflation, smaller folds form with polyurethane cuffs, and aspiration of secretions above the cuff can be prevented or reduced. Some investigators have attempted to prevent aspiration by modifying the shape of the cuff.[177] In comparison with standard cuffs with cylindrical shapes, cuffs designed with a smooth, tapering shape allow elimination of folds for a full circumference of the trachea or cuff contact zone, irrespective of the cuff material.

Assessments in medical ICU patients have shown that polyurethane cuffs reduce risks of developing VAP.[178] The polyurethane-cuffed ETT has also been reported to show benefits in reducing early postoperative pneumonia in cardiac surgical patients.[179,180] Results from earlier studies have been contradicted by a landmark multicenter study[181] that compared preventive benefits of cuffs of cylindrical PVC, cylindrical polyurethane, conical PVC, or conical polyurethane and found no reduction of VAP with the use of polyurethane or conical cuffs. Likewise, Monsel and colleagues did not find any advantage in using conical-shaped ETT cuffs.[182] In our opinion, because of the lack of clear clinical evidence regarding the benefits of better-quality cuffs, their use should be only limited to specific patients at very high risk of developing VAP.

It is important to maintain the internal ETT cuff pressure between 25 and 30 cm H_2O to prevent aspiration of contaminated secretions into the lower airways and to avoid tracheal injury. Several studies[183,184] have demonstrated that the ETT cuff is frequently underinflated or hyperinflated using standard management. Continuous control of internal cuff pressure reduces risks of significant deflation and pulmonary aspiration.

Ventilatory settings may play a role in the pathogenesis of VAP. In particular, positive end-expiratory pressure (PEEP) may decrease the incidence of VAP by counteracting hydrostatic pressure exerted by oropharyngeal secretions above the ETT cuff, hence reducing pulmonary aspiration.[185,186] Lucangelo and colleagues[187] assessed the effects of 5–8 cm H_2O PEEP in normoxemic ventilated patients and showed a reduction in the rate of VAP. Thus in the absence of major contraindications, a low level of PEEP should be maintained.

Tracheal Tubes Coated With Antimicrobial Agents

Coating the ETT with antimicrobial agents, such as silver, is a promising strategy to prevent biofilm formation on its internal surface and VAP.[44] Olson and colleagues[188] tested a silver-coated ETT in dogs challenged with *P. aeruginosa* instilled into the oropharynx. Using the new tube, the investigators were able to postpone colonization of the ETT's inner surface and reduce pulmonary bacterial burden. Similarly, Berra and colleagues[189] studied a silver sulfadiazine/chlorhexidine–coated ETT in sheep. After 24 hours of MV, standard ETTs and ventilatory circuits were heavily colonized, whereas the novel coated ETT fully avoided colonization. Interestingly, the efficacy of silver-based coatings seems to decrease over time. Indeed, animal studies reported heavy colonization of silver-coated ETTs after 72 hours of MV. To date, only one laboratory study[190] has shown the absence of ETT biofilm formation up to 168 hours of MV when silver sulfadiazine ETTs were regularly cleaned with the Mucus Shaver.[191] The North American Silver-Coated Endotracheal Tube (NASCENT) randomized trial[192] compared the preventive effects of a silver-coated vs. conventional ETT. The silver-coated ETT was associated with a lower incidence of microbiologically confirmed VAP (4.8% vs. 7.5%; $P = .03$), for a relative risk reduction of 35.9%. A retrospective cohort analysis by Afessa and colleagues[193] showed that the silver-coated ETT was associated with reduced mortality in patients with VAP (14% vs. 36% in silver and control ETT, respectively, $P = .03$). Mortality was higher in those without VAP. In conclusion, ETT coated with antimicrobial agents could reduce the incidence of VAP, but the evidence supporting its use comes only from one study, with significant limitations.[194] Thus clinicians should carefully consider benefits and limitations of these ETTs and properly direct the use of silver-coated tubes to patients expected to be ventilated for longer periods and with higher risks for nosocomial pneumonia. Shorr and colleagues[195] analyzed the cost-effectiveness of the silver-coated ETT and found that per each prevented VAP, US$12,840 was saved.

Aspiration of Subglottic Secretions

Aspiration of colonized subglottic secretions through dedicated ETTs potentially prevents leakage across the cuff. A meta-analysis[196] has shown that drainage of subglottic secretions reduced the overall risk ratio (RR) for VAP by half (RR = 0.55; 95% CI = 0.46–0.66; $P < .01$). In a multicenter trial by Lacherade and colleagues,[197] 333 patients were randomized to be intubated with either an ETT that allowed drainage of subglottic secretions or a standard ETT. Microbiologically confirmed VAP occurred in 14.8% of the patients in the treatment group, compared with 25.6% of the patients intubated with a standard tube ($P = .02$). Interestingly, subglottic secretion drainage has been consistently associated with tracheal injury in clinical[198,199] and laboratory studies.[43,200]

Tracheostomy

Tracheostomized patients present the same risks for aspiration of pathogen-laden secretions pooled above the cuff as orotracheally intubated patients. A meta-analysis[201] that assessed outcomes of early versus late tracheostomy found that early tracheostomy did not reduce the incidence of VAP. Early tracheostomy may improve patient comfort, ability to communicate, and capability for oral feeding reduce the need for sedation and analgesia and airway resistance in comparison with standard ETTs. These factors are of paramount importance during the weaning period to shorten the duration of tracheal intubation.

Ventilator Circuit Management

Clinical trials in adults[202–204] and meta-analyses[205] have demonstrated that a routine change of the ventilator circuit does not decrease risks for VAP or costs. Therefore circuits should not be changed unless soiled or damaged. Importantly, inadvertent flushing of the contaminated condensate into the lower airways (or by nebulizers) should always be avoided by careful emptying of ventilator circuits and water traps.[206]

A meta-analysis[207] that assessed the effects of heated humidifiers (HHs) and heat and moisture exchangers (HMEs) on prevention of nosocomial pneumonia showed no differential effect on pneumonia prevention. To date, neither humidification strategy can be recommended as a pneumonia prevention tool. However, it is rational to deliver inspiratory gases at body temperature or slightly below and at the highest relative humidity to prevent loss of heat and moisture from the airways, adverse change in rheologic properties of secretions, and

impairment of mucociliary clearance. The use of HH is selectively indicated in patients with hypothermia, prolonged MV, thick secretions, and chronic respiratory disorders. Finally, studies[208–210] testing less frequent changes of HMEs have not found increased risks for VAP. HMEs should be changed periodically (i.e., every 72 hours or when overtly contaminated) to ensure good performance.

Closed tracheal suctioning systems have been introduced in clinical settings to avoid adverse events associated with ventilator disconnection during open tracheal suctioning in addition to exogenous contamination by suction catheters entering the ETT. Various meta-analyses[211–213] have compared the closed and the open tracheal suction system in mechanically ventilated patients and found no advantage of either for VAP prevention.

The use of a saline solution instilled into the ETT before tracheal suctioning remains controversial. A systematic review[214] reported decreased patient oxygenation in most studies. One study[215] found a lower incidence of microbiologically proven VAP (saline instillation versus no treatment: 23.5% vs. 10.8%; $P = .008$). Likewise, a later study found that when closed tracheal suction systems with HMEs were used, saline instillation was advantageous in reducing the incidence of VAP.[216] Importantly, in sedated patients in the semirecumbent position and with the ETT internal surface highly colonized, saline instillation may increase risks for translocation of pathogens into the airways.

Body Position

Early studies demonstrated that intubated patients are at higher risk for gastropulmonary aspiration when placed in the supine position (0 degrees) as compared with a semirecumbent position (45 degrees).[84,217,218] One randomized trial[219] demonstrated a reduction in the incidence of VAP in patients positioned in the semirecumbent position as opposed to completely supine, particularly during enteral feeding. A later randomized trial[220] found limited feasibility of the intervention and no differences in VAP incidence. Given available evidence,[221] intubated patients should be preferentially kept in the semirecumbent position (30–45 degrees) rather than supine (0 degrees), especially when receiving enteral feeding.

Laboratory reports[222,223] have challenged the preventive benefits of the semirecumbent position. Theoretically, a tracheal orientation above horizontal might facilitate aspiration across the ETT cuff. The Gravity-VAP study was a randomized trial that studied 194 endotracheally intubated patients positioned in the lateral-Trendelenburg position (LTP) in comparison with 201 in the standard semirecumbent position. The authors found that the LTP could further reduce VAP, specifically in patients with healthy lungs upon intubation, but LTP feasibility appeared challenging.[224]

Rotating Bed

Several ICU beds permit the rotation of patients along the longitudinal axis from one lateral position to the other. These appear to reduce extravascular lung water, improve the ventilation-perfusion ratio, and enhance mobilization of airway secretions. Meta-analyses[225,226] have shown a significant reduction in the incidence of VAP among patients undergoing rotation therapy. Staudinger and colleagues[227] studied the effects of continuous lateral rotation therapy and found a VAP incidence of 11% in the rotation group and 23% in the control group ($P = .048$). Those authors also found that the duration of ventilation (8 ± 5 vs. 14 ± 23 days; $P = .02$) and length of stay (25 ± 22 days vs. 39 ± 45 days; $P = .01$) were significantly shorter in the rotational group. In conclusion, in patients at higher risk for prolonged immobilization and respiratory infection, continuous lateral rotation therapy may add to other preventive measures for VAP.

Stress Ulcer Prophylaxis and Enteral Feeding

Sucralfate, histamine type 2 blockers (H_2 blockers), and proton pump inhibitors (PPIs) are the most common medication for stress ulcer prophylaxis. Of these, sucralfate is the only treatment that does not cause gastric alkalinization. Early studies found a higher incidence of pneumonia in patients with alkalinized gastric contents,[87,88] whereas others have not.[90] Cook and colleagues[228] found a higher risk of GI bleeding using sucralfate and no significant difference in VAP incidence: 19.1% and 16.2% in patients treated with H_2 blockers or sucralfate, respectively. Likewise, in a meta-analysis,[229] PPIs were more effective than H_2 blockers at reducing upper GI bleeding, without differences in VAP (RR = 1.06; 95% CI = 0.73–1.52; $P = .76$). Krag and colleagues[91] recently studied 3298 ICU patients who were randomized to receive either pantoprazole or placebo. At 90 days, the RR of mortality was 1.02; 95% CI 0.91–1.13; $P = .76$ and no difference was found in the development of respiratory infections between groups. In conclusion, GI bleeding is a serious complication in critically ill patients. The actual risk for VAP is unknown when appropriate methods of enteral feeding (i.e., avoiding large gastric residual volumes) or other preventive measures are used in combination with stress ulcer prophylaxis. Therefore clinicians should probably limit stress ulcer prophylaxis to high-risk patients and weigh the potential benefit of sucralfate (with potentially less VAP and more GI bleeding) versus H_2 blockers/PPIs (with potentially more VAP and less GI bleeding).

Enteral nutrition has been considered a risk factor for the development of VAP because of increased incidence of gastric alkalinization, gastroesophageal reflux, and gastropulmonary aspiration. However, its alternative, parenteral nutrition, is associated with higher risks for catheter-related infections, complications of line insertions, higher costs, and loss of intestinal villous architecture, which may facilitate enteral microbial translocation. A large meta-analysis[230] of 11 studies comprising more than 500 critically ill patients found that the use of parenteral nutrition was associated with more infectious complications, compared with early enteral nutrition (OR = 1.47; 95% CI = 0.90–2.38; $P = .12$). Conversely, studies in medical ICU patients have demonstrated a higher risk for VAP with early enteral feeding.[231,232] Therefore in medical ICU patients, the benefits of early nutrition should be balanced with associated increased risks for VAP.

Many ICU patients experience impaired gastric emptying. Placement of the feeding tube beyond the pylorus has the potential to achieve nutrition goals without increased risks for gastropulmonary aspiration. A meta-analysis by Jiyong and colleagues[233] found that small bowel feedings were associated with a lower incidence of pneumonia (RR = 0.63; 95% CI = 0.48–0.83; $P = .001$). In an interesting report by Davies and collaborators,[234] in mechanically ventilated patients with mildly elevated gastric residual volumes who were already receiving nasogastric nutrition, early postpyloric nutrition did not increase energy delivery or reduce the frequency of pneumonia. Therefore postpyloric feeding should be preferred only when impaired gastric emptying is present. Finally, a landmark study[235] challenged the utility of routine monitoring of residual gastric volume in 449 patients receiving invasive MV and early enteral nutrition. VAP occurred in 16.7% of the patients without routine monitoring, in comparison with 15.8% in the control group.

Modulation of Oropharyngeal and Gastrointestinal Colonization

Given the pivotal role of oropharyngeal colonization in the development of VAP, many decontamination strategies have been developed, which include caregiver handwashing, oral hygiene and tooth brushing,[236] selective oral decontamination with topical nonabsorbable antibiotics,[237] and oropharyngeal rinsing with antiseptics.[238] Chlorhexidine

is a cationic chlorophenyl *bis*-biguanide antiseptic that has long been used as an inhibitor of dental plaque formation and gingivitis. A meta-analysis[238] of studies assessing the benefits of chlorhexidine on the reduction of VAP reported fewer lower respiratory tract infections in cardiac surgery patients (RR = 0.56; 95% CI = 0.41–0.77) but without a significant mortality difference (RR = 0.88; 95% CI = 0.25–2.14). Results in noncardiac ICU populations have been inconsistent. Most of the studies described in earlier years used chlorhexidine concentrations up to 0.2%. This concentration may not be effective in most ICU patients with high levels of oropharyngeal colonization. Studies[239,240] have demonstrated significant reductions in VAP rates when chlorhexidine concentration was increased to 2%. Importantly, in recent years, arguments have been raised against the use of chlorhexidine because of associated increased mortality risk.[241] These findings could be misleading or imply that extensive pulmonary aspiration of chlorhexidine might occur in patients in the semirecumbent position. Additional data are needed to resolve this issue.

Selective digestive decontamination (SDD) comprises a combination of nonabsorbable antibiotics against gram-negative pathogens (i.e., tobramycin and polymyxin E) plus either amphotericin B or nystatin. These agents are administered into the GI tract to prevent oropharyngeal and gastric colonization with aerobic gram-negative bacilli and *Candida* spp. while preserving the anaerobic flora. Some regimens include a short course of systemic antibiotics (i.e., cefotaxime). SDD was originally applied to oncologic and hematologic patients with severe immunosuppression.[242,243] In the early 1980s Stoutenbeek and colleagues introduced this practice into critical care medicine.[244] Since then, a remarkable number of clinical trials and meta-analyses confirmed the benefits associated with the use of SDD, which has been associated with reduced incidence of VAP, bacterial bloodstream infections, and mortality.[245] Currently, SDD is primarily applied in a minority of European centers with low levels of MDR.

Randomized clinical trials[237,246,247] and meta-analyses[245] confirmed that SDD confers protection against nosocomial pneumonia. Several factors, however, should be taken into account before advocating its use worldwide. First, investigations on the intestinal microbiota highlight the variability, interactions, and complexity of GI bacterial colonies and systemic consequences of changes in gut colonization.[248–250] Indeed, it is known that more than 10^{11} bacteria per gram of feces, comprising more than 1000 different species, are present in our intestinal system.[251] Large interindividual variations in bacterial patterns are evident even among humans living in the same geographic region.[252] Considering the increasing interest of the critical care field on individualized medicine, the implementation of a unit-wide single SDD regimen for all ICU population subtypes seems unwise. In addition, even the selectivity of SDD against aerobic gram-negative bacteria has been challenged.[253] Thus the impact of SDD on the intestinal microbiota and the resulting alterations of bacterial diversity need further evaluation. Second, one of the most recurrent arguments for not using SDD is that microorganisms not addressed by the regimen may be selected (i.e., MRSA and *Enterococcus* spp.) or MDR for the applied antibiotics may increase. An increase in anaerobic flora antibiotic resistance genes during SDD, particularly highly transferable genes conferring resistance to aminoglycosides, has been corroborated.[248] In line with these results, Oostdijk and collaborators[246] found increases in aminoglycoside-resistant gram-negative bacteria during SDD use. Finally, in one older study[254] by the same group that explored recolonization after SDD, increased intestinal colonization occurred with gram-negative bacteria resistant to ceftazidime, tobramycin, or ciprofloxacin. Likewise, resistance to ceftazidime increased gradually in the respiratory tract during SDD and even further postintervention for all three antibiotics used in the SDD regimen. This suggests that there are still several unknown effects of SDD that need to be addressed. Of note, in a recent study[255] the effects of SDD/SOD (selective oropharyngeal contamination) on bloodstream infections was conducted in ICUs with high prevalence of antibiotic resistance. Mortality rate was not affected by the interventions, and antibiotic resistance did not vary throughout the study periods. Only one study[256] has demonstrated that a short course of cefuroxime in patients with structural coma or severe burns was an effective prophylactic strategy to decrease the VAP rate. However, routine use of parenteral antibiotics is not recommended until more data become available.

Several clinical trials have attempted to modify GI and oropharyngeal growth of pathogens through the use of probiotics. Probiotics are innocuous microorganisms that can be administered either as individual strains or in various combinations. These microorganisms are often administered with nondigestible food ingredients that facilitate bacterial growth and activity (prebiotics). Products containing both probiotics and prebiotics are called *synbiotics*. A meta-analysis[257] on the effects of probiotics suggests that probiotics may reduce the incidence of VAP. The low quality of the evidence does not enable one to draw firm conclusions regarding utility.

DIAGNOSIS

How best to establish the diagnosis of VAP remains controversial.[258–261] Clinical signs suggestive of pneumonia, such as fever, tachycardia, and leukocytosis, are nonspecific in critically ill patients.[262,263] Moreover, the chest radiograph is often difficult to interpret, and it may not reveal subtle lung infiltrates, which are better detected by computed tomography (CT) scans.[264] When infiltrates are evident, the differential diagnosis is challenging (i.e., cardiogenic and noncardiogenic pulmonary edema, pulmonary contusion, and atelectasis).

Few studies have examined the accuracy of portable chest radiographs for making the diagnosis of VAP.[265,266] In mechanically ventilated patients with autopsy-proven VAP, no single radiographic sign had a diagnostic accuracy greater than 68%.[267] In patients with ARDS, marked heterogeneity of radiographic abnormalities has been reported. A clinical study showed the presence of lung infection in only 42% of the patients with clinically suspected VAP.[268] The presence of air bronchograms may increase the specificity of chest radiographs in ARDS patients.

The Clinical Pulmonary Infection Score (CPIS) is based on six clinical assessments.[269] The CPIS showed a good correlation ($r = 0.84$; $P < .0001$) with quantitative bacteriology of BAL samples. Moreover, a value ≥6 was the threshold to accurately identify patients with pneumonia. In recent years the value of CPIS in the diagnosis of VAP has been reconsidered,[104] and it should be emphasized that the score remains to be validated in a large prospective study, especially in patients with bilateral pulmonary infiltrates. Several diagnostic biomarkers have also been investigated to improve diagnostic accuracy. In 2016 results of the BioVAP study, a multicenter study that investigated the kinetics of biomarkers to predict VAP, were published.[270] The authors found that C-reactive protein (CRP) and CRP slopes over time presented moderate diagnostic accuracy, whereas procalcitonin, pro-adrenomedullin, and soluble urokinase plasminogen receptor (SUPAR)[271] performed poorly. Finally, in the recent VAPrapid2 multicenter, randomized controlled trial (RCT),[272] 214 patients were randomized to biomarker-guided recommendations on antibiotics, quantifying interleukin (IL)-1-beta and IL-8 in BAL fluid, or routine use of antibiotics. The authors did not find any difference in antibiotic-free days in the 7 days after BAL.

The presence of bacteria in the lower airways of intubated patients is not sufficient to diagnose VAP, because it could be only nonpathogenic colonization or VAT. In one study, cultures of endotracheal

aspirate from patients with respiratory failure and histologically documented pneumonia simultaneously obtained from the trachea and lung tissue agreed in only 40% of cases, with a 82% sensitivity and 27% specificity.[273] Similarly, in another study, only 23% of colonized patients subsequently developed VAP.[60] The use of Gram staining for the diagnosis of VAP has also been debated. In a meta-analysis pooling data from 21 studies,[274] sensitivity and specificity of Gram staining were only 79% and 75%, respectively, with a positive predictive value of 40%. Yet the diagnostic accuracy seems higher when narrowed to the diagnosis of VAP caused by *S. aureus*. In a recent meta-analysis[275] pooling data from 1665 respiratory samples, overall sensitivity and specificity were 68% and 95%, respectively. However, in clinical scenarios with *S. aureus* prevalence between 5% and 20%, a negative predictive value of 95% was found.

Many sampling procedures of respiratory secretions, such as sputum collection, endotracheal aspirates, BAL, and protected specimen brush (PSB), are available. In addition, there are several microbiologic techniques, including Gram staining and intracellular organism count, for specimens obtained via BAL. Each diagnostic technique has advantages and limitations and provides different diagnostic specificity and sensitivity.

Qualitative cultures of endotracheal aspirates have a high percentage of false-positive results. Conversely, quantitative culture techniques are more reliable if appropriate cutoff criteria are applied. When patients develop pneumonia, pathogens are present in the lower respiratory tract secretions at concentrations of at least 10^5 to 10^6 colony-forming units (CFU)/mL.[276–279] The current diagnostic threshold proposed for tracheal aspirates is 10^6 CFU/mL. Similarly, PSB collects between 0.001 and 0.01 mL of secretions. Therefore the presence of more than 10^3 bacteria in the originally diluted sample (1 mL) represents 10^5 to 10^6 CFU/mL in pulmonary secretions. Finally, 10^4 CFU/mL is considered the cutoff for BAL, which collects 1 mL of secretions in 10–100 mL of effluent.

In one study,[279] only 40% of the microorganisms cultured in endotracheal aspirate samples coincided with those obtained from PSB specimens. Also, when quantitative cultures of different lower respiratory tract specimens were compared with postmortem quantitative lung biopsy cultures, all techniques for detecting VAP were of limited value.[280]

A major problem in the management of patients with suspicion of VAP is the concurrent use of antibiotics. The indiscriminate administration of antimicrobial agents for patients in the ICU may contribute to the emergence of MDR pathogens and raise the risk of superinfections with increased morbidity and mortality and expose the patient to antibiotic-related adverse effects and higher costs.[281] On the other hand, correct and prompt treatment of pneumonia results in better patient survival.[33,282,283] Inadequate empirical antibiotic treatment, initiated before obtaining the results of cultures from respiratory secretions, was associated with greater hospital mortality compared with antibiotic regimens that provided adequate antimicrobial coverage based on microbiologic culture results.[284–287] However, the choice of initial antibiotic treatment is often difficult because of previous antibiotic treatment,[288] prevalence of MDR pathogens, and colonizing pathogens.[289,290]

Several rapid molecular techniques (i.e., polymerase chain reaction [PCR]) have been developed to expedite identification of causative pathogens of nosocomial pneumonia through microbial DNA, helping to guide prompt administration of appropriate antibiotic therapy.[291] The available assays are either pathogen specific (i.e., to identify MRSA)[292] or are aimed to identify, through multiplex PCR assays, a broad spectrum of pathogens that cause nosocomial pneumonia.[293–295] Further studies and clinical validation are needed to help identify for the clinician when and how PCR can be used. In a remarkable study by Paonessa and colleagues,[274] the impact of a novel rapid diagnostic MRSA testing was compared with usual care in a small population of 45 patients. Duration of anti-MRSA antibiotics was reduced using the rapid test, and although the study was underpowered, hospital mortality was 13.6% in the intervention group and 39.1% for usual care (95% CI of difference, −3.3 to 50.3, $P = .06$). Additionally, efforts have been made to detect rapidly the most important MDR genes, such as *mecA, blaKPC, blaIMP, blaVIM,* and *blaOXA*.[296] Finally, a Spanish study tested a rapid E-test antibiogram for six antibiotic agents that could provide antibiotic susceptibility within 24 hours and found that the use of this technique resulted in more appropriate and reduced use of antibiotics in VAP patients.[297]

Ventilator-Associated Events Surveillance Algorithm

The Centers for Disease Control introduced the ventilator-associated events (VAEs) surveillance definition algorithm[298] to monitor complications in mechanically ventilated patients (Fig. 68.2). This new algorithm was developed to monitor objectively pulmonary complications associated with worse outcomes in mechanically ventilated patients. Importantly, reports had demonstrated poor concordance between infection-related ventilator-associated condition (IVAC), possible and probable VAP, and VAP diagnosed with standard criteria.[299,300] In a study by Bouadma and collaborators,[301] sensitivity and specificity of diagnosing VAP were 0.92 and 0.28 for the ventilator-associated condition and 0.67 and 0.75 for IVAC, respectively. Boyer and colleagues[302] studied 1209 patients ventilated for ≥2 calendar days with 5.5% VAE. The most common causes of VACs included IVACs (50.7%), ARDS (16.4%), pulmonary edema (14.9%), and atelectasis (9.0%). The sensitivity of the VAE algorithm for the detection of VAP was only 25.9% (95% CI = 16.7%–34.5%). Thus the VAE algorithm should be considered a powerful benchmarking tool that has only marginal value for the diagnosis of VAP.

Diagnostic Strategies for Hospital-Acquired Pneumonia

Recommendations regarding diagnostic strategies to be applied in patients with clinical suspicion of VAP diverge between the most recent American[1] and European guidelines.[2] In particular, based on the results of a large meta-analysis on diagnostic techniques,[303] the latest American guidelines recommend (weak recommendations with low-quality evidence) noninvasive sampling with semiquantitative cultures. The European guidelines, by contrast, recommend distal quantitative sampling (i.e., BAL) before antibiotic use. The intent of that approach is to reduce overall use of antibiotics, because several previous studies in this field were limited by the lack of antimicrobial de-escalation upon obtaining positive or negative culture results.

An ideal diagnostic strategy for patients with clinical suspicion of HAP should reach the following objectives:

1. Accurately identify patients with true pulmonary infection and isolate the causative microorganisms to initiate appropriate antimicrobial coverage and subsequently to optimize therapy based on the susceptibility of the pathogens.
2. Identify patients with extrapulmonary sites of infection.
3. Withhold and/or withdraw antibiotics in patients without infection.

The diagnosis of nosocomial pneumonia begins with clinical suspicion. The presence of new or progressive radiographic infiltrates plus at least two of three clinical criteria (fever/hypothermia, leukocytosis/leukopenia, and purulent secretions) represents the starting point to begin diagnostic procedures.

Based on our clinical expertise and recognizing potential heterogeneity in worldwide practice in this field, two diagnostic algorithms could be used when there is clinical suspicion of nosocomial pneumonia. The

Patient has a baseline period of stability or improvement on the ventilator, defined by ≥ 2 calendar days of stable or decreasing daily minimum FiO_2 or PEEP values. The baseline period is defined as the 2 calendar days immediately preceding the first day of increased daily minimum PEEP or FiO_2

↓

After a period of stability or improvement on the ventilator, the patient has at least one of the following indicators of worsening oxygenation: 1) Minimum daily FiO_2 values increase > 20 over the daily minimum FIO_2 in the preceeding 2 calendar days (the baseline period) for ≥ 2 calendar days

↓

Ventilator-Associated Conditions (VAC)

On or after calendar day 3 of mechanical ventilation and within 2 calendar days before or after the onset of worsening oxygenation, the patient meets both of the following criteria:

1) Temperature ≥ 38°C or ≤ 36°C or white blood cell count ≥ 12,000 cells/mm³ or ≤ 4000 cells/mm³

AND

2) A new antimicrobial agent(s) is started and is continued for ≥ 4 days

↓

Infection-Related Ventilator-Associated Complication (IVAC)

On or after calendar day 3 of mechanical ventilation and within 2 calendar days before or after the onset of worsening oxygenation, ONE of the following criteria is met:

1) Purulent respiratory secretions (from one or more specimen collections), defined as secretions from the lungs, bronchi, or trachea that contain ≥ 25 neutrophils and < 10 squamous epithelial cells per low power field [lpf x 100] (or corresponding semi-quantitative results)
2) Positive culture (qualitative, semi-quantitative or quantitative) of sputum, endotracheal aspirate, bronchoalveolar lavage, lung tissue, or protected specimen brushing

Exclude: Normal respiratory/oral flora, mixed respiratory/oral flora or equivalent; *Candida* species or yeast not otherwise specified; Coagulase-negative *Staphylococcus* species; *Enterococcus* species

↓

Possible VAP

On or after calendar day 3 of mechanical ventilation and within 2 calendar days before or after the onset of worsening oxygenation, ONE of the following criteria is met:

1) Purulent respiratory secretions (from one or more specimen collections – and defined as for possible VAP)

AND one of the following:

- Positive quantitative culture of endotracheal aspirate ≥ 10^5 cfu/mL or equivalent semiquantitative and follow result
- Positive quantitative culture of BAL ≥ 10^4 cfu/mL or equivalent semi-quantitative result
- Positive quantitative culture of lung tissue ≥ 10^4 cfu/gr mL or equivalent semi-quantitative result
- Positive quantitative culture of PSB ≥ 10^3 cfu/mL or equivalent semi-quantitative results

Same organism exclusions as noted for possible VAP

2) One of the following (without requirements for purulent respiratory secretions):

- Positive pleural fluid culture (where specimen was obtained during thoracentesis or initial placement of chest tube and NOT from an indwelling chest tube)
- Positive lung histopathology
- Positive diagnostic test for *Legionella* spp.
- Positive diagnostic tests on respiratory secretions for influenza virus, respiratory syncytial virus, adenovirus, parainfluenza virus, rhinovirus, human metapneumovirus, coronavirus

↓

Probable VAP

Fig. 68.2 Ventilator-Associated Events Surveillance Protocol. *BAL*, Bronchoalveolar lavage; *CFU*, colony-forming unit; *FiO_2*, fraction of inspired oxygen; *PEEP*, positive end-expiratory pressure; *VAP*, ventilator-associated pneumonia. (Full surveillance protocol available at http://www.cdc.gov/nhsn/acute-care-hospital/vae/index.html for eligible antimicrobials.)

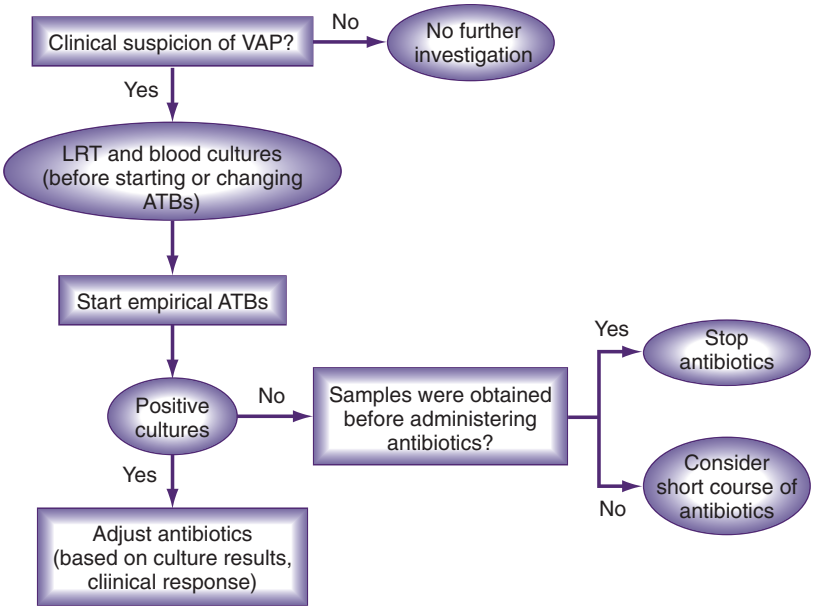

Fig. 68.3 Clinical Noninvasive Strategy for Diagnosis and Management of VAP. *ATBs,* Antibiotics; *LRT,* lower respiratory tract; *VAP,* ventilator-associated pneumonia. (Adapted from American Thoracic Society. Guidelines for the management of adults with hospital-acquired, ventilator-associated, and healthcare-associated pneumonia. *Am J Respir Crit Care Med.* 2005;171:388–416.)

clinical approach recommends treating every patient suspected of having a pulmonary infection with new antibiotics even when the likelihood of infection is low (Fig. 68.3). However, samples of respiratory secretions (e.g., endotracheal aspirate or sputum) should be obtained before the initiation of antibiotic treatment. In this strategy, the selection of appropriate empirical therapy is based on risk factors and local resistance patterns. The etiology of pneumonia is defined by semiquantitative cultures of endotracheal aspirates or sputum, with an initial microscopic examination of the Gram stain. Antimicrobial therapy is adjusted according to culture results or clinical response. The semiquantitative culture of tracheal aspirates has the advantage that no specialized microbiologic techniques are required, and the sensitivity is high. This clinical strategy provides antimicrobial treatment to the majority of the patients with suspicion of HAP and yields a low rate of false negatives. If the tracheal aspirate culture does not demonstrate pathogens and the patient has not received new antibiotics within the previous 72 hours, the diagnosis of pneumonia is unlikely.[304] This strategy is useful in centers where bronchoscopic methods are not always available. The main drawback of this strategy is that the high sensitivity of semiquantitative cultures of tracheal aspirates leads to an overestimation of the incidence of HAP and overuse of antibiotics.

Bacteriologic strategies are based on the results of quantitative cultures of lower respiratory secretions (Fig. 68.4). The procedure used to collect the samples (endotracheal aspirate, BAL, or PSB) may be invasive (bronchoscopic) or noninvasive (blind procedures). The bacteriologic strategy attempts to identify accurately patients with true HAP so that only infected patients are treated and clinical outcomes are improved.[286,305] Such an approach reduces the risks for overuse of antibiotics, because quantitative cultures yield fewer microorganisms above the threshold in comparison to semiquantitative cultures. Among the disadvantages of the bacteriologic strategy is the possibility of obtaining false-negative results that lead to delayed antibiotic treatment in a patient with pneumonia. Moreover, results using the bacteriologic strategy may lack reproducibility, and often no microbiologic information is available at the time that empirical antibiotic therapy is initiated.

Four RCTs[286,306–308] have assessed the impact of diagnostic strategies on antibiotic use and outcome in patients with clinically suspected VAP. In three small studies,[286,306,307] invasive diagnostic techniques resulted in a greater number of antibiotic changes than noninvasive techniques; however, no differences in mortality and morbidity were found when either invasive (PSB and/or BAL) or noninvasive (quantitative endotracheal aspirate cultures) techniques were used. In contrast, a larger trial[308] showed a reduction in mortality, reduced use of antibiotics, and increased number of antibiotic-free days using invasive diagnostic techniques. This study was limited, however, by the use of qualitative cultures of tracheal aspirates, thereby limiting comparison with other clinical trials. Irrespective of the methods used to obtain respiratory samples, it is strongly recommended that samples be obtained before starting new antibiotics, or a lower sampling threshold should be used in patients with recent antibiotic changes.[309,310]

In a noteworthy trial,[311] quantitative culture of BAL fluid and culture of endotracheal aspirate were compared in critically ill patients with suspected VAP. This study was part of a larger 2-by-2 factorial design also comparing empirical antimicrobial monotherapy (a carbapenem) and combination therapy (a carbapenem plus a fluoroquinolone). A total of 740 patients in 28 ICUs throughout Canada and the United States were enrolled. The authors found no difference in the 28-day mortality rate between the BAL group and the endotracheal aspiration group (18.9% and 18.4%, respectively; $P = .94$). The BAL group and the endotracheal aspiration group also had similar rates of targeted therapy and days alive without antibiotics. At least 40% of the screened patients were excluded because they were at risk for colonization with *Pseudomonas* spp. or MRSA or were immunosuppressed. Therefore translation of these findings into clinical practice is challenging because many ICU patients evaluated for suspected VAP fall into these latter categories. In a key meta-analysis,[303] no differences in mortality rates were uncovered for using quantitative cultures versus qualitative cultures (RR = 0.91; 95% CI = 0.75–1.11), nor were differences found regarding the number of days on MV, the length of ICU stay, or antibiotic changes. Likewise, there was no effect of invasive versus noninvasive diagnostic methods. Yet results from many included studies were limited by inadequate de-escalation upon obtaining culture results.

Practical Implementation of a Diagnostic Strategy in Suspected VAP or VHAP

In clinical practice, the development of local guidelines can combine both clinical and bacteriologic strategies (Box 68.2). The diagnostic protocol begins with clinical suspicion of a nosocomial respiratory infection (Fig. 68.5). In mechanically ventilated patients, the presence of an infiltrate on chest radiograph differentiates between the possible presence of pneumonia and tracheobronchitis. The next step is to sample the lower respiratory tract (Table 68.1) to identify the causative microorganism. Respiratory tract specimens can be obtained by expectoration, bronchial aspirate, BAL, or PSB. The latter two techniques can be performed with bronchoscopy or blindly through a protected telescoping. Several other samples should also be collected, as noted in Box 68.2.

TREATMENT

Once the clinical decision to initiate antimicrobial therapy has been made, the following issues should be considered to achieve the best antimicrobial efficacy and reduce overuse of antibiotics:

- The most likely etiologic microorganisms
- Choice of the empirical antimicrobials likely to be active against these microorganisms

BOX 68.2 Diagnostic Protocol to Combine Clinical and Bacteriologic Strategies for the Diagnosis of Ventilator-Associated Pneumonia

1. As soon as pneumonia or infection associated with mechanical ventilation is suspected and before initiating new empirical antibiotic treatment, collect samples as follows*:
   - Expectoration
   - Tracheobronchial aspirate (BAS)**
   - Bronchoalveolar lavage (BAL) or mini-BAL**
   - Protected brush specimen (PBS)**
2. Two blood cultures
3. In cases of evidence for parapneumonic effusion, obtain pleural fluid sample
4. Obtain *Legionella pneumophila* and *Streptococcus pneumoniae* antigens in urine
5. In patients on long-term mechanical ventilation with previous antibiotic treatment, corticosteroid administration, and chronic lung comorbidities, galactomannan in serum and BAL could be assayed to identify invasive pulmonary aspergillosis
6. Other laboratory tests: complete blood cell count, serum electrolytes, liver and renal function tests, C-reactive protein, procalcitonin, arterial blood gases

*Samples should be sent immediately to the microbiology department or, if not available, maintained in a refrigerator at 4°C (only respiratory samples) for a maximum of 1 hour for Gram staining, intracellular organism counting (only in BAL and mini-BAL), and quantitative cultures. The collection of lower respiratory secretion samples should not delay the initiation of empirical treatment in patients with severe sepsis.

**These techniques may be performed by bronchoscopy or blind procedures. Quantitative cultures are performed with the respiratory secretions obtained by BAS, BAL, or PBS. The cutoff count to diagnose pneumonia is the following: BAS 10^6 CFU/mL, BAL 10^4 CFU/mL, and PSB 10^3 CFU/mL. *CFU,* Colony-forming unit.

MDR, Multidrug resistant; *VAP,* ventilator-associated pneumonia.

- Adjustment of therapy after microbiologic results and duration of treatment

Likely Etiologic Microorganisms

As detailed in previous paragraphs, microorganisms causing VAP originate from the oropharyngeal flora of the patient. Underlying chronic diseases, specific risk factors, acute inflammatory processes, and factors specific to each hospital or ICU can facilitate abnormal bacterial colonization of the oropharynx and may predispose patients to infection with specific organisms. Therefore the selection of initial antimicrobial therapy must be tailored to the local prevalence of pathogens and antimicrobial patterns of resistance at each institution.[119] The dynamics of change of oropharyngeal flora during hospital stay can be described as follows (Fig. 68.6):

1. Healthy subjects are colonized with normal oropharyngeal flora, among which pathogenic microorganisms, such as *S. pneumoniae*, group A streptococci, or meningococci, may be transiently found.
2. Patients with chronic comorbidities or an acute inflammatory process have impaired immune responses. As a result, *S. aureus* and Enterobacteriaceae can colonize the oropharynx.
3. Patients who have received antibiotic treatment frequently become colonized with resistant pathogens, including ESBL + Enterobacteriaceae, *Enterobacter* spp., *P. aeruginosa*, or MRSA.
4. Patients who have received broad-spectrum antibiotics for more than 7 days are often colonized by MDR microorganisms (i.e., *A. baumannii, S. maltophilia, B. cepacia,* and gram-positive microorganisms).

Changes in the oropharyngeal flora tend to occur progressively; the presence of microorganisms during one stage often overlaps with the next stage.

Choice of Empirical Antimicrobials Likely to Be Active Against Causative Microorganisms

The American[1] and European guidelines[2] concur that before the commencement of antibiotic therapy, patients should be stratified according to their risks of being infected with MDR pathogens. American guidelines emphasize several risk factors for MDR, as shown in Box 68.3. European guidelines, however, classify as "high-risk HAP/VAP" patients those who require broad-spectrum antibiotic coverage, those with septic shock, >15% mortality risk,[3,12] or specific risk factors for MDR (see Box 68.3). Conversely, patients without risk factors for MDR and 15% or less chance of mortality are classified as low-risk HAP/VAP. Potential limitations of guidelines and recommendations should be taken into account when used for the prediction of possible causative pathogens. Ekren and colleagues[104] validated the 2016 Infectious Disease Society of America/American Thoracic Society (IDSA/ATS) guidelines[1] using a Spanish repository of HAP/VAP and found high sensitivity for detecting MDR pneumonia using recommended risk factors but very low specificity, potentially increasing the risk of overtreatment or use of inappropriate antibiotics. The antibiotics recommended by the latest American and European guidelines are shown in Table 68.1 and Table 68.2. Recommendations are similar, yet the American guidelines advocate empiric treatment for MRSA in ICUs where MRSA is isolated in at least 10% of the samples, in comparison with 25% for the European guidelines. In addition, as for the empiric treatment against gram-negative pathogens, European guidelines suggest use of monotherapy even in patients with high risk of mortality and/or risks of harboring MDR gram-negative pathogens, assuming a single agent is active for >90% of the gram-negative

ICU, Intensive care unit; *MDR,* multidrug resistant; *VAP,* ventilator-associated pneumonia.

pathogens isolated in the ICU. Furthermore, American guidelines discourage the use of aminoglycosides if alternative agents are available because of possible low epithelial lining fluid concentrations of this class of antibiotics.[313] European guidelines highlight aminoglycosides as an appropriate second anti–gram-negative agent. Another difference between the American and European guidelines is in the use of colistin. Americans recommend against the use of colistin for VAP because of potential nephrotoxicity and need to reduce risk for resistance for this last-line antibiotic. European guidelines instead recommend colistin in VAP caused by *Acinetobacter* spp.

An algorithm for the initial management of patients with nosocomial respiratory infection and selection of appropriate antimicrobials is shown in Fig. 68.7. Adequate dosing of antibiotics for empirical therapy is summarized in Table 68.3. Broad-spectrum empirical antibiotic therapy should be rapidly de-escalated as soon as microbiologic data become available, with the intent to limit the emergence of resistance in the hospital. Fig. 68.7, Table 68.1, and Table 68.2 detail empirical therapy, which should be based on the patient's risk of colonization by MDR organisms. With regard to the need for dual therapy against gram-negative pathogens, Aarts and colleagues[314] performed a meta-analysis of 11 trials randomizing 1805 patients. No mortality difference was detected for patients receiving monotherapy versus combination therapy (RR = 0.94, 0.76–1.16). Likewise, there was no significant difference in treatment failure in patients with clinically suspected pneumonia (RR = 0.88, 0.72–1.07; see Fig. 68.4) or microbiologically proven pneumonia (RR = 0.86, 0.63–1.16).

Novel Intravenous Antibiotics

Drug resistance is increasing worldwide, and several drugs are at various stages of clinical research and development aimed at appropriately treating infections caused by microorganisms resistant to our current arsenal. Several antimicrobials against gram-positive (i.e., tedizolid) and gram-negative pathogens (i.e., cefiderocol or plazomicin) are being tested in phase III clinical trials.[315] In a pivotal multicenter noninferiority trial,[316] 726 patients with VAP were randomly assigned to receive either 3 g of ceftolozane-tazobactam or 1 g meropenem intravenously every 8 hours up to 14 days. At 28 days, 24% of patients in the ceftolozane-tazobactam group and 25% in the meropenem group had died (weighted treatment difference 1.1%, 95% CI −5.1 to 7.4), and similar rates of serious treatment-related adverse events were observed. In another noninferiority trial, ceftazidime-avibactam was compared with meropenem for the treatment of HAP/VAP.[317] Sixty-nine and seventy-three percent of the patients who received ceftazidime-avibactam or meropenem, respectively, achieved the positive primary outcomes set for the study. In studies that focused on outcomes other than respiratory infections, ceftazidime-avibactam has also compared favorably against colistin for positive outcomes in treating carbapenem-resistant Enterobacteriaceae[271] and as a salvage therapy against *K. pneumoniae* carbapenemase enzyme producers.[271] In the TANGO II clinical trial,[318] meropenem-vaborbactam was compared with standard therapy in a multicenter clinical study in patients with infections caused by carbapenem-resistant Enterobacteriaceae, including HAP/VAP. Lower 28-day all-cause mortality and nephrotoxicity

TABLE 68.2 Initial Empirical Antibiotic Treatment for Nosocomial and Ventilator-Associated Pneumonia in Patients With High Mortality Risk and/or Risk Factors for Infection by Multidrug-Resistant Pathogens and Septic Shock

Probable Microorganism	Combined Antibiotic Treatment
Microorganisms from Table 68.1 plus:	Antipseudomonal cephalosporin (ceftazidime or cefepime)*
Pseudomonas aeruginosa	*or*
Klebsiella pneumoniae (ESBL+)†	Carbapenem (imipenem, meropenem)*
Acinetobacter spp.†	*or*
Other nonfermenting gram-negative bacilli	Beta-lactam/beta-lactamase inhibitor (piperacillin-tazobactam)*
Methicillin-resistant *Staphylococcus aureus* (MRSA)	+
Legionella pneumophila‡	Antipseudomonal fluoroquinolone (ciprofloxacin, levofloxacin)**
	or
	Aminoglycoside** (amikacin), gentamicin
	±
	Linezolid or vancomycin***

*The choice of beta-lactam is made as follows: patients who have not received any antipseudomonal beta-lactam within the last 30 days should be administered piperacillin-tazobactam or an antipseudomonal cephalosporin. Patients who have received these drugs should be given empirical therapy with a carbapenem. Patients with infection by ESBL-producing microorganisms should be treated with carbapenem regardless of the results of the antibiogram.
** American guidelines discourage the use of aminoglycosides as first choice for the second antipseudomonal therapy, whereas European guidelines are in favor. Potential use of an antipseudomonal fluoroquinolone should be considered in cases of renal failure or concomitant use of vancomycin.
***American guidelines recommend empirical therapy aimed against MRSA in units in which >10% of *S. aureus* isolates are methicillin resistant. European guidelines recommend empirical therapy aimed against MRSA in units in which >25% of *S. aureus* isolates are methicillin resistant. The antibiotic of choice is either vancomycin (except in patients allergic to this medication, with creatinine values ≥1.6 mg/dL, or in patients presenting with signs of empirical treatment failure after 48 hours of antibiotic therapy) or linezolid. (ψ) For epidemiologic surveillance, nasal and perineal cultures should be performed on admission and at 1-week intervals thereafter while remaining in the ICU.
†If an ESBL+ strain, such as *K. pneumoniae* or *Acinetobacter* spp. is suspected, a carbapenem is the first choice.
‡If *L. pneumophila* is suspected, the combination antibiotic regimen should include a macrolide (e.g., azithromycin), or a fluoroquinolone (e.g., ciprofloxacin, levofloxacin) should be used rather than an aminoglycoside.
ESBL, Extended-spectrum beta-lactamase; *GNB,* gram-negative bacilli.

were found in comparison with standard intravenous antibiotics (25% versus 44%) in the subcohort of patients with HAP/VAP. An innovative algorithm based on the evidence gathered from clinical trials on the use of novel antibiotics against nosocomial pneumonia has been recently proposed by Zaragoza and collaborators.[271] The algorithm envisions future empirical and targeted treatment for critically ill patients with nosocomial pneumonia, which could be potentially recommended in the next decade.

Nebulized Antibiotics

Intravenous administration of antibiotics for nosocomial pneumonia has several limitations, including insufficient lung distribution, development of adverse side effects, and exerting selective pressure for development of MDR. Additionally, intravenous antibiotics are often underdosed in critically ill patients because of sepsis-related higher volumes of drug distribution and the influence of hyperdynamic states. Coadministration of nebulized antibiotics is a potential therapeutic alternative[319] to overcome these limitations. Additionally, systemic exposure to antibiotics and potential adverse effects are dramatically reduced by the aerosol route. Finally, nebulized antibiotics can potentially reduce the risk of developing MDR infections.[320] In laboratory models, nebulized amikacin reached pulmonary concentrations 30 times higher than intravenous administration. In a pivotal study by Lu and colleagues,[321] 20 patients with susceptible or intermediate-resistant gram-negative pathogens received nebulized ceftazidime and amikacin, whereas 17 patients infected with susceptible strains received intravenous ceftazidime and amikacin. After 8 days of treatment, cure rates were similar among tested groups. However, acquisition of treatment-associated antibiotic resistance was higher in the intravenous cohort. In a later study, Niederman and colleagues[322] randomized 69 mechanically ventilated patients with gram-negative VAP to receive aerosolized amikacin concomitantly with systemic antibiotics. They found that amikacin distributed well throughout the lung parenchyma, with high tracheal and alveolar levels but with a serum concentration below the renal toxicity threshold. Several factors play a critical role in lung deposition of nebulized antibiotics during MV.[323] First, the extent and severity of lung infection critically affect their lung distribution.[324] Second, vibrating plate nebulizers increase the efficiency of aerosol delivery to 40%–60%.[325,326] Finally, humidification and angular geometry of the ventilatory circuit should be taken into account during nebulization. In addition, ventilatory settings that ensure laminar inspiratory flow provide better distal lung deposition of aerosolized particles.[327] Irrespective of the potential benefits of nebulized antibiotics and advances in the field, two large RCTs recently failed to find any improvement in major outcomes during treatment with nebulized antibiotics.[328,329] As a good example, Niederman and collaborators[328] randomized 508 VAP patients to receive aerosolized amikacin every 12 hours as an adjunct to standard intravenous antibiotics and found that mortality up to 32 days from commencement of therapy did not differ between study groups (OR + 0.841; 95% CI 0.55–1.27; $P = .43$). In accordance with those marginal results, the latest American guidelines[1] recommended against the use of nebulized

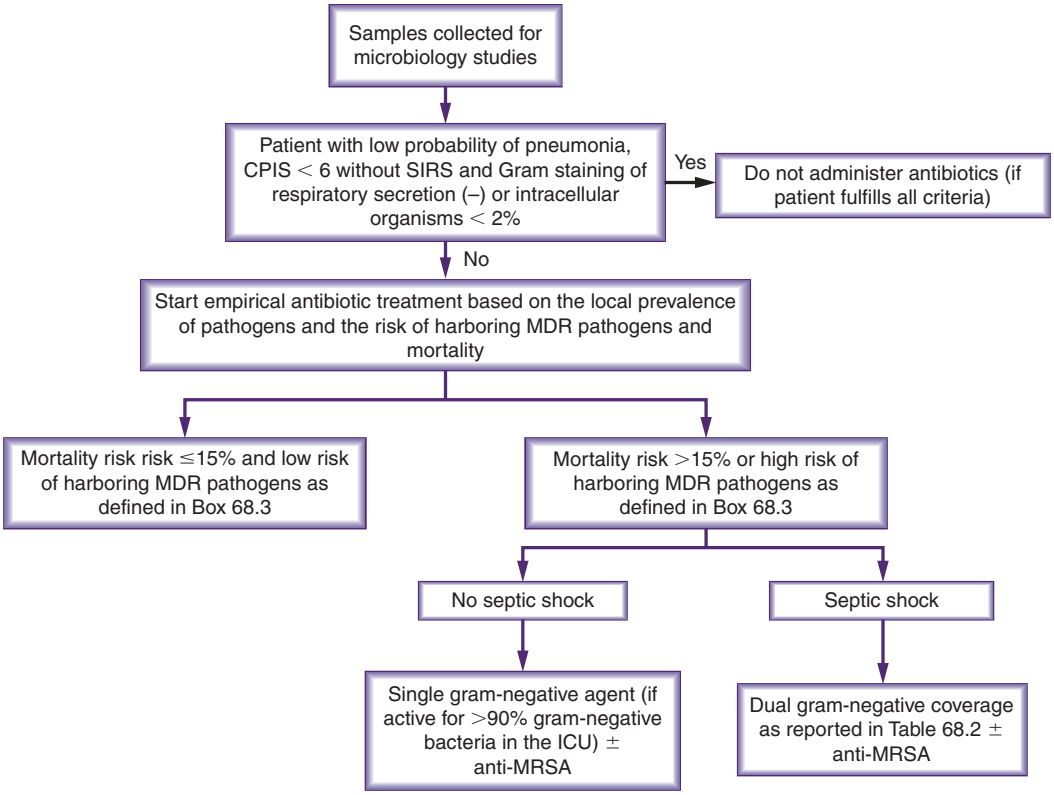

Fig. 68.7 Algorithm for the Treatment of Patients with Suspicion of Nosocomial Respiratory Infection. SIRS comprises at least two of the following: temperature >38°C or <36°C; heart rate >90 beats/min; respiratory rate >20 breaths/min or partial pressure of carbon dioxide ($PaCO_2$) <32 mm Hg; and leukocytes >12,000/mm^3, <4000/mm^3, or the presence of >10% immature neutrophils. *CPIS*, Clinical Pulmonary Infection Score; *ICU*, intensive care unit; *MDR*, multidrug resistant; *MRSA*, methicillin-resistant *Staphylococcus aureus*. *SIRS,* Systemic inflammatory response syndrome.

TABLE 68.3 Recommended Initial Intravenous Antibiotic Dosage for Empirical Treatment of Patients With Nosocomial and Ventilator-Associated Pneumonia

Antibiotic	Doses	Interval of Administration	Perfusion Time
Non-Antipseudomonal Cephalosporins			
Ceftriaxone	2 g	24 hours	½–1 hour
Cefotaxime	2 g	6 hours	½–1 hour
Antipseudomonal Cephalosporins and other Classes			
Ceftazidime	2 g	8 hours	2–3 hours
Cefepime	1–2 g	8 hours	2–3 hours
Imipenem	0.5 or 1 g	6 or 8 hours	1 hour
Meropenem	1 g	8 hours	2–3 hours
Piperacillin-tazobactam	4–0.5 g	6 hours	2–3 hours
Fluoroquinolones			
Levofloxacin	500 mg	12 hours*	½ hour
Ciprofloxacin	400 mg	8 hours	½ hour
Amikacin	15–20 mg/kg	24 hours**	½–1 hour
Gentamicin	5-7 mg/Kg^	24 hours	1/2 hour
Vancomycin	15 mg/Kg	8–12 hours***	1–3 hours
Linezolid	600 mg	12 hours	1 hour

*Administer this dose for 3 days and after continue with 500 mg/24 h. Alternatively, administer 750 mg every 24 hours.
**Adjust the dosage according to pharmacokinetic/pharmacodynamic (PK/PD) parameters.
***Initiate this dose within 24 hours, measure trough blood levels before the following dosage, and adjust the levels according to values. Dosages are based on normal renal and hepatic function.
^In case of multiple daily dosing (3 mg/Kg load, then 2 mg/kg every 8 hours), therapeutic monitoring is recommended to acheive goal peak >8 mcg/ml and through < 2mcg/ml

antibiotics in VAP, whereas European guidelines[2] favored inhaled antibiotics in addition to systemic therapy in VAP caused by gram-negative bacilli that are not responding to intravenous treatment alone (weak recommendation with low-quality evidence).

Antimicrobial Therapy in Special Situations

In geographic areas with a documented presence of community-acquired MRSA, severe pneumonia with radiologic images of cavitation, and presence of gram-positive cocci in respiratory secretions, empirical treatment with linezolid or vancomycin may be appropriate. Recently, an outbreak of MRSA and linezolid-resistant *S. aureus* (LRSA) was reported in an intensive care department of a 1000-bed tertiary care university teaching hospital in Madrid, Spain, and was associated with nosocomial transmission and extensive usage of linezolid.[115,116] Tigecycline may be a useful alternative in this setting, but clinical experience is scanty.

Infections by *L. pneumophila* serogroup 1 can be diagnosed by a *Legionella* urinary antigen test. This test should be routinely obtained if the hospital water supply is known to be colonized with *L. pneumophila* serogroup 1. A fluoroquinolone or a macrolide would be an appropriate treatment for *L. pneumophila* infection.

Modifications of Therapy and Duration of Treatment

A suggested flowchart for the follow-up of patients with nosocomial pneumonia is shown in Fig. 68.8. After 72 hours, treatment should be adjusted based on microbiologic results. The initial beta-lactam should be continued if the microorganism is susceptible to the empirical beta-lactam originally prescribed. If not, another beta-lactam should be introduced. The empirical antibiotic against MRSA should be discontinued if the presence of this pathogen is not confirmed by cultures. Discontinuation of the fluoroquinolone, and especially the aminoglycoside, should be considered after 3–5 days of treatment. The bactericidal activity of aminoglycosides and fluoroquinolones leads to a rapid reduction in the bacterial load during the first days of treatment. After this time, monotherapy may be sufficient. This tapering approach would decrease the emergence of resistant mutants and minimize nephrotoxicity caused by aminoglycosides.

The majority of VAP infections that occur in patients without immunodeficiency, cystic fibrosis, empyema, lung abscess, cavitation, or necrotizing pneumonia can be effectively treated with 8 days or less of antimicrobial therapy, provided that a good clinical response to therapy has been observed.[2] In a meta-analysis[330] that pooled data from four RCTs comparing short (7–8 days) with long (10–15 days) treatment periods, no difference in mortality was found. There was an increase in antibiotic-free days for the short-course treatment, and a trend to lower relapse rates in the long-course treatment was observed (OR = 1.67; 95% CI = 0.99–2.83; P = .06).

Four situations may justify prolonged treatment: (1) infection by intracellular microorganisms, such as *Legionella* spp.; (2) the presence of biofilms or prosthetic devices; (3) development of tissue necrosis, formation of abscesses, or infection within a closed cavity, such as empyema; and (4) the persistence of the original infection (such as perforation or endocarditis). If the clinical course from the pneumonia is favorable, as defined by defervescence, improvement in partial pressure of oxygen/fraction of inspired oxygen (PaO_2/FiO_2), and reduction in CRP levels within the first 3–5 days of antimicrobial therapy, treatment may be withdrawn

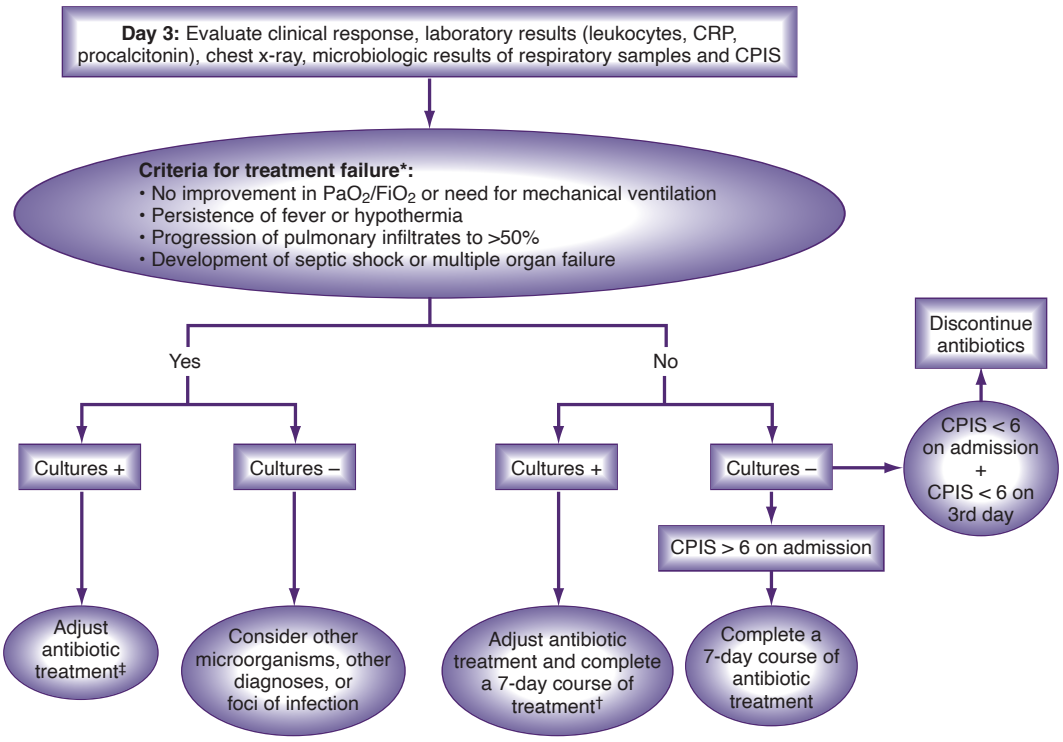

Fig. 68.8 Suggested Algorithm for the Follow-Up of Patients with Nosocomial Pneumonia and VAP. *Criteria of treatment failure taken from Ioanas M, Ferrer M, Cavalcanti M, et al. Causes and predictors of non-response to treatment of the ICU-acquired pneumonia. *Crit Care Med.* 2004;32:938–945. †In cases in which the etiologic agent is *Pseudomonas aeruginosa* or *Acinetobacter* spp., treatment should be maintained for 14 days. ‡Patients with criteria of treatment failure and in whom MRSA is isolated should be administered linezolid. If a GNB is isolated, consultation is recommended. *CPIS,* Clinical Pulmonary Infection Score; *CRP,* C-reactive protein; *FiO_2,* fraction of inspired oxygen; *GNB,* gram-negative bacilli; *MRSA,* methicillin-resistant *Staphylococcus aureus*; *PaO_2,* partial pressure of oxygen; *VAP,* ventilator-associated pneumonia.

after 7 days. If the causative microorganism is a nonfermenting gram-negative bacillus, the treatment can be extended beyond 14 days. A large prospective, multicenter, randomized trial study comparing the efficacy of 8-day and 15-day antibiotic regimens for treating VAP suggested that an 8-day regimen reduces antibiotic use and decreases the emergence of pulmonary MDR bacteria without modification of the prognosis.[331] However, this study observed that in cases of pneumonia produced by nonfermenting gram-negative bacilli, eradication of these microorganisms from bronchial secretions was less complete with the shorter regimen. On the other hand, the 14-day treatment regimen was associated with a trend toward colonization by MDR pathogens and a higher frequency of reinfection. Finally, antimicrobials may be withdrawn in patients with clinical suspicion of ICU-acquired pneumonia who have a CPIS lower than 6 on the third day of treatment. In this setting, the patient likely does not have pneumonia, or the pneumonia is sufficiently mild such that prolonged antibiotic treatment is not required. Finally, most recent European guidelines[2] suggest that procalcitonin—an inflammatory biomarker investigated both for the diagnosis of VAP and response to treatment[271]—could play a role in appropriately shortening or prolonging duration of treatment in specific circumstances, such as inappropriate antibiotic treatments, infections caused by MDR or extensively drug-resistant microorganisms, or when using second-line antibiotics such as colistin and tigecycline.

Treatment Failure

At least 3 days of antibiotic treatment are needed to achieve clinical improvement. Thus treatment failure should be assessed between 3 and 5 days after the initiation of antibiotic therapy. The rate of treatment failure ranges between 30% and 50%, which highlights the severity and complexity of this pulmonary infection. In our previous observations,[3] we developed a systematic definition of treatment failure composed of the following: (1) no improvement in PaO_2/FiO_2 or need for intubation because of pneumonia; (2) persistence of fever or hypothermia, together with purulent respiratory secretions; (3) increase in the pulmonary infiltrates on chest radiograph of greater than or equal to 50%; or (4) occurrence of septic shock or multiple organ dysfunction syndrome. Thus we found that no improvement in the Sequential Organ Failure Assessment (SOFA) score and PaO_2/FiO_2 highly predicted worse 28-day mortality. Importantly, treatment failure could be a surrogate endpoint for clinical trials to compare novel treatments. Upon evidence of treatment failure, respiratory samples should be reobtained and the initial empirical therapy rapidly readjusted. CT scan or lung ultrasound[332,333] may help to detect cavitation, pleural effusion, and other causes for treatment failure.

Implementation of Therapeutic Guidelines

Although guideline-recommended strategies may provide significant benefits for patients, their implementation is often difficult to achieve.[334] Soo Hoo and colleagues[335] developed hospital protocols to manage patients with severe HAP based on the 1996 ATS guidelines.[336] After the guidelines were introduced into clinical settings, the authors found that adequate antibiotic therapy was administered in more than 81% of the patients with pneumonia, compared with 46% before implementation ($P < .01$). Moreover, a lower mortality at 14 days was found after implementation of the guidelines ($P = .03$). Similarly, Ibrahim and coworkers developed a protocol to provide appropriate initial antibiotic treatment for patients with VAP and encouraged a 7-day course of treatment.[337] Patients with VAP who were treated as directed by the protocol more often received adequate antimicrobial treatment than those treated empirically (94%, in comparison to 48% before protocol implementation; $P < .001$). The length of treatment was reduced by 6 days, and a second episode of VAP was less likely to occur after implementation.

KEY POINTS

- Nosocomial pneumonia is a common complication occurring in critically ill patients and is the leading cause of nosocomial infection–related death. VAP develops in tracheally intubated patients.
- Etiologic agents for VAP differ according to the population of ICU patients, duration of hospital stay, and prior antimicrobial therapy. Nosocomial pneumonia caused by MDR pathogens is associated with the highest morbidity and mortality.
- Preventive strategies, grouped as bundles, should be implemented in hospital settings. Several preventive strategies have shown efficacy in decreasing the incidence of pneumonia. In particular, the most effective strategies focus on reduction of cross-transmission, diminishing the likelihood of aspiration across the tracheal tube cuff, and decreasing bacterial load in the oropharynx.
- In the presence of clinical suspicion of nosocomial pneumonia, diagnostic strategies should include an early collection of respiratory samples *before* starting or changing antibiotics.
- The choice of empirical treatment should be based on the most likely etiologic microorganisms and the antimicrobials likely to be active against these microorganisms. Response to therapy should be reassessed after 3–5 days and antimicrobials adjusted or de-escalated to reduce the burden of the disease.

ANNOTATED REFERENCES

Esperatti M, Ferrer M, Theessen A, et al. Nosocomial pneumonia in the intensive care unit acquired by mechanically ventilated versus nonventilated patients. *Am J Respir Crit Care Med.* 2010;182(12):1533–1539.
The first study that defines ICU-acquired pneumonia comparing pneumonia acquired in the ICU by mechanically ventilated versus nonventilated patients. Interestingly, the etiology and outcomes of nosocomial pneumonia acquired in the ICU are similar regardless of whether pneumonia is acquired or not during ventilation, indicating they may depend on patients' underlying severity rather than previous intubation.

International ERS/ESICM/ESCMID/ALAT guidelines for the management of hospital-acquired pneumonia and ventilator-associated pneumonia: guidelines for the management of hospital-acquired pneumonia (HAP)/ventilator-associated pneumonia (VAP) of the European Respiratory Society (ERS), European Society of Intensive Care Medicine (ESICM), European Society of Clinical Microbiology and Infectious Diseases (ESCMID) and Asociacion Latinoamericana del Torax (ALAT). *Eur Respir J.* 2017;50(3):1700582.
Latest European guidelines published by a joint committee of the ERS, ESICM, ESCMID, and ALAT. As highlighted and inclusively described in the chapter, several recommendations differ from the American guidelines.

Labeau SO, Van de Vyver K, Brusselaers N, et al. Prevention of ventilator-associated pneumonia with oral antiseptics: a systematic review and meta-analysis. *Lancet Infect Dis.* 2011;11(11):845–854.
A meta-analysis investigating the effect of oral antiseptics in the prevention of ventilator-associated pneumonia. Overall, antiseptic use resulted in a significant risk reduction of ventilator-associated pneumonia (RR = 0.67; 95% CI = 0.50–0.88; P 5 0.004). In particular, chlorhexidine application was shown to be effective especially in cardiosurgical patients, whereas the effects associated with povidone-iodine remain unclear.

Management of adults with hospital-acquired and ventilator-associated pneumonia: 2016 clinical practice guidelines by the Infectious Diseases Society of America and the American Thoracic Society. *Clin Infect Dis.* 2016;63(5):e61–e111.
Latest American guidelines published by a joint committee of the American Thoracic Society and the Infectious Diseases Society of America. In comparison with the latest guidelines in 2005, various differences in the risk factors for harboring multidrug-resistance pathogens and antibiotic treatments can be identified. Guidelines do not include recommendation on preventive measures

Melsen WG, Rovers MM, Groenwold RH, et al. Attributable mortality of ventilator-associated pneumonia: a meta-analysis of individual patient data from randomised prevention studies. *Lancet Infect Dis.* 2013;13(8):665–671.
A meta-analysis pooling data from 6284 patients in 24 trials that shows that the overall attributable mortality for ventilator-associated pneumonia is 13%, with higher mortality rates in surgical patients and patients with midrange severity scores at admission (i.e., acute physiology and chronic health evaluation score [APACHE] 20–29 and simplified acute physiology score [SAPS 2] 35–58). Attributable mortality was close to zero in trauma, medical patients, and patients with low or high severity of illness scores.

Muscedere J, Rewa O, McKechnie K, et al. Subglottic secretion drainage for the prevention of ventilator-associated pneumonia: a systematic review and meta-analysis. *Crit Care Med.* 2011;39(8):1985–1991.
A meta-analysis that shows that the overall risk ratio (RR) for ventilator-associated pneumonia using tracheal tubes allowing subglottic secretion aspiration is 0.55. The use of subglottic secretion aspiration was also associated with reduced intensive care unit length of stay, decreased duration of mechanical ventilation, and increased time to first episode of ventilator-associated pneumonia.

Oostdijk EA, de Smet AM, Blok HE, et al. Ecological effects of selective decontamination on resistant gram-negative bacterial colonization. *Am J Respir Crit Care Med.* 2010;181(5):452–457.
The authors studied the effects of selective digestive decontamination (SDD) and selective oropharyngeal decontamination (SOD) on the development of antibiotic resistance after ICU discharge. During SDD, average proportions of patients with intestinal colonization with pathogens resistant to either ceftazidime, tobramycin, or ciprofloxacin were 5%, 7%, and 7%, respectively, and increased to 15%, 13%, and 13% post intervention (P = .05), respectively. During SDD and SOD, resistance levels in the respiratory tract were not more than 6% for all three antibiotics, but increased gradually for ceftazidime during the intervention and to levels of 10% or more for all three antibiotics post intervention (P 5 0.05). Thus SDD and SOD have a marked rebound effect of ceftazidime resistance after discontinuation of intervention.

Philippart F, Gaudry S, Quinquis L, et al. Randomized intubation with polyurethane or conical cuffs to prevent pneumonia in ventilated patients. *Am J Respir Crit Care Med.* 2015;191(6):637–645.
Multicenter, prospective, randomized clinical study in 621 patients with expected ventilation longer than 2 days randomized to be intubated with a cuff composed of cylindrical polyvinyl chloride, cylindrical polyurethane, conical polyvinyl chloride, or conical polyurethane. No differences in tracheal colonization and VAP were found among groups.

Price R, MacLennan G, Glen J, SuDDICU Collaboration. Selective digestive or oropharyngeal decontamination and topical oropharyngeal chlorhexidine for prevention of death in general intensive care: systematic review and network meta-analysis. *BMJ.* 2014;348:doi:10.1136/bmj.g2197.
Latest meta-analysis of randomized controlled trials that recruited adult patients in general intensive care units and studied selective digestive decontamination (SDD), selective oropharyngeal decontamination (SOD), or oropharyngeal chlorhexidine compared with standard care or placebo. SDD was the only intervention that decreased mortality (OR = 0.73; 95% CI = 0.64–0.84).

Rello J, Sa-Borges M, Correa H, et al. Variations in etiology of ventilator-associated pneumonia across four treatment sites: implications for antimicrobial prescribing practices. *Am J Respir Crit Care Med.* 1999;160(2):608–613.
A study supporting the theory that the selection of initial antimicrobial therapy must be tailored to the local prevalence of pathogens and antimicrobial patterns of resistance.

Core Principles of Cardiovascular Physiology and Pathophysiology in Critical Illness

Sheldon Magder

INTRODUCTION

Metabolism in almost all living organisms is energized by the chemical reduction of oxygen (O_2). As such, provision of O_2 to tissues is of central importance for living beings, especially in the high O_2 consumption (VO_2) of mammals and birds. Accordingly, VO_2 has evolved to be tightly related to the organism's energy demands. The Fick principle, a statement of conservation of mass, indicates that VO_2 is determined by the flow of blood and the extraction of O_2 by tissues. As such, maintenance of appropriate blood flow to match tissue needs is fundamental to normal homeostasis. This is evident in the tight linear relationship between cardiac output and VO_2 under normal physiologic conditions.

It might be expected that there would be widespread agreement on the regulation of such a key factor as the control of cardiac output. However, two conflicting conceptual approaches remain. One is that of Levy and others,[1,2] which argues that the arterial pressure produced by the heart is the force that determines blood flow in the circulation. The alternative approach is that of Arthur Guyton.[3,4] He argued that the primary role of the heart in the generation of blood flow is to allow venous blood to drain back to the heart. In his argument, the heart can never pump out more than what comes back to it. The main force in Guyton's approach is the recoil pressure created by the volume filling the veins and venules because this force determines what comes back to the heart to be pumped out again (Fig. 69.1). Arterial pressure then is determined by pumping a stroke volume against the vascular resistance. The arterial pressure itself, though, does not determine the amount of flow in the circulation (except by acting as an afterload and inhibiting ejection) and, more importantly, what comes back to the heart. As a simple illustration of this point, the right ventricle (RV) and left ventricle (LV) produce the same blood flow but with very different pressures. This chapter presents the Guytonian view of the circulation universe.

THE GUYTONIAN UNIVERSE

Central to the Guytonian view is that the volume that fills vasculature structures creates an elastic recoil force by stretching the walls of vessels (Fig. 69.2).[5] This elastic force is present even when there is no blood flow. Evidence for this is that blood will flow from a cut vein in a person with an arrested heart. The average elastic recoil pressure that fills all vascular structures when there is no flow is called the *mean circulatory filling pressure* (MCFP). The role of the heart in this concept is "permissive" in that by emptying the blood from the ventricles, the upstream volume in the veins can return to the heart (see Fig. 69.2). This volume is then pumped out again.

Over 70% of blood volume resides in small veins and venules. Thus the elastic recoil force of these vessels, as determined by the volume distending them and the compliance of their walls, or its inverse elastance, is the major determinant of the elastic recoil force. When blood is flowing, blood volume redistributes among the different vascular compartments based on the resistance into and out of each region and their relative compliances. Under flow conditions, the pressure in the veins and venules directly upstream from the heart is called the *mean systemic filling pressure* (MSFP, note the "S" instead of "C") and is a major determinant of the return of blood flow to the heart. Under normal conditions, MCFP and MSFP are similar, but the relationship can change with alterations in cardiac function because of the changes in distribution of blood volume.

By lowering right atrial pressure (Pra) and central venous pressure (CVP), the heart allows venous volume to return to the heart. The heart, though, obviously has a second key function, which is its "restorative" function, in that it puts the blood back into the system (see Fig. 69.2). The compliance of arterial vessels is less than 1/40th of venous vessels. Thus putting the relatively small stroke volume into stiff arteries produces the high arterial pressure, but there is very little change in the pressure in the veins and venules, that is the MSFP, when this volume is removed from the massive systemic venous volume. As already mentioned, in the Guyton model arterial pressure does not determine cardiac output, but rather cardiac output and the downstream systemic arterial resistance determine arterial pressure. The stroke volume then distributes throughout the vasculature based on the distribution of regional vascular resistances.[6] There is an additional determinant of arterial pressure, and that is a critical closing pressure proximal to the microcirculation (Fig. 69.3).[6,7] This factor affects the position of the vascular resistance line and magnifies or offsets changes in the slope of the resistance line. The actual cardiac output is determined by the interaction of the return of blood to the heart from the veins and venules, which is called the *return function,* and cardiac function as defined by Ernest Starling.

Venous Return

It may seem strange that vascular compliance, a static property, is so important for the generation of blood flow in the circulation. The explanation is that pulsatile flow in a tube occurs from a region with a

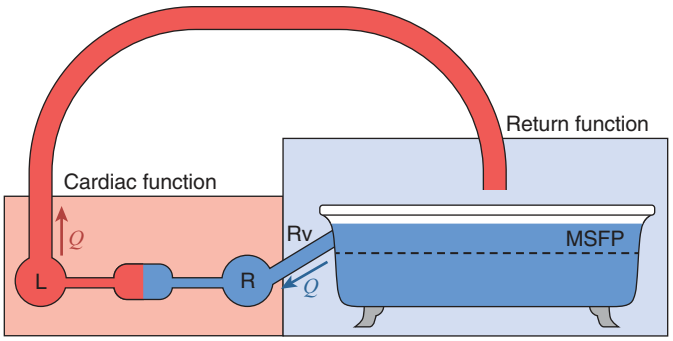

Fig. 69.1 General model of the circulatory system. Cardiac output is determined by the interaction of a pump function, *left side*, and a return function, *right side*. ***L,*** Left heart; ***MSFP,*** mean systemic filling pressure; ***Q,*** cardiac output; ***R,*** right heart; ***Rv,*** resistance to venous return.

high pressure to an area with a lower pressure. If the closed loop vasculature was made up only of stiff vessels, the pressure wave produced with each stroke volume would be instantaneously transmitted through the system and there would be no pressure difference to drive flow (Fig. 69.4). Thus for flow to occur, the pressure wave and volume pulse have to be transiently taken up in a region that has a higher compliance; that region is the veins and venules, which have a large volume at a low pressure and as such are very compliant (see Fig. 69.4). This is analogous to the characteristics of a bathtub (see Fig. 69.2). Drainage from a bathtub is determined by the height of the water above the hole at the bottom. Inflow from the tap only increases outflow from the tub by adding volume and raising the height of water in the tub, but the pressure coming out of the taps does not alter flow from the drain. Similarly, the pressure going into the veins and venules does not determine outflow from the veins; only the volume entering per time (i.e., flow) does this.

Based on this discussion, the determinants of the return function are the volume that stretches the vascular walls, the compliance of the walls of the veins and venules, and the resistance to flow between the venous system and the RV (see Fig. 69.2). The compliance of arteries and capillaries only add a very small component to the total vascular compliance and can be ignored for simplification.

Guyton provided a useful graphical approach to understanding the return function (Fig. 69.5). He plotted Pra on the *x*-axis because he considered it to be the variable being controlled, and thus the independent variable. The *y*-axis is flow (or venous return). The *x*-intercept is the MSFP. The lower the Pra, the greater the flow. The slope of the venous return line is −1/venous resistance (−1/Rv). This inverted relationship occurs because the inflow pressure, MSFP, remains relatively constant and the outflow pressure, Pra, is lowered by the heart. The function then is plotted against the outflow pressure, which is Pra. When Pra falls below its surrounding pressure, which is atmospheric pressure when breathing spontaneously, the floppy veins collapse where they enter the thoracic cavity, which has a negative pressure relative to atmospheric pressure. This does not stop flow but creates a flow limitation, what is called a *vascular waterfall*.[8] When that happens, lowering Pra further does not increase venous return. This can be very evident when attempts are made to increase the speed of a mechanical device supporting the heart and there is insufficient upstream pressure to support the flow. When intrathoracic pressure is raised by mechanical ventilation, the collapse of veins occurs when Pra is less than pleural pressure.

It is important to introduce another term, and that is capacitance (Fig. 69.6). By now it should be clear that the volume stretching veins and venules determines flow, rather than total blood volume. The reason is that under resting conditions 70% of blood volume simply rounds out vessel walls but does not stretch them. This is called "*unstressed*" *volume*.[9,10] Thus only about 30% of blood volume—the

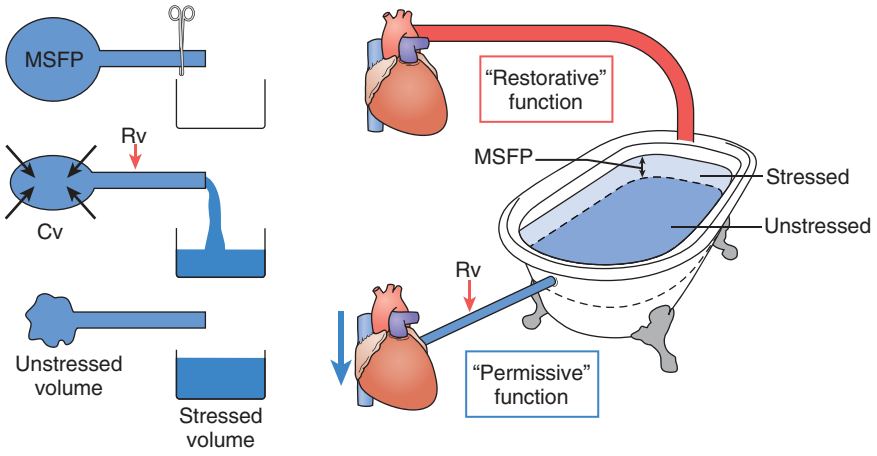

Fig. 69.2 Role of the heart and venous elastic recoil in the determination of cardiac output. The *left side* shows the principle of venous elastic recoil. In the *top part* an elastic balloon is clamped; the elastic recoil creates a pressure, which would be the equivalent of mean systemic filling pressure (*MSFP*) in veins and venules. In the *middle part*, the clamp is removed and flow occurs based on the compliance of the wall of the balloon (*Cv*) and the resistance draining it (*Rv*). The *bottom part* shows that after emptying is finished, the volume that came out is the volume that stretched the balloon (i.e., *stressed volume*), and the volume remaining in the balloon is *unstressed volume*.

The *right side* shows the equivalent of a bathtub in the veins and venules. Here the height is equivalent to MSFP and is produced by the volume (*stressed*) above the outlet on the side of the tub. The volume below the hole is *unstressed*. By lowering right atrial pressure (i.e., emptying the ventricle), the heart is permissive and allows volume to flow back to the heart. It also is (*restorative*), in that it puts the volume it got back into the circulation during systole.

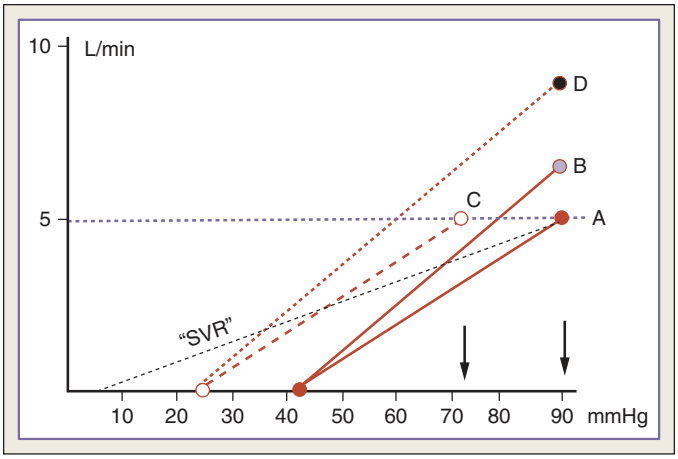

Fig. 69.3 Pressure-flow relationship of systemic arterial vasculature. The *line* labeled *SVR* (systemic vascular resistance) shows the standard line of the inverse of vascular resistance from mean arterial to Pra/CVP (right atrial pressure/central venous pressure; 5 mm Hg in this example). *A* shows what the inverse resistance line would be if there is a critical closing pressure in arterioles of 42 mm Hg; the actual resistance is much less. *B* shows the effect of a decrease in this resistance; there is a rise in flow for the same mean pressure. *C* indicates what happens if the slope of the line did not change but the critical closing pressure decreased. The same flow ***(horizontal dotted line)*** can occur with a much lower mean arterial pressure. *D* shows what happens when there is both a decrease in resistance (*the slope*) and a fall in the critical closing pressure. There is a much higher flow for the same initial mean arterial pressure.

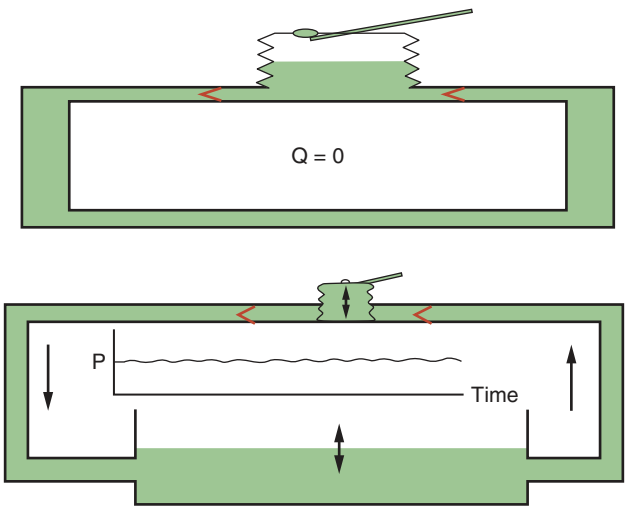

Fig. 69.4 Importance of a compliance in a closed loop system with pulsatile flow. The figure shows a circuit with a "bellows" to pump the fluid, valves to control the direction of flow, and stiff pipes. When the bellows are pumped, no flow occurs because there is no region that can transiently take up volume and pressure, which is necessary to allow the pulse to go through the system. In the *bottom part*, there is an opening that allows a change in volume with a change in height, which is the equivalent of pressure. This is the equivalent of a compliance and allows pulsatile flow (*insert* shows mild pressure waves in this very compliant region).

stressed volume—actually stretches vessel walls.[9] This means that in a 70-kg person, only about 1.3–1.4 L of a total blood volume of 5.5 L actually creates MSFP, the force that is critical for the return of blood to the heart. This needs to be considered when infusing liters of volume to increase cardiac output.

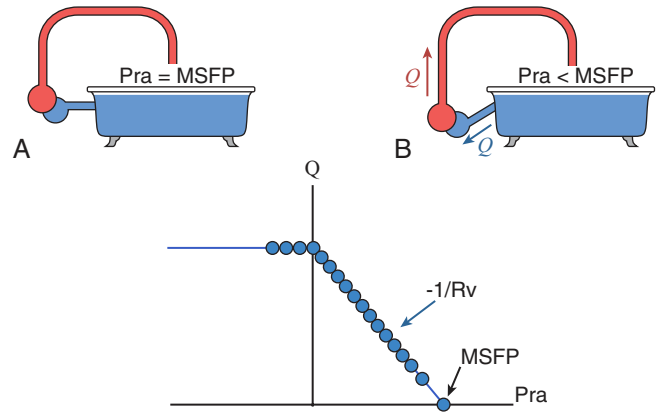

Fig. 69.5 Guyton's venous return curve. Guyton placed cardiac output (*Q*) on the *y*-axis and the right atrial pressure (*Pra*) on the *x*-axis. When Pra = mean systolic filling pressure (*MSFP*), there is no flow (*x*-intercept). The lower the Pra, the greater the flow to a maximum value that occurs when the pressure inside the great vessels is less than the pressure surrounding them (atmospheric when breathing with room air). In the collapse range, flow does not stop; it just does not increase with more negative Pra. The slope of the venous return line before the collapse is −1/venous resistance (−1/*Rv*). Q refers to flow.

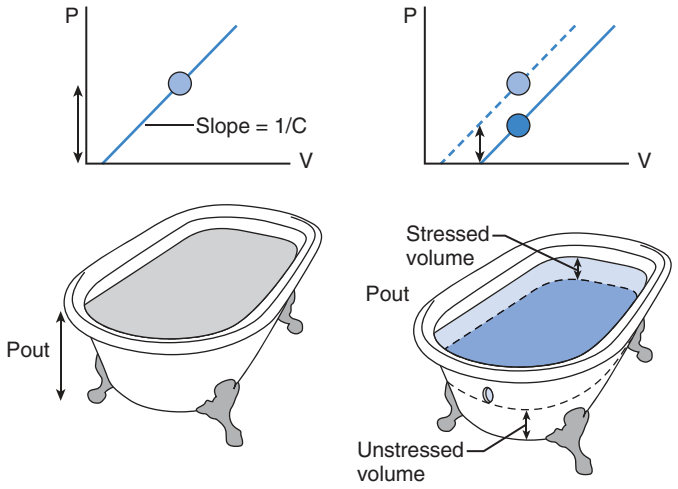

Fig. 69.6 Concept of capacitance. The *bottom part* shows a tub with the hole on the bottom and another with the hole on the side. When the hole is on the bottom, the force driving fluid out is the height of the water above the bottom (*Pout*). This is graphically shown with pressure (*P*) versus volume (*V*) in the *upper part* of the figure. When the hole is on the side, only the volume above the hole (stressed volume) generates Pout and comes out.

Cardiac Function

Output from the heart is determined by the rate of contractions (heart rate) and the amount ejected per beat (stroke volume), which in turn is determined by preload, afterload, and contractility[11] (Fig. 69.7). The fundamental role of preload was demonstrated by Otto Frank and later by Ernest Starling.[12] They appreciated that the greater the initial stretch of cardiac muscle before the onset of contraction, the greater the force produced by the muscle. Starling even correctly hypothesized that this was because stretch of muscle fibers increases overlap of chemically active sites, an insight obtained without knowing about the existence of actin and myosin in sarcomeres, which are the basis of the

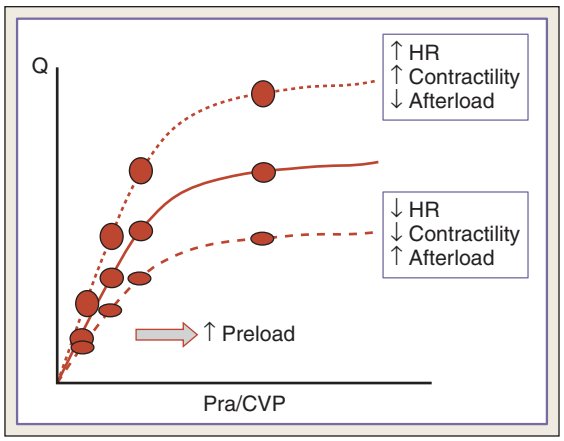

Fig. 69.7 Cardiac function curve. The plot shows the change in cardiac output (*Q*) with a change in right atrial pressure (*Pra*) or central venous pressure (*CVP*). An increase in heart rate (*HR*), contractility, or decrease in afterload move the curve upward, and the opposite actions move the curve down. Each curve is a set of outputs for a given preload with HR, contractility, and afterload constant.

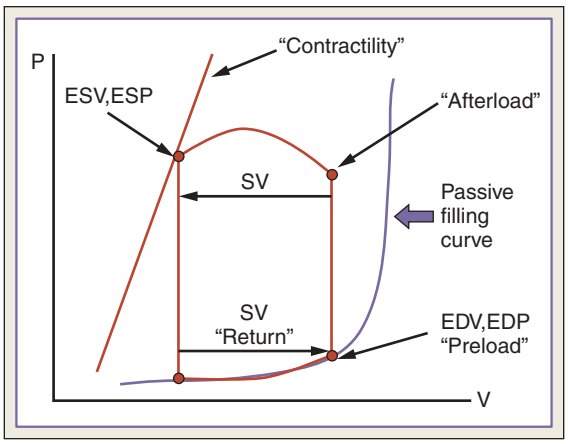

Fig. 69.8 The ventricular pressure (P) versus volume (V) plot. In diastole there is a passive filling curve which has a sharp break. Systole begins at the end-diastolic volume-pressure (V-P) point with an isovolumetric rise in pressure until the aortic valve opens ***(closed circle).*** Blood is then ejected and ventricular volume decreases until the end-systolic volume-pressure line is reached. This is at the end-systolic volume-pressure point. The outflow valve then closes, and there is isovolumetric relaxation back to the passive filling curve. The equivalents of preload, afterload, and contractility are shown. Forward stroke volume must match stroke return if all other factors are constant. ***SV,*** Stroke volume.

current sliding filament hypothesis for muscle force development.[12,13] The significance of this length-tension property is that the exact volume that fills the heart during diastole is ejected on the next beat if all other properties, which are heart rate, contractility, and afterload, stay the same. Although the initial muscle length directly determines the force of contraction and the volume emptied, preload refers to a force, so that preload should be defined as the pressure required to stretch the sarcomere at a given compliance and not by the volume. This "law of the heart" provides perfect matching of what can be called the "stroke return" to the heart and the "stroke output," or stroke volume. It also ensures that in the steady-state stroke output from the LV perfectly matches that of the RV. The importance of this can be understood by some simple calculations. If the RV pumps 100 mL per beat with a heart rate of 70 beats/min and the LV pumps 99 mL per beat—a 1% difference—and total blood volume is 5.5 L, in an hour and a half the total blood volume would be in the lungs! Thus matching of RV and LV outputs must be perfect over time. This can be a significant clinical problem when mechanical devices are used to bypass the ventricles. Unlike cardiac muscle, these devices have minimal "preload" responsiveness. If RV output is set greater than LV output, pulmonary edema rapidly develops.

Unlike skeletal muscle, cardiac muscle cannot be stretched beyond a defined limit. Thus there is a maximal end-diastolic volume and consequently maximal stroke volume. When this limit is reached, further volume loading only increases the diastolic pressure but does not increase muscle length and thus does not change stroke volume. Most often, cardiac filling is limited by the RV, which is very compliant within the range of normal diastolic volumes but has a sharp decrease in its compliance when filling becomes limited[14,15] (see Fig. 69.7). This limit to RV filling normally occurs partially because of a limit to stretch imposed by the pericardium, but also by the limit to stretch imposed by the myocardial wall. When RV filling is limited, stroke volume of the LV is also affected because the LV only can put out what the RV heart transfers to it. This RV limitation provides a protective mechanism that prevents overfilling of the LV and a consequent increase in pulmonary capillary pressures and pulmonary edema.

Ernest Starling provided a useful graphical approach to help illustrate the preload responsiveness of the heart (see Fig. 69.7). Right atrial diastolic pressure is plotted on the *x*-axis and the output of blood from the LV on the *y*-axis. (Starling actually plotted the output on the *x*-axis and Pra on the *y*-axis, but the real independent variable is Pra, which should be on the *x*-axis.[16]) This plot shows that cardiac output in response to an increase in preload rises to a maximum value; beyond that point a sharp plateau appears. No further increase in cardiac output occurs with further increases in Pra/CVP. The plot assumes that contractility, afterload, and heart rate remain unchanged. In this plot, the status of everything between the right atrium and the aortic output are included (see Fig. 69.1).

Another other way to understand function of the heart is through an analysis of the pressure-volume relationship of the ventricles (Fig. 69.8). In this analysis, there is a passive diastolic filling curve, a phase of isovolumetric contraction until the ventricular outflow valve opens, ejection of the stroke volume, then isovolumetric relaxation, followed again by the phase of passive filling. The pressure-volume plot gives a clear explanation for why the steady-state stroke volume must match stroke return. It also indicates the roles of preload, afterload, contractility, and heart rate.

Preload is the final pressure before the onset of systole and, as such, determines the final stretch of myocardium before the onset of contraction. The passive filling curve also indicates the limit to ventricular filling (Figs. 69.8 and 69.9).

Afterload refers to the force (pressure) the myocardium faces after it begins to contract. The value is approximated by the pressure at the opening of the outflow valves from the ventricles (pulmonary valve for the RV and aortic valve for the LV). The afterload really should be the generated tension, but because ventricular volume during ejection is falling while the pressure is rising, the tension is quasi-constant. The greater the afterload, the smaller the stroke volume (see Figs. 69.8 and 69.9). This restriction relates to the time available for contraction after valve opening, which will become clearer in the discussion that follows on contractility. Under normal conditions, changes in LV afterload only have a small effect on stroke volume, but the effect is much greater when contractility of the heart is decreased.

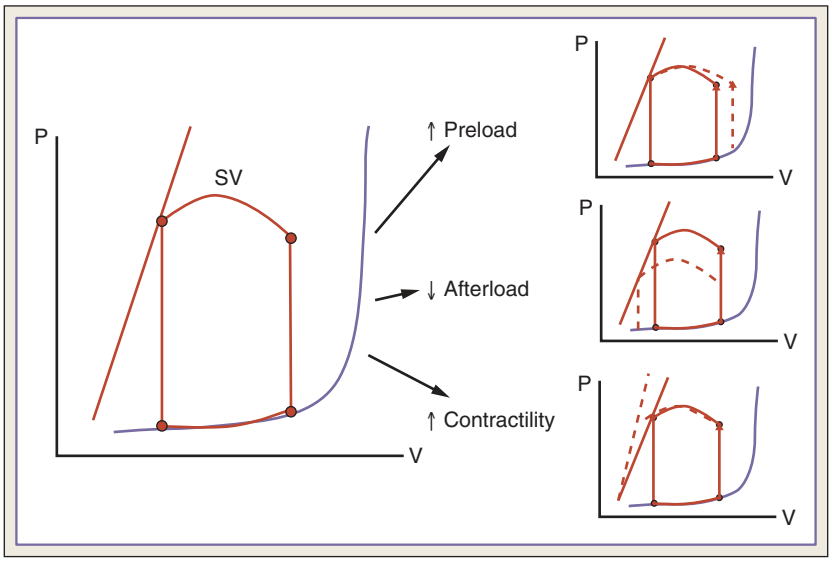

Fig. 69.9 Effects of increased preload, decreased afterload, and increased contractility on the volume (*V*)-pressure (*P*). relationship of the ventricles. All three of these increase stroke volume (*SV*).

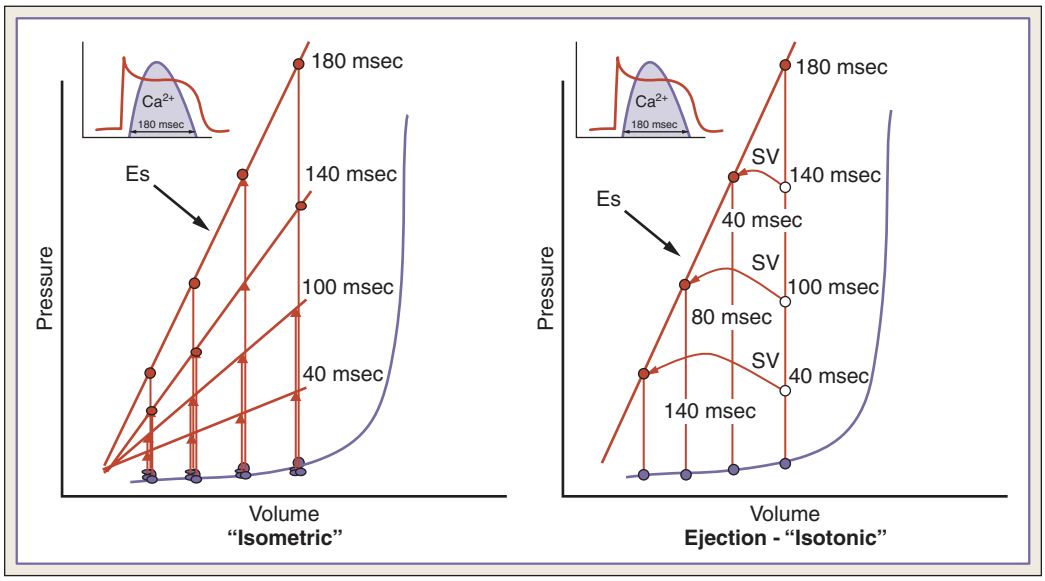

Fig. 69.10 Suga and Sagawa's concept of time-varying elastance. The slope of a line on the pressure versus volume relationship is elastance. During the contraction phase, at each instant during systole, all pressure-volume points fall on the same elastance. The numbers indicate the time during the cycle for each line. The *top insert* shows Ca^{2+} moving into the cell during the plateau of the action potential. In this case, the inflow lasts 180 msec, which is what determines the time to the maximum elastance for the cycle. The *left side* shows isovolumetric contraction (i.e., no ejection). The *right side* shows the outflow valve opening at different times. The total cycle time is still always 180 msec, but the lower the opening pressure, the more the time to eject blood, and stroke volume (*SV*) thus is larger.

The third property is contractility. This refers to the speed and extent of shorting of the muscle for a given afterload and preload. This property is best explained by what Suga and Sagawa called "a time varying elastance" (Fig. 69.10).[11,17,18] In very careful studies in isolated hearts from rabbits, they showed that the ventricular muscle becomes progressively stiffer (i.e., increases its elastance) during the contractions phase and then relaxes. On a plot of developed pressure versus ventricular volume, this appears as an elastance line that becomes steeper and steeper during the cardiac contraction cycle and then relaxes. The steepest elastance line gives the maximum possible pressure for any volume in the ventricle. The steepness of the line is determined by how quickly the muscle can stiffen in the time available for myocardial contraction. That time of contraction in turn depends on the amount of time for Ca^{2+} to be released into the cytoplasm, the amount of Ca^{2+} released, and how fast it is taken up during each cycle. These factors regulate the turnover of actin and myosin binding sites.

Depression of cardiac function means that a lower maximum elastance slope is inscribed during the cycle. The consequence is a lower stroke volume for the same preload, afterload, and heart rate. The normal end-systolic elastance slope for the LV is very steep, which is why changes in afterload only have a small effect on stroke volume in a normal heart (see Fig. 69.9). The effect of afterload on the RV, though, is much greater because the maximum elastance of the RV is only about a third of that of the LV. The lesser slope of the elastance line of the RV accounts for the systolic pressure sensitivity of this ventricle.

Another factor that is considered by some to be a determinant of cardiac output is aortic elastance.[19] This value is estimated from a line drawn from its end-diastolic volume and pressure point to the end-systolic volume-pressure point. It thus incorporates stroke volume and the pressure generated in the aorta at the end of systole; the change in pressure for change in volume gives elastance units. However, this is simply a reflection of ventricular afterload, which is already considered in the pressure-volume analysis of the ventricle and is likely better estimated by aortic valve opening. Based on Sagawa's concept of a time-varying elastance, the pressure generated in the aorta or pulmonary artery by ventricular ejection can never be higher than the pressure generated by the ventricle so that the aortic properties do not provide a load but do affect aortic valve opening. Furthermore, what is being called aortic elastance is a dynamic elastance and is dominated by vascular resistance and the downstream critical closing pressure. Finally, active LV ejection ends in the middle to two-thirds of systole so that the ventricle is relaxing before the end-systolic pressure-volume point. The aortic elastance analysis therefore adds little information to the simple consideration that aortic valve opening gives an estimate of LV coupling with the aorta, and this is easily seen at the end-diastolic pressure.

Right Ventricular Limitation Versus Dysfunction

In critically ill patients, RV output is frequently the limiting factor for cardiac output. This is especially so in patients with sepsis and in those who are post cardiac surgery. Three terms need to be distinguished. If a normal RV with normal end-systolic elastance is excessively filled, RV output becomes limited by the diastolic passive filling curve. Giving more volume will not increase LV output, but this is not failure of the RV. It is rather the physical limitation of its filling. When RV dysfunction is present, the end-systolic pressure-volume line is flatter and Pra/CVP must be greater for a given stroke volume, but if RV filling is not limited, stroke volume still can increase when there is an increase in venous return, allowing the LV stroke volume also to rise. When RV dysfunction is present, the limit of RV filling occurs at a lower Pra so that stroke volume is constrained to a lower range. The term *RV failure* should be used to indicate that there is both RV dysfunction and RV limitation so that the RV cannot provide adequate filling to the LV. It needs to be remembered that even if there is complete failure of RV contraction, Pra/CVP can never be higher than MSFP so that a high Pra/CVP only can occur by excessive volume administration and an MSFP that rises above normal values.

INTERSECTION OF RETURN AND CARDIAC FUNCTION

Actual cardiac output is determined by the interaction of the cardiac function and the return function. This is well described by Guyton's graphical analysis, which provides a mathematical solution to the interaction of these two functions (Fig. 69.11). Because the cardiac function

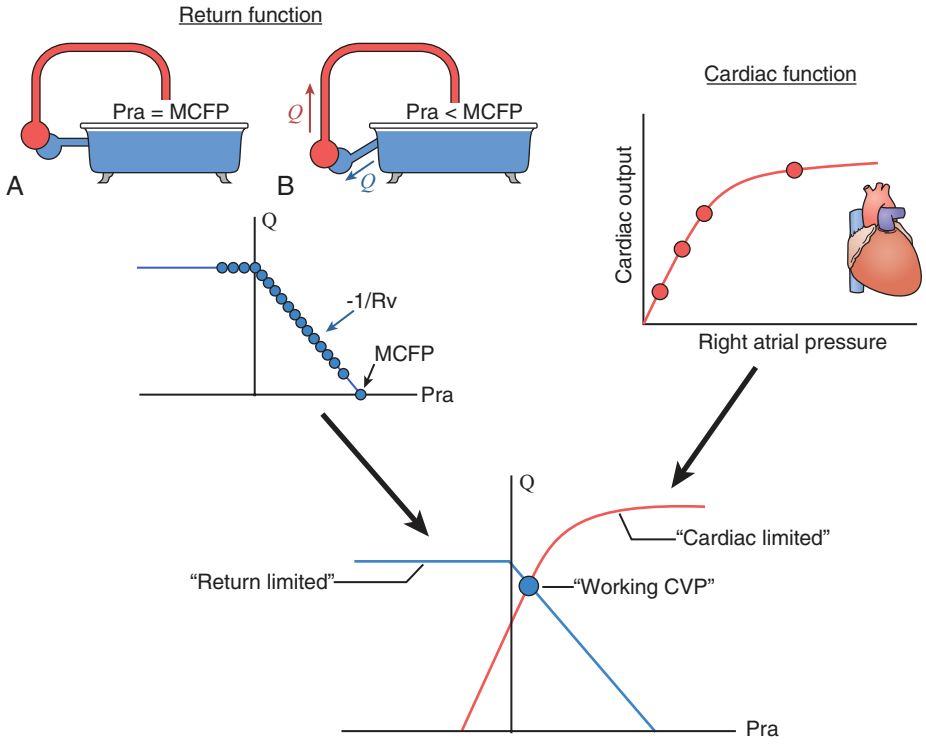

Fig. 69.11 Interaction of the cardiac function and venous return curves and the determination of cardiac output (*Q*). The *upper left* part shows the return curve, and the *upper right* part shows cardiac function. The two have the same axis so that they can be plotted together. This allows a graphical solution to determining the intersection of the two functions and the determination of the "working" cardiac output, "working" Pra/CVP, and "working" venous return. *CVP*, Central venous pressure; *MSVP*, mean systolic filling pressure; *PRa*, right atrial pressure; *Rv*, venous resistance.

and venous return curves share the same vertical axis, they can be plotted together (see Fig. 69.11). Where they intersect gives the "working" cardiac output, Pra, and venous return. With this analysis, respective changes in Pra/CVP and cardiac output indicate whether the process is the result of a primary change in cardiac function or in the return function.

Changes in Return Function

Role of Volume

One of the most common interventions in critically ill patients is the administration of a bolus of a fluid intended to increase cardiac output and arterial pressure, but this often is done without consideration of what volume can and cannot do. As in equation 1, a rise in blood pressure with a volume infusion must occur by increasing cardiac output because a volume infusion should not increase systemic vascular resistance. Any rise in cardiac output occurs by increasing MSFP and shifting the venous return curve to the right. This results in the venous return curve intersecting the cardiac function curve at a higher Pra/CVP and cardiac output. However, there are important caveats to seeking this response (Fig. 69.12). As already discussed (see Figs. 69.7 and 69.11), the cardiac function curve has a steep rise and a sharp plateau. When the VR curve intersects the plateau of the cardiac function curve, further increases in Pra/CVP do not change cardiac output and only provide "wasted preload": that is, a rise in Pra/CVP with no change in cardiac output. Without an increase in cardiac output, there should be no change in blood pressure, and the only physiologic accomplishment is increased fluid filtration at the capillary level and consequent congestion of upstream organs and dilution of the hemoglobin concentration. It also needs to be emphasized that the ascending part of the cardiac function curve (see Fig. 69.7) is steep, so that even a 1 mm Hg increase in CVP should produce close to a 0.5 L/min increase in cardiac output and 2 mm Hg rise in Pra—a 1 L/min increase. Thus if Pra/CVP is increased by 2 mm Hg with a volume bolus and cardiac output does not increase, more volume is not the clinical answer and is only harmful. As a last point, cardiac output frequently rises without a change in blood pressure, especially when the systolic pressure exceeds 100 mm Hg. This likely occurs because the baroreceptors have become reset at a lower threshold so that the rise in arterial pressure produces peripheral dilatation to maintain a constant arterial pressure. It can be shown in modeling studies that the maintenance of blood pressure allows for a larger increase in cardiac output because there is no associated increase in afterload to offset the increase in stroke volume.

There is an intrinsic mechanism for increasing stressed volume, and that control is to change capacitance (Figs. 69.6 and 69.13). A baroreceptor-induced activation of sympathetic pathways can contract the smooth muscle in the walls of small venules and veins, especially in the splanchnic region. This recruits unstressed volume into the stressed vascular volume, which is called a *decrease in capacitance.* A strong sympathetic response by this mechanism can recruit 10 mL/kg of unstressed volume into the stressed compartment. To put this into better perspective, in a 70-kg male this transfer would increase a stressed volume of 1400 mL by 700 mL:, a 50% increase, and this occurs in seconds because it is a reflex response. To do the equivalent with an infusion of a crystalloid would require over 2 L of fluid because of the distribution of the fluid between the vascular space and interstitial space. Capacitance also can be decreased by alpha-agonists such as norepinephrine. The importance of capacitance is that administration of alpha-adrenergic blocking drugs or narcotics removes this venous tone and can result in a rapid increase in capacitance, fall in MSFP, and fall in cardiac output. The clinical response should then be to give a volume bolus. Importantly, vascular smooth muscle only can constrict the vessel to some limit. When that limit is reached, this mechanism cannot be used by the body to defend its stroke volume. Furthermore, whenever MSFP is increased, it is likely that there also is increased capillary filtration and loss of vascular volume.

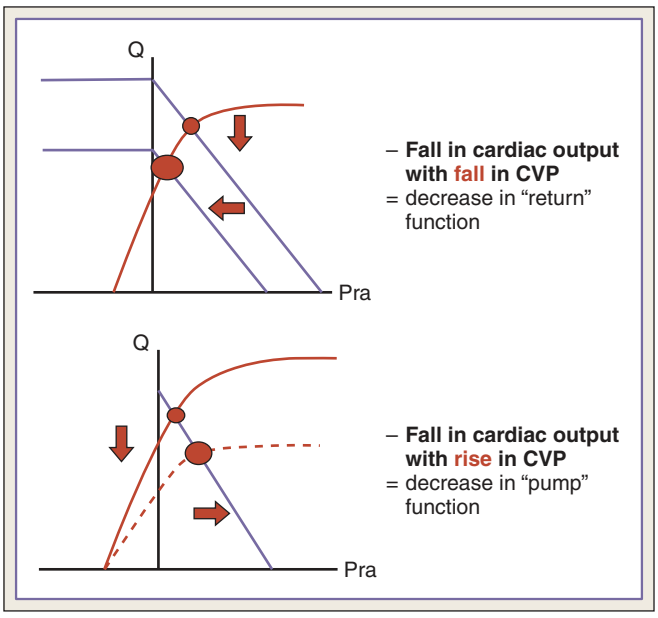

Fig. 69.12 Comparison of a change in cardiac function versus change in return function on cardiac output (*Q*) and right atrial pressure (*Pra*). When cardiac function changes, the change in cardiac output and Pra/CVP go in opposite directions. When the venous return function changes, the changes in cardiac output and Pra/CVP go in the same direction. *CVP*, Central venous pressure; Q, cardiac output.

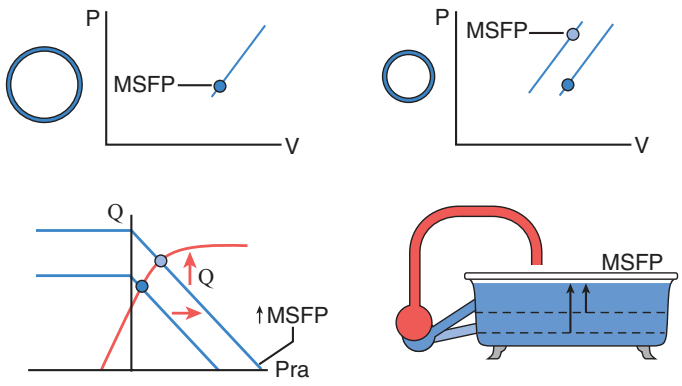

Fig. 69.13 Effect of a decrease in capacitance on cardiac output (*Q*). The *bottom right* is a cartoon of the major vascular components. A change in capacitance is the equivalent of lowering the opening on the side of the tub, which means mean systolic filling pressure (*MSVP*) is increased. The *upper left* shows the pressure vs. volume relationship (*P-V*) of the vasculature. The *upper right* shows a decrease in capacitance in a vessel, which occurs if the circumference is reduced (note *reduced circle*). This produces a leftward shift of the P-V line and rise in MSFP for the same volume. The *bottom left* is the venous return–cardiac function relationship. A decrease in capacitance shifts the venous return curve to the right, which intersects the cardiac function curve at a higher value and thus increases cardiac output (1) by the Starling mechanism. *PRa*, Right atrial pressure.

Venous Resistance

The pressure gradient from the MSFP to the right atrium normally is only in the 4–8 mm Hg range because venous resistance is low, but it still is physiologically significant. A decrease in venous resistance can increase cardiac output because the VR curve then intersects the cardiac function curve at a higher Pra/CVP. This likely is a factor in the high-cardiac-output states of early sepsis and liver disease. However, as with a rise in MSFP and rightward shift of the VR curve, this only is effective if the VR curve intersects the ascending part of the cardiac function curve.

Change in Cardiac Function

When cardiac function changes, changes in Pra/CVP and cardiac output occur in opposite directions. For example, better cardiac function is associated with a fall in Pra/CVP and a rise in cardiac output (see Fig. 69.12). Large increases in cardiac output under physiologic conditions, such as during exercise, primarily occur by heart rate increasing. The associated upward shift of the cardiac function curve with an increase in heart rate makes the heart much more "preload sensitive" because the ascending part of the cardiac function curve is much steeper and the plateau higher. In a normal heart, any increase in contractility, as characterized by a steeper end-systolic elastance curve, only mildly increases cardiac output (see Fig. 69.9). This underwhelming response takes place because the end-systolic pressure-volume line is already very steep, and making it steeper adds little to the stroke volume. However, if cardiac contractility is depressed, as in a patient who is septic or has another cause of depressed contractility, the effect of an inotrope can be marked.

In most shock states the blood pressure, and thus the afterload, is already low and little is gained by lowering systemic vascular resistance further; more often, clinicians try to increase resistance. However, some patients with cardiogenic shock present with an elevated systemic vascular resistance. In these patients carefully lowering vascular resistance with a drug such as nitroprusside can be helpful. This also argues for not raising arterial pressure more than is physiologically necessary in cardiogenic shock because the rise in arterial pressure decreases stroke volume to a greater extent when contractility is depressed.

PHYSIOLOGICALLY BASED APPROACH AT THE BEDSIDE

A good place to start is with the consideration that arterial pressure is determined by the product of cardiac output and the systemic vascular resistance (Fig. 69.14). Because a decrease in blood pressure triggered the clinical concern and systemic vascular resistance is a calculated value, the first key variable to evaluate is cardiac output. If the cardiac output is normal or elevated, the primary pathologic process is a fall in systemic vascular resistance. Unfortunately, most of the time it is not easy to directly measure cardiac output, but it is still possible to make a clinical judgment of the cardiac output status based on peripheral temperature, lactate, central venous saturation, organ function, and clinical context. However, when the situation is critical and the assessment of cardiac output uncertain, some measure of cardiac output is advantageous. It is important to appreciate that ejection fraction does indicate stroke volume or cardiac output, the variables that count. Thus if using echocardiography, a flow measurement may also be necessary. If the problem is deemed to be primarily a decrease in systemic vascular resistance, that is, distributive shock, the differential diagnosis is very clear and is listed in Box 69.1. The primary therapy then is to restore peripheral resistance, and for that, norepinephrine is an appropriate drug. The assumption is that the increased systolic pressure will result in a more normal distribution of blood flow by local metabolic regulation. Some increase in cardiac output can be helpful, too, but when this is done by trying to increase preload with fluids, it must be remembered that fluid loading is also likely to increase capillary leak.

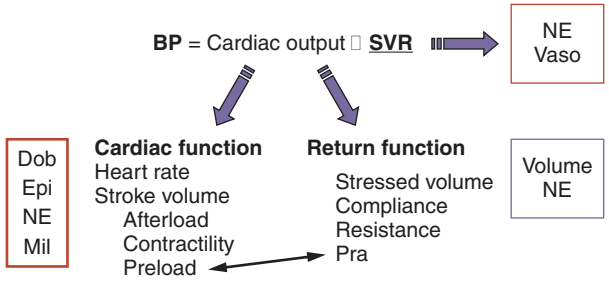

Fig. 69.14 Approach to managing shock. See text for details. ***BP,*** Blood pressure; ***Dob,*** dobutamine; ***Epi,*** epinephrine; ***Mil,*** milrinone; ***NE,*** norepinephrine; ***SVR,*** systemic vascular resistance; ***Vaso,*** vasopressin.

If a decrease in the cardiac output is considered the primary problem, it next needs to be determined whether the inadequate cardiac output is the result of decreased pump function or decreased return function (see Fig. 69.14). The Pra/CVP and clinical context give an indication of which it is. If the Pra/CVP is on the high side with a low cardiac output, the primary problem is depressed cardiac function, and inotropic therapy with dobutamine, epinephrine, or milrinone is indicated. It also is important to make sure that a low heart rate is not part of the problem. If Pra/CVP is on the low side, the return function is likely the primary problem and volume boluses are appropriate. In sepsis, norepinephrine also can be helpful because it constricts capacitance vessels and thereby recruits unstressed into stressed volume and acts like a volume infusion without giving volume.[20] Furthermore, norepinephrine does not increase venous resistance and may even decrease it, and it has a modest inotropic effect on the heart.

In this discussion only the Pra/CVP and not the pulmonary artery occlusion pressure has been used to assess preload status, even when the pulmonary occlusion pressure can be measured. This choice is made because Pra/CVP indicates the interaction of the heart as a whole with the venous return function.[21] Concentrating on Pra/CVP is especially important when cardiac limitation occurs at the right heart because once there is RV limitation, filling of the left heart is not a variable that can be manipulated to improve cardiac output. If a pulmonary artery occlusion pressure can be obtained, that value can be a useful indicator of the risk of pulmonary edema and can be used to modify fluid therapy, or even encourage diuresis, but a low value may prove a flawed indication for giving volume.

It is not within the scope of this chapter to delve into the heart-lung interactions of shock, but one important physiologic concern must be

BOX 69.1 Causes of a Distributive Vascular State

- Sepsis
- Drugs (vasodilators)
  - Milrinone
  - Nitroprusside
  - Hydralazine
- Arterial-venous shunts
- Spinal/epidural anesthetics
- Spinal injury
- Cirrhosis
- Thyroid disease (hyperthyroidism)
- Anaphylaxis
- Corticosteroid deficiency
- Anemia (severe, long-standing)
- Beriberi (thiamine, B_1) deficiency

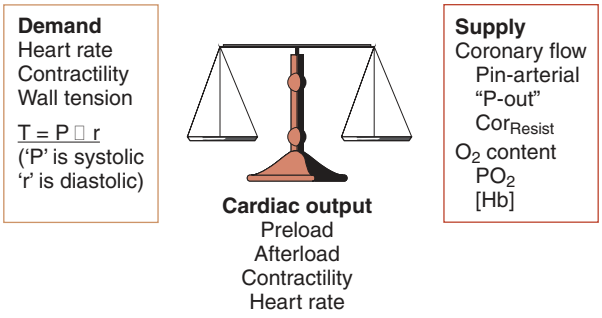

Fig. 69.15 Supply-demand balance of the heart. The *left side* shows the determinants of myocardial oxygen demand, and the *right side* shows the determinants of the supply of blood through the coronary circulation. The *middle* shows the determinants of cardiac function; these overlap with the demand factors. *T* is tension; *P* is systolic pressure; *r* is the ventricular radius; *Pin* is the arterial pressure perfusing the coronary arteries; *P-out* is the outflow pressure, which is a critical closing pressure in the myocardial wall; Cor_{Resist} is the coronary vascular resistance; and *[Hb]* is hemoglobin concentration.

highlighted. When RV limitation is present and there is "wasted preload," application of a mode of positive-pressure ventilation can decompress the heart by shifting the intersection of cardiac function and venous return function. Because the person's right heart likely is on the flat part of its function curve, lowering Pra/CVP will not decrease cardiac output. The decrease in transmural Pra/CVP may improve left-sided filling pressure. Ventricular decompression also may improve coronary flow.

SUPPLY–DEMAND CONSIDERATIONS

The heart has high aerobic demands and minimal anaerobic reserves. Thus demand for O_2 must be closely matched by the delivery of O_2. The major determinants of cardiac O_2 demand are heart rate, contractility, and ventricular wall tension[22] (Fig. 69.15). Wall tension is determined by the systolic pressure and the ventricular radius. Therefore it should be evident that the determinants of myocardial O_2 demand overlap with the determinants of cardiac function, which are heart rate, preload, afterload, and contractility. An increase in heart rate, rate of rise of systolic pressure, peak systolic pressure, or ventricular diameter all increase myocardial O_2 demand. Delivery of O_2 to the heart is determined by the hemoglobin concentration, arterial O_2 saturation, the pressure difference from the aorta to the myocardial wall, and the coronary vascular resistance. When coronary vessels are normal, coronary vasodilatory reserves are very large; blood flow to heart can increase fivefold from resting heart rates to the maximum.[23] However, this is not true when there are proximal coronary artery stenoses. In that situation the adverse impact of raising heart rate or arterial pressure needs to be considered. The effect of inotropes is complicated. The increase in contractility and heart rate increase myocardial O_2 demand, but this can be offset by reducing the ventricular radius, which acts to reduce wall stress. The inotrope may increase a very low arterial pressure because of inadequate cardiac output, but in the setting of coronary narrowing it also will improve coronary perfusion, potentially improving contractile function. On the other hand, use of high doses of vasoconstrictor drugs may override local metabolic dilatation in heart muscle and decrease coronary perfusion while increasing myocardial O_2 demand. Thus any interventions made in patients with obstructive coronary disease must be done with careful monitoring and consideration of all positive and negative consequences.

CONCLUSION

In the Guytonian universe it always is necessary to consider the effects of the underlying processes and treatments on cardiac function and return function. Directional changes in cardiac output and Pra/CVP give an indication of how these two functions are behaving. When managing cardiogenic shock, it is best to start by considering whether the problem is primarily distributive—that is a decrease in vascular resistance—or primarily inadequate cardiac output. If it is primarily inadequate cardiac output, the question becomes is the problem primarily with cardiac function or the return function. The directional changes in cardiac output and Pra/CVP give the answer in a physiologically based approach to shock.

KEY POINTS

- The four determinants of cardiac function are heart rate, preload, afterload, and contractility.
- The determinants of venous return are stressed volume, compliance of the systemic venous compartment, resistance to venous return, and right atrial pressure.
- The volume stretching the systemic veins creates the MSFP.
- The working cardiac output is determined by the intersection of cardiac function and return function.
- The heart only can pump out what comes back to it—in the steady state, stroke volume must equal stroke return.
- Stroke output by the ventricles is constrained by the limit of diastolic filling, and usually this occurs in the right heart.
- Venous return becomes limited when the pressure inside the great veins is less than their surrounding pressure; this is atmospheric pressure when not intubated.
- Normally only about 30% of blood volume is stressed, and it is this stressed volume that creates the force returning blood to the heart.
- Unstressed vascular volume can be recruited into stressed volume by reflex or alpha-adrenergic drugs; this is called a decrease in vascular capacitance.
- Capacitance can be increased by drugs that reduce sympathetic tone, MSFP, and the venous return function.
- Capacitance cannot be measured in an intact person and only can be estimated clinically.
- The determinants of myocardial oxygen demand include heart rate, wall tension (which is determined by the ventricular radius and systolic pressure), and contractility; these same variables are key determinants of cardiac function.

Acute Coronary Syndromes: Therapy

Brian Baturin and Steven M. Hollenberg

DEFINITION AND CLINICAL MANIFESTATIONS

Acute coronary syndromes are a family of disorders that share similar pathogenic mechanisms and represent different points along a common continuum. They include ST elevation myocardial infarction (STEMI), non–ST segment elevation acute coronary syndrome (NSTE-ACS), and unstable angina (UA) pectoris. These syndromes account for nearly 2 million hospitalizations annually in the United States, and if patients who die before reaching the hospital are included, the mortality may be as high as 25%. The common link among the various acute coronary syndromes is the rupture of a vulnerable, but previously quiescent, coronary atherosclerotic plaque. Exposure of plaque contents to the circulating blood pool triggers the release of vasoactive substances and activation of platelets and the coagulation cascade. The extent of resultant platelet aggregation, thrombosis, vasoconstriction, and microembolization dictates the clinical manifestations of the syndrome.

Acute coronary syndromes were traditionally classified by the presence or absence of Q waves, but more recently the classification has shifted and has become based on the initial electrocardiogram (ECG). Patients are divided into three groups: (1) those with STEMI, (2) those without ST elevation but with enzyme evidence of myocardial damage (NSTE-ACS), and (3) those with UA. Classification according to a presenting ECG coincides with current treatment strategies because patients presenting with ST elevation benefit from immediate reperfusion and should be treated with fibrinolytic therapy or urgent revascularization. In contrast, fibrinolytic agents are not effective in patients without ST elevation.

PATHOPHYSIOLOGY OF ACUTE CORONARY SYNDROMES

Myocardial ischemia results from an imbalance between oxygen supply and demand and usually develops in the setting of obstructive atherosclerotic coronary artery disease, which limits blood supply. The pathophysiology of unstable coronary syndromes and myocardial infarction (MI) usually involves dynamic partial or complete occlusion of an epicardial coronary artery because of acute intracoronary thrombus formation.

The inciting event underlying the development of acute coronary syndromes is the rupture of an intracoronary atherosclerotic plaque.[1] The possible sequelae of plaque rupture include thrombus formation with a total occlusion resulting in STEMI, or dissolution of the thrombus, healing of the fissure, and clinical stabilization with subtotal occlusion, which can lead to either NSTE-ACS or UA.

Atherosclerotic plaques are composed of a lipid core, which includes cholesterol, oxidized low-density lipoproteins (LDLs), macrophages, and smooth muscle cells, covered by a fibrous cap. Plaque rupture occurs when external mechanical forces exceed the tensile strength of the fibrous cap. After plaque rupture, the clinical consequences depend largely on the balance between prothrombotic and antithrombotic forces.[2,3] The lipid core contains tissue factor and other thrombogenic materials that lead to platelet activation and aggregation. Fibrinolytic factors, such as tissue plasminogen activator, prostacyclin, and nitric oxide, act to counteract the potential for thrombosis. A major factor in the outcome of plaque rupture is blood flow. With subtotal occlusion, high-grade stenosis, or vasospasm, thrombus begins to propagate downstream in the arterial lumen. In contrast to the initial thrombi that are platelet rich, these thrombi contain large numbers of red cells enmeshed in a web of fibrin. The former would be expected to respond best to antiplatelet therapy and the latter to antithrombotic and fibrinolytic therapy.

STEMI

Epidemiology

STEMI comprises approximately 25%–40% of ACS presentations, although more recent data show a decline in the percentage of ACS caused by STEMI between 1999 and 2008.[4,5] In-hospital mortality and 1-year mortality rates from STEMI have decreased significantly with improvements in reperfusion therapy and guideline-directed medical therapy (GDMT); current in-hospital mortality can be as low as 4%–6%, and 1-year mortality ranges from 7% to 18%.[6,7] Nonetheless, not all eligible patients with STEMI receive reperfusion therapy; registry data from 2017 estimated an overall early ECG miss rate of 7%, with the majority of those patients being elderly, and variability up to 30% between multiple large-volume emergency departments.[8]

Women, people with diabetes, and patients with renal disease appear to have worse outcomes when presenting with STEMI. Approximately 23% of patients with STEMI in the United States have diabetes mellitus, and three-fourths of all deaths among patients with diabetes mellitus are related to coronary artery disease. Patients with chronic renal disease, particularly those on dialysis, are less likely to receive GDMT; only 45% of eligible patients on dialysis received reperfusion therapy, and only 70% received aspirin on admission. At discharge, only 67% of patients on dialysis were prescribed aspirin, and only 57% were prescribed beta-blockers.[7,9] Women and patients on dialysis tend to have higher bleeding complications associated with antithrombotic therapy.[9,10]

Diagnosis and Treatment of STEMI

Symptoms suggestive of MI may be similar to those of ordinary angina but are typically greater in intensity and duration. Nausea, vomiting, and diaphoresis may be prominent features, and malaise and even

stupor attributable to low cardiac output can occur. Compromised left ventricular function may result in pulmonary edema with the development of pulmonary bibasilar crackles and jugular venous distention; a fourth heart sound can be present with small infarcts or even mild ischemia, but a third heart sound is usually indicative of more extensive damage.

A consensus group to standardize the definition of MI defines the changes diagnostic of STEMI as new ST elevation at the J-point ≥1 mm (0.1 mV) in at least two contiguous leads, except leads V_2–V_3, where the threshold is higher (≥1.5 mm in women and ≥2 mm in men) or new left bundle branch block (LBBB).[10,11] The specificity of new LBBB has been challenged by a multicenter, longitudinal study published in which 4% of patients presenting with possible ACS had an LBBB presumed to be new, and of these, only 39% were diagnosed with ACS.[12] Similar findings have been reported elsewhere.[13] In the GUSTO-1 trial, of the 26,003 North American patients presenting with possible ACS, 131 (0.5%) with confirmed acute MI had an LBBB.[14] A new or presumed new LBBB should not be considered diagnostic of acute MI in isolation, but when the clinical presentation strongly suggests ACS, and especially when shock is present, LBBB should be regarded as a STEMI equivalent.

Patients presenting with suspected myocardial ischemia should undergo a rapid evaluation, continuous monitoring, and reassessment. (See Fig. 70.1 for an algorithm for the initial evaluation and management of STEMI). The 2013 American College of Cardiology Foundation/American Heart Association (ACCF/AHA) Guidelines for the Management of ST-Elevation Myocardial Infarction emphasize the importance of choosing some type of reperfusion therapy as soon as possible when appropriate. In addition to antiplatelet therapy, an early decision to perform percutaneous coronary intervention (PCI), transfer to a PCI-capable facility, or administer fibrinolytic therapy should be made. The timeliness of reperfusion is as important as the choice of therapy.[15]

The preferred method for reperfusion in STEMI is PCI if it can be done in a timely manner, defined as the time from first medical contact (FMC) to device of less than 90 minutes. Emergency medical services (EMS) transport directly to a PCI-capable hospital for primary PCI is the recommended triage strategy for patients with STEMI.[9] If a patient initially presents to a non–PCI-capable hospital and door in–door out time is anticipated to be less than 30 minutes, transfer to a PCI-capable hospital should be arranged if the FMC to device time is anticipated to be less than or equal to 120 minutes. If the FMC to device time is longer than 120 minutes, fibrinolytics should be considered, with probable transfer to a PCI-capable facility after fibrinolytic therapy for STEMI.[9] Practical considerations regarding transport to a PCI-capable facility should be reviewed carefully before foregoing fibrinolytics for PCI.

Fibrinolytic Therapy

Evidence from multiple clinical trials demonstrates the ability of fibrinolytic agents administered early in the course of an acute MI to reduce infarct size, preserve left ventricular function, and reduce

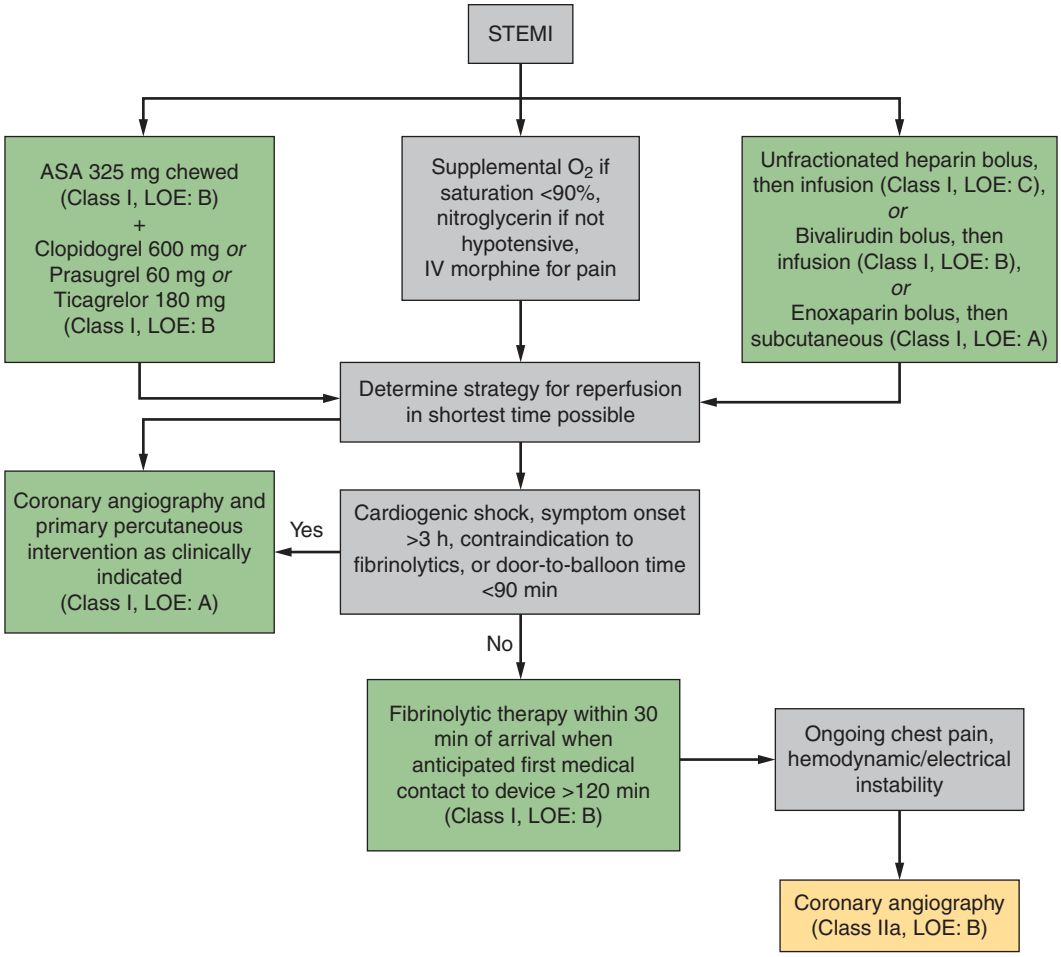

Fig. 70.1 Algorithm for the initial management of patients with ST elevation myocardial infarction (*STEMI*). *ASA*, Acetyl salicylic acid; *IV*, intravenous; *LOE*, level of evidence.

Box 70.1 Indications for and Contraindications to Fibrinolytic Therapy in ST Elevation Myocardial Infarction

Indications for Fibrinolytic Therapy When There Is a >120-Minute Delay From First Medical Contact to Primary Percutaneous Coronary Intervention

- Presentation within 12 hours of symptom onset (COR 1, LOE A)
- Evidence of ongoing ischemia 12–24 hours after symptom onset and a large area of myocardium at risk or hemodynamic instability (COR IIa, LOE C)
- Fibrinolytics are contraindicated for the treatment of ST depression (non–ST elevation acute coronary syndrome), except if true posterior myocardial infarction or when associated with ST elevation in lead aVR (COR III, LOE B)

Contraindications

Absolute

- Any prior intracranial hemorrhage
- Known structural cerebral vascular lesion (e.g., arteriovenous malformation)
- Known malignant intracranial neoplasm (primary or metastatic)
- Ischemic stroke within 3 months (EXCEPT acute ischemic stroke within 4.5 hours)
- Suspected aortic dissection
- Active bleeding or bleeding diathesis (excluding menses)
- Significant closed-head or facial trauma within 3 months
- Intracranial or intraspinal surgery within 2 months
- Severe uncontrolled hypertension (unresponsive to emergency therapy)
- For streptokinase, prior treatment within the previous 6 months

Relative

- History of chronic, severe, poorly controlled hypertension
- Significant hypertension on presentation (SBP >180 mm Hg or DBP >110 mm Hg)
- History of prior ischemic stroke >3 months
- Dementia
- Known intracranial pathology not covered in absolute contraindications
- Traumatic or prolonged (>10 minutes) cardiopulmonary resuscitation
- Major surgery (<3 weeks)
- Recent (within 2–4 weeks) internal bleeding
- Noncompressible vascular punctures
- Pregnancy
- Active peptic ulcer
- Oral anticoagulant therapy

COR, Class of recommendation; *DBP,* diastolic blood pressure; *LOE,* level of evidence; *SBP,* systolic blood pressure.

short-term and long-term mortality.[16–18] Patients treated early derive the most benefit.[18]

Indications for and contraindications to fibrinolytic therapy are listed in Box 70.1. Because of the small, but nonetheless significant, risk of bleeding complications (most notably, intracranial hemorrhage, which occurs in 0.7%–1.8% of high-risk patients treated with fibrinolytics), the selection of patients with acute MI for the administration of a fibrinolytic agent should be undertaken with prudence and caution.[19] This is of special importance in intensive care unit (ICU) patients, who may have a predisposition to bleeding complications because of multiple factors. In this setting, emergent coronary angiography (with PCI as clinically indicated) is usually preferable.

Commonly administered fibrinolytics include the fibrin-specific agents tenecteplase, reteplase, and alteplase; the non–fibrin-specific agent streptokinase is infrequently used. After the administration of fibrinolytics for STEMI, the patient should be monitored for signs and symptoms of adequate reperfusion, as indicated by relief of symptoms and/or hemodynamic/electrical instability coupled with resolution of the highest initial ST elevation (preferably 50%, but at least some).[20] Complete (or near-complete) ST segment resolution at 60 or 90 minutes after fibrinolytic therapy is a useful marker of a patent infarct artery.[21–23] If signs of adequate reperfusion are not evident within 90 minutes ("failed fibrinolysis"), patients should be urgently transferred to a PCI-capable facility with intent to perform rescue PCI.[9] In patients with clinically successful fibrinolysis, trial data suggest that death, recurrent MI, recurrent ischemia, new or worsening heart failure (HF), or shock at 30 days is reduced with routine angiography compared with patients who underwent an ischemia-guided approach, with the greatest benefit in high-risk patients.[24–27]As such, in centers without angiographic capability, transfer to a PCI-capable facility after fibrinolytic therapy is recommended.

Patients with STEMI and signs of shock or severe HF should be immediately transferred to a PCI-capable facility irrespective of when the MI occurred or when fibrinolytics were given.[28]

In contrast to the treatment of STEMI, fibrinolytics have shown no benefit and an increased risk of adverse events when used for the treatment of NSTE-ACS or UA.[29] Based on these findings, there is currently no role for fibrinolytic agents in these latter syndromes.

Primary PCI in Acute Myocardial Infarction

The major advantages of primary PCI over fibrinolytic therapy include a higher infarct artery patency with a higher rate of normal flow, lower rates of recurrent ischemia, reinfarction, the need for emergency repeat revascularization, and a lower risk of intracranial hemorrhage.[17,30] Placement of drug-eluting stents is now routine.[31,32] Coronary angiography also affords the ability to stratify risk based on the severity and distribution of coronary artery disease. Data from several randomized trials have indicated that PCI is preferable to fibrinolytic therapy for acute MI patients at a higher risk.[30]

Achieving reperfusion in a timely manner correlates with improvement in the infarct size, left ventricular function, and survival.[20,33] The ultimate goal is to restore adequate blood flow through the infarct-related artery to the infarct zone and to limit microvascular damage and reperfusion injury. The latter is accomplished with adjunctive and ancillary treatments that are discussed later.

Previous clinical practice guidelines recommended against PCI of non–culprit artery stenoses at the time of primary PCI in patients with STEMI. Recent randomized controlled trials since this recommendation have demonstrated that multivessel PCI at the time of culprit artery PCI or as a staged procedure may be safe and beneficial. The largest of these trials was the COMPLETE study, which demonstrated a significant decrease in a composite outcome of cardiovascular (CV) death or MI in those patients with complete revascularization.[34] Given these findings, PCI of a non-culprit vessel may be considered either at the time of primary PCI or as a staged procedure in patients presenting with a STEMI.[34,35] In patients with cardiogenic shock, however, multivessel PCI was not shown to be effective, and so this is not recommended in this setting.[36]

Coronary Artery Bypass Graft Surgery in Patients With STEMI

Subsets of patients who present with STEMI are better served with coronary artery bypass graft (CABG) surgery. Patients with failed PCI

TABLE 70.1 Timing of Urgent Coronary Artery Bypass in Patients With ST Elevation Myocardial Infarction in Relation to the Use of Antiplatelet Agents

Drug	Recommendation	COR	LOE
Aspirin	Aspirin should not be withheld before urgent CABG	I	C
Clopidogrel or ticagrelor	Discontinue at least 24 hours before urgent on-pump CABG	I	B
Eptifibatide or tirofiban	Discontinue at least 2 to 4 hours before urgent CABG	I	B
Abciximab	Discontinue at least 12 hours before urgent CABG	I	B

CABG, Coronary artery bypass grafting; *COR,* class of recommendation; *LOE,* level of evidence.
Adapted from O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guidelines for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2013;127:e362–e425.

or whose coronary anatomy is not amenable to PCI but who have ongoing symptoms of ischemia, cardiogenic shock, severe HF, or other high-risk features should be considered for CABG.[37] CABG is also recommended in patients who require not only revascularization but also the repair of a mechanical defect, such as a ventricular septal defect, free wall rupture, or papillary muscle rupture.[9] The previously reported increased mortality in CABG patients who recently had a STEMI needs to be balanced against the need for revascularization. Consideration must be given to the timing of urgent CABG in relation to the administration of antiplatelet agents in patients with a recent STEMI. Table 70.1 provides a summary of these recommendations. The risk of major bleeding and mediastinal re-exploration is higher in patients on dual antiplatelet therapy, but if therapy can be held for 3–5 days, the magnitude of this risk is uncertain.[38,39] The risk of postoperative bleeding may be higher in patients previously given prasugrel.[40]

Adjunctive Therapy

Aspirin

Aspirin is the best known and the most widely used of all the antiplatelet agents because of its low cost and relatively low toxicity. Aspirin inhibits the production of thromboxane A_2 by irreversibly acetylating the serine residue of the enzyme prostaglandin H_2 synthetase. Aspirin has been shown to reduce the mortality in acute infarction to the same degree as fibrinolytic therapy, and its effects are additive to fibrinolytics.[41] In addition, aspirin reduces the risk of reinfarction.[42,43] Unless contraindicated, all patients with a suspected ACS should be given aspirin as soon as possible at a dose of 162–325 mg of a non–enteric-coated preparation. The maintenance dose is typically 81 mg daily.

Adenosine Diphosphate $P2Y_{12}$ Receptor Blockers

Dual antiplatelet therapy with addition of an adenosine diphosphate $P2Y_{12}$ receptor blocker is routine. $P2Y_{12}$ inhibitors include clopidogrel, prasugrel, and ticagrelor.[9]

Clopidogrel is a prodrug that is converted in the liver to the active thiol metabolite via the cytochrome P-450 (CYP) 3A, 1A, 2B, and 2C subfamilies. The active metabolite binds irreversibly to the $P2Y_{12}$ component of the adenosine diphosphate (ADP) receptor on the platelet surface, preventing the activation of the GPIIb/IIIa receptor complex and reducing platelet aggregation for the remainder of the platelet's lifespan, which is approximately 7–10 days. The onset of the inhibition of platelet aggregation is dose-dependent, within 2 hours of a loading dose, although peak effect is closer to 6 hours. A 600-mg loading dose of clopidogrel provides more rapid platelet inhibition and is preferred to a 300-mg loading dose.[44]

Prasugrel is a thienopyridine that irreversibly binds to the $P2Y_{12}$ component of the ADP receptor with a more rapid onset of action.[45] Like clopidogrel, prasugrel is a prodrug metabolized to both an active and inactive metabolite, but a higher proportion is metabolized to an active metabolite, resulting in a higher level of inhibition of platelet aggregation than clopidogrel. The onset of inhibition of platelet aggregation can be achieved in less than 30 minutes with a loading dose of 60 mg, but peak effect occurs in approximately 4 hours.[46]

Ticagrelor is a reversible, non-thienopyridine $P2Y_{12}$ receptor antagonist that does not require metabolic conversion to the active drug. Like prasugrel, ticagrelor has a more rapid onset of action than clopidogrel with ~41% inhibition of platelet aggregation within 30 minutes of an 180-mg loading dose and peak effect in approximately 2 hours.

Which $P2Y_{12}$ receptor antagonist to use is dependent on the chosen reperfusion strategy. In those patients receiving fibrinolysis, early concomitant administration of clopidogrel has shown clear evidence of benefit with reduced endpoints of death, MI, or recurrent ischemia.[47,48] The TREAT trial compared the use of ticagrelor or clopidogrel after fibrinolysis after initial administration of clopidogrel in most (90%) patients. There was no difference in major, fatal, or intracranial bleeding at 30 days and 1 year, and the composite outcome (vascular death, MI, or stroke) was also similar.[49]

When primary PCI is intended, recent randomized trials have demonstrated improved outcomes with the use of ticagrelor or prasugrel, as discussed later. The choice of agent depends on various factors, including familiarity, local practice, and cost. In the randomized, double-blind TRITON-TIMI 38 trial, patients treated with prasugrel had a significant reduction in nonfatal MI when compared with those treated with clopidogrel.[50] The rate of major bleeding was higher in the prasugrel group, as was the rate of life-threatening bleeding. A post hoc analysis of the TRITON-TIMI 38 trial identified either harm in patients with a history of transient ischemic attack (TIA) or stroke and no benefit in patients either older than 75 years or those weighing less than 60 kg. The Food and Drug Administration (FDA) has labeled a history of TIA and/or stroke as an absolute

contraindication to prasugrel use, whereas weight less than 60 kg or age over 75 years remain relative contraindications.[51]

The PLATO trial compared ticagrelor with clopidogrel in 18,000 patients presenting with ACS, 38% of whom had a STEMI; the primary endpoint (MI, stroke, or CV death) occurred less often with ticagrelor, although there were more strokes and episodes of intracranial hemorrhage with ticagrelor.[52] Interestingly, ticagrelor was less effective in North America than in the rest of the world, probably because of an interaction with the aspirin maintenance dose (more patients in the United States took a median aspirin dose ≥300 mg/dL).[53] Hence, when ticagrelor is used with aspirin as a component of dual antiplatelet therapy, the dose of aspirin should not exceed 100 mg.[54]

The ISAR-REACT-5 trial compared prasugrel with ticagrelor in 4018 patients who presented with ACS (41% of patients with STEMI) and showed an increased rate of the primary endpoint (a composite of death, MI, or stroke at 1 year) in the ticagrelor arm with similar rates of bleeding in both groups.[55] This result was not expected based on the results of the PLATO and TRITON-TIMI 38 trials and might be explained by an open-label design or relatively fewer patients.

Dual antiplatelet therapy with aspirin and $P2Y_{12}$ inhibition is given to all patients undergoing fibrinolysis or PCI, as described earlier. However, the data suggest that even patients not undergoing reperfusion benefit from the addition of clopidogrel or ticagrelor to aspirin.[48,56] COMMIT-CCS-2 randomized over 45,000 patients, most with STEMI but only 54% treated with fibrinolytics and almost none treated with PCI, to 75 mg of clopidogrel daily.[48] All-cause mortality was significantly reduced from 8.1% in the placebo group to 7.5% in the clopidogrel group, without increased bleeding in the clopidogrel group. A subanalysis of PLATO demonstrated benefit of ticagrelor compared with clopidogrel in patients with ACS and no reperfusion.[56] On the basis of these data, patients presenting with MI should be considered for clopidogrel or ticagrelor regardless of whether or not they underwent reperfusion therapy. Prasugrel has not shown superiority to clopidogrel in patients with ACS without reperfusion.

Glycoprotein IIb/IIIa Receptor Antagonists

Glycoprotein IIb/IIIa receptor antagonists inhibit the final common pathway of platelet aggregation, blocking the cross-linking of activated platelets.[57] In the era of dual antiplatelet therapy using $P2Y_{12}$ inhibitors and aspirin, the role of the addition of a glycoprotein IIb/IIIa inhibitor in primary angioplasty for STEMI is uncertain. Upstream use (before PCI) has failed to show benefit and is no longer recommended. Current guidelines suggest that use of a glycoprotein IIb/IIIa inhibitor at the time of PCI for STEMI cannot be recommended as routine but may be beneficial and is typically considered on an individual patient basis. For example, the use of a glycoprotein IIb/IIIa inhibitor at the time of PCI may be appropriate if the patient has a large thrombus burden, has no or slow reflow, or there was insufficient loading with a $P2Y_{12}$ receptor antagonist.[58]

Anticoagulants in Patients Undergoing PCI

For patients undergoing PCI who have already been treated with aspirin and a $P2Y_{12}$ inhibitor, both unfractionated heparin (UFH) and bivalirudin are acceptable anticoagulant regimens.[58] Bivalirudin is a direct thrombin inhibitor (DTI) that inhibits both clot-bound and circulating thrombin. It is an alternative to UFH in patients with a history of heparin-induced thrombocytopenia (HIT). Previous studies have concluded that bivalirudin is at least equivalent to heparin plus a glycoprotein IIb/IIIa inhibitor in reducing ischemic events.[59–61] More recent trials, which reflect contemporary practices such as more frequent potent antiplatelet agent use (ticagrelor or prasugrel), a radical approach to PCI, and decreased use of IIb/IIIa glycoprotein inhibitors, have concluded that compared with bivalirudin, heparin is similar in or reduces the incidence of major adverse ischemic events in the setting of primary PCI, with no increase in bleeding complications.[62,63] A 2017 registry study evaluated outcomes in more than 65,000 patients with STEMI with an even distribution of administration of UFH and bivalirudin. After adjustment, there was no difference in outcomes but a higher rate of stent thrombosis with bivalirudin.[64] Table 70.2 gives doses of antiplatelet and anticoagulant therapy for the management of STEMI.

Other Medical Therapies

Nitrates

Nitrates have a number of beneficial effects in acute MI. They reduce myocardial oxygen demand by decreasing preload and afterload and may also improve myocardial oxygen supply by increasing subendocardial perfusion and collateral blood flow to the ischemic region.[65] Patients with ST elevation caused by occlusive coronary artery spasm may have dramatic resolution of ischemia with nitrates. In addition to their hemodynamic effects, nitrates reduce platelet aggregation. Despite these benefits, the GISSI-3 and ISIS-4 trials failed to show a significant reduction in mortality from routine acute and chronic nitrate therapy.[66,67] Nonetheless, nitrates remain the first-line agents for the symptomatic relief of angina pectoris and when myocardial infarction is complicated by hypertension or congestive heart failure. Nitrates should be avoided in patients with right ventricular infarct, hypotension (systolic blood pressure [SBP] <90 mm Hg or >30 mm Hg below baseline), hypertrophic cardiomyopathy, severe aortic stenosis, or phosphodiesterase-5-inhibitor use within the previous 24–48 hours.

Beta-Blockers

Beta-blockers are beneficial both in the early management of MI and as long-term therapy. In the prefibrinolytic era, early intravenous atenolol was shown to significantly reduce reinfarction, cardiac arrest, cardiac rupture, and death.[68] However, more recent data have shown that although the early administration of intravenous beta-blockers followed by oral dosing may lower the reinfarction rate at 4 weeks, there may be an increase in the risk of developing HF and cardiogenic shock.[69] Based on these findings, routine use of intravenous beta-blockers in the absence of systemic hypertension is no longer recommended. However, oral beta-blockers should be administered to patients within the first 24 hours of having a STEMI as long as the following conditions are not present: signs of HF, cardiogenic shock or a low-output state, significant atrioventricular (AV) conduction disease, or active wheezing because of reactive airway disease.[9] Unless contraindicated, beta-blockers should be continued beyond the hospitalization.

Renin–Angiotensin–Aldosterone System Inhibitors

The renin–angiotensin–aldosterone system (RAAS) inhibitors include angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and aldosterone antagonists. ACE inhibitors decrease circulating angiotensin II levels and increase levels of bradykinin, which in turn stimulates production of nitric oxide by endothelial nitric oxide synthase. In the vasculature, ACE inhibition promotes vasodilation and tends to inhibit smooth muscle proliferation, platelet aggregation, and thrombosis.

ACE inhibitors have been shown unequivocally to improve hemodynamics, functional capacity and symptoms, and survival in patients with chronic congestive heart failure and to prevent the development of congestive heart failure in patients with asymptomatic left ventricular dysfunction.[70–72] This information was the spur for trials evaluating

TABLE 70.2 Adjunctive Antiplatelet and Anticoagulant Therapy to Support Reperfusion With Primary Percutaneous Coronary Intervention

Drug	Dosing	COR	LOE
Antiplatelet Therapy			
Aspirin	162–325 mg loading	I	B
Aspirin	81 to 325 mg daily maintenance	I	A
Clopidogrel	600 mg loading	I	B
	75 mg daily maintenance for 1 year	I	B
Prasugrel	60 mg loading	I	B
	10 mg daily maintenance for 1 year	I	B
Ticagrelor	180 mg loading	I	B
	90 mg twice a day maintenance for 1 year	I	B
GP IIb/IIIa Receptor Antagonists in Conjunction with Unfractionated Heparin or Bivalirudin in Selected Patients			
Abciximab	Bolus, then infusion	IIa	A
Tirofiban	Bolus, then infusion; reduce infusion by 50% with CrCl < 30 mL/min	IIa	B

ACT, Activated clotting time; *COR,* class of recommendation; *LOE,* level of evidence; *PCI,* percutaneous coronary intervention; *UFH,* unfractionated heparin.

Adapted from O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guidelines for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2013;127:e362–e425.

the benefit of the prophylactic administration of ACE inhibitors in the post-MI period.

The ACE inhibitor captopril was shown to improve survival in patients with left ventricular dysfunction (ejection fraction <40%) after MI in the SAVE trial.[73] A smaller but still significant reduction in mortality was seen when all patients were treated with captopril in the ISIS-4 study, with greater benefits in patients with left ventricular dysfunction.[67] The mechanisms responsible for the benefits of ACE inhibitors probably include limitation in the progressive left ventricular dysfunction and enlargement (remodeling) that often occur after infarction, but a reduction in ischemic events was seen as well.

Immediate intravenous ACE inhibition, particularly with enalaprilat, has not been shown to be beneficial,[74] but oral ACE inhibition should be started early in the hospital course after STEMI. An ACE inhibitor should be administered within the first 24 hours to all patients with a STEMI and left ventricular dysfunction or HF.[9] Possible contraindications to ACE inhibitor use include hypotension, shock, or a history of renal failure or hyperkalemia with ACE inhibitor or ARB use. Baseline renal function should be taken into consideration when initiating an ACE inhibitor or an ARB, but renal failure is not an absolute contraindication to their use. Patients should be started on low doses of oral agents and titrated to maximally tolerated doses. STEMI patients who are intolerant to an ACE inhibitor should be given an ARB. In particular, valsartan has been shown to be noninferior to captopril in the VALIANT (Valsartan in Acute Myocardial Infarction) trial.[75]

Aldosterone has also been implicated in deleterious left ventricular remodeling after MI. Early initiation (<7 days post MI) of the aldosterone antagonist eplerenone has a proven mortality benefit and should be given to patients with STEMI and no contraindications who are already receiving an ACE inhibitor and beta-blocker and who have a left ventricular ejection fraction (EF) less than or equal to 40% and either symptomatic HF or diabetes mellitus.[9,76] More recent data have pointed towards some benefit with aldosterone antagonists in patients presenting with a STEMI without HF,[77,78] but the guidelines do not recommend their use in STEMI patients when HF is not present. Contraindications to the use of an aldosterone antagonist include creatinine greater than 2.5 mg/dL in men and more than 2.0 mg/dL in women or potassium higher than 5.0 mEq/L.

Lipid-Lowering Agents

Multiple studies have shown that statin use in patients after ACS can prevent death, recurrent MI, and stroke.[79,80] Use of a high-intensity statin is preferred and should be initiated before discharge to improve compliance.[7,9] In patients with ACS, high-intensity statin therapy should be given regardless of the LDL level. Among the currently available statins, only high-dose atorvastatin (80 mg daily) has been studied in clinical trials and shown to reduce death and ischemic events among patients with ACS.[81,82] It is uncertain if this represents a class effect or is specific to atorvastatin. High-intensity rosuvastatin (20–40 mg daily) is known to lower LDL comparably to atorvastatin and may be used particularly in patients with intolerance to the latter.[83] Contraindications to statin use include a history of statin-induced rhabdomyolysis or significant myopathy and/or acute liver injury.

Calcium Channel Blockers

Randomized clinical trials have not demonstrated that routine use of calcium channel blockers improves survival after MI.[84] In fact, meta-analyses suggest that high doses of the short-acting dihydropyridine nifedipine increased mortality in MI.[85] Adverse effects of calcium channel blockers include bradycardia, AV block, and an exacerbation of HF.

Oxygen

When given to normoxic patients with MI, supplemental oxygen has the potential to exert a direct vasoconstrictor effect on the coronary arteries.[86] The AVOID trial randomized 441 patients with confirmed STEMI to supplemental oxygen or none regardless of oxygen saturation and showed an increase in recurrent MI and cardiac arrhythmias and an increase in myocardial infarct size on CMR with oxygen.[87,88] The DETO2X trial randomized 6629 patients with MI and oxygen saturation >90% to supplemental oxygen or none and found no difference in all-cause mortality at 1 year with oxygen use.[88,89] Supplemental oxygen therapy in patients with STEMI but without hypoxia is no longer recommended.[88,89]

UA AND NSTE-ACS

UA and NSTE-ACS should be considered part of the spectrum of ACS, with elevated cardiac troponin differentiating NSTE-ACS from UA. The key to the initial management of patients with ACS who present without ST elevation is risk stratification. The overall risk of a patient is related to both the severity of preexisting heart disease and the degree of plaque instability. Risk stratification is an ongoing process, which begins with hospital admission and continues through discharge (Fig. 70.2).

The risk of ACS increases with age. ST segment depression on the ECG identifies patients at higher risk for clinical events.[90] However, a normal 12-lead ECG does not exclude an NSTE-ACS and is seen in approximately 1%–6% of patients with ACS.[91] For example, a left circumflex coronary artery occlusion can be "electrically silent" and may only be detected using posterior leads V_7–V_9. If there is a high clinical suspicion for ACS, a repeat ECG should be done in 15- to 30-minute intervals for the first hour.[92] Nonspecific ST- and T-wave changes can be seen on ECG in the absence of ACS. See Table 70.3 for non-ACS causes of ST- and T-wave changes.

Cardiac Biomarkers in NSTE-ACS

Biochemical markers of cardiac injury are predictive of outcome. The preferred biomarker for the diagnosis of myocardial necrosis is troponin. Cardiac troponin T and cardiac troponin I are sensitive markers of cardiac injury, particularly when used with the recommended diagnostic cut point of the 99th percentile of healthy controls.[93,94] Newer high-sensitivity assays are now being used and have led to decreasing diagnosis of UA and an increase in the diagnosis of NSTE-ACS.[11,95] Elevated levels of troponin T are associated with an increased risk of cardiac events and a higher 30-day mortality.[96] Conversely, low levels are associated with low event rates, although the absence of troponin elevation does not guarantee a favorable prognosis and is not a substitute for good clinical judgment. Troponins are elevated in MI as early as 2–4 hours after symptom onset and may persist for several days after the initial event.

An elevated cardiac troponin level in the absence of overt ischemic heart disease is a common finding in both acute and nonacute processes, particularly with newer, high-sensitivity assays. When serum cardiac troponin is present but the clinical information does not suggest ACS, the clinician should look for other causes.

Approach to Revascularization of NSTE-ACS

Two predominant pathways have emerged in the management of patients with NSTE-ACS and are referred to as an *early invasive approach* or an *ischemia-guided approach*. An early invasive approach is defined as coronary angiography within 24 hours of admission with PCI if appropriate.

Risk stratification is the key to managing patients with NSTE-ACS. Patients with NSTE-ACS who have refractory angina, hemodynamic or electrical instability, severe HF, or worsening mitral regurgitation and who lack serious comorbidities or contraindications should be taken urgently for cardiac catheterization.[92] Recent subanalyses of trials examining when to perform coronary angiography in UA/NSTE-ACS have demonstrated improved outcomes with an early invasive strategy in patients with elevated risk scores (TIMI >2 or GRACE >140) without contraindications.[97,98] When considering an invasive strategy, the patient's ability to tolerate anticoagulation, antiplatelet, or antithrombotic therapy must be considered. An early invasive strategy should not be considered for patients who are deemed low risk or who have significant comorbidities such as bleeding, advanced liver or renal failure, end-stage lung disease, or advanced-stage cancer such that the risk of PCI outweighs the benefit.

When no indication for immediate angiography is present, patients should then undergo risk assessment with a risk calculator, most commonly the Thrombolysis in Myocardial Infarction (TIMI) risk score or the Global Registry of Acute Coronary Events (GRACE) risk score. These tools take into account patient and clinical factors to provide a prognosis after UA/NSTE-ACS.[99,100] An initial strategy of medical management with attempts at stabilization and delayed invasive strategy is warranted in patients with a lower risk.

Guideline-Directed Medical Therapy for UA/NSTE-ACS

Standard medical therapy for the early management of patients presenting with UA/NSTE-ACS includes analgesics, nitrates, and antiplatelet and antithrombotic therapy. Other medications that should be considered include high-dose statin, beta-blockers, and renin–angiotensin blockers. See Table 70.4 for a summary of recommendations for the use of medications in UA/NSTE-ACS.

Based on risk stratification. *ASA,* Acetyl salicylic acid; *ECG,* electrocardiogram; *GRACE,* Global Registry of Acute Coronary Events (GRACE) risk score; *LOE,* level of evidence; *SQ,* subcutaneous; *TIMI,* Thrombolysis in Myocardial Infarction (TIMI) risk score.

TABLE 70.3 Non–Acute Coronary Syndrome Causes of ST- and T-Wave Changes on Electrocardiogram

Disease/Condition	ECG Finding
Left ventricular aneurysm	ST elevation in precordial leads, Q waves, T-wave inversions (low amplitude)
Pericarditis or myocarditis	Widespread concave ST elevation and PR depression throughout most of the leads Reciprocal ST depression and PR elevation in lead aVR (± V_1)
Right bundle branch block	ST depressions and T-wave inversions in the right precordial leads
Left ventricular hypertrophy	Downsloping ST segments into an inverted T wave in the lateral leads ("LV strain pattern") ST elevations and tall positive T waves are also common findings in leads V_1 and V_2
Hyperkalemia	Peaked T waves
Prinzmetal angina	ST elevation in an anatomic distribution
Stress-induced cardiomyopathy	ST elevation
Brugada pattern	"Coved" ST elevation in V_1–V_3
CNS disease	Deep T-wave inversions ST depression
Early repolarization	J-point elevation of ≥0.1 mV in two adjacent leads Widespread concave ST elevation, most prominent in the mid-to-left precordial leads (V_2–V_5) No reciprocal ST depression to suggest ST elevation myocardial infarction (except in aVR)

CNS, Central nervous system.

TABLE 70.4 Recommendations for the Use of Medications in Non–ST Elevation Myocardial Infarction/Unstable Angina

Therapy	COR	LOE
Oxygen		
Oxygen, only if SpO_2 < 90% or respiratory distress	I	C
Nitrates		
Sublingual nitroglycerin	I	C
IV nitroglycerin for persistent ischemia, heart failure, or hypertension	I	B
Nitrates are contraindicated with recent phosphodiesterase inhibitor use	III: Harm	B
Analgesics		
Morphine sulfate for ongoing ischemic pain despite maximal medical therapy	IIb	B
Nonsteroidal antiinflammatory drugs (except aspirin) should not be initiated or should be discontinued	III: Harm	B
Beta-Blockers		
Oral beta-blockers should be initiated within the first 24 hours, in the absence of contraindications*	I	A
Use of metoprolol succinate, carvedilol, or bisoprolol is recommended in patients with non-ST-elevation acute coronary syndrome and reduced systolic function with stabilized heart failure	I	C
Reasonable to continue beta-blocker therapy in patients with normal left ventricular function with non-ST-elevation acute coronary syndrome	IIa	C
Intravenous beta-blockers are contraindicated in patients with risk factors for or evidence of shock	III	B
Statin Therapy		
Initiate or continue high-intensity statin therapy† in patients with no contraindications	I	A
Obtain a fasting lipid profile, preferably within 24 hours	IIa	C
Renin–Angiotensin–Aldosterone Inhibitors		
Angiotensin-converting enzyme inhibitors should be started and continued indefinitely in all patients with left ventricular ejection fraction < 40% and those with hypertension, diabetes mellitus, or stable chronic kidney disease unless contraindicated	I	A
Angiotensin receptor blockers should be given to patients intolerant to angiotensin-converting enzyme inhibitors with a left ventricular ejection fraction < 40%	I	A
Aldosterone blockade is recommended in patients post myocardial infarction without significant renal dysfunction who have a left ventricular ejection fraction < 40%, diabetes mellitus, or heart failure who are receiving therapeutic doses of angiotensin-converting enzyme inhibitors and beta-blockers	I	A

*Decompensated heart failure, low-output state, risk for cardiogenic shock, bradycardia, evidence of atrioventricular nodal conduction disease.
†Atorvastatin or rosuvastatin.
COR, Class of recommendation; *IV,* intravenous; *LOE,* level of evidence; *SpO_2,* arterial blood oxygen saturation.

Initial Antiplatelet/Anticoagulant Therapy in Patients With Definite or Likely NSTE-ACS

Antiplatelet Therapy

Antiplatelet therapy includes aspirin, $P2Y_{12}$ receptor inhibitors, and glycoprotein IIb/IIIa inhibitors. As previously noted, aspirin is a mainstay of therapy for all ACSs. A loading dose of 162 mg to 325 mg non–enteric-coated aspirin is the initial antiplatelet therapy. Both the VA Cooperative Study Group[42,101] and the Canadian Multicenter Trial[102] showed that aspirin reduces the risk of death or MI by approximately 50% in patients with UA or NSTE-ACS. Aspirin also reduces events after resolution of an ACS, and 81 mg should be continued indefinitely if not contraindicated. In patients who are aspirin-intolerant (allergy or significant gastrointestinal [GI] intolerance), a loading dose of clopidogrel followed by a daily maintenance dose should be administered.[9]

Similar to patients with STEMI, patients with NSTE-ACS and UA benefit from the use of $P2Y_{12}$ receptor inhibitors in addition to aspirin. This benefit—a decrease in CV death, MI, or stroke—was established in the CURE trial and was seen not only in patients who underwent PCI but also in those managed medically.[103]

Ticagrelor has a faster onset of action when compared with clopidogrel and has a faster recovery of platelet function. Patients with NSTE-ACS in the PLATO trial showed a reduction in the composite outcome of death from vascular causes, MI, or stroke in patients treated with ticagrelor compared with clopidogrel.[52] Major bleeding events did not differ between the groups, although bleeding not related to CABG occurred more often with ticagrelor.

Prasugrel has a more rapid onset of action and can achieve a greater level of platelet inhibition when compared with clopidogrel. Taking into account the results of the TRITON-TIMI 38 and ISAR-REACT 5 trials, prasugrel can be a useful alternative to clopidogrel considering that approximately 20%–25% of the population may be resistant to clopidogrel.[104] It is reasonable to administer prasugrel if diagnostic coronary angiography and PCI are intended. However, the use of prasugrel is not recommended for "up-front" therapy before planned PCI in patients with NSTE-ACS because of an increase in bleeding complications without a significant reduction in composite endpoints when compared with dosing at the time of PCI.[105] The TRILOGY ACS trial compared prasugrel with clopidogrel in UA/NSTE-ACS patients treated with a noninvasive strategy and demonstrated no difference in the primary efficacy endpoint (a composite of death from CV causes, nonfatal MI, or nonfatal stroke).[106] Table 70.5 summarizes the dosing of clopidogrel, prasugrel, and ticagrelor in the treatment of UA/NSTE-ACS.

Anticoagulant Therapy

Heparin is an important component of primary therapy for patients with unstable coronary syndromes without ST elevation. When added to aspirin, heparin has been shown to reduce refractory angina and the development of MI,[42] and a meta-analysis of the available data indicates that the addition of heparin reduces the composite endpoint of death or MI.[107]

UFH, however, can be difficult to administer because the anticoagulant effect is unpredictable in individual patients. Therefore activated partial thromboplastin time (APTT) or factor Xa levels must be monitored closely. The potential for heparin-associated thrombocytopenia is also a safety concern. The recommended regimen is weight-based and adjusted using a standardized nomogram.

Low-molecular-weight heparins (LMWHs) have several advantages over UFH. Because they bind less avidly to heparin-binding proteins, there is less variability in the anticoagulant response and a more predictable dose-response curve, obviating the need to monitor APTT. The incidence of thrombocytopenia is lower (but not absent), and patients with HIT with antiheparin antibodies cannot be switched to LMWH. LMWH is less susceptible to inactivation by platelet factor 4. Finally, LMWHs have longer half-lives and can be given by subcutaneous injection.

Several trials have documented beneficial effects of LMWH therapy in unstable coronary syndromes.[108,109] Specific considerations with the use of LMWH include a decreased clearance in renal insufficiency and the lack of a commercially available test to measure the anticoagulant effect. Enoxaparin is dosed by weight and in the presence of impaired renal function (CrCl <30 mL/min) the dose should be reduced.

TABLE 70.5 Dosing of Clopidogrel, Prasugrel, and Ticagrelor in Patients With NSTEMI

Drug	Loading Dose	Maintenance Dose
Clopidogrel	300 mg or 600 mg	75 mg
Prasugrel†	60 mg*	10 mg
Ticagrelor‡	180 mg	90 mg BID

*Recommended to be given at time of coronary angiography when percutaneous coronary intervention is intended.

†Net harm in patients with a history of cerebrovascular events and no clinical benefit in patients older than 75 years of age or those with low body weight (<60 kg) (Wiviott SD, Braunwald E, McCabe CH, et al. Prasugrel versus clopidogrel in patients with acute coronary syndromes. *N Engl J Med.* 2007;357:2001–2015.)

‡The recommended maintenance dose of aspirin to be used with ticagrelor is 81 mg daily.

Adapted from Amsterdam EA, Wenger NK, Brindis RG, et al. 2014 AHA/ACC guidelines for the management of patients with non-ST-elevation acute coronary syndromes: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2014; 130:e344–e426.

Direct Thrombin Inhibitors

Bivalirudin is a DTI. As opposed to heparin, bivalirudin binds directly to both circulating and clot-bound thrombin and inhibits the conversion of fibrinogen to fibrin in the final step of the clotting cascade. DTIs have several theoretical advantages over heparin. Heparin binds to a number of tissue and plasma proteins, which alters its bioavailability and clearance. Heparin may also have a platelet-activating effect in ACS. Lastly, DTIs do not bind to platelet factor 4 and therefore avoid the problem of HIT.

Bivalirudin is the only DTI indicated for use in ACS and is recommended in the setting of HIT. When an early invasive strategy is employed, more contemporary data have shown similar outcomes as compared with heparin without a difference in bleeding. Given this, in the era of DAPT and radial artery access, both bivalirudin and heparin are reasonable when coronary angiography is planned. When pursuing a conservative approach without intention of revascularization, LMWH or UFH should be used in preference to bivalirudin.[92]

Glycoprotein IIb/IIIa Antagonists

Previous studies had suggested reduced incidence of a composite outcome of death and MI with glycoprotein IIb/IIIa inhibition in NSTE-ACS,[110] but these studies were conducted before the era of dual

antiplatelet therapy, which is now standard practice. The most recent data suggest a glycoprotein IIb/IIIa inhibitor can be given in addition to aspirin and an anticoagulant if the patient is considered high risk (troponin positive) and not pretreated with a $P2Y_{12}$ inhibitor. If a high-risk patient is pretreated with a $P2Y_{12}$ inhibitor, a glycoprotein IIb/IIIa inhibitor can be given at the time of PCI in addition to aspirin and an anticoagulant.[92,111]

Complications of Acute Myocardial Infarction

Ventricular Free Wall Rupture

Ventricular free wall rupture typically occurs during the first 5 days after an infarction and within 2 weeks in over 90% of cases. The incidence of left ventricular free wall rupture in all comers with STEMI is low (about 1%). Not surprisingly, the incidence in those who die after STEMI is much higher, ranging from 7% to 26%.[112–114] The classic patient is elderly, female, and presents with an anterior wall infarction. Early use of fibrinolytic therapy reduces the incidence of cardiac rupture, but late use may actually increase the risk. Pseudoaneurysm with leakage may be heralded by chest pain, nausea, and restlessness, but frank free wall rupture presents as a catastrophic event with shock and electromechanical dissociation. Pericardiocentesis may be necessary to relieve acute tamponade, ideally in the operating room, because the pericardial effusion may tamponade the bleeding. Salvage is possible with expeditious thoracotomy and repair, either with a patch or by direct suturing.[115] For those patients who make it to the operating room for repair, mortality approaches 60%.[9]

Ventricular Septal Rupture

Septal rupture presents as severe HF or cardiogenic shock, with a loud pansystolic murmur and parasternal thrill. Ventricular septal rupture most commonly occurs within 24 hours of reperfusion (typically with fibrinolytic therapy) in patients with a STEMI.[116] The hallmark finding is a left-to-right intracardiac shunt ("step up" in oxygen saturation from the right atrium to the right ventricle), but the diagnosis is most easily made with echocardiography. Rapid institution of supportive pharmacologic measures and mechanical support, such as intraaortic balloon pumping, is necessary. Operative repair is the only viable option for long-term survival. Even if surgical repair is done promptly, mortality remains high, ranging from 20% to 87%.[116–118]

Acute Mitral Regurgitation

Ischemic mitral regurgitation is usually associated with inferior myocardial infarction and ischemia or infarction of the posterior papillary muscle because of its singular blood supply. An anterior papillary muscle rupture can also occur, although is less common, as it is typically supplied by two coronary arteries. Papillary muscle rupture has a bimodal incidence, either within 24 hours or 3–7 days after an acute MI. It presents dramatically with pulmonary edema, hypotension, and cardiogenic shock. When a papillary muscle ruptures, the murmur of acute mitral regurgitation may be limited to early systole because of a rapid equalization of pressures in the left atrium and ventricle. More important, the murmur may be soft or inaudible, especially when the cardiac output is low.[119]

Echocardiography is extremely useful in the differential diagnosis, which includes free wall rupture, ventricular septal rupture, and infarct extension with pump failure. Hemodynamic monitoring with pulmonary artery catheterization may also be helpful. Management includes afterload reduction with an intraaortic balloon pump or another mechanical circulatory support device as a temporizing measure. Inotropic or vasopressor therapy may also be needed to support cardiac output and blood pressure. Definitive therapy, however, is surgical valve repair or replacement, which should be undertaken as soon as possible because clinical deterioration can be sudden.[119,120]

RIGHT VENTRICULAR INFARCTION

Right ventricular infarction occurs in up to 30% of patients with an inferior infarction and is clinically significant in 10%.[121] The combination of a clear chest radiograph with jugular venous distention in a patient with an inferior wall MI should lead to the suspicion of a coexisting right ventricular infarct. The diagnosis is substantiated by demonstration of ST segment elevation in the right precordial leads (V_{3R}–V_{5R}) or by characteristic hemodynamic findings on right heart catheterization (elevated right atrial and right ventricular end-diastolic pressures with normal to low pulmonary artery occlusion pressure and low cardiac output). Echocardiography can demonstrate depressed right ventricular contractility.[122] Patients with cardiogenic shock on the basis of right ventricular infarction have a better prognosis than those with left-sided pump failure.[120] This may be caused in part by the fact that the right ventricular function tends to return to normal over time with supportive therapy, although such therapy may need to be prolonged.[123]

In patients with right ventricular infarction, right ventricular preload should be maintained with fluid administration. In some cases, however, fluid resuscitation may increase pulmonary capillary occlusion pressure but may not increase cardiac output, and overdilation of the right ventricle can compromise left ventricular filling and cardiac output.[123] Inotropic therapy may be more effective in increasing cardiac output in some patients, and monitoring with serial echocardiograms may also be useful to detect right ventricular overdistention. Maintenance of AV synchrony is also important in these patients to optimize right ventricular filling.[122] For patients with continued hemodynamic instability, intraaortic balloon pumping may be useful, particularly because elevated right ventricular pressures and volumes increase wall stress and oxygen consumption and decrease right coronary perfusion pressure, exacerbating right ventricular ischemia. Immediate reperfusion of the occluded coronary territory is also crucial.[124] Percutaneous right ventricular mechanical support may be an option in selected cases as well.

CARDIOGENIC SHOCK

Epidemiology and Pathophysiology

Cardiogenic shock, resulting either from left ventricular pump failure or mechanical complications, represents the leading cause of in-hospital death after MI.[125,126] Cardiogenic shock should be considered in the presence of persistent hypotension (SBP $<$90 mm Hg or mean arterial pressure 30 mm Hg lower than baseline) with reduced cardiac index ($<$1.8 L/min/m^2 without support or $<$2.2 L/min/m^2 with support) and adequate or elevated filling pressures.[127] Patients may have cardiogenic shock at initial presentation, but shock most often evolves over several hours.[128]

Cardiac dysfunction in patients with cardiogenic shock is usually initiated by MI or ischemia. The initial ischemic event leads to myocardial dysfunction, which in turn worsens the ongoing ischemia, creating a downward spiral (Fig. 70.3). Compensatory mechanisms that retain fluid in an attempt to maintain cardiac output may add to the vicious cycle and further increase diastolic filling pressures. The interruption of this cycle of myocardial dysfunction and ischemia forms the basis for the therapeutic regimens for cardiogenic shock. Early recognition of cardiogenic shock and timely management (revascularization) are paramount to improved mortality.

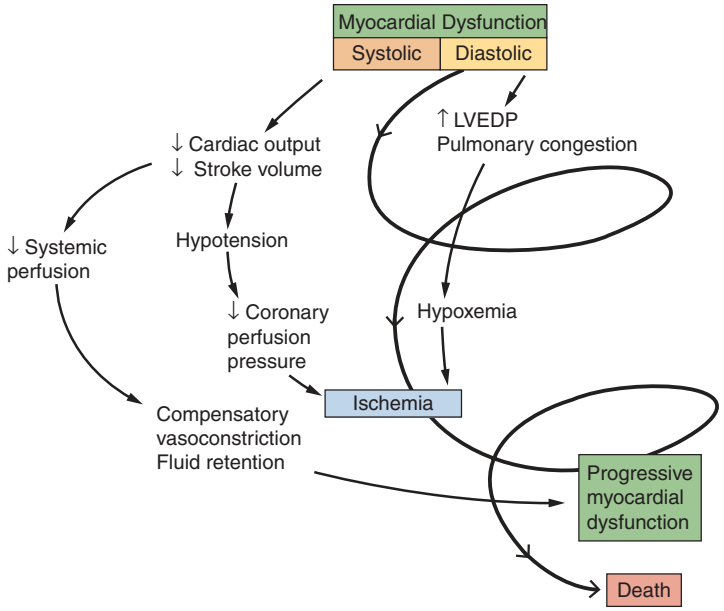

Fig. 70.3 The "downward spiral" in cardiogenic shock. Stroke volume and cardiac output fall with left ventricular (LV) dysfunction, producing hypotension and tachycardia that reduce coronary blood flow. Increasing ventricular diastolic pressure reduces coronary blood flow, and increased wall stress elevates the myocardial oxygen requirements. All of these factors combine to worsen ischemia. The falling cardiac output also compromises systemic perfusion. Compensatory mechanisms include sympathetic stimulation and fluid retention to increase preload. These mechanisms can actually worsen cardiogenic shock by increasing myocardial oxygen demand and afterload. Thus a vicious circle can be established. ***LVEDP,*** Left ventricular end-diastolic pressure. (Adapted with permission from Hollenberg SM, Kavinsky CJ, Parrillo JE. Cardiogenic shock. *Ann Intern Med.* 1999;131:47–59.)

Initial Management

Maintenance of adequate oxygenation and ventilation is critical. Many patients require intubation and mechanical ventilation if only to reduce the work of breathing and facilitate sedation and stabilization before cardiac catheterization. Electrolyte abnormalities should be corrected, and morphine (or fentanyl if systolic pressure is compromised) used to relieve pain and anxiety. Arrhythmias and a heart block may have important effects on cardiac output and should be corrected promptly with antiarrhythmic drugs, cardioversion, or cardiac pacing. Amiodarone is the preferred antiarrhythmic drug for sustained ventricular or atrial tachyarrhythmias in the setting of cardiogenic shock.

Both pharmacologic and mechanical forms of circulatory support should be used to reverse hypotension and maintain organ and coronary artery perfusion. Patients are commonly diaphoretic, and relative hypovolemia may be present in as many as 20% of patients with cardiogenic shock, so fluid boluses, titrated to clinical endpoints of heart rate, urine output, and blood pressure, should be considered as an initial measure unless frank pulmonary edema is present. Patients who do not respond rapidly to initial fluid boluses or those with poor physiologic reserve should be considered for invasive hemodynamic monitoring. Optimal filling pressures vary from patient to patient; hemodynamic monitoring can be used to construct a Starling curve at the bedside, identifying the filling pressure at which the cardiac output is maximized. Maintenance of adequate preload is particularly important in patients with a right ventricular infarction.

Vasopressor and inotropic agents remain the mainstay of first-line therapy in the management of cardiogenic shock. Catecholamine agents, such as norepinephrine, epinephrine, dopamine, dobutamine, and phenylephrine, have both vasopressor and inotropic effects, but it is useful to distinguish vasopressor effects (those aimed at maintaining blood pressure) and inotropic effects (those aimed at increasing myocardial contractility and thus cardiac output) to allow for titration of dose to effect. When arterial pressure remains inadequate, therapy with vasopressor agents may be required to maintain coronary perfusion pressure to break the vicious cycle of progressive hypotension with further myocardial ischemia. The most commonly used vasopressors include norepinephrine, phenylephrine, and epinephrine. Norepinephrine acts on both α_1- and β_1-adrenergic receptors, thus producing potent vasoconstriction in addition to a modest increase in cardiac output[129] and is the preferred first-line agent. A subgroup analysis of a multicenter randomized trial comparing norepinephrine with dopamine in patients with shock demonstrated a lower 28-day mortality with norepinephrine.[130] Phenylephrine, a selective α_1-adrenergic agonist, acts as a potent vasoconstrictor that augments systemic vascular resistance (SVR) without greatly affecting contractility or cardiac output. Phenylephrine may be used when tachyarrhythmias limit therapy with other vasopressors. Epinephrine has potent β_1-adrenergic receptor activity and moderate β_2- and α_1-adrenergic receptor effects. The net effect can be an increase in cardiac output and decreased SVR, with escalating doses causing a greater increase in SVR. Epinephrine is typically used in addition to norepinephrine in septic shock and for the management of hypotension after CABG.

Vasopressor infusions need to be titrated carefully in patients with cardiogenic shock to maximize coronary perfusion pressure with the least possible increase in myocardial oxygen demand. Hemodynamic monitoring, with serial measurements of cardiac output, filling pressures, and other parameters, such as mixed venous oxygen saturation, can allow for titration of the dosage of vasoactive agents to the minimum dosage required to achieve the chosen therapeutic goals.[131] However, reperfusion therapy should not be delayed for the placement of a pulmonary artery catheter.

After initial stabilization and restoration of adequate blood pressure, tissue perfusion should be assessed. If tissue perfusion is adequate but significant pulmonary congestion remains, diuretics may be employed.

Vasodilators such as intravenous nitroglycerin or nitroprusside can be considered as well, depending on the blood pressure.

If tissue perfusion remains inadequate, cardiovascular support with inotropic agents should be initiated. There is no firm guideline-based recommendation regarding which inotropic agent to use in the setting of cardiogenic shock. Typically used inotropes include dobutamine, dopamine, and norepinephrine (which can act as both a vasopressor and inotrope). Dobutamine, a selective β_1-adrenergic receptor agonist, can improve myocardial contractility and increase cardiac output. Dobutamine may exacerbate hypotension in some patients and can precipitate tachyarrhythmia. Dobutamine is typically reserved for patients with SBP >80 mm Hg. Epinephrine can increase cardiac output but often at the expense of a substantial increase in myocardial oxygen demand. In some situations, a combination of a vasopressor and an inotrope can be more effective than either agent used alone. Phosphodiesterase inhibitors such as milrinone are less arrhythmogenic than catecholamines but have the potential to cause hypotension and should be used with caution in patients with tenuous clinical status.

Mechanical Support in Cardiogenic Shock

Intraaortic balloon counterpulsation (IABP) reduces the systolic afterload and augments diastolic perfusion pressure, increasing cardiac output and improving coronary blood flow, without an increase in oxygen demand.[132] IABP does not, however, produce a significant improvement in blood flow distal to a critical coronary stenosis.[132,133] The timing and utility of IABP in patients with STEMI complicated by cardiogenic shock, however, remain uncertain.[134,135] The IABP-SHOCK II trial randomized 600 patients with cardiogenic shock complicated by acute MI to either IABP or no IABP at the time of PCI. There was no difference in all-cause mortality at 30 days or 12 months: nor was there any significant difference in any of the subgroups.[136] Some randomized patients in this trial received an IABP after PCI when they were hemodynamically stable and might not have been expected to derive great benefit. In addition, 10% of patients in the control group crossed over to IABP therapy. IABP is widely available, is easy to place, and has a lower cost compared with other support devices; as such, IABP may still have some role in the stabilization of selected patients with cardiogenic shock.

In appropriate settings, more intensive support with mechanical circulatory support devices may also be implemented. Such devices include left ventricular assist devices (LVADs), such as the TandemHeart percutaneous left atrial–to–femoral arterial ventricular assist device or the Impella percutaneous transvalvular left ventricular assist device, and percutaneous cardiopulmonary bypass support with the use of extracorporeal membrane oxygenation (ECMO). The percutaneous LVADs provide better hemodynamics compared with IABP, with higher cardiac indices and mean arterial pressures and lower filling pressures and improve metabolic parameters. Percutaneous LVADs, however, have not been shown to improve mortality in randomized trials.[137]

Reperfusion Therapy

Although fibrinolytic therapy reduces the likelihood of the subsequent development of shock after the initial presentation, it is clearly less effective in patients with cardiogenic shock than in those without[138] and has not been shown to reduce mortality in patients with established cardiogenic shock.[66,139]

To date, emergency percutaneous revascularization is the only intervention that has been shown to reduce mortality rates consistently in patients with cardiogenic shock. An extensive body of observational and registry studies has shown consistent benefits from revascularization.[140] These data have been confirmed in the SHOCK study, a randomized, multicenter international trial that assigned patients with cardiogenic shock to receive optimal medical management (including IABP and fibrinolytic therapy) or to cardiac catheterization with revascularization using percutaneous transluminal coronary angioplasty (PTCA) or CABG.[29,141] The trial enrolled 302 patients and was powered to detect a 20% absolute decrease in 30-day all-cause mortality rates. Mortality at 30 days was 46.7% in patients treated with early intervention and 56% in patients treated with initial medical stabilization, but this difference did not quite reach statistical significance ($P = .11$).[28] At 6 months, the absolute risk reduction with early invasive therapy in the SHOCK trial was 13%, and this risk reduction was maintained at 12 months.[141] The subgroup analysis showed a substantial improvement in mortality rates in patients younger than 75 years of age at both 30 days and 6 months.[141] Put into perspective with the results from other randomized controlled trials of patients with acute MI, an important point emerges: despite the moderate relative risk reduction (0.72, confidence interval [CI] 0.54–0.95) the absolute benefit is important, with 9 lives saved for 100 patients treated at 30 days (number needed to treat 10.8) and 13.2 lives saved for 100 patients treated at 1 year in the SHOCK trial (number needed to treat 7.6). Based on these data, the presence of cardiogenic shock in the setting of acute MI is an indication for emergency revascularization, either by percutaneous intervention or CABG.[9]

See Box 70.2 for a summary of complications caused by acute MI.

Box 70.2 Complications Caused by Acute Myocardial Infarction

- Cardiogenic shock
- Mechanical
  - Rupture of the left ventricular free wall
  - Rupture of the interventricular septum
  - Acute mitral regurgitation
- Left ventricular aneurysm
- Ventricular arrhythmia
- Bradycardia or atrioventricular block
- Pericarditis
- Bleeding

KEY POINTS

- ACSs are a family of disorders that exist along a clinical continuum. Prompt recognition and early initiation of treatment are paramount to decrease morbidity and mortality.
- Acute STEMI is a medical emergency requiring urgent treatment with revascularization of the ischemic territory. After initial management, multiple medical therapies have been shown to provide clinical benefit.
- Improvements and advancements in reperfusion therapy and GDMT has greatly decreased the mortality attributable to STEMI.
- In patients with NSTE MI or UA, clinical trials have demonstrated improved outcomes with prompt antiplatelet and antithrombotic therapy. Reperfusion strategy is dependent on multiple factors, which dictate the decision between an early invasive or ischemic-guided approach.
- Complications of acute MI include ventricular free wall rupture and acute mitral regurgitation often the result of papillary muscle rupture. The treatment for the majority of mechanical complications is generally surgical, with poor overall survival.
- Cardiogenic shock related to acute MI is a consequence of a hemodynamic spiral as a result of ischemia begetting myocardial dysfunction, which begets further ischemia. Therapeutic interventions include prompt revascularization, pharmacologic vasopressor and inotropic support, and various forms of mechanical circulatory support.

Randomized trial evaluating optimal timing for coronary angiography and reperfusion in patients with NSTE-ACS that showed no difference in outcomes between a very early PCI strategy (,12 hours) and a delayed strategy (24–72 hours) except in higher-risk patients (GRACE score .140), in whom benefit from earlier intervention was found.

Levine GN, Bates ER, Blankenship JC, et al. 2015 ACC/AHA/SCAI focused update on primary percutaneous coronary intervention for patients with ST-elevation myocardial infarction: an update of the 2011 ACCF/AHA/SCAI guideline for percutaneous coronary intervention and the 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction. *J Am Coll Cardiol.* 2016;67(10):1235–1250.
Update to guideline statement on primary percutaneous coronary intervention in patients with STEMI. This update changed recommendations for PCI to non–culprit arteries to IIb from III. This was based on multiple randomized controlled trials showing reduction in cardiovascular composite outcomes with multivessel PCI. The statement also addresses aspiration thrombectomy during STEMI and makes routine use of this a class III recommendation.

O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: executive summary. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines: Developed in collaboration with the American College of Emergency Physicians and Society for Cardiovascular Angiography and Interventions. *Catheter Cardiovasc Interv.* 2013;82(1):E1–E27.
The latest clinical guideline statement for care of patients with STEMI clearly displays current recommendations for the management of these patients with the discussion regarding the clinical trials that led to the class of recommendation.

Thiele H, Akin I, Sandri M, et al. PCI strategies in patients with acute myocardial infarction and cardiogenic shock. *N Engl J Med.* 2017;377(25):2419–2432.
Although the benefit of revascularization in patients with STEMI and cardiogenic shock is well established by the SHOCK trial, this randomized trial studied the utility of intervening on nonculprit vessels at the time of revascularization in patients with cardiogenic shock. Nonculprit PCI in this setting led to an increased incidence of death or severe renal failure requiring dialysis compared with culprit PCI only, suggesting that this strategy should not be employed routinely in patients with shock.

Supraventricular Arrhythmias

Irina Savelieva

CLASSIFICATION AND EPIDEMIOLOGY

Supraventricular arrhythmias include rhythms arising from the sinus node and the adjacent atrial tissue (inappropriate sinus tachycardia, sinoatrial reentry tachycardia), both the right and left atria (atrial tachycardia, flutter, and fibrillation), the atrioventricular (AV) node (AV nodal reentry tachycardia, accelerated ectopic junctional rhythm), and the AV node with involvement of an accessory pathway or multiple pathways (AV reentry tachycardia) (Fig. 71.1).

Atrioventricular Nodal Reentry Tachycardia and Atrioventricular Reentry Tachycardia

AV nodal reentry tachycardia and AV reentry tachycardia are usually referred to as *paroxysmal supraventricular tachycardias* (SVTs). They are often seen in young patients with little or no structural heart disease, although a congenital heart abnormality giving rise to increased atrial pressure and dilatation (e.g., Ebstein anomaly, atrial septal defect, Fallot tetralogy) can coexist in a small percentage of patients with these arrhythmias.[1] The first presentation is common between age 12 and 30 years, and the prevalence is approximately 2.5 per 1000. Women are twice as likely as men to present with AV nodal reentry tachycardia.

Atrial Flutter and Fibrillation

Atrial fibrillation is the most common supraventricular arrhythmia, affecting 1%–2% of the general population, especially the elderly. It is usually associated with cardiovascular pathologies, among which hypertension and congestive heart failure prevail.[2] About a third of patients, however, present with no underlying heart disease and are considered to have "lone" atrial fibrillation. The incidence of isolated atrial flutter is largely unknown and is believed to be in the range of 0.037%–0.88% per 1000 person-years, but at least half of these patients also have atrial fibrillation as a coexistent arrhythmia.

Atrial Tachycardia

Atrial tachycardia affects 0.34%–0.46% of patients with arrhythmias. It is common in younger individuals after surgical correction of congenital heart disease and in the elderly, in whom it often occurs in association with atrial fibrillation.

Other Supraventricular Tachycardias

Inappropriate sinus tachycardia and sinoatrial reentry tachycardia are less well-defined clinical and electrocardiographic entities, and their prevalence and associated conditions are not well characterized. Sinoatrial reentry tachycardia is found incidentally in 1.8%–16.9% of patients undergoing electrophysiologic studies for other supraventricular tachyarrhythmias.

CLINICAL PRESENTATION

The leading symptom of most supraventricular tachyarrhythmias, particularly AV nodal reentry tachycardia and AV reentry tachycardia, is rapid, regular palpitations, usually with an abrupt onset; they can occur spontaneously or be precipitated by simple movements. A common feature of tachycardias that involve circulation through the AV node is termination by the Valsalva maneuver. In younger individuals with no structural heart disease, the rapid heart rate can be the main pathologic finding. Other symptoms may include anxiety, dizziness, dyspnea, neck pulsation, central chest pain, weakness, and occasionally polyuria caused by the release of atrial natriuretic peptide in response to increased atrial pressures (more common in atrial tachycardia and AV nodal reentry tachycardia). Prominent jugular venous pulsations caused by atrial contractions against closed AV valves may be observed during AV nodal reentry or AV reentry tachycardia.

True syncope is relatively uncommon unless uncontrolled tachycardia over 200 beats per minute is sustained for a long period, especially in patients who remain standing. Syncope has been reported in 10%–15% of patients, usually just after onset of the arrhythmia or in association with a prolonged pause after its termination. However, in older patients with concomitant heart disease such as aortic stenosis, hypertrophic cardiomyopathy, and cerebrovascular disease, significant hypotension and syncope may result from profound hemodynamic collapse associated with only moderately fast ventricular rates.

It is essential to recognize that patients presenting with AV reentry tachycardia may also present with atrial fibrillation. If an accessory pathway has a short antegrade effective refractory period (<250 ms), it may conduct impulses to the ventricles at an extremely high rate and cause ventricular fibrillation. The incidence of sudden death is 0.15%–0.39% per patient-year, and this may be the first manifestation of the disease in younger individuals.

Irregular palpitations may be the result of atrial premature beats, atrial flutter with varying AV conduction block, atrial fibrillation, or multifocal atrial tachycardia. Although highly symptomatic, these arrhythmias usually have a benign hemodynamic prognosis. However, in patients with depressed ventricular function, uncontrolled atrial fibrillation can reduce cardiac output and precipitate hypotension and congestive heart failure. Atrial fibrillation in association with slow AV conduction or complete block (Frederick syndrome) may result in hemodynamic collapse. Inappropriate sinus tachycardia and nonparoxysmal accelerated junctional rhythm are characterized by relatively slow heart rates and gradual onset and termination.

ELECTROCARDIOGRAPHY

Whenever possible, a 12-lead electrocardiogram (ECG) should be taken during the tachycardia. If a patient with an arrhythmia is

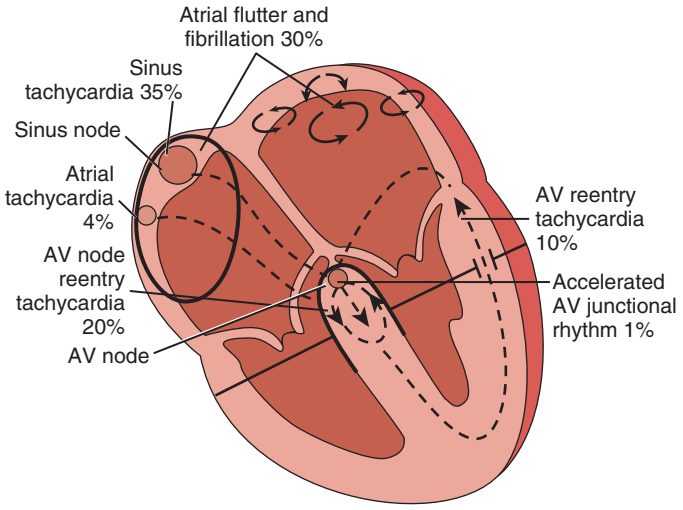

Fig. 71.1 Supraventricular tachyarrhythmias encountered in the emergency setting. *AV,* Atrioventricular.

hemodynamically unstable, a monitor strip should be obtained from the defibrillator before electrical discharge.

Narrow-Complex Tachycardias

The typical ECG feature is narrow QRS complexes less than 120 ms. In this case, the tachycardia is almost always supraventricular, and the differential diagnosis relates to its mechanism (Fig. 71.2).

Wide-Complex Tachycardias

The differential diagnostic features of wide-complex tachycardias favoring a supraventricular origin of the arrhythmia include but are not limited to preexistent bundle branch block; rate-dependent aberrancy; antidromic AV reentry tachycardia, when an accessory pathway conducts and excites the ventricles antegradely; and prominent electrolyte abnormalities (e.g., hypokalemia) or heart muscle disease (cardiomyopathy), all of which may result in QRS widening (Fig. 71.3). If the diagnosis of SVT cannot be proved, the patient should be treated as if ventricular tachycardia is present. Immediate direct current (DC) cardioversion is the treatment for any hemodynamically unstable tachycardia.

ATRIOVENTRICULAR NODAL REENTRY TACHYCARDIA

Mechanism

In AV nodal reentry tachycardia, there are two functionally and anatomically different pathways within the AV node: one is characterized by a short effective refractory period and slow conduction, and the other has a longer effective refractory period and faster conduction. In sinus rhythm, the atrial impulse that depolarizes the ventricles usually conducts through the fast pathway. If the atrial impulse (e.g., an atrial premature beat) occurs early, when the fast pathway is still refractory, the slow pathway takes over in propagating the atrial impulse to the ventricles; the impulse then travels back through the fast pathway, which by then has recovered its excitability, thus initiating the most common "slow-fast," or typical, AV nodal reentry tachycardia.

Electrocardiographic Presentation

In sinus rhythm, the ECG is usually normal unless other unrelated abnormalities are present. During AV nodal reentry tachycardia, the rhythm is regular, with narrow QRS complexes and a rate of 140–250 beats per minute. The atria are activated retrogradely, producing inverted P waves in leads II, III, and aVF. Because atrial and ventricular depolarization occur simultaneously, the P waves are often obscured

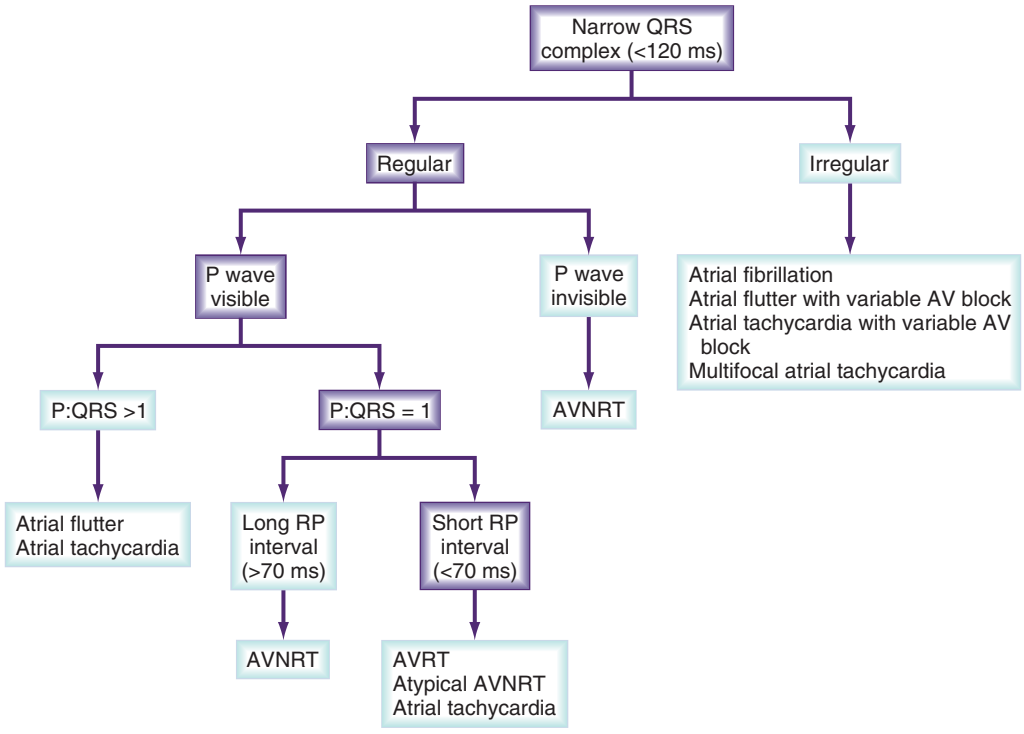

Fig. 71.2 Differential diagnosis for narrow QRS complex (presumably supraventricular) tachycardias. Note that ventricular tachycardia may present with narrow QRS complexes (e.g., fascicular tachycardia). *AV,* Atrioventricular; *AVNRT,* atrioventricular nodal reentry tachycardia; *AVRT,* atrioventricular reentry tachycardia.

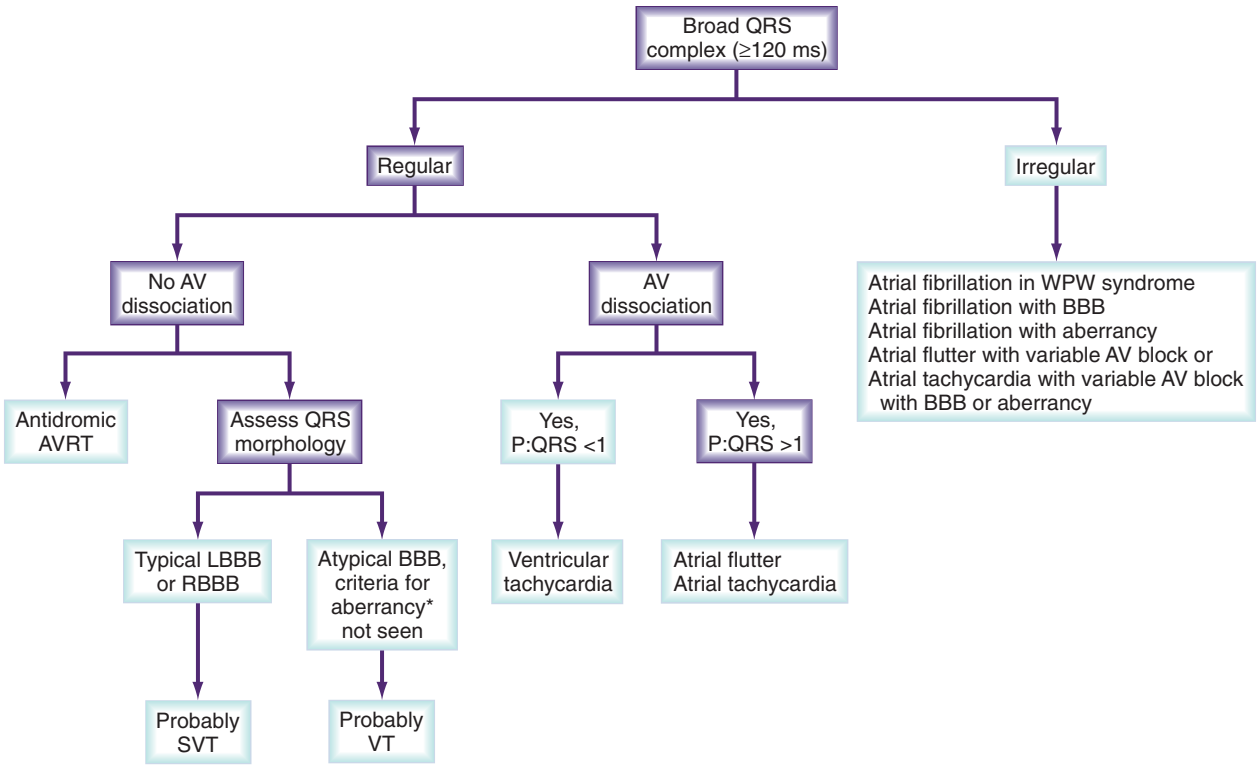

Fig. 71.3 Differential diagnosis for wide QRS complex tachycardias. *AV,* Atrioventricular; *AVRT,* atrioventricular reentry tachycardia; *BBB,* bundle branch block; *LBBB,* left bundle branch block; *RBBB,* right bundle branch block; *SVT,* supraventricular tachycardia; *VT,* ventricular tachycardia; *WPW,* Wolff-Parkinson-White. *Criteria for aberrancy: rate dependency, triphasic QRS complexes, rSR in V_1 with R >, QRS width <140 ms, QRS deflections are discordant in precordial leads, absence of fusion complexes and capture beats.

by the QRS complexes and cannot be detected on the surface ECG (Fig. 71.4A). However, in about one-third of cases of slow-fast AV nodal reentry tachycardia, a terminal positive deflection may be present in lead aVR or V_1 (or both), imitating right bundle branch block, or pseudo-S waves may be noted in the inferiorly oriented leads; these findings reflect retrograde activation of the atria. Tachycardia using these pathways in reverse ("fast-slow," or long RP, tachycardia) is less common, occurring in 5%–10% of cases.

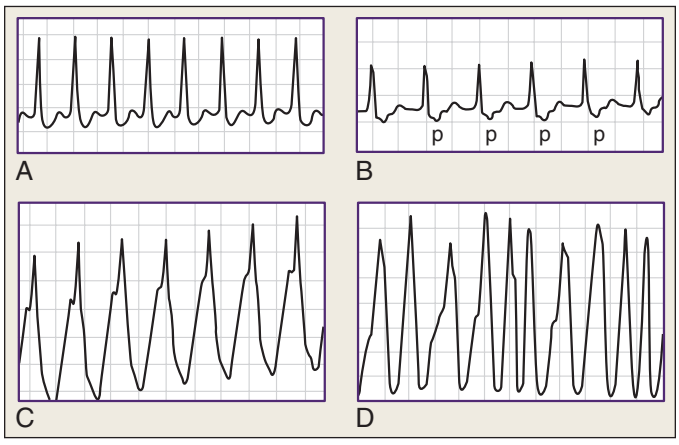

Fig. 71.4 A, Atrioventricular nodal reentry tachycardia, slow-fast type. Note narrow QRS complexes and absence of P waves. **B,** Atrioventricular reentry orthodromic tachycardia. Retrograde inverted P waves follow QRS complexes in leads II, III, and aVF. **C,** Atrioventricular reentry antidromic tachycardia with wide QRS complexes. Electrocardiogram during sinus rhythm with a QRS complex morphology identical to that seen during tachycardia may be helpful in the diagnosis. **D,** Atrial fibrillation in preexcitation syndrome with a fast ventricular rate response.

ATRIOVENTRICULAR REENTRY TACHYCARDIA

Accessory Pathways

AV reentry tachycardia occurs as a result of an anatomically distinct AV connection termed an *accessory pathway,* produced by incomplete separation of the atria and ventricles during fetal development. The most common AV accessory pathway (often called a *Kent bundle*) is located around the mitral or tricuspid annulus. In about 10% of cases, there are multiple pathways.

Accessory pathways are capable of conduction in either or both directions. Accessory pathways that are capable of antegrade conduction are referred to as *manifest,* demonstrating a delta wave during sinus rhythm when the atrial impulses conduct over the accessory pathway without encountering AV delay. The PR interval is short (<120 ms), and the QRS complex is wide; this occurs because the atrial impulse enters nonspecialized ventricular myocardium, and depolarization progresses slowly at first, giving rise to the delta wave before it is overtaken by a depolarization wavefront propagating via the normal conduction tissue. An accessory pathway that is capable of only retrograde conduction is termed *concealed* and does not produce a short PR interval or delta wave during sinus rhythm.

Mechanism and Electrocardiographic Presentation

The reentry circuit of orthodromic AV reentry tachycardia involves the AV node and an accessory pathway, with the impulses conducting from

the atria to the ventricles over the AV node and traveling in the reverse direction through the accessory pathway (see Fig. 71.4B). In antidromic AV reentry tachycardia, the reentrant impulses conduct antegradely from the atria to the ventricles via an accessory pathway and retrogradely via the AV node or a second accessory pathway (see Fig. 71.4C). Antidromic AV reentry tachycardia is uncommon (<10% of cases). Atrial fibrillation is usually encountered in patients with antegradely conducting pathways (see Fig. 71.4D).

Acute Management

In an emergency, distinguishing between AV nodal reentry tachycardia and AV reentry tachycardia may be difficult, but it is usually not critical because both tachycardias respond to the same treatment. If the patient is hemodynamically stable, vagal maneuvers, including carotid sinus massage, the Valsalva maneuver, and facial immersion in cold water (diving reflex), can terminate tachycardia in about 50% of patients (Box 71.1).[3] Commercially available gel packs can be used as cold compresses instead of facial immersion, but the most important elements are wet nostrils and breath-holding.

Pharmacologic Termination

AV blocking agents, such as adenosine, verapamil, diltiazem, and beta-blockers, are effective in terminating both AV nodal reentry and AV reentry tachycardia (Table 71.1).[1]

Adenosine

Intravenous (IV) adenosine is effective in diagnosing, slowing the rate, and often terminating narrow-complex tachycardias. Adenosine usually terminates AV nodal reentry tachycardia and AV reentry tachycardia but rarely interrupts the atrial flutter circuit and does not suppress automatic atrial tachycardia; it can, however, produce high-degree AV block during which the tachycardia persists (Fig. 71.5). It has no effect on most ventricular tachycardias. Adenosine is advantageous compared with verapamil because of its rapid onset and absence of a

BOX 71.1 Vagal Maneuvers to Terminate Tachycardia

Carotid Sinus Massage

Ensure that there is no significant carotid artery disease (carotid bruits).
Monitor the electrocardiogram continuously.
Place the patient in the supine position with the head slightly extended.
Start with right carotid sinus massage.
Apply firm rotatory or steady pressure to the carotid artery at the level of the third cervical vertebra for 5 seconds.
If no response, massage the left carotid sinus.
Generally, right carotid sinus massage decreases sinus node discharge, and left carotid sinus massage slows atrioventricular conduction.
Do not massage both carotids at the same time.
A single application of carotid sinus pressure is effective in about 20%–30% of patients with paroxysmal supraventricular tachycardias; multiple applications terminate tachycardia in about 50% of patients.
Asystole is a potential but rare complication.

Valsalva Maneuver

Valsalva maneuver involves an abrupt voluntary increase in intrathoracic and intraabdominal pressures by straining.
Monitor the electrocardiogram continuously.
Place the patient in the supine position.
The patient should not take a deep inspiration before straining.
Ideally, the patient blows into a mouthpiece of a manometer against a pressure of 30–40 mm Hg for 15 seconds.
Alternatively, the patient strains for 15 seconds while breath-holding.
Transient acceleration of tachycardia usually occurs during the strain phase as a result of sympathetic excess.
On release of strain, the rate of tachycardia slows because of the compensatory increase in vagal tone (baroreceptor reflex); it may terminate in about 50% of patients.
Termination of tachycardia may be followed by pauses and ventricular ectopics.

TABLE 71.1 Acute Pharmacologic Rate Control in Atrial Tachyarrhythmias

Drug	Route of Administration	Dose	Onset	Potential Adverse Effects
Verapamil	Intravenous	5–10 mg (0.075–0.15 mg/kg) over 2 min; if no response, additional 5–10 mg after 15–30 min; 3–10 mg every 4–6 h for rate control	3–5 min	Hypotension, bradycardia, heart block, possible deterioration of ventricular function in the presence of organic heart disease
Diltiazem	Intravenous	0.25 mg/kg over 2 min; if no response, additional 0.35 mg/kg after 15–30 min; followed by 5–15 mg/h infusion for rate control	2–7 min	
Esmolol	Intravenous	0.5 mg/kg over 1 min, followed by 0.05–0.2 mg/kg/min for 4 min; if no response after 5 min, 0.5 mg/kg for 1 min, followed by 0.1 mg/kg for 4 min; infusion 0.05–0.2 mg/kg/min for rate control	2–3 min	Hypotension, bradycardia, heart block, possible deterioration of ventricular function in the presence of organic heart disease
Metoprolol	Intravenous	2.5–5 mg over 2 min followed by repeat doses if necessary (total 10–15 mg)	5 min	
Atenolol	Intravenous	2.5 mg over 2 min, followed by repeat doses if necessary (total 10 mg) or infusion 0.15 mg/kg for 20 min	5–10 min	
Propranolol	Intravenous	1 mg over 1 min (total 10–12 mg; 0.15 mg/kg)	5 min	
Digoxin	Intravenous	0.5–1 mg, followed by 0.25 mg every 2–4 h (maximum, 1.5 mg)	30–60 min	Bradycardia, atrioventricular block, atrial arrhythmias, ventricular tachycardia

Intravenous amiodarone can also be effective for rate control, especially in patients with poor left ventricular function, but there is insufficient evidence to support this recommendation. The rate-slowing effect of amiodarone is usually delayed by 1–2 hours.

Fig. 71.5 A, Adenosine usually terminates atrioventricular reentry tachycardias. **B** and **C,** It rarely interrupts the atrial flutter circuit or suppresses automatic focal atrial tachycardia, but produces high-degree atrioventricular block during which the tachycardia persists.

negative inotropic effect in patients with poor left ventricular function and those with significant hypotension.

Adenosine is administered as a very rapid 3- to 6-mg IV bolus; if this is ineffective, another 6- to 12-mg bolus can be given 2–5 minutes later. Adenosine is metabolized very quickly, with an effective half-life of 10 seconds. Adverse effects, including dyspnea, facial flushing, and chest tightness, are therefore short-lived, but in about 12% of patients, adenosine may shorten the atrial effective refractory period and provoke atrial flutter or fibrillation or accelerate conduction over the accessory pathway and produce a rapid ventricular response. In a proportion of patients, ventricular premature beats and nonsustained ventricular tachycardia may occur after the successful termination of the SVT.[4] Some individuals, particularly heart transplant recipients, are unusually sensitive to adenosine and require a lower dose (1 mg).

Verapamil and Diltiazem

Verapamil is administered as a 5- to 10-mg IV bolus over 2 minutes, and the effect on the tachycardia should occur in 5–10 minutes. If necessary, a second bolus of 10 mg can be given 30 minutes after the initial dose. Vagal maneuvers can be effective at this stage. Verapamil should not be used for wide-complex tachycardias. IV verapamil is contraindicated in patients with poor left ventricular function or heart failure, and it should not be administered after pretreatment with oral, or especially IV, beta-blockers. It should not be used for atrial fibrillation associated with preexcitation syndrome because it may result in acceleration of conduction over an antegradely conducting accessory pathway (especially with a short effective refractory period), resulting in a rapid ventricular response and ventricular fibrillation. Diltiazem is an alternative to verapamil, but diltiazem has been associated with lower effective rates. Diltiazem has the same contraindications as verapamil.

DC cardioversion or pharmacologic conversion with IV ibutilide, propafenone, or flecainide is appropriate for termination of atrial fibrillation with preexcitation.

Beta-Blockers

Among beta-blockers, esmolol, administered as an IV infusion at a rate of 50–200 μg/kg/min, is the agent of choice because of its rapid onset. More readily available IV metoprolol, atenolol, and propranolol can also be considered (see Table 71.1). Excessive bradycardia caused by AV node–blocking agents can be countered with IV injection of atropine 0.6–2.4 mg in divided doses of 0.6 mg.

Other Antiarrhythmic Agents

Because adenosine, verapamil, diltiazem, and beta-blockers are so highly effective in terminating AV nodal reentry tachycardia and AV reentry tachycardia, specific antiarrhythmic drugs such as propafenone, flecainide, sotalol, ibutilide, and amiodarone are seldom needed in the acute setting. Digoxin is not useful because it is often ineffective and may facilitate conduction over the accessory pathway, shorten the atrial effective refractory period, and promote atrial fibrillation.

Atrial Pacing

In patients with implantable devices, antitachycardia pacing functions can be used to terminate the arrhythmia. However, there is also a risk of inducing atrial fibrillation with a rapid ventricular response in a patient with an antegradely conducting accessory pathway.

Long-Term Management

Patients with AV nodal reentry tachycardia and AV reentry tachycardia should be referred to a cardiologist for electrophysiologic evaluation and long-term management. Both pharmacologic and nonpharmacologic alternatives, including ablation of an accessory pathway, are widely available.

ACCELERATED ATRIOVENTRICULAR RHYTHM

Accelerated AV rhythm is produced by abnormal automaticity in the AV node. It is a narrow QRS complex tachycardia (unless bundle branch block is present), with a ventricular rate ranging from 70 to 250 beats per minute. AV dissociation is also present because the atria are activated normally by the sinus node impulse, whereas the ventricles are depolarized from an accelerated junctional site (Fig. 71.6). This arrhythmia is commonly the result of digitalis toxicity, and drug withdrawal is the usual therapy. If the rate of the AV node pacemaker is not fast, atropine can be given to increase the sinus node discharge rate until the sinus node resumes its dominance.

ATRIAL FIBRILLATION AND ATRIAL FLUTTER

Atrial fibrillation with a fast ventricular response is the most common supraventricular arrhythmia encountered in the emergency department in both younger adults with first-onset arrhythmia and older patients presenting with decompensation. Atrial flutter shares these clinical presentations and requires similar initial therapy. The acute management of both arrhythmias is therefore considered together.

Fig. 71.6 Accelerated junctional rhythm with independent sinus node activity.

Atrial Flutter

Mechanism

Classification of atrial flutter is based on the ECG presentation and electrophysiologic mechanisms. The most common type is typical isthmus-dependent atrial flutter. Incisional reentry atrial flutter occurs after surgical correction for congenital heart disease. There are also various forms of atypical flutters, such as atypical right atrial isthmus-dependent flutter (double-wave and lower loop reentry) and left atrial flutter, in which the circuit contains the pulmonary vein or mitral valve annulus.[5]

Typical, or isthmus-dependent, atrial flutter involves a macroreentrant right atrial circuit around the tricuspid annulus. The wavefront circulates down the lateral wall of the right atrium, through the eustachian ridge between the tricuspid annulus and the inferior vena cava, and up the interatrial septum, giving rise to the most frequent pattern, referred to as *counterclockwise flutter*. Reentry can also occur in the opposite direction (clockwise or reverse flutter).

Electrocardiographic Presentation

Atrial flutter is usually an organized atrial rhythm with an atrial rate typically between 250 and 350 beats per minute. In the more common counterclockwise flutter, F waves are negative in leads II, III, aVF, and $V_{5–6}$ and positive in leads $V_{1–2}$ (Fig. 71.7A). Clockwise atrial flutter is typically characterized by positive F waves in leads II, III, and aVF and negative waves in leads $V_{1–2}$.

Treatment with propafenone, flecainide, and amiodarone to prevent recurrent atrial fibrillation without adding an AV-blocking agent (beta-blocker or nondihydropyridine calcium antagonist) can organize the arrhythmia into typical atrial flutter with AV conduction of 1:1 or 2:1, producing a ventricular rate response of 150 beats per minute or higher (see Fig. 71.7B). The probability of 1:1 conduction is increased in the presence of an accessory pathway with a short effective refractory period.

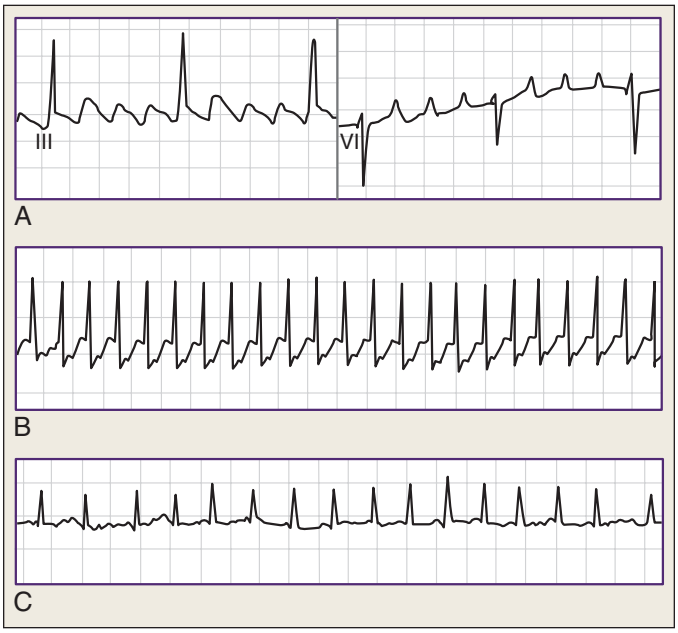

Fig. 71.7 **A,** Typical counterclockwise atrial flutter. F waves are negative in leads II, III, aVF, and $V_{5–6}$ and positive in leads $V_{1–2}$. **B,** Atrial flutter with 1:1 atrioventricular conduction and a ventricular rate of 270 beats per minute in a patient treated with flecainide. **C,** Atrial fibrillation with fast, uncontrolled ventricular rate.

Long-Term Management

The precise mechanism of atrial flutter is important for long-term management (e.g., catheter ablation) but has little influence on the initial approach. Patients with all types of atrial flutter should be referred for electrophysiologic evaluation with a view to ablation. Atrial fibrillation may develop even after successful ablation, and the patient should be followed up carefully.

Atrial Fibrillation

Electrocardiographic Presentation

Atrial fibrillation is defined as rapid oscillations or fibrillatory F waves that vary in size, shape, and timing (see Fig. 71.7C). The ventricular response rate is variable and depends on the rate and regularity of atrial activity, the refractory properties of the AV node itself, and the balance between sympathetic and parasympathetic tone. RR intervals are irregular unless the patient has complete AV block or a paced rhythm.

Classification

The clinical classification of atrial fibrillation includes first detected, paroxysmal (up to 7 days), persistent (more than 7 days), long-standing persistent (>1 year), and permanent (accepted) forms of the arrhythmia. Classification is essential for deciding between rhythm restoration and rate control. First-onset atrial fibrillation, if the duration of the episode is less than 48 hours, is a clear indication to restore sinus rhythm by either electrical or pharmacologic means. Because atrial fibrillation may be asymptomatic, the "first detected episode" should not be regarded as necessarily the true onset of the arrhythmia, in which case formal anticoagulation (see later discussion) and rate control may be preferred. Persistent or permanent atrial fibrillation should be treated initially by rate control and anticoagulation when appropriate.

Long-Term Management

Recognition of the pulmonary veins as the source of atrial premature beats or rapid atrial tachycardia that triggers atrial fibrillation or drives the atria prompted the development of ablation techniques that may "cure" the arrhythmia. In symptomatic permanent or persistent atrial fibrillation, AV node ablation and permanent pacing are effective in rate and symptom control. Any patient with first-onset or recurrent atrial fibrillation should be referred to a cardiologist for long-term management.

Acute Management

Acute therapy for atrial flutter and atrial fibrillation depends on the clinical presentation. Emergency electrical cardioversion is indicated for patients with hemodynamic collapse and progressively deteriorating left ventricular systolic function.

Direct Current Cardioversion

Atrial flutter can be converted with DC shock energy as low as 25–50 J, but because a 100-J shock is virtually always successful, it should be considered as the initial shock strength. In recent-onset atrial fibrillation, sinus rhythm can be restored by a shock of 100 J, but it is generally recommended that cardioversion be started with an initial shock energy level of 200 J or greater. In patients with an arrhythmia of unknown duration, heavier individuals, and those with chronic obstructive lung disease and pulmonary emphysema, an initial setting of 300–360 J is appropriate. Success may occur on the third or subsequent attempt at an intensity that initially proved ineffective.

Rate Control

Rate control is pertinent to all atrial tachyarrhythmias, particularly if restoration of sinus rhythm is deferred. IV verapamil, diltiazem, and

beta-blockers can rapidly control the ventricular response rate in atrial fibrillation[2] (see Table 71.1), but their efficacy may be less in atrial flutter. The decrease in the ventricular rate (approximately 20%–30%), time to maximal effect (20–30 minutes), conversion rate (12%–25%), and adverse reactions (usually hypotension and bradycardia, although left ventricular dysfunction and high-degree heart block may also occur) are reportedly similar with both classes of drugs. Beta-blockers are preferable if thyrotoxicosis is suspected as a cause of the arrhythmia.

IV digoxin is no longer the treatment of choice when rapid rate control is essential because of the delayed onset of its therapeutic effect (>60 minutes). However, because of its positive inotropic action, digoxin may be safer to use in patients with poor ventricular function and moderately fast ventricular rates. Digoxin may convert flutter to fibrillation, in which rate control is easier to accomplish.

There is evidence that IV amiodarone may be effective in rate control when other AV node–blocking agents have no effect on the ventricular response or are contraindicated.

Pharmacologic Cardioversion

If the arrhythmia is hemodynamically stable and of recent onset, pharmacologic cardioversion can be effective.

Flecainide and propafenone. Pharmacologic cardioversion of atrial fibrillation can be accomplished with the IC class of antiarrhythmic drugs—flecainide or propafenone—administered orally as a single dose of 300 or 600 mg, respectively (Table 71.2).[2] Placebo-controlled randomized studies show an efficacy rate of 60%–80% between the third and eighth hour after drug ingestion. Both oral and IV routes of administration are equally effective, although with IV injection, restoration of sinus rhythm can be achieved more quickly.

Flecainide is given as a slow IV injection of 2 mg/kg over 10– 30 minutes, up to the maximum dose of 150 mg. Propafenone is administered as a slow IV injection of 1.5–3 mg/kg, up to 300–600 mg. Because these drugs can significantly slow the atrial rate (from 300–350 beats/min to 200 beats/min), which may result in 1:1 AV conduction, beta-blockers or calcium antagonists with negative dromotropic effects on AV node conduction (verapamil, diltiazem) should be used concomitantly. Other cardiovascular effects include reversible QRS widening and (rarely) left ventricular decompensation. Because of their negative inotropic effects, flecainide and propafenone are contraindicated in patients with severe structural heart disease and a poor ejection fraction.

Class IC drugs are usually ineffective for the conversion of atrial flutter because they slow conduction within the reentrant circuit and prolong the flutter cycle length but rarely interrupt the circuit. These drugs pose the risk of increased (e.g., 2:1 or 1:1) AV conduction. Reported efficacy rates are as low as 13%–40% with IV flecainide and propafenone.

Ibutilide. The class III agent ibutilide is administered intravenously as a 10-minute injection of 1–2 mg and is particularly effective in terminating atrial flutter, with a success rate of about 60%. Its administration may be associated with excessive QT interval prolongation, however, because of rapid delayed rectifier potassium current (I_{Kr}) blockade, which may increase the risk of torsades de pointes. It is less effective in atrial fibrillation. Higher doses of ibutilide administered as two successive infusions of 1 mg are usually required to terminate fibrillation. The advantage of ibutilide is that it may be effective in the conversion of arrhythmias of up to 30 days' duration, but the success rate drops significantly to 20%–30%. The safety of ibutilide in patients with poor left ventricular function is unknown.

Amiodarone. Amiodarone administered intravenously at a dose of 5 mg/kg for 1 hour, followed by an infusion of 20 mg/kg over 24 hours, is effective in converting both atrial fibrillation and flutter, but the effect is significantly delayed.[6,7] However, because of its ability to control the ventricular rate, low likelihood of torsades de pointes, and absence of a negative inotropic effect, amiodarone can be used safely in patients with significant structural heart disease and those who are critically ill.

Procainamide and sotalol. Procainamide administered as a slow IV injection of 1000 mg over 20–30 minutes, followed, if necessary, by an infusion of 2 mg/min over 1 hour, converts atrial flutter or fibrillation of less than 48 hours' duration, but its efficacy is limited in longer-lasting arrhythmias. It is less effective than propafenone, flecainide, and ibutilide.

Sotalol is not indicated for the pharmacologic cardioversion of atrial flutter or fibrillation because its efficacy does not exceed 11%–13%; however, it may satisfactorily control the ventricular rate.

Vernakalant. This drug is given by a short IV infusion (3 mg/kg over 10 minutes). If after a 15-minute waiting period the arrhythmia persists, a second infusion of 2 mg/kg may be given over 10 minutes. In recent-onset (<72 hours) atrial fibrillation, about 50% of cases will terminate on average 12 minutes from the start of the first infusion. Vernakalant may be given to patients with underlying structural heart

TABLE 71.2 Antiarrhythmic Drugs for Pharmacologic Conversion of Atrial Tachyarrhythmias

Drug	Route of Administration	Dose	Potential Adverse Effects
Flecainide	Oral or intravenous	Loading oral dose 200–300 mg or slow injection 1.5–2 mg/kg over 10–20 min; if no response, infusion 1.5 mg/kg for 1 h, then 0.1–0.25 mg/kg over 24 h	Rapidly conducted atrial flutter, possible deterioration of ventricular function in the presence of organic heart disease, monomorphic ventricular tachycardia
Propafenone	Oral or intravenous	Loading oral dose 450–600 mg or 1.5–2 mg/kg over 10–20 min, followed by infusion 5–10 mg/kg if needed	
Ibutilide	Intravenous	1 mg over 10 min; if no response, additional 1 mg	QT prolongation, torsades de pointes, hypotension
Amiodarone	Intravenous (preferably central line)	5–7 mg/kg over 30–60 min, followed by infusion 20 mg/kg for 24 h (total 1200–1800 mg)	Hypotension, bradycardia, QT prolongation, torsades de pointes (?), gastrointestinal upset, constipation, phlebitis
Procainamide	Intravenous	1000 mg over 30 min, followed by 2 mg/min infusion	QRS widening, torsades de pointes, rapid atrial flutter
Vernakalant	Intravenous	3 mg/kg over 10 min; after 15-min break, 2 mg/kg unless arrhythmia terminated	Hypotension, postfibrillation bradycardia

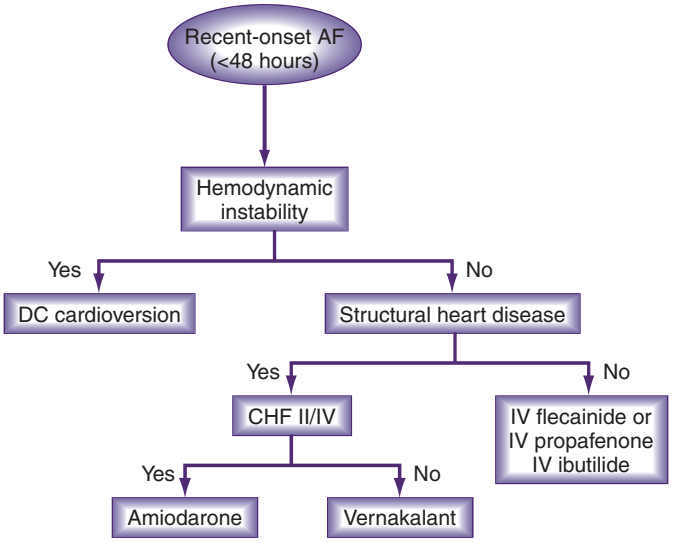

Fig. 71.8 Choice of antiarrhythmic for pharmacologic cardioversion of atrial fibrillation. *AF*, Atrial fibrillation; *CHF*, congestive heart failure; *DC*, direct current; *IV*, intravenous.

disease but not to patients with grades II/IV congestive heart failure. Proarrhythmia effects are uncommon, but hypotension and postermination bradycardia may occur.[8]

The choice of an antiarrhythmic agent for cardioversion is illustrated in Fig. 71.8.

Atrial Pacing

Burst overdrive atrial pacing can terminate atrial flutter in about 80% of cases and is feasible after cardiac surgery, when patients frequently have epicardial atrial pacing wires, or in patients with implantable dual-chamber pacemakers and defibrillators. High-frequency (50 Hz or 3000 beats/min) atrial pacing is available in some of the latest models for the termination of early-onset atrial fibrillation, but its efficacy has not yet been established. Atrial burst overdrive pacing may induce sustained atrial fibrillation, although short periods of fibrillation often precede conversion to sinus rhythm.

Anticoagulation

Anticoagulation is imperative if the arrhythmia persists for more than 24–48 hours or if its duration is unknown. Atrial flutter and atrial fibrillation pose similar risks of thromboembolism, and the same criteria for anticoagulation should be applied in patients with either arrhythmia. In hemodynamically stable arrhythmias of more than 48 hours or of unknown duration, rate control and 3 weeks of anticoagulation with warfarin (international normalized ratio 2.0–3.0) should be considered before any intervention (electrical or pharmacologic cardioversion, catheter ablation).[9]

Transesophageal Echocardiography–Guided Cardioversion

If, for any reason, deferral of cardioversion is not indicated, the transesophageal echocardiography–guided approach, with short-term anticoagulation using low-molecular-weight heparin, is a safe and effective alternative.[10] It may be clinically beneficial in patients with recent-onset arrhythmias or in individuals at high risk of bleeding complications during prolonged anticoagulation therapy.[11] Compared with unfractionated heparin, low-molecular-weight heparin therapy does not involve prolonged IV administration or laboratory monitoring and therefore has the potential to greatly simplify cardioversion-related anticoagulation therapy in low-risk individuals. Postcardioversion anticoagulation should be considered if atrial fibrillation has been present for 48 hours or more, or if thromboembolic risk factors are present.[9,12]

ATRIAL TACHYCARDIA

Mechanism

The mechanism of atrial tachycardia is attributed to enhanced automaticity, triggered activity, or intraatrial reentry. Macroreentrant atrial tachycardia often occurs after surgery for congenital heart disease. Focal atrial tachycardia typically originates along the crista terminalis in the right atrium, in the pulmonary veins entering the left atrium, or around one of the atrial appendages.

Electrocardiographic Presentation

The heart rate varies from 120 to 250 beats per minute, P waves precede the QRS complexes, and PP intervals are regular (see Fig. 71.5B). The PR interval is linked to the rate of the tachycardia and is longer than in sinus rhythm at the same rate. P-wave morphology is usually different from that observed during sinus rhythm and depends on the site of origin. Left atrial tachycardia presents with negative P waves in leads I, aVL, V_5, and V_6. Automatic atrial tachycardia may present as an incessant variety, leading to tachycardia-induced cardiomyopathy.

Atrial Tachycardia With Atrioventricular Block

Tachycardia with AV block occurs commonly in patients with organic heart disease, and in 50%–75% of cases, it results from digitalis toxicity (Fig. 71.9). Digoxin-specific antibody fragments are available for the reversal of life-threatening overdosage.

Multifocal Atrial Tachycardia

This tachycardia presents as rapid, irregular atrial activity with discrete P waves of varying morphology and is considered a transitional rhythm between atrial tachycardia and fibrillation. However, it may occur in patients with chronic severe pulmonary disease as a result of theophylline or beta-agonist overdose. Elimination of the causative factor may reduce the need for antiarrhythmic therapy. IV verapamil can accomplish rate control.

Acute Management

DC cardioversion converts atrial tachycardia based on the reentry mechanism or triggered activity, but it may not terminate automatic tachycardia. Similarly, atrial overdrive pacing may slow the tachycardia rate but seldom suppresses the automatic focus.

It is generally accepted that beta-blockers and calcium antagonists, particularly verapamil, can either terminate the tachycardia or produce rate control. Adenosine can terminate atrial tachycardia, but the most common response to adenosine is to create AV block and thereby reveal the unaffected tachycardia (see Fig. 71.5B and C).

Flecainide, propafenone, sotalol, and amiodarone are effective in converting atrial tachycardia. If the arrhythmia occurs as a result of digitalis intoxication, therapy includes the cessation of digoxin and IV administration of potassium.

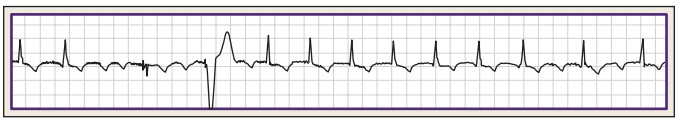

Fig. 71.9 Atrial tachycardia with varying atrioventricular block caused by digitalis toxicity.

Long-Term Management

Patients with atrial tachycardia should be referred to a cardiologist because the arrhythmogenic focus can be found and ablated in up to 86% of cases.

INAPPROPRIATE SINUS TACHYCARDIA

Inappropriate sinus tachycardia is a persistent increase in resting heart rate unrelated or out of proportion to the level of physical or emotional stress. It is found predominantly in women and is not uncommon in health professionals. Sinus tachycardia caused by intrinsic sinus node abnormalities such as enhanced automaticity or abnormal autonomic regulation of the heart, with excess sympathetic and reduced parasympathetic input, is not unusual. The main therapy is beta-blockers, although ivabradine, a drug that blocks the main current responsible for diastolic depolarization in the sinus node, is being increasingly used in Europe.[13] In general, sinus tachycardia is a secondary phenomenon, and the underlying cause should be actively investigated. Depending on the clinical setting, acute causes include fever, hypotension, infection, anemia, thyrotoxicosis, hypovolemia, acute heart failure, acute pulmonary embolism, and shock. Sinus tachycardia may be associated with the abuse of drugs such as amphetamines.

KEY POINTS

- SVT is characterized by narrow QRS complexes, but differentiating SVT from ventricular tachycardia may be necessary when bundle branch block, rate-dependent aberrancy, and antidromic AV reentry tachycardia are present.
- If the diagnosis of SVT cannot be proved, the arrhythmia should be treated as ventricular tachycardia.
- Immediate DC cardioversion is the treatment for any hemodynamically unstable tachycardia.
- In hemodynamically stable paroxysmal junctional tachycardias (AV nodal reentry tachycardia and AV reentry tachycardia), vagotonic maneuvers should be tried first because they may terminate tachycardia in about 50% of patients without the need to resort to pharmacologic therapy.
- IV adenosine, verapamil, and esmolol are first-line drug therapies for paroxysmal junctional tachycardias, but adenosine and verapamil should not be used for wide-complex tachycardias and atrial fibrillation with preexcitation.
- DC cardioversion or pharmacologic conversion with IV ibutilide or flecainide is appropriate for the termination of atrial fibrillation associated with preexcitation syndrome.
- IV verapamil, diltiazem, esmolol, metoprolol, and propranolol can rapidly accomplish rate control in atrial fibrillation but may be less effective in atrial flutter.
- Beta-blockers are preferable in atrial fibrillation associated with thyrotoxicosis.
- Pharmacologic cardioversion of atrial fibrillation in the absence of severe underlying heart disease can be attained using oral or IV flecainide or propafenone, vernakalant, and IV ibutilide, but the last is more effective in atrial flutter.
- Propafenone, flecainide, and vernakalant may result in atrial flutter with slow atrial rates and 2:1 or 1:1 AV conduction; verapamil, diltiazem, or beta-blockers should be available to treat this complication. Ibutilide can significantly prolong the QT interval and cause polymorphic ventricular tachycardia that, if sustained, may require DC cardioversion.
- IV amiodarone should be considered as first-line drug therapy in patients with severely impaired left ventricular function.
- Accelerated AV rhythm and atrial tachycardia with AV block commonly occur as a result of digitalis toxicity; digitalis withdrawal is the usual therapy.
- Anticoagulation is indicated if atrial fibrillation or flutter persists for more than 48 hours or if the duration is unknown; anticoagulation and rate control should be the initial therapy in these patients.
- An alternative approach is transesophageal echocardiography, to exclude the presence of atrial thrombi or dense spontaneous echocontrast, and short-term anticoagulation with low-molecular-weight heparin, followed by DC or pharmacologic cardioversion.
- Patients with paroxysmal junctional tachycardias, atrial tachycardia, atrial flutter, and first-onset or recurrent atrial fibrillation should be referred to a cardiac electrophysiologist/cardiologist for assessment and long-term management planning; effective nonpharmacologic therapies are available for these arrhythmias.

Ventricular Arrhythmias

Raúl J. Gazmuri, Cristina Santonocito, Salvatore R. Aiello, and Donghee Kim

Cardiac arrhythmias are common in critically ill patients and a frequent reason for hospital admission to areas with capability for continuous electrocardiographic monitoring and personnel trained in their recognition and management (e.g., intensive care units [ICUs] and telemetry units).

Arrhythmias are supraventricular if they originate above the atrioventricular (AV) node, such as in atrial tissue or pulmonary veins. They may compromise stroke volume and create hemodynamic instability because of excessive heart rate and/or reduced ventricular filling after losing the atrial contribution to preload. However, in the absence of accessory conduction pathways bypassing the AV node (e.g., Wolf-Parkinson-White syndrome), supraventricular arrhythmias are rarely life-threatening and may be managed without immediate urgency by pharmacologic or electrical means. In contrast, arrhythmias such as ventricular tachycardia (VT) and ventricular fibrillation (VF) that originate in the ventricular tissue may be life-threatening and require immediate treatment.

NORMAL ELECTROPHYSIOLOGY

Anatomic Synopsis

The electrical impulse originates in the sinoatrial (SA) node, located high on the right atrium near its junction with the superior vena cava (Fig. 72.1). The impulse propagates through muscle fibers and specialized internodal pathways (composed of Purkinje-type fibers) to converge on the AV node, located in the interatrial septum near the tricuspid valve. The impulse then travels through the bundle of His, its left and right branches, and the Purkinje system to activate both ventricles simultaneously. A ring of fibrous tissue interposed between the atria and the ventricles prevents spread of the impulse through muscle fibers, enabling the AV node to function as a relay and filter, preventing 1:1 conduction under conditions of very rapid atrial activation such as atrial flutter (rate ~300 s^{-1}) or atrial fibrillation (rate ~600 s^{-1}).

Action Potential and Pacemaker Activity

Action Potential

Action potentials, once initiated in pacemaker cells, propagate through both atria and ventricles. The electrical impulse depolarizes cardiac myocytes and opens voltage-dependent Ca^{2+} channels. Influx of Ca^{2+} causes Ca^{2+}-induced Ca^{2+} release via ryanodine receptors located in the sarcoplasmic reticulum to activate contractile proteins and elicit contraction. Each action potential is produced as a result of time- and voltage-dependent opening and closing of different types of plasma membrane ion channels, mainly involving influx of Na^+ and Ca^{2+} (inward currents) and efflux of K^+ (outward currents).[1–3]

Cells from the Purkinje system and muscle tissue have a stable resting potential of approximately −90 mV (negative inside), largely as a result of a background (also called *leak*) K^+ current known as *inward rectifier* (I_{K1}). Because this K^+ channel is open at rest, it "anchors" the membrane potential to a voltage close to the K^+ equilibrium potential. Because of its inward rectification properties, I_{K1} is turned off during depolarization, which is critical for maintaining the action potential duration.

Phase 0 is the initial rapid upstroke of the action potential. Triggering an action potential requires depolarization to a level between −70 and −80 mV, which is the threshold for activation of fast voltage-gated Na^+ channels (I_{Na})[3] and is normally achieved upon arrival of another action potential. The I_{Na} drives the membrane potential toward the Na^+ equilibrium potential, reversing the membrane potential to approximately +20 mV (overshoot). This is *phase 0* of the action potential and is followed by repolarization in four phases (Fig. 72.2).

Phase 1 is the early rapid repolarization period that occurs just after the upstroke (phase 0) of the action potential. *Phase 1* is produced by activation and subsequent inactivation of a "transient" K^+ current (I_{To}) and is composed of "fast" recovering (I_{Tof}) and slowly recovering (I_{Tos}) currents. I_{Tof} is thought to be the predominant contributor to I_{To} in ventricular myocardium.[4] Because K^+ channels that produce I_{To} are expressed at higher levels in the subendocardium and mid-myocardium than in the subendocardium, I_{To} contributes to the repolarization inhomogeneity.[5]

Phase 2, the plateau phase, is produced by Ca^{2+} influx via opening of L-type voltage-gated Ca^{2+} channels ($I_{Ca\text{-}L}$)[6,7] and K^+ efflux via a *delayed rectifier K^+ channel* (I_K). Both I_{Ca} and I_K are activated by the initial depolarization produced by Na^+ influx during *phase 0*. The relatively small inward (I_{Ca}) and outward currents (I_K) produce little net current, resulting in a near-flat *phase 2*. During the plateau phase, Ca^{2+} channels slowly inactivate with time and Ca^{2+} influx decreases, but the K^+ current (I_K) increases with time, producing a net increase in outward current near the end of *phase 2*.

Phase 3 corresponds to the late strong repolarization and is produced by the delayed rectifier K^+ current. The delayed rectifier K^+ current (I_K) has a rapid (I_{Kr}) and a slow (I_{Ks}) component.[8,9] Although both I_{Ks} and I_{Kr} are critical for producing the strong repolarization, they possess quite different activation and inactivation kinetics. The magnitude of I_{Kr} is greater than that of I_{Ks} during the rapid repolarization phase, and therefore I_{Kr} plays an important role in bringing the cell membrane potential back toward the resting state. Both are implicated in acquired and heritable forms of long QT syndrome.[10] Near the end of the repolarization phase, I_{K1} begins to increase as the cell membrane potential returns toward −90 mV and thus partly contributes to the final setting of the resting potential.

Phase 4 is the resting fully repolarized state and is produced by reopening of the inward rectifier background K^+ channels as the cell membrane potential is brought close to −90 mV. During this phase, the ionic balance is restituted by the action of the Na/K pump. This is an important phase that allows diastolic filling of the relaxed ventricle.

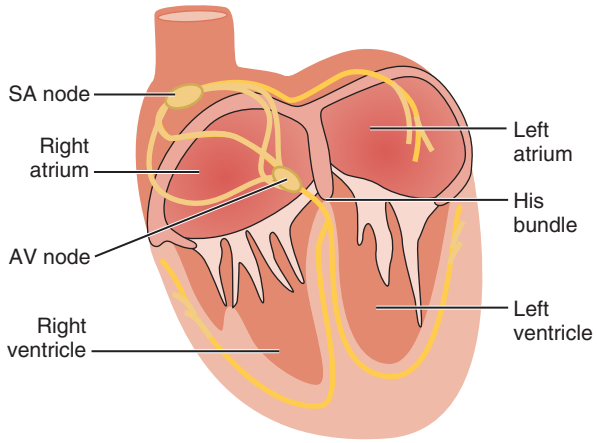

Fig. 72.1 Conduction system of the heart. *AV,* Atrioventricular; *SA,* sinoatrial.

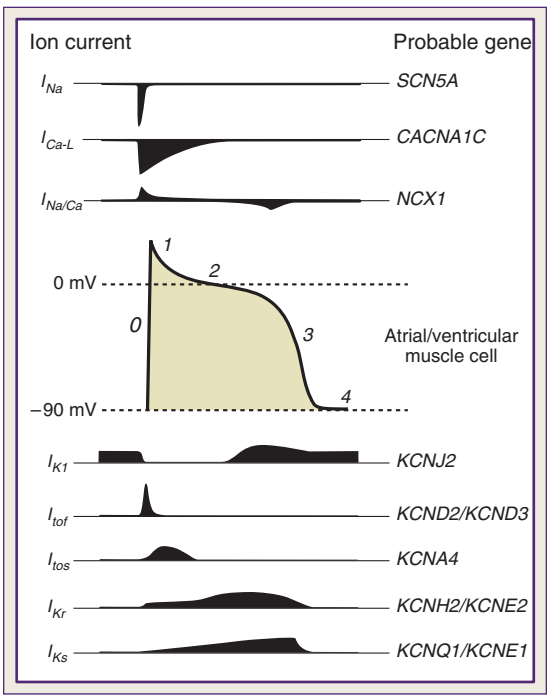

Fig. 72.2 Action potential of a cardiac muscle cell, depicting the main underlying inward and outward currents and respective gene products. Distinctive phases of the action potential are numbered. *Voltage* (mV) refers to the potential on the intracellular side of the plasma membrane relative to an outside reference. Notice that resting potential is negative inside at approximately −90 mV, indicating the cell at rest is polarized (phase 4). Beginning of the action potential is signaled by a rapid reduction in such potential, with inside voltage reaching 0 mV (depolarization) and then becoming transiently positive (overshoot) during phase 0, to be followed by phases 1, 2, and 3 as voltage returns to resting potential on phase 4.

Pacemaker Activity

In cells of the SA and AV nodes, voltage-gated Na^+ channels are in the inactive state, and *phase 0* is produced by $I_{Ca\text{-}L}$.[11] Because the activation kinetics of $I_{Ca\text{-}L}$ are slower than that of I_{Na}, *phase 0* is slanted and in part responsible for the slow SA and AV node conduction velocity (~50 $cm{\cdot}s^{-1}$) relative to that in the His-Purkinje system (~400 $cm{\cdot}s^{-1}$) and muscle cells (~100 $cm{\cdot}s^{-1}$). Pacemaker activity of SA and AV node cells results from slow *phase 4* depolarization (known as prepotential or *pacemaker potential*) to ~−40 mV. Slow depolarization involves opening of the hyperpolarization-activated inward Na^+ current (also known as the "funny current," I_F) and opening of T-type voltage-gated Ca^{2+} channels ($I_{Ca\text{-}T}$). The T-type Ca^{2+} channel is activated at a more negative membrane potential than that of the L-type Ca^{2+} channel and thus contributes to the pacemaker potential. The *phase 3* repolarization produced by activation of the delayed rectifier K^+ current (I_K) is a prerequisite for subsequent activation of I_F. I_K is large at the beginning of *phase 3* but decreases quickly with time as the cell membrane potential becomes negative, and this event helps start the subsequent slowly depolarizing pacemaker potential *(phase 4)*. Cells of the His–Purkinje system have latent prepotential activity and can become active when SA or AV node activity is depressed or their impulses are blocked (i.e., "escape rhythm"). Muscle cells exhibit prepotential activity only under abnormal circumstances.

The preceding paragraphs describe the primary ionic mechanisms that produce *phase 0 through phase 4* of the cardiac action potentials. Other ion channels, antiporters, pumps, and receptor agonists can also modulate the shape of the action potential in response to various stimuli such as high sympathetic tone and hypoxia. For example, a nonselective cationic channel gated at resting potential by intracellular Ca^{2+} is present in cardiac myocytes. This channel produces an inward Na^+ current (I_{NS})[12] that may contribute to delayed afterdepolarizations when Ca^{2+} is released from the sarcoplasmic reticulum. $I_{K(ATP)}$ is a K^+ current carried through channels inhibited by intracellular adenosine triphosphate (ATP) and is opened under conditions of ischemia and hypoxia. $I_{K(ATP)}$ contributes to action potential shortening and the characteristic ST-segment elevation observed during myocardial ischemia.[13,14]

The sarcolemmal Na^+/Ca^{2+} exchanger is another important modulator of the action potential. Because it exchanges one Ca^{2+} for three Na^+, it generates a current ($I_{Na/Ca}$) whose direction depends on Na^+ and Ca^{2+} gradients and the membrane potential.[14,15]

Adrenergic receptor stimulation also modulates the action potential by modifying channel activity.[16–18] For example, beta-1 adrenoceptor stimulation increases $I_{Ca\text{-}L}$ activity and Ca^{2+} influx, enhancing inotropic action. Beta-1 adrenoceptor stimulation also activates K^+ channels, shortening the action potential duration.[19] Alpha-1 adrenoceptor stimulation acting via Gq protein on the Na^+/K^+ pump, K^+ channels, and phospholipase C can alter impulse initiation and repolarization, an effect linked to triggered arrhythmias via early and delayed afterdepolarizations and abnormal automaticity during ischemia and reperfusion.[20,21]

Muscarinic receptors (M_1) coupled to Gi protein are highly expressed in pacemaker and atrial cells. M_1 receptor stimulation by acetylcholine released from the efferent vagus nerve innervating the cells of the SA and AV nodes produces slowing of the heart rate and conduction velocity, which is a parasympathetic response.[22]

Cardiomyocytes can also react to mechanical forces through stretch-activated ion channels and other mechanisms, including mechanical modulation of Ca^{2+} handling and interaction with other mechanosensitive cells.[23,24] These mechanisms are probably involved in commotion cordis,[25] precordial thump,[26] and fist pacing.[27]

MECHANISMS OF VENTRICULAR TACHYARRHYTHMIAS

Abnormalities in impulse generation and conduction are responsible for the genesis and maintenance of ventricular tachyarrhythmias.

Abnormalities in Impulse Generation

Abnormalities in impulse generation are generally the result of automaticity or triggered activity.

Automaticity

Automaticity refers to the emergence of ectopic pacemaker activity resulting from enhanced normal automaticity or development of abnormal automaticity.

Enhanced normal automaticity occurs when cells with intrinsic pacemaker potentials (e.g., cells from the AV node or His–Purkinje system) that are normally suppressed by the SA node fire at rates that escape such suppression. This phenomenon may result from effects on *phase 4* prepotentials yielding earlier development of action potentials (i.e., less maximal polarization, faster depolarization, or lower threshold potential) or from shortening of the action potential duration with earlier return to *phase 4*. Enhanced normal automaticity is usually the result of adrenergic stimulation, which increases the slope of the pacemaker potential by acting on I_F.

Development of abnormal automaticity refers to impulses originating in cells without intrinsic pacemaker potential and typically occurs by generation of depolarizing currents during *phase 4* (e.g., ischemia).[28] Abnormal automaticity can develop in atrial and ventricular muscle cells and in specialized tissues other than the SA and AV node. Examples include accelerated idioventricular rhythms and some VTs developing 24–72 hours after acute myocardial infarction.[29]

Triggered Activity

Triggered activity refers to arrhythmias that arise from afterdepolarizations, defined as alterations in membrane potential that occur during repolarization.[30] Afterdepolarizations are considered early if they develop during *phase 2, phase 3,* or early *phase 4* of the action potential and are characterized by transient retardations in repolarization (Fig. 72.3). If of enough magnitude, they can trigger an "extra" action potential. Early afterdepolarizations are typically associated with conditions that prolong the action potential (e.g., increased sympathetic tone, exogenous catecholamines, hypoxia, acidosis, bradycardia, etc.), enabling increased Ca^{2+} entry through $I_{Ca\text{-}L}$[31] and can trigger torsades de pointes, a form of VT. In the setting of heart failure, Ca^{2+} sparks occurring during *phase 2* or *phase 3* consequent to loss of synchrony in Ca^{2+} release at the start of the action potential can generate enough $I_{Na/Ca}$ current to trigger early afterdepolarizations.[32]

Afterdepolarizations are considered delayed if they develop in late *phase 4* and may also reach the threshold for triggering an action potential (see Fig. 72.3). The main underlying abnormality is intracellular Ca^{2+} overload, triggering Ca^{2+} release from the sarcoplasmic reticulum[31] and depolarizing currents (i.e., inward $I_{Na/Ca}$ currents).[33] Delayed afterdepolarizations are classically associated with digitalis toxicity; however, they can also occur with myocardial stretch, hypertrophy, catecholamines, ischemia, and reperfusion. In heart failure, increased expression of the Na^+-Ca^{2+} exchanger along with abnormalities in the ryanodine receptor predispose to delayed afterdepolarizations.[33]

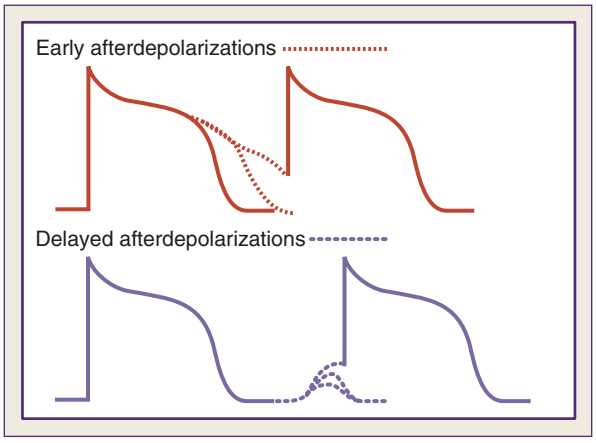

Fig. 72.3 Afterdepolarizations *(dotted lines).* Early afterdepolarizations are retardations in repolarization with prolongation in action potential duration *(upper figure).* Delayed afterdepolarizations represent spontaneous depolarizations that occur after repolarization is over *(lower figure).* Afterdepolarizations that reach a threshold trigger an action potential.

Abnormalities in Impulse Conduction (Reentry)

Abnormalities in impulse conduction leading to reentry account for the vast majority of sustained VTs. Reentry occurs when a propagating impulse reenters and reexcites a region of previously excited tissue after its refractory period is over. Several forms of reentry have been described, including circus movement, *phase 2,* and reflection.[34]

Circus Movement

Circus movement is the most widely studied reentry model and encompasses four distinct models: ring, leading circle, figure of eight, and spiral wave.

The *ring model* is the simplest,[35] and it is useful to illustrate the basic mechanism of reentry (Fig. 72.4). The ring model requires two contiguous paths separated by unexcitable tissue. One path—*b* in Fig. 72.4—has a zone of unidirectional block, whereas the other path—*a* in Fig. 72.4—allows slow but bidirectional conduction. Once the impulse traveling path *a* reaches path *b,* it propagates retrogradely to subsequently reenter path *a.* To establish reentry, the circling impulse wavelength must be shorter than the reentry circuit path length, allowing its leading edge to find tissue in an excitable state. The circling impulse wavelength is the product of conduction velocity and refractory period, and conditions that slow conduction or shorten refractoriness favor reentry. The ring model commonly involves AV accessory pathways and the AV node. Reentry is usually triggered by the arrival of a premature beat. Unidirectional block may result from increased refractoriness caused by anatomic abnormalities (e.g., fibrosis, accessory pathway, bundle branch block) or functional defects (e.g., ischemia, action of drugs).

The *leading circle model* is similar to the ring model but without requiring anatomic obstacles and can develop in structurally uniform myocardium by a properly timed premature impulse.[36]

The *figure-of-eight model* was first described in experimental myocardial infarction. It encompasses two reentry circuits moving alongside a functional conduction block (ischemia or infarct) in opposite directions, forming a pretzel-like configuration.[37]

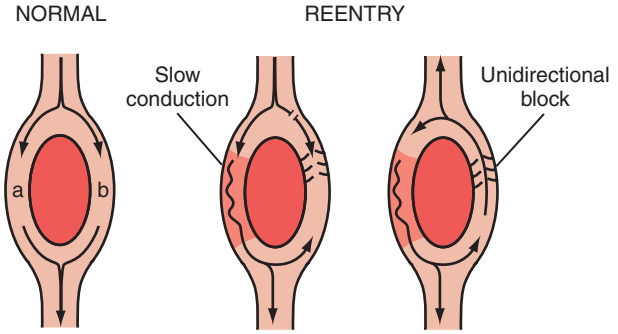

Fig. 72.4 Ring model of reentry.

The *spiral wave model* is a more complex version of the leading circle model and involves a core and filaments and can be described as reentry in two dimensions.[38] It has been used to explain monomorphic and polymorphic VTs and VF. In monomorphic VT, the spiral wave is anchored and unable to drift, whereas in polymorphic VTs—such as torsades de pointes—the spiral is thought to drift. In VF, the spiral wave is thought to break up into multiple rotating spiral waves that continuously extinguish and re-create. Yet some authors have proposed a single rapidly shifting spiral, and others have postulated a stationary rotor whose frequency of excitation is exceedingly high, resulting in multiple areas of intermittent block.[39]

Phase 2

Phase 2 reentry refers to local reexcitation consequent to repolarization heterogeneity with areas of markedly shortened repolarization—essentially obliterating *phase 2* of the action potential—next to areas of normal repolarization. Local reexcitation may precipitate VT during myocardial ischemia.[40] Action potentials of normal duration may alternate with ones of shorter duration during myocardial ischemia, yielding beat-to-beat alternans (temporal dispersion) and site-to-site alternans (spatial dispersion) and promote regions with conduction block and regions with injury current, leading to reentry and VTs. The degree of spatial and temporal dispersion progresses during ischemia, suggesting this mechanism may be an important trigger of VT and VF during acute myocardial ischemia.[41,42] In the surface electrocardiogram (ECG), dispersion of the action potential duration manifests as T-wave alternans, which is a predictor of VF.[43]

Reflection

Reflection refers to a back-and-forth propagation of the impulse over the same functionally unexcitable tissue, with recurrent activation of the proximal region as a result of electrotonic currents.[44] The area of unexcitable tissue could result from ischemia and lead to extrasystolic activity. Reflection differs from classic reentry in that the impulse travels along the same pathway in both directions.

PREEXISTING CONDITIONS PREDISPOSING TO VENTRICULAR ARRHYTHMIAS

Channelopathies

The term *channelopathies* has been coined to identify a group of diseases caused by abnormalities on ion channels.[45,46] These abnormalities distort the action potential, primarily accentuating the inherent instability of repolarization and increase the risk of polymorphic VT of the torsades de pointes type. Channelopathies may be hereditary or acquired.

Hereditary Channelopathies

Most hereditary channelopathies originate from mutations in genes encoding for Na^+, K^+, and Ca^{2+} channels and are largely represented by congenital long QT syndrome (LQTS),[47–51] Brugada syndrome,[52–55] and catecholaminergic polymorphic ventricular tachycardia (CPVT).[56–58] Less common channelopathies include short QT syndrome (SQTS)[59] and early repolarization syndrome (ERS).[60–62] All contribute with varying penetrance to sudden cardiac arrest in young individuals.[63,64]

Long QT Syndrome

LQTS was first described in 1957 by Jervell and Lange-Nielsen in patients with long QT intervals, episodes of torsades de pointes, and deafness.[65] The syndrome is transmitted by autosomal recessive inheritance and is known as *Jervell and Lange-Nielsen syndrome*. In 1963 and 1964, Romano and colleagues[66] and Ward[67] independently reported patients with an almost identical disorder but without deafness. The syndrome is transmitted by autosomal dominant inheritance and is known as *Romano-Ward syndrome*. Of 17 genes reported as being causative for LQTS, only 3 genes (*KCNQ1, KCNH2, SCN5A*) are considered definitive genes for typical LQTS, 9 genes (*ANKB, KCNE1, KCNE2, KCNJ2, CAV3, SCN4β, AKAP9, SNTA1, KCNJ5*) are classified as having limited evidence, and 4 genes (*CALM1, CALM2, CALM3, TRDN*) are found to have strong or definitive evidence as a cause of LQTS with atypical features, including neonatal AV block. The remaining *CACNA1C* gene has moderate evidence for causing LQTS.[68]

Jervell and Lange-Nielsen syndrome and Romano-Ward syndrome are primarily responsible for LQTS1 and account for nearly 50% of all genotyped families. LQTS2 accounts for nearly 40%, and long LQTS3 for about 5%. The remaining types are much less frequent.[69]

The common mechanistic thread is a perturbed balance between I_{Na} and I_K during *phase 2* of the action potential, yielding prolongation of repolarization, slowed $I_{Ca\text{-}L}$ inactivation, late Ca^{2+} influx, and early afterdepolarizations, predisposing to torsades de pointes.[70]

LQTS should be suspected in young individuals who present with syncope or episodes of sudden cardiac arrest precipitated by exercise, emotional distress, or conditions that prolong the QT interval. A family history of unexplained syncope or sudden cardiac arrest should raise suspicion. The diagnosis should be suspected when the corrected QT interval ($QTc = QT_{(ms)} \cdot \sqrt{R - R_{(ms)}}$) exceeds 470 ms in males (normal <422 ms) and 480 ms in females (normal <432 ms). Genetic testing for identifying the various LQTS subtypes is becoming readily available.[69] Genes with limited evidence for disease causation should not be routinely tested in the evaluation of patients and families with LQTS.[68]

The clinical implication is based on the application of precision medicine in clinical care and requires the accurate and appropriate use of genetic testing to optimize the care of patients and families. In addition to LQTS, several studies have shown that even milder prolongation of the QTc in adults (>450 ms in men and >470 ms in women) increases the risk of sudden cardiac arrest.[71]

Recently, mutations in calmodulin genes *CALM1* and *CALM2* have been shown to cause an extremely severe form of LQTS with QT prolongation >600 ms, T-wave alternans, cardiac arrest in infancy, and intermittent 2:1 AV block.[72,73]

A recent study showed that patients with LQTS have a significantly higher incidence of diabetes and higher incidence of neurologic (mostly epilepsy) and psychiatric disorders, suggesting that LQTS may be considered a multiorgan disease.[74]

The management of LQTS starts with discontinuing all drugs known to prolong the QT interval and correcting electrolyte imbalances and metabolic conditions that could trigger torsades de pointes. Restriction of participation in athletic activities is generally recommended along with use of beta-blockers and antiarrhythmic agents (e.g., mexiletine or flecainide). In selected cases an implantable defibrillator, cardiac sympathetic denervation, or both may be necessary.

Catecholaminergic Polymorphic Ventricular Tachycardia

CPVT is a highly malignant arrhythmogenic disorder that may present with sudden cardiac arrest induced by exercise or emotion, typically in children or adolescents without structural heart disease.[58] CPVT is associated with two main mutations that affect Ca^{2+} handling by the sarcoplasmic reticulum. One involves an autosomal dominant mutation on the ryanodine receptor gene *RyR2* (i.e., CPVT type 1). The mutation reduces the affinity of FKBP12.6 for *RyR2,* lowering the threshold for Ca^{2+} release from the sarcoplasmic reticulum.[57] Beta-adrenergic stimulation intensifies Ca^{2+} release and in part explains the effects of exercise and emotion.

The second is an autosomal recessive mutation on the calsequestrin 2 gene *CASQ2* (CPVT type 2). Within the sarcoplasmic reticulum, the CASQ2 protein serves as the major Ca^{2+} reservoir. The mutation causes a negatively charged domain that alters Ca^{2+} binding.[56]

The ECG at rest is typically normal with occasional U waves and bradycardia. Beta-blockers are the cornerstone of therapy, with an implantable cardioverter defibrillator (ICD) indicated in high-risk individuals. Flecainide inhibits the RyR2 receptor and can suppress or terminate the arrhythmias. Familial screening is indicated once the diagnosis is established.

Short QT Syndrome

SQTS is a more recently described syndrome[59] characterized by tall and peaked T waves with QT intervals ≤300 ms insensitive to changes in heart rate in structurally normal hearts. Individuals are at risk of developing atrial fibrillation and VF. A family history may be present, including sudden death at a young age.

The shortened QT interval results from increased outward K^+ currents during *phase 2* and *phase 3* of the action potential associated with autosomal dominant mutations in the *KCNH2*, *KCNJ2,* and *KCNQ1* genes.

ICD implantation is a class I recommendations in survivors of cardiac arrest and in patients with spontaneous sustained VT with or without syncope. Among various drugs, quinidine and sotalol could be effective by prolonging the QT interval.[59]

Brugada Syndrome

Another important hereditary channelopathy is Brugada syndrome, described in 1992 by the Brugada brothers,[52–55] who reported sudden cardiac arrest in individuals with structurally normal hearts but ST-segment elevation in V_1–V_3 and a QRS resembling right bundle branch block.

Brugada syndrome exhibits predominantly an autosomal dominant pattern of inheritance, with an average worldwide prevalence of 5:10,000.[75] Mutations have been identified in 10 genes.[76] Loss of function caused by a mutation in the *SCN5A* gene (encoding for the I_{Na} alpha subunit) accounts for approximately 20% of cases. The other 80% depends on mutations involving *GPD1-L, CACNA1C, CACNB2, SCN1B, KCNE3, SCN3B, MOG1, KCNE5,* and *KCND3*.[76]

The predominant genetic defect of the *SCN5A* gene leads to an accelerated inactivation of I_{Na}, leaving I_{To} unopposed and resulting in rapid repolarization with shortened action potential duration. In addition, the predominant epicardial expression of I_{To} allows normally depolarized endocardium to reexcite, prematurely repolarizing the epicardium and generating reentry, which in turn, can precipitate polymorphic VT.

The ST-segment elevation can adopt various shapes related to the severity of the I_{Na}/I_{To} imbalance. With increasing severity, saddleback, coved, and triangular shapes are recognized.[70] These changes are dynamic and can change in the same affected individual, as shown in Fig. 72.5.

Brugada syndrome exhibits variable expressivity, reduced penetrance, and "mixed phenotypes" where families may include members with Brugada syndrome and members with SQTS, LQTS, atrial fibrillation, disease of the conduction system, and even structural heart disease.[75]

Genetic testing can be useful when there is a personal and family history along with the characteristic electrocardiographic pattern identified at rest or after drug challenge.

Patients with Brugada syndrome may have concealed or intermittent forms, unmasked (or precipitated) by febrile states, vagotonic agents, alpha-adrenergic agonists, beta-adrenergic blockers, tricyclic or tetracyclic antidepressants, a combination of glucose and insulin and hypokalemia, and alcohol and cocaine toxicity.[77] Concealed Brugada syndrome can be unmasked by class IC antiarrhythmic drugs—for example, ajmaline (1 mg/kg intravenous [IV] in 5 minutes), flecainide (2 mg/kg IV in 10 minutes), or procainamide (10 mg/kg IV in 10 minutes). Such testing carries a 0.5% risk of precipitating VF. Ajmaline is favored because of its shorter half-life.[76] The test is considered positive if an additional 1-mm ST-segment elevation (0.08 second after the J point) occurs in leads V_1, V_2, and V_3. The test has high specificity and high sensitivity (94% and 80%, respectively).[78]

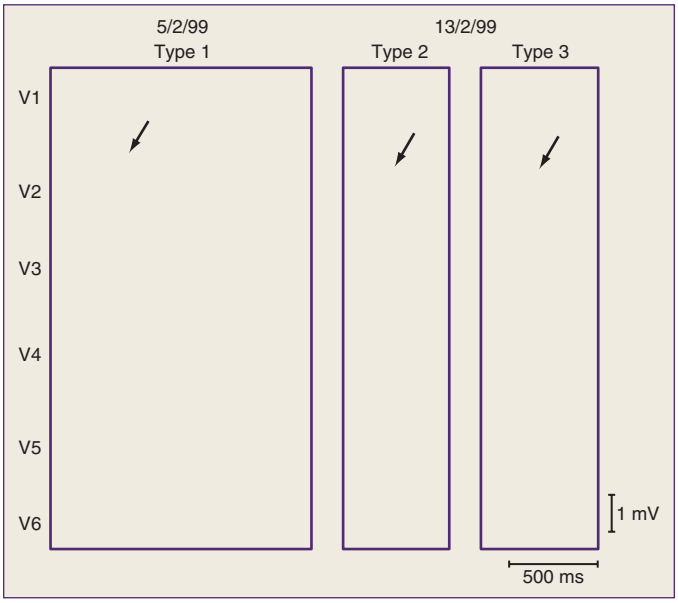

Fig. 72.5 Representative tracings in a patient with Brugada syndrome, demonstrating dynamic changes in V_1–V_2 after resuscitation from cardiac arrest. *Type 1* refers to the coved-type ST-T configuration, whereas *type 2* and *type 3* refer to the saddleback ST-T configuration. (From Wilde AA, Antzelevitch C, Borggrefe M, et al.; Study Group on the Molecular Basis of Arrhythmias of the European Society of Cardiology. Proposed diagnostic criteria for the Brugada syndrome: Consensus report. *Circulation.* 2002;106:2514–2519.)

Patients with suspected Brugada syndrome should be referred to specialized centers on inherited arrhythmias, which focus on counseling in daily life activities (e.g., avoiding excessive alcohol intake, treating fever aggressively, and decreasing exercise activity progressively). A familial screening should be performed to achieve early identification of affected relatives who could be at risk. The second step is a discussion on the therapeutic approach. The preferred management of Brugada syndrome is ICD implantation[54] after risk assessment, with a strong recommendation in symptomatic patients with a spontaneous ECG pattern. Less clear is the indication of ICD implantation in patients with intermediate risk.[79]

Quinidine and hydroquinidine can prevent spontaneous changes in the ECG and reduce the risk of VT and VF, presumably through inhibition of I_{To}.[80–82] However, because of limited data, it cannot be suggested for primary prevention, and the use should be discussed on a case-by-case basis in highly specialized centers.[83] Recently, ablation of the substrate located in the anterior epicardial region of the right ventricular outflow tract has been shown to reduce episodes of VF in patients with an ICD.[84] Determining which patients need pharmacologic treatment and those who would benefit from more aggressive treatment such as sympathectomies and implantable defibrillators is not always clear.

In addition, several diseases, such as myocardial ischemia, acute pericarditis, pulmonary embolism, right ventricular compression, and

metabolic disorder (e.g., hyperkalemia or hypokalemia and hypercalcemia) can exhibit a Brugada-like type 1 ECG pattern.[85,86] These Brugada syndrome phenocopies cannot be differentiated from true Brugada syndrome because of their identical ECG patterns, and a systematic diagnostic approach needs to avoid misdiagnosis.[79]

Early Repolarization and Early Repolarization Syndrome

Early repolarization is generally defined by a J-point elevation on the ECG >0.1 mV in two adjacent leads with a slurred or notched morphology affecting the inferior and/or lateral leads.[87] It is a condition commonly affecting between 1% and 5% of the general population,[60] with a higher incidence up to 13% in certain populations.[88] Early repolarization was previously thought to be a completely benign finding; however, studies and case reports suggest a higher risk of arrhythmias, mainly idiopathic VF in such patients,[61,62,89] and is common in patients who present with idiopathic VF and experience recurrence of VF.[90]

Early repolarization is mainly sporadic; however, genetic inheritance is being noted in the literature, and a wide array of both loss-of-function and gain-of-function genetic mutations have been reported.[91–93] Some studies have stratified the risk of developing arrhythmia based on the patterns of early repolarization on ECG.[87] Type 1 is associated with early repolarization in the lateral leads. This pattern is thought to be largely benign. Type 2 is associated with early repolarization in the inferior or inferolateral leads and is associated with a moderate level of risk. Type 3 is associated with early repolarization in the inferior, lateral, and right precordial leads and appears to be associated with the highest relative risk.[94]

It is important to differentiate between early repolarization in which only the classic ECG findings are found in an asymptomatic individual with ERS, which includes the classic ECG findings of early repolarization in a survivor of sudden cardiac death (SCD) with evidence of VF after an extensive workup has ruled out any other cardiac abnormalities.[95]

A class 1 recommendation for patients with asymptomatic early repolarization on the ECG is to observe. In this patient population in the acute setting of VF requiring defibrillation, isoproterenol was shown to be effective in suppressing the episode.[96] ICD is a class 1 recommendation in patients with ERS who are survivors of SCD.[97]

Acquired Channelopathies

Acquired channelopathies are common, with advanced heart failure being an important cause affecting the expression of ion channels regardless of the primary etiology.[98] There is downregulation of I_{To} and I_{K1} causing QT prolongation, possibly an adaptive response allowing a longer interval for excitation-contraction. Yet it predisposes to inhomogeneous repolarization, early afterdepolarizations, and triggered arrhythmias. There is also upregulation of the Na^+/Ca^{2+} exchanger—responsive in part to downregulation of the sarcoplasmic reticulum Ca^{2+}-ATPase (SERCA2a)[99]—yielding larger $I_{Na/Ca}$, also predisposing to delayed afterdepolarizations and triggered arrhythmias.

An increasingly important mechanism of acquired channelopathies is the use of drugs that prolong the QT interval; most of them are associated with drugs that block I_{Kr}, which is carried by subunits of the human ether-á-go-go *(HERG)* gene.[100] The list is long and includes antiarrhythmic and non-antiarrhythmic drugs. The University of Arizona's Health Sciences Center maintains a list of drugs categorized based on their potential to induce torsades de pointes (available at www.crediblemeds.org) and includes drugs with known risk, drugs with possible risk, drugs with conditional risk, and drugs to avoid in congenital LQTS.

The importance of drug-induced LQTS has mandated pharmaceutical companies to screen early in the process of drug development, mostly for effects on the *HERG* gene product.[100]

Other Conditions

The QT interval may be prolonged by cocaine abuse, organophosphate compounds, subarachnoid hemorrhage, stroke, myocardial ischemia, fasting using liquid protein–modified diets, autonomic neuropathy, and human immunodeficiency virus disease.[101–105] Electrolyte abnormalities can not only prolong but also shorten the QT interval. Some of these conditions and others not associated with channelopathies are discussed next.

Electrolyte Abnormalities

Electrolyte abnormalities rarely precipitate but often contribute to VTs, mostly in relation to abnormalities in serum K^+, Mg^{2+}, and Ca^{2+}.[106]

Hypokalemia (serum K^+ <3.5 mM) makes the resting membrane potential more negative, rendering cells less excitable and reducing the firing rate of pacemaker cells. Hypokalemia also prolongs the QT interval and flattens the T wave,[10] consequent to a dependency of I_{kr} conductivity on the square root of extracellular K^+ and resulting in a prolongation of repolarization at lower serum K^+, an effect more pronounced in the mid-myocardial region (greater I_{Kr}/I_{ks} ratio).

Hyperkalemia (serum K^+ >5.5 mM) makes the resting membrane potential less negative, rendering cells more excitable. By increasing I_{Kr}, hyperkalemia accelerates repolarization and shortens the action potential, explaining the characteristic peaked and tall T waves. With severe hyperkalemia, the rise rate of *phase 0* is reduced, slowing conduction and leading—at very high serum K^+ levels—to widespread blocks (i.e., widened P waves and widened QRS interval). A very rapid serum K^+ rise can precipitate VF, probably by reentry after developing areas of conduction block.

Mg^{2+} is a cofactor of the Na^+/K^+ pump and hence important for maintaining intracellular K^+ and the resting membrane potential. Mg^{2+} also modulates the effects of various K^+ and Ca^{2+} channels. Hypomagnesemia is associated with QT prolongation and increased risk of ventricular arrhythmias. This effect is usually compounded by other electrolyte deficits, including hypokalemia and hypocalcemia.

Serum Ca^{2+} is also important. Hypocalcemia increases the QT interval—predisposing to VT—whereas hypercalcemia exerts the opposite effects, reducing the QT interval. Changes in intracellular calcium contribute to arrhythmias associated with acute ischemia and reperfusion and may be important in the genesis of VT induced by exercise and by digitalis.

Hypothermia

Moderate (32°C–35°C) and severe (<32°C) hypothermia can predispose to VTs by QT prolongation and QT dispersion.[107] Typically, patients with hypothermia develop J waves (also known as *Osborn waves*) in the ECG, which reflect accentuation of the inhomogeneity of repolarization caused by the predominant distribution of I_{To} in subepicardial and mid-myocardial regions.[108]

Hypoglycemia

Acute hypoglycemia can trigger VT and VF in patients with diabetes mellitus.[109] The mechanism involves QT prolongation by direct suppression of repolarizing K^+ currents. In addition, the neuroendocrine stress response to hypoglycemia, via release of catecholamines, favors intracellular Ca^{2+} entry and reduction in serum K^+, further compounding the risk, especially in patients with coronary artery disease, acute myocardial infarction, left ventricular hypertrophy, autonomic neuropathy, congestive heart failure, and those taking medications that prolong the QT interval.

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is characterized by progressive replacement of the right ventricular muscle cells

by fibrous tissue and fat.[110] ARVC may be familial with autosomal dominant inheritance.[111] Patients present with palpitations and syncope, and this is an important cause of sudden cardiac arrest in subjects younger than 35 years, especially when related to exercise.[112]

The ECG is abnormal in 90% of cases, showing T-wave inversions beyond lead V_1 and epsilon waves in leads V_1–V_3. The QRS complex may be widened (>110 ms), with complete or incomplete right bundle branch block morphology. There are ventricular premature beats with left bundle branch configuration.

CLINICAL DIAGNOSIS

The first element to recognize is wide QRS complexes. They may indicate an origin in ventricular tissue; however, supraventricular ectopic activity can produce wide QRS complexes in the presence of preexistent or rate-dependent bundle branch blocks or aberrant pathways. The diagnostic clue is dissociation from atrial activity, which is often difficult to establish, having to rely on other indirect features, as discussed later. Ventricular arrhythmias present in several forms.[113]

Premature Ventricular Contractions

Premature ventricular contractions (PVCs) are isolated ventricular ectopic beats. The QRS is typically wide with opposing T-wave polarity and a full compensatory pause. PVCs may present one after each normal QRS in the form of bigeminy and also as couplets (two consecutive PVCs).

Ventricular Tachycardia

VT is defined as three or more consecutive ventricular ectopic beats with a rate typically greater than 100 bpm, often ranging between 130 and 170 bpm. QRS complexes are 120 ms or longer. However, wide QRS complex tachycardias can also be supraventricular when the impulse originates above the bifurcation of the His bundle but is conducted with aberrancy (see later).[114] VTs are classified as *monomorphic* if all QRS complexes have similar morphology and *polymorphic* if they have variable morphology. VTs are considered *nonsustained* if they last less than 30 seconds and *sustained* if they last 30 seconds or longer.

Nonsustained VTs are rarely symptomatic but are an independent risk factor for sudden cardiac death in patients with severe congestive heart failure.[115] Most sustained VTs present with palpitations, chest discomfort, and weakness or with more severe symptoms such as dizziness, angina, syncope, seizures, and even SCD.

Monomorphic Ventricular Tachycardia

Monomorphic VTs are the most common type of VTs and are usually associated with structural heart disease. The mechanism is commonly reentry operating within or around damaged myocardium. Examination of the jugular veins may show cannon A waves, indicative of AV dissociation.

A standard 12-lead ECG reveals a wide-complex tachycardia with regular complexes of similar morphology. A representative tracing is shown in Fig. 72.6. Establishing the diagnosis requires excluding the possibility of supraventricular tachycardia (SVT) with aberrancy. It is appropriate to assume that a wide-complex tachycardia is VT until proven otherwise in patients with myocardial ischemia, heart failure, and hemodynamic instability. SVT with aberrancy should be suspected if there is a history of previous aberrant rhythms, accessory pathways, and baseline or rate-induced bundle branch block. The ECG should be examined for evidence of AV dissociation (i.e., P waves and QRS complexes at uncoupled rates), which is specific for VT. Use of an esophageal lead could be useful by amplifying atrial potentials.

Some special forms of VT tend to be mistaken for SVT with aberrancy.[116] These include bundle branch reentrant tachycardia, in which the impulse travels down the right bundle branch, across the interventricular septum, and up the left bundle branch.[117] The morphology resembles SVT with left bundle branch block (LBBB) and is common among patients with nonischemic dilated cardiomyopathy.[118] Right ventricular outflow tract tachycardia is another condition caused by triggered activity from delayed afterdepolarizations that most commonly originate in the right ventricular outflow tract.[119] The tachycardia usually presents with LBBB morphology and right axis deviation. Right ventricular outflow tract tachycardias occur in structurally normal hearts, typically in young individuals, and are responsive to verapamil or adenosine.[120] Finally, there are fascicular tachycardias that originate from either fascicle of the left bundle branch. They occur in structurally normal hearts, mimic SVT with aberrancy, and are responsive to beta-blockers and verapamil.[121]

ECG algorithms are available to help differentiate VT from SVT. A widely accepted four-step algorithm was developed by Brugada and colleagues in the early nineties and reported to have 98.7% sensitivity and 96.5% specificity for VT.[122] However, more recent studies found the Brugada criteria to have lower sensitivity and specificity when used by emergency department physicians and cardiologists.[123] Vereckei and

Fig. 72.6 ECG tracing (leads II, III, and V_1) showing couplets followed by an 11-beat episode of nonsustained monomorphic ventricular tachycardia.

colleagues proposed a simpler criteria based on analysis of aVR and reported greater sensitivity and specificity.[124] The aVR lead is useful because in normal sinus rhythm and in SVTs, the ventricular activation wavefront moves away from aVR, typically yielding a QS complex and not an R wave, which is the step 1 criterion in the new algorithm (Fig. 72.7).

Polymorphic Ventricular Tachycardia

Polymorphic VTs have irregular rhythms, usually compromise hemodynamic function, and may quickly degenerate into VF. Variation in QRS morphology represents changes in the electrical axis. One special form of polymorphic VT is torsades de pointes. This is a descriptive term denoting a rotating electrical axis in 180 degrees along an imaginary axis ("twisting points"); it is typically associated with LQTS. Representative tracings are shown in Fig. 72.8.

Accelerated Idioventricular Rhythm

Accelerated idioventricular rhythm (AIVR) is a form of automatic ventricular arrhythmia characterized by regularly wide QRS complexes with a rate between 50 and 120 bpm. It is often slightly faster than the underlying sinus rhythm. AIVR does not produce symptoms, and the treatments for VT do not apply.[125] Its presence may indicate underlying myocardial ischemia.

Ventricular Fibrillation

VF is recognized by the abrupt onset of irregular waveforms of varying contour, duration, and amplitude without identifiable QRS and T waves accompanied by the ability of the heart to generate blood flow precipitating unconsciousness within seconds. VTs or SVTs that conduct through accessory pathways (e.g., Wolff-Parkinson-White syndrome) may be the initiating rhythm. Generalized seizures and agonal breathing may follow.

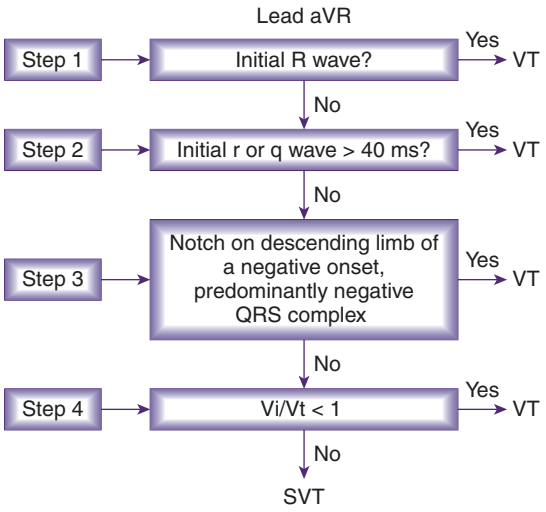

Fig. 72.7 aVR algorithm for distinguishing wide-complex monomorphic ventricular tachycardia (*VT*) from supraventricular tachycardia (SVT). VT is diagnosed whenever the analysis of aVR yields a positive answer to each successive step. In step 4, Vi and Vt refer to ventricular activation velocity measured as the vertical excursion (in millivolts) during the initial (*Vi*) and terminal 40 ms (*Vt*) of the QRS complex. When the initial or terminal 40 ms displays both positive and negative deflections, the sum of their absolute values (disregarding polarity) is used to calculate Vi and Vt, with the ratio Vi/Vt determining whether the rhythm is VT or SVT. (From Vereckei A, Duray G, Szenasi G, et al. Application of a new algorithm in the differential diagnosis of wide QRS complex tachycardia. *Eur Heart J.* 2007;28:589–600.)

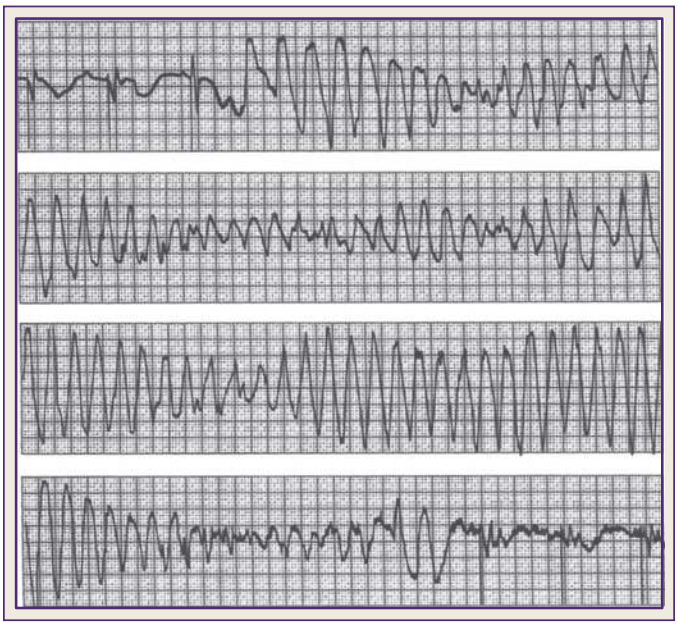
ACUTE MANAGEMENT

PVCs and episodes of nonsustained VT are of little hemodynamic significance in the structurally normal heart and may occur associated with the use of stimulants, electrolyte abnormalities, hypoxemia, catecholamine discharge, and medications, to name a few conditions. The management should focus on removing contributing factors. The risk of progression to sustained VT is low. Even the notorious R-on-T phenomenon has been shown to be of prognostic significance for development of VF only in patients with a predisposing substrate such as Brugada syndrome.[126] Antiarrhythmic drugs are typically not required. Persistence of nonsustained VT after an episode of critical illness should prompt assessment of underlying cardiac substrate and possible triggers.

The management of sustained VTs requires concurrent diagnostic and therapeutic interventions.[83] This is particularly the case in pulseless VT, polymorphic VT, and VF, when delivery of unsynchronized electrical shocks and advanced cardiac life support should be instituted without delay. In less urgent situations, treatment should focus on identifying the



A

B

Fig. 72.8 Torsades de pointes. **A,** Patient with a demand ventricular pacemaker developed QT prolongation (≈640 milliseconds, seen during paced rhythm) after treatment with amiodarone for recurrent ventricular tachycardia (VT). An episode of torsades de pointes developed that spontaneously terminated with resumption of a paced ventricular rhythm. **B,** Tracing from a young boy with congenital long QT syndrome and marked prolongation of the QTU interval (≈600 milliseconds). TU alternans is noted before a late premature complex, occurring on the downslope of the TU wave, which initiates an episode of VT. (From Braunwald E, Zipes D, Libby P, eds. *Heart Disease: A Textbook of Cardiovascular Medicine,* 6th ed. Philadelphia: Saunders; 2001:868.)

substrate and the triggering events. Arrhythmogenic conditions commonly present in critically ill patients include hemodynamic and respiratory abnormalities, endogenous or exogenous adrenergic states, acid-base and electrolyte imbalances, presence of proarrhythmic drugs, prolongation of the QT interval, ongoing myocardial ischemia, and mechanical stimulation of cardiac structures. Often, the treatment of these factors suffices to terminate the arrhythmic episode. Specific antiarrhythmic interventions should take into consideration the type of rhythm and the degree of hemodynamic stability.

Ventricular Arrhythmias With Preserved Blood Flow

Monomorphic Ventricular Tachycardia

Direct-current synchronized cardioversion and IV antiarrhythmic agents are acceptable first-line options. Antiarrhythmic agents have the advantage of having a persistent effect after termination of the event and that anesthetic agents are not required; however, patients may experience adverse effects, including hypotension and increased susceptibility to arrhythmias, given that most agents cause QT prolongation.

The American College of Cardiology/American Heart Association/European Society of Cardiology (ACC/AHA/ESC) 2017 guidelines for management of patients with ventricular arrhythmias[83] recognize various drugs available in IV formulation for VT, including beta-blockers, sotalol, lidocaine, and amiodarone, with availability contingent on the specific country. Close monitoring is recommended, as IV procainamide can cause transient hypotension,[127] especially in patients with severe left ventricular dysfunction. For patients with sustained monomorphic VT who are hemodynamically unstable, are refractory to electrical shocks, or have recurrent episodes despite procainamide or other agents, IV amiodarone is considered a reasonable choice.[128,129] The initial effect of amiodarone is to slow down AV nodal conduction and block adrenergic stimulation. However, effects on ventricular conduction and refractoriness develop more gradually, achieving the maximal effect only after weeks or months of treatment.[130,131]

When sustained monomorphic VTs are associated with an acute ischemic substrate (i.e., unstable angina or myocardial infarction), lidocaine is considered a reasonable initial choice.[132] Calcium channel blockers such as verapamil and diltiazem should not be used to terminate wide-QRS-complex tachycardia of unknown origin, especially when myocardial dysfunction is present.

Addition of a second antiarrhythmic agent is discouraged to avoid compounding proarrhythmic effects. Thus a single agent should be used and proceed to direct-current synchronized electrical cardioversion if optimal dosing fails.

Direct-current synchronized cardioversion should be considered first-line treatment in patients who are unstable or in those with borderline blood pressure who could experience further deterioration by the vasodilator and antiinotropic effects of antiarrhythmic agents. Monophasic waveform electric shocks at an initial energy of 100 J or higher are effective, with comparable or lower energy levels expected to be effective using biphasic waveform electric shocks. Transvenous pacing with override pacing can terminate monomorphic VT and should be considered in instances of failed cardioversion or frequent recurrence despite antiarrhythmic medication.

Ventricular Arrhythmias With Cessation of Effective Blood Flow

Cessation of blood flow occurs with pulseless VT, VF, and polymorphic VT. The immediate priority is to reestablish an organized electrical activity with mechanically competent pump function, typically requiring the unsynchronized delivery of electric shocks, with cardiopulmonary resuscitation contingent on the duration of the arrhythmia and the response to electrical shocks.

Ventricular Fibrillation and Pulseless Ventricular Tachycardia

Current resuscitation algorithms consider VF and pulseless VT as rhythms requiring delivery of electric shocks upon their recognition through an automated external defibrillator or through manual defibrillators along with quality chest compressions. If VT/VF persists after the third shock, IV amiodarone is recommended.[133] The energy level of the initial electric shock depends on the specific device. For biphasic waveform defibrillators, the energy level typically ranges from 150 to 200 J. The specific energy level should be selected based on the manufacturer's specification. If the available defibrillator uses monophasic waveforms, the energy level should be 360 J. The probability of survival after VF and pulseless VT is inversely related to the time elapsed between the onset of the arrhythmia and the delivery of electric shocks and the quality of cardiopulmonary resusciation.[134]

Electrical storm is a rather uncommon but highly lethal phenomenon defined as recurrent episodes of VF occurring mainly during an acute myocardial infarction, and conventional antiarrhythmic drug therapy—including lidocaine and procainamide—often fails to secure a stable sinus rhythm.

Polymorphic Ventricular Tachycardia

Polymorphic VT with cessation of effective blood flow is treated as VF with unsynchronized shocks at the same energy as for VF. As with all ventricular arrhythmias, substantial effort must be directed at identifying and correcting the causes.

Polymorphic VT with a normal QT interval is most frequently associated with acute myocardial ischemia but also with cardiomyopathies, idiopathic polymorphic VT, and catecholaminergic VT. In this setting, use of IV beta-blockers[135] or IV amiodarone[136] is effective. Coronary angiography should be considered for recurrent polymorphic VT when ischemia is suspected.[137]

Polymorphic VT with prolonged QT interval is usually associated with bradycardia. The management includes discontinuation of drugs that prolong the QT interval, correction of electrolyte abnormalities, and avoidance of catecholamines. In the setting of congenital LQTS, beta-blockers (or sympathetic interruption), pacing, and implantation of an ICD should be considered. In the acquired forms of LQTS, IV magnesium, overdrive pacing, and beta-blockers after pacing are recommended interventions, with recent work suggesting the potential for treatment through gene therapy.[138,139]

CONCLUSION

VTs are important and common manifestations of cardiac and extracardiac abnormalities in critically ill patients. In addition to the traditional assessment based on ECGs and hemodynamic manifestations, understanding and recognizing the processes that affect ion channels, pumps, exchangers, and signaling mechanisms are important for proper management. There is also increased awareness that mutations affecting cardiac channels are prevalent and clinically relevant. The intensivist should be alert and prepared to identify them and provide the necessary initial treatment and referral when appropriate. Initial enthusiasm for antiarrhythmic agents has diminished as the pro-arrhythmic effects of various compounds have become evident. Some drugs are no longer recommended as first-line agents, whereas others have become components of accepted algorithms. More emphasis is currently being placed on understanding arrhythmogenic mechanisms and on correcting the precipitating and maintaining factors.

KEY POINTS

- Hereditary and acquired abnormalities in cardiac ion channels can alter the action potential, mostly by prolonging repolarization, and predispose to VTs, especially torsades de pointes.
- Ventricular arrhythmias are the result of abnormalities in impulse generation (automaticity and triggered activity) and impulse conduction (reentry).
- Proper management of VTs requires assessment of precipitating and sustaining conditions; often, the removal of these conditions is all that is needed.
- A long QT interval in the baseline ECG should prompt a diligent search for possible drugs, metabolic abnormalities, or hereditary channelopathies.
- VTs in critically ill patients are often precipitated by cardiac, metabolic, and respiratory processes.
- AV dissociation is a reliable sign that a wide-complex tachycardia is ventricular; this may be evident on the surface 12-lead ECG or after analyzing an esophageal lead.
- Direct-current synchronized cardioversion should be considered first-line treatment in patients with VT who are hemodynamically unstable or have heart failure.

Conduction Disturbances and Cardiac Pacemakers

Lorenzo Pitisci, Georgiana Bentea, Ricardo E. Verdiner, and Ruben Casado-Arroyo

CONDUCTION DISTURBANCES

Patients admitted to the intensive care unit (ICU) frequently have conduction disturbances because of their acute medical condition or underlying risk factors. The clinical manifestation varies broadly from asymptomatic to life-threatening events. Locating and understanding the conduction disturbances are vital to stratifying the patient's risk and choosing the best medical or invasive therapy option.

Normal Cardiac Conduction

Depolarization of the myocardium begins spontaneously from a specialized group of cells forming the sinoatrial (SA) node located in the superior and posterior portion of the right atrium (RA). They are regulated by the sympathetic and parasympathetic nervous system. The activity of the cells cannot be seen on a surface electrocardiogram (ECG).

SA depolarization spreads through the right then left atrium, resulting in the P wave seen on the surface ECG. Because the atria and ventricles are electrically isolated, the impulse must travel through the atrioventricular (AV) node, located in the lower part of the atrial septum and regulated by the sympathetic and parasympathetic nervous system as well, to generate the PR interval on ECG.

The impulse is transmitted to the ventricles through the bundle of His, dividing into right and left bundle branches to finally diffusely ramify to form the Purkinje network, resulting in the QRS wave on ECG. The ventricular repolarization can be observed as the T wave on ECG. The atria repolarization is hidden by the ventricular depolarization (QRS).

Bradycardia

Bradycardia is defined as a heart rate (HR) <60 bpm. It can be divided into two categories: sinus node dysfunction (SND), when the rate of impulses arising from the SA node is lower than expected, and AV block, when there is failure to propagate the impulse from the atrium to the ventricle. SND and AV block share common etiologies and may be present at the same time. Nevertheless, their prognosis and treatment are not the same. A high-quality 12-lead surface ECG is mandatory to help differentiate them. Etiologies of bradyarrhythmia are listed in Table 73.1.

Sinus Node Dysfunction

SND refers to a number of conditions causing symptoms and inappropriate atrial rates (bradycardia, sinus pauses, and sinus arrest).[1-4] Symptoms could include weakness, chronotropic incompetence (inability to reach a targeted heart rate), palpitations, and syncope. The mechanism is either an inner pacemaker defect or an SA block (Table 73.2). Degenerative age-related SA fibrosis is the main cause of SND, affecting patients in their seventies and eighties. The fibrotic process, however, is not just limited to the SA. SND is often associated with AV node fibrosis as well. Patients with symptoms attributable to SND have a higher risk of cardiovascular events, including syncope, atrial fibrillation, and heart failure (HF). Moreover, the development of chronotropic incompetence with age is associated with an increased risk of cardiovascular death and overall mortality. Usually, SND is chronic and the result of irreversible causes. Even when clinical presentation is acute and potentially reversible, as in acute myocardial infarction, electrolyte/metabolic disturbances, dysthyroidism, and iatrogenesis (e.g., beta-blocker [BB] use), symptoms are typically mild, stable, and generally do not require therapy apart from correcting the metabolic disturbances and stopping the medication that generated the syndrome. In brady-tachy syndrome (a variant of SND), SND is responsible for pauses after termination of atrial tachyarrhythmia and often needs either invasive ablation of the arrythmia, permanent pacing, or both. Table 73.3 shows a description of the different etiologies of SND.

Atrioventricular Block

AV block encompasses all possible lesions, congenital or acquired, that may interrupt or delay the normal propagation of the sinus node impulse to the ventricles. The most common cause is degenerative. Congenital (Fallot, transposition of the great arteries, etc.) and systemic disorders (amyloidosis, Fabry disease, etc.) are rarer nonreversible etiologies (Table 73.4). As block level and position are associated with different prognoses and therapeutic options, locating block sites helps in understanding the mechanism and stratifying the patient's risk. AV node location (supra-Hisian) is characterized by a slower progression of the disease and a more sustained and reliable junctional escape mechanism with better response to chronotropic drugs (atropine, isoproterenol). On surface ECG, the QRS complex is usually thin. In contrast, intra- and infra-Hisian AV blocks are characterized by a broader QRS complex (>120 ms), poorer prognosis, faster progression, less reliable junctional escape mechanism, and poor or paradoxical response to chronotropic drugs. Some clinical maneuvers can help to identify the level of the disease. Carotid sinus massage, which increases the vagal tone and slows the sinus rate and conduction through the AV node, would further deteriorate nodal block. It may improve the infra-Hisian block by improving the His-Purkinje conduction of slower sinus beats. Atropine, isoproterenol, and exercise would improve a supra-Hisian block but would deteriorate an infra-Hisian block.

AV blocks are also categorized according to a three-degree scale. In first-degree AV block (BAV 1°), every P wave is conducted to the ventricles with an increased conduction delay (PR >200 ms) (Fig. 73.1A). BAV1° is usually asymptomatic and requires no treatment.

TABLE 73.1 Etiologies of Bradyarrhythmias

Intrinsic	Extrinsic
Idiopathic (aging) degeneration	Exaggerated vagal activity: vasovagal, situational, carotid sinus hypersensitivity
Ischemic heart disease	Drug effects: antiarrhythmics, digoxin, clonidine, opioids, lithium, dexmedetomidine
Infiltrative heart disease: sarcoidosis, amyloidosis, hemochromatosis	Electrolyte disturbances: hyperkalemia
Vasculitis because of collagenopathies: rheumatoid arthritis, systemic lupus erythematosus	Hypothyroidism
Infective heart disease: myocarditis, endocarditis, Lyme disease, Chagas disease	Hypothermia
Surgical trauma: catheter ablation procedures, valve replacement (including transcatheter aortic valve implantation)	Hypoxia
Congenital diseases	Increased intracranial pressure
Myopathies (Dannon disease)	

TABLE 73.2 Types of Sinus Node Dysfunction

	Sinus Bradycardia	Sinus Pause/Arrest	Sinus Node Exit Block	Bradycardia-Tachycardia Syndrome
Definition and pathogenesis	SA node discharges at rates inferior to the physiologic needs of the individual.	No spontaneous SA node impulse formation (automaticity) longer than 3 sec (85% of such cases are symptomatic).[5]	First-degree SA exit block reflects a conduction delay of the SA impulse in the perinodal region Second-degree SA exit block is a periodic failure of the sinus impulse to exit the sinus node. Mobitz I (Wenckebach) when the SA node discharges at a constant rate with progressive prolongation of conduction within the perinodal area (hence electrical impulses reach the atrial myocardium with a progressive delay). Mobitz II includes the failure of multiple impulses to exit the sinus node. Third-degree SA exit block reflects a complete conduction block in the SA junction.	Alternating paroxysms of regular or irregular atrial tachyarrhythmias and sinus node dysfunction. The syndrome occurs in more than 50% of individuals with SA node dysfunction.[6]
ECG patterns	Sinus rhythm of less than 60 bpm, 40–50 bpm in athletes and healthy young individuals.[7]	The absence of P waves with sinus pause, which is not equal to the sum of PP intervals.	First-degree SA exit block cannot be identified on a regular ECG. It can be observed during direct electrophysiologic recording by measuring SA conduction time. Second-degree SA exit block: Mobitz I (Wenckebach) is characterized by a progressive shortening of the PP interval until block occurs with a pause of less than two times the shortest PP interval. Mobitz II is characterized by constant PP intervals and a pause that equals the sum of PP intervals. Third-degree SA exit block cannot be accurately distinguished from sinus arrest in the surface ECG.	Alternating sinus pauses with episodes of paroxysmal AF, atrial flutter, or re-entrant atrial tachycardias.

AF, Atrial fibrillation; *ECG,* electrocardiogram; *SA,* sinoatrial.

In second-degree AV blocks (BAV 2°), some P waves are not conducted to the ventricles. BAV 2° are divided into two types:

1. Mobitz I is defined by a progressively longer PR period on consecutive beats, ultimately followed by a blocked P wave. The next PR period is then reset to the shortest duration and it repeats (Wenckebach conduction). The block location is usually nodal (72%) (see Fig. 73.1B).
2. Mobitz II does not follow the same scheme and preserves a certain degree of P-wave conduction (see Fig. 73.1C). The block location is usually intra-Hisian (20%) or infra-Hisian (80%).

The clinical presentation of first-degree AV block is usually benign and only very rarely are symptoms felt to be directly related to first-degree AV block. There are no signs or symptoms that are either sensitive or specific for first-degree AV block.

Most patients with high AV block will present with some degree of symptoms, though the severity of the symptoms can be quite variable. Symptoms in high AV block (Mobitz II) may include fatigue, dyspnea, chest pain, presyncope, syncope, Stokes-Adams attack, and sudden cardiac arrest.

The P:R ratio is used to describe how many P and QRS waves are contained in one repetitive block. The higher the ratio, the more severe the block. A case of 2:1 BAV 2° can be particularly challenging to determine whether it is Mobitz type I or II.

High-degree or high-grade blocks refer to more than two consecutive nonconducted P waves without a complete loss of AV conduction

TABLE 73.3 Etiologies of Sinus Node Dysfunction

Congenital Sinus Node Dysfunction Long QT syndrome, Brugada syndrome, congenital heart disease, noncompaction cardiomyopathy
Acquired Sinus Node Dysfunction Myocardial ischemia
Infective heart disease
Dengue fever, Chagas disease, encephalitis, endocarditis, Legionnaires disease, typhoid, diphtheria, rheumatic carditis
Autoimmune diseases
Systemic lupus erythematosus, systemic sclerosis
Infiltrative diseases
Hemochromatosis, cardiac lipomatosis, amyloidosis
Endocrine disease
Hypothyroidism, hyperthyroidism, hyperparathyroidism, phaeochromocytoma
Autonomic dysfunction
Carotid hypersensitivity syndrome, athletic training, intracranial hypertension
Drugs
Antiarrhythmics, digitalis, ticagrelor, lacosamide, carbamazepine, lithium, ropinirole, ranitidine, clonidine, diphenylhydantoin
Iatrogenic
Cardiac surgery procedures, especially for congenital pathologies
Radiofrequency catheter ablation of arrhythmias
Percutaneous coronary intervention: right coronary artery stent implantation because of iatrogenic occlusion of sinus node artery

TABLE 73.4 Etiologies of Reversible Conduction Disturbances

Electrolyte disturbances	Hyperphosphatemia or hypophosphatemia
	Acidosis
	Hypoglycemia
Hypoxemia/hypercapnia	Sleep apnea, alcohol and/or drug abuse
Ischemia	Acute myocardial infarction
Heart surgery	Maze procedure
	Valve replacement
Infectious	Lyme disease
	Acute rheumatic fever
	Diphtheria, *Legionella*, psittacosis, typhoid fever, *Listeria*, malaria, leptospirosis, dengue fever
	Viral syndrome
Dysthyroidism	Hypothyroidism
Hypervagotonia	Stress, pain, carotid compression, other
Drugs	Beta-blockers
	Non-dihydropyridine calcium channel blockers
	Digoxin and antiarrhythmic drugs
	Lithium, methyldopa, risperidone, cisplatin, interferon
Autoimmune disease	Sarcoidosis, ankylosing spondylitis, rheumatoid arthritis, scleroderma, lupus

(Fig. 73.2). These latter types are more intra- or infra-Hisian and associated with a poorer prognosis.

In cases of acute myocardial infarction, acute AV blocks secondary to right or circumflex coronary artery (responsible for AV and His bundle vascularization in most of the cases) occlusion are usually nodal and associated with a good prognosis and rapid recovery. Those

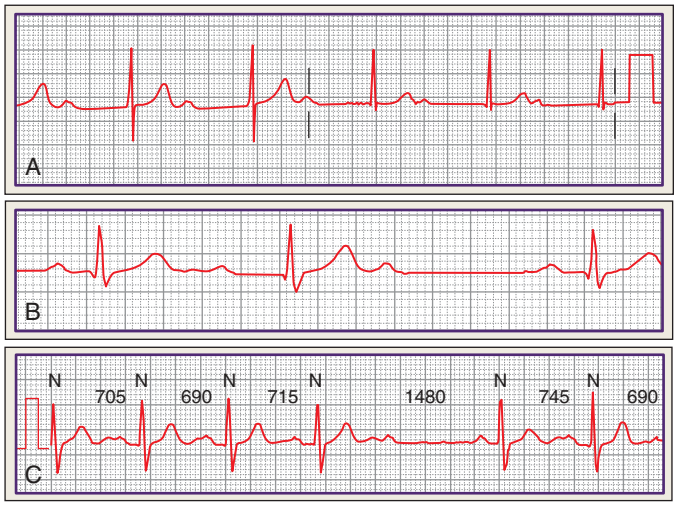

Fig. 73.1 Atrioventricular Block. A, Electrocardiogram from a patient with first-degree atrioventricular block. The PR interval is approximately 290 milliseconds. All P waves are being conducted to the ventricles. The PR interval is constant. **B,** Electrocardiogram rhythm strip from a patient with second-degree atrioventricular block type I. Note progressive prolongation of the PR interval until failure of conduction occurs. The pattern of conduction is 3:2. **C,** Electrocardiogram demonstrating second-degree atrioventricular block type II. The PR interval is constant before and after the blocked P waves. The QRS complex is widened.

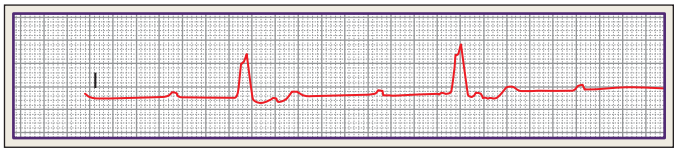

Fig. 73.2 Complete Heart Block. The PR intervals are irregular because the ventricles and atria represent two independent sources of depolarization.

secondary to left anterior descending artery (LAD) occlusion (responsible for right and left anterior bundle brunch vascularization) are associated with a poorer prognosis (infra-Hisian location) and fatal ventricular arrythmia.

Laboratory testing. Measurements of electrolytes, glycemia, pH, renal function, thyroid function, and Lyme serologic testing (if clinical suspicion of Lyme carditis) should be performed in any acute bradyarrhythmia, as they are common and reversible causes that can be treated promptly with possible normalization of conductance disturbances.

Imaging in patients with conduction disorder. Conduction disturbances are encountered in a wide range of cardiovascular and systemic disease with very different prognoses and treatments. Assessment of heart structure and function is highly useful in order to exclude cardiomyopathies, valvular heart diseases, tumors, infections (endocarditis with abscess formation), congenital anomalies, infiltrative processes, great vessel disease, and pericardial diseases. Except for sinus bradycardia and first-degree AV block with no evidence of structural heart disease, it is recommended to perform a transthoracic echocardiography. This is especially true in newly identified left bundle branch block (LBBB; patients with LBBB have a higher prevalence of both noncardiovascular and cardiovascular comorbidities, including structural heart disease),[8] AV block Mobitz II, and high-grade AV block. Magnetic resonance imaging (MRI) can be helpful in diagnosing an infiltrative or dilated cardiomyopathy. Cardiac computed tomography (CT) is helpful for the assessment of valve calcification and coronary artery disease.

Acute medical therapy for bradycardia. The initial management of the patient with AV block depends on the presence and severity of any signs and symptoms related to the ventricular rate (Fig. 73.3). Unstable patients may require pharmacologic therapy and, in some cases, should also receive temporary pacing to increase heart rate and cardiac output. Once the patient is hemodynamically stable, assessment and treatment for any potentially reversible causes should occur, followed by placement of a permanent pacemaker for patients without an identifiable reversible etiology.

Regarding the pharmacologic therapy, atropine should be used in patients with symptomatic bradycardia or hemodynamic (HD) compromise with SND except in patients with heart transplant, in which paradoxical heart block is observed.[9,10] Isoproterenol may be used in symptomatic bradycardia/HD compromise with SND, but there are no data to either support or discourage its use in sinus bradycardia.[7,10,11]Atropine should be used in patients with symptomatic bradycardia or HD compromise with second- or third-degree AV block with caution when the block location is thought to be intranodal or infranodal because of paradoxical worsening of conduction.[7] Isoproterenol may be used in patients with symptomatic bradycardia or HD compromise with second- or third-degree AV block if the likelihood of myocardial ischemia is low.

Calcium channel blocker– or beta-blocker–induced SND and/or AV block. Patients with bradycardia-induced symptoms or hemodynamic instability caused by BBs, calcium channel blocker (CCB) overdose, or high-dose insulin therapy should be given glucagon intravenously to increase heart rate and to improve symptoms. Only if bradycardia is the result of CCB therapy should intravenous (IV) calcium be administrated to improve symptoms. Hypercalcemia is rare, but close monitoring is mandatory and central vein infusion is preferred. Hemodialysis

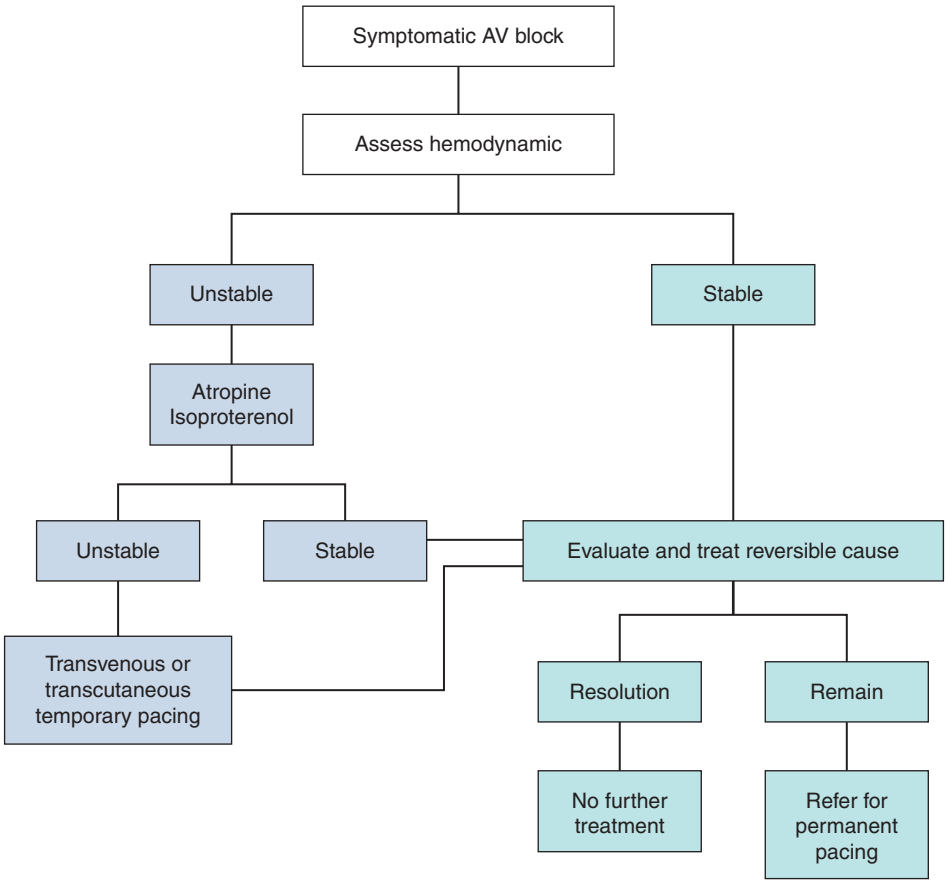

Fig. 73.3 Acute Management of Symptomatic Atrioventricular (*AV*) Block.

may be needed in specific circumstances, although this is uncommon. Given the low toxicity of these antidotes in relation to the severity and the low frequency of BB/CCB overdose, there are no randomized trials to support their use in clinical practice.

Digoxin overdose–induced SND and/or AV block. Bradycardia-induced symptoms or hemodynamic instability by digoxin overdose should be reversed with digoxin Fab antibody fragment. Observational studies have reported a clinical response within 30–45 minutes.[5,6,12] Bradycardia can be treated with atropine and hypotension with IV boluses of isotonic crystalloid in the meantime. Hemodialysis is not recommended. Potassium levels should be monitored. Adverse effects include HF, tachycardia, and hypokalemia; allergic reactions are rare.

Bradycardia in heart transplant and spinal cord injury. SND in the context of denervation after spinal cord injury or after heart transplant is challenging, as atropine may have a paradoxical effect.[9] Administration of oral theophylline was associated in two studies of 15 and 29 patients with increased HR >90 bpm. The evidence concerning aminophylline is less clear.

Patients with bradycardia-induced symptoms or hemodynamic instability with spinal cord injury should be given aminophylline or theophylline orally for 4–6 weeks to improve heart rate and symptoms.

Temporary pacing for bradycardia SND. Temporary pacing should be used for acute treatment of severe symptomatic bradycardia or ventricular arrythmia triggered during bradycardia with hemodynamic instability when medical treatment is failing. It can be delivered transcutaneously until an internal temporary right ventricular (RV) lead is inserted.

Permanent pacing for bradycardia. If all reversible causes of bradycardia are excluded and/or corrected, permanent pacing is considered. A large number of patients are treated with BBs or CCBs, and studies have shown that the withdrawal of these drugs rarely reversed the AV block and only delayed the permanent pacemaker insertion.[13–15] Because AV block secondary to sarcoidosis rarely recovers, many clinicians choose an early strategy to pacemaker implantation in these particular cases (Table 73.5).

Heart surgery and TAVI. Symptomatic and/or hemodynamic instability caused by SND and, most frequently, AV block are not rare after cardiac surgery. The aortic and tricuspid valves are located just next to the AV node and the mitral valve next to the bundle of His. Temporary epicardial leads are recommended during heart valve surgery. Permanent pacing is recommended after 5–7 days of persisting symptoms.

Transcatheter aortic valve implantation (TAVI) procedures are at high risk of periprocedural conduction disturbances requiring permanent pacing (12.6%–17.5% in recent registers).[16,17] The most robust preprocedural predictor is the presence of right bundle branch block (RBBB) (multivariable odds ratio: 2.8–46.7 times).[17] If there is no previous RBBB and no conduction changes peri- or post-procedure, the temporary pacemaker can be removed as early as the first 24 hours. If complete AV block or high-degree AV block occurs, permanent pacing is recommended.[17]

TABLE 73.5 Pacing Modes

Pacing Mode	Indication
VVI(R)	Symptomatic bradycardia and AV asynchrony (atrial tachyarrhythmia)
AAI(R)	Symptomatic sinus node dysfunction if AV node conduction preserved
DDD(R)	Symptomatic bradycardia and AV synchrony (i.e., SND and AV block)
DDI(R)	Idem DDD/DDDR and paroxysmal supraventricular tachycardia
DOO/VOO	Asynchrony mode (i.e., MRI mode)

A, atrial; *AV,* atrioventricular; *D,* A+V; *O,* no response to sensing; *I,* inhibition; *MRI,* magnetic resonance imaging; *SND,* sinus node dysfunction; *R,* responsiveness; *V,* ventricular.

CARDIAC IMPLANTED DEVICES

Permanent Pacing

Many patients have implanted cardiac devices such as pacemakers and defibrillators. These devices are made of one pulse generator containing the battery and one to three leads connected to the RA, RV, or left ventricle (LV) either through the endocardium or epicardium. Every pacemaker patient should have a card containing all information about the device (leads, brand, type, and implantation date). When the information is missing or incomplete, chest x-ray can be helpful to understand how many leads are present, if their integrity is preserved, and if their position is correct. An intracardiac leadless pacemaker can be implanted instead if there are potential hazards with using a conventional device. In a prospective multicenter study evaluating its implantation in 725 patients, 719 devices were deployed with success, with a 96% primary safety endpoint (complication rate was about 4%, with cardiac perforation/tamponade 1.6%, HF 0.9%, and fistula or aneurysm at puncture site 0.7%). No dislodgment was observed.[18] Specific brand controllers are available to modify parameters and retrieve information such as battery life, pacing threshold and sensitivity, and lead impedance.

Temporary Cardiac Pacing

About 20% of patients presenting with bradycardia in the emergency room will need temporary pacing.[10] In general, any patient with bradycardia causing symptoms or hemodynamic instability that is unresponsive to atropine ought to be considered for temporary pacing. These devices (transcutaneous or endocardial) are typically used transiently to compensate for an acute symptomatic bradycardia until it resolves or a permanent pacemaker can be placed.

Transcutaneous pacing was introduced in the 1950s.[19] Pacemakers pads are placed anteriorly (right upper chest and lateral to the apex of the heart) or in an anteroposterior position. The generator unit is typically set to 70 bpm, and the current is increased up to 40–80 mA for adults until the myocardium captures the signal at every beat based on continuous ECG monitoring and arterial pulse check. For safety, the current is then set 10 mA above the upper capture limit.[20,21]

Because of the sedation required and possible AV asynchrony, transcutaneous pacing is only used as a fast bridge to transvenous endocardial pacing. The latter is more stable and much better tolerated by patients. Using the Seldinger wire technique, an electrode catheter is inserted through a sheath in either the femoral, subclavian, or jugular vein. Under fluoroscopy and/or echo guidance,[22] the electrode is connected to a pulse generator pacing at maximum output at 70 bpm and advanced cautiously in the right ventricle. The device is positioned properly when the surface ECG shows 70 bpm paced with LBBB morphology, and the position is confirmed with a chest x-ray, fluoroscopy, or echo.

Adverse complications of endocardial pacing range from 14% to 40% and are linked to the extent of pacing[23,24]: venous thromboses, pulmonary emboli (femoral approach mostly), perforation, life-threatening arrythmia, loss of capture, and death. Because the electrode is passively applied against the endocardium, dislodgment is common (lateral head movement when introduced through the jugular approach as an example). Temporary pacing should be as short of

a duration as possible. Fewer complications were reported with jugular access and fluoroscopic or echo-guided lead placement.[22,25] When durable temporary pacing is needed (i.e., infection), a temporary pacemaker with active fixation leads is more suitable.[26] Importantly, temporary pacing should never delay emergency cardiac reperfusion in the case of ischemia-induced bradycardia.

When establishing temporary pacing, the pacing threshold should be determined, and the pacing energy should then be set at two to three times this minimum output. Thresholds should be checked daily.

Pacing Modes

The North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group created a code consisting of five letters to describe pacemaker functions known as the *NBG pacemaker* (see Table 73.5). The first letter indicates the cavities that are paced. The second letter indicates the cavities that are sensed. The third letter indicates the response of the device if the programmed event occurs. The fourth letter indicates if a special rate function is activated (i.e., rate responsiveness function using accelerometers inside the pulse generator allowing the basal heart rate to increase in case of physical activity). The fifth describes any anti-tachycardia functions or resynchronization function. Unipolar sensing and pacing use the pulse generator as the anode and the distal lead as the cathode. This arrangement is very sensitive to noise. Bipolar sensing and pacing use the lead's distal part as the anode and cathode, allowing less noise, more robust sensing, and lower energy consumption. The pacemaker and intracardiac device must be controlled by a trained cardiologist.

Complications of Pacing and Management (Table 73.6)

Undersensing: Failure to Sense

Undersensing refers to a situation in which a spontaneous depolarization of the observed cavity occurs and is not recognized by the device and so does not inhibit an impulse generation by the pacemaker (Fig. 73.4). There are multiple causes of undersensing, such as inadequate cardiac signal, pacemaker programmed to a value insufficient to sense intrinsic activity, change in native signal after implantation, ectopic beats, lead maturation, lead failure, pulse generator failure, environmental electrical fields, magnet application, and noise detection. Undersensing can be responsible for asynchrony and precipitating HF.

TABLE 73.6 Management of Pacing System Malfunction

Problem	Solution
Pacing Stimuli Present With Loss of Capture	
Lead dislodgment or malposition (hours and days after implantation)	Reposition of the lead
Inflammation at the electrode interface	Reposition of the lead and/or increasing the output of the pulse generator
Increase in capture threshold (several months after implantation)	Increase output, identify etiology
Subthreshold pacemaker output programming	Increase output
Lead failure	Identify problem (loss of capture, undersensing or oversensing, insulation breach) and provide the specific treatment
Battery depletion	Change battery
Recording system artifact	Identify problem
Pacing Stimulus With Failure to Sense (Undersensing)	Generally, management should implicate programming the sensitivity to a more sensitive value, avoiding inappropriate sensing of noncardiac signals and also:
Inadequate signal	Identify problem (low amplitude of the signal, slew rate or inappropriate frequent content)
Pacemaker programmed to a value insufficient to sense intrinsic activity	Change the programmed sensitivity
Change in native signal since implantation	Identify etiology
Ectopic beats	ECG to confirm the ectopic cardiac activity
Lead maturation	Evaluate the change in sensing
Lead failure, most frequently insulation failure	Replace the lead
Pulse generator failure	Replace the generator, not the leads
Environmental electric fields	Identify the electric field
Magnet application	Remove the magnet
Noise detection	Identify the etiology
Management of undersensing	Evaluate the characteristics of the native signals to determine why they are not being sensed; program the sensitivity
Electromagnetic Interference	
Therapeutic radiation	Evaluation before and after the procedure
External cardioversion	Avoid the delivery of energy to the pulse generator Evaluation before and after the procedure
Magnetic resonance imaging	Evaluation before and after the procedure
Electrocautery	Use bipolar cautery, reprogramming, or magnet application

ECG, Electrocardiogram.

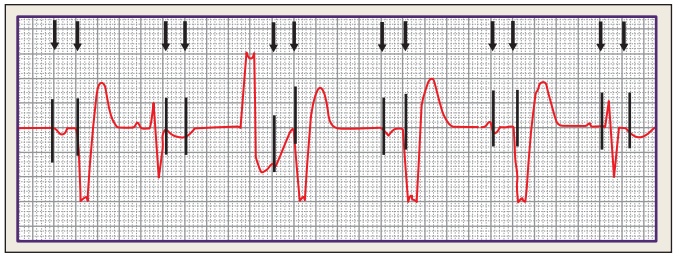

Fig. 73.4 Failure to Sense. Atrial and ventricular pacing spikes are seen around the intrinsic QRS complexes. Pacemaker activity does not lead to capture.

Position and integrity of the lead must be checked by x-ray and the device controlled by a trained cardiologist.

Oversensing

Oversensing refers to a situation in which a signal (noise, far-field) is interpreted as a spontaneous depolarization of the observed cavity, which then inhibits the impulse generation of the device. Pacemaker-dependent patients will have a poor tolerance for this type of event. This was common in the past with unipolar leads but is now quite rare.

Failure to Capture

Failure to capture occurs when a pacing stimulus is generated, but fails to trigger myocardial depolarization the expected cavity (Fig. 73.5). There are various causes of failure to capture, including lead dislodgement or malposition, inflammation and fibrosis at the electrode/myocardial interface, increase in capture threshold, subthreshold pacemaker output programming, lead failure, battery depletion, and recording system artifact. Position and integrity of the lead must be checked by x-ray and the device controlled by a trained cardiologist.

Fusion

Fusion refers to the situation in which the cavity depolarization is triggered by the intrinsic rhythm and pacemaker firing at the same time, resulting in a hybrid QRS.

Pseudo-fusion refers to a similar phenomenon, but the pacemaker firing does not affect the intrinsic QRS shape (Fig. 73.6).

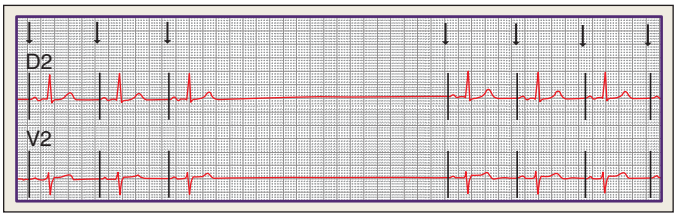

Fig. 73.5 Failure to Pace. An unduly long interval passes after the third QRS complex before another beat occurs. The pacemaker should have fired before this intrinsic beat.

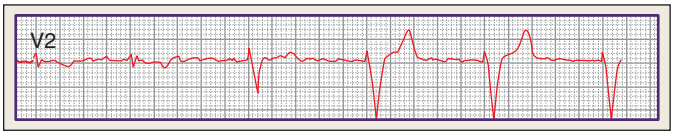

Fig. 73.6 With fusion, the pacemaker fires at the same time as the intrinsic rhythm, resulting in a hybrid QRS.

Cardiac Implanted Devices

- A cardiologist or electrophysiologist should be consulted when cardiac implanted device malfunction is suspected.
- Placing a magnet over a permanent pacemaker temporarily "reprograms" the pacer into an asynchronous mode (causing the pacemaker to fire at its preprogrammed rate regardless of the underlying intrinsic rhythm).
- MRI may be safe in a pacemaker patient if the cardiac implanted device is MRI compatible, is programmed, and is monitored. Verification of the leads and manufacturer-guaranteed MRI compatibility are mandatory.
- Pacemaker failure has three causes:
  a. **Output/capture failure:** Output failure is suspected if the heart rate is below the programmed lower rate and pacing spikes are absent. Capture failure can occur when the generated pacing stimulus does not initiate myocardial depolarization. Output or capture failure can also occur if the appropriate cardiac chamber is not paced.
  b. **Detection:** Problems with detecting intracardiac signals. In undersensing, the pacemaker fails to detect spontaneous myocardial depolarization, which results in asynchronous pacing. In oversensing, the pacemaker senses electrical signals that it should not normally encounter, which results in inappropriate inhibition of the pacing stimulus.
  c. **Pseudo-malfunction**: The pacemaker appears to be malfunctioning when in fact it is actually normal pacemaker behavior (e.g., rate-related).

KEY POINTS

Conduction Disturbances

- Patient history, drug list, and physical examination help make the correct diagnosis and determine choice of therapy.
- AV node block is most often caused by medications, ischemia, or increased parasympathetic tone. In most cases they are reversible. Infranodal blocks, however, are rarely reversible.
- When symptomatic bradyarrhythmia is present, negative chronotropic drugs should be withdrawn unless required for other purposes.
- Locating the site of an AV block helps stratify patient risk and prognosis:
  a. Asymptomatic first-degree and second-degree Mobitz I AV blocks are mostly nodal and do not require treatment.
  b. Symptomatic second-degree Mobitz II AV blocks and third-degree AV blocks are usually infranodal and often require definitive pacing.
- After heart surgery, bradyarrhythmias are frequent, especially after aortic valve surgery or TAVI. In symptomatic patients, temporary pacing is recommended. A decision about permanent pacemaker placement should not be made before 5–7 days after the procedure.

Myocarditis and Acute Myopathies

Fredric Ginsberg and Joseph E. Parrillo

MYOCARDITIS

Myocarditis is defined as inflammation of heart muscle.[1] Many different etiologic agents have been implicated in this disease, but viral infections are the most common cause. Myocarditis can be associated with autoimmune and other systemic diseases and can be caused by adverse drug reactions.[2] The clinical picture of myocarditis varies widely, from asymptomatic patients who fully recover without specific therapy and who suffer no long-term sequelae, to critically ill patients with heart failure and cardiogenic shock. There are no standardized, specific, and widely agreed-upon criteria for making the diagnosis of myocarditis or for determining a specific cause in many patients.[3] Last, there has been controversy regarding the most appropriate medical therapy for this condition.

On pathologic examination of myocardial biopsy specimens or at autopsy, myocarditis is usually apparent as infiltration of myocardium with lymphocytes, macrophages, and fibroblasts, accompanied by myocyte necrosis (myocytolysis).[3] It is this type of myocarditis, termed *lymphocytic myocarditis,* that will be referred to in this chapter unless otherwise specified. Other types of inflammatory reactions are seen less frequently in myocarditis and involve giant cells, eosinophils, or granulomas and can be associated with specific clinical conditions.

The global incidence of myocarditis is estimated at 22 cases/100,000 annually. It is more common in males, and more severe cases tend to occur in women and children.[4] In most patients with myocarditis, a specific cause is not found.[5] It is presumed that in North America and Europe, the most common etiologic agent is viral.[1] Identification of particular viral etiologies may vary by geography and over time. Coxsackie B enterovirus was felt to be the most common cause up to the 1990s, but human herpesvirus 6, cytomegalovirus, and parvovirus B19 have been implicated as causative agents more frequently over the past 20 years.[2] Hepatitis C has also been found to be a common etiology in some populations.[6] Other viral causes include H1N1 influenza A, Epstein-Barr virus (EBV), and herpes simplex 1 and 2. Myocarditis is a common finding in patients infected with human immunodeficiency virus (HIV). However, the causative agent responsible in these cases may be HIV or a secondary viral infection such as cytomegalovirus.[1,6,7] Infectious illnesses such as Lyme disease, acute rheumatic fever, and diphtheria often have myocarditis as a prominent feature. In Central and South America, the most common cause of myocarditis is the protozoan *Trypanosoma cruzi*, the cause of Chagas disease (Table 74.1). Systemic and autoimmune diseases such as systemic lupus erythematosus (SLE), polymyositis, scleroderma, sprue, Whipple disease, and sarcoidosis can be complicated by myocarditis, and myocarditis can be a feature of infiltrative cardiomyopathies seen in hemochromatosis or amyloidosis. Other specific forms of myocarditis include hypersensitivity or eosinophilic myocarditis, which can be caused by allergic reactions to medications, including smallpox vaccination,[8] and giant cell myocarditis (GCM). Lastly, myocarditis can be associated with doxorubicin cardiomyopathy or with peripartum cardiomyopathy (Box 74.1).[9–11]

In 2020 an international pandemic of an acute respiratory illness occurred, called *coronavirus disease 2019 (COVID-19),* caused by infection with a novel coronavirus, the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). The illness is characterized by pneumonia, often progressing to acute respiratory failure. Seven to twenty-eight percent of patients hospitalized with this illness demonstrate acute cardiac injury, defined as a combination of elevated serum troponin, electrocardiogram (ECG) changes consistent with myocardial injury, and/or left ventricular (LV) systolic dysfunction demonstrated on ECG. Myocarditis may be a mechanism of cardiac injury in some of these patients. However, there have only been a very small number of patients with a diagnosis of myocarditis that was confirmed by cardiac magnetic resonance imaging (MRI) or tissue sampling. One report described cardiomegaly, localized ST-segment elevation on ECG, marked troponin elevation, and acute heart failure associated with low left ventricular ejection fraction (LVEF) in a patient with COVID-19 pneumonia. Another report described biventricular heart failure and cardiac MRI findings diagnostic of acute myocarditis. LV function returned to normal within weeks in both cases.[12,13] One report described a patient with cardiogenic shock; impaired LV systolic function; no coronary artery obstruction; and endomyocardial biopsy showing low-grade interstitial and endocardial inflammation with macrophages, myocyte lysis, and viral particles seen in interstitial cells.[14] There have also been reports of a mild mononuclear cell infiltrate on myocardial specimens at autopsy in patients who died from COVID-19 illness.[15] Other causes of myocardial damage are also likely in these patients, including infection-mediated coronary vasculitis, microvascular coronary thrombosis, stress cardiomyopathy, exacerbation of atherosclerotic coronary artery disease, oxygen supply-demand mismatch, and a hyperinflammatory state causing a cardiomyopathy similar to that associated with sepsis.[16]

Unfortunately, it is difficult to make a clinical diagnosis of a specific viral cause of myocarditis. Antiviral antibody titers in acute- and convalescent-phase sera do not aid in the diagnosis, as viruses are highly prevalent in the general population, and antibody levels vary over time and do not correlate well with the onset of symptoms of acute myocarditis.[17,18] Viral cultures of tissue specimens are unreliable.[5] The identification of viral genomes incorporated in myocyte DNA by the use of methods such as polymerase chain reaction (PCR) is highly suggestive but does not specifically prove that the virus is the cause.

PATHOGENESIS

Based on observations of human myocarditis and murine models of the disease caused by coxsackie B3, the pathogenesis of viral myocarditis can be described in three stages.[2,19] The first stage is initiated by

TABLE 74.1 Causes of Myocarditis/Inflammatory Cardiomyopathy

INFECTIOUS MYOCARDITIS	
Bacterial	*Staphylococcus, Streptococcus, pneumococcus, meningococcus, gonococcus, Salmonella, Corynebacterium diphtheriae, Haemophilus influenzae, Mycobacterium tuberculosis, Mycoplasma pneumoniae, Brucella*
Spirochetal	*Borrelia burgdorferi*, (Lyme disease), *Leptospira* (Weil disease)
Fungal	*Aspergillus, Actinomyces, Blastomyces, Candida, Coccidioides, Cryptococcus, Histoplasma, Mucormycoses, Nocardia, Sporothrix*
Protozoal	*Trypanosoma cruzi, Toxoplasma gondii, Entamoeba, Leishmania*
Parasitic	*Trichinella spiralis, Echinococcus granulosus, Taenia solium*
Rickettsial	*Coxiella burnetii* (Q fever), *Rickettsia rickettsii* (Rocky Mountain spotted fever), *R. tsutsugamushi*
Viral	RNA viruses: coxsackieviruses A and B, echoviruses, polioviruses, influenza A and B viruses, respiratory syncytial virus, mumps virus, measles virus, rubella virus, hepatitis C virus, dengue virus, yellow fever virus, Chikungunya virus, Junin virus, Lassa fever virus, rabies virus, human immunodeficiency virus-1
	DNA viruses: adenoviruses, parvovirus B19, cytomegalovirus, human herpes virus-6, Epstein-Barr virus, varicella-zoster virus, herpes simplex virus, variola virus, vaccinia virus
IMMUNE-MEDIATED MYOCARDITIS	
Allergens	Tetanus toxoid, vaccines, serum sickness
	Drugs: penicillin, cefaclor, colchicine, furosemide, isoniazid, lidocaine, tetracycline, sulfonamides, phenytoin, phenylbutazone, methyldopa, thiazide diuretics, amitriptyline
Alloantigens	Heart transplant rejection
Autoantigens	Infection-negative lymphocytic, infection-negative giant cell
	Associated with autoimmune or immune-oriented disorders: systemic lupus erythematosus, rheumatoid arthritis, Churg-Strauss syndrome, Kawasaki disease, inflammatory bowel disease, scleroderma, polymyositis, myasthenia gravis, insulin-dependent diabetes mellitus, thyrotoxicosis, sarcoidosis, Wegener granulomatosis, rheumatic heart disease (rheumatic fever)
TOXIC MYOCARDITIS	
Drugs	Amphetamines, anthracyclines, cocaine, cyclophosphamide, ethanol, fluorouracil, lithium, catecholamines, interleukin-2, trastuzumab, clozapine
Heavy metals	Copper, iron, lead (rare, more commonly causes intramyocyte accumulation)
Miscellaneous	Scorpion sting, snake and spider bites, bee and wasp stings, carbon monoxide, inhalants, phosphorus, arsenic, sodium azide
Hormones	Phaeochromocytoma, vitamins: beriberi
Physical agents	Radiation, electric shock

viral infection and replication within myocytes. Viral proteases and activation of proinflammatory cytokines initiate myocyte damage.[20] The presence of this viral replication phase is difficult to detect clinically, because patients may be asymptomatic during this phase or may only have nonspecific viremic symptoms. In addition, there is no rapid screening test to confirm most viral infections. Parvovirus B19 may preferentially infect endothelial cells in coronary arteries, venules, and capillaries, and myocardial damage may be a result of impaired blood flow.[21]

The second stage involves host immune activation. Stimulation of cellular immunity and humoral responses attenuates viral proliferation and can result in recovery from the illness. However, unabated immune activation can result in activated T cells targeting myocardial antigens that cross-react with viral peptides. This leads to release of cytokines such as tumor necrosis factor, interleukin-1, and interleukin-6, resulting in further damage to myocytes and the cytoskeleton.[1,20] Activation of CD4 cells and antibody production plays a less important pathogenetic role. This secondary immune response to viral infection may play a greater role in disease pathogenesis than the primary infection and may be genetically influenced. Incomplete clearing of virus or recurrent viral replication may also cause persistence of inflammation and myocardial damage. Evidence supporting these mechanisms includes the following: Myocardial biopsy with recombinant DNA techniques can detect viral genomes in 20%–35% of patients. Tissue-specific autoantibodies have been detected in 25%–73% of patients with evidence of myocarditis on biopsy, with antibodies directed against contractile, structural, and mitochondrial myocyte proteins. Inappropriate expression of the major histocompatibility complex can frequently be demonstrated on biopsy specimens.[1] Elevated levels of inflammatory cytokines are detected in patients with active myocarditis.

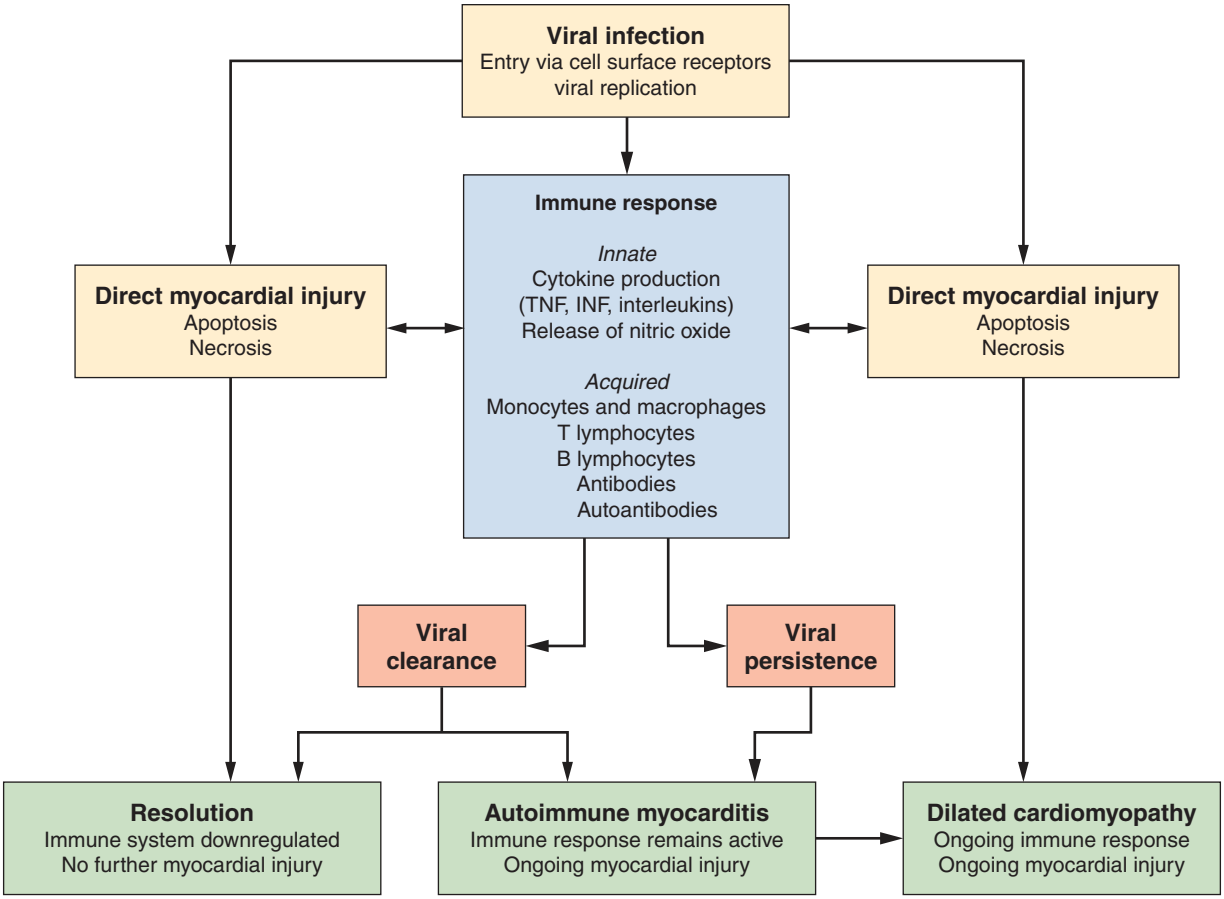

Fig. 74.1 The pathogenesis of viral myocarditis involves direct myocardial injury from viral infection in addition to immunomediated myocyte damage from cytokines, proteases, and autoantibodies. The outcome of these processes can be healing of inflammation and resolution of ongoing active myocarditis or chronic dilated cardiomyopathy. *INF*, Interferon; *TNF*, tumor necrosis factor. (Adapted from Blauwer LA, Cooper LT. Myocarditis. *Prog Cardiovasc Dis*. 2010;52:274–288.)

Either persistent overactivation of cellular immune activity or incomplete clearing with persistent or recurrent viral replication can lead to the third stage, which is marked by cellular apoptosis, ongoing necrosis, and fibrosis. Significant myocardial damage leads to LV dilatation and remodeling, neurohormonal activation, systolic dysfunction, and manifestations of heart failure.[20,22] These processes can then abate, with reduction in LV size and improvement of LV function, or can continue to progress with development of dilated cardiomyopathy, worsening ventricular function, and chronic heart failure. Chronic dilated cardiomyopathy is the major long-term sequela of acute myocarditis (Fig. 74.1).

CLINICAL PRESENTATION AND DIAGNOSIS

The incidence of myocarditis is difficult to determine, as many cases are mild with subclinical disease. Myocarditis is diagnosed on clinical grounds, as there are no specific clinical diagnostic criteria. The presentation of myocarditis varies widely. Patients can be asymptomatic, as myocarditis is found in 1%–10% of autopsy specimens of young adults who had no history of cardiac illness. Myocarditis can be found at autopsy in up to 20% of cases of young, apparently healthy adults who die suddenly and unexpectedly.[1,5,11] It is estimated to be the third most common cause of sudden cardiac death in young athletes.[4]

Patients with myocarditis most commonly present with dyspnea (72%), chest pain (32%), and symptoms of arrhythmia (18%).[23] The presentation may be indistinguishable from acute coronary syndromes caused by coronary artery disease. There may be a preceding viral prodrome with fever, malaise, and arthralgias. Physical examination can show fever, tachycardia, S3 and S4 gallop sounds, and a pericardial rub if pericarditis is present. Signs of heart failure can be present, including pulmonary rales and wheezes, elevated jugular venous pressure, and peripheral edema. Murmurs of mitral regurgitation and tricuspid regurgitation may be heard. Infrequently, the presentation is fulminant and severe, with acute heart failure, pulmonary edema, and cardiogenic shock.[5]

The differential diagnosis includes acute myocardial infarction (AMI), isolated pericarditis, or chest pain from pulmonary causes, including pulmonary embolism or pneumonia. Generalized sepsis is also a consideration. Myocarditis involving the right ventricle may mimic findings in right ventricular (RV) cardiomyopathy.

Laboratory findings can include leukocytosis, eosinophilia, and an elevated erythrocyte sedimentation rate. The cardiac biomarkers creatine phosphokinase (CPK), troponin T, and troponin I may be elevated, with sensitivity of troponin I reported at 34%–53% and specificity of 89%.[18,24] Rheumatologic serologic markers and HIV status should be evaluated in selected cases.

The 12-lead ECG is an insensitive test for the diagnosis of myocarditis. ECG findings are nonspecific and include sinus tachycardia and nonspecific ST-segment depression and T-wave inversion most often. Patients may present with chest pain and ST-segment elevation with a

BOX 74.2 Results of ECG, Laboratory Testing, and Imaging in Acute Myocarditis

ECG, Holter, or Stress Test
AV block I–III, bundle branch block, sinus arrest
Extrasystoles
Supraventricular tachycardia, atrial fibrillation
Ventricular tachycardia, ventricular fibrillation, asystole
ST-segment and T-wave changes (ST-segment elevation, T-wave inversion)
Intraventricular conduction delay
New Q waves

picture mimicking AMI or acute pericarditis. More severe cases can be associated with supraventricular or ventricular arrhythmias, conduction disturbances, and heart block.[1] QTc prolongation over 440 msec, QRS duration over 120 msec, and abnormal QRS axis have been associated with a poorer prognosis.[25]

Echocardiography is essential to diagnose and quantitate regional and global LV wall motion abnormalities, LV and RV size and function, the presence of pericardial effusion, and valvular regurgitation. RV involvement may be seen in 25% of patients.[18] Fulminant myocarditis is characterized by a nondilated left ventricle with severe systolic dysfunction and increased wall thickness reflecting myocardial edema.[26] Pericardial effusion may be present. Cardiac catheterization and coronary angiography are often necessary to exclude acute ischemia resulting from coronary artery disease as the cause of chest pain or acute heart failure (Box 74.2).

Cardiac Magnetic Resonance Imaging

There is increasing use of cardiac MRI with contrast enhancement as a noninvasive method to diagnose myocarditis.[27–30] Diagnostic criteria were published in 2009 called the "Lake Louise criteria."[31] These include (1) focal or diffuse myocardial edema in T2-weighted images, (2) early gadolinium enhancement (EGE) on T1 imaging indicating myocardial hyperemia, and (3) late gadolinium enhancement (LGE) indicating necrosis and fibrosis specifically located in subepicardial or mid-myocardial regions.[32] Myocardial edema may be localized or global and is not always associated with EGE. LGE may be diffuse or patchy, and is most often seen in basal and mid-inferolateral segments of the left ventricle or the base of the interventricular septum (see Box 74.2 and Fig. 74.2). Diagnostic sensitivity is improved when all three techniques are assessed. In a meta-analysis of reported studies, diagnostic accuracy of these criteria are 83%, with a sensitivity of 80% and specificity of 87%. Diagnostic accuracy is 68% when only LGE is present. Novel cardiac MRI T1 and T2 mapping procedures are being investigated and are proposed to supplement the Lake Louise criteria to improve diagnostic accuracy. These techniques offer quantitative tissue characterization and may correct for technical limitations of standard cardiac MRI techniques.[33] Cardiac MRI is more likely to be abnormal when performed more than 7 days after onset of symptoms. It may also detect pericardial inflammation and effusion (seen in 32%–57% of patients) and gives information regarding LV function. Cardiac MRI can also be used to direct myocardial biopsy in patients with patchy uptake.[31,34,35]

Advantages of cardiac MRI include that it is noninvasive and low risk, sampling error is avoided (a problem with endomyocardial biopsy, see later), and it can be used serially over time to assess a patient's course. However, cardiac MRI may be normal in patients with milder forms of myocarditis, and it does not distinguish between viral and other etiologies of the disease. It is also more difficult to apply in critically ill patients with cardiogenic shock.

The value of cardiac MRI in estimating prognosis is unclear. Prognosis is better in patients with edema and hyperemia but without LGE.[32] However, in a series of 203 consecutive patients with a diagnosis of myocarditis, all of whom had LGE and 70% of whom presented with chest pain, 10.8% experienced a major cardiac event (sudden death, heart failure, serious ventricular arrhythmia, or cardiac transplant). A multivariate analysis concluded that only reduced LVEF was an independent predictor of major events. Extent, pattern, and location of LGE were not significant predictors.[36] It is important to realize that cardiac MRI may provide diagnostic information regarding myocarditis; however, it does not predict clinical outcomes.

ENDOMYOCARDIAL BIOPSY

Percutaneous endomyocardial biopsy (EMB) is used to aid in the diagnosis of myocarditis and is considered the definitive diagnostic technique. The Dallas criteria have been accepted as the standard for histopathologic diagnosis, but the utility of the Dallas criteria is strongly debated (see later). These criteria define "active myocarditis" as the presence of an inflammatory myocardial infiltrate (more than five lymphocytes per high-power field) accompanied by myocyte necrosis. "Borderline myocarditis" is defined as inflammation without myocyte necrosis. However, there is no difference in prognosis in patients with either of these biopsy results. Thus lymphocyte infiltration (with or without myocyte necrosis) is the most important diagnostic criterion. A more recent pathologic definition of myocarditis is the presence on EMB of a focal or diffuse mononuclear cell infiltrate of lymphocytes and macrophages, with >14 cells/mm^2, with <4 monocytes/mm^2 and CD-3–positive lymphocytes >7/mm^2,[4] which emphasizes that immunohistochemistry to identify upregulated human leukocyte antigen (HLA) proteins and examining specimens for viral genomes using PCR should also be performed.[25,37,38] Viral myocarditis is considered to be present when there is evidence for active inflammation with a positive molecular test for virus on EMB, and autoreactive or autoimmune myocarditis is diagnosed when inflammation is present without viral markers.[39] Findings in eosinophilic myocarditis

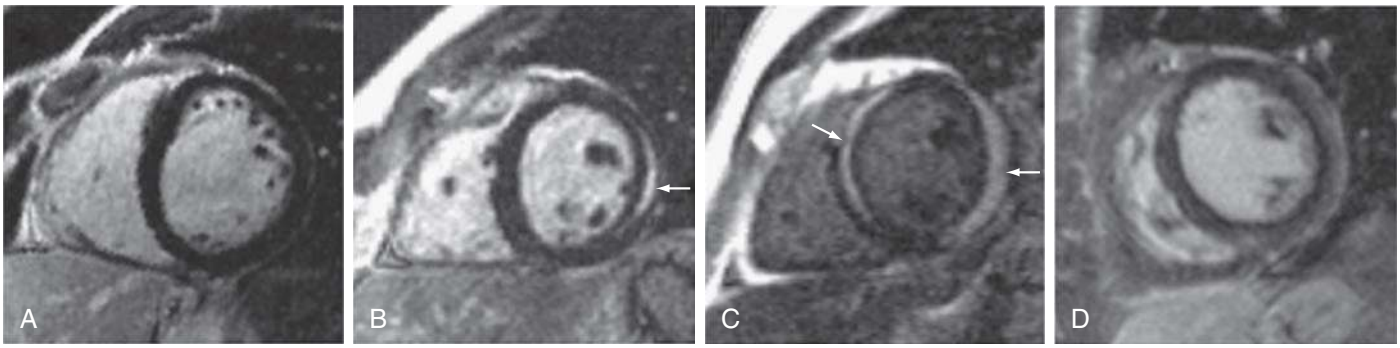

Fig. 74.2 Cardiac magnetic resonance imaging with late gadolinium enhancement (LGE): normal and abnormal findings in myocarditis. **A,** Normal myocardium with no evidence of LGE. **B,** Regional subepicardial enhancement of the lateral wall *(arrow).* **C,** Subepicardial enhancement of lateral and midwall enhancement of the septum *(arrows).* **D,** Diffuse subepicardial enhancement. include intense eosinophilic infiltrate with histiocytes, lymphocytes, and plasma cells. Pathology of GCM shows infiltration with giant cells, with lymphocytes and myonecrosis but without granulomas.

A positive EMB has a high positive predictive value, but there are a number of significant limitations. A high frequency of interobserver variation has been noted among pathologists in applying the Dallas criteria. Biopsies are not sensitive in diagnosing myocarditis, as various series have reported positive RV biopsy results in only 10%–67% of patients with myocarditis suspected on clinical grounds or with recent-onset idiopathic dilated cardiomyopathy. This variability may relate to the timing of biopsies in respect to the stage or chronicity of the patient's illness. In addition, sampling error is possible when myocardial inflammation is patchy and not global or may predominantly involve the LV free wall.[37] Thus diagnostic yield is improved by performing a biopsy earlier in a patient's clinical course, taking more than six biopsy specimens, and performing LV biopsies. In addition, immunohistochemical staining for HLAs can improve diagnostic sensitivity. EMB may also be useful to diagnose persistence of viral activity. Novel analyses assess viral transcription activity and messenger RNA (mRNA) expression.[19,40,41] EMB should be performed in centers with a high-volume experience and with proven safety and availability of appropriate pathologic techniques.[42] Recent reports indicate a very low rate of serious complications related to EMB in experienced centers, <0.1%.[39] It is important to emphasize that a negative biopsy finding does not preclude the diagnosis of myocarditis.

In the majority of patients, diagnosis is made on clinical grounds combined with cardiac MRI findings, and the clinical course is one of steady improvement. EMB is not necessary in these patients. EMB should be strongly considered in cases of suspected myocarditis when pathology results will affect management decisions. An American Heart Association/American College of Cardiology/European Society of Cardiology (AHA/ACC/ESC) scientific statement offered recommendations concerning the appropriate use of EMB based on patients' clinical presentations.[43] EMB was deemed useful, beneficial, and effective (class I indication) in patients with acute heart failure with hemodynamic compromise after causes such as coronary artery disease are excluded. EMB in this setting is necessary to diagnose GCM and eosinophilic myocarditis, which most often present with severe heart failure or arrhythmias, as immunosuppressive therapy is mandated in these conditions. A class I indication for EMB was also recommended for patients with new-onset, subacute heart failure or duration of illness of 2 weeks to 3 months and who fail to improve with medical therapy for heart failure or who demonstrate severe ventricular arrhythmia or advanced heart block. EMB should be considered if causes such as sarcoidosis or autoimmune disease are suspected.[44] EMB should always be performed before initiating immunosuppressive therapy (Box 74.3).

BOX 74.3 Indications for Endomyocardial Biopsy

- Exclusion of potential common etiologies of dilated cardiomyopathy (familial, ischemic, alcohol, postpartum, cardiotoxic exposures) and the following:
- Subacute or acute symptoms of heart failure refractory to standard management
- Substantial worsening of left ventricular (LV) systolic function despite optimal pharmacologic therapy
- Suspicion for giant cell myocarditis: younger patient, severe acute heart failure, hemodynamically significant ventricular arrhythmia, advanced heart block
- Suspicion of eosinophilic myocarditis: severe heart failure with rash, fever, peripheral eosinophilia
- Suspicion or diagnosis of systemic autoimmune disease such as systemic lupus erythematosus, scleroderma, or polyarteritis nodosum
- New-onset cardiomyopathy in the presence of suspected sarcoidosis or amyloidosis

An algorithm has been proposed outlining the steps in the evaluation of patients suspected of having acute myocarditis (Fig. 74.3).

CLINICAL COURSE

The clinical course of acute myocarditis is variable. The majority of patients diagnosed with myocarditis will improve, and those with mild symptoms most often recover without complications. Eight to twelve percent of young, apparently healthy adults who die suddenly from a cardiac cause are found to have myocarditis at autopsy, suggesting that patients even with apparently mild illness can suffer fatal arrhythmias.[19] In over 50% of patients, clinically recognized myocarditis will resolve in 4 weeks. However, 25% will develop persistent abnormalities of ventricular function, and roughly 10% to 20% may develop dilated cardiomyopathy with chronic, severe heart failure.[3,38] Fifteen to twenty-five percent of patients who present with new-onset dilated cardiomyopathy have evidence of antecedent myocarditis.[3] Patients with heart failure

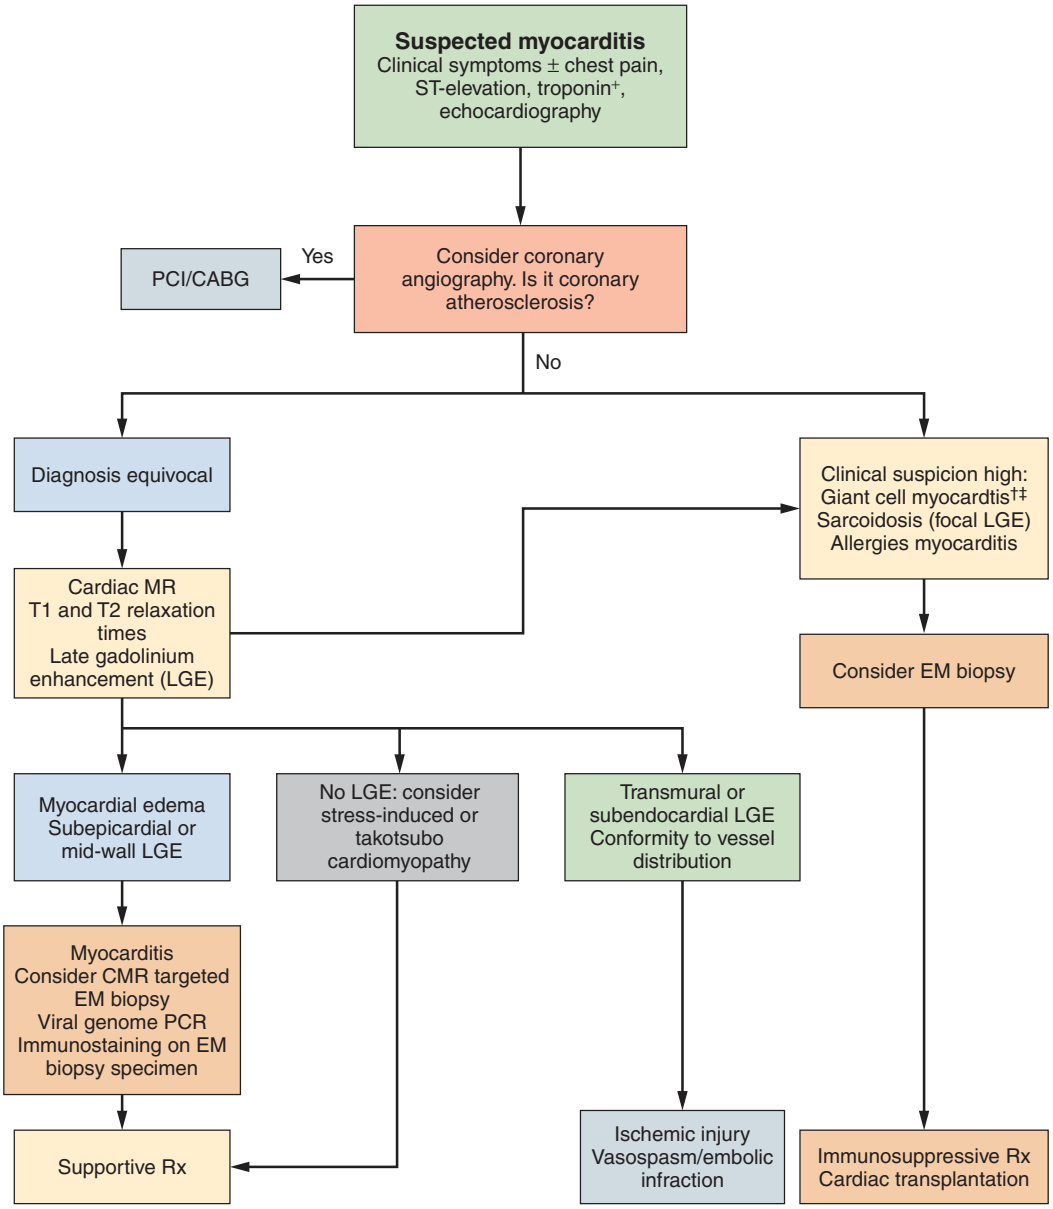

Fig. 74.3 Diagnostic Algorithm for Suspected Acute Myocarditis. *CABG*, coronary artery bypass grafting; *CMR*, cardiac magnetic resonance; *EM*, endomyocardial; *PCI*, percutaneous coronary intervention; *PCR*, polymerase chain reaction; *Rx*, treatment. (Adapted from Nelson KH, Li T, Afonso L. Diagnostic approach and role of MRI in the assessment of acute myocarditis. *Cardiol Rev.* 2009;17:24–30.)

and LV dysfunction will experience spontaneous resolution of their illness within 12 months in up to 40% of cases, without long-term sequelae. Roughly one-quarter of patients with acute myocarditis and ejection fraction below 35% will improve, one-half will develop chronic cardiomyopathy and heart failure, and one-quarter will deteriorate and may be candidates for cardiac transplantation.[45]

A minority of patients with acute myocarditis present critically ill with acute severe heart failure and cardiogenic shock. This presentation is termed *fulminant myocarditis* (FM). Most often these patients give a history of symptoms of a viral illness during the previous weeks, with a distinct time of onset of heart failure symptoms. These patients require hemodynamic support, including inotropes, vasopressors, and possibly mechanical circulatory support. This presentation is contrasted with that of patients with myocarditis who have chest pain and may have heart failure but not cardiogenic shock, termed *nonfulminant myocarditis* (NFM). These patients demonstrate a less distinct time of onset of heart failure symptoms and do not require vasoactive support. Direct cytolysis of myocytes caused by viral infection and replication is felt to be particularly important in FM. Early and extensive loss of myocytes and myocardial tissue leads to the rapid development of severe heart failure.

An early study comparing FM with NFM included 147 patients with heart failure caused by biopsy-positive active myocarditis, with ejection fraction less than 40%. Ten percent of patients were diagnosed with FM and 90% had NFM.[9] With aggressive treatment, patients with FM actually had better long-term survival rates: 93% at 1 year and 93% at 11 years. Patients with NFM had an 85% 1-year survival rate and a 45% survival rate at 11 years.[10] However, this early reported experience has not been confirmed in more contemporary studies (see later).

PROGNOSIS

It is important to examine the patient population under study and the criteria used for diagnosing myocarditis in any series assessing prognosis and mortality. No clinical markers reliably predict which patients with myocarditis will recover or worsen.[10] Early trials reported a 1-year mortality rate of 20% and 5-year mortality of 56% in patients with biopsy-confirmed lymphocytic myocarditis.[46] Another earlier trial reported 181 patients with myocarditis confirmed by EMB using the Dallas criteria, immunohistochemical staining, and PCR. LV biopsy was performed in 90% of patients. Patients were followed for an average of 59 months, and 22% died or received cardiac transplantation. Multivariate analysis concluded that functional class III and IV heart failure and a positive immunohistochemical result were the only predictors of a poor outcome, and treatment with beta-blockers was associated with better outcomes[40] (Fig. 74.4).

In more contemporary reports, the prognosis for patients who present with chest pain and other features similar to acute coronary syndrome, without heart failure or reduced LVEF, is favorable. In a series of 203 consecutive cases of acute myocarditis confirmed with LGE on CMR, 70% presented with chest pain without hemodynamic compromise, and none of these patients suffered cardiac arrest or required heart transplantation.[36] More recent series have shown that patients with FM have worse outcomes compared with NFM. In a report of 187 consecutive patients with acute myocarditis with symptoms <30 days, 80% underwent cardiac MRI and 27% had EMB. A reported 25.5% of FM patients died in hospital or required cardiac transplantation, and 18.2% died in hospital. Serious ventricular dysrhythmia and complete heart block occurred more often. Nine-year survival was 64%. In contrast, none of the NFM patients died or required transplant, and 9-year survival was 100%. LVEF was significantly lower in the FM group, and a lower LVEF correlated with a poorer prognosis. Females had a lower incidence of myocarditis, but their disease was more severe. Women comprised 57% of the FM group and only 12% of NFM. In FM, LVEF did tend to improve during the first few weeks of follow-up, but few recovered to normal, and LVEF was more likely to be abnormal at long-term follow-up than in NFM.[47] In another retrospective series of 220 patients with duration of illness <30 days and abnormal EMB, 165 patients had FM. Sixty-day mortality in this group was 27.8%, and 1-year mortality was 43%, compared with 1.8% and 9%, respectively, in 55 patients with NFM. GCM was associated with the worst prognosis. In patients with lymphocytic myocarditis, 60-day mortality was 19.5% in FM and 0% in NFM. Average LVEF was 22% in FM and 32% in NFM. Life-threatening ventricular arrhythmia occurred in 46.9% of FM and 16.7% of NFM. Mechanical circulatory support was used in 69% of FM and was not used in NFM. In patients with FM and eosinophilic myocarditis, 60-day mortality was 21%[48] (Figs. 74.5 and 74.6).

Thus contrary to early reports, the short- and long-term prognosis of FM is worse than NFM. The presence of early and severe hemodynamic compromise is the major determinant of a poorer outcome.

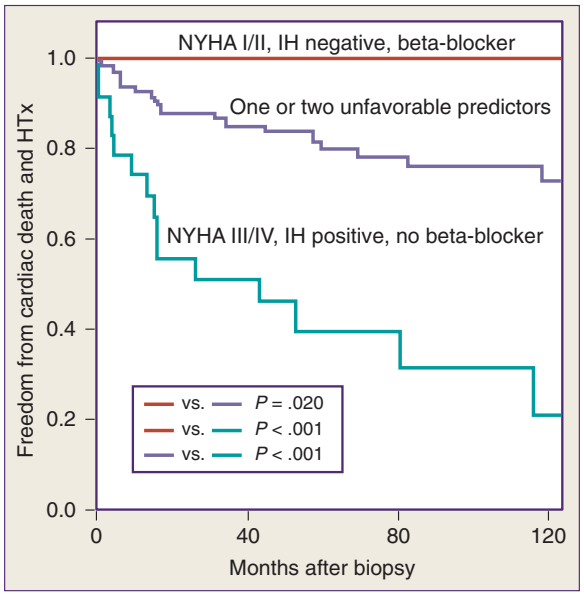

Fig. 74.4 Prognosis for patients with acute myocarditis was predicted by three factors: NYHA functional class, positive immunohistology for myocarditis at EMB, and therapy with beta-blockers. *EMB,* Endomyocardial biopsy; *NYHA,* New York Heart Association. (From Kindermann I, Kindermann M, Kandolf R, et al. Predictors of outcome in patients with suspected myocarditis. *Circulation.* 2008;118:639–648.)

GIANT CELL MYOCARDITIS

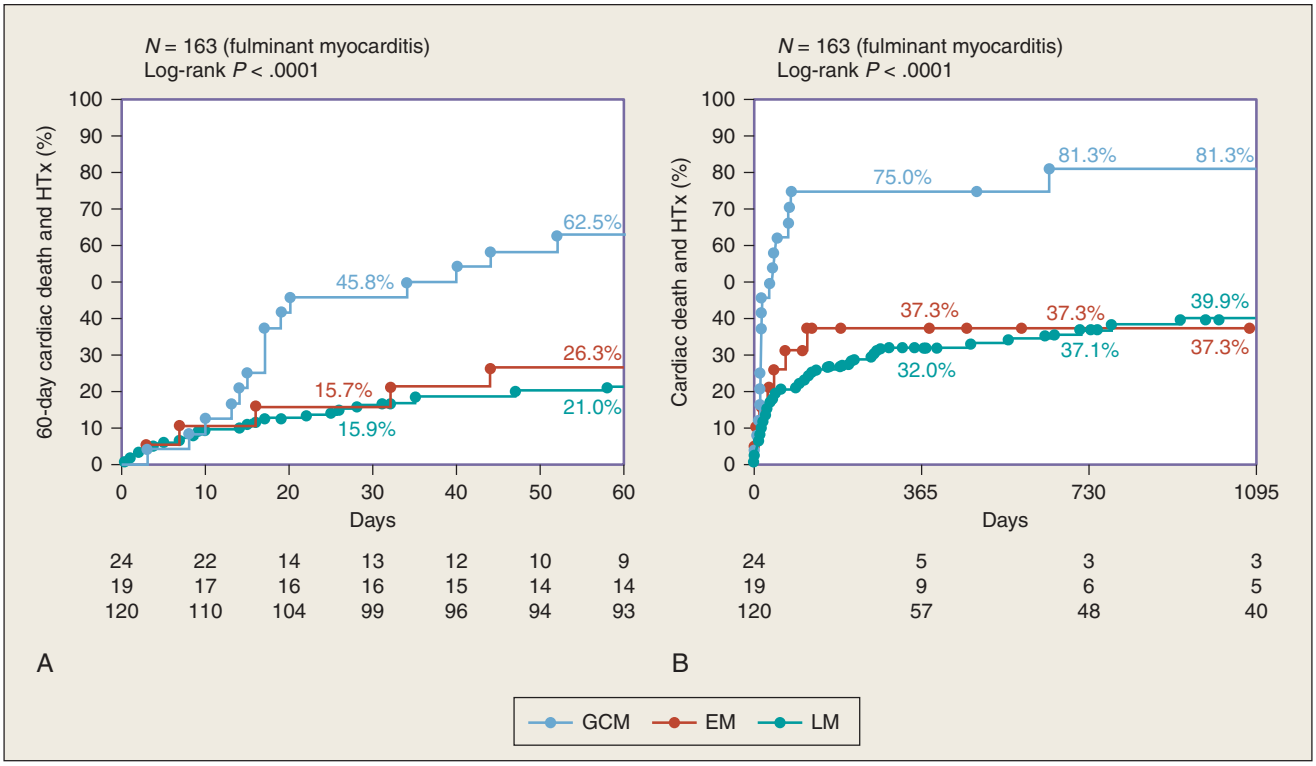
GCM is a distinct form of myocarditis, characterized by severe heart failure, life-threatening ventricular arrhythmias, and high-grade heart block. The pathogenesis is not clearly defined, although autoimmune mechanisms involving CD4 T lymphocytes are believed to play an important role. Usually the heart alone is affected without multisystem illness, but occasionally it is associated with an autoimmune disease such as inflammatory bowel disease, celiac disease, or rheumatoid arthritis or with neoplasm such as thymoma or lymphoma.[49] It has a rapidly progressive course, without significant likelihood of spontaneous resolution. On EMB, a diffuse or multifocal infiltration with inflammatory giant cells and lymphocytes is seen with myonecrosis. Eosinophils and plasma cells may be seen. Granulomas and fibrosis are not present. This differs from the myocarditis occurring with sarcoidosis in that patients with GCM have a more acute and severe illness, patients tend to be younger, and granulomas are not present on EMB as they are in sarcoidosis.

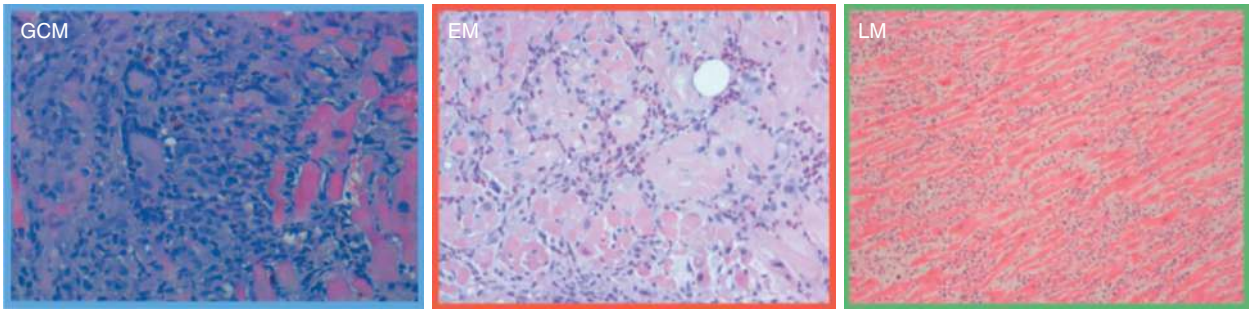
One retrospective study reported on 63 patients with biopsy-confirmed GCM.[50] Seventy-five percent presented with heart failure; 14% presented with severe ventricular arrhythmias; and 11% with chest pain, an abnormal ECG, or heart block. Other series report a presentation mimicking AMI in 6%–19% with complete heart block in 5%–8%.[51]

The prognosis of untreated GCM is poor, with median survival of 5.5 months and 89% dying or undergoing heart transplant. EMB is essential to make this diagnosis in order to initiate immunosuppressive therapy early in the course of the disease. In uncontrolled series, immunosuppressive therapy was associated with improved survival from 3 months in 30 patients not given immunosuppressive drugs to 11.5 months in patients given prednisone plus azathioprine and 12.6 months in patients in whom cyclosporine was added. More recent reports describe 5-year survival without cardiac transplant of 52%–75% with multidrug immunosuppression. Implantable cardioverter defibrillator (ICD) therapy is often used. Initial experience indicated that the prognosis after heart transplant was worse compared with other forms of heart disease, although more recent results describe similar posttransplant survival.[51]

EOSINOPHILIC MYOCARDITIS

Eosinophilic myocarditis, also termed *hypersensitivity myocarditis,* is a rare form of myocarditis characterized by eosinophilic infiltration and degranulation on endomyocardial biopsy. It is believed that





C

Fig. 74.5 Prognosis in Fulminant Myocarditis According to Histologic Type of Myocarditis. Giant cell myocarditis (*GCM*) vs. eosinophilic myocarditis (*EM*) vs. lymphocytic myocarditis (*LM*). (From Ammirati E, Veronese G, Brambatti M, et al. Fulminant versus acute nonfulminant myocarditis in patients with left ventricular systolic dysfunction. *J Am Coll Cardiol.* 2019;74:299–311.)

pathogenesis involves a direct role of eosinophil-mediated myocyte damage. There can be associated arteritis. This entity is distinct from eosinophilic endocarditis (Loffler endocarditis). The clinical manifestations are not specific, aside from a high incidence of eosinophilia in peripheral blood. Patients usually present with heart failure caused by LV systolic dysfunction. Fever and rash may be present. Untreated, the disease is often rapidly fatal.[8]

The cause is believed to be a hypersensitivity reaction, usually to medication or, rarely, in association with parasitic infections. Drugs most often implicated are sulfonamides, diuretics, angiotensin-converting enzyme (ACE) inhibitors, cephalosporins, digoxin, or dobutamine. Eosinophilic myocarditis has been reported to occur weeks after smallpox vaccination, with an incidence of 1 in 16,000 vaccinated.[52] Untreated, the clinical course is unfavorable, often with rapidly worsening heart failure and sudden death caused by ventricular arrhythmia. Treatment involves discontinuing all potentially offending medication and the use of high-dose corticosteroids with azathioprine.[44] Excellent responses to immunosuppressives, in addition to some spontaneously resolving illness, have been reported.[53,54]

Eosinophilic myocardial infiltration has been reported in 2%–7% of myocardial biopsy specimens of patients awaiting cardiac transplantation or in the explanted heart after transplant. The cause is unclear, but dobutamine therapy, sodium bisulfite used as a preservative in dobutamine solutions, and the use of LV assist devices have been implicated. The presence of eosinophilic myocarditis in this setting did not have an adverse affect on posttransplant survival and did not recur in the transplanted heart.[55,56]

Immune Checkpoint Inhibitor–Associated Myocarditis

Immune checkpoint inhibitors (ICIs) are a new class of medication effectively used to treat certain cancers, including melanoma, lung cancers, and lymphoma. These drugs are monoclonal antibodies that

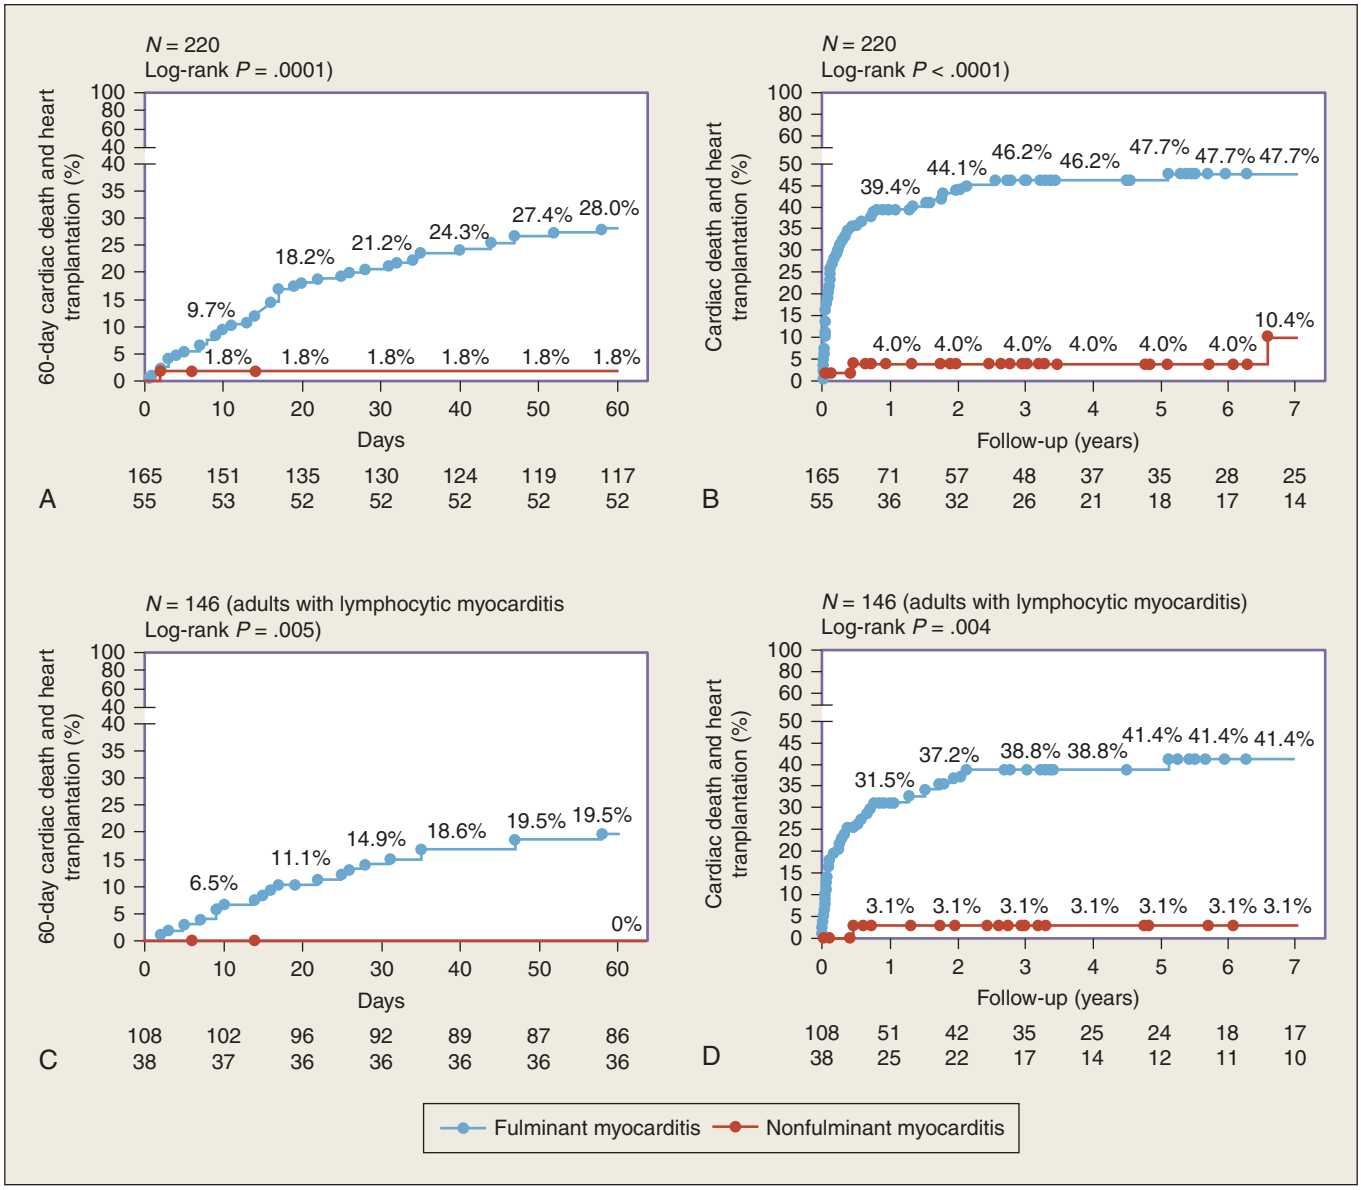


Fig. 74.6 Survival curves in all patients with fulminant myocarditis (FM) vs. nonfulminant myocarditis (NFM) and in patients with lymphocytic myocarditis and FM vs. NFM. (From Ammirati E, Veronese G, Brambatti M, et al. Fulminant versus acute nonfulminant myocarditis in patients with left ventricular systolic dysfunction. *J Am Coll Cardiol.* 2019;74:299–311.)

block the regulatory checkpoints on T cells that maintain self-tolerance, resulting in activation and increased function of T cells. After these drugs were approved for use as cancer chemotherapy, an adverse effect, acute lymphocytic myocarditis, was reported.[57] Although this complication is uncommon, it is the most severe adverse effect of these drugs and has a high fatality rate. Current incidence is estimated at 0.06%–2.4% of patients treated with these drugs. Patients with this complication most often present with new-onset heart failure. Other presentations include chest pain, cardiac arrhythmia, cardiogenic shock, pericardial effusion, and cardiac tamponade. Other organ systems may also be affected, including skeletal muscle myositis and hepatitis, although half of patients with myocarditis do not demonstrate other organ involvement. These drugs can block one of three different checkpoints, and drugs that block cytotoxic T-lymphocyte antigen 4 (CTLA-4) are reported to have a higher incidence of myocarditis. Combining two of these drugs is also associated with increased risk. Endomyocardial biopsy reveals inflammatory infiltrates with T lymphocytes and, less commonly, macrophages and giant cells, with variable fibrosis. Inflammation involving the conduction system and sinus node is also reported. Seventy-five percent of cases present within 6 months of beginning treatment and often present within the first few weeks after the initial dose.[58,59]

A review of 88 reported cases with ICI-associated myocarditis described that in addition to symptoms of heart failure, patients presented with weakness, chest pain, syncope, and fever. More than 90% of patients had significant elevation of serum troponin, and 91% had ECG abnormalities such as ST-segment changes, including pathologic ST-segment elevation, bundle branch block, and heart block including complete heart block. Seventy-seven percent had LVEF <50% on ECG. Sustained ventricular tachycardia (VT) and low cardiac output syndrome/cardiogenic shock were frequent. The mortality rate of ICI-associated myocarditis was 50%, three-quarters of these the result of

cardiac causes.[60] Another series reported similar characteristics, and 46% of these patients died or suffered cardiogenic shock, complete heart block, or cardiac arrest.[61] In both series, initial LVEF at diagnosis was not predictive of prognosis. At present there is no specific screening methodology recommended that can result in early recognition of this condition.

Treatment of ICI-associated myocarditis involves cessation of chemotherapy and urgent administration of high-dose corticosteroids, such as 1000 mg methylprednisolone daily. Additional immunosuppressive agents such as mycophenolate and tacrolimus may also be considered. Supportive care is also recommended, including therapies for heart failure, pacemakers, antiarrhythmic drugs, and mechanical support as appropriate. If the patient improves, ICI therapy should not be resumed.[62]

THERAPY

General Management of Heart Failure

The treatment of myocarditis is based on the clinical presentation. Patients with mild disease can be treated expectantly, with avoidance of strenuous exercise for several weeks.[3] Animal models indicate that strenuous exercise can worsen myocarditis. Elimination of unnecessary medications is important in patients with eosinophilia. Nonsteroidal antiinflammatory drugs should be avoided because they may worsen myocarditis.[5] The routine use of anticoagulants for prophylaxis of systemic emboli is not recommended. Patients who present with symptoms of arrhythmia or heart failure should be hospitalized, with continuous cardiac rhythm monitoring performed for evaluation of potential life-threatening arrhythmias or conduction abnormalities. If these are diagnosed, they are treated in a similar matter as in patients with other causes of heart disease, using antiarrhythmic drugs or pacemakers. However, a period of observation is recommended to assess for improvement of cardiac function before implantation of an ICD.

There are data in murine models of myocarditis supporting the use of ACE inhibitors, angiotensin blockers, and beta-blockers. These drugs reduce inflammation and lessen necrosis and fibrosis.[2,3,19,34] There are convincing data in humans supporting the use of these medications in addition to aldosterone antagonists in patients with dilated cardiomyopathy. Therefore in patients with myocarditis and heart failure, the use of standard multidrug medical therapy for heart failure and LV systolic dysfunction is indicated.[3,11] These medications have been shown to improve symptoms, prolong life, and regress the adverse LV remodeling in patients with dilated cardiomyopathy of various causes.[63–65]

Treatment with ACE inhibitors should be initiated at low doses, with upward titration to maximally tolerated doses. Potential side effects include renal insufficiency, hyperkalemia, and angioedema. Relative contraindications to the use of ACE inhibitors include renal failure, hyperkalemia, bilateral renal artery stenosis, and hepatic failure. Patients with hypotension should be treated with parenteral vasopressors or circulatory assist devices before initiation of low-dose ACE inhibitor therapy.

In one study, beta-adrenergic blockade was associated with improved survival in a multivariate analysis of patients with acute myocarditis.[40] Large randomized controlled clinical trials of patients with chronic heart failure with reduced LVEF, including patients with idiopathic dilated cardiomyopathy, have unequivocally shown benefit from beta-blockers in patients with LV systolic dysfunction,[66–68] and these agents should also be used in patients with heart failure caused by myocarditis. Beta-blockers should be initiated after patients are on a stable dose of ACE inhibitors and when signs of fluid overload have resolved. Contraindications to beta-blocker therapy include bronchospastic disease or severe chronic obstructive lung disease, heart block, or significant underlying bradycardia. Hypotension should be corrected before initiating beta-blocker therapy.

Digoxin has been shown in animal models to decrease levels of cytokines, but digoxin was associated with adverse outcomes in one murine model of myocarditis. Digoxin can be used to control rapid ventricular rates in patients with atrial fibrillation. The use of digoxin should be considered in patients with significant LV systolic dysfunction, after ACE inhibitors and beta-blockers have been initiated. However, no survival benefit for digoxin has ever been shown in patients with heart failure resulting from dilated cardiomyopathy.[69] Contraindications to the use of digoxin include renal failure or heart block.

Lastly, the use of the aldosterone antagonist spironolactone has been shown to have symptomatic and survival benefit in patients with chronic systolic heart failure.[70] In experimental models, these agents can reverse the progressive myocardial fibrosis that occurs in the remodeling process of dilated cardiomyopathy. These agents have not been studied in patients with myocarditis, but their use should be strongly considered in patients with severe LV dysfunction (ejection fraction $<35\%$) and symptomatic heart failure.[2] Contraindications to the use of aldosterone antagonists include renal insufficiency with serum creatinine levels above 2.0 mg%, or hyperkalemia. Serum potassium levels needs to be carefully monitored during initiation and dose titration.

In critically ill patients with severe heart failure and low cardiac index without serious hypotension, parenteral vasodilators should be used. Intravenous nitroprusside reduces systemic vascular resistance, mean systemic arterial pressure, and pulmonary capillary wedge pressure and can improve the cardiac index. It is used with invasive hemodynamic monitoring with a pulmonary artery catheter to best gauge the appropriate dose of medication and to accurately assess response to therapy. Prolonged use of nitroprusside is associated with accumulation of the toxic metabolites. Intravenous nitroglycerin is also an effective venodilator and coronary vasodilator with a less arterial dilating property than nitroprusside. The use of nitroglycerin in cases of myocarditis has not been studied. Patients often develop tolerance to this drug.

Patients with severe myocarditis may develop cardiogenic shock, respiratory failure, and end-organ hypoperfusion. In these instances, treatment with inotropic agents or vasopressors is indicated. Dobutamine is a potent $beta_1$-agonist with less $beta_2$- and alpha-agonist properties. Dobutamine has favorable short-term hemodynamic effects, increasing myocardial contractility, reducing systemic vascular resistance, and reducing pulmonary capillary wedge pressure. However, dobutamine can be proarrhythmic, and patients can develop tolerance to the drug. Milrinone is a parenteral inotropic agent that works by inhibiting phosphodiesterase. This drug leads to increased inotropy and decreased systemic vascular resistance and pulmonary capillary wedge pressure, with resultant increased stroke volume and cardiac index. Milrinone may cause hypotension. It is less proarrhythmic than dobutamine, and it does not induce tolerance.[71,72] Arterial vasoconstrictors such as norepinephrine and dopamine can be used in patients with refractory hypotension and poor end-organ perfusion.

In patients with fulminant myocarditis and cardiogenic shock not responding to pharmacologic therapy, mechanical circulatory support with intraaortic balloon counterpulsation (IABP), percutaneous mechanical ventricular assist devices (p-VADs), or extracorporeal membrane oxygenation (ECMO) should be used. ECMO is often used in children with fulminant myocarditis. Mechanical circulatory support improves hemodynamics, end-organ perfusion, and coronary flow and may allow for beneficial reverse remodeling

TABLE 74.2 Medical Therapy for Heart Failure in Acute Myocarditis and Advanced Supportive Therapies

Heart failure with left ventricular (LV) systolic dysfunction	Loop diuretics Beta-blockers (metoprolol succinate, carvedilol, bisoprolol) Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers Aldosterone blockers Digoxin
Severe heart failure with reduced cardiac output	Intravenous vasodilators (nitroprusside, nitroglycerin) Intravenous inotropes (milrinone, dobutamine), vasopressors (norepinephrine)
Cardiogenic shock not responding to medical therapy	Intraaortic balloon counterpulsation Extracorporeal membrane oxygenation (ECMO) Mechanical circulatory support: percutaneous or implanted ventricular assist device (VAD) Cardiac transplantation

and spontaneous resolution of LV dysfunction to occur. Patients with fulminant myocarditis should be given a reasonable time to recover ventricular function before cardiac transplantation is performed. Cardiac transplantation is the final option for treating critically ill patients with myocarditis (Table 74.2).

Immunosuppressive Therapy

Because autoimmune mechanisms are responsible for myocardial injury and the clinical manifestations of myocarditis, therapy with immunosuppressive drugs has been studied. Given the high rate of spontaneous recovery of LV function, placebo-controlled trials are essential to properly evaluate the effects of therapy. In addition, heterogeneous patient populations, consisting of patients with acute myocarditis and chronic dilated cardiomyopathy, have been included in older immunosuppressive trials, confounding the interpretation of results.

High-dose daily prednisone therapy was used for a 3-month course in 102 patients with dilated cardiomyopathy, 59% of whom were classified as having "reactive" myocarditis on endomyocardial biopsy.[73] The authors found a significant improvement in LVEF at 3 months in treated patients with reactive myocarditis, but this improvement was not sustained at 9 months. Improvement did not occur in patients with nonreactive biopsies treated with prednisone. No significant mortality benefit from immunosuppressive treatment was noted, although this was not a prespecified primary endpoint.

The Myocarditis Treatment Trial enrolled 111 patients with a positive endomyocardial biopsy finding and LVEF <45%. These patients had a protracted clinical course, with a duration of illness of less than 2 years.[46] Three treatment groups were compared: daily prednisone plus azathioprine, prednisone plus cyclosporine, and placebo. Mortality was 20% at 1 year and 56% at 3 years. These investigators found no difference in ejection fraction at week 28 or week 52, no change in LV size at week 28, and no difference in 1-year mortality between treated and untreated groups. Their conclusion was that these immunosuppressive strategies were not beneficial. Significant limitations of this study include a 30% dropout rate and significant interobserver variability among pathologists' diagnoses of biopsy specimens despite using the Dallas criteria.

In view of the limitations of histopathologic diagnosis using the Dallas criteria, another group of investigators used immunohistologic markers of inflammation, upregulation of HLA, to diagnose active myocarditis as an indication for immunosuppressive therapy.[74] These criteria have the advantage of indicating that autoimmunity is playing a role in pathogenesis. Also, because HLA is distributed throughout the entire myocardium, biopsy sampling error is eliminated as a confounding variable in assessing response to therapy. These patients also had a more chronic course of disease. Eighty-four of 202 patients with idiopathic dilated cardiomyopathy with duration >6 months and ejection fraction under 40% were found to have strong expression of HLA in biopsy specimens and were randomized to receive placebo or prednisone plus azathioprine for 3 months. At 3 months follow-up, a significant improvement in the prespecified secondary endpoints of LVEF, LV volumes, and functional capacity was seen in the treated group, and this improvement was maintained at 2 years (71.8% improvement in the treated group vs. 30.8% in the untreated group). However, there was no improvement in the prespecified composite primary endpoints of death, cardiac transplant, or hospital readmission. This study was limited by a 31% dropout rate.

In another study, patients with positive EMB specimens and progressive heart failure who responded to 6 months of therapy with prednisone and azathioprine were more likely to have circulating cardiac autoantibodies and no viral genome in their myocardium as compared with nonresponders.[75] Another randomized, placebo controlled trial of prednisone plus azathioprine was performed in 85 patients with chronic heart failure (>6 months illness) with active lymphocytic myocarditis on EMB and absence of viral genome on PCR. There was significant improvement in LVEF in the treated group (average ejection fraction increased from 26.5% to 45.6%) and no improvement in controls (average ejection fraction 27.7%–21.3%). In addition, there was significant improvement in LV dimensions and patients' functional status in the group receiving immunosuppression. This study suggests that this therapy may have favorable effects in patients who persist with active myocardial inflammation after the virus has been cleared[76] (Fig. 74.7).

Studies have suggested that in patients with heart failure and low ejection fraction, intravenous immunoglobulin (IVIg) has a pronounced antiinflammatory effect as measured by circulating levels of inflammatory markers.[77] Uncontrolled studies suggested benefit in patients with myocarditis from treatment with IVIg.[78,79] However, a placebo-controlled double-blind trial of IVIg in patients with myocarditis or idiopathic dilated cardiomyopathy of less than 6 months' duration showed no significant improvement with therapy as assessed by ejection fraction or functional capacity at 6 and 12 months.[80] In this study, average LVEF improved from 25 ± 8% at baseline to 41 ± 17% at 6 months in both treated and untreated groups. The 1-year event-free survival rate was 91.9% in both groups, indicating a favorable prognosis. Therefore the use of IVIg is not supported by any randomized trial.[81]

In summary, there is no evidence that patients with lymphocytic myocarditis or idiopathic dilated cardiomyopathy benefit from the *routine* use of immunosuppressive therapy. This treatment should be considered in patients with myocarditis who develop early signs of severe heart failure or who experience progressive worsening of LV function. EMB should be performed before initiating immunosuppression, and active inflammation should be seen, preferentially without viral genome detected on immunohistology. Immunosuppressive therapy should be used in patients with myocarditis associated with autoimmune diseases such as SLE, eosinophilic or granulomatous forms of the disease, and in GCM (Box 74.4).

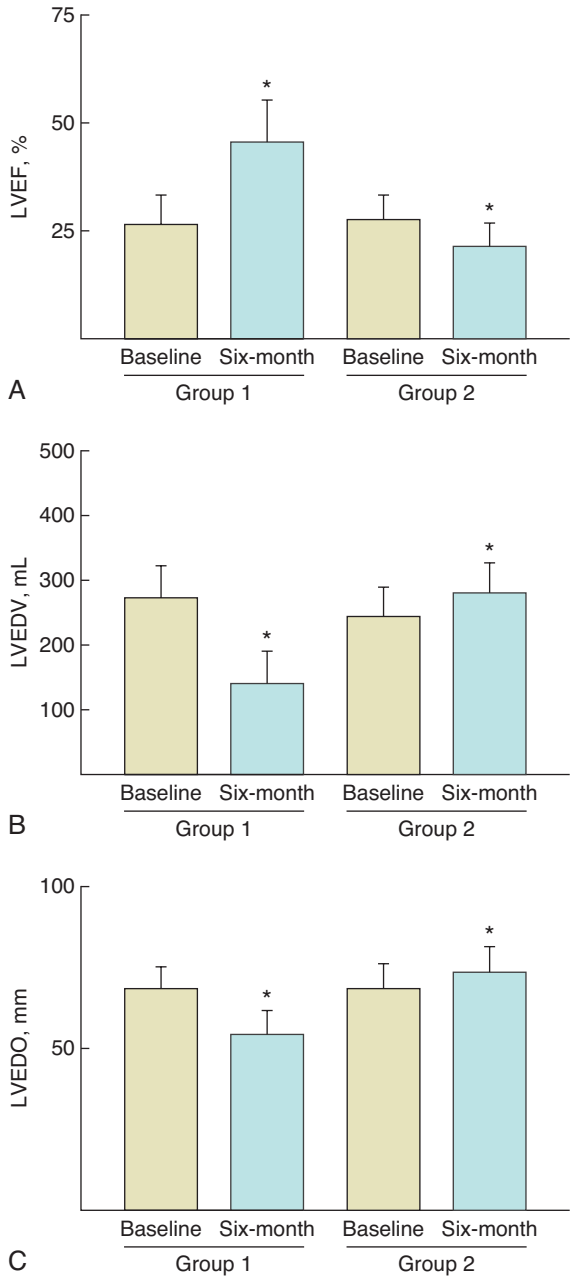

Fig. 74.7 Left ventricular function and size at baseline *(pink bars)* and at 6 months *(blue bars)* in patients with myocarditis. Group 1 was treated with immunosuppressive therapy and group 2 with placebo. (From Frustaci A, Russo MA, Chimenti C. Randomized study on the efficacy of immunosuppressive therapy in patients with virus-negative inflammatory cardiomyopathy: The TIMIC trial. *Eur Heart J.* 2009;30:1999.)

SUMMARY

The most common cause of myocarditis is viral infection, and autoimmune mechanisms are involved in the pathogenesis. Patients with myocarditis can present with acute chest pain, mimicking acute ischemic heart disease or other cardiopulmonary illnesses, or can present with heart failure. A smaller percentage of patients present with acute severe heart failure and cardiogenic shock. Oral and parenteral pharmacologic therapies that are used in patients with heart failure not caused by myocarditis are also used in these patients. FM is characterized by severe heart failure and cardiogenic shock. These patients need intensive, aggressive pharmacologic therapy and may require mechanical circulatory support. Cardiac MRI is an important tool in the diagnosis of myocarditis and may help with prognostication. EMB is a safe technique used to diagnose myocarditis in sicker patients and to decide on immunosuppressive therapy, although it is limited by sampling error and by current histopathologic techniques for assessing disease activity. Newer immunohistologic methods may better define those patients who will respond to immunosuppressive therapy. Patients with myocarditis and progressive myocardial failure despite conventional heart failure therapy should be considered for immunosuppressive therapy on a case-by-case basis.

BOX 74.4 Indications for Immunosuppressive Therapy in Myocarditis

Inflammation present on endomyocardial biopsy and:

1. Continued severe heart failure symptoms despite good medical therapy
2. Progressive worsening of heart failure symptoms or LV systolic function despite good medical therapy
3. Fulminant myocarditis
4. Presence of giant cell myocarditis
5. Presence of eosinophilic myocarditis
6. Presence of myocarditis in association with a systemic autoimmune disease (e.g., SLE, inflammatory bowel disease, polymyositis).

LV, Left ventricular; *SLE,* systemic lupus erythematosus.

STRESS CARDIOMYPATHY

A distinctive cardiomyopathy with acute onset, frequently precipitated by emotional or physical stress, is termed *stress cardiomyopathy.* This cardiomyopathy was first described in patients in Japan in 1991[82] and has subsequently been described elsewhere.[83,84] It is characterized by the sudden onset of chest pain and/or dyspnea, ECG changes mimicking AMI, and mild elevation of serum troponin. The syndrome is precipitated by extreme emotional or physical stress in >70% of cases.[85] The characteristic LV wall motion abnormality, seen in 75%–80% of cases, is akinesis or dyskinesis of a large area of the LV apex (Figs. 74.8 and 74.9). Coronary artery stenosis is not present or does not contribute to the cause. Other names for the cardiomyopathy are transient apical ballooning syndrome (TABS), describing the distinctive LV wall motion abnormality, or takotsubo, so named because the takotsubo pot used by Japanese fishermen to trap octopus has a shape similar to the left ventricle in this condition ("short neck, round flask").[84–87] Particular diagnostic criteria have been proposed (Box 74.5).

Precipitators of stress cardiomyopathy include arguments with family members, the death of loved ones, or sudden financial setbacks. Physical stresses include medical procedures such as thoracentesis or biopsy, institution of cancer chemotherapy or hemodialysis, and hip fracture and noncardiac surgeries. Stress cardiomyopathy in younger males can be associated with substance abuse disorders or withdrawal. A similar acute cardiomyopathy can occur as a complication of acute central nervous system illnesses, including subarachnoid hemorrhage, ischemia or hemorrhagic stroke, head trauma, and encephalitis. This is termed *neurogenic stunned myocardium*. The pathophysiology is felt to be similar to stress cardiomyopathy (see later).

Stress cardiomyopathy has been reported to occur in approximately 1.7%–2.2% of admissions for acute coronary syndrome in Japan and the United States,[88,89] with an annual incidence of 15–30 per 100,000 in the United States. It may be more common than currently recognized. There is a marked preponderance for postmenopausal females to be affected by this condition, 86%–100% in reported series,

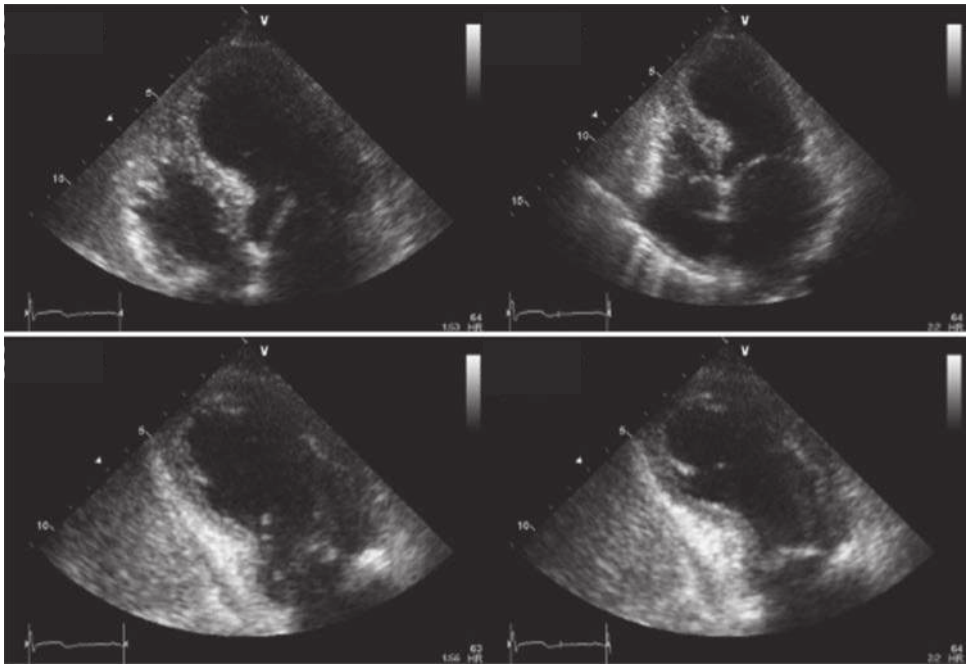

Fig. 74.8 End-diastolic and end-systolic apical four- and two-chamber echocardiographic views demonstrating the typical apical and mid-ventricular wall motion abnormalities seen in stress cardiomyopathy. (From Gianni M, Dentali F, Grandi AM, et al. Apical ballooning syndrome or takotsubo cardiomyopathy: a systematic review. *Eur Heart J.* 2006;27:1523–1529.)

Fig. 74.9 Left ventriculogram showing typical wall motion abnormalities in stress cardiomyopathy. *Arrows* in systole indicate hyperkinesis of basal inferior and anterior segments, with dyskinesia of remaining wall segments. (From Sharkey SW, Lesser JR, Zenovich AG, et al. Acute and reversible cardiomyopathy provoked by stress in women from the United States. *Circulation.* 2005;111:472–479.)

with a mean age of 63–67 years. Many subsequent reports have described this condition in younger patients, including a subset of patients with cannabis use disorder. Sixty-six to ninety percent of patients will present with chest pain, and 15%–20% will present with dyspnea, pulmonary edema, or shock. ECG is abnormal in 95% of cases. The most common abnormalities seen are ST-segment elevation in precordial leads (40%) or in lead aVR or marked T-wave inversions in the precordial leads. ST-segment depression is uncommon. These findings are indistinguishable from acute coronary syndromes caused by coronary artery disease. Elevation of creatine kinase-MB (CK-MB) and troponin is seen in the majority of patients, but the enzyme rise is typically lower than would be expected, given the marked ECG and LV wall motion abnormalities. Serum brain natriuretic peptide (BNP) levels tend to be markedly elevated.[90]

Correct diagnosis involves emergency coronary angiography to exclude acute coronary syndrome resulting from obstructive coronary artery disease. Echocardiography and left ventriculography show moderate-to-severe LV dysfunction in these patients, with characteristic

BOX 74.5 Diagnostic Criteria for Stress Cardiomyopathy According to the Heart Failure Association of the European Society of Cardiology

1. Transient regional wall motion abnormalities of left ventricle or right ventricle myocardium, which are frequently, but not always, preceded by a stressful trigger (emotional or physical).
2. The regional wall motion abnormalities usually extend beyond a single epicardial vascular distribution and often result in circumferential dysfunction of the ventricular segments involved.
3. The absence of culprit atherosclerotic coronary artery disease, including acute plaque rupture, thrombus formation, and coronary dissection or other pathologic conditions, to explain the pattern of temporary LV dysfunction observed (e.g., hypertrophic cardiomyopathy, viral myocarditis).
4. New and reversible electrocardiography abnormalities (ST-segment elevation, ST-segment depression, LBBB, T-wave inversion, and/or QTc prolongation) during the acute phase (3 months).
5. Significantly elevated serum natriuretic peptide (BNP or NT-proBNP) during the acute phase.
6. Positive but relatively small elevation in cardiac troponin measured with conventional assay (i.e., disparity between the troponin level and the amount of dysfunctional myocardium present).
7. Recovery of ventricular systolic function on cardiac imaging at follow-up (3–6 months).

BNP, Brain natriuretic peptide; *LBBB,* left bundle branch block; *LV,* left ventricular; *NT-proBNP,* N-terminal-pro hormone BNP.

hyperkinesis of inferior-basal and basal-septal segments, with severe hypokinesis or dyskinesis involving mid-anteroseptal, apical, and inferior-apical wall segments. A small percentage of patients will demonstrate different contraction abnormalities, with akinesis involving the mid-anterior and mid-inferior walls, with normal motion or hypercontractility of the apex and basal segments, or akinesis localized to basal segments or particular regions of the left ventricle. The right ventricle is affected rarely. Thrombus in the left ventricle is not uncommon. Acutely, LVEF is reduced to 20%–40%.[85,86] Up to 20% of patients may demonstrate an LV outflow tract gradient resulting from basal septal hyperkinesis and transient systolic anterior motion of the anterior leaflet of the mitral valve.[83,84]

Patients with stress cardiomyopathy often present critically ill, with pulmonary edema (15%–45%), hypotension, and shock. Cardiogenic shock can develop because of marked LV systolic dysfunction and decreased stroke volume. Shock can also be exacerbated by the development of an LV outflow tract gradient. Cardiogenic shock has been reported in 5% of patients at presentation and has occurred during the course of the illness in 6%–46% of patients in different series.[83,85–88] Ventricular arrhythmia, including torsades de pointes, is seen in 5%–10% of patients, and atrial fibrillation may occur in 5%–15%.

Suspicion of stress cardiomyopathy and urgent diagnosis are important, as therapy and prognosis differ substantially from acute coronary syndromes caused by coronary artery disease. Stress cardiomyopathy should not be treated with thrombolytic therapy, as coronary occlusion is not involved in the pathogenesis. Beta-blocker therapy is recommended, although registries have not shown improved in-hospital outcomes with this medication. Anticoagulation is recommended if LV thrombus is diagnosed. If cardiogenic shock develops, treatment with IABP is advised. Inotropic therapy should be used judiciously or not at all. Dobutamine and other beta-agonists may worsen cardiogenic shock by increasing hyperkinesis of the basal portion of the heart and causing or aggravating an LV outflow tract gradient. There have been case reports of patients with stress cardiomyopathy whose hypotension progressed to frank cardiogenic shock after initiation of inotropic therapy. Because a hyperadrenergic state has been proposed to be the major pathogenic mechanism, empiric use of beta-blockers while patients are being supported with IABP has been used successfully. Echocardiography can be useful to guide therapy. For those with extensive wall motion abnormalities but no outflow obstruction, IABP support without beta-blockers is recommended. Administration of the alpha-agonist phenylephrine can also be considered in cases with a high LV outflow tract gradient, as this drug increases afterload, causing LV dilatation and a decrease in mitral valve systolic anterior motion and lowering of intraventricular gradients. The initial course may be complicated by severe ventricular arrhythmia.

Stress cardiomyopathy has a prognosis that approximates that of acute coronary syndromes, with an in-hospital mortality rate of 4%.[91] Aggressive therapy of hemodynamic compromise and cardiogenic shock is indicated. In almost all patients, the marked apical wall motion abnormalities begin to improve within days, and LV function can be expected to recover to normal during the ensuing 1–6 months. However, in a small percentage of patients wall motion abnormalities may persist for up to 1 year. Follow-up in various series has shown recovery of LVEF to normal in most instances. The large majority of survivors will recover completely with normal functional status. The long-term prognosis is good. In one series, only 2 out of 72 patients had recurrence of TABS within 13 months. In another series, the recurrence of TABS was calculated at 2.9% per year. Over a 4-year follow-up, long-term survival of patients who recovered from TABS was equivalent to sex- and age-matched control groups without a history of TABS.[85,92]

The pathogenesis of TABS is unknown. A hyperadrenergic state, precipitated by acute stress and causing myocardial stunning, is proposed, with activation of noradrenergic neurons and release of systemic catecholamines and norepinephrine and neuropeptides in the myocardium, which can be toxic to myocytes and can cause vascular dysfunction. One study documented supraphysiologic levels of serum catecholamines and stress neuropeptides in patients during the acute phase of the illness, likely caused by adrenal and sympathoneuronal hyperactivity. The apex of the left ventricle may be more sensitive to the deleterious effects of adrenergic hyperstimulation than other LV wall segments.[86] Transient multivessel coronary spasm has also been proposed, but this has not been demonstrated at the time of acute coronary angiography in the vast majority of patients. Additionally, in most patients the extent of LV wall motion abnormality is larger than the distribution of a single coronary artery. Cardiac MRI has not shown evidence of infarction or myocarditis.[89]

In summary, stress cardiomyopathy should be suspected in patients who present with symptoms and ECG findings consistent with AMI, who have the typical large apical wall motion abnormality seen on echocardiography or left ventriculography, and whose symptoms are precipitated by severe emotional or physical stress. Diagnosis is confirmed when urgent cardiac catheterization and coronary angiography demonstrate no significant coronary artery occlusion or stenosis.

TACHYCARDIA-INDUCED CARDIOMYOPATHY

A sustained rapid heart rate can lead to the acute development of LV dilation and systolic dysfunction, with symptoms of heart failure. This is termed *tachycardia-induced cardiomyopathy* (TICMP). The definition includes sustained heart rate over 100/min, exclusion of other causes of LV dysfunction, and complete recovery to baseline after adequate control of heart rate.[93] This can occur in otherwise normal hearts, or tachycardia may exacerbate heart failure in patients with

preexisting cardiomyopathy. Supraventricular or ventricular arrhythmias of any type can lead to this syndrome. Arrhythmias that may be responsible for TICMP include atrial fibrillation, atrial flutter, automatic atrial tachycardia, atrioventricular (AV) node re-entry tachycardia, supraventricular tachycardia (SVT) involving accessory pathways, accelerated junctional tachycardia, VT (from RV and LV sites), sustained rapid cardiac pacing, and even very frequent premature ventricular contractions or prolonged, sustained ventricular bigeminy. The development of TICMP is related to the rate of the tachycardia and the duration of the arrhythmia, and in TICMP caused by ventricular arrhythmia, the frequency, site of origin, and coupling intervals are important.[93,94] It is not known how long the tachycardia needs to be present in order to cause LV dysfunction, but sustained arrhythmia for days to weeks is likely necessary. The presence of an underlying predisposing substrate has been postulated, as not all patients with sustained tachycardia will develop cardiomyopathy.[95]

Animal models of TICMP have been established and studied to elucidate pathophysiologic mechanisms and clinical correlates. In these models, sustained, rapid atrial or ventricular pacing leads to severe biventricular systolic and diastolic dysfunction with four-chamber dilation and change in LV geometry to a more spherical shape. Within 24 hours of initiating rapid pacing, there is a fall in cardiac output and blood pressure. During the first week, pulmonary artery pressure rises, and there is an increase in left and right ventricular filling pressures. Neurohormonal activation occurs typical for dilated cardiomyopathy. Cardiac output and ejection fraction fall and ventricular volume increases over 3–5 weeks. When pacing is discontinued, cardiac output improves to near normal in 48 hours, and hemodynamics are normal within 4 weeks. Ejection fraction recovers to normal in 1–2 weeks, although end-diastolic volume remains high at 12 weeks, suggesting persistent remodeling. Structural cardiac changes seen include myocyte hypertrophy, apoptosis, and altered extracellular matrix. Proposed pathophysiologic mechanisms include myocardial energy depletion, ischemia, matrix remodeling with fibrosis, and altered myocyte handling of calcium.[95–98]

One study described EMB results in 19 patients diagnosed with TICMP. Compared with biopsy specimens in patients with inflammatory cardiomyopathy and dilated cardiomyopathy from other nonischemic causes, there was less fibrosis in TICMP (63% "mild," 37% "moderate"), more frequent infiltration with macrophages, and less prominent T lymphocytes. Electron microscopy revealed severely disturbed mitochondrial distribution.[93]

TICMP can occur at any age, from infants to the elderly. It has been reported to occur in fetuses with sustained SVT, which resolved with correction of the arrhythmia.[96] The incidence and prevalence of TICMP are not known. One study analyzed patients who were hospitalized for treatment of heart failure who had rapid atrial fibrillation and no prior diagnosis of cardiac illness. One-third of this group were determined to have TICMP. These patients had smaller ventricles initially and had better long-term prognosis, with lower rehospitalization and mortality rates.[99] In other observations, males were more frequently affected than females, the mean heart rate was 122/min, 84% of patients had atrial fibrillation as the inducing arrhythmia, and the average LVEF was 30%, with improvement by 15% at follow-up.[93] Patients with rapid atrial fibrillation and cardiomyopathy treated with AV node ablation also show improved cardiac function over time, indicating that tachycardia was more important in the pathophysiology than the lack of atrial-ventricular synchrony.

The diagnosis of TICMP should be suspected in any patient with impaired ventricular function in the setting of sustained SVT or VT. The diagnosis is clear when LV function before the onset of tachycardia was demonstrated to be normal and no intercurrent illness other than the arrhythmia has occurred. The diagnosis is confirmed when LV function rapidly improves with correction of the arrhythmia.

Treatment of TICMP is to rapidly restore normal heart rate. This can be done with parenteral rate-slowing medication, including beta-blockers such as esmolol or metoprolol, or calcium channel blockers such as diltiazem. Verapamil may aggravate hypotension and LV dysfunction and should be avoided. Adenosine can rapidly convert AV nodal re-entry tachycardia to sinus rhythm. Intravenous digoxin can also be considered, although its onset of action is delayed. Type I drugs such as procainamide can be prescribed for SVT associated with accessory pathways. Electrical cardioversion and ablation techniques can rapidly terminate supraventricular and ventricular arrhythmias and restore sinus rhythm. In patients with atrial flutter or atrial fibrillation, reliable control of the heart rate to a range of 60–90 per minute is a reasonable alternative to conversion of the arrhythmia to sinus rhythm.

In patients with TICMP who have received appropriate arrhythmia therapy, heart failure symptoms improve rapidly. LV systolic function will generally recover to normal within 4 weeks if there is no other underlying heart disease. Twenty-four to forty-eight hour cardiac rhythm monitoring is often necessary to ensure that heart rate is controlled during activity and at rest.[96] In a report of 11 patients with atrial flutter and abnormal systolic function who underwent atrial flutter ablation, ejection fraction improved from an average of 31% at baseline to 41% within 7 months of ablation. Lack of resolution of cardiomyopathy was predicted by a lower baseline ejection fraction.[100] A series of 24 patients with TICMP was reported whose cardiomyopathy initially resolved with arrhythmia control but who experienced repeated rapid decline in LV function and recurrent heart failure when their arrhythmias recurred. These patients again had improvement or normalization of ejection fraction after repeated arrhythmia control within 6 months. However, three of the patients died suddenly and unexpectedly, emphasizing that structural and electrical abnormalities may persist on a chronic basis.[101]

KEY POINTS

- Myocarditis is most often caused by a viral infection. Myocardial damage is mediated through activation of cellular immune mechanisms.
- The clinical course of myocarditis can be benign, with complete resolution, or the illness can be more severe, with the development of dilated cardiomyopathy and congestive heart failure. Cardiogenic shock and fatal arrhythmias can occur.
- The pharmacologic therapy of heart failure associated with myocarditis is similar to therapy used in other forms of dilated cardiomyopathy Severe cases may require the use of mechanical circulatory support.
- FM is an infrequent but severe form of myocarditis marked by severe heart failure and cardiogenic shock, requiring treatment with vasopressors, inotropes, and at times mechanical circulatory support. The prognosis is worse than in NFM. Significant improvement in LV function often occurs.
- Cardiac MRI is useful for the diagnosis of myocarditis. EMB can also be used for diagnosis and to decide on immunosuppressive therapy in severe cases.
- Immunosuppressive therapy based on the EMB results should not be used routinely in the treatment of myocarditis but should be strongly considered in patients who have severe heart failure early in the course of the illness, who have clinical characteristics of a treatable form of myocarditis, or whose condition deteriorates despite the use of conventional heart failure treatment.
- Stress cardiomyopathy, also called TABS, is an acute, severe cardiomyopathy often precipitated by emotional or physical stress, with a presentation similar to AMI. Patients will usually make a full recovery after intensive care during the acute phase of the illness.

Pericardial Diseases

Bernhard Maisch and Arsen D. Ristic

ETIOLOGY AND CLASSIFICATION OF PERICARDIAL DISEASE

The spectrum of pericardial diseases consists of congenital defects, pericarditis (dry, effusive, effusive-constrictive, or constrictive), neoplasms, and cysts. The etiologic classification comprises infectious pericarditis, pericarditis in systemic autoimmune diseases, type 2 (auto) immune process, postmyocardial infarction syndrome, and autoreactive (chronic) pericarditis.[1,2]

PERICARDIAL SYNDROMES

Congenital Defects of the Pericardium

Congenital defects of the pericardium are found in 1 in 10,000 autopsies. Pericardial absence can be partial left (70%), partial right (17%), or total bilateral (rare). Additional congenital abnormalities occur in approximately 30% of patients. Most patients with total pericardial absence are asymptomatic. Homolateral cardiac displacement and augmented heart mobility impose an increased risk for traumatic aortic dissection.[3] Partial left-side defects can be complicated by herniation and strangulation of the heart through the defect (causing chest pain, shortness of breath, syncope, or sudden death). Surgical pericardioplasty (Dacron, Gore-Tex, or bovine pericardium) is indicated for imminent strangulation.

Acute Pericarditis

Acute pericarditis is dry, fibrinous, or effusive, independent of its etiology. The major symptoms are retrosternal or left precordial chest pain (which radiates to the trapezius ridge, can be pleuritic or simulate ischemia, and varies with posture) and shortness of breath. A prodrome of fever, malaise, and myalgia is common, but elderly patients may not be febrile. A pericardial friction rub can be transient and monophasic, biphasic, or triphasic. A pleural effusion may be present. The heart rate is usually rapid and regular. Echocardiography is essential to detect effusion and concomitant heart or paracardial disease (Table 75.1).[4–11]

Hospitalization and symptomatic treatment are warranted. Nonsteroidal antiinflammatory drugs (NSAIDs) are the mainstay. Indomethacin should be avoided in elderly patients owing to its effect on reducing flow in the coronaries. Ibuprofen (300–800 mg TID) is preferred for its rare side effects, favorable impact on coronary blood flow, and large dose range.[4] Colchicine 0.5 mg at least twice daily for 3 months added to aspirin or another NSAID reduced the recurrence rate impressively in the COPE trial,[12] even at the first episode of pericarditis or even as monotherapy in "idiopathic" effusions. Colchicine is well tolerated, with fewer side effects than NSAIDs. Systemic corticosteroids should be restricted to connective tissue diseases and autoreactive or uremic pericarditis. Intrapericardial steroid application, as long-acting crystalloid triamcinolone, is effective for autoreactive effusions and avoids systemic side effects.[2]

Chronic Pericarditis

Chronic (>3 months) pericarditis includes effusive (inflammatory or hydropericardium in heart failure), adhesive, and constrictive forms.[4] Symptoms (chest pain, palpitations, and fatigue) are usually mild and related to the degree of cardiac compression and pericardial inflammation. The detection of curable causes (e.g., tuberculosis; toxoplasmosis; myxedema; or viral, autoimmune, and systemic diseases) allows successful specific therapy. Symptomatic treatment and pericardiocentesis should be applied, if indicated. For recurrences, the etiology should be investigated intensely, and if no specific therapy is effective, balloon pericardiotomy or pericardiectomy may be considered.

Recurrent Pericarditis

The term *recurrent pericarditis* encompasses (1) the intermittent type (symptom-free intervals without therapy) and (2) the incessant type (discontinuation of antiinflammatory therapy precipitates a relapse). Massive pericardial effusion, overt tamponade, or constriction is rare. Symptomatic management relies on exercise restriction and regimens used for acute pericarditis. Colchicine may be effective when NSAIDs and corticosteroids fail to prevent relapses.[12,13] It should be considered the first-choice treatment for recurrent pericarditis according to the CORE trial. Corticosteroids should be used only in patients with a poor general condition or in frequent crises.[4] A common mistake could be to use a dose too low to be effective or to taper the dose too rapidly. The recommended regimen is prednisone 1–1.5 mg/kg for at least 1 month. If patients do not respond adequately, azathioprine (75–100 mg/day) or cyclophosphamide can be added.[14]

Corticosteroids should be tapered over a 3-month period. Toward the end of the taper, introduce antiinflammatory treatment with colchicine (0.5 mg BID or TID) or an NSAID. Renewed treatment should continue for 3–6 months. Recently, it has been demonstrated in "idiopathic" pericarditis that previous corticosteroid treatment was a risk factor for recurrence or chronicity. Therefore corticosteroids should be administered after the definite exclusion of viral or bacterial infection of the pericardium. Pericardiectomy is indicated only for frequent and highly symptomatic recurrences resistant to medical treatment.[15]

Pericardial Effusion and Cardiac Tamponade

Pericardial effusion may appear as transudate (hydropericardium), exudate, pyopericardium, or hemopericardium. Large effusions are common with neoplastic, tuberculous, cholesterol, and uremic pericarditis and with myxedema and parasitoses. Loculated effusions are more common when scarring has supervened (e.g., postsurgical,

TABLE 75.1 Diagnostic Pathway and Sequence of Performance in Acute Pericarditis

Diagnostic Measure	Characteristic Findings
Obligatory	
Auscultation	Pericardial rub (monophasic, biphasic, or triphasic)
ECG*	*Stage I:* anterior and inferior concave ST-segment elevation. PR-segment deviations opposite to P-wave polarity.
	Early stage II: all ST junctions return to the baseline. PR segments deviated.
	Late stage II: T waves progressively flatten and invert.
	Stage III: generalized T-wave inversions in most or all leads.
	Stage IV: ECG returns to prepericarditis state.
Echocardiography	Effusion types B to D (Horowitz).
	Signs of tamponade.
Blood analyses	Erythrocyte sedimentation rate, C-reactive protein, lactate dehydrogenase, leukocytes (inflammation markers).
	Troponin I,† CK-MB (markers of myocardial involvement).
Chest radiograph	Ranging from normal to "water bottle" shape of the heart shadow.
	Performed primarily to reveal pulmonary or mediastinal pathology.
Mandatory in Tamponade, Optional in Large/Recurrent Effusions or if Previous Tests Inconclusive in Small Effusions	
Pericardiocentesis/drainage	Polymerase chain reaction and histochemistry for etiopathogenetic classification of infection or neoplasia.
Optional or if Previous Tests Inconclusive	
CT	Effusions, pericardium, and epicardium.
MRI	Effusions, pericardium, and epicardium.
Pericardioscopy, pericardial/epicardial biopsy	Establishing the specific etiology.

Data from Refs. 2, 3, and 7–19.
CK-MB, Creatine kinase-MB; *CT,* computed tomography; *ECG,* electrocardiogram; *MRI,* magnetic resonance imaging.
*Typical lead involvement: I, II, aVL, aVF, and V_3–V_6. The ST segment is always depressed in aVR, frequently in V_1, and occasionally in V_2. Stage IV may not occur, and there are permanent T-wave inversions and flattenings. If an ECG is first recorded in stage III, pericarditis cannot be differentiated by ECG from diffuse myocardial injury, "biventricular strain," or myocarditis. ECG in early repolarization is very similar to stage I. Unlike stage I, this ECG does not acutely evolve, and J-point elevations are usually accompanied by a slur, oscillation, or notch at the end of the QRS just before and including the J point (best seen with tall R and T waves—large in an early repolarization pattern). Pericarditis is likely if, in lead V_6, the J point is greater than 25% of the height of the T-wave apex (using the PR segment as a baseline).
†A rise in cardiac muscle troponin I (cTnI) was detected in 38/118 patients (32.2%); more frequently in younger, male patients; and with ST-segment elevation and pericardial effusion at presentation. An increase beyond 1.5 ng/mL was rare (7.6%) and associated with CK-MB elevation. cTnI increase was not a negative prognostic marker for the incidence of recurrences, constrictive pericarditis, cardiac tamponade, or residual left ventricular dysfunction.

posttraumatic, or purulent pericarditis). Effusions that develop slowly can be remarkably asymptomatic, whereas rapidly accumulating smaller effusions can present as tamponade. Cardiac tamponade is the decompensated phase of cardiac compression caused by effusion accumulation, leading to increased intrapericardial pressure. Heart sounds are distant. Orthopnea, cough, and dysphagia, occasionally with episodes of unconsciousness, can be observed. Insidiously developing tamponade may present as signs of its complications (renal failure, abdominal plethora, shock liver, worsening of glaucoma,[16] and mesenteric ischemia). Tamponade without two or more inflammatory signs (typical pain, pericardial friction rub, fever, or diffuse ST-segment elevation) is usually associated with a malignant effusion (likelihood ratio, 2.9).[17]

Electrocardiography demonstrates low QRS and T-wave voltages, PR-segment depression (Fig. 75.1), ST-segment/T-wave changes, bundle branch block, and electrical alternans (rarely seen in the absence of tamponade).[4] Microvoltage and electrical alternans are reversible after the drainage of the effusion and resolution of the inflammatory process.[11] In chest radiography, large effusions are depicted as globular cardiomegaly with sharp margins ("water bottle" silhouette) (Fig. 75.2). The size of effusions noted during echocardiography can be graded as (1) small (echo-free space in diastole <10 mm), (2) moderate (10–20 mm; Fig. 75.3), (3) large (≥20 mm), or (4) very large (≥20 mm and

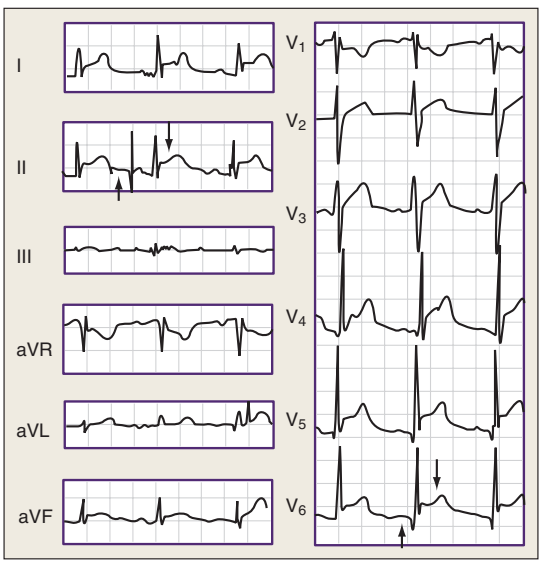

Fig. 75.1 Typical electrocardiographic changes in acute pericarditis: PR depression *(small arrow)* and concave ST-segment elevation *(large arrow)*.

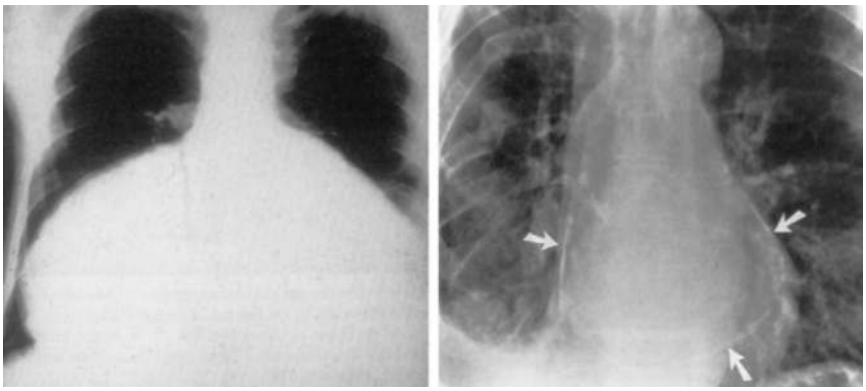

Fig. 75.2 Chest radiographs in a patient with a very large pericardial effusion—"water bottle" sign *(left)*—and in a patient with constrictive pericarditis and pericardial calcifications *(white arrows, right).*

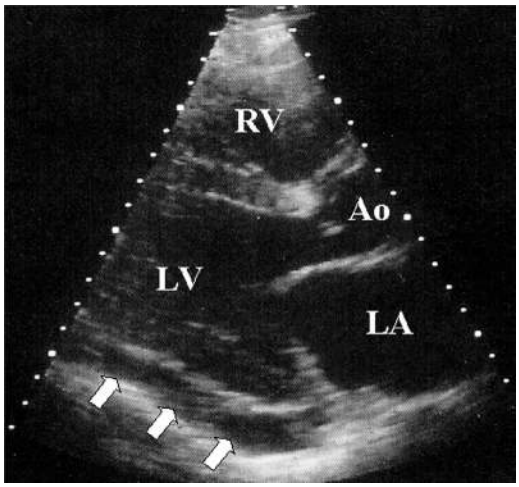

Fig. 75.3 Echocardiographic findings in a small to moderate pericardial effusion *(white arrows).* Long-axis parasternal view. *Ao,* Aortic root; *LA,* left atrium; *LV,* left ventricle; *RV,* right ventricle.

compression of the heart). In large pericardial effusions, the heart may move freely within the pericardial cavity ("swinging heart"), inducing pseudoprolapse and pseudosystolic anterior motion of the mitral valve, paradoxical motion of the interventricular septum, and midsystolic aortic valve closure (Table 75.2).[18–20] Up to one-third of patients with an asymptomatic large pericardial chronic effusion develop unexpected cardiac tamponade. Triggers for tamponade include hypovolemia, paroxysmal tachyarrhythmia, and intercurrent acute pericarditis.

Constrictive Pericarditis

Constrictive pericarditis is a rare, but severely disabling, consequence of chronic inflammation of the pericardium, leading to impaired filling of the ventricles and reduced ventricular function. Until recently, increased pericardial thickness has been considered an essential diagnostic feature of constrictive pericarditis. However, in a large surgical series from the Mayo Clinic, constriction was present in 18% of patients with normal pericardial thickness.[21] Tuberculosis, mediastinal irradiation, and previous surgical procedures are frequent. Constrictive pericarditis may rarely develop only in the epicardial layer in patients with a previously removed parietal pericardium.[22] Transient constrictive pericarditis is an uncommon but important entity because pericardiectomy is not indicated in these patients.[23]

Patients complain of fatigue, peripheral edema, breathlessness, and abdominal swelling, which may be aggravated by a protein-losing enteropathy. In decompensated patients, venous congestion, hepatomegaly, pleural effusions, and ascites may occur. Hemodynamic impairment can be additionally aggravated by systolic dysfunction caused by myocardial fibrosis or atrophy. Differential diagnosis has to include acute dilatation of the heart, pulmonary embolism, right ventricular infarction, pleural effusion, chronic obstructive lung disease, and restrictive cardiomyopathy. The best way to distinguish constrictive pericarditis from restrictive cardiomyopathy is by Doppler and/or tissue Doppler echocardiographic analysis of respiratory changes with or without changes in preload.[24] However, physical findings, an electrocardiogram (ECG), chest radiography (see Fig. 75.2, right), computed tomography (CT) (Fig. 75.4, left), magnetic resonance imaging (MRI) (see Fig. 75.4, right), hemodynamics, and endomyocardial biopsy may be helpful as well.[4]

Pericardiectomy is the only treatment for permanent constriction. The indications are based on clinical symptoms, echocardiographic findings, CT/MRI, and heart catheterization. A primary installation of cardiopulmonary bypass (CPB) is not recommended, as diffuse bleeding can occur after systemic heparinization. Pericardiectomy for constrictive pericarditis has a mortality rate of 6%–12%,[25] and complete normalization of cardiac hemodynamics is reported in only 60% of patients. Major complications include acute perioperative cardiac insufficiency and ventricular wall rupture. Cardiac mortality and morbidity with pericardiectomy are mainly caused by the presence of myocardial atrophy or myocardial fibrosis that was not recognized before surgery. The exclusion of patients with extensive myocardial fibrosis and/or atrophy has reduced the mortality rate of pericardiectomy to 5%. Postoperative low cardiac output should be treated by fluid substitution and catecholamines, high doses of digitalis, and intraaortic balloon pump in the most severe cases. If indications for surgery are established early, long-term survival after pericardiectomy corresponds to that of the general population. However, if severe clinical symptoms are present for a longer period before surgery, even complete pericardiectomy may not achieve total restitution.

Pericardial Cysts

Congenital pericardial cysts are uncommon; they may be unilocular or multilocular, with a diameter ranging from 1 to 5 cm. Inflammatory cysts comprise pseudocysts, in addition to encapsulated and loculated pericardial effusions, caused by rheumatic pericarditis, bacterial infection (particularly tuberculosis), trauma, and cardiac surgery. Most patients are asymptomatic, and cysts are detected incidentally on chest

TABLE 75.2 Diagnosis of Cardiac Tamponade

Clinical presentation	Elevated systemic venous pressure,* hypotension,† pulsus paradoxus,‡ tachycardia,§ dyspnea, or tachypnea with clear lungs
Precipitating factors	Drugs (cyclosporine, anticoagulants, thrombolytics), recent cardiac surgery, indwelling instrumentation, blunt chest trauma, malignancies, connective tissue disease, renal failure, septicemia‖
ECG	Can be normal or nonspecifically changed (ST-T wave), electrical alternans (QRS, rarely T), bradycardia (end stage), electromechanical dissociation (agonal phase)
Chest radiograph	Enlarged cardiac silhouette with clear lungs
M-mode/two-dimensional echocardiogram	Diastolic collapse of the anterior RV free wall,¶ RA collapse, LA and rarely LV collapse, increased LV diastolic wall thickness "pseudohypertrophy," IVC dilatation (no collapse in inspiration), "swinging heart"
Doppler	Tricuspid flow increases and mitral flow decreases during inspiration (reverse in expiration)
	Systolic and diastolic flows are reduced in systemic veins in expiration, and reverse flow with atrial contraction is increased
M-mode color Doppler	Large respiratory fluctuations in mitral/tricuspid flows
Cardiac catheterization	Confirmation of the diagnosis and quantification of the hemodynamic compromise
	RA pressure is elevated (preserved systolic × descent and absent or diminished diastolic and descent)
	Intrapericardial pressure is also elevated and virtually identical to RA pressure (both pressures fall in inspiration)
	RV mid-diastolic pressure is elevated and equal to the RA and pericardial pressures (no dip-and-plateau configuration)
	Pulmonary artery diastolic pressure is slightly elevated and may correspond to the RV pressure
	Pulmonary capillary wedge pressure is also elevated and nearly equal to intrapericardial and RA pressure
	LV systolic and aortic pressures may be normal or reduced
	Documenting that pericardial aspiration is followed by hemodynamic improvement**
	Detection of coexisting hemodynamic abnormalities (LV failure, constriction, pulmonary hypertension)
	Detection of associated cardiovascular diseases (cardiomyopathy, coronary artery disease)
RV/LV angiography	Atrial collapse and small hyperactive ventricular chambers
Coronary angiography	Coronary compression in diastole

Data from Refs. 31–41.
ECG, Electrocardiogram; *IVC,* inferior vena cava; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.
*Jugular venous distention is less notable in hypovolemic patients or in "surgical tamponade." An inspiratory increase or lack of fall of pressure in the neck veins (Kussmaul sign), when verified by tamponade or after pericardial drainage, indicates effusive-constrictive disease.
†Heart rate is usually greater than 100 beats per minute but may be lower in patients with hypothyroidism or uremia.
‡Pulsus paradoxus is defined as a drop in systolic blood pressure greater than 10 mm Hg during inspiration, while diastolic blood pressure remains unchanged. It is easily detected by simply feeling the pulse, which diminishes significantly during inspiration. Clinically significant pulsus paradoxus is apparent when the patient is breathing normally. When this sign is present only in deep inspiration, it should be interpreted with caution. The magnitude of pulsus paradoxus is evaluated by sphygmomanometry. If pulsus paradoxus is present, the first Korotkoff sound is not heard equally well throughout the respiratory cycle, but only during expiration at a given blood pressure. The blood pressure cuff is therefore inflated above the patient's systolic pressure. Then it is slowly deflated, while the clinician observes the phase of respiration. During deflation, the first Korotkoff sound is intermittent. Correlation with the patient's respiratory cycle identifies a point at which the sound is audible during expiration but disappears when the patient breathes in. As the cuff pressure drops further, another point is reached when the first blood pressure sound is audible throughout the respiratory cycle. The difference in systolic pressure between these two points is the clinical measure of pulsus paradoxus. Pulsus paradoxus is absent in tamponade complicating an atrial septal defect and in patients with significant aortic regurgitation.
§Occasional patients are hypertensive, especially if they have preexisting hypertension.
‖Febrile tamponade may be misdiagnosed as septic shock.
¶Right ventricular collapse can be absent in elevated right ventricular pressure and right ventricular hypertrophy or in right ventricular infarction.
**If after drainage of the pericardial effusion, the intrapericardial pressure does not fall below atrial pressure, effusive-constrictive disease should be considered.

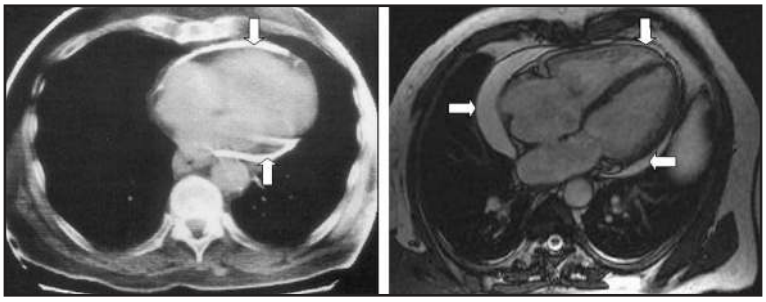

Fig. 75.4 Computed tomography findings in constrictive pericarditis *(left). White vertical arrows* are depicting thickened pericardium and pericardial calcification. The magnetic resonance imaging results of a patient with effusive-constrictive pericarditis are shown in the *right image. Horizontal arrows* show a loculated pericardial effusion, and the *vertical arrow* shows thickened pericardium.

radiographs as an oval, homogeneous radiodense lesion, usually at the right cardiophrenic angle. However, patients can also present with chest discomfort, dyspnea, cough, or palpitations, owing to compression of the heart. Echocardiography is useful, but additional imaging by CT (density readings) or MRI is often needed.[26] Treatment of congenital and inflammatory cysts involves percutaneous aspiration and ethanol sclerosis.[27] If this is not feasible, video-assisted thoracotomy or surgical resection may be necessary. Echinococcal cysts usually originate from ruptured hydatid cysts in the liver and lungs. Their surgical excision is not recommended; percutaneous aspiration and instillation of ethanol or silver nitrate after pretreatment with albendazole (800 mg/day for 4 weeks) is recommended instead.[27]

SPECIFIC FORMS OF PERICARDITIS

Viral Pericarditis

Viral pericarditis is the most common infection of the pericardium. Inflammatory abnormalities are the result of direct viral attack, the immune response (antiviral or anticardiac), or both. Early viral replication in pericardial and epimyocardial tissue elicits cellular and humoral immune responses against the virus and/or cardiac tissue. Deposits of immunoglobulin (Ig) M, IgG, and occasionally IgA can be found in the pericardium and myocardium for years. Various viruses can cause pericarditis, including enteroviruses, echoviruses, adenoviruses, cytomegaloviruses, Epstein-Barr virus, herpes simplex, herpes human virus 6 (HHV6), influenza viruses, parvovirus B19 (PVB19), hepatitis C, and human immunodeficiency virus (HIV). In the past few years, PVB19 and HHV6 have been increasing and enteroviruses, echoviruses, and adenoviruses have been decreasing as causes; these trends have also been observed in myocarditis. Attacks of enteroviral pericarditis follow the seasonal epidemics of coxsackievirus A and B and echovirus infections. Cytomegalovirus (CMV) pericarditis has an increased incidence in immunocompromised and HIV-infected hosts. Infectious mononucleosis may also present as pericarditis.

Diagnosing viral pericarditis is not possible without evaluating pericardial effusion and/or pericardial/epicardial tissue, preferably by polymerase chain reaction (PCR) or in situ hybridization. A fourfold rise in serum antibody levels is suggestive, but not diagnostic, of viral pericarditis.

Treatment of viral pericarditis is directed toward resolving symptoms (see "Acute Pericarditis"), preventing complications, and eradicating the virus. In patients with chronic or recurrent symptomatic pericardial effusion and confirmed viral infection, the following specific treatments are under investigation[28]:

1. CMV pericarditis: hyperimmune globulin once per day 4 mL/kg on days 0, 4, and 8 and 2 mL/kg on days 12 and 16
2. Coxsackievirus B pericarditis: interferon alfa or interferon beta 2.5×10^6 IU/m^2 subcutaneously three times per week
3. Adenovirus, PVB19, and HHV6 perimyocarditis: immunoglobulin treatment with 20 g or more intravenously on days 1 and 3 for 6 to 8 hours, which may be repeated and combined with ganciclovir to become effective for virus elimination

Pericardial manifestations of HIV infection can result from infective, noninfective, and neoplastic (Kaposi sarcoma and/or lymphoma) diseases. Infective (myo)pericarditis results from local HIV infection and/or from other viral, bacterial (e.g., *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Mycobacterium avium*, *M. tuberculosis*), and fungal coinfections (*Cryptococcus neoformans*). In progressive disease, the incidence of echocardiographically detected pericardial effusion may be up to 40%. Cardiac tamponade is rare. During treatment with retroviral compounds, lipodystrophy can develop (best demonstrated by MRI), with intense paracardial fat deposition leading to heart failure. Treatment is generally symptomatic, whereas in large effusions and cardiac tamponade, pericardiocentesis is necessary. The use of corticosteroid therapy is contraindicated except in patients with secondary tuberculous pericarditis, as an adjunct to tuberculostatic treatment.[29]

Bacterial Pericarditis

Purulent pericarditis in adults is rare but always fatal if not treated.[30,31] The mortality rate in treated patients is 40%, mostly because of cardiac tamponade, toxicity, and constriction. It is usually a complication of an infection originating elsewhere in the body, arising by contiguous spread or hematogenous dissemination.[32] Predisposing conditions are pericardial effusion, immunosuppression, chronic diseases (e.g., alcohol abuse, rheumatoid arthritis), cardiac surgery, and chest trauma. The disease appears as an acute, fulminant infectious illness of short duration. Percutaneous pericardiocentesis must be promptly performed, and the obtained pericardial fluid should undergo Gram staining, acid-fast staining, and fungal staining, followed by cultures of the pericardial and body fluids. Rinsing of the pericardial cavity, combined with effective systemic antibiotic therapy, is mandatory (antistaphylococcal antibiotic plus aminoglycoside, followed by tailored antibiotic therapy according to the pericardial fluid and blood culture results).[30] Intrapericardial instillation of antibiotics (e.g., gentamicin) is useful but not sufficient. Frequent irrigation of the pericardial cavity with urokinase or streptokinase using large catheters may liquefy the purulent exudate,[31] but open surgical drainage through a subxiphoid pericardiotomy is preferable. Pericardiectomy is required in patients with dense adhesions, a loculated and thick purulent effusion, recurrence of tamponade, persistent infection, and progression to constriction.[30] Surgical mortality is up to 8%.

Tuberculous Pericarditis

In the past decade, tuberculous pericarditis in developed countries has been primarily seen in immunocompromised patients, such as those with acquired immunodeficiency syndrome (AIDS). The mortality rate in untreated effusive tuberculous pericarditis approaches 85%. Pericardial constriction occurs in 30%–50% of patients.

The clinical presentation is variable: acute pericarditis with or without effusion; cardiac tamponade; silent, often large, pericardial effusion with a relapsing course; toxic symptoms with persistent fever; acute constrictive pericarditis; subacute constriction; effusive-constrictive or chronic constrictive pericarditis; and pericardial calcifications. The diagnosis is made by identification of *M. tuberculosis* in the pericardial fluid or tissue and/or the presence of caseous granulomas in the pericardium. Importantly, PCR can identify the DNA of *M. tuberculosis* rapidly from only 1 μL of pericardial fluid. Increased adenosine deaminase activity and interferon gamma concentration in pericardial effusion are also diagnostic, with a high sensitivity and specificity. Both pericardioscopy and pericardial biopsy have also improved the diagnostic accuracy for tuberculous pericarditis (Fig. 75.5). Pericardial biopsy enables rapid diagnosis with better sensitivity than pericardiocentesis (100% vs. 33%).

Pericarditis in a patient with proven extracardiac tuberculosis is strongly suggestive of a tuberculous etiology (several sputum cultures should be taken). The tuberculin skin test may be falsely negative in 25%–33% of tests and falsely positive in 30%–40% of patients. The more accurate enzyme-linked ImmunoSpot test detects T cells specific for *M. tuberculosis* antigen.[33] Perimyocardial tuberculous involvement is also associated with high serum titers of antimyolemmal and antimyosin antibodies. The diagnostic yield of pericardiocentesis in tuberculous pericarditis ranges from 30% to 76% according to methods used for analyzing pericardial effusions. Pericardial fluid demonstrates high specific gravity, high protein levels, and a high white blood cell count (from 0.7 to 54×10^9/L).

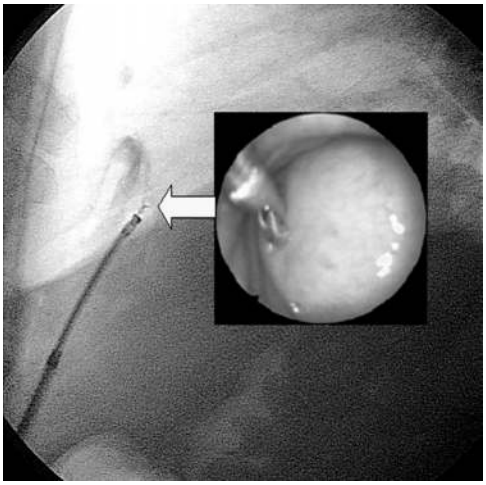

Fig. 75.5 Flexible percutaneous pericardioscopy and epicardial biopsy *(arrow).*

Various antituberculous drug combinations of different durations (6, 9, or 12 months) have been used.[34,35] Prevention of constriction in chronic pericardial effusion of undetermined etiology by "ex iuvantibus" antitubercular treatment was not successful. The use of corticosteroids remains controversial.[34,35] A meta-analysis of patients with effusive and constrictive tuberculous pericarditis[34,35] suggested that tuberculostatic treatment combined with corticosteroids might be associated with fewer deaths and less frequent need for pericardiocentesis or pericardiectomy. If given, prednisone should be administered in relatively high doses (1–2 mg/kg/day) because rifampicin induces its liver metabolism.[4] This dose is maintained for 5–7 days and progressively reduced in 6–8 weeks. If constriction develops despite combination therapy, pericardiectomy is indicated.

Pericarditis in Renal Failure

Renal failure is a common cause of pericardial disease, producing large pericardial effusions in up to 20% of patients. Two forms have been described:

1. Uremic pericarditis: this occurs in 6%–10% of patients with advanced renal failure (acute or chronic) before dialysis has been instituted or shortly thereafter. It results from inflammation of the visceral and parietal pericardium and correlates with the degree of azotemia (blood urea nitrogen >60 mg/dL).
2. Dialysis-associated pericarditis: this occurs in up to 13% of patients on maintenance hemodialysis and occasionally with chronic peritoneal dialysis. It is the result of inadequate dialysis and/or fluid overload. Pathologic examination of the pericardium shows adhesions between the thickened pericardial membranes ("bread and butter" appearance). The clinical features may include transient pericardial rubs, fever, and pleuritic chest pain, but many patients are asymptomatic. Because of autonomic impairment in uremic patients, the heart rate may remain slow (60–80 beats/min) during tamponade, despite fever and hypotension. Anemia, caused by induced resistance to erythropoietin, may worsen the clinical picture. The ECG may not show the typical diffuse ST-segment/T-wave elevations observed with other causes of acute pericarditis, owing to a lack of myocardial inflammation.[36] If the ECG is typical of acute pericarditis, intercurrent infection must be suspected.

Most patients with uremic pericarditis respond rapidly to hemodialysis or peritoneal dialysis with resolution of chest pain and the pericardial effusion. To avoid hemopericardium, heparin-free hemodialysis should be used. Hypokalemia and hypophosphatemia should be prevented by supplementing the dialysis solution when appropriate. Intensified dialysis usually leads to resolution of the pericarditis within 1–2 weeks.[37] Peritoneal dialysis, which does not require heparinization, may be therapeutic in pericarditis resistant to hemodialysis or if heparin-free hemodialysis cannot be performed. NSAIDs and systemic corticosteroids have limited success when intensive dialysis is ineffective.[38] Cardiac tamponade and large chronic effusions resistant to dialysis must be treated with pericardiocentesis. Large, nonresolving symptomatic effusions should be treated with intrapericardial instillation of corticosteroids after pericardiocentesis or subxiphoid pericardiotomy (triamcinolone hexacetonide 50 mg every 6 hours for 2–3 days).[38] Pericardiectomy is indicated only in severely symptomatic patients refractory to other treatment owing to its potential morbidity and mortality. After renal transplantation, pericarditis has also been reported in 2.4% of patients. Uremia or infection (CMV) may be the causes.

Autoreactive Pericarditis and Pericarditis in Systemic Autoimmune Diseases

The diagnosis of autoreactive pericarditis is established using the following criteria[2]:

1. Pericardial fluid containing increased number of lymphocytes, in addition to mononuclear cells greater than 5000/mm^3 (autoreactive lymphocytic) or antibodies (e.g., antisarcolemmal) against heart muscle tissue (autoreactive antibody mediated)
2. Inflammation in epicardial/endomyocardial biopsy samples of more than 14 cells/mm^2
3. Exclusion of active viral infection both in the pericardial effusion and endomyocardial/epimyocardial biopsy samples (no virus isolation, no IgM titer against cardiotropic viruses in the pericardial effusion, and PCR negative for major cardiotropic viruses)
4. Tuberculosis, *Borrelia burgdorferi, Chlamydia pneumoniae,* and other bacterial infections excluded by PCR and/or cultures
5. Neoplastic infiltration absent in the pericardial effusion and biopsy samples
6. Exclusion of systemic metabolic disorders and uremia

For autoreactive pericarditis, intrapericardial treatment with triamcinolone is effective, with rare side effects.

Pericarditis occurs in many systemic autoimmune diseases: rheumatoid arthritis, systemic lupus erythematosus, progressive systemic sclerosis, polymyositis/dermatomyositis, mixed connective tissue disease, seronegative spondyloarthropathies, systemic and hypersensitivity vasculitides, Behçet syndrome, granulomatosis with polyangiitis, and sarcoidosis.[4] Intensified treatment of the underlying disease and symptomatic management are indicated.

The Postcardiac Injury Syndrome: Postpericardiotomy Syndrome

Postcardiac injury syndrome develops within days to months after cardiac injury, pericardial injury, or both.[4,39,40] It resembles postmyocardial infarction syndrome, with both conditions appearing to be variants of a common immunopathologic process. Pericardial effusion also occurs after orthotopic heart transplantation (21% of patients). It is more frequent in patients receiving aminocaproic acid during the operation.[41] Cardiac tamponade after open heart surgery is more common after valve surgery than after coronary artery bypass grafting and may be related to the preoperative use of anticoagulants.[42]

Warfarin administration in patients with early postoperative pericardial effusion imposes the greatest risk, particularly in those who did not undergo pericardiocentesis and drainage of the effusion.[43] Symptomatic treatment is generally the same as in acute pericarditis (NSAIDs

or colchicine for several weeks or months), but this has been questioned recently.[44] In patients undergoing cardiac surgery, perioperative use of colchicine compared with placebo reduced the incidence of postpericardiotomy syndrome but with an increased rate of gastrointestinal adverse effects.[45] Long-term (3–6 months) oral corticosteroids, or preferably pericardiocentesis and intrapericardial instillation of triamcinolone (300 mg/m^2), are therapeutic options in refractory forms. Redo surgery is rarely needed.

Postinfarction Pericarditis

Two forms of postinfarction pericarditis can be distinguished: an "early" form (pericarditis epistenocardiaca) and a "delayed" form (Dressler syndrome). Epistenocardiac pericarditis, caused by direct exudation, occurs in 5%–20% of transmural myocardial infarctions but is rarely discovered clinically. Dressler syndrome occurs from 1 week to several months after myocardial infarction and has symptoms and manifestations similar to those of postcardiac injury syndrome. It does not require a transmural infarction, and it can also appear as an extension of epistenocardiaca pericarditis. Its incidence is 0.5%–5% and is lower still in patients treated with thrombolytics (<0.5%) but more frequent in cases of pericardial bleeding after antithrombotic treatment. Of note, ECG changes are often overshadowed by myocardial infarction changes. Stage I ECG changes are uncommon and suggest "early" postmyocardial infarction syndrome, whereas failure to evolve or "resurrection" of previously inverted T waves strongly suggests myocardial infarction pericarditis. Postinfarction pericardial effusion greater than 10 mm is most frequently associated with hemopericardium, and two-thirds of these patients may develop tamponade/free wall rupture.[46] Urgent surgical treatment is lifesaving. If immediate surgery is not available or contraindicated, pericardiocentesis and intrapericardial fibrin glue instillation could be an alternative in subacute tamponade.[46,47] Ibuprofen, which increases coronary flow, is the agent of choice. Aspirin, up to 650 mg every 4 hours for 2–5 days, has also been successfully applied. Corticosteroids can be used for refractory symptoms but may delay healing after the infarction.[4]

Traumatic Pericardial Effusion and Hemopericardium in Aortic Dissection

Direct pericardial injury can be induced by accidents or iatrogenic wounds. Iatrogenic tamponade occurs most frequently in percutaneous mitral valvuloplasty, during or after transseptal puncture, particularly if no biplane catheterization laboratory is available and a small left atrium is present. Whereas puncture of the interatrial septum is asymptomatic, passage through the free wall induces immediate chest pain. If high-pressure–containing structures are punctured, rapid deterioration occurs. However, if only the atrial wall is perforated, tamponade may be delayed for 4–6 hours. Rescue pericardiocentesis is successful in 95%–100% of cases, with less than 1% mortality.

Transection of the coronary artery and acute or subacute cardiac tamponade occur very rarely during percutaneous coronary interventions.[48] A breakthrough in the treatment of coronary perforation has been the development of membrane-covered graft stents.

During right ventricular endomyocardial biopsy, the catheter may pass through the myocardium, particularly when the bioptome has not been opened before reaching the endocardial border or has been directed toward the right ventricular free wall instead of toward the septum. Frank cardiac perforations are accompanied by sudden bradycardia and hypotension. Perforation rates of 0.3%–5% have been reported, leading to tamponade and circulatory collapse in less than half of cases.[49] The incidence of pericardial hemorrhage with left ventricular endomyocardial biopsy is lower (0.1%–3.3%). Severe complications, leading to procedure-related mortality, were reported in only 0.05% of more than 6000 cases in a worldwide survey and in none of the 2537 patients at our center.[49]

Pacemaker leads penetrating the right ventricle or epicardial electrodes may cause pericarditis with tamponade, adhesions, or constriction.[50,51] A right bundle branch block instead of the usual left bundle branch block is a clue that this has occurred.

Blunt chest trauma is a major risk of motor vehicle accidents. The deceleration force can lead to myocardial contusion with intrapericardial hemorrhage, cardiac rupture, pericardial rupture, or herniation. Transesophageal echocardiography or immediate CT should be performed. Pericardial laceration and partial extrusion of the heart into the mediastinum and pleural space may also occur after injury.

In dissection of the ascending aorta, pericardial effusion can be found in 17%–45% of patients and 48% of autopsy cases. In a clinical series of aortic dissection, pericardial tamponade was found by CT, MRI, or echocardiography in 17%–33% of patients with type I dissection, 18%–45% with type II dissection, and 6% with type III dissection. Pericardiocentesis is contraindicated, owing to the risk of intensified bleeding and extension of the dissection.[52] Surgery should be performed immediately.

Neoplastic Pericarditis

Primary tumors of the pericardium are 40 times less common than metastatic ones.[4] Mesothelioma, the most common primary tumor, is almost always incurable. The most common secondary malignant tumors are lung cancer, breast cancer, malignant melanoma, lymphoma, and leukemia. Effusions may be small or large with imminent tamponade (frequent recurrences) or constriction. Tamponade may even be the initial sign of malignant disease. With small effusions, most patients are asymptomatic. The onset of dyspnea, cough, chest pain, tachycardia, and jugular venous distention is observed when the volume of fluid exceeds 500 mL. Pulsus paradoxus, hypotension, cardiogenic shock, and paradoxical movement of the jugular venous pulse are important signs of cardiac tamponade. The diagnosis is based on confirmation by cytology or biopsy of malignant infiltration within the pericardium. Of note, in almost two-thirds of patients with documented malignancy, pericardial effusion is caused by nonmalignant diseases (e.g., radiation pericarditis, opportunistic infections). The chest radiograph, CT, and MRI may reveal mediastinal widening, a hilar mass, or pleural effusion.[4] The analysis of pericardial fluid and pericardial or epicardial biopsy is essential for the confirmation of malignant pericardial disease.

Cardiac tamponade is an absolute indication for pericardiocentesis. In suspected neoplastic pericardial effusion without tamponade, systemic antineoplastic treatment as baseline therapy can prevent recurrences in up to 67% of cases. However, pericardial drainage is recommended in all patients with large effusions because of the high recurrence rate (40%–70%).[46–55] Prevention of recurrences may be achieved by intrapericardial instillation of sclerosing agents, cytotoxic agents, or immunomodulators. Intrapericardial treatment tailored to the type of the tumor indicates that administration of cisplatin is effective in secondary lung cancer, and intrapericardial instillation of thiotepa appears to be highly effective in breast cancer pericardial metastases.[56–58] No patient in these studies showed signs of constrictive pericarditis. Tetracyclines as sclerosing agents also control malignant pericardial effusions in around 85% of cases, but side effects and complications are quite frequent: fever (19%), chest pain (20%), and atrial arrhythmias (10%).[55] Although intrapericardial administration of radionuclides has yielded very good results, it is not widely accepted because of the logistic problems connected with radioactivity. Radiation therapy is very effective (93%) in controlling malignant pericardial effusions in patients with radiosensitive tumors, such as lymphoma and leukemia.

However, radiotherapy of the heart itself can cause myocarditis and pericarditis.

RARE FORMS OF PERICARDIAL DISEASE

Fungal pericarditis occurs mainly in immunocompromised patients or in the course of endemic, acquired fungal infections. It is caused by endemic *(Histoplasma, Coccidioides)* or opportunistic fungi *(Candida, Aspergillus, Blastomyces)* and semifungi *(Nocardia, Actinomyces)*. Diagnosis is obtained by staining and culturing pericardial fluid or tissue. Antifungal antibodies in serum are also helpful in establishing the diagnosis. Treatment with fluconazole, ketoconazole, itraconazole, amphotericin B, liposomal amphotericin B, or amphotericin B lipid complex is indicated. NSAIDs can support the treatment with antifungal drugs. Patients with histoplasmosis pericarditis do not need antifungal therapy but respond to NSAIDs given for 2–12 weeks. Sulfonamides are the drugs of choice for nocardiosis. A combination of three antibiotics, including penicillin, should be given for actinomycosis. Pericardiocentesis or surgical treatment is indicated for hemodynamic impairment. Pericardiectomy is indicated in fungal constrictive pericarditis.

Radiation pericarditis may begin during exposure (very rare) or months to years later, with a latency of up to 15–20 years. Its occurrence is influenced by the applied source, dose, fractionation, duration, radiation-exposed volume, form of mantle field therapy, and age of the patient. The effusion may be serous or hemorrhagic, later on with fibrinous adhesions or constriction; it is typically without tissue calcification. The symptoms may be masked by the underlying disease or chemotherapy. Imaging should start with echocardiography, followed by cardiac CT or MRI, if necessary. Pericarditis without tamponade may be treated conservatively, but effusions respond favorably to intrapericardial triamcinolone instillation. Pericardiocentesis and fluid analysis can rule out neoplastic progression to the pericardium.[59] Pericardial constriction occurs in up to 20% of patients, requiring pericardiectomy. Operative mortality is high (21%) and postoperative 5-year survival is poor (1%), mostly because of myocardial fibrosis.

Chylopericardium refers to a communication between the pericardium and thoracic duct. It may be the result of trauma, congenital anomalies, complications of open heart surgery, mediastinal lymphangiomas, lymphangiomatous hamartomas, lymphangiectasis, and obstruction or anomalies of the thoracic duct. Infection, tamponade, or constriction may aggravate the prognosis. The pericardial fluid is sterile, odorless, and opalescent, with a milky white appearance and the microscopic finding of fat droplets. The chylous nature of the fluid is confirmed by its alkaline reaction, specific gravity between 1010 and 1021, Sudan III stain for fat, and high concentrations of triglycerides (5–50 g/L) and protein (22–60 g/L). Enhanced CT, alone or combined with lymphography, can identify not only the location of the thoracic duct but also its lymphatic connection to the pericardium.

Treatment depends on the etiology and amount of chylous accumulation. Chylopericardium after thoracic or cardiac operations is preferably treated by pericardiocentesis and diet (medium-chain triglycerides).[60] If further production of chylous effusion continues, surgical treatment is mandatory. When conservative treatment and pericardiocentesis fail, creation of a pericardioperitoneal window is a reasonable option.[61] Alternatively, when the course of the thoracic duct is precisely identified, its ligation and resection just above the diaphragm is the most effective treatment.

Drug- and toxin-related pericarditis, tamponade, adhesions, fibrosis, or constriction may be induced by several drugs.[4] Mechanisms include drug-induced lupus reactions, idiosyncrasy, "serum sickness," foreign substance reactions, and immunopathy. Management is based on discontinuation of the causative agent and symptomatic treatment.

Pericardial effusion in hypothyroidism occurs in 5%–30% of patients.[4] Fluid accumulates slowly, and tamponade occurs rarely. In some cases, cholesterol pericarditis may be observed. The diagnosis is based on serum levels of thyroxine and thyroid-stimulating hormone. Bradycardia, low QRS voltage and T-wave inversion or flattening on the ECG, cardiomegaly on a chest radiograph, and pericardial effusion on echocardiography, in addition to a history of radiation-induced thyroid dysfunction, myopathy, ascites, pleural effusion, and uveal edema may be observed.[62] Therapy with thyroid hormone decreases the pericardial effusion.

Pericardial effusion and constriction in pregnancy may manifest as a minimal to moderate, clinically silent hydropericardium by the third trimester. Cardiac compression is rare. ECG changes of acute pericar-

KEY POINTS

- The diagnosis of acute pericarditis is based on clinical presentation (chest pain, pericardial friction rub) and typical four-stage ECG changes. For etiologic diagnosis, pericardiocentesis, pericardioscopy, and pericardial/epicardial biopsy may be necessary.
- Echocardiography is essential in all patients with pericarditis to detect pericardial effusion and determine its physiologic significance and to check for signs of constriction, concomitant heart disease, or paracardial pathology.
- A large proportion of patients usually classified as having "idiopathic" pericarditis actually have viral and autoreactive pericarditis. The diagnosis of viral pericarditis is not possible without the evaluation of pericardial effusion and/or pericardial/epicardial tissue, preferably by PCR or in situ hybridization.
- PCR identification of *M. tuberculosis,* high adenosine deaminase activity, and interferon gamma concentration in pericardial effusion are diagnostic with a high sensitivity and specificity for tuberculous pericarditis.
- Pericardiocentesis is indicated for cardiac tamponade; for a high suspicion of purulent, tuberculous, or neoplastic pericarditis; or in patients with a very large effusion without signs of tamponade (>20 mm in echocardiography in diastole). Electrical alternans and pulsus paradoxus are clinically important signs of the advanced stages of cardiac tamponade and indicate the need for prompt pericardial drainage.
- Aortic dissection is a major contraindication to pericardiocentesis. Relative contraindications include uncorrected coagulopathy; anticoagulant therapy; thrombocytopenia less than 50,000/mm^3; and small, posterior, and loculated effusions.
- In cardiac wounds, postinfarction myocardial rupture, or dissecting aortic hematoma, emergency cardiac surgery is lifesaving. Loculated effusions may require open surgery or thoracoscopic drainage.
- Postinfarction pericardial effusions larger than 10 mm in diastole are frequently associated with cardiac rupture. Urgent surgical treatment is indicated.
- Intrapericardial instillation of antineoplastic (e.g., cisplatin, thiotepa) and/or sclerosing agents (e.g., gentamicin) can prevent recurrences of neoplastic pericardial effusions. Intrapericardial instillation of triamcinolone is highly effective in preventing recurrences in patients with autoreactive pericardial effusion and avoids the adverse effects of systemic corticosteroid therapy.
- Pericardiectomy is the only treatment for permanent constrictive pericarditis. However, surgery should not be performed too early to avoid operating on patients with transient constriction. Even more important is not to perform surgery too late or in patients with myocardial fibrosis and/or atrophy. If indications for surgery are established early enough, long-term survival after pericardiectomy corresponds to that of the general population.

ditis in pregnancy should be distinguished from the slight ST-segment depression and T-wave changes seen in normal pregnancy. Occult constriction becomes manifest in pregnancy because of the increased blood volume. Most pericardial disorders are managed as in nonpregnant women.[63,64] However, caution is necessary because high-dose aspirin may prematurely close the ductus arteriosus, and colchicine is contraindicated in pregnancy. Pericardiotomy and pericardiectomy can be safely performed if necessary and do not impose a risk for subsequent pregnancies.[64,65]

Fetal pericardial fluid can be detected by echocardiography after 20 weeks' gestation and is normally 2 mm or less in depth. A greater amount of fluid should raise questions about the possibility of Rh disease (hydrops fetalis), neoplasia, hypoalbuminemia, immunopathy, or maternally transmitted mycoplasmal or other infections.

Emergency Heart Valve Disorders

Jason P. Linefsky and Catherine M. Otto

Key concepts in the management of a critically ill patient with valvular heart disease are the use of echocardiography to provide an accurate diagnosis of disease severity and the appropriate use of invasive hemodynamic monitoring to optimize loading conditions. Physical examination is not reliable for diagnosing the presence or severity of valvular heart disease, particularly in patients with acute hemodynamic compensation. Handheld echocardiography may provide clues to the presence of valve disease but does not replace the need for a complete diagnostic study when this diagnosis is suspected. With acute valve regurgitation or prosthetic valve thrombosis, urgent surgical intervention may be necessary. In critically ill patients who are poor surgical candidates, rapid relief of valve obstruction can be lifesaving, including transcatheter balloon valvotomy for rheumatic mitral stenosis or transcatheter aortic valve implantation for calcific aortic stenosis (Fig. 76.1).

MITRAL REGURGITATION

Etiology

Mitral regurgitation may be caused by disease or the distortion of any component of the mitral valve apparatus—the mitral annulus, leaflets, chordae, and papillary muscles—and by alterations in left ventricular (LV) geometry or systolic function (Fig. 76.2).[1] Primary causes of acute mitral regurgitation include endocarditis and myxomatous valve disease (mitral valve prolapse) with spontaneous chordal rupture [2] Bacterial endocarditis results in acute mitral regurgitation because of the destruction of valve tissue, often with leaflet perforation.[3]

Acute secondary mitral regurgitation may be the result of an acute cardiomyopathy (e.g., takotsubo cardiomyopathy) or coronary disease with acute myocardial infarction or papillary muscle rupture Moderate to severe mitral regurgitation caused by papillary muscle involvement or regional myocardial dysfunction complicates 12% of acute myocardial infarctions and is associated with an increased risk of heart failure or death.[4,5]

Iatrogenic acute mitral regurgitation is a rare complication of balloon mitral valvotomy.[6] Acute mitral regurgitation also may complicate the use of transaortic axial flow ventricular assist devices if the catheter interferes with normal mitral valve closure or disrupts the valve apparatus when the device is removed.[7]

The management of acute mitral regurgitation differs depending on the cause, making the identification of the correct etiology essential during evaluation.

Clinical Presentation

Acute mitral regurgitation presents with acute pulmonary edema and is a surgical emergency (Figs. 76.3 and 76.4).[8] Mitral chordal rupture results in the acute presentation of heart failure, often in patients unaware of the diagnosis of mitral valve prolapse. Patients with mitral valve perforation caused by endocarditis present with pulmonary edema superimposed on the signs and symptoms of endocarditis. Papillary muscle rupture or dysfunction after myocardial infarction (MI) usually presents several days after acute MI; in some cases, the initial presentation is of acute pulmonary edema, with the MI being clinically silent.

Chronic mitral regurgitation is usually well tolerated even when there is a superimposed hemodynamic load such as systemic infection, pregnancy, or trauma. However, mitral regurgitant severity may acutely worsen by at least two mechanisms. An increase in afterload, for example, with a hypertensive crisis, may increase regurgitant severity caused by an increased driving pressure from the left ventricle to the left atrium. An alteration in the LV geometry, for example, with ventricular dilation caused by decompensated heart failure may change the orientation of the papillary muscles such that leaflet closure is impaired, resulting in a larger regurgitant orifice area.[9] In this situation, a vicious cycle may ensue where LV dilation worsens mitral regurgitant severity, which increases LV dilation.

Diagnosis

A high level of clinical suspicion is needed to make a diagnosis of acute mitral regurgitation (Table 76.1).[8] Acute pulmonary edema often obscures the signs and symptoms of the underlying disease process. The classical finding is a holosystolic murmur at the apex, radiating to the axilla. Although there is some correlation between murmur loudness and regurgitant severity with chronic regurgitation, the murmur may be soft with acute severe mitral regurgitation. In patients with severe mitral regurgitation after MI, a murmur cannot be appreciated in up to 50% of patients.

Thus in patients presenting with acute pulmonary edema or cardiogenic shock, prompt echocardiography is essential. Transthoracic images are often diagnostic, allowing the identification of the etiology of valve dysfunction, quantitation of regurgitant severity, estimation of pulmonary pressures, and measurement of ventricular size and systolic function. If transthoracic images are nondiagnostic, transesophageal echocardiography (TEE) can be performed at the bedside in the intensive care unit (ICU). TEE provides excellent images of valve anatomy and the Doppler evaluation of valve function.

Other diagnostic tests are based on the clinical presentation. Multiple blood cultures should be obtained in febrile patients with systemic or pulmonary edema to exclude the possibility of endocarditis. In patients with an abnormal electrocardiogram (ECG), chest pain, or a history of coronary artery disease, coronary angiography may be needed.

In patients with acute pulmonary edema or cardiogenic shock after MI, the differential diagnosis includes acute mitral regurgitation, a ventricular septal defect, or a contained rupture of the ventricular free

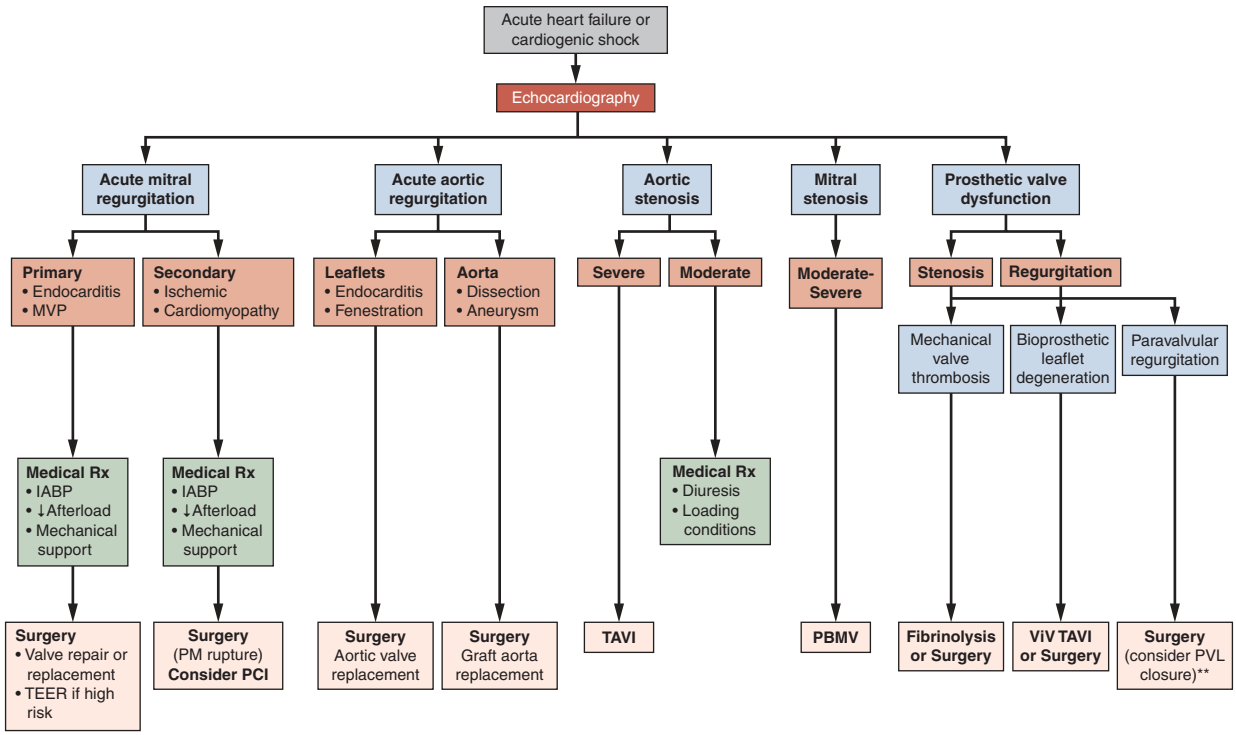

Fig. 76.1 Flowchart for the Diagnosis and Management of Acute Valvular Heart Disease. Echocardiography is recommended in all acutely ill patients with heart failure or cardiogenic shock because physical examination is not reliable to exclude significant valvular heart disease. Management depends on both valve hemodynamics (stenosis or regurgitation) and the etiology of valve dysfunction. *IABP,* intraaortic balloon pump; *MVP,* mitral valve prolapse; *PBMV,* percutaneous mitral balloon valvotomy; *PCI,* percutaneous coronary intervention; *PM,* papillary muscle; *PVL,* paravalvular leak; *TAVI,* transcatheter aortic valve implantation; *TEER,* transcatheter edge-to-edge repair; *ViV,* valve in valve.

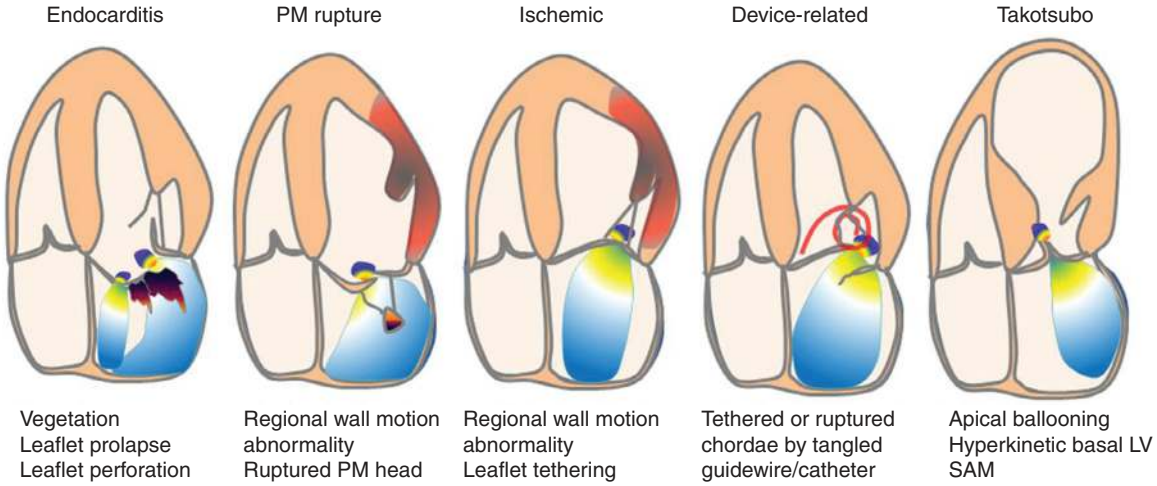

Fig. 76.2 Schematic Examples of the Cause of Acute Mitral Regurgitation. *LV,* Left ventricle; *PM,* papillary muscle; *SAM,* systolic anterior motion. (From Watanabe N. Acute mitral regurgitation. *Heart.* 2019;105:671–677.)

wall. All these possibilities can be diagnosed by echocardiography in an experienced center.

When imaging is nondiagnostic or discrepant with clinical findings, invasive hemodynamic monitoring with a Swan-Ganz catheter for the measurement of pulmonary pressure and cardiac output may be considered in patients with suspected acute mitral regurgitation. At the time of placement, oxygen saturations in the right atrium, right ventricle, and pulmonary artery should be measured. A ventricular septal defect results in a "step-up" in oxygen saturation between the right atrium and ventricle secondary to oxygenated blood from the left ventricle entering the right ventricle. The pulmonary artery balloon-occluded (wedge) pressure tracing should be examined for the presence of a giant "v-wave," which supports the diagnosis of acute mitral regurgitation but is not always present.

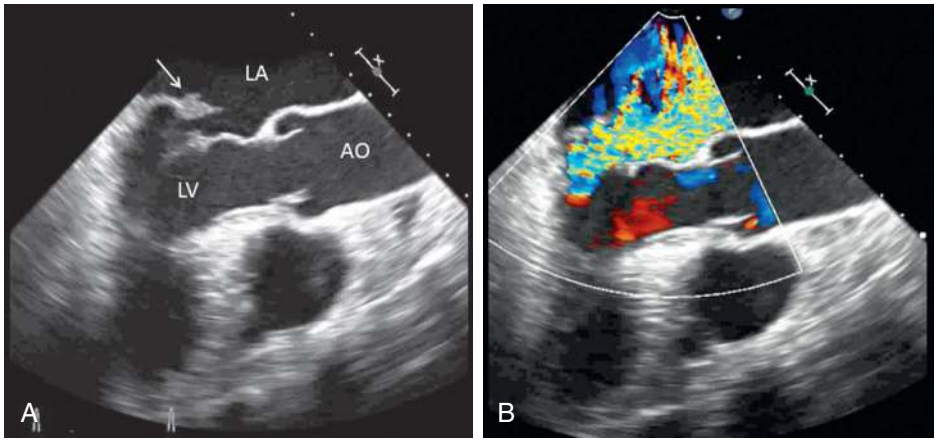

Fig. 76.3 Two-dimensional transesophageal echocardiogram **(A)** in a 72-year-old male with known mitral valve prolapse; ruptured chordae resulted in flail of the mitral posterior leaflet (*arrow*) and acute worsening of symptoms. Color Doppler **(B)** shows severe eccentric mitral regurgitation with a mosaic pattern through the noncoapting mitral valve. *AO,* Aorta; *LA,* left atrium; *LV,* left ventricle.

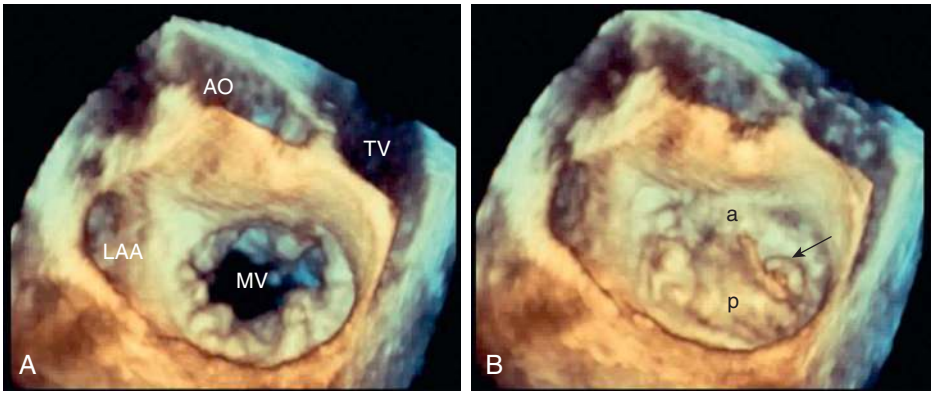

Fig. 76.4 Three-dimensional (3D) echocardiography of the same patient as in Fig. 76.3 in both diastole **(A)** and systole **(B)**. 3D imaging provided a "surgeon's view," allowing instant viewing of the mitral valve en face to assist operative planning for potential repair. In systole, the posterior leaflet (*p*) can be seen to prolapse above the anterior (*a*) leaflet, and ruptured chordae with flail segments can be seen *(arrow)*. *AO,* Aorta; *LAA,* left atrial appendage; *MV,* mitral valve; *TV,* tricuspid valve.

TABLE 76.1 Diagnostic Approach to Acute Valve Dysfunction

Physical examination	Unreliable Consider valve dysfunction in all patients with pulmonary edema
Echocardiography (transthoracic)	Accurate diagnosis of etiology of disease Quantitation of severity of stenosis or regurgitation Measurement of ventricular ejection fraction Estimation of pulmonary pressures
Transesophageal echocardiography	Sensitive for detection of valvular vegetations Detection of paravalvular abscess Essential for prosthetic mitral valve dysfunction Useful for prosthetic aortic valve dysfunction
Right heart catheterization	Not reliable for the diagnosis of valve disease May be helpful for optimizing loading conditions
Chest computed tomography	Sensitive and specific for diagnosis of aortic dissection
Angiography	Used when coronary angiography is needed

BOX 76.1 Therapeutic Approach to Acute Valve Dysfunction

1. Accurate diagnosis with echocardiography; differentiates acute valve dysfunction from acute decompensation with chronic valve disease.
2. Treat the underlying disease process associated with decompensation (endocarditis, acute myocardial infarction, anemia, etc.).
3. Optimize loading conditions using diuretics, vasodilators, and other agents with invasive hemodynamic monitoring.
4. Consult the cardiac surgery team as soon as the diagnosis is made.
5. Intraaortic balloon pump for acute mitral regurgitation.
6. Consider surgical or percutaneous intervention.

Management

In patients with acute heart failure associated with chronic mitral regurgitation, management is directed at treating the process leading to decompensation and optimizing loading conditions (Box 76.1). For example, in a patient with a systemic infection, treating the infection, controlling fever and tachycardia, and invasive monitoring to optimize

preload and afterload are used. Medical therapy typically includes afterload reduction with nitroprusside or other vasodilators and preload reduction with diuretics.[10] The goal is to support the patient through the period of decompensation. Typically, hemodynamics returns to the baseline-compensated state after the acute illness.

In contrast, acute severe mitral regurgitation is a medical and surgical emergency. Mortality is extremely high without the restoration of valve competence; even with prompt valve surgery, the 30-day mortality is 23%.[11] Medical stabilization should occur concurrently with consultation by a cardiac surgeon. Acutely, the placement of an intraaortic balloon pump (IABP) provides optimal afterload reduction while improving diastolic coronary blood flow. Advanced circulatory support with extracorporeal membrane oxygenation (ECMO) or a ventricular assist device also has been used successfully for patient stabilization in some cases.[12,13] However, valve replacement or repair is the definitive therapy for acute severe mitral regurgitation, with the timing and type of intervention dependent on mitral regurgitation etiology and patient factors.

Spontaneous chordal rupture can usually be treated early with mitral valve repair. Some high-risk patients may be candidates for mitral transcatheter edge-to-edge repair (TEER) with placement of a clip that attaches to both the anterior and posterior leaflet, reducing mitral regurgitation severity while creating a double-orifice valve in diastole.[14]

In patients with endocarditis, acute severe mitral regurgitation is an indication for early surgical intervention (during the initial hospitalization), without waiting for completion of antibiotic therapy. Other indications for early surgical intervention in patients with endocarditis include any valve dysfunction causing heart failure, paravalvular abscess formation, infection caused by highly resistant organisms, or persistent infection despite appropriate antibiotic therapy.[15–17] In a large prospective multicenter study, early surgery was associated with a lower mortality than medical therapy (12% vs. 21%).[18] Valve repair is preferred but may not be possible, depending on the extent of tissue destruction.

In patients with acute ischemic mitral regurgitation, treatment depends on the exact etiology of valve dysfunction.[19] In patients with acute mitral regurgitation caused by a regional wall-motion abnormality, myocardial function and mitral regurgitation may improve after percutaneous revascularization.[20] In these patients, the use of an IABP and medical therapy may be advantageous during the acute episode, with weaning of therapy as myocardial function improves.

Mitral regurgitation caused by partial or complete papillary muscle rupture requires surgical intervention. Although the risk of surgery is high, with an operative mortality rate of about 50%, the outcome is worse with medical therapy, with a mortality of 75% at 24 hours and 95% within 2 weeks after complete papillary muscle rupture. With the use of echocardiography, partial papillary muscle rupture can be recognized; prognosis in these patients depends on the extent of myocardial damage and severity of mitral regurgitation. With partial papillary muscle rupture, some surgeons prefer to stabilize the patient and delay surgery for 6–8 weeks after MI to avoid operating on the necrotic myocardial tissue. However, many patients cannot be stabilized, so acute intervention must be considered. Risk factors for adverse outcomes with surgery include older age, female gender, and poor LV systolic function.

Given the high risk of surgical intervention in many patients with acute severe mitral regurgitation, other options also should be considered (Table 76.2). Mitral TEER reduces mitral regurgitation by clipping together the two leaflets of the mitral valve, both reducing mitral regurgitation severity and creating a double-orifice valve in diastole with some degree of stenosis. TEER is currently recommended for the treatment of symptomatic severe primary mitral regurgitation when surgical risk is high or prohibitive, active infection has been excluded, and valve anatomy is amenable to this approach.[17,21] In patients with acute ischemic mitral regurgitation caused by papillary muscle rupture, prompt surgical intervention continues to be recommended,[22] although TEER might be considered in decompensated patients with a high surgical risk.[23]

AORTIC REGURGITATION

Etiology

The most common causes of acute aortic regurgitation are endocarditis, rupture of a congenital aortic leaflet fenestration, blunt trauma, and acute aortic dissection.[24,25] Endocarditis results in aortic regurgitation by the destruction of the valve leaflet tissue, with a high percentage of cases also having paravalvular abscess formation.[26,27]Aortic dissection results in acute aortic regurgitation either because of the enlargement of the aortic annulus, resulting in inadequate central closure of the leaflets, or extension of dissection into the valve region, resulting in a flail aortic valve leaflet.

Clinical Presentation

The acute backflow of blood from the aorta to the left ventricle in diastole results in an acute elevation in LV end-diastolic pressure, with consequent pulmonary edema. Because there is no time for compensatory LV dilation, forward cardiac output falls abruptly owing to the regurgitant flow across the valve in diastole, so patients with acute aortic regurgitation also may be in cardiogenic shock. Decreased coronary perfusion pressure results in diffuse subendocardial ischemia, further impairing ventricular function.

Diagnosis

The clinical diagnosis of acute aortic regurgitation differs markedly from that of chronic aortic regurgitation (Fig. 76.5).[24,25] In contrast to the high-pitched diastolic decrescendo murmur of chronic aortic regurgitation, there is a "to-and-fro" murmur across the aortic valve that many clinicians fail to recognize as an indication of aortic regurgitation. The pulse pressure is narrow because of the low forward stroke volume, and peripheral signs of aortic regurgitation are not seen. As with acute mitral regurgitation, physical examination findings are often subtle, so a high index of suspicion and prompt echocardiography are needed to make this diagnosis.

Acute aortic regurgitation should be considered in patients with signs or symptoms of endocarditis, with a personal or family history of aortic root disease, and with a presentation consistent with acute aortic

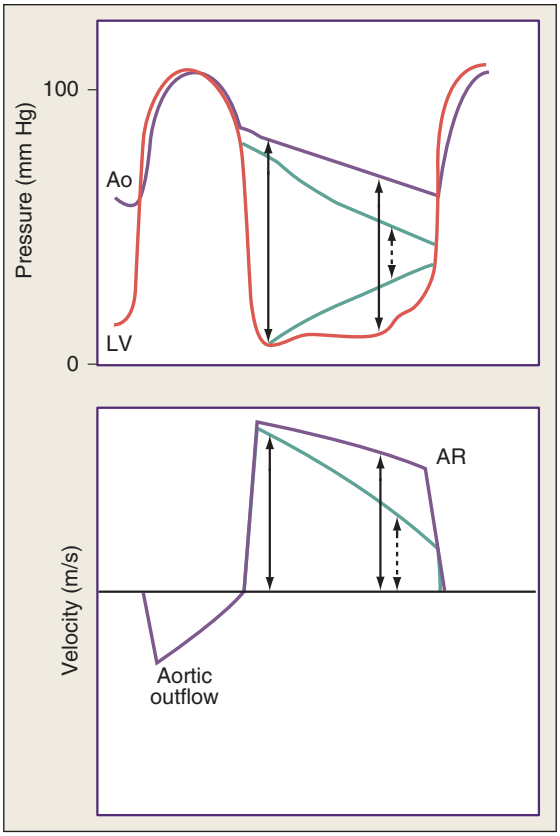

Fig. 76.5 Left ventricular (*LV*) and central aortic (*Ao*) pressures and corresponding Doppler velocity curves are shown for chronic *(purple lines)* and acute *(green lines)* aortic regurgitation. The shape of the velocity curve is related to the instantaneous pressure differences across the valve over the cardiac cycle, as stated in the Bernoulli equation. With acute aortic regurgitation (*AR*), aortic pressures fall more rapidly and ventricular diastolic pressure rises more rapidly, resulting in a steeper deceleration slope on the Doppler curve. (From Otto CM. *Textbook of Clinical Echocardiography*. 5th ed. Philadelphia: Saunders; 2013:316.)

dissection.[28] Endocarditis causing acute aortic regurgitation may be the first presentation of a congenital bicuspid aortic valve but increasingly is seen on normal trileaflet valves, often associated with drug use.[29]

Echocardiography allows the imaging of the aortic valve and root and determination of the severity of aortic regurgitation based on a combination of two-dimensional (2D) imaging and pulsed, continuous-wave, and color Doppler modalities (Figs. 76.6 and 76.7).[30] The continuous-wave Doppler curve shows a steep diastolic slope corresponding to the rapid equalization of diastolic pressure in the aorta and left ventricle. With severe acute regurgitation, there is no pressure gradient at end diastole, so cuff diastolic blood pressure is equal to LV end-diastolic pressure. Echocardiography also allows the accurate assessment of LV size and systolic function. When the differential diagnosis includes aortic dissection, transthoracic echocardiography (TTE) is inadequate to exclude this possibility. Instead, TEE or computed tomography (CT) images should be obtained.

Management

Acute aortic regurgitation is a surgical emergency.[24] Preoperative management is supportive, with ventilatory support and invasive hemodynamic monitoring. While the diagnosis is being made, therapy may include the use of diuretics, inotropic agents, and nitroprusside or other vasodilators in an attempt to stabilize hemodynamics.[24] However, an IABP is contraindicated, as inflation of the balloon in the descending thoracic aorta in diastole will increase the amount of backflow across the aortic valve.[31]

If acute aortic regurgitation is the result of aortic dissection, acute surgical intervention is needed. The surgical approach may be the replacement of the ascending aorta and valve with a combined prosthetic valve and aortic graft. When the valve leaflets are normal, some centers will preserve the native valve by reimplanting the native valve (and coronary arteries) in the prosthetic conduit (called the *David procedure*).

When acute aortic regurgitation is the result of endocarditis, surgical options include a mechanical valve, a heterograft tissue valve such as a porcine aortic valve or bovine pericardial valve, or a cryopreserved homograft aortic valve. Rarely, the patient may undergo valve repair if

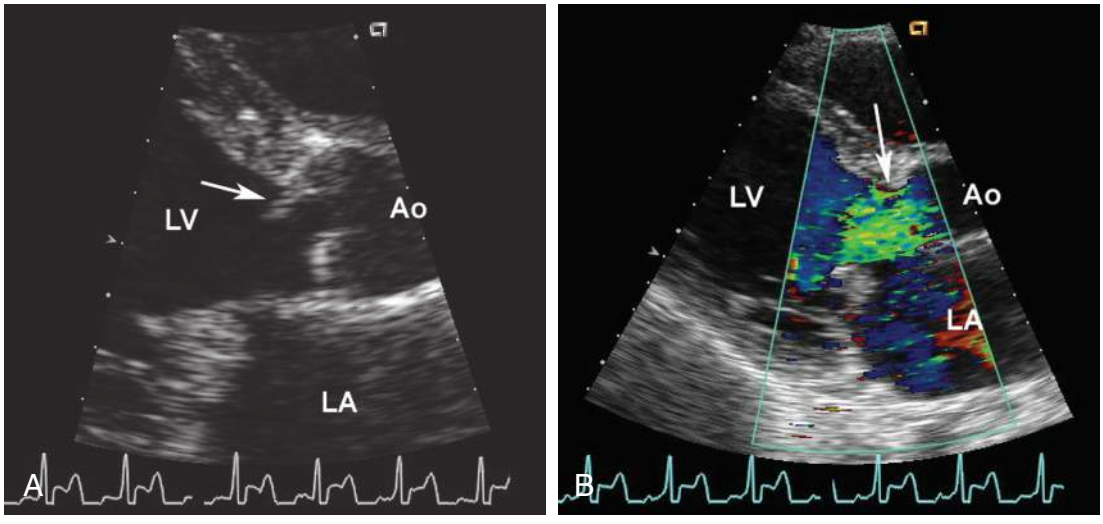

Fig. 76.6 Endocarditis Resulting in Acute Severe Aortic Regurgitation. In a long-axis view of the aortic valve **(A)**, a flail aortic valve leaflet is seen *(arrow),* with the leaflet *(arrow)* prolapsing into the left ventricular outflow tract in diastole. Color-flow Doppler imaging **(B)** in the same view shows a broad jet of diastolic flow filling the outflow tract, consistent with severe regurgitation. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle.

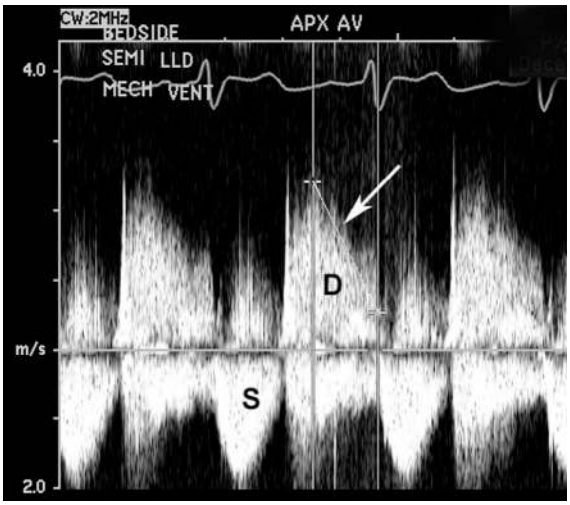

Fig. 76.7 Same patient as Fig. 76.6. Continuous-wave Doppler recording of flow across the aortic valve shows an increased antegrade velocity in systole (*S*) consistent with a high transaortic stroke volume. In diastole (*D*), a dense signal of retrograde flow is seen, with a steep deceleration slope *(arrow)* consistent with rapid equalization of pressures between the aorta and left ventricle in diastole from acute regurgitation.

there is a simple perforation with adjacent normal leaflet tissue and no evidence of active infection.

MITRAL STENOSIS

Etiology and Clinical Presentation

Mitral stenosis is almost always the result of rheumatic disease, with only rare cases of calcific mitral stenosis seen in the elderly. Rheumatic mitral stenosis is a slowly progressive disease with an insidious decline in exercise tolerance and symptom onset over many years.[32] However, in an asymptomatic patient with compensated moderate or severe mitral stenosis, acute decompensation can occur in the setting of increased systemic hemodynamic demands. Because mitral stenosis is more common in women (80% of cases) and occurs during the reproductive years, the most common emergency presentation of mitral stenosis is a pregnant woman with heart failure. Many of these patients are unaware of the underlying valve disease and are initially diagnosed during pregnancy. The clinical presentation may also be caused by or exacerbated by the onset of atrial fibrillation.

A large atrial myxoma may mimic the clinical presentation of mitral stenosis, presenting with acute hemodynamic compromise caused by obstruction of the mitral valve orifice by the tumor mass.

Diagnosis

The apical diastolic rumble and opening snap of mitral stenosis is challenging to appreciate even in a quiet room with optimal patient positioning and is frequently inaudible in the ICU setting. However, the diagnosis is easily made by TTE, with the mitral leaflet showing the characteristic findings of rheumatic disease: commissural fusion, chordal shortening and fusion, and restriction of the diastolic opening of the leaflets (Fig. 76.8).[33] The mitral valve area can be quantitated by 2D or three-dimensional planimetry or the Doppler pressure half-time method, with severe stenosis defined as a valve area of less than 1.5 cm^2. TTE also provides information on LV size and systolic function, left atrial size, pulmonary pressure, and any associated valve lesions. If evaluation for left atrial thrombus is needed, TTE has a sensitivity of only 60% compared with that of nearly 100% of the transesophageal approach.

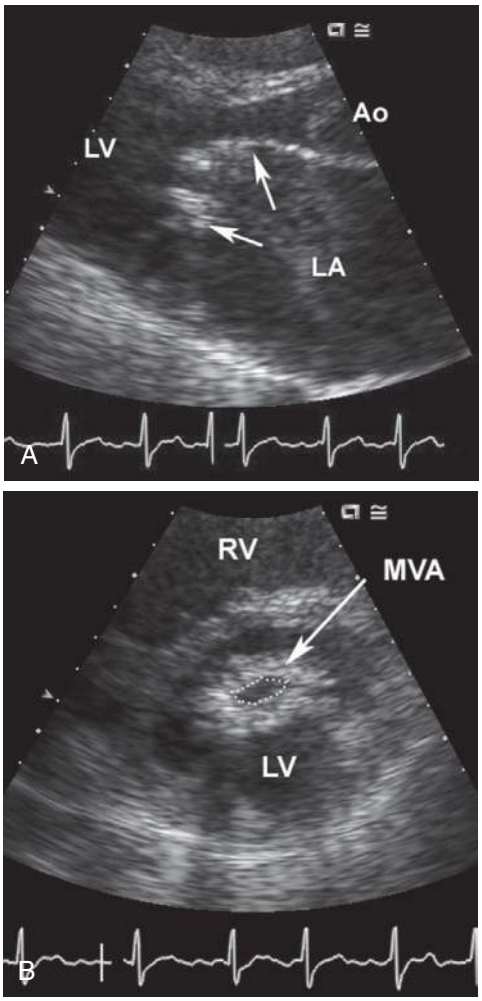

Fig. 76.8 In a patient with mitral stenosis, the long-axis view **(A)** demonstrates the classic findings of the diastolic doming of leaflets *(arrows)* caused by commissural fusion, with thickening predominantly at the leaflet tips. In the short-axis view **(B)**, the restricted mitral orifice with fusion of the commissures is visualized, providing accurate measurement of the valve area by direct planimetry. In this case, the valve area of 0.7 cm^2 indicates severe valve obstruction. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *MVA,* mitral valve area; *RV,* right ventricle.

Management

Most patients with mitral stenosis and acute decompensation can be managed conservatively with the treatment of the superimposed illness. Efforts should be directed toward decreasing overall metabolic demand and increasing oxygen delivery by controlling fever, maintaining a normal hemoglobin level, and providing supplemental oxygen. If atrial fibrillation is present, rate control is essential, preferably with conversion back to sinus rhythm. Even when sinus rhythm is present, beta-blockers may improve ventricular diastolic filling by prolonging the duration of diastole as the heart rate is decreased.[34] Invasive hemodynamic monitoring and ventilatory support may be needed when severe heart failure is present.

In patients who do not respond to conservative therapy, emergency intervention should be considered. The optimal intervention is percutaneous balloon mitral valvotomy (PBMV), which typically results in an increase in mitral valve area to more than 1.5 cm^2 (Fig. 76.9).[35] PBMV can be safely performed even during pregnancy.[36–38] Patients with a left atrial thrombus, coexisting moderate to severe mitral regurgitation, or

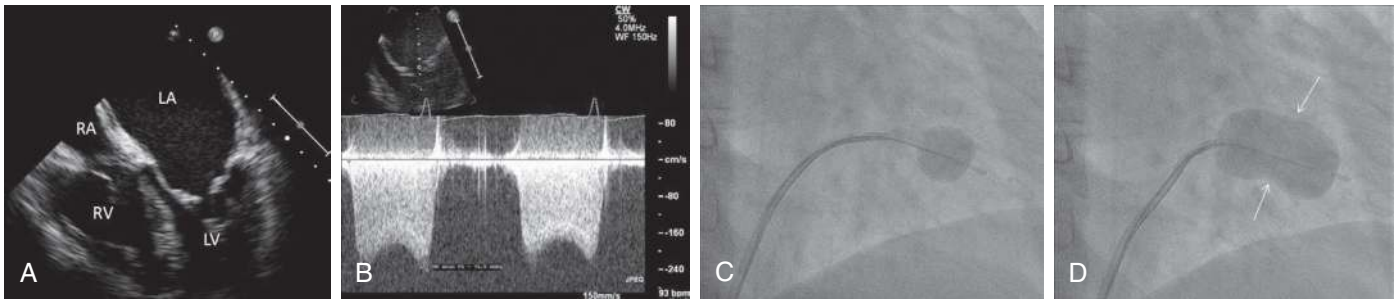

Fig. 76.9 This 48-year-old female underwent percutaneous balloon mitral valvotomy (PBMV) for severe symptomatic rheumatic mitral stenosis and acute pulmonary edema. The transesophageal echocardiogram four-chamber view demonstrates restricted diastolic mitral valve opening with hockey-stick deformation and severely enlarged left atrium **(A)**. Continuous-wave Doppler before PBMV measures a severely elevated mean gradient of 15 mm Hg **(B)**. Fluoroscopic images show the use of an Inoue balloon distally inflated across the mitral valve via a transseptal catheter **(C)**. The initial distal inflation stabilizes the position of the balloon, allowing for full inflation to split the mitral valve commissures; a waist *(white arrows)* in the balloon is seen from the resistance of the mitral valve **(D)**. Successful PBMV reduced the mean gradient to 6 mm Hg and relieved the patient's symptoms. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

heavily calcified and deformed mitral valves are not candidates for PBMV; in these patients, surgical mitral valve replacement may be needed.

AORTIC STENOSIS

Etiology and Clinical Presentation

Valvular aortic stenosis in adults most often is the result of calcification of a normal trileaflet or congenital bicuspid valve (Fig. 76.10A). Rheumatic aortic stenosis is less common and is invariably accompanied by mitral valve involvement. In younger adults, congenital aortic stenosis may be encountered; some of these patients have restenosis after prior commissurotomy in childhood.

Like mitral stenosis, aortic valve stenosis is a chronic, slowly progressive disease that presents acutely only in patients who have not been receiving regular medical care or with previously asymptomatic moderate to severe stenosis who present with acute decompensation caused by a superimposed systemic condition.[39–41] Young women with congenital aortic stenosis may present with angina or heart failure during pregnancy. In older adults, asymptomatic patients with moderate to severe valve obstruction may present with heart failure in the setting of pneumonia, anemia, or other conditions with increased metabolic demands.

Diagnosis

Classic physical examination findings for aortic stenosis include a delayed and decreased carotid upstroke, a narrow pulse pressure, a single second heart sound (S2), and a systolic ejection murmur at the aortic region that radiates to the carotids. However, although a grade 4 murmur (palpable thrill) with a single S2 and diminished carotids is specific for severe stenosis, these findings are very insensitive for the diagnosis. In particular, when a patient is decompensated, the murmur may be soft, and carotid upstrokes may be altered by coexisting vascular disease or loading conditions.[42]

Echocardiography provides reliable evaluation of aortic stenosis severity based on the maximum velocity through the narrowed orifice, mean pressure gradient, and valve area, calculated with the continuity equation (see Fig. 76.10B). Disease severity is a continuum, and velocities may be relatively low despite severe stenosis when stroke volume is reduced. In general, stenosis can be graded as severe (jet velocity >4 m/sec

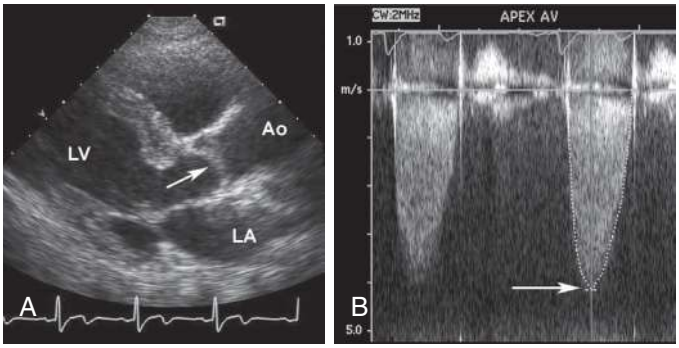

Fig. 76.10 A, In this 26-year-old pregnant woman with a loud systolic murmur, the long-axis view shows doming of the aortic valve in systole *(arrow).* Short-axis images confirmed a unicuspid aortic valve. **B,** Continuous-wave Doppler examination of the aortic valve demonstrates a high-velocity signal consistent with severe aortic stenosis. The maximum velocity of 4.2 m/sec corresponds to a maximum transaortic pressure gradient of 69 mm Hg and a mean gradient of 41 mm Hg. Valve area, calculated by the continuity equation, was 0.8 cm^2. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle.

or a valve area <1.0 cm^2 with a lower jet velocity), moderate (jet velocity, 3–4 m/sec), or mild (jet velocity <3 m/sec). Echocardiography also allows the evaluation of ventricular systolic and diastolic function and any associated valve disease.[31]

Management

Most patients with decompensated aortic stenosis can be managed conservatively by (1) treating the underlying disease process that led to decompensation and (2) restoring the patient's normal loading conditions. However, in patients who have denied symptoms or have not been receiving medical care, the first presentation of severe aortic stenosis may be syncope or pulmonary edema. In these patients, aortic stenosis is the cause of decompensation, as evidenced by very severe valve obstruction, often with a low ejection fraction. Treatment is urgent aortic valve replacement, with transcatheter aortic valve implantation now replacing surgical intervention for most patients with acute decompensation. Although patients undergoing emergency transcatheter valve implantation have a higher 30-day (8.7% vs. 4.3%) and

1-year mortality (29.1% vs. 17.5%) than patients undergoing a nonemergent procedure, these adverse outcomes primarily are related to baseline patient characteristics, with data strongly supporting the benefit of relief of valve obstruction when severe stenosis is the cause of clinical decompensation.[43–46]

If there is any delay in availability of valve replacement, the cautious use of nitroprusside may improve hemodynamics if the mean arterial pressure is above 60 mm Hg.[47,48] If aortic valve replacement is temporarily contraindicated, primarily because of an active infection, balloon aortic valvuloplasty might be considered.

RIGHT-SIDED VALVE DISEASE

Pulmonic valve disease is almost always congenital in origin, with a chronic disease course. Tricuspid valve stenosis is rare and usually accompanies rheumatic mitral valve disease. Tricuspid valve endocarditis often results in acute severe regurgitation; pulmonic valve endocarditis is rare. Cases of acute traumatic disruption of the tricuspid valve with blunt chest trauma have been described, although myocardial contusion or thoracic aorta disruption is more common.[49] Acute severe tricuspid regurgitation results in a low forward cardiac output and signs of an elevated right atrial pressure.[17,50] Numerous studies show that significant tricuspid regurgitation is associated with adverse cardiovascular outcomes. The role of transcatheter procedures for reduction of tricuspid regurgitant severity is currently under investigation.

PROSTHETIC VALVES

Mechanical Valves

Prosthetic mechanical heart valves are highly durable, with complications most often the result of valve thrombosis or paravalvular regurgitation. Valve thrombosis occurs in the setting of inadequate anticoagulation and may result in functional valve stenosis if movement of the valve occluder is restricted or valve regurgitation if the clot prevents full closure of the valve. The clinical presentation of valve thrombosis is similar to that of native valve stenosis or regurgitation. Echocardiography provides key information on the presence and severity of valve dysfunction. TEE is especially important with mitral prosthetic valves (Fig. 76.11); the valve itself blocks ultrasound penetration from a transthoracic approach.

The treatment of prosthetic valve thrombosis depends on the severity of valve obstruction. Evaluation includes TTE and TEE to detect a thrombus and evaluate valve hemodynamics, plus either fluoroscopy or cine-computed tomographic imaging to evaluate valve occluder motion. When only a small thrombus and mild hemodynamic compromise are present, conservative therapy with full-dose intravenous anticoagulation for several days may be adequate. When severe stenosis is present, either repeat surgical intervention or slow-infusion, low-dose fibrinolytic therapy is recommended.[17] Fibrinolytic therapy success rates are >90%, with rates of embolic events and major bleeding both <2%. Surgical intervention has a 30-day mortality as high as 10%–15%. The decision between surgery and systemic fibrinolysis should be made by a heart valve team with consideration of multiple factors, including availability of surgical expertise, clinical symptoms, thrombus burden, and patient choice. Fibrinolytic therapy is reasonable with left-sided thrombosis, with mild symptoms of recent onset or a small clot burden and patients who are high-to-prohibitive-risk surgical candidates.[17,51–53]

Paravalvular regurgitation early after valve replacement may be related to suture dehiscence at a site of annular calcification. Paravalvular regurgitation may be associated with hemolytic anemia, which can be treated conservatively if mild, but may require reoperation if severe recurrent anemia is present. The new onset of paravalvular regurgitation should prompt careful evaluation for endocarditis (see Chapter 117). Paravalvular regurgitation has been successfully treated with percutaneous techniques in high-risk surgical candidates with refractory heart failure and hemolytic anemia (Fig. 76.12).[23,54,55]

Tissue Valves

Tissue valves are subject to the degeneration of the leaflets, with superimposed calcification that may result in stenosis or regurgitation. Usually, this is a slowly progressive process with presentation 10–15 years after valve implantation.[56] As with native valve disease, acute decompensation may occur in patients with chronic prosthetic valve dysfunction if there is a superimposed hemodynamic stress. Valve thrombosis also is a concern with bioprosthetic valves, particularly after transcatheter aortic valve implantation.[57]

Acute regurgitation of a tissue valve can result from endocarditis or a leaflet tear caused by tissue degeneration. Tears in the valve leaflet typically occur adjacent to an area of calcification secondary to the increased stress on the normal leaflet tissue. As with mechanical valves, both transthoracic and transesophageal imaging are needed for the full evaluation of suspected prosthetic tissue valve dysfunction. Treatment is similar to that for native valves, with medical stabilization followed by surgery for repeat valve replacement. However,

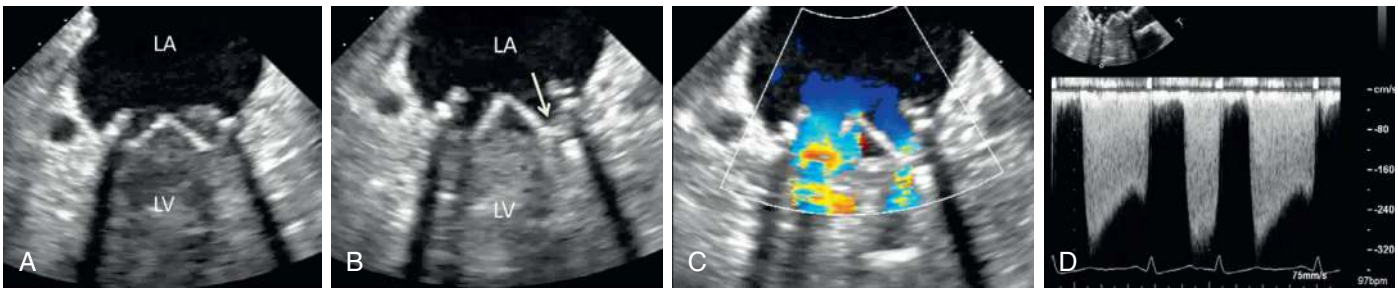

Fig. 76.11 Transesophageal echocardiogram of a thrombosed bileaflet mechanical mitral valve in a 43-year-old female who stopped anticoagulation for a dental procedure with inadequate bridging. In systole **(A)**, the bright occluder can be seen in a closed position, causing reverberation artifact into the left ventricle (*LV*). During diastole **(B)**, there is a minimal opening of the occluder *(white arrow)* from the acute thrombus. Color-flow Doppler **(C)** shows flow primarily through only one side of the valve, whereas there is only a very narrow jet at the site of the stuck leaflet. Continuous-wave Doppler **(D)** estimated a severely elevated mean gradient of 24 mm Hg, and the patient required emergent surgical valve replacement with a bioprosthesis. *LA*, Left atrium.

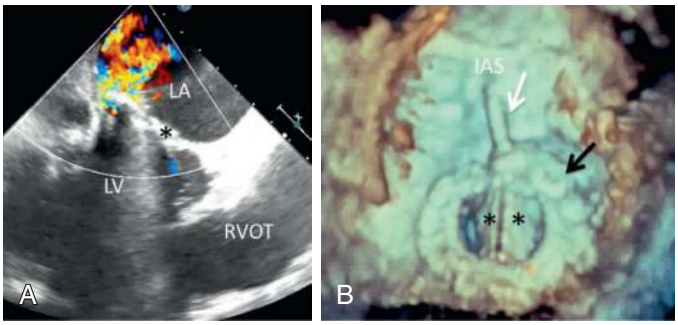

Fig. 76.12 Severe paravalvular leak in a 72-year-old male with a history of multiple mitral valve (MV) replacements because of previous endocarditis presenting with symptomatic heart failure and hemolytic anemia. Two-dimensional transesophageal color Doppler **(A)** shows eccentric regurgitation around the closed prosthetic MV occluder (*) during systole. Three-dimensional echocardiography **(B)** assists with paravalvular closure of the defect using an Amplatzer plug *(black arrow)*. A second plug is required in this case and can be seen being deployed via a transseptal catheter *(white arrow)* during diastole with an open MV occluder. *IAS,* Interatrial septum; *LA,* left atrium; *LV,* left ventricle; *RVOT,* right ventricular outflow tract.

many patients are at a very high surgical risk because of advanced age, comorbidities, and repeated sternotomy; in these patients, a transcatheter bioprosthetic "valve-in-valve" implantation may be performed at experienced centers.[58,59]

KEY POINTS

- Echocardiography is the first step in the diagnosis of acute valve disease; physical examination is not reliable, and valve disease should be considered in all patients with acute heart failure.
- Acute mitral regurgitation may be the result of primary diseases of the valve apparatus, such as spontaneous chordal rupture or endocarditis, or secondary to an acute cardiomyopathy or acute ischemic heart disease.
- Treatment of acute mitral regurgitation depends on the cause of valve dysfunction, ranging from coronary revascularization for acute ischemia to emergency surgery for a flail leaflet or ruptured papillary muscle. Medical therapy, an IABP, or an LV support device may be needed for stabilization before intervention.
- Acute aortic valve regurgitation may be primary diseases of the valve leaflets, such as endocarditis, or because of aortic dissection with distortion of normal aortic valve anatomy.
- Endocarditis causes destruction of valve tissue with acute regurgitation and heart failure. Early surgery, before completion of antibiotic therapy, improves clinical outcomes.
- In critically ill patients who are poor surgical candidates, rapid relief of valve obstruction can be lifesaving, including transcatheter balloon valvotomy for rheumatic mitral stenosis or transcatheter aortic valve implantation for calcific aortic stenosis.
- Prosthetic valve thrombosis may require acute surgical intervention, with selected patients responding to increased anticoagulation or fibrinolytic therapy.

This review article summarizes the clinical presentation, diagnosis, and management of acute valvular heart disease. It provides additional echocardiographic illustrations and references to complement this chapter.

Sun JC, Davidson MJ, Lamy A, et al. Antithrombotic management of patients with prosthetic heart valves: current evidence and future trends. *Lancet*. 2009;374:565–576.
This review of antithrombotic therapy for prosthetic valves covers preventive anticoagulation and management of thrombotic complications. For obstructive valve thrombosis, the authors recommend thrombolytic therapy and echocardiographic monitoring, with surgery reserved for patients with contraindications to thrombolysis or those who do not respond to thrombolytic therapy. Smaller (<5 mm) nonobstructive thrombi can usually be managed with standard anticoagulation alone.

Pulmonary Hypertension and Right Ventricular Failure

Lewis J. Rubin and John Selickman

Pulmonary hypertension (PH) is defined by an elevated mean pulmonary artery pressure (mPAP) of >20 mm Hg and may be precapillary or postcapillary in etiology.[1] Precapillary PH is further characterized by an elevated pulmonary vascular resistance (PVR) of ≥3 Wood units and a pulmonary arterial wedge pressure of ≤15 mm Hg. Management of postcapillary PH, which is caused by left-sided heart dysfunction, typically involves treating the underlying process. Medications used to treat precapillary PH are often not only ineffective for postcapillary PH but may in fact be harmful, potentially leading to the development of pulmonary edema or systemic hypotension.

The World Health Organization (WHO) categorizes PH into five groups based on their underlying pathophysiology: (1) pulmonary arterial hypertension (PAH), (2) PH caused by left heart disease, (3) PH caused by lung diseases and/or hypoxia, (4) PH caused by pulmonary artery obstructions, and (5) PH with unclear and/or multifactorial mechanisms. PAH can be idiopathic (IPAH, previously known as *primary PH* [PPH]) or may occur in association with a variety of underlying disease processes, such as collagen vascular disease, portal hypertension, congenital systemic-to-pulmonary shunts, drug or toxin exposure, or human immunodeficiency virus (HIV) infection.[2] IPAH is principally a disease of young women, but it can affect all age groups and both sexes. A genetic predisposition may underlie a substantial proportion of these cases and is referred to as *heritable pulmonary arterial hypertension* (HPAH).[3–9]

Initial therapy may be directed at an underlying cause or contributing factors, such as using continuous positive airway pressure (CPAP) and supplemental oxygen for PH associated with obstructive sleep apnea. After the identification and treatment of underlying associated disorders and contributing factors, specific therapy for PAH should be considered. IPAH carried a very poor prognosis (median survival rate of approximately 2.8 years from the time of diagnosis) through the mid-1980s. Subsequently, a number of therapeutic options have been developed, and 14 have been approved by the U.S. Food and Drug Administration (FDA), falling into three classes of drugs: (1) prostanoids, including epoprostenol (intravenous), treprostinil (subcutaneous, intravenous, inhaled, or oral), iloprost (inhaled), and selexipag (oral); (2) endothelin receptor antagonists (ERAs), including bosentan, ambrisentan, and macitentan (all oral); and (3) drugs acting on the nitric oxide pathway, including the phosphodiesterase (PDE) type-5 inhibitors, sildenafil and tadalafil (both oral), and the guanylate cyclase activator, riociguat (oral).

DIAGNOSIS

Symptoms, Signs, and Clinical History

As a result of the insidious onset of symptoms, PAH is often advanced at the time of diagnosis. Dyspnea upon exertion is the most common presenting symptom, but it is sometimes attributed to deconditioning or another cardiorespiratory ailment. Chest pain mimicking angina pectoris may also occur. Patients with advanced disease may present with syncope or signs and symptoms of right-sided heart failure, including lower extremity edema, jugular venous distention, and ascites.

The clinical history should focus initially on the exclusion of underlying causes of PH. Important clues to an underlying condition might include a previous history of a heart murmur, deep venous thrombosis (DVT) or pulmonary embolism, Raynaud phenomenon, arthritis, arthralgias, rash, heavy alcohol consumption, hepatitis, heavy snoring, daytime hypersomnolence, morning headache, and morbid obesity. A careful family history should be obtained. Medication exposure, particularly to appetite suppressants and amphetamines, should be noted. Cocaine is a powerful vasoconstrictor that may contribute to the development of PH, and intravenous drug use has also been associated with the development of PAH.

Physical Examination

Signs of PAH may not become apparent until late in the disease. Findings such as an accentuated second heart sound, a systolic murmur over the left sternal border, jugular venous distention, peripheral edema, and ascites might suggest the presence of PH and right ventricular (RV) dysfunction. Associated systemic diseases, such as collagen vascular disease or liver disease, may also become apparent during routine examination.

Laboratory Evaluation

Laboratory evaluation can provide important information in detecting associated disorders and contributing factors. A collagen vascular screen including antinuclear antibodies, rheumatoid factor, and erythrocyte sedimentation rate is often helpful in detecting autoimmune disease, although some patients with IPAH will have a low-titer positive antinuclear antibody test.[10] The scleroderma spectrum of disease, particularly limited scleroderma, or the CREST syndrome (i.e., calcinosis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasias), has been associated with an increased risk of the development of PAH.[11,12] Liver function tests (aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase) may be elevated in patients with RV failure and passive hepatic congestion but may also be associated with underlying liver disease. Liver disease with portal hypertension has been associated with the development of PH. Thyroid disease may occur with increased frequency in patients with IPAH and should be excluded with thyroid function testing.[13] HIV testing and hepatitis serologic studies should be performed. Routine laboratory studies, such as complete blood cell count, complete metabolic panel, prothrombin time, and partial thromboplastin time, are recommended during the initial evaluation and as indicated to monitor the patient's long-term clinical status.

Echocardiography

Transthoracic echocardiography (TTE) is the initial test of choice in assessing the severity of PH and detecting left-sided heart disease. Findings may include elevated peak tricuspid regurgitant jet velocity, elevated estimated pulmonary artery systolic pressure, RV enlargement, flattening of the interventricular septum, and compression of the left ventricle.[14] Bubble contrast echocardiography may detect a right-to-left shunt, but exclusion of a left-to-right intracardiac shunt may require cardiac catheterization with an oximetry series. Echocardiography may be useful as part of a long-term follow-up,[15,16] although not all patients have suitable echocardiographic windows.

Radiographic Evaluation and Exclusion of Thromboembolic Disease

Chest radiography may reveal an enlargement of the central pulmonary vessels and evidence of RV enlargement. Evidence of parenchymal lung disease may also be apparent. When parenchymal lung disease is suspected, pulmonary function testing and high-resolution computed tomography (CT) of the chest may be indicated. Because of its high sensitivity, ventilation/perfusion (V/Q) scanning is the imaging modality of choice to exclude chronic thromboembolic disease–related PH (CTEPH), which is among the most preventable and treatable causes of PH. Diffuse mottled perfusion can be seen in IPAH, whereas larger segmental and subsegmental mismatch defects are suggestive of CTEPH. Because any process that leads to decreased perfusion without an associated decrease in ventilation will result in a mismatch, V/Q scanning lacks specificity for CTEPH. CT pulmonary angiography (CTPA) is thus an important adjunct to V/Q scanning, not only to exclude other disease processes in which similar mismatch defects can be seen but also to define the extent and location of thromboembolic disease before surgical evaluation. Although CTPA remains the imaging modality of choice for acute pulmonary embolism, it lacks the sensitivity of V/Q scanning for CTEPH, particularly at the subsegmental level, and caution should be exercised when using it to exclude CTEPH.[17]

Pulmonary Function Testing

Pulmonary function testing is indicated to detect underlying parenchymal lung disease. The diffusing capacity is often reduced in pulmonary vascular disease, consistent with impaired gas exchange.

Right-Sided Heart Catheterization and Vasoreactivity Testing

Right-sided heart catheterization remains an important part of the evaluation. Left-sided heart dysfunction and intracardiac shunts can be excluded, the degree of PH can be accurately quantified, cardiac output can be measured, and PVR can be calculated. Acute pulmonary vasoreactivity can be assessed using a short-acting agent, such as prostacyclin (epoprostenol), inhaled nitric oxide, or intravenous adenosine. The consensus definition of a positive acute vasodilator response in a patient with PAH is a decrease in mPAP by $\geq$10 mm Hg to $\leq$40 mm Hg with increased or unchanged cardiac output. The primary objective of acute vasodilator testing in patients with PAH is to identify the subset of patients who might be effectively treated with oral calcium channel blockers; response to a short-acting pulmonary vasodilator has been shown to be predictive of a response to calcium channel blockers.[18] Unstable patients or those in severe right-sided heart failure who would not be candidates for treatment with calcium channel blockers need not undergo vasodilator testing.

TREATMENT

General Care

Warfarin, Oxygen, Diuretics, Digoxin, and Vaccination

Although earlier studies suggested improved survival with oral anticoagulation in PAH,[19] the benefits were primarily seen in patients with IPAH and not present in those with other forms of PAH. More recent studies have not only failed to demonstrate a survival advantage in patients with IPAH treated with anticoagulation, but they have demonstrated an increased mortality in patients with PAH secondary to most other causes.[20] Generally, patients with PAH who are treated with chronic intravenous epoprostenol are anticoagulated in the absence of contraindications, owing in part to the additional risk of catheter-associated thrombosis. All patients with CTEPH should receive lifelong anticoagulation.

Hypoxemia is a pulmonary vasoconstrictor and can contribute to the development or progression of PAH. It is generally considered important to maintain oxygen saturations greater than 90% at all times, although data supporting the role of supplemental oxygen in PH are largely based on expert opinion or extrapolated from clinical trials that evaluated its use in patients with chronic obstructive pulmonary disease (COPD). Although no randomized controlled trials have yet addressed the role of supplemental oxygen in PH, a post hoc analysis of data from a large, observational study demonstrated improved survival among patients with PAH and severely reduced diffusing capacity who were treated with supplemental oxygen.[21]

Diuretics are indicated in patients with evidence of RV failure and volume overload. Careful dietary restriction of sodium and fluid intake is important in the management of patients with PAH and right-sided heart failure. Rapid and excessive diuresis may produce systemic hypotension, renal insufficiency, and syncope. Serum electrolytes and measures of renal function should be followed closely in patients receiving diuretic therapy.

Although not extensively studied in PAH, digitalis is sometimes used in refractory RV failure or atrial dysrhythmias. Drug levels should be followed closely, particularly in patients with impaired renal function.

Because of the potentially devastating effects of respiratory infections in patients with PH, immunization against influenza, coronavirus disease 2019 (COVID-19), and pneumococcal pneumonia is recommended.

Calcium Channel Blockers

Patients with IPAH who respond to vasodilators and calcium channel blockers generally have improved survival.[18] Unfortunately, this tends to represent a relatively small proportion of patients, comprising less than 20% of patients with IPAH and even fewer patients with other causes of PAH.

Prostacyclin Receptor Agonists

Prostacyclin, a metabolite of arachidonic acid produced primarily in the vascular endothelium, is a potent systemic and pulmonary vasodilator that also has antiplatelet aggregatory effects. A relative deficiency of endogenous prostacyclin may contribute to the pathogenesis of PAH.[22]

Epoprostenol. Epoprostenol therapy is complicated by the need for continuous intravenous infusion. The drug is unstable at room temperature and is generally best kept cold before and during infusion. It has a very short half-life in the bloodstream (<6 minutes), is unstable in an acidic pH, and cannot be taken orally. Because of the short half-life, the risk of rebound worsening with abrupt or inadvertent interruption of

the infusion, and its effects on peripheral veins, it should be administered through an indwelling central venous catheter. Common side effects of epoprostenol therapy include headache, flushing, jaw pain with initial mastication, diarrhea, nausea, a blotchy erythematous rash, and musculoskeletal aches and pain (predominantly involving the legs and feet). These tend to be dose dependent and often respond to a cautious reduction in dose. Severe side effects can occur with an overdose of the drug. Acutely, overdosage can lead to systemic hypotension. Chronic overdosage can lead to the development of a hyperdynamic state and high-output cardiac failure.[23] Abrupt or inadvertent interruption of the epoprostenol infusion should be avoided because this may lead to a rebound worsening of PH, with symptomatic deterioration and even death. Other complications of chronic intravenous therapy with epoprostenol include line-related infections, catheter-associated venous thrombosis, systemic hypotension, thrombocytopenia, and ascites.

Treprostinil. Treprostinil, a prostacyclin analog with a half-life of 3 hours, is stable at room temperature. A placebo-controlled, randomized trial demonstrated that continuous subcutaneous treprostinil improved exercise tolerance, although the 16-meter median difference between treatment groups in 6-minute walking distance was relatively modest.[24] Treprostinil also improved hemodynamic parameters. Common side effects included headache, diarrhea, nausea, rash, and jaw pain. Side effects related to the infusion site were common (85% of patients complained of infusion-site pain, and 83% had erythema or induration at the infusion site). Treprostinil is also approved for both intravenous delivery based on bioequivalence with the subcutaneous route and as an inhaled preparation administered in doses of 18–54 μg, four times daily.[25]

A multicenter, randomized, double-blind, placebo-controlled trial evaluating the use of inhaled treprostinil in patients with PH secondary to interstitial lung disease demonstrated a small improvement in exercise capacity and 15% reduction in N-terminal pro-B-type natriuretic peptide (a biomarker of cardiac overload) after 16 weeks, without any increase in serious adverse events, thus making it one of the only medications to demonstrate clinical efficacy in this population.[26]

Inhaled iloprost. Iloprost is a chemically stable prostacyclin analog with a serum half-life of 20–25 minutes[27] and is a potent pulmonary vasodilator. In uncontrolled and controlled studies of iloprost for various forms of PAH,[28,29] inhaled iloprost at a total daily dose of 15–45 μg divided in 6–9 inhalations improved functional class, exercise capacity, and pulmonary hemodynamics for periods up to 1 year of follow-up. The treatment was generally well tolerated except for mild coughing, minor headache, and jaw pain in some patients. The most important drawback of inhaled iloprost is the relatively short duration of action, requiring the use of six to nine inhalations per day.

Beraprost. Beraprost sodium is an orally active prostacyclin analog[30] that is absorbed rapidly under fasting conditions. It has been evaluated in patients with intermittent claudication,[31] Raynaud phenomenon, and digital necrosis from systemic sclerosis,[32] with variable results. Although several small, open, uncontrolled studies reported beneficial hemodynamic effects with beraprost in patients with IPAH, two randomized double-blind, placebo-controlled trials have shown only modest improvement and suggest that beneficial effects of beraprost may diminish with time.[33,34]

Selexipag. Selexipag is a selective *nonprostanoid* prostacyclin receptor agonist that is administered orally. Its efficacy in patients with PAH was demonstrated in a randomized, double-blind, placebo-controlled trial.[35] The primary endpoint was a composite of death from any cause or complication related to PAH (disease progression, hospitalization, initiation of parenteral prostanoid or long-term oxygen, need for lung transplantation, or need for balloon atrial septostomy). The primary endpoint occurred in significantly fewer patients randomized to the selexipag group, primarily because of a decrease in disease progression and decreased hospitalizations. Approximately 80% of patients enrolled were already on PH therapy (either ERAs, PDEs, or both) at the time of enrollment, but an additional benefit of selexipag was still present in a subgroup analysis of these patients. Headache, diarrhea, nausea, and jaw pain were the most common adverse events.

Endothelin Receptor Antagonists

Endothelin-1 is a vasoconstrictor and a smooth muscle mitogen that may contribute to the pathogenesis of PAH. Endothelin-1 expression, production, and concentration in plasma[36,37] and lung tissue[38] are elevated in patients with PAH, and these levels are correlated with disease severity. The main adverse effects associated with ERAs are peripheral edema, hepatotoxicity, and potent teratogenicity.

Bosentan. Bosentan is a dual ERA that has been shown to improve pulmonary hemodynamics and exercise tolerance and delay the time to clinical worsening in patients with PAH.[39] The most frequent and potentially serious side effect with bosentan is dose-dependent abnormal hepatic function (as indicated by elevated levels of alanine aminotransferase and aspartate aminotransferase). Because of the risk of potential hepatotoxicity, the FDA requires that liver function tests be performed at least monthly in patients receiving this drug. Bosentan may also be associated with the development of anemia, which is typically mild. Hemoglobin and hematocrit should also be checked regularly.

Ambrisentan. Ambrisentan is a selective ERA that has shown efficacy in PAH. In a double-blind, placebo-controlled, randomized, multicenter study, patients with PAH were randomized to one of three doses of ambrisentan ranging from 2.5 to 10 mg once daily for 12 weeks. Patients receiving ambrisentan had statistically significant improvements in exercise capacity, time to clinical worsening, quality of life, and dyspnea.[40]

Macitentan. Macitentan is a dual ERA that reduces disease progression in PAH and is associated with a low incidence of liver function abnormality and peripheral edema. In a double-blind, placebo-controlled, randomized, multicenter study, patients with PAH were randomized to a once-daily dose of either 3 mg macitentan, 10 mg macitentan, or placebo for a median duration of 85 weeks.[41] The primary endpoint (composite of death, atrial septostomy, lung transplantation, initiation of prostanoid, or worsening of PAH) was significantly lower in both macitentan groups compared with placebo. Patients receiving macitentan also had improved exercise capacity and cardiac hemodynamics (decreased PVR and increased cardiac output). The incidence of peripheral edema and elevation of serum aminotransferases was similar in all three groups, although a higher incidence of nasopharyngitis, headache, and anemia was seen with macitentan.

Cyclic Guanosine Monophosphate Pathway Enhancers

Nitric oxide (NO) is a potent vasodilator and one of the principal mediators of pulmonary vascular tone. It is synthesized from L-arginine by NO synthases and exerts its effects on vascular smooth muscle through activation of soluble guanylate cyclase (sGC), leading to increased production of cyclic guanosine monophosphate (cGMP). cGMP acts directly on vascular smooth muscle and leads to vasodilation and decreased cellular proliferation. PAH is associated with both decreased production of endogenous NO and increased production of phosphodiesterase type 5 (PDE5), an enzyme that hydrolyzes cGMP and limits intracellular signaling.[42,43] Drugs that selectively inhibit cGMP-specific PDEs (or PDE5 inhibitors) augment the pulmonary vascular response to endogenous or inhaled NO in models of PH.[44,45]

Sildenafil. Sildenafil, an oral medication initially approved for erectile dysfunction, is a potent specific PDE5 inhibitor that blocks acute

hypoxic pulmonary vasoconstriction in healthy adult volunteers and acutely reduces mPAP in patients with PAH.[46] Several randomized studies have demonstrated sildenafil's efficacy in PAH, both as monotherapy and in combination with other agents.[47,48] Sildenafil treatment in animal models with experimental lung injury reduced PAP, but gas exchange worsened owing to impaired V/Q mismatch.[49,50] Accordingly, caution is advised when using sildenafil to treat PH in patients with severe lung disease. Side effects commonly observed include headache, dyspepsia, and flushing.

Tadalafil. Tadalafil, another oral PDE5 inhibitor previously approved for erectile dysfunction, is approved for the treatment of PAH based on a randomized clinical trial demonstrating increased exercise capacity and decreased time to clinical worsening.[51] Unlike sildenafil, it has the advantage of once-daily administration, although side effects appear to be similar.

Riociguat. Riociguat is a novel agent that increases production of cGMP through stimulation of sGC. In a randomized placebo-controlled trial, patients treated with oral riociguat for 12 weeks had improved exercise capacity, pulmonary hemodynamics, and decreased time to clinical worsening.[52] Riociguat is the only drug approved for the treatment of inoperable CTEPH, and it has been shown to both improve exercise capacity and decrease vascular resistance in this population.[53] Common side effects include headache, dyspepsia, and dizziness. It should not be used in combination with PDE inhibitors because of the risk of systemic hypotension, and its use is contraindicated in pregnancy because of teratogenicity.

Combination Therapy

The AMBITION trial demonstrated that treatment-naïve PAH patients treated with the initial combination therapy of ambrisentan and tadalafil had a significant reduction in the relative risk of disease progression.[54] Additionally, greater reductions in N-terminal pro-brain natriuretic peptide and greater improvements in exercise capacity were observed in patients who were treated with monotherapy compared with those using either agent alone. Based on these findings, many experienced clinicians have begun initiating PAH treatment with the combination of an ERA and a PDE5 inhibitor.

Nitric Oxide

NO contributes to the maintenance of normal vascular function and structure. It is particularly important in the normal adaptation of the lung circulation at birth, and impaired NO production may contribute to the development of neonatal PH.

Inhaled nitric oxide. Inhaled NO has been shown to have potent and selective pulmonary vasodilator effects during brief treatment of adults with IPAH.[55] It is an effective pulmonary vasodilator in newborns with PH (persistent PH of the newborn [PPHN]); children with congenital heart disease; and patients with postoperative PH, acute respiratory distress syndrome, or those undergoing lung transplantation.[56] It is of substantial benefit in PPHN, decreasing the need for support with extracorporeal membrane oxygenation (ECMO).[57] Although inhaled NO has been used in diverse clinical settings, especially in intensive care medicine, FDA approval for this therapy is limited to newborns with hypoxemic respiratory failure at this time.

In chronic PAH, the use of inhaled NO has been primarily for acute testing of pulmonary vasoreactivity during cardiac catheterization or for acute stabilization of patients during deterioration.

Lung Transplantation

PAH accounts for only 2.7% of adult lung transplants[58] and is generally reserved for those who are failing despite the best available medical therapy. Lung transplantation in general is challenging, but it is even more so in patients whose primary indication for transplant is PAH.[59] Patients transplanted for PAH have a higher 3-month mortality rate (23%) than those transplanted for any other indication.[58] However, patients with PAH who survive to 1 year posttransplant have a higher median long-term survival (10.0 years) than groups transplanted for most other indications, including both COPD (7.0 years) and interstitial lung disease (ILD) (6.9 years).[58]

The higher early mortality in PAH patients may be related to higher anesthetic and operative risks, the need for cardiopulmonary bypass,[60] and the increased occurrence of postoperative reperfusion pulmonary edema in patients with PAH undergoing single-lung transplantation. In this situation, reperfusion pulmonary edema may be aggravated by the increased blood flow to the newly engrafted lung. In addition, V/Q mismatching can be particularly severe.[61] Most centers therefore seem to prefer bilateral lung transplantation for patients with PAH.[62] The International Society for Heart and Lung Transplantation (ISHLT) recommends early referral for patients with PAH to ensure there is adequate time to both complete the transplant evaluation and find a suitable graft. Referral should be considered for all patients with significant RV dysfunction or progressive disease despite appropriate therapy, need for parenteral prostacyclin, high-risk variants (e.g., pulmonary veno-occlusive disease), signs of hepatic or renal dysfunction secondary to PAH, or life-threatening complications such as hemoptysis.[63]

Special Situations in the Intensive Care Unit

DVT Prophylaxis

Patients with PAH are likely at increased risk for DVT and are certainly at increased risk for poor outcomes as the result of DVT. Patients with PAH are prone to a more sedentary lifestyle and to chronic venous congestion of the lower extremities owing to increased right-sided cardiac filling pressures. Hospitalization in the intensive care unit (ICU), often with discontinuation of anticoagulation in anticipation of invasive procedures, likely places these patients at even higher risk for DVT. For these reasons, meticulous attention must be paid to DVT prophylaxis.

Procedures and Surgery

Procedures and surgery in patients with PAH can be associated with substantially increased operative and perioperative risks. In addition, appropriate precautions should be undertaken to optimize outcomes. As always, careful consideration should be given to whether an invasive procedure is absolutely necessary.

Vasovagal Events

Patients with severe PAH are prone to vasovagal events. Pain, nausea, vomiting, or even defecation can lead to a vasovagal event in patients with severe PAH, as cardiac output may be disproportionately dependent on heart rate. Moreover, the bradycardia and systemic vasodilatation that accompany a vasovagal event can result in an abrupt decrease in systemic arterial pressure, leading to syncope or even cardiopulmonary arrest. Therefore patients should be closely monitored for their heart rate during invasive procedures, with readily available atropine or a similar agent.

Avoidance of Hypoxemia and Hypercarbia

Hypoxemia and hypercarbia are both pulmonary vasoconstrictors and can contribute to the worsening of PH. Oversedation can lead to ventilatory insufficiency and precipitate clinical deterioration. Caution should be used in laparoscopic procedures in which carbon dioxide is used for abdominal insufflation, because absorption can lead to hypercarbia. The induction of anesthesia and intubation for surgical

procedures can be a particularly high-risk period for patients with PAH because of the increased risk for vagal events, hypoxemia, hypercarbia, and shifts in intrathoracic pressure with associated changes in cardiac filling pressures.

Pregnancy

The hemodynamic changes in pregnancy are substantial, and volume shifts occur immediately postpartum, with cardiac filling pressures increasing as a result of decompression of the vena cava and the return of uterine blood into the systemic circulation. The changes induced by pregnancy impose a significant hemodynamic stress in women with IPAH, leading to an estimated 30%–50% mortality rate.[64,65] Because of high maternal and fetal morbidity and mortality rates, most experts recommend effective contraception and early fetal termination in the event of pregnancy.[66] There have been case reports of successful treatment of pregnant IPAH patients with chronic intravenous epoprostenol,[67–69] inhaled NO,[70–72] and oral calcium channel blockers.[73] ERAs and guanylate cyclase stimulants (riociguat) are classified as teratogenic and should be avoided in this setting. In general, management includes early hospitalization for monitoring, supportive therapy with cautious fluid management, supplemental oxygen, diuretics, and dobutamine, as needed. The use of a pulmonary artery catheter for close hemodynamic monitoring and titration of vasodilator and cardiotonic therapy also has been recommended. Recommendations regarding the mode of delivery remain controversial.

Portopulmonary Hypertension

Patients with chronic liver disease have an increased prevalence of pulmonary vascular disease.[74,75] Two forms of pulmonary vascular disease can complicate chronic liver disease: (1) hepatopulmonary syndrome (HPS) and (2) portopulmonary hypertension (PPHTN). Both tend to occur in patients with chronic, late-stage liver disease, and each may increase the risk associated with liver transplantation.

Hypoxemia and intrapulmonary shunting characterize HPS. Shunting manifests echocardiographically as the late appearance (after three to five cardiac cycles) of bubble contrast in the left side of the heart. Treatment is generally supportive with supplemental oxygen, although patients with HPS and severe hypoxemia should be evaluated for liver transplant, which remains the only definitive treatment. Hypoxemia improves or resolves altogether in the majority of patients with HPS posttransplant.

PPHTN occurs in patients with chronic, late-stage liver disease and portal hypertension.[76] It often differs hemodynamically from IPAH, and these differences may affect the approach to therapy. Patients with PPHTN have lower pulmonary arterial diastolic and mean pressures, higher cardiac outputs, and lower pulmonary and systemic resistances.[77] Later-stage patients may develop hemodynamic findings similar to those of patients with IPAH, and this group may have a poorer prognosis and be at higher risk with attempted liver transplantation. It is occasionally possible to turn a patient who is an otherwise marginal candidate for liver transplant resulting from PPHTN into an acceptable one through aggressive treatment of the PAH. Supplemental oxygen should be used as needed to maintain saturations ≥90% at all times, and diuretic therapy should be used to control edema and ascites. There have been a number of case reports and small case series describing the use of intravenous epoprostenol for treatment of PPHTN,[78–82] although management of PAH in PPHTN is largely extrapolated from studies that evaluated PAH secondary to other causes.

Unlike HPS, transplant is not a treatment for PPHTN; although patients may demonstrate an improvement in PH after liver transplantation,[83] others may worsen. It may be possible to wean a select few patients off PAH medications after liver transplantation, but this should probably be done very gradually and under close observation. Because of the potential for hepatoxicity, caution is advised when using ERAs in this population.

KEY POINTS

- The evaluation of patients with PH is directed at the detection of underlying contributing factors and associated conditions, such as left-sided cardiac dysfunction, congenital heart disease, pulmonary thromboembolic disease, collagen vascular disease, parenchymal lung disease, obstructive sleep apnea, liver disease, amphetamine or appetite suppressant use, intravenous drug use, or HIV infection.
- Patients with severe PH are particularly prone to vasovagal events, and when these occur they can lead to severe consequences, including syncope, cardiopulmonary arrest, and death.
- Hypoxemia and hypercarbia are both pulmonary vasoconstrictors and can contribute to the worsening of PH.
- The induction of anesthesia and intubation for surgical procedures can be a particularly high-risk time for patients with PAH, as they are at risk for vagal events, hypoxemia, hypercarbia, and shifts in intrathoracic pressure with associated changes in cardiac filling pressures.

Hypertensive Crisis: Emergency and Urgency

Shweta Bansal and Stuart L. Linas

Hypertension is a common problem, and population data suggest its incidence is increasing globally. One billion individuals worldwide now have hypertension.[1] Nearly one in three US adults has hypertension. Compared with two-thirds in the past decade, currently half of these individuals do not have their blood pressure under control. One-third of those in whom it is not controlled are unaware of their diagnosis.[2,3] The exact risk of hypertensive crisis is not clear, but most authors estimate it to be less than 1%. A carefully conducted descriptive analysis from the Nationwide Emergency Department (ED) Sample's ED visits report hypertensive emergencies in fewer than 2 in 1000 adult ED visits and 6 in 1000 visits carrying any diagnosis of hypertension in 2013. These data reveal a prevalence much lower than previously thought.[4–6]

Hypertensive emergency is defined as an elevated blood pressure associated with evidence of acute end-organ damage. With acute damage to vital organs such as the kidney, heart, and brain, there is a significant risk of morbidity in hours without therapeutic intervention. Both the absolute level of blood pressure and the time course of the elevation determine the development of an emergency. In general with hypertensive emergency, the diastolic blood pressure is above 120 mm Hg. However, in children, gravid females, and previously normotensive individuals, hypertensive emergencies may occur with relatively minor increases in blood pressure. It is very important to identify this syndrome early to prevent end-organ damage and institute appropriate therapy as soon as the diagnosis is made. Malignant hypertension is a specific syndrome in which a markedly elevated blood pressure is associated with hypertensive neuroretinopathy.

Individuals with *hypertensive urgency* have an elevated blood pressure (systolic blood pressure [SBP] often >180 mm Hg and diastolic pressure often >115 mm Hg) without evidence of acute end-organ damage. Hypertensive urgency may be associated with chronic, stable complications such as stable angina, previous myocardial infarction, chronic congestive heart failure, chronic renal failure, previous transient ischemic attacks, or previous cerebrovascular accident with no threat of an acute insult. The focus of this chapter is on both types of hypertensive crises, with the emphasis on hypertensive emergency.

PATHOPHYSIOLOGY OF HYPERTENSIVE EMERGENCY

The precise pathophysiology of hypertensive emergency is unknown. An abrupt increase in blood pressure is one of the initiating events in the transition from simple hypertension or normotension to hypertensive emergency. The product of cardiac output and peripheral vascular resistance determines blood pressure. The initial blood pressure increase is likely secondary to an increase in vascular resistance. Considerable evidence suggests that mechanical stress in the arteriolar wall leads to vascular myogenic responses and disruption of endothelial integrity.[7] With disruption of vascular integrity, diffuse microvascular lesions develop.[8,9] Fibrinoid necrosis of the arterioles and myointimal proliferation are seen in vulnerable organs and are considered the histologic hallmark of hypertensive emergency.[8,9] Endothelial damage also causes impaired production of nitric oxide. These maladaptive responses result in increases in peripheral resistance and set up a vicious cycle, where relative hypoperfusion from vasoconstriction causes a further increase in vasoactive hormones. For example, hypoperfusion causes activation of the renin–angiotensin–aldosterone system, and evidence suggests angiotensin II may directly injure the vascular wall by activation of genes for proinflammatory cytokines (e.g., interleukin-6) and also of nuclear factor κB.[10,11] Other vascular-toxic influences may contribute to increased peripheral vascular resistance, including hyperviscosity; immunologic factors; and other hormones, including catecholamines, vasopressin, and endothelin.[12–14] The end result of these changes is a significant increase in peripheral vascular resistance, with ischemia of heart, brain, and kidneys.

In considering hypertensive emergencies and their treatment, the impact of blood pressure on cerebrovascular physiology is important. For example, hypertensive encephalopathy is a distinct clinical syndrome that occurs when rapidly rising central perfusion pressures (CPPs) exceed the ability of the central nervous system (CNS) to autoregulate. *Autoregulation* of cerebral blood flow (CBF) refers to the ability of the brain to maintain a constant CBF as the CPP varies between 60 and 150 mm Hg. In the setting of chronic hypertension, the range of autoregulation is increased to a range of 80–160 mm Hg. Autoregulation of CBF is a function of CPP (derived from the mean arterial pressure [MAP] minus the venous pressure) and cerebral vascular resistance (CVR), according to the following equation:

$$CBF = CPP/CVR$$

Under normal physiologic conditions, the backflow in the cerebral venous system or venous pressure is near zero, and the arterial pressure determines the CPP. With acute brain injury, as seen with subarachnoid hemorrhage, stroke, and intracranial hemorrhage, the ability of the brain to autoregulate and maintain CBF is impaired. Inability to autoregulate CBF is also seen in hypertensive emergency when the MAP is greater than 140 mm Hg. Failure of autoregulation leads to transmission of elevated blood pressure resulting in endothelial damage, with blood–brain barrier disruption leading to fluid and protein transudation, vasogenic edema, and further cerebral vasoconstriction causing infarcts in the brain.

DIAGNOSIS OF HYPERTENSIVE EMERGENCIES

Medical History, Physical Examination, and Laboratory Evaluation

From 40% to 50% of hypertensive emergencies arise in patients with preexisting hypertension without identifiable secondary causes.[15,16] Essential hypertension is the underlying disorder in the majority of Black individuals.[17–19] In contrast, from 50% to 60% of white patients with malignant hypertension have an identifiable cause (Box 78.1). Renovascular hypertension secondary to either fibromuscular dysplasia or atherosclerosis is not uncommon. Hypertensive emergency can occur in individuals with no hypertensive history, as in preeclampsia, pheochromocytoma, drug withdrawal, and acute glomerulonephritis. A medication history, including over-the-counter medications and illegal drug use, should be ascertained from every patient. Malignant hypertension is a unique clinical and pathologic syndrome where increases in blood pressure and target-organ damage are caused by changes in the vasculature characterized by fibrinoid necrosis and a proliferative endarteritis. Risk factors associated with the development of malignant hypertension include age between 30 and 50 years,[20] male gender,[7] Black background,[16] and smoking (increases the risk by 2.5- to 5-fold).[21]

The clinical presentation of hypertensive emergency may include headache that is generally located occipitally or anteriorly, with a steady quality. Other symptoms include visual complaints (scotoma, diplopia, hemianopsia, blindness), neurologic symptoms (focal deficits, stroke, transient ischemic attacks, seizures, confusion, somnolence), ischemic chest pain, renal symptoms (nocturia, polyuria, hematuria), back pain (aortic aneurysm), and gastrointestinal complaints (nausea, vomiting). Weight loss occurs as the high levels of circulating renin and angiotensin induce a diuresis.[22] These patients often present with intravascular volume depletion, which has strong implications for treatment.

The blood pressure is measured in both arms with the patient lying and standing. Pathologic processes such as atherosclerosis, Monckeberg medial calcification, and metastatic calcification as experienced in end-stage renal disease (ESRD), cause stiffening of the vascular wall, which can prevent vessel compression by external compression with a blood pressure cuff. This results in an artificial and at times extreme increase in the systolic and diastolic blood pressures, or "pseudohypertension." Clues to pseudohypertension include a markedly elevated blood pressure in an individual without evidence of end-organ damage. The diagnosis is suggested by a palpable radial artery despite proximal compression with a sphygmomanometer (Osler maneuver).[23]

A dilated funduscopic examination should be performed on all individuals. Arteriolar thickening reflects chronic hypertension and is manifested by increased light reflex, vascular tortuosity, and arteriovenous nicking where the arterioles cross the venules. These changes have no prognostic significance with regard to hypertensive emergency. However, as hypertension increases in severity, there are additional findings caused by the breakdown of the blood–retina barrier, leading to retinal hemorrhage and leakage of lipids, causing hard exudates or cotton-wool spots as a result of nerve ischemia and swelling of the optic nerve with papilledema.[24]

A complete cardiovascular examination should include a careful evaluation for evidence of left ventricular hypertrophy and heart failure and peripheral pulse examination for absence or delay suggestive of aortic dissection. Chest x-ray or point-of-care ultrasonography can be used to discriminate cardiac from noncardiac dyspnea.[25,26] Examination of the abdomen should include evaluation for enlarged kidneys, as seen with polycystic kidney disease, and for evidence of aortic aneurysm. Last, a careful neurologic examination should be done to rule out any evidence of a cerebrovascular accident. Alterations in mental status may indicate a stroke or hypertensive encephalopathy. The initial laboratory evaluation should include a serum sodium, chloride, potassium, bicarbonate, creatinine and blood urea nitrogen, complete blood count (with a peripheral smear to identify schistocytes), prothrombin time, activated partial thromboplastin time, serum and urine toxicology screen, pregnancy test when appropriate, an electrocardiogram, and a urinalysis (Box 78.2). Evidence of intravascular hemolysis is common and may make it difficult to differentiate hypertensive emergency from primary vasculitis with secondary hypertension.[27,28] The renin–angiotensin–aldosterone axis is markedly activated, as evidenced by hypokalemia and metabolic alkalosis.[4,29] The blood urea nitrogen and creatinine are often

BOX 78.1 Syndromes of Hypertensive Crisis

- Malignant hypertension
- Nonmalignant hypertension with target-organ disorders
  - Patient requiring emergency surgery with poorly controlled hypertension
  - Hyperviscosity syndrome
  - Postoperative patient
  - Renal transplant patient: acute rejection, transplant renal artery stenosis
  - Quadriplegic patient with autonomic hyperreflexia
  - Severe burns
  - Acute aortic dissection
  - Intracranial hemorrhage, ischemic stroke, or subarachnoid hemorrhage
  - Hypertensive encephalopathy
  - Myocardial ischemia/acute left ventricular failure
  - Preeclampsia/eclampsia
  - Antiphospholipid antibody syndrome
  - Acute renal failure
    - Scleroderma renal crisis
    - Chronic glomerulonephritis
    - Reflux nephropathy
    - Analgesic nephropathy
    - Acute glomerulonephritis
    - Radiation nephritis
    - Ask-Upmark kidney
    - Chronic lead intoxication
  - Renovascular hypertension
    - Fibromuscular dysplasia
    - Atherosclerosis
  - Endocrine hypertension
    - Congenital adrenal hyperplasia
    - Pheochromocytoma
    - Oral contraceptives
    - Aldosteronism
    - Cushing disease/syndrome
  - Systemic vasculitis
  - Atheroembolic renal crisis
  - Drugs
    - Oral contraceptives
    - Nonsteroidal antiinflammatory agents
    - Atropine
    - Corticosteroids
    - Sympathomimetics
    - Erythropoietin
    - Lead intoxication
    - Cyclosporine
  - Catecholamine excess states
    - Pheochromocytoma
    - MAO/tyramine interaction
    - Antihypertensive withdrawal
    - Cocaine intoxication, sympathomimetic overdose

MAO, Monoamine oxidase.

BOX 78.2 Proposed Diagnostic Studies in Patients With Suspected Hypertensive Emergency

Laboratory Analysis
- Hemoglobin, platelet count
- Serum creatinine, sodium, potassium, bicarbonate, lactic dehydrogenase (LDH), haptoglobin, prothrombin time, activated partial thromboplastin time
- Serum and urine toxicology screen
- Quantitative urinalysis for protein, urine sediment for erythrocytes, leukocytes, cylinders, and casts

Diagnostic Examination
- ECG (ischemia, arrhythmias, left ventricular hypertrophy)
- Fundoscopy

On Indication
- Troponin-T, creatine kinase (CK) and its isoenzyme MB (CK-MB)
- Pregnancy test
- Peripheral blood smear (for assessment of schistocytes)
- Plasma renin activity and plasma aldosterone levels, serum metanephrines
- Connective tissue disorders serology
- Chest x-ray (fluid overload)
- Transthoracic echocardiography (cardiac structure and function) or point-of-care cardiac and lung ultrasound (cardiac pulmonary edema)
- CT (or MRI) brain (intracranial hemorrhage)
- CT angiography of thorax and abdomen (acute aortic disease)
- Renal ultrasound (postrenal obstruction, kidney size, left-to-right difference)

CT, Computed tomography; *ECG,* electrocardiogram; *MRI,* magnetic resonance imaging.

BOX 78.3 Differential Diagnosis of Hypertensive Encephalopathy

Cerebral infarction
Subarachnoid hemorrhage
Intracerebral hemorrhage
Subdural or epidural hematoma
Brain tumor or other mass lesion
Seizure disorder
Central nervous system vasculitis
Encephalitis/meningitis
Drug ingestion
Drug withdrawal

elevated. The urinalysis may show small amounts of proteinuria and hematuria with occasional erythrocyte casts.[7] Marked increases in proteinuria suggest a primary glomerular process such as glomerulonephritis as the etiology of the elevated blood pressure.

If hypertensive encephalopathy is suspected, magnetic resonance imaging (MRI) of the brain should be performed. Edema seen posteriorly, particularly in the parieto-occipital regions (a finding earlier called *posterior leukoencephalopathy* and now the widely accepted term *posterior reversible encephalopathy syndrome [PRES]*) and rarely in the brainstem, is a manifestation of hypertensive encephalopathy.[30,31] It is important to consider and eliminate other conditions with a similar clinical presentation (Box 78.3). Several important diagnostic considerations help exclude other causes of altered mental status: (1) symptoms of generalized brain dysfunction tend to develop over time (12–24 hours) with hypertensive encephalopathy, as compared with acutely in ischemic stroke or cerebral hemorrhage; (2) focal neurologic findings are unusual with hypertensive encephalopathy unless there is an associated bleed; (3) papilledema is almost always noted with hypertensive encephalopathy and, if absent, should raise suspicion of another etiology; and (4) in comparison with an acute CNS bleed, mental status with hypertensive encephalopathy improves within 24–48 hours of treatment.

TREATMENT OF HYPERTENSIVE EMERGENCY

Patients with hypertensive emergency are best treated parenterally with intensive care monitoring by arterial cannulation or automated blood pressure cuff measurement. In general, the need to lower the blood pressure and the rate at which this should occur are dictated by the clinical setting. Excessive falls in pressure should be avoided, given the potential for resulting in renal, cerebral, and coronary ischemia.

In most but not all settings, blood pressure can be reduced acutely by 20%–25% within minutes to hours.[4] Although the autoregulatory range of CBF is reset upward in chronic hypertension, the lower limit of the autoregulation remains approximately 25% below the resting MAP in patients with both normotension and chronic hypertension.[32] When the arterial blood pressure falls below this lower limit, CBF progressively decreases and symptoms of low CBF, including nausea, yawning, hyperventilation, clamminess, and syncope, develop. To protect cerebral function, after an initial reduction of blood pressure by 20% within the first hour, blood pressure is further reduced over the next 2–6 hours to the 160/110 mm Hg range as long as the patient remains stable.[4] Assuming continued stability, the blood pressure may then be decreased to 140/90 mm Hg over the next 24–48 hours.[4] With these decreases in blood pressure, CBF autoregulation is usually maintained. There are several clinical settings where additional issues and alternative approaches to reducing blood pressure should be considered. In ischemic stroke, immediate reduction of blood pressure is usually not indicated except when the blood pressure is over 220/120 mm Hg or the patient requires thrombolytic therapy. Recent data indicate that acute blood pressure reduction is of no benefit (CATIS trial) or even harmful (SCAST trial).[33,34] In intracerebral hemorrhage (ICH), acute lowering of SBP to 140 mm Hg is recommended based on weak evidence. Results of the INTERACT2 study support this recommendation, although further lowering to 126 mm Hg did not result in any additional benefit in the ATACH2 trial.[35,36] In acute aortic dissection, if the patient tolerates it, a rapid blood pressure reduction in 15–30 minutes to a SBP under 100 mm Hg is clinically warranted. Finally, more rapid reduction in blood pressure is also recommended in patients with active unstable angina or congestive heart failure with pulmonary edema.

Exceptions to rapid blood pressure reduction may include older patients with carotid stenosis, given that these individuals are particularly susceptible to CNS hypoperfusion. Significant reduction of blood pressure in the setting of ischemic stroke may not be beneficial (discussed later). Overall, blood pressure management in patients with stroke or intracranial bleeding is controversial, because the loss of CBF autoregulation and the presence of brain edema require high systemic pressures to provide adequate cerebral perfusion.

SPECIFIC TREATMENT RECOMMENDATIONS FOR HYPERTENSIVE EMERGENCY BASED ON ETIOLOGY

General Comments on Medications Used to Treat Hypertensive Emergency

The classes of parenteral antihypertensive agents available to treat hypertensive emergency include direct vasodilators (sodium nitroprusside, nitroglycerin), alpha- and beta-adrenergic blockers (labetalol), alpha-adrenergic blockade (phentolamine), angiotensin-converting enzyme (ACE) inhibitors (enalaprilat), calcium channel blockers (nicardipine and clevidipine), and dopamine agonists (fenoldopam). Some of the advantages and disadvantages of these medications are detailed in Table 78.1. There is

TABLE 78.1 Treatment of Hypertensive Crisis: Intravenous Medications

Drug Name and Mechanism of Action	Indications/Advantages/Dose	Disadvantages/Adverse Effects/ Metabolism Cautions
Sodium Nitroprusside Nitric oxide compound; vasodilation of arteriolar and venous smooth muscle Increases cardiac output by decreasing afterload	Useful in most hypertensive emergencies Onset of action immediate, duration of action 1–2 minutes Dose: 0.25 μg/kg/min Maximum dose: 8–10 μg/kg/min	Contraindicated in high-output cardiac failure, congenital optic atrophy. Anemia and liver disease at risk of cyanide toxicity: acidosis, tachycardia, change in mental status, almond smell on breath. Risk of thiocyanate toxicity with renal disease: psychosis, hyperreflexia, seizure, tinnitus. Cautious use with increased intracranial pressure. Do not use maximum dose for more than 10 minutes. Crosses the placenta.
Nitroglycerin Directly interacts with nitrate receptors on vascular smooth muscle Primarily dilates venous bed Decreases preload	Use with symptoms of cardiac ischemia, perioperative hypertension in cardiac surgery Initial dose: 5 μg/min Maximum dose: 100 μg/min	Contraindicated in angle-closure glaucoma, increased intracranial pressure. Blood pressure decreased secondary to decreased preload, cardiac output—avoid when cerebral or renal perfusion compromised. Caution with right ventricular infarct.
Labetalol Beta- and alpha-adrenergic blockade Alpha:beta-blocking ratio is 1:7	Onset of action 2–5 minutes, duration 3–6 hours Bolus 20 mg, then 20–80 mg every 10 minutes for maximum dose 300 mg Infuse at 0.5–2 mg/min	Avoid in bronchospasm, bradycardia, congestive heart failure, greater than first-degree heart block, second/third trimester pregnancy. Use caution with hepatic dysfunction, inhalational anesthetics (myocardial depression). Enters breast milk.
Esmolol Cardioselective beta-1-adrenergic blocking agent	Use with aortic dissection Use during intubation, intraoperative, and postoperative hypertension Onset of action 60 seconds, duration 10–20 minutes 200–500 μg/kg/min for 4 minutes, then infuse 50–300 μg/kg/min	See labetalol. Not dependent on renal or hepatic function for metabolism (metabolized by hydrolysis in red blood cells).
Fenoldopam Postsynaptic dopamine-1 agonist; decreases peripheral vascular resistance; ten times more potent than dopamine as vasodilator	May be advantageous in kidney disease, increases renal blood flow, increases sodium excretion, no toxic metabolites Initial dose: 0.1 μg/kg/min, with titration every 15 minutes No bolus	Contraindicated in glaucoma (may increase intraocular pressure) or allergy to sulfites; hypotension, especially with concurrent beta-blocker. Check serum potassium every 6 hours. Concurrent acetaminophen may significantly increase blood levels. Dose-related tachycardia.
Hydralazine Primarily dilates arteriolar vasculature	Primarily used in pregnancy/eclampsia Dose: 10 mg every 20–130 minutes; maximum dose 20 mg Decreases blood pressure in 10–20 minutes Duration of action 2–4 hours	Reflex tachycardia; give beta-blocker concurrently. May exacerbate angina. Half-life 3 hours, affects blood pressure for 100 hours. Depends on hepatic acetylation for inactivation.
Phentolamine Alpha-adrenergic blockade	Used primarily to treat hypertension from excessive catecholamine excess (e.g., pheochromocytoma) Dose: 5–15 mg Onset of action 1–2 minutes, duration 3–10 minutes	Beta-blockade is generally added to control tachycardia or arrhythmias. As in all catecholamine excess states, beta-blockers should never be given first, as the loss of beta-adrenergically mediated vasodilatation will leave alpha-adrenergically mediated vasoconstriction unopposed and result in increased pressure.
Nicardipine Dihydropyridine calcium channel blocker; inhibits transmembrane influx of calcium ions into cardiac and smooth muscle	Onset of action 10–20 minutes, duration 1–4 hours Initial dose: 5 mg/h to maximum of 15 mg/h	Avoid with congestive heart failure, cardiac ischemia. Adverse effects include tachycardia, flushing, headache.
Clevidipine Short-acting dihydropyridine calcium channel antagonist[47]	Initial dose: 1 mg/h; can be increased to 21 mg/h	Reduces blood pressure without affecting cardiac filling pressures or causing reflex tachycardia. It has been endorsed as first-line treatment option for acute ischemic stroke
Enalaprilat Angiotensin-converting enzyme inhibitor	Onset of action 15–20 minutes, duration 12–24 hours Dose: 1.25–5 mg every 6 hours	Response not predictable, with high renin states may see acute hypotension. Hyperkalemia in setting of reduced glomerular filtration rate. Avoid in pregnancy.
Trimethaphan Nondepolarizing ganglionic blocking agent; competes with acetylcholine for postsynaptic receptors	Used in aortic dissection Dose: 0.5–5 mg/min	Does not increase cardiac output. No inotropic cardiac effect. Disadvantages include parasympathetic blockade, resulting in paralytic ileus and bladder atony and development of tachyphylaxis after 24–96 hours of use.

no consensus on the most effective antihypertensive medications in the setting of a CNS insult and no large randomized trials demonstrating the superiority of a given agent. Rather, the choice of antihypertensive therapy should be individualized to the patient and clinical setting. With the availability of newer agents such as nicardipine, clevidipine, and fenoldopam, most authors now caution against the use of nitroprusside, which can increase intracranial pressure (ICP) and has a low safety margin. Vasodilators increase blood volume and therefore have the potential to increase ICP. Animal and human studies in the setting of a normal ICP show no effect of nitroprusside on ICP.[27–29] However, in studies on animals and humans with preexisting increased ICP, nitroprusside further increased the ICP, likely reflecting vasodilatation on the background of decreased cranial compliance.[37–41] When sodium nitroprusside is contraindicated, other treatment options include labetalol and nicardipine. Fenoldopam, which is an agonist of the vasodilator dopamine-1 receptor, shares with nitroprusside a rapid onset and short duration of action. In addition, in contrast to nitroprusside, fenoldopam increases renal blood flow, induces natriuresis, and produces no toxic metabolites.[42–46]

Malignant Hypertension

As noted earlier, malignant hypertension is a specific syndrome characterized by markedly elevated pressures in conjunction with hypertensive neuroretinopathy. Funduscopic examination often reveals flame-shaped hemorrhages, cotton-wool spots, or papilledema. Malignant hypertension is also associated with nephropathy, encephalopathy, microangiopathic hemolytic anemia, and cardiac ischemia. Untreated malignant hypertension is a rapidly fatal disorder, with a mortality of more than 90% within 1 year, as reported in a classic series by Kincaid-Smith and colleagues.[8] In this series, deaths were the result of renal failure (19%), congestive heart failure (13%), renal failure plus congestive heart failure (48%), stroke (20%), and myocardial infarction (1%). More contemporary studies report 7%–15% mortality over 5 years in patients with treated malignant hypertension compared with 2.5% in matched hypertensive controls.[48,49] In these cohorts, patients with malignant hypertension had a more favorable cardiovascular risk profile compared with hypertensive controls but a higher prevalence of renal insufficiency.[48,49]

Aggressive therapy to prevent progressive ischemic injury in malignant hypertension is critical. Nitroprusside had been the preferred agent; however, because of concerns related to increased ICP, cyanide toxicity in the setting of anemia or liver disease, thiocyanate toxicity in the setting of renal failure, and the availability of the newer agents, its utility has decreased over the years. A number of parenteral agents, including fenoldopam and nicardipine, have been used as successful alternatives to nitroprusside. If nitroprusside is used, thiocyanate levels should be monitored and the duration of therapy kept to less than 72 hours whenever possible. Fenoldopam has no toxic metabolites and may protect renal function.[42–46] Premature discontinuation of parenteral therapy may cause rebound hypertension. Oral therapy is usually started after the pressure has been stabilized on parenteral therapy, and the latter is then slowly weaned.

Renal failure is common with malignant hypertension, and, in a vicious cycle, the renal failure exacerbates the hypertension. Aggressive treatment can arrest and reverse renal damage. Because the arteriolopathy of malignant hypertension includes fixed anatomic lesions, initial lowering of blood pressure may worsen renal function. Dialysis may be required in patients presenting with a creatinine greater than 4.5 mg/dL.[50] In the majority of patients, renal function begins to improve after 2 weeks of therapy. Of the patients who require dialysis, 50% will regain sufficient function to discontinue dialysis.[51] Recovery of renal function is predicted when the combined length of both kidneys is 20.2 cm or more but is felt to be unlikely when the length is 14.2 cm or less.[52] The mean time to recovery is approximately 2–3 months, but recovery after up to 26 months has been reported.[53] In patients with malignant hypertension secondary to glomerulonephritis, eventual deterioration to ESRD may occur despite blood pressure control.[54] In contrast, renal function tends to remain well preserved in patients without underlying glomerulonephritis if the blood pressure is well controlled.

Hypertensive Encephalopathy

In hypertensive encephalopathy, the MAP exceeds the limits of autoregulation, and brain edema develops from extravasation of plasma proteins. If hypertensive encephalopathy is untreated, coma and death may follow.[55] The challenge of hypertensive encephalopathy is appropriate lowering of blood pressure in the setting of CNS ischemia and edema. The hallmark of hypertensive encephalopathy is improvement within 12–24 hours of adequate blood pressure reduction. The MAP should be cautiously reduced by no more than 15% over 2–3 hours. Neurologic complications have been reported from reductions in MAP of 40% or more.[56]

Hypertensive encephalopathy is one of the medical conditions believed to cause reversible posterior leukoencephalopathy, a condition that results from reversible vasogenic subcortical edema without infarction.[30,31] This syndrome is characterized by headache, decreased alertness, changes in behavior including confusion and diminished speech, seizures, and alterations in visual perceptions. It is rapidly reversible with lowering of the blood pressure.[30,31] An MRI examination shows characteristic findings, including white matter edema in the posterior cerebral hemispheres.[30]

There is a growing literature supporting a shared pathologic process between hypertensive encephalopathy and eclampsia. Both syndromes have the same clinical features and imaging findings. Eclampsia during pregnancy, in addition to postpartum eclampsia, has also been associated with reversible posterior leukoencephalopathy.[30,31]

In previously normotensive patients, including those with eclampsia, blood pressure should be normalized. If the mental status worsens with treatment, the pressure should be allowed to increase until neurologic symptoms resolve and then be reduced to within the normal range over several days to allow restoration of autoregulation.

Ischemic Cerebral Infarction

When the CPP decreases below the level of autoregulation, ischemia develops. In response, there may be a marked elevation in arterial blood pressure to maintain perfusion, which tends to spontaneously return to baseline 24–48 hours after the acute event. Thus treatment of acutely increased blood pressure may not be required. After an ischemic cerebrovascular accident, it is also important to consider other causes that may contribute to an increase in blood pressure, including a full bladder, nausea, pain, preexisting hypertension, hypoxia, or increased ICP. Oftentimes, simply calming the patient, treating the pain, and relieving a full bladder may reduce the blood pressure.

Data from animal studies show that in the area surrounding the ischemic infarct, there are "neurons at risk" that rely on collateral circulation to maintain perfusion.[57] These neurons are nonfunctional but not dead, a phenomenon referred to as *ischemic penumbra,* and they can potentially be rescued by reperfusion.[58] The degree to which this occurs in humans is not known. In addition, in acute stroke, autoregulation is impaired, and CBF is therefore not preserved in a predictable manner. As a result of these changes, acute reductions in blood pressure could potentially increase the area of infarct, resulting in severe clinical consequences.

Comprehensive guidelines for the treatment of stroke recommend that for patients determined to be candidates for administration of

intravenous recombinant tissue plasminogen activator, the blood pressure must be reduced if the SBP is >185 mm Hg or the diastolic blood pressure is >110 mm Hg, and the patient must be carefully monitored before, during, and after administration of this compound. The same blood pressure criteria have been used in recent trials examining the effect of thrombectomy with or without prior thrombolysis.[59–61] Thrombolytic therapy is contraindicated if the blood pressure is >185/100 mm Hg.[62]

Questions remain as to how to manage individuals with ischemic stroke who are not candidates for thrombolysis. There are no good data from randomized controlled trials to guide blood pressure management. A prospective observational study analyzing the impact of blood pressure lowering in the setting of ischemic stroke in 1092 patients suggested an improved outcome at 3 months with modest reductions in SBP between 10 and 27 mm Hg. However, the authors noted that the benefit of blood pressure reduction waned with age. If the systolic pressure was lowered by more than 27 mm Hg, the odds ratio for a poor outcome at 3 months increased more than 5-fold at age 70–76 years, nearly 10-fold for 76–80 years, and nearly 15-fold in patients older than 80 years.[63] Moreover, recently published randomized controlled studies, where patients were enrolled as long as 30–48 hours after stroke onset, do not show any significant difference in mortality and functional outcome with aggressive hypertension treatment.[33,34] In the absence of any definitive data, the current recommendation is that if there is no indication for acute lowering of the blood pressure (e.g., acute ischemic damage to vital organs such as cardiac ischemia or aortic dissection), then the threshold for treatment should be a SBP over 220 mm Hg or a diastolic blood pressure over 120 mm Hg, with the aim to lower the blood pressure 15%–25% over the first 24 hours in the acute phase of ischemic stroke.[62]

Subarachnoid Hemorrhage

Approximately 10% of cerebrovascular accidents are caused by subarachnoid hemorrhage, which remains a devastating entity with a mortality rate of 50%–60% at 30 days and a 50% dependency rate in survivors.[64] Subarachnoid hemorrhage increases ICP and decreases cerebral perfusion, causing global ischemia. Complications include an ICH or the development of hydrocephalus. Management of these patients is significantly different from those with ischemic stroke. In contrast to ischemia, intracranial bleeding induces intense vasospasm in neighboring vessels 4–12 days after the initial bleed, increasing the risk for significant cerebral ischemia. The mental status evaluation may be used to guide therapy, with an intact mental status implying adequate cerebral perfusion.

Markedly elevated pressures increase the risk of rebleeding. The goal is a 20%–25% reduction in blood pressure over 6–12 hours, but not to less than 160–180/100 mm Hg.[65] Labetalol and nicardipine are the preferred agents, as they have no significant adverse effects on ICP or CPP.[4] There are clinical data to show that treatment with oral nimodipine within 4 days of the acute event decreases vasospasm and cerebral ischemia.[46] Nimodipine may also directly protect against ischemic damage to nerve cells by blocking calcium uptake into cells.

Intracerebral Hemorrhage

ICH accounts for 10%–20% of all strokes and affects more than 1 million people worldwide annually.[66,67] Hypertension is a major risk factor; 75% of affected individuals have preexisting hypertension.[68] Although patients with ICH may present with nausea, vomiting, change in mental status, hypertension, headache, and a focal neurologic examination, the definitive diagnosis must be made by neuroimaging. Unlike ischemic stroke, where blood pressure generally returns to normal within 24–48 hours, in ICH, the most rapid decline in blood pressure occurs in the first 24 hours, but it may remain elevated for 7–10 days.[58] The hematoma compresses normal tissue, creating an area of ischemia, increasing ICP, and further decreasing CPP. Autoregulation is altered, making cerebral perfusion critically dependent on systemic blood pressure.[69]

There is no clear consensus on the appropriate treatment of hypertension in the setting of acute ICH. The central issue is whether aggressive lowering of blood pressure reduces the risk of intracerebral bleeding without disrupting blood flow to collateral areas. Some argue that decreasing blood pressure lowers the risk of hemorrhage extension, edema, and associated systemic complications, particularly when SBP exceeds 200 mm Hg, a level associated with hematoma growth in some studies.[66,68,69] A retrospective analysis of 76 patients with ICH and hypertension showed that maximum SBP was significantly associated with hematoma enlargement, particularly if the SBP was ≥160 mm Hg.[70] The greatest risk of hematoma extension is in the first few hours after the initial result and can occur in up to a third of affected individuals.[71,72] Others argue that not treating hypertension allows continued perfusion of areas at risk from low blood flow.[69] Taking these factors into account, two recent randomized controlled trials, INTERACT2 and ATACH2, evaluated the impact of rapid lowering of elevated blood pressure within 6 hours or 4.5 hours of symptom onset, achieved over 1 hour, on death and disability in patients with ICH and SBP between 150 and 220 mm Hg or more than 180 mm Hg, respectively.[35,36] The mean minimal achieved SBP was 150 mm Hg and 126 mm Hg, respectively, in the INTERACT2 and ATACH2 trials. Although there was no significant reduction in death and disability in the two trials, patients assigned to intensive treatment had improved functional outcomes at 3 months in INTERACT2 and worse renal adverse events in ATACH2.[35,36]

The recommendation is as follows for treatment of hypertension in ICH[73]: (1) If there is no suspected elevation of the ICP and the SBP is 150–180 mm Hg, consider aggressive lowering of SBP to 140 mm Hg. (2) In the setting of suspected ICH, ICP should be monitored and consideration given to aggressive lowering of the blood pressure with continuous or intermittent intravenous medication when the SBP is over 180 mm Hg or the MAP is over 130 mm Hg, keeping the CPP above 60–80 mm Hg. (3) Aggressive lowering of blood pressure using intravenous medication and blood pressure monitoring every 5 minutes should be considered when the SBP is over 220 mm Hg or the MAP is over 150 mm Hg. The optimal goal blood pressure is uncertain, but an SBP of 140–160 mm Hg is a reasonable target.

There is no consensus on the agent of choice. Concern revolves around the impact of different antihypertensives on ICP. Common to all agents is a decrease in MAP and a decrease in CPP. Vasodilating agents may increase CBF and in the setting of decreased cranial compliance may potentially increase ICP, further decreasing CPP.[40,69] The combination of decreased cerebral compliance, decreased CBF, and altered autoregulation—as occurs in chronic hypertension—makes the administration of any antihypertensive agent potentially dangerous. No large randomized studies are available to guide therapy. Combination alpha- and beta-blockers are recommended when antihypertensive treatment is indicated in ICH. Risks of this therapy include worsening of bradycardia associated with the Cushing response. However, in the setting of normal cranial compliance and an increased ICP, vasodilators are probably safe. Because of the very high levels of circulating catecholamines with an intracerebral bleed, beta-blockade is added when vasodilator therapy alone is ineffective.

Head Trauma

Head trauma complications include skull fractures, epidural hematomas, subdural hematomas, intracerebral hematomas, and diffuse axonal damage. With trauma, there is often edema. Acute increases in ICP

are initially prevented by flow of blood and cerebrospinal fluid (CSF) from the cranial vault. However, with increasing edema, ICP eventually increases. In most trauma centers, ICP monitoring has become the standard of care.[74] Anywhere from 31% to 61% of patients with a closed head injury may have defective autoregulation.[75] If autoregulation is intact, increasing the MAP will cause vasoconstriction and produce no change in ICP. With altered autoregulation, increasing the MAP may cause vasodilatation, increasing blood volume and leading to edema and increased ICP. The goal is to maintain a minimum CPP of 70 mm Hg and an MAP above 90 mm Hg. If an antihypertensive agent is needed, a major consideration is its impact on ICP. A combination alpha- and beta-blocker or nicardipine may be preferred when there is decreased intracranial compliance and increased ICP.[76,77] In the absence of ICH, vasodilators may be preferred.

Aortic Dissection

Aortic dissection begins with a tear in the intima of the aorta that is propagated by the aortic pulse wave. Myocardial contractility, heart rate, and blood pressure contribute to the aortic pulse wave. There are two types of aortic dissections: type A and type B. Type A dissections are often associated with a tear in the intima of the proximal aorta next to a coronary artery and may extend to the aortic arch.[78] Type B dissections occur in the descending aortic arch and usually begin with an intimal tear next to the subclavian artery.[79] Risk factors for dissection include advanced atherosclerosis, Marfan syndrome, Ehlers-Danlos syndrome, and coarctation of the aorta.[80] Symptoms occur as the expanding hematoma causes pressure on the vasculature. This may cause myocardial infarction, stroke, spinal cord or bowel infarction, and acute renal failure. Kidney ischemia may develop, leading to refractory hypertension.[81] Dissection to the aortic root can precipitate acute aortic insufficiency, and rupture of the ascending aorta leads to hemopericardium and tamponade.[82]

Both types of dissections may present with severe, often tearing pain in the chest, back, or abdomen, accompanied by diaphoresis, nausea, or vomiting. Dissection is often, but not always, associated with hypertension.[83] Discrepancies in peripheral pulses may be observed. Chest pain is reportedly present in only half of individuals with type B dissections.[84] The diagnosis may be confirmed with computed tomography (CT) or MRI. Multiplane transesophageal echocardiography is also used. Type A dissections usually require surgery to prevent the catastrophic consequences of great vessel occlusion, aortic insufficiency, or tamponade. Type B dissections may usually be treated medically[85,86] unless there is rupture, in which case open or endovascular repair is indicated. A recent meta-analysis suggested that endovascular repair may be preferred.[85]

Treatment for both type A and type B dissections is initiated based on clinical suspicion alone, given the high mortality associated with this entity. The first goal of treatment is to decrease myocardial contractility and heart rate with a beta-blocking agent. Reasonable initial targets are a heart rate less than 60 beats per minute and an SBP between 100 and 120 mm Hg. Esmolol has advantages in the acute setting because of its short half-life and ability to titrate to effect. Next, the blood pressure is reduced to the lowest tolerable level until pain is relieved. Relief of pain suggests arrest of ongoing aortic dissection. In addition to beta-blockade, vasodilators may be required to control blood pressure. The most established agent has been nitroprusside; however, nicardipine, nitroglycerin, and fenoldopam are appropriate for this situation.[87] Prior treatment with beta-blockade prevents reflex cardiac stimulation and a potential increase in the aortic pulse wave seen with nitroprusside. Even normotensive individuals should be treated with antihypertensive medications to keep the heart rate and shear forces low.

Pulmonary Edema

Many patients who present with pulmonary edema have long-standing antecedent hypertension with concentric left ventricular hypertrophy and well-preserved systolic contraction.[88,89] They develop acute diastolic dysfunction in response to abrupt increases in cardiac afterload because of increased systemic blood pressure.[90] With poor diastolic relaxation, the left ventricle requires markedly elevated filling pressures, leading to pulmonary venous hypertension and edema. The therapeutic goal is to decrease afterload, improve diastolic relaxation, and decrease pulmonary pressure. Vasodilators are the agents of choice, as they improve diastolic relaxation and lower pulmonary venous pressure.[91] A beta-blocker may also be used. Nitroprusside is often used because it reduces preload and afterload, improving left ventricular function and reducing myocardial oxygen demand. Modest decreases in pressure improve symptoms markedly. In less emergent settings, ACE inhibitors or calcium channel antagonists have been shown to improve diastolic function and cause regression of concentric ventricular hypertrophy.[92]

In patients with left ventricular failure secondary to poor systolic function, vasodilators are the agents of choice. Nitroglycerin is preferred with cardiac ischemia. Nitroprusside may be used in patients refractory to nitrites. Whereas nitroglycerin dilates intercoronary collateral vessels more than small resistance arterioles and improves perfusion of ischemic myocardium, nitroprusside dilates resistance arterioles predominantly, thereby resulting in a potential steal of blood flow away from ischemic areas. Diuretics are used to reduce left ventricular end-diastolic volume.

In the setting of acute myocardial infarction, acute catecholamine release and sympathetic outflow contribute to hypertension. The hypertension usually resolves in a few hours with sedation and pain control alone. Diastolic blood pressures over 100 mm Hg should be treated with nitroglycerin. The pressure is rapidly, but cautiously, reduced to near-normotensive levels; overshoot hypotension can worsen coronary perfusion. Therapy can usually be stopped within 24 hours. There is considerable evidence that early use of beta-blocking agents may reduce ultimate infarct size independent of blood pressure control.[93]

Perioperative Hypertension

Perioperative hypertension is a major risk factor for the development of postoperative hypertension.[94] Whenever possible, it is preferred to postpone elective surgery until the blood pressure has been well controlled over days to weeks. However, when waiting is not an option, lowering the blood pressure to below 180/110 mm Hg before noncardiac surgery is recommended.[94] In patients with chronic hypertension on adequate treatment, oral medications should be taken the morning of surgery. Adequate blood pressure control reduces the risk of bleeding from suture lines, premature graft closure, and ischemic damage to organs at risk.

Induction of anesthesia and surgical stimuli increase sympathetic activity, causing elevated blood pressure both intraoperatively and postoperatively. This response may be exaggerated in uncontrolled hypertension, with decreased use of deep anesthesia and absence of prolonged sedation. As anesthesia continues, there is generally a fall in blood pressure. Rapid and wide fluctuations in blood pressure leading to intraoperative hypotension, stroke, myocardial ischemia, or acute renal failure are more common in individuals with a hypertensive history.

Patients taking hypertensive therapy before surgery should continue treatment after surgery, changing to an equivalent intravenous medication if they are unable to take oral medications. If patients have been on a beta-blocker or clonidine, this medication should be continued postoperatively to prevent rebound hypertension. Effective pain control and avoidance of hypoxia may be sufficient to treat the hypertension. If intravenous medication is necessary, nitroglycerin is preferred for the

post–coronary bypass patient. Fenoldopam, with its impact on increasing renal blood flow, is also recommended, especially in clinical settings where renal ischemia is a risk. Clevidipine has been gaining popularity in this setting because of its rapid onset and short duration of action with limited effect on cardiac preload and output. However, there is limited experience with this drug, and cost is an issue.[95]

Catecholamine-Associated Hypertension

Hypertensive emergency related to excess catecholamine secretion can result from the ingestion of sympathomimetic agents such as cocaine; amphetamines; phencyclidine, phenylpropanolamine (diet pills); decongestants such as ephedrine and pseudoephedrine; and other agents, including atropine, ergot alkaloids, and tricyclic antidepressants. It may also be caused by tyramine ingestion in conjunction with monoamine oxidase (MAO) inhibitor therapy, autonomic dysfunction, withdrawal from certain antihypertensive medications, and pheochromocytoma (Box 78.4). Critically elevated pressures can result and cause myocardial infarction, aortic dissection, and stroke.

Pheochromocytoma is a rare cause of hypertension.[96] Excess catecholamine secretion by the tumor results in a sustained elevation of blood pressure in the majority of cases, and peripheral catecholamine uptake and storage lead to paroxysmal symptoms when the catecholamines are released in response to stimuli. Symptoms of pheochromocytoma include headache, palpitations, hypertension, anxiety, abdominal pain, and diaphoresis. Patients may present with orthostatic changes in blood pressure, a clue to the diagnosis.[97] For the patient with hypertensive emergency, the treatment of choice is the short-acting parenteral alpha-antagonist phentolamine. After blood pressure reduction, beta-blockade is generally added to control tachycardia or arrhythmias. As in all catecholamine excess states, beta-blockers should not be used as initial therapy. Loss of beta-adrenergically mediated vasodilatation leaves alpha-adrenergically mediated vasoconstriction unopposed and results in increased pressure. An oral regimen of the nonselective alpha-antagonist phenoxybenzamine can be used in less critical situations. Labetalol has been effective in treating hypertension related to pheochromocytoma in selected patients. However, as its beta-blockade exceeds its alpha-blocking effect, severe hypertension has been reported.[98]

Gestational Hypertension, Preeclampsia, and Eclampsia

Gestational hypertension is defined as an SBP of at least 140 mm Hg and a diastolic blood pressure of at least 90 mm Hg on two separate blood pressure measurements done 6 hours apart. It occurs after 20 weeks of pregnancy in patients known to previously be normotensive.[99] Up to 50% of these women develop preeclampsia if gestational hypertension develops before 30 weeks of gestation. *Preeclampsia* is defined as gestational hypertension with 300 mg or more of protein on a 24-hour urine (urine dipstick 1+). A 24-hour urine is necessary because dipstick urine protein correlates poorly with 24-hour urine protein in gestational hypertension.[100] Preeclampsia should also be suspected in patients with hypertension developing after 20 weeks' gestation and is associated with nausea, vomiting, cerebral symptoms, abnormal liver function tests, and thrombocytopenia, even in the absence of proteinuria. Preeclampsia develops in 5% of all pregnancies and occurs twice as often in primigravid versus multigravid women.[101] Preeclampsia also appears in women with a history of multiple pregnancies but with a new partner.[101] In the setting of molar pregnancy, it is seen in up to 70% of individuals.[102] During normal pregnancy, blood pressure is initially decreased and then slowly rises toward the normal range during the third trimester. In preeclampsia, intravascular volume is low despite peripheral edema, and the renin–angiotensin system is activated. Progression to seizures defines eclampsia and may occur with diastolic pressures of as low as 100 mm Hg. Clinical treatment includes bedrest and parenteral magnesium.

With regard to hypertensive treatment in pregnancy, the optimal blood pressure has not been defined; however, emerging evidence is suggesting to individualize treatment target decisions taking other risk factors into account.[101a] The goal is to prolong the pregnancy until the fetus can be delivered and reduce maternal complications. In the case of mild preeclampsia, there are no large studies to guide therapy.[101] With more severe preeclampsia, treatment is given to prevent cerebral hemorrhage. The recommendation is to initiate antihypertensive therapy when the SBP is above 160 mm Hg or the diastolic blood pressure is above 110 mm Hg. Intravenous labetalol and nicardipine have been shown to be a safe and effective treatment to keep the SBP 140–155 mm Hg and the diastolic blood pressure 90–105 mm Hg.[101] Treatment with hydralazine is no longer recommended, as it has been associated with adverse perinatal outcomes.[103] A good blood pressure control has been reported with the use of oral nifedipine. Fewer doses were required and less time needed to achieve control, and the adverse-effect profile was similar to intravenous labetolol.[104] In an updated opinion, the American College of Obstetricians and Gynecologists Committee added oral nifedipine as a first-line therapy.[105] Concern for neuromuscular blockade and severe hypotension with the contemporaneous use of nifedipine and magnesium sulfate were not substantiated in a large retrospective review.[106] However, because both drugs are calcium antagonists, careful monitoring is advisable. Nitroprusside should be avoided because of the risk of cyanide toxicity in the fetus. ACE inhibitors should also be avoided because of their potential impact on the fetal kidney.

BOX 78.4 Tyramine-Containing Foods

Chianti wine
Chicken liver
Soy sauce
Yeast
Avocados
Fermented sausage
Bananas
Canned figs
Coffee
Certain beers

Other Hypertensive Situations

The renal crisis of scleroderma is an aggressive form of malignant hypertension in which proliferative endarteritis precedes hypertension. Ischemic-induced activation of the renin–angiotensin system causes the hypertension. The incidence of this condition among patients with scleroderma ranges from 8% to 13%, and it is more common among Blacks.[107] Progression to ESRD occurs in 1–2 months without treatment. Aggressive pressure control with ACE inhibitors leads to a long-term survival of about 50%–70%.[108]

Hypertension is a feature of both primary and secondary antiphospholipid antibody syndromes, occurring in up to 93% of patients.[109] Malignant hypertension occurs in this syndrome secondary to both microvasculopathy and emboli to the renal artery. Antihypertensive treatment is similar to that for malignant hypertension. Successful treatment outcomes have been reported with anticoagulation.[109]

One-fourth of patients with extensive second- or third-degree burns develop severe hypertension in the first few days, likely the result of high levels of circulating catecholamines and renin. Nitroprusside

and phentolamine (in countries where it is still available) are other treatments.

Drugs that inhibit the vascular endothelial growth factor pathway have been approved for use in several malignancies. Its increased use has shown an increased incidence in proteinuria and hypertension, which can be severe and associated with acute end-organ damage.[110,111] There is some evidence that renin–angiotensin system blockade and a low-sodium diet were helpful in controlling blood pressure.[112]

Patients with transverse spinal cord lesions at the T6 level or higher, including patients with Guillain-Barré syndrome, have dysreflexia in which noxious stimuli in dermatomes below the level of the lesion trigger a massive sympathetic discharge. This leads to severe hypertension, bradycardia, diaphoresis, and headache. In 90% of patients, distention of the bladder or bowel causes the dysreflexia, and prompt decompression leads to resolution of hypertension.[113] Drugs that have been used successfully in treating this condition include nitroprusside, phentolamine, and labetalol.

HYPERTENSIVE URGENCY

Hypertensive urgency refers to patients in whom blood pressure is severely elevated, but based on detailed history, physical examination, and laboratory evaluation, there is no evidence of acute end-organ damage related to the current episode of hypertension, although there may be evidence of previous hypertension-induced end-organ damage. Although long-term control of blood pressure in this setting can prevent complications resulting from stroke, myocardial infarction, or congestive heart failure, there is no evidence that acute reduction of blood pressure results in any improvement in short- or long-term prognosis. Unfortunately, the term *urgency* is a misnomer and has led to overly aggressive management of many patients. Aggressive treatment with intravenous drugs or even oral agents, such as clonidine or nifedipine, to rapidly lower blood pressure can lead to cumulative effects causing hypotension, sometimes after discharge from the emergency room. A recent retrospective cohort analysis reported prevalence of hypertensive urgency in 4.6% of office visits. Referrals to the emergency department compared with home management were associated with more hospitalization but no difference in major adverse cardiovascular events at 7 days, 1 month, or 6 months.[114] A more appropriate clinical term to describe this condition is *severe uncomplicated hypertension,* because there is no need for urgent reduction of blood pressure, as would be required in patients with true hypertensive emergencies (Box 78.5).

The treatment of choice is gradual pressure reduction over a few days in the outpatient setting. The choice of antihypertensive agent is based on ease of administration and side-effect profile rather than on rapid blood pressure reductions. Frequently, restarting a previously effective regimen is all that is necessary. It is critically important to follow these patients over the next 24–48 hours to ensure the blood pressure is appropriately reduced. Although medicolegal issues may pressure physicians into loading these patients with medication to observe on-the-spot control of their blood pressure, this practice has been questioned as having no clear rational scientific basis.

BOX 78.5 Severe Uncomplicated Hypertension

Severe hypertension (diastolic blood pressure >115 mm Hg) in association with one or more of the following:
Chronic renal failure
Chronic congestive heart failure
Stable angina
Previous myocardial infarction
Transient ischemic attacks
Previous cerebrovascular accident

KEY POINTS

- Hypertension crisis is defined as new or progressive end-organ damage associated with high blood pressure and requires immediate blood pressure control over the course of minutes to hours.
- Hypertensive urgency defines a very high blood pressure in the absence of end-organ damage, is a misnomer, and does not require acute reduction of blood pressure; rather, acute aggressive reduction could be harmful.
- The pathophysiology of hypertensive emergency is not clear but is proposed to involve a sudden rise in blood pressure causing vascular myogenic response and endothelium damage resulting in an increase in vasoactive hormones and vessel damage (fibrinoid necrosis and myointimal proliferation). This sets up a vicious cycle of an increase in peripheral vascular resistance and worsening of hypertension.
- Management of hypertension emergencies begins with careful assessment of blood pressure, end-organ damage (most of the time brain, heart, and kidney), identification of reversible insults, and institution of parenteral antihypertensives in most circumstances.
- The choice of antihypertensives and level of blood pressure reduction depend on the etiology and type of hypertensive organ damage.

Pathophysiology and Classification of Shock States

Mark E. Astiz

PATHOPHYSIOLOGY OF SHOCK

Circulatory shock represents a final common pathway of cardiovascular failure. Septic shock is the most common cause of shock followed by cardiogenic and hypovolemic shock.[1] Mortality remains high, particularly for patients with septic and cardiogenic shock, where it approaches 40%.[2,3] From a physiologic perspective, circulatory shock is defined as a syndrome in which blood flow is inadequate to meet cellular metabolic requirements.[4] Clinically, shock is manifested by organ hypoperfusion, which is most evident in the skin and peripheries, kidneys, and brain. The principal signs of circulatory shock are as follows: cool, clammy, and cyanotic extremities; decreased pulses; oliguria with a urine output <0.5 mL/kg/h; and confusion, disorientation, and obtundation.

Mechanisms Underlying Impaired Cardiovascular Performance

The development of shock is related to alterations in the components of the circulatory system that regulate cardiovascular performance. The first component is intravascular volume, which regulates mean circulatory pressures and venous return to the heart. Decreases in intravascular volume limit venous return to the heart and cardiac output. The heart is the second component. Cardiac output is determined by heart rate, contractility, and loading conditions. Abnormalities in rhythm and heart rate may limit cardiac output. Impaired cardiac contractility decreases effective ventricular ejection and compromises stroke volume. Abnormalities in valvular function may also limit cardiac output. The third component is the resistance circuit; it consists of the arteriolar bed, where the major decreases in vascular resistance occur. Arteriolar tone plays an important role in ventricular loading conditions, arterial pressure, and distribution of systemic blood flow. Excessive decreases in arteriolar tone lead to hypotension and limit effective organ perfusion, whereas excessive increases in arteriolar tone impede cardiac ejection by increasing ventricular afterload. Differences in arteriolar tone between organs can result in maldistribution of blood flow and mismatching of blood supply with tissue metabolic demands. The capillaries are the fourth component. They are the site of nutrient exchange and fluid flux between the intravascular and extravascular spaces. Increases in capillary permeability result in tissue edema and loss of intravascular volume. Decreases in capillary cross-sectional area, secondary to either obstruction or impairment in endothelial cell function, compromise nutrient blood flow. The opening of arteriovenous connections, which bypass the capillary network, may play a role in tissue hypoperfusion. The venules are the fifth component. They are the site of the lowest shear stress in the circulatory system and are thus the site most prone to occlusion from alterations in cell rheology. Venular resistance contributes 10%–15% of total vascular resistance. Increases in venular tone increase capillary hydrostatic pressures, thereby promoting the extravascular movement of fluid. The sixth component is the venous capacitance circuit. More than 80% of the total blood volume resides in large-capacitance vessels. Increases in venous tone decrease venous capacitance, redistributing blood volume centrally and thereby increasing venous return to the heart. Decreases in venous tone increase venous capacitance and decrease effective arterial blood volume and venous return. The seventh component is mainstream patency. Obstruction of the systemic or pulmonary circuit impedes ventricular ejection, and venous obstruction limits venous return to the ventricles.

Hemodynamic Assessment

Circulatory performance can be assessed from hemodynamic parameters. A low heart rate may limit cardiac output, whereas an increased heart rate can compromise stroke volumes by limiting ventricular filling times. Bradyarrhythmias indicate structural abnormalities, effects of drugs, hypoxia, or other metabolic stimuli. Severe bradyarrhythmias can also represent reflex-mediated responses, as occurs in cases of severe hemorrhagic shock and acute inferior wall myocardial infarction. Tachyarrhythmias may be the result of underlying cardiac disease or pharmacologic or environmental stimuli. Alternatively, increases in the heart rate may reflect compensatory responses to maintain cardiac output.

In patients with circulatory shock, blood pressure should be monitored using intravascular measurements.[4] Vasoconstriction related to compensatory mechanisms to maintain arterial pressure and the use of pharmacologic agents limits the accuracy of noninvasive measurements. This is particularly true in hypodynamic forms of circulatory failure.

For most vital organs, autoregulatory and neuronal mechanisms maintain blood flow independent of blood pressure at a mean arterial pressure of 60–130 mm Hg. At either higher or lower levels of pressure, blood flow becomes linearly dependent on blood pressure. Diseases such as hypertension can shift this relationship and increase the critical level of arterial pressure required for organ perfusion. Similarly, impaired autoregulatory mechanisms present in a variety of pathologic states expand the range of pressure-dependent blood flow.

The level of arterial pressure is not a reliable indicator of circulatory performance and tissue perfusion.[5,6] In states of hypodynamic circulatory shock such as traumatic injury, cardiac failure, and obstructive shock, hypotension is a late marker of critical hypoperfusion. As cardiac output falls, blood pressure is initially maintained by increases in peripheral vascular resistance largely mediated by the sympathoadrenal system. It is only after these mechanisms have been exhausted that hypotension develops. Accordingly, tissue hypoperfusion may be present despite normal levels of blood pressure as blood flow

is redirected toward more vital organs. Conversely, hypotension may exist without evidence of organ hypoperfusion. In some vasodilated states, increases in cardiac output maintain vital organ blood flow despite decreased levels of arterial pressure.

Filling pressures have traditionally been used as measures of ventricular preload and to guide fluid resuscitation. However these measurements correlate poorly with blood volume, end-diastolic volumes, and fluid responsiveness.[7] Echocardiographic techniques can provide an alternative assessment of chamber size and end-diastolic volumes, whereas fluid responsiveness is best assessed with dynamic measurements that reflect the response of stroke volume to changes in loading conditions. Examples include respiratory variations in pulse pressure, velocity time integral, and stroke volume on mechanical ventilation. Alternatively, changes in stroke volume may be assessed during passive leg raising or after volume challenge.

Cardiac output can be measured by multiple techniques.[4,8] Pulmonary artery thermodilution has been supplanted by less-invasive techniques, including lithium dilution, bioreactance, echocardiography, esophageal Doppler, and arterial pulse contour analysis. Echocardiographic measurements and esophageal Doppler can be used to assess ventricular ejection and provide diagnostic information regarding the presence of pericardial tamponade and valvular function. The response of stroke volume to changes in ventricular loading during fluid infusion is also useful to assess cardiac function. A good response indicates preserved cardiac function, whereas lack of response may be related to either cardiac dysfunction or inadequate fluid volumes. However, the adequacy of cardiac output in meeting tissue metabolic demands must be assessed independently by monitoring indices of tissue perfusion and oxygen metabolism. A low cardiac output may be adequate when metabolic requirements are decreased—for example, in deep sedation or hypothermia. In contrast, an increased cardiac output may not be adequate when metabolic requirements are increased or maldistribution of blood flow exists, such as in septic shock.

Systemic vascular resistance is an indicator of arterial tone; it is calculated from cardiac output and arterial pressure. Increases in systemic vascular resistance are the result of vasoconstriction and represent compensatory mechanisms directed at maintaining blood pressure in the setting of a decreased cardiac output. Excessive increases in vascular resistance increase ventricular afterload and the impedance to ejection. Decreases in vascular resistance are the result of vasodilation, decreases in blood viscosity, or presence of arteriovenous connections. Vasodilation may be pathologic, as occurs in septic shock and liver disease, or it may be adaptive, as occurs in hyperdynamic stress after major surgery and traumatic injury. Venous tone is much harder to assess clinically. In most cases, changes in venous tone parallel changes in arterial tone. Modest increases in central venous pressures in the setting of large-volume infusion and the absence of intravascular volume loss suggest decreased venous tone.

CLASSIFICATION OF SHOCK

Hinshaw and Cox proposed a classification of circulatory shock involving four subsets: hypovolemic, cardiogenic, distributive, and obstructive.[9] This classification can be simplified into two categories with typical hemodynamic profiles (Table 79.1). The first category, hypodynamic shock, includes the hypovolemic, cardiogenic, and obstructive shock subsets. The second category, hyperdynamic shock, includes the distributive shock subset.

The central features of hypodynamic shock are a low cardiac index and a high-resistance vasoconstricted state. Increased oxygen extraction and lactic acidosis usually parallel the decrease in cardiac output. In cases of hypodynamic shock, the development of organ dysfunction is directly related to inadequate global blood flow. Common causes of hypovolemic shock are hemorrhage, dehydration, and massive capillary leak. Acute decreases in blood volume of 25% result in tachycardia and orthostatic hypotension. The loss of 40% of blood volume is associated with severe hypotension and clinical shock. Decreased filling pressures are the hallmark of hypovolemic shock, in contrast to cardiogenic shock in which filling pressures are elevated. Acute myocardial infarction involving 40% or more of ventricular mass is the most common cause of cardiogenic shock. Cardiomyopathies and severe valvular lesions are other important causes of cardiogenic shock. Severe stress may also induce severe reversible cardiac dysfunction. Finally, obstructive shock is most commonly caused by pericardial tamponade, acute pulmonary embolism, and tension pneumothorax. Dynamic obstruction to left ventricular output may also lead to circulatory shock. Because filling pressures are usually increased in these settings (owing to outflow obstruction, impaired ventricular filling, and decreased ventricular compliance), distinguishing between obstructive shock and cardiogenic shock can be difficult.

Hyperdynamic circulatory shock is characterized by a high cardiac index and a low-resistance vasodilated state. Filling pressures may be increased or normal, depending on volume status and myocardial competence. Common causes of hyperdynamic shock include sepsis, anaphylaxis, drug intoxications, spinal shock, and adrenal insufficiency. The underlying hemodynamic defect is maldistribution of blood flow and/or blood volume such that effective nutrient blood flow is compromised. In contrast to hypodynamic shock, oxygen extraction may be normal or decreased despite evidence of hypoperfusion.[10] Direct mediator-related effects coupled with tissue hypoperfusion lead to cellular injury and organ dysfunction in patients with septic shock.

A considerable overlap may exist between these different syndromes. Early in septic and anaphylactic shock, before fluid infusion, a significant hypovolemic component usually exists. Hypovolemia may also be present in a small group of patients presenting with shock secondary to acute myocardial infarction. In the presence of severe

sepsis-related myocardial depression, patients with septic shock can develop a hypodynamic profile. Similarly, patients in cardiogenic shock after myocardial infarction and cardiac surgery may demonstrate significant vasodilation because of the activation of mediator cascades while on cardiopulmonary bypass.[11] Alternatively, dynamic left ventricular outflow obstruction related to systolic anterior movement of the mitral valve may complicate ischemic and stress-related cardiogenic shock.[12]

Progression of Shock

Critical reductions in tissue perfusion elicit a complex set of reflexes that are directed at maintaining cardiac output and arterial pressure.[13] Activation of the sympathetic nervous system increases heart rate and contractility. The release of catecholamines, angiotensin, vasopressin, and endothelins increases arteriolar and venous tone, thereby increasing arterial blood pressure and shifting blood volume from the capacitance vessels to the central circulation. In addition, blood flow is redirected from skeletal muscle, subcutaneous tissue, and splanchnic circulation to the heart and brain. Vasopressin and activation of the renin–angiotensin system serve to enhance water and sodium retention, thereby protecting intravascular blood volume.

Progression of the shock state is marked by further declines in blood pressure that compromise coronary perfusion and cardiac performance. Increases in peripheral vascular resistance increase afterload and impede left ventricular ejection. Damage-associated molecular patterns are activated, initiating a systemic inflammatory response. Terminal phases of shock are marked by the development of an endotheliopathy with resulting damage to the endothelial glycocalyx, breakdown in paracellular tight junctions, and increase in microvascular permeability.[14] Microvascular vasomotor dysfunction is marked by loss of arteriolar tone with paradoxically increased venular resistance. Leukostasis, impaired erythrocyte rheology, platelet activation, and activation of the coagulation cascade further impair microvascular blood flow.

This pathophysiology is altered in hyperdynamic forms of circulatory failure such as septic shock, in which inflammatory mediators released by interaction of microbial-associated molecular patterns with pattern-recognition receptors play a prominent role.[15] These patients are characterized by arterial and venous vasodilation coupled with an increased cardiac output. The influence of vasodilatory substances such as nitric oxide and prostacyclin predominates over the effects of endogenous and exogenous vasopressor substances. In some forms of vasodilatory shock, inappropriately low levels of vasopressin, cortisol, and angiotensin II may contribute to refractoriness to catecholamines. Decreases in capillary cross-sectional area, secondary to the interactions of activated leukocytes, platelets, endothelial cells, and activation of the clotting cascade, limit effective nutrient blood flow despite the increase in cardiac output.[16] Concomitant injury to the endothelial glycocalyx and paracellular tight junctions increases microvascular permeability, resulting in loss of intravascular fluid. Progressive hypotension, which is refractory to fluid infusion and vasopressors, results in worsening tissue hypoperfusion, acidosis, and organ failure. A hypodynamic circulation develops as a terminal event.

Oxidative Metabolism in Shock

The primary metabolic defect in circulatory shock is impaired oxidative metabolism with resulting cellular and organ failure. This impairment is most commonly the result of decreases in tissue oxygen supply caused by either global decreases in blood flow or maldistribution of blood flow at a regional or microcirculatory level. Systemic oxygen consumption may initially be increased yet inadequate to meet tissue metabolic requirements; however, the terminal phases of all forms of shock are characterized by decreases in oxygen consumption. In experimental studies, mortality is directly related to the cumulated deficit in oxygen metabolism.[17]

Oxygen delivery is determined by cardiac output, hemoglobin concentration, and arterial oxygen saturation. Under normal circumstances, oxygen consumption is independent of oxygen delivery and cardiac output (Fig. 79.1). Increases in cellular oxygen extraction, from a normal level of 25% to a maximum of level of 80%, maintain oxygen consumption as blood flow is reduced. When oxygen extraction is maximized, a critical level of oxygen delivery (DO_2crit) is reached below which oxygen consumption decreases and anaerobic metabolism ensues. Alterations in vasomotor reflexes caused by sepsis or drugs limit maximal oxygen extraction, resulting in critical tissue hypoxia and anaerobic metabolism at higher levels of oxygen delivery.

Aerobic adenosine triphosphate (ATP) generation is dependent on glycolysis occurring in the cytoplasm and oxidative phosphorylation occurring in the mitochondria (Fig. 79.2). Under anaerobic conditions, ATP generation is limited to the 2 moles of ATP generated in the cytoplasm, compared with the 38 moles of ATP generated aerobically. The decreased entry of pyruvate into the citric acid cycle results in the accumulation of lactic acid and the generation of additional hydrogen ions from the hydrolysis of ATP. Accordingly, the presence of lactic acidosis serves as an indicator of critical cellular deficits in high-energy phosphate metabolism. The normal level of lactate is 0.4–1.2 mEq/L. Levels greater than 1.5 mEq/L are associated with an increased mortality rate in septic shock.[18]

Oxidative metabolism may also be altered by mechanisms independent of tissue hypoperfusion. Indeed, decreased mitochondrial activity in sepsis has been postulated to be potentially adaptive and represent a state of hibernation. Alternatively, inflammatory mediators, including nitric oxide, oxygen radicals, calcium, and tumor necrosis factor, may directly

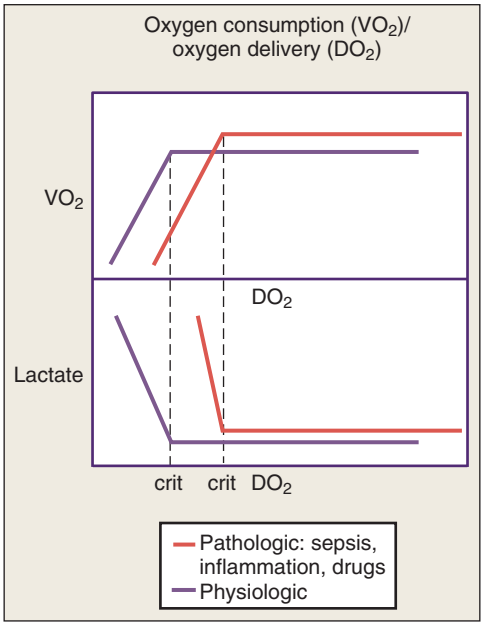

Fig. 79.1 Oxygen consumption–oxygen delivery relationships. Oxygen consumption (VO_2) is independent of oxygen delivery (DO_2) until a critical level of DO_2 is reached at which oxygen extraction is maximized. At that level of oxygen delivery (DO_2crit), VO_2 becomes linearly dependent on DO_2, and anaerobic metabolism manifested by lactic acidosis ensues. This relationship shifts upward and to the right when the ability of the tissues to extract oxygen is impaired because of alterations in the distribution of blood flow.

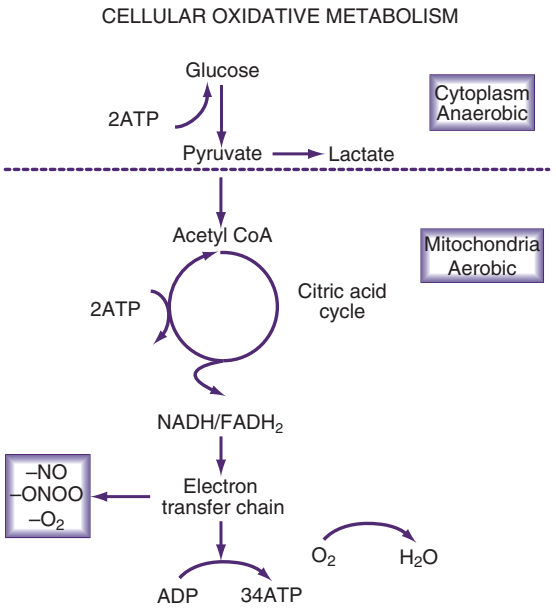

Fig. 79.2 Cellular oxidative metabolism. Glucose is metabolized anaerobically in the cytoplasm and aerobically in the mitochondria under conditions of normal tissue perfusion. Under conditions of shock, high-energy phosphate generation (adenosine triphosphate [*ATP*]) is limited to anaerobic pathways. Nitric oxide (*NO*), peroxynitrite ($ONOO^-$), and superoxide (O_2^-) are potential inhibitors of the electron transfer chain. *ADP,* Adenosine diphosphate; $FADH_2$, reduced flavin adenine dinucleotide; *NADH,* reduced nicotinamide adenine dinucleotide.

impair mitochondrial function. Decreased mitochondrial biogenesis, mitochondrial swelling, increased mitochondrial autophagy, and decreased mitochondrial respiratory complex activity have all been observed in patients with septic shock.[19,20] Similarly, impaired mitochondrial function has been described in animal models of traumatic and hemorrhagic shock. The specific role of mitochondrial abnormalities in organ dysfunction in shock is still being elucidated and could potentially lead to mitochondrial-based therapeutic interventions.[19,20]

The accumulation of tissue carbon dioxide (CO_2) parallels the decrease in oxygen metabolism in circulatory shock.[21] Increases in tissue CO_2 levels are manifested by venous hypercapnia and decreases in venous pH. The resulting widening of the arterial-venous CO_2 gradient is proportional to the degree of circulatory failure.[22] The normal gradient is less than 5 mm Hg, and it increases to 40 mm Hg or more during cardiac arrest. Decreased clearance of CO_2 generated by oxidative processes is responsible for the initial increase in tissue CO_2 levels. With the onset of anaerobic metabolism, a tissue CO_2 excess is generated from the titration of anaerobically derived acids by bicarbonate. The increase in tissue CO_2 levels has been associated with impaired myocardial performance in vitro.

Monitoring Perfusion Failure

Acute circulatory failure can be identified by clinical evaluation focusing on mentation, urine output, and peripheral perfusion. Heart rate, arterial pressure, and cardiac output are important but correlate poorly with survival in critically ill patients.[5,6] The primary difficulty with each of these measures is in the early stages of circulatory failure where compensatory mechanisms may frequently obfuscate the degree of systemic hypoperfusion.[23] Similarly, despite stabilization after initial resuscitative efforts, patients with septic shock and high-risk surgical patients will frequently have evidence of persisting deficits in tissue perfusion that are associated with increased mortality.[5,24] These observations have led to the use of indices of tissue oxygen metabolism as markers of tissue perfusion and the adequacy of resuscitative efforts.

Mixed venous oxygen saturation (SvO_2), measured on blood taken from the pulmonary artery, is used as an index of tissue oxygenation. Venous blood is in equilibrium with the tissues. Mixed venous blood, representing a weighted mean of all the venous effluents, reflects overall tissue oxygenation. Because increased oxygen extraction is the primary compensatory mechanism to maintain oxygen consumption, decreases in SvO_2 are an early marker of compromised tissue perfusion. In cardiogenic shock, SvO_2 tracks cardiac function and systemic perfusion.[2] The same is not true in septic shock and other settings, where the relationship between venous blood and tissue oxygenation is altered by maldistribution of blood flow.[10] In these circumstances, the ability of the tissues to extract oxygen is limited by decreases in effective nutrient flow such that SvO_2 may be normal or increased despite the presence of tissue hypoxia and anaerobic metabolism. Accordingly, although mixed venous desaturation is indicative of tissue hypoxia, normal levels do not preclude tissue hypoperfusion.

Central venous oxygen saturation ($ScvO_2$), measured in samples taken from the superior vena cava and right atrium, serves as an alternative to SvO_2. In critically ill patients, $ScvO_2$ is generally 5% higher than SvO_2; however, the correlation is inconsistent depending, in part, on the location of the tip of the central venous catheter. Although targeting therapy to $ScvO_2$ does not improve outcome in septic shock, persistence of $ScvO_2$ <70% of levels is associated with increased mortality in sepsis and identifies a group of patients that could benefit from efforts to increase oxygen delivery.[25]

Lactate concentration is a useful marker of critical hypoperfusion. Increases in lactate levels indicate the presence of anaerobic metabolism and tissue energy deficits. Although the initial blood level of lactate has prognostic significance, the inability to clear lactate over time is more discriminating and is associated with increased mortality in a broad range of critically ill patients.[26,27] In patients with septic shock, factors other than hypoperfusion may contribute to lactate accumulation. These factors include increased muscle ATPase activity, increased hepatic flux of alanine from skeletal muscle, decreased pyruvate dehydrogenase activity, decreased hepatic clearance of lactate, and dysfunctional mitochondrial respiration. Despite these concerns, increases in lactate concentration are associated with decreases in the intracellular redox potential in patients with septic shock, suggesting that it is a useful marker of cellular energy metabolism.[28]

Oxygen consumption and oxygen delivery are global markers of systemic oxygen metabolism. Oxygen consumption, a measure of overall metabolic requirements, is calculated from cardiac index, hemoglobin, and arterial and venous oxygen saturation. It can also be measured directly from expired gases. Oxygen delivery is calculated from cardiac output, hemoglobin, and arterial saturation; it is a measure of the total amount of oxygen being delivered to the tissues. Although increased values of oxygen consumption and oxygen delivery have been observed in survivors compared with nonsurvivors, considerable overlap exists between the two groups. Efforts to titrate therapy to values associated with survival, "optimal goals," have produced mixed results.[29] These differences, in part, reflect the varying metabolic requirements of individual patients and the heterogeneity in the response of the control and treatment groups to hemodynamic interventions.

The decrease in CO_2 clearance in circulatory shock can be used to monitor ongoing perfusion failure. Widening of the gap between central venous and arterial partial pressure of CO_2 (PCO_2) to >6 mm Hg can be used to identify patients who may not be adequately resuscitated despite $ScvO_2$ >70%.[30] End-tidal CO_2 measurements are useful in monitoring perfusion during cardiopulmonary resuscitation.

Cardiac arrest results in marked decreases in pulmonary blood flow and accompanying decreases in CO_2 excretion. End-tidal CO_2 values move toward zero during arrest and increase with successful resuscitation.[31]

There have been many attempts to use measures of local or regional perfusion as indices of overall systemic perfusion. These are all predicated on the premise that decreased blood flow to specific organs may serve as an early indicator of systemic hypoperfusion. Toe temperature, subcutaneous oxygen tensions, transcutaneous oxygen tension, gastric tonometry, sublingual tonometry, laser Doppler, and near-infrared spectroscopy are some examples of regional measures that did not achieve widespread clinical use. Newer efforts aimed at tissue oxygen monitoring include the use of specialized urinary catheters to track bladder tissue oxygen levels. A recent study revisited the importance of monitoring peripheral tissue perfusion by comparing interventions guided by digital capillary refill time (CRT) with those guided by lactate clearance in patients with septic shock.[32] No significant differences in mortality and organ failure were observed between the two groups. However, lower Sequential Organ Failure Assessment (SOFA) scores and lower mortality in the CRT patients with less severe organ dysfunction suggest that regional measures may be complementary to systemic measures in assessing for underlying tissue hypoperfusion.

An area of current interest is the monitoring of the microcirculation in critically ill patients. Techniques such as orthogonal polarization spectral imaging, sidestream dark-field imaging, and more recently, incident dark-field imaging have been used to directly visualize microcirculatory flow using handheld vital microscopy. Alterations in microcirculatory function have been described in a number of disease states.[33] Decreases in capillary blood flow have correlated with mortality in patients with septic and cardiogenic shock. Using these techniques, evidence of impaired microvascular blood flow has been reported in critically ill patients despite improvement in systemic hemodynamic variables. This incongruence between the response of the macrocirculation and that of the microcirculation may have important clinical implications.[34] Optimal techniques, the most discriminating measurements, and whether titration of therapy to these indices of microcirculatory blood flow will affect the outcome remain to be elucidated.[33]

Organ Failure

The primary causes of organ dysfunction in circulatory shock are ischemic injury, mediator-related organ dysfunction, and reperfusion injury. Ischemic injury occurs when anaerobic metabolism ensues and high-energy phosphate production falls below the level required to maintain cellular pumps and membrane integrity. It is the major factor contributing to organ failure in patients with cardiogenic and hypovolemic shock. The direct effect of inflammatory mediators, coupled with an ischemic injury, plays a major role in organ dysfunction in septic shock. Tumor necrosis factor, nitric oxide, and superoxide radicals are examples of mediators directly affecting cellular and organ function. Reperfusion injury occurs upon restoration of tissue perfusion after an absence of blood flow (Fig. 79.3). The initial injury is related to the release of oxygen radicals, increased membrane permeability, and intracellular calcium accumulation. The later phase involves cytokines, activated neutrophils, endothelial cell dysfunction, and microvascular occlusion.[35] Reperfusion injury may be important in hemorrhagic and traumatic shock; its role in cardiogenic shock and septic shock is less clear.

Cardiac dysfunction is related to ischemia and myocardial necrosis in shock secondary to myocardial infarction. Reperfusion injury may play a role in patients after acute coronary revascularization. Myocardial depressant substances such as nitric oxide and cytokines cause myocardial depression in patients in septic shock and possibly in hemorrhagic shock.[36] Impaired responsiveness to catecholamines and adrenergic receptor downregulation occur in septic and cardiogenic

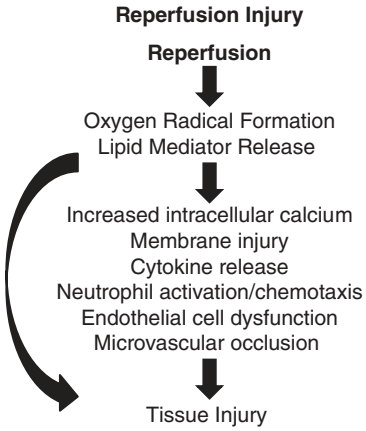

Fig. 79.3 Reperfusion injury. Under ischemic conditions, adenosine triphosphate (ATP) is metabolized to hypoxanthine and xanthine dehydrogenase is converted into xanthine oxidase. During reperfusion, superoxide is produced from hypoxanthine and oxygen by xanthine oxidase. Superoxide and its metabolites produce cellular injury and membrane disruption, resulting in the release of prostanoids and leukotrienes. The lipid mediators and oxygen radicals act as chemoattractants for neutrophils, which injure tissues through the release of elastases, proteases, and additional oxygen radicals.

shock. Increases in pulmonary vascular resistance cause right ventricular failure in patients with pulmonary embolism and may be important in septic shock, particularly when acute respiratory distress syndrome is present.

Respiratory failure frequently complicates circulatory shock. Cardiac failure, fluid overload, and acute lung injury related to the release of inflammatory mediators and activation of neutrophils result in increased lung water and intrapulmonary shunt. Dead space may be increased because of either underlying disease and/or pulmonary vascular endothelial damage in acute lung injury syndromes. Decreased respiratory muscle perfusion, coupled with hypoxia and increased work of breathing, contributes to respiratory muscle failure. In patients with septic shock, inflammatory mediators may also directly impair diaphragmatic activity.[37]

Renal dysfunction in shock is related to multiple mechanisms. Initially, as cardiac output decreases, glomerular filtration is maintained by increases in efferent arteriolar tone. Release of atrial natriuretic peptide related to increased atrial pressures may help protect renal blood flow in patients with cardiogenic shock. As shock progresses, the increases in afferent arteriolar tone result in renal ischemia and acute tubular necrosis. The activation of neutrophils and endothelial cells coupled with tubular epithelial cell injury and intrarenal shunting also plays important roles in renal injury associated with septic shock.[38]

A characteristic pattern that involves centrilobar necrosis and marked transaminase elevation is observed in patients with ischemic hepatic injury associated with hypodynamic circulatory states.[39] Activation of Kupffer cells and release of inflammatory mediators exacerbate ischemic injury in patients in septic and traumatic shock. In septic shock, hepatobiliary transporters and canalicular cell contractility are impaired, resulting in intrahepatic cholestasis. Hepatic metabolic failure and impaired amino acid clearance are also features of septic shock.

Splanchnic mucosal blood flow is compromised early in shock, as blood flow gets redirected to more vital organs Splanchnic hypoperfusion related to shock and the use of vasopressors contribute to the development of stress ulceration, acalculous cholecystitis, intestinal necrosis, and pancreatitis. Loss of the integrity of the intestinal barrier leads to the release of inflammatory mediators into the mesenteric

lymphatics and, less frequently, the translocation of bacteria, which in turn contribute to organ failure.[40]

Thrombocytopenia is observed in a majority of patients with septic shock. The coagulation cascade is activated in septic and traumatic shock by the pathogen and damage-associated molecular patterns.[14] Disseminated intravascular coagulation is marked by impaired fibrinolysis and increased consumption of clotting factors. Clinical manifestations are bleeding and microvascular thrombosis. Large-volume asanguineous fluid resuscitation may unmask these tendencies by additional hemodilution of clotting factors and platelets. The development of hypothermia exacerbates coagulopathies in patients with circulatory shock.

Disorientation and delirium are common in patients in shock. Hypotension, metabolic abnormalities, hypoxia, and medications all contribute to neurologic dysfunction. Alterations in cerebrovascular reactivity and direct toxic effects of inflammatory mediators may also play a role in cerebral injury.[41] Severe hypotension, mean arterial pressure well below 60 mm Hg, can result in ischemic injury of the arterial border zones in the cortex and spinal cord. In some survivors of critical illness, long-term impairment of cognitive function has been reported.

Microvascular blood flow is impaired in all forms of circulatory failure.[14,16,33] The microcirculation is characterized by heterogeneous blood flow and decreased capillary perfusion. Rheologic abnormalities of neutrophils and erythrocytes impede microvascular blood flow. Increased expression of neutrophil integrins, platelet P-selectin, endothelial cell adhesion molecules, and thrombin activation result in cellular aggregation and microvascular obstruction. Decreased endothelial cell nitric oxide synthetase activity impairs normal vasodilatory reflexes and decreases the microvascular response to hypoxia.

Shock is associated with impairment of regulation of immunologic function. Immunosuppressive substances, including interleukin-10, transforming growth factor beta, and adenosine, are released that decrease cellular and humoral immunity. Altered signaling in afferent and efferent neural pathways contributes to impaired immune homeostasis. Dendritic cell- and monocyte-mediated antigen processing is impaired, as is neutrophil function. Apoptosis of lymphocytes, dendritic cells, and monocytes is increased. In addition, expansion of myeloid-derived suppressor cells may contribute to the persistent inflammation, immunosuppression, and catabolism syndrome resulting in recurrent infections and prolonged intensive care unit (ICU) stay.[42]

CLINICAL ASPECTS OF SHOCK

Approach to Circulatory Shock

The approach to patients with circulatory shock involves restoration of cardiopulmonary stability and rapid assessment of the underlying disease process (Fig. 79.4). Patients should be assessed for clinical evidence of organ hypoperfusion. Initial efforts should be directed at achieving a minimal level of blood pressure and ventilation associated with survival. The VIP approach prioritizes these efforts by focusing on *v*entilation, *i*nfusion, and *p*ump activity.[43] Subsequent interventions should be focused on restoration of perfusion and organ function. A systematic approach, which incorporates physiologic endpoints, indices of systemic perfusion, and an algorithm for therapeutic interventions based on the pathophysiology of the underlying shock state, results in the best outcomes.[4] Definitive therapy depends on the cause of the shock state and may require additional diagnostic and therapeutic interventions. These efforts should be pursued in a timely manner and, by necessity, may need to occur concurrently with resuscitative efforts. Finally, deviation from the expected clinical course and response to therapy should prompt a reassessment of the presumed cause of the shock state.

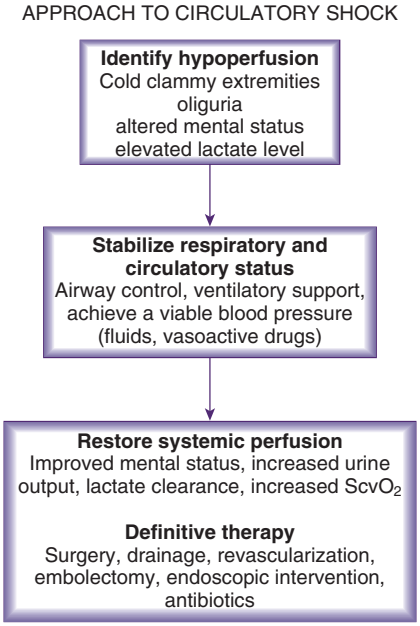

Fig. 79.4 Initial approach to patients with circulatory shock. *$ScvO_2$*, Central venous oxygen saturation.

KEY POINTS

- Circulatory shock is defined as a syndrome in which blood flow is inadequate to meet cellular metabolic requirements. The principal clinical manifestation of shock is that of organ hypoperfusion, which is most evident in the peripheral circulation, kidneys, and brain.
- The development of shock is related to alterations in the major components of the circulatory system that regulate cardiovascular performance. These are intravascular volume, cardiac function, arteriolar resistance, capillary circulation, venules, the venous capacitance circuit, and mainstream patency.
- Circulatory performance can be assessed from the cardiac rate and rhythm, arterial blood pressure, cardiac filling pressures, cardiac output, and systemic vascular resistance. Although shock is frequently defined by hypotension, the level of arterial pressure is not a reliable indicator of circulatory performance and tissue perfusion.
- Circulatory shock can be divided into four subsets: hypovolemic, cardiogenic, distributive, and obstructive. This classification can be simplified into two broad categories with typical hemodynamic profiles. The first category, hypodynamic shock, includes the hypovolemic, cardiogenic, and obstructive shock subsets. The second category, hyperdynamic shock, includes distributive shock. The central features of hypodynamic shock are a low cardiac output and vasoconstriction manifested by a high vascular resistance. Hyperdynamic circulatory shock is characterized by a high cardiac output, and vasodilation is manifested by a low vascular resistance.
- The primary metabolic defect in circulatory shock is impaired oxidative metabolism. This impairment is most commonly caused by decreases in tissue oxygen supply owing to either global decreases in blood flow or maldistribution of blood flow. Cellular oxidative metabolism may also be impaired by mechanisms independent of tissue hypoperfusion. Accumulation of tissue CO_2 parallels the development of tissue hypoxia in circulatory shock.
- Controversy exists over the optimal manner in which to monitor tissue perfusion in patients with circulatory shock. Commonly used variables such as heart rate, arterial pressure, and cardiac output correlate poorly with survival in critically ill patients. These observations have led to the use of indices of systemic oxygen metabolism as markers of tissue perfusion and the adequacy of resuscitative efforts.

- The primary causes of organ dysfunction in circulatory shock are ischemic injury related to tissue hypoperfusion, mediator-related organ dysfunction, and reperfusion injury. The relative importance of these mechanisms varies with the cause of the shock state and the specific organ being examined.
- The approach to patients with circulatory shock involves a rapid assessment of the underlying disease process and restoration of cardiopulmonary stability. The patient should be assessed for the etiology of the shock syndrome and evidence of organ hypoperfusion. Initial efforts to achieve cardiopulmonary stability should focus on ventilation, fluid infusion, and cardiac function. Restoration of systemic perfusion and definitive therapy directed at the etiology of the shock state should follow.

Resuscitation From Circulatory Shock

Antonio Messina, Massimiliano Greco, Alessandro Protti, and Maurizio Cecconi

INTRODUCTION

Shock can be defined as a state of circulatory failure to deliver sufficient oxygen to balance the demands of the tissues, which results in tissue hypoxia: a deficiency in the bioavailability of oxygen to the tissues of the body. Circulatory shock assessment is often a challenging and common clinical scenario (i.e., up to one-third of patients admitted to the intensive care unit [ICU] are in circulatory shock[1]). This should be considered a time-related syndrome needing prompt recognition to avoid multiorgan dysfunction and death. For this purpose, the assessment of clinical and nonclinical signs of acute circulatory dysfunction is of pivotal importance to define and target the therapeutic strategy at the bedside. First of all, the source of the hemodynamic instability should primarily be presumed by the physical examination of the patient and from details retrieved from the past and present medical history. For instance, in the large multicentric randomized European Sepsis Occurrence in Acutely Ill Patients II (SOAP II) trial, acute circulatory dysfunction was related to septic shock in the vast majority of the 1679 ICU patients enrolled (62%), whereas cardiogenic shock (16%), hypovolemic shock (16%), and other types of distributive (4%) or obstructive (2%) shock were less frequent.[2] Considering this prevalence, a de novo acute circulatory failure presented in the emergency department should be primarily considered a septic event, and accordingly treated, in the absence of any evident clinical signs of a different pattern (i.e., an evident fluid or blood loss, signs and symptoms of severe right or left acute ventricle dysfunction). The challenge of shock management is to balance fluid administration (preload), heart contractility, and vascular tone (afterload) to avoid the detrimental effects of over-resuscitation or under-resuscitation.[3–5] Basically, circulatory shock may be caused by a deficit related to the pump (heart function or heart flow) or by reduced circulatory flow. Hypovolemia can be "absolute" after severe hydration defects, plasma, or blood loss; it can be "relative" when fluid administration is insufficient to compensate for a loss in vascular tone in the context of sepsis or anaphylaxis (or use of large doses of sedative drugs). In that context, there is a discrepancy between the content (volume) and vascular capacity, and abnormal sympathetic tone is associated with altered capillary recruitment. The clinical examination is a cornerstone in shock, but is notoriously inaccurate in assessing the exact value of cardiac output (CO) and the intravascular volume status.[6,7] For these reasons, the goal of shock management can be achieved only adding bedside quantitative and qualitative evaluation of cardiovascular system function, based on an integrated approach of clinical examination, critical care echocardiography, and hemodynamic monitoring.[1]

FROM MACRO TO MICRO CIRCULATION: PATHOPHYSIOLOGY OF INADEQUATE OXYGEN USE BY THE CELLS

To better understand the systemic effects of the imbalance between oxygen delivery and consumption, some basic concepts of oxygen delivery to the cells and cellular energy metabolism should be appraised (Fig. 80.1).

1. Global oxygen delivery (DO_2) is the total oxygen carried by blood to the cells and is calculated as the product of the oxygen content in arterial blood (CaO_2) and CO.

$$DO_2 = CO * CaO_2 = CO * (1.36 \times Hb * \%saturation) + (0.003 \times PO_2)$$

   Dissolved oxygen contributes little to total oxygen content because of the limited solubility.
2. The DO_2 continuously balances the peripheral oxygen uptake or consumption (VO_2). Failure to maintain the DO_2:VO_2 ratio is initially compensated by increased oxygen extraction and a fall in mixed venous oxygen content. The normal ratio of delivery to consumption (DO_2:VO_2 ratio) is approximately 5:1. In fact, DO_2 and VO_2 are linked by a simple relationship called the *oxygen extraction ratio* (ERo_2 − %). Under physiologic conditions, DO_2 is larger than VO_2 and the ERo_2 is roughly 20% (<2.4 mL O_2/kg/min for a 12 mL O_2/kg/min DO_2). This DO_2:VO_2 ratio is high enough that cellular respiration is not supply dependent, and VO_2 is predominantly a function of tissue oxygen demand: "consumption drives delivery." VO_2 becomes supply dependent when the DO_2:VO_2 ratio falls below 2:1, producing a biphasic DO_2:VO_2 relationship.[8] This critical level of the DO_2:VO_2 relationship (the so-called "critical DO_2") corresponds to the maximal oxygen extraction.
3. Cells require oxygen for the production of adenosine triphosphate (ATP), the principal energy source. ATP is hydrolyzed to adenosine diphosphate (ADP) and inorganic phosphate (Pi) by ATPs in the cytosol:

$$ATP \leftrightarrow ADP + Pi + H^+ \text{ (yielding 7.3 kcal/mol)}$$

   Energy released is used for the maintenance of membrane integrity, ionic pumps, and other specialized functions, such as contractility of muscle cells and impulse transmission in neurons.
4. Because the body's stores of ATP will last no more than a few minutes, it must be continuously synthesized, and under physiologic conditions, the vast majority of ATP molecules are generated by the process of oxidative phosphorylation of glucose. Aerobic generation of ATP occurs in the mitochondria via oxidative phosphorylation

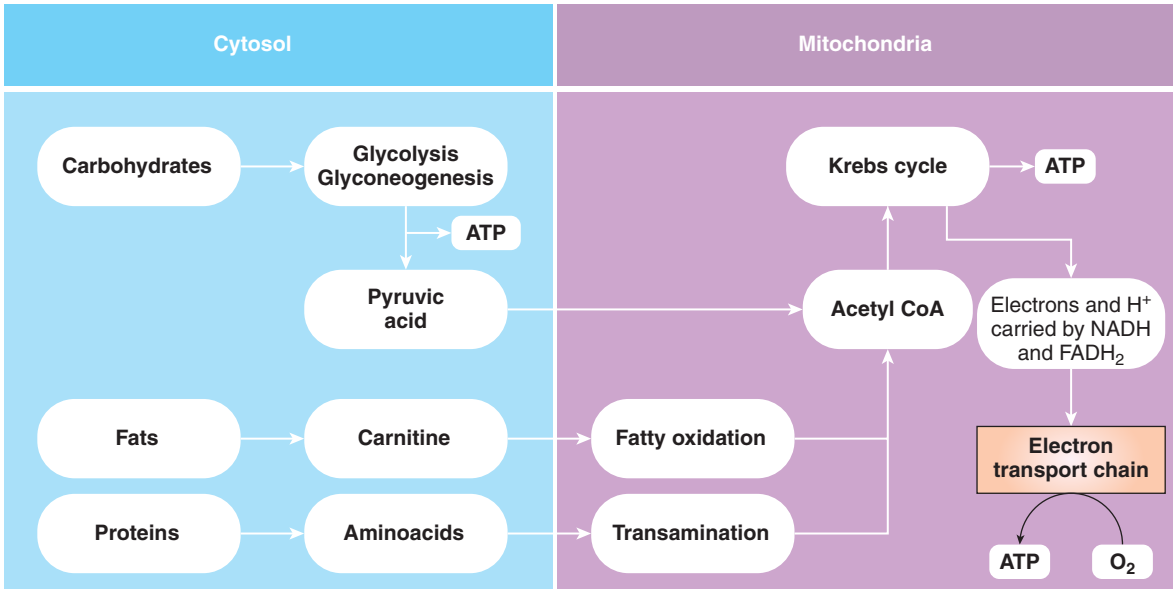

Fig. 80.1 Schematic Illustration of the Energetic Substrate Metabolism in Cells. NADH and $FADH_2$ are redox cofactor created during the Krebs cycle and used during the last part of cellular respiration, the electron transport chain. *ATP,* Adenosine triphosphate; *$FADH_2$,* reduced flavin adenine dinucleotide; *NADH,* reduced nicotinamide adenine dinucleotide.

along the electron transport chain in which reduced nicotine adenine dinucleotide (NADH) and reduced flavin adenine dinucleotide ($FADH_2$) are reduction-oxidized (redox) by molecular oxygen:

$$NADH + ½\ \mathbf{O_2} + H^+ \leftrightarrow H_2O + NAD^+$$

This yields 52.6 kcal/mol, which is used in the electron transport chain to create ATP from ADP + Pi + H^+.

The first stage of oxidative phosphorylation is the conversion of glucose to pyruvic acid; this occurs in the cytoplasm. The second stage, the oxidation of pyruvic acid, can only occur in the mitochondria as part of the Krebs (citric acid) cycle (Fig. 80.1). Oxidative phosphorylation is a more efficient process than substrate-level phosphorylation, yielding up to eight times more ATP than the anaerobic pathway per mole of glucose. In fact, this process produces a net 36 molecules of ATP (or 1270 kJ of available energy) for every glucose molecule oxidized.

5. Anaerobic generation of ATP occurs in the cytosol and in the mitochondria via ATP-generating reactions that catalyze the following substrates with ADP into ATP:

1,3-Diphosphoglycerate + ADP ↔* 3-diphosphoglycerate + ATP*

Phosphoenolpyruvate + ADP ↔** pyruvate + ATP

1,3-Succinyl CoA + ADP ↔*** succinate + ATP

* = Phosphoglycerate kinase (related enzyme)
** = Pyruvate kinase (related enzyme)
*** = Succinyl CoA synthase (related enzyme)

6. Lactate increase in blood level is the consequence of alterations in cellular energy metabolism caused by acquired derangements in cellular respiration. Lactate is produced according to the following cytoplasmic reaction:

$$Pyruvate + NADH + H^+ \leftrightarrow Lactate + NAD^+$$

This biochemical reaction promotes lactate formation, causing a 10-fold lactate/pyruvate ratio. Hence, the lactate increase in the blood is the result of a pyruvate production exceeding its use by the mitochondria. Because the pyruvate is essentially produced via glycolysis, any increase in glycolysis, regardless of its origin, can cause lactatemia. Pyruvate is principally metabolized into the mitochondria by means of the aerobic oxidation pathway, using the Krebs cycle. The synthesis of lactate in the cell is dependent on the ATP/ADP and NADH/NAD ratios, which are both related to the oxygen use in the mitochondria. In fact, hypoxia inhibits mitochondrial oxidative phosphorylation, leading to a decrease in the ATP/ADP ratio and an increase in the NADH/NAD ratio. This metabolic condition inhibits both the pyruvate carboxylase (converting pyruvate into oxaloacetate) and the pyruvate dehydrogenase (converting pyruvate into acetyl CoA).[9] When the physiologic pathway of pyruvate use is affected by alterations in the redox potential of the cell, the excess of pyruvate concentration is shifted to lactate production and to the less efficient anaerobic glycolysis.

According to Connett and colleagues,[10] it is possible to define three theoretical thresholds of cell hypoxia:

1. The first is crossed when cellular oxygen decreases but ATP production is maintained at a level sufficient to match ATP demand by metabolic adaptation (i.e., redox recruitment, alteration of phosphorylation states, increased glycolysis). The critical level of mitochondrial PO_2 for oxidative phosphorylation depends on the ability of a cell to adapt the phosphorylation process metabolically and the level of ATP demand.
2. The second occurs when steady-state ATP turnover can be maintained only by the production of ATP from anaerobic glycolysis by the Embden-Meyerhof pathway. This highly inefficient pathway generates only 2 molecules of ATP per 1 molecule of glucose metabolized. For highly metabolic tissues such as the brain, kidney, and liver, anaerobic glycolysis is too cumbersome to be effective, and these organs develop ATP depletion rapidly under hypoxic conditions. Dysoxia can be defined below this threshold.
3. The third threshold is crossed when glycolysis becomes insufficient to produce enough ATP to maintain cell function and structural integrity. This last step leads to cellular damage and death.

FROM MICRO TO MACRO CIRCULATION: SYSTEMIC TARGETS OF RESUSCITATION FROM CIRCULATORY SHOCK

Circulatory shock is a clinical diagnosis based on signs and symptoms of inadequate tissue perfusion. This implies an often-neglected physiologic cornerstone (Table 80.1): there is no correlation between the pure CO and mean arterial pressure (MAP) measurements, and shock. Moreover, whenever present, this correlation is not linear. Clearly, very low values of CO and MAP are harmful; however, neither their absolute values nor the changes in response to therapy accurately reflect the adequacy of peripheral blood flow. In other words, normal or even high values of CO and MAP could be insufficient if metabolic demand is unbalanced (Fig. 80.2).

As a matter of fact, the ability of ICU physicians to correctly estimate CO values at the bedside is particularly misleading. In a recent review, physicians' estimates of CO based on clinical examinations were correct in 42%–62% (more or less the accuracy of flipping a coin), and two studies reported that 20%–25% of the CO estimations were completely incongruent (meaning that the estimated CO was increased, whereas the objective CO was decreased or vice versa).[6] For this reason, the diagnosis of circulatory shock should be mainly based on the clinical assessment of DO_2-VO_2 mismatch.

Eighty years ago, Ebert et al. described the skin of septic shock patients as being "pale, often sweaty."[11] Mottling skin has been recently proposed using a semiquantitative approach based on mottling extension around the knee: a clinical score ranging from 0 (indicating no mottling) to 5 (an extremely severe mottling area that goes beyond the fold of the groin). Scores ≥4 and persistence of high values during the first 6 hours after ICU admission were both associated with the lowest chance of survival.[12] An increase in mottling was associated with increased lactate levels and decreasing urinary output, but not with CO values, confirming that the progression of shock cannot be assessed only by CO.[12,13]

TABLE 80.1 Physiologic Targets and Goals During Circulatory Shock

Physiological Variables	Advantages	Drawbacks	Clinical Utility
Blood pressure	Easy to perform Costless index Target value (SBP >90 mm Hg, MAP >65 mm Hg)	Low SBP and MAP, when taken alone, are not predictors of fluid responsiveness	Part of the bedside standard clinical examination Hypotension must be promptly recognized and when associated with tachycardia should trigger the clinician to start fluid resuscitation unless clear evidence of severe cardiac failure
SI	Easy to perform Costless index (normal value 0.5–0.7) Linear and inverse correlation with CO	SI >1 could also be increased in cardiogenic and obstructive shock	Useful index facing a shocked patient SI ≥1 is a possible sign of hypovolemia, but a cardiogenic component of the shock must be excluded
CRT	Easy to perform Costless index	Operator dependent Affected by different durations of pressure, ambient, and skin temperatures	Part of the bedside standard clinical examination in the ICU If CRT ≤2 seconds, should be considered normal To standardize the maneuver, use just enough pressure to remove the blood at the tip of the physician's nail, illustrated by the appearance of a thin white distal crescent (blanching) under the nail, for 15 seconds
Skin mottling	Easy to perform Costless index	Operator dependent Not applicable in patients with dark skin Affected by the ambient and skin temperatures	Part of the bedside standard clinical examination in the ICU Should be standardized considering a score ranging from 0 (indicating no mottling) to 5 (an extremely severe mottling area that goes beyond the fold of the groin)
Lactate	Quickly available May trigger further evaluation in subclinical (cryptic) shock Target value (≤2 mmol/L)	Normolactatemia does not exclude ACD It is not a direct measure of tissue perfusion Influenced by lactate clearance	Lactate normalization is indicative of successful resuscitation Persistence of severe hyperlactatemia (>10 mmol/L for >24 h) is associated with negative prognosis Patients with lactate level >2 mmol/L should be carefully monitored Patients with persistent lactate level >4 mmol/L should be considered for ICU admission
$ScVO_2$	Quickly available Target value (when low at presentation)	Need for a CVC in the superior cava vein	The optimization of low $ScVO_2$ (<70%) has been successfully used in a protocolized approach to septic shock Normal or high values are less indicative of the degree of shock
ΔPCO_2	Quickly available Target value (2–6 mm Hg)	Need for a CVC in the superior cava vein	High values (>6 mm Hg) can identify inadequate resuscitated patients (insufficient blood flow to the tissues)

See the text for further explanations.
ACD, Acute circulatory dysfunction; *CO,* cardiac output; *CRT,* capillary refill time; *CVC,* central venous catheter; ΔPCO_2 (also called GAP CO_2), the venous-to-arterial CO_2 tension difference; *ICU,* intensive care unit; *MAP,* mean arterial pressure; *SBP,* systolic blood pressure; $ScVO_2$, central venous oxygen saturation; *SI,* shock index.

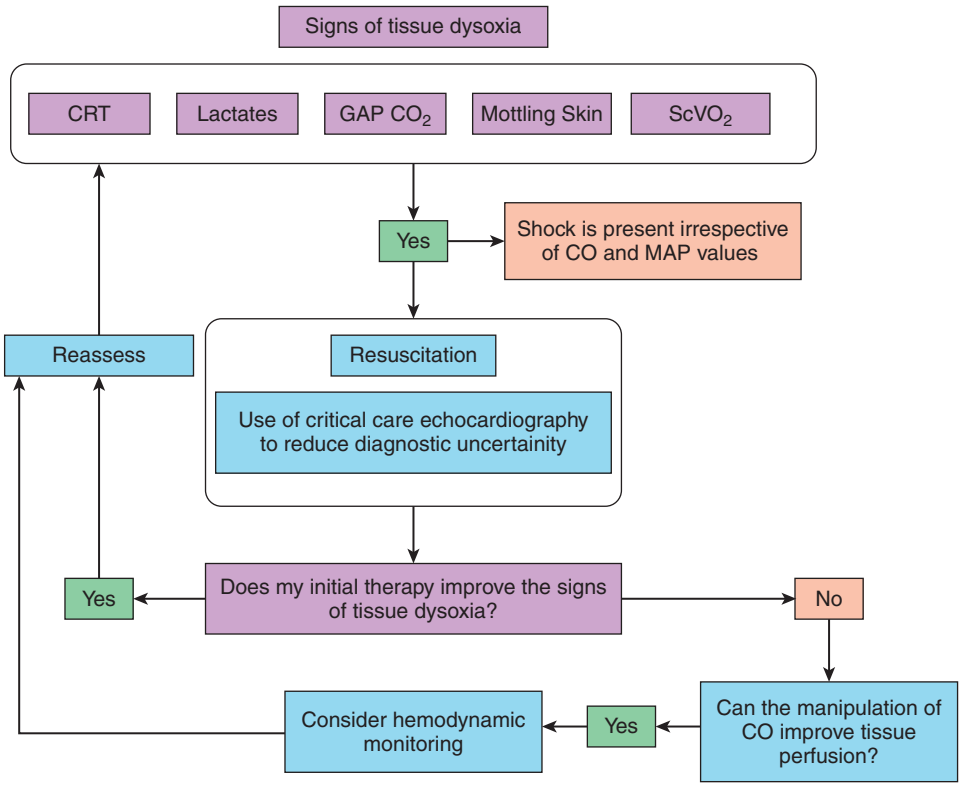

Fig. 80.2 Schematic Illustration of an Integrated Approach to Circulatory Shock. The clinical presentation and examination, with the past medical history of the patient, are key aspects of initial diagnosis. Consider the source of hemodynamic instability starting from the most common: septic shock → cardiogenic shock → hypovolemic shock → distributive → obstructive. Whenever available, the critical care echocardiography (i.e., an oriented and focused echocardiographic examination performed and interpreted at the bedside by the intensivists) could help in the initial diagnosis and further assessment of the response to fluid therapy. *CO,* Cardiac output; *CRT,* capillary refill time; *GAP CO_2,* the venous-to-arterial CO_2 tension difference; *MAP,* mean arterial pressure; *$ScVO_2$,* central venous oxygen saturation.

Another easy-to-learn, inexpensive, repeatable, and reliable bedside clinical parameter is the capillary refill time (CRT). The CRT measures the time required to recolor the tip of a finger after pressure is applied to cause blanching. Because this maneuver depends on the applied pressure, Ait-Oufella and colleagues recommended using just enough pressure to remove the blood at the tip of the physician's nail, illustrated by the appearance of a thin white distal crescent under the nail, for 15 seconds.[11] CRT at 6 hours after inclusion was strongly predictive of 14-day mortality (area under the curve of 0.84 [75 - 94]). Hernández and colleagues reported that CRT <4 seconds detected 6 hours after resuscitation was associated with resuscitation success, with normalization of lactate levels 24 hours after the occurrence of severe sepsis/septic shock.[14] A prospective cohort study of 1320 adult patients hospitalized in the emergency room for hypotension showed a consistent association between CRT and in-hospital mortality.[15]

Serum lactate is a more objective metabolic surrogate to guide fluid resuscitation. The Surviving Sepsis Campaign guideline suggests guiding resuscitation to normalize lactate in patients with elevated levels.[16] Irrespective of the source, increased lactate levels are associated with worse outcomes,[17] and lactate-guided resuscitation significantly reduced mortality as compared with resuscitation without lactate monitoring.[16] Because serum lactate is not a direct measure of tissue perfusion,[18] this single value is less informative than the trend of lactate clearance. However, serum lactate normalization is indicative of shock reversal, whereas severe hyperlactatemia is associated with very poor outcomes. Recently published data showed that lactate >4 mmol/L associated with hypotension led to a mortality rate of 44.5% in ICU patients with severe sepsis or septic shock.[17] For instance, a large retrospective study showed that a subgroup of ICU patients with severe hyperlactatemia (lactate >10 mmol/L) had a 78.2% chance of mortality, which increased up to 95% if hyperlactatemia persisted for more than 24 hours.[19]

The venous-to-arterial CO_2 tension difference (ΔPCO_2) and central venous oxygen saturation ($ScVO_2$) provides adjunctive relevant clinical information. According to a modified Fick equation, ΔPCO_2 is linearly linked to CO_2 generation and inversely linked to CO.[20] ΔPCO_2 ranges between 2 and 6 mm Hg under normal conditions and should be considered as a marker of the adequacy of blood flow to wash out the CO_2 produced by the tissues rather than as a marker of tissue oxygen deficit.[20]

$ScVO_2$ reflects the balance between oxygen delivery and consumption, being a surrogate value of mixed venous oxygen saturation (normally the $ScVO_2$ is 2%–3% lower than SvO_2).[21] Because a low $ScVO_2$ is indicative of inadequate oxygen delivery, this parameter has been previously considered a therapeutic target in the management of early phases of septic shock.[22–24] However, this approach has been challenged by the negative results of three subsequent large multicenter randomized controlled trials[25–27] and is no longer recommended.[16] Given that the ARISE, PROMISE, and PROCESS trials probably included populations of less severe critically ill patients with respect to the study of Rivers and colleagues[22] (i.e., lower baseline lactate levels, $ScVO_2$ at or above the target value at the admission, and lower mortality in the control group[25–27]),

the normalization of low $ScvO_2$ in the early phase of septic shock can still be considered a good predictor of successful resuscitation. On the contrary, the persistence of high blood values of $ScvO_2$ is associated with mortality in septic shock patients, probably indicating an irreversible impairment of the oxygen extraction by the cells.[28]

Arterial blood pressure (ABP) depends on several factors: the amount of blood ejected by the heart, the arterial compliance, and the systemic vascular resistance; the arterial system modulates vessel tone in order to keep perfusion pressure (i.e., MAP) constant.

Although arterial hypotension is not per se a sign of acute circulatory dysfunction, a systolic ABP lower than 90 mm Hg (or less than 40 mm Hg in previously hypertensive patients) or a MAP less than 65 mm Hg should be promptly recognized. Facing a shocked patient in the first minutes, one of the fundamental questions should be if she or he would benefit from fluid therapy. The MAP value alone is not sufficient to trigger fluid resuscitation: a low MAP may not be associated with hypovolemic or septic shock or, in contrast, might be maintained adequately thanks to a compensatory mechanism like an increase in vascular resistance.[1] Moreover, low systolic ABP could be associated with either a normal or a low diastolic ABP-value (i.e., 40 mm Hg). As one of the main determinants of diastolic ABP is the arteriolar tone, a low systolic and diastolic ABP suggest a low vascular tone, especially in the presence of tachycardia, and therefore the need for an early vasopressor may be warranted.[29]

Tachycardia is an important early sign of shock, but it can also be caused by pain, anxiety, fever, anemia, or inflammation. For these reasons, it should not be used alone as a predictor of fluid responsiveness.[1,30] In a patient in shock, both hypotension and tachycardia should trigger the clinician to start fluid resuscitation unless clear evidence of severe cardiac failure is present.

A useful and easy indicator of hypovolemia is the "shock index" (SI): that is, the ratio of heart rate divided by systolic blood pressure (HR/SBP). This index was originally described in trauma patients, but its relevance has also been demonstrated in septic patients.[31] The SI has a linear and inverse correlation with the CO, and in healthy adults the normal range is 0.5–0.7. A value ≥ 1 is related to the extent of hypovolemia, but it is important to underline that it could also be increased in cardiogenic and obstructive shock. Therefore with an SI ≥ 1, fluid therapy should be started, while always checking for a possible cardiac component of the shock.[29]

Another insidious marker of possible hypoperfusion is urinary output.[29] Oliguria is a nonspecific symptom and could already be present with mild dehydration. Moreover, urinary output may not reflect systemic hypoperfusion during early circulatory dysfunction: some neurohormonal compensatory mechanisms could be responsible for preserving and sometimes even increasing renal blood flow, and in this case extra fluids could alter renal perfusion by increasing venous congestion. In synthesis, fluid administration does not necessary lead to a restoration of normal diuresis, and oliguria could be the result of profound intrarenal microcirculatory abnormalities that are not related to hypoperfusion.[32]

Finally, an attractive method to investigate a hypovolemic status is the passive leg raising (PLR) test. It can be considered a brief and completely reversible "self-volume challenge" because of the shift of around 300 mL of blood from the legs to the intrathoracic compartment to avoid the risk of fluid overload. Of course, the effect of PLR is time limited, with the apex of the increasing CO occurring 1 minute after starting the manuver.[33,34] The reliability of the PLR is known to be significant when a direct measurement of the CO is available. However, changes in the pulse pressure after the PLR (i.e., the difference between systolic and diastolic pressure) could be useful in the assessment of fluid responsiveness, despite a lower sensitivity and specificity as compared with changes in CO.[35]

A PHYSIOLOGIC CAUSE-RELATED APPROACH TO CIRCULATORY SHOCK

Circulatory Shock Caused by CO Limitation (Cardiogenic, Obstructive)

Cardiogenic shock is characterized by a global reduction in DO_2 because of a reduction in CO caused by either a myocardial dysfunction (myogenic injury—infectious, viral, or ischemic disease; a major valvular disease; a severe arrhythmia) or a mechanical obstacle to the cardiac flow (pulmonary embolism, tension pneumothorax, or a raised pericardial pressure). Cardiogenic shock complicates 5%–10% of cases of acute myocardial infarction and is the leading cause of death after this event.

Principles of treatment of myocardial dysfunction (see also Chapters 70 and 74): The characteristic of cardiogenic shock after myocardial dysfunction is the peripheral vasoconstriction and vital end-organ damage, which reflect ineffective CO and insufficient circulatory compensation. This compensatory effect may initially improve coronary and peripheral perfusion; however, it contributes to increased cardiac afterload, which exacerbates the damage in the myocardium. Inotropes are routinely used to improve CO in cardiogenic shock, but at the expense of tachyarrhythmias, increased myocardial VO_2, and adverse effects on regional blood flow. Vasopressors could be used in this setting and should be titrated to a MAP with a typical goal of >65 mm Hg. Vasopressin has less pulmonary vasoconstriction than norepinephrine and may be more beneficial as a first-line vasopressor in patients with acute right ventricle failure.[36]

Specific treatments of CO limitation-related mechanic conditions are reported elsewhere in this book (see Chapters 65, 66, 75, and E9).

Circulatory Shock Caused by Volume Depletion: Decreased Cao_2 (Anemia)

The goals of initial resuscitation for hemorrhagic shock are (1) to arrest ongoing bleeding, (2) to restore the effective circulating blood volume, and (3) to restore tissue perfusion. The modern management protocol of hemorrhagic shock has been mainly developed based on the treatment of trauma patients. This involves prompt control of the source of bleeding by means of damage control surgery and has been expanded to the early management of trauma patients as damage control resuscitation, with the purpose of preventing the lethal triad of coagulopathy, hypothermia, and acidosis. A degree of hypotension is permitted in this context, and fluid repletion should avoid hemodilution and should be mainly based on transfusion of red blood cells, plasma, and platelets in a high unit ratio (>1:2) or reconstituted whole blood in a 1:1:1 unit ratio. Specific principles of the treatment of hypovolemic shock resulting from hemoglobin loss are reported in Chapters 125 and 141.

Circulatory Shock Caused by Volume Depletion: Decreased Cao_2 (Hypoxemia, Poisoning)

Hemoglobin's capacity to carry O_2 can also be limited by structural damages inhibiting its physiologic activity. For instance, during carbon monoxide poisoning, a decrease in DO_2 results from a loading competition on hemoglobin between carbon monoxide and O_2 and is "maximized" by abnormal O_2 use (carbon monoxide interacts with oxidative phosphorylation) and a decrease in ERO_2 capabilities. In this particular case, shock is both quantitative and distributive. In the presence of severe hypoxemia because of an acute respiratory disorder, decreased SaO_2 leads to a decreased CaO_2, and Do_2 that largely depends on an associated increase in CO. Specific principles of the treatment of poisoning are reported in Chapter 140. For a comprehensive evaluation of hypoxemic disorders, please refer to Part IV of this book.

Circulatory Shock Caused by Decreased ER_{O_2}: Distributive Shock

This type of shock is related to:

1. Altered flow redistribution among organs secondary to inflammation (mainly caused by sepsis), anaphylaxis, or some drugs (e.g., large doses of sedative agents)
2. Decrease in capillary recruitment secondary to altered vascular reactivity, increased intravascular coagulation, increased blood cell adhesion, and/or endothelial edema
3. Abnormal mitochondrial function (mitochondrial injury or dysfunction) described as "cytopathic hypoxia," or more precisely as cytopathic dysoxia, a situation in which cells cannot synthesize ATP despite having sufficient global DO_2.

Although septic shock is one of the distributive shocks, the pathophysiology of septic shock is different from other distributive shock diseases. The pathophysiology and the clinical course of septic shock are more complex and vary over the course of the disease, with variable degrees of intravascular volume depletion, peripheral vasodilation, and cardiac dysfunction. Specific principles of the treatment of septic shock are reported in Chapter 118.

KEY POINTS

- Shock can be defined as a state of circulatory failure to deliver sufficient oxygen to balance the demands of the tissues, which results in tissue hypoxia—a deficiency in the bioavailability of oxygen to the tissues of the body.
- The challenge of shock management is to balance fluid administration (preload), heart contractility, and vascular tone (afterload) to avoid the detrimental effects of over-resuscitation or under-resuscitation.
- Shock is caused by a septic source in the vast majority of critically ill patients, whereas cardiogenic, hypovolemic, and other types of distributive or obstructive shock are less frequent.
- Circulatory shock is a clinical diagnosis based on signs and symptoms of inadequate tissue perfusion. This implies an often-neglected physiologic cornerstone: there is not (always) a correlation between the pure CO and MAP measurements and shock.
- The clinical examination is a cornerstone in shock but is notoriously inaccurate to assess the exact value of CO and the intravascular volume status.
- The goal of shock management can be achieved only by adding bedside quantitative and qualitative evaluation of cardiovascular system function, based on an integrated approach of clinical examination, critical care echocardiography, and hemodynamic monitoring.

The European Society of Intensive Care Medicine invited 12 experts to form a task force to update a previous consensus (Antonelli et al. Intensive Care Med. *2007;33:575–590). The task force was developed to answer the following questions: (1) What are the epidemiologic and pathophysiologic features of shock in the ICU? (2) Should we monitor preload and fluid responsiveness in shock? (3) How and when should we monitor stroke volume or CO in shock? (4) What markers of regional and microcirculation can be monitored, and how can cellular function be assessed in shock? (5) What is the evidence for using hemodynamic monitoring to direct therapy in shock?*

Cecconi M, Hernandez G, Dunser M, et al. Fluid administration for acute circulatory dysfunction using basic monitoring: narrative review and expert panel recommendations from an ESICM task force. *Intensive Care Med.* 2019;45(1):21–32.
An international team of experts in the field of fluid resuscitation was invited by the ESICM to form a task force to systematically review the evidence concerning fluid administration using basic monitoring. The work included a particular emphasis on pre-ICU hospital settings and resource-limited settings. The work focused on four main questions: (1) What is the role of clinical assessment to guide fluid resuscitation in shock? (2) What basic monitoring is required to perform and interpret a fluid challenge? (3) What defines a fluid challenge in terms of fluid type, ranges of volume, and rate of administration? (4) What are the safety endpoints during a fluid challenge?

De Backer D, Biston P, Devriendt J, et al. Comparison of dopamine and norepinephrine in the treatment of shock. *N Engl J Med.* 2010;362(9):779–789.
Pivotal randomized controlled study assigning patients with hypotension persisting despite fluid administration either to norepinephrine infusion or to dopamine infusion to restore normal blood pressure. The results showed that the rate of arrhythmia was significantly higher in the dopamine group than in the norepinephrine group. Moreover, among patients whose shock was cardiogenic in nature, the 28-day mortality was significantly higher in the dopamine group than in the norepinephrine group.

Inotropic Therapy

Jean-Louis Teboul, Xavier Monnet, and Mathieu Jozwiak

RATIONALE FOR USING INOTROPIC THERAPY IN THE CRITICALLY ILL

Two different objectives for using inotropes in the critically ill have been considered: (1) the attempt to improve cardiac function in patients with low blood flow related to reduced myocardial contractility and (2) the attempt to achieve supranormal values of cardiac output in order to prevent or reduce oxygen debt; in this situation, inotropes might be given after volume resuscitation, even in the absence of formally documented myocardial depression.

Use of Inotropes for Reversing Impaired Myocardial Contractility

The first category of situations where inotropic therapy is generally considered includes cardiogenic shock, acute heart failure, or acute exacerbation of chronic heart failure. However, although the use of such therapy in these clinical conditions seems logical on a classic pathophysiologic basis, no demonstration of a beneficial impact on morbidity and mortality can be found in the literature. Moreover, almost all the commercially available inotropes have been shown to be associated with an increased mortality rate when given on a long-term basis to patients with chronic heart failure. It has been postulated that the long-term use of inotropes leads to the deterioration of left ventricular function through the acceleration of myocardial cell apoptosis.[1] Additionally, the beneficial effects on the mortality rate with agents known to have negative inotropic effects such as beta-blockers is now well established in patients with chronic heart failure with preserved ejection fraction[2] or reduced ejection fraction.[3] Therefore inotropic therapy is generally reserved for patients with cardiogenic shock. Under these conditions, clinicians can expect short-term positive effects of intravenous inotropic therapy, allowing cardiovascular stabilization. Inotropic therapy can also be used in patients with refractory heart failure who are waiting for mechanical circulatory support (left ventricular assist devices, extracorporeal life support) and/or cardiac transplantation. In those with potentially reversible causes of acute heart failure (such as myocardial infarction or acute myocarditis), short-term inotropic therapy must be considered as an appropriate bridge to coronary revascularization or recovery. The development of bedside echocardiography in the intensive care unit (ICU) should allow the appropriate use of inotropic therapy because this method provides a more accurate assessment of systolic cardiac function than traditional invasive methods such as pulmonary artery catheterization.

Use of Inotropes for Achieving Supranormal Levels of Oxygen Delivery or for Being Incorporated in a Goal-Directed Therapeutic Approach

High-Risk Surgical Patients

The concept of attempting to achieve supranormal hemodynamic endpoints emerged from studies in high-risk surgical patients. In a prospective study in high-risk patients undergoing surgery, Shoemaker and colleagues showed that the use of supranormal hemodynamic values as therapeutic endpoints was associated with a reduction in mortality rate from 33% to 4%.[4] In the protocol group, dobutamine and dopamine were given as inotropic drugs, even in the absence of evidence of reduced cardiac contractility, when volume resuscitation (and packed red blood cells, if necessary) failed to achieve supranormal values of oxygen delivery[4] (>600 mL/min/m^2). Thereafter, some debate concerning the perioperative fluid management strategy has emerged, especially during abdominal surgery. On the one hand, restricted perioperative fluid management could decrease the rate of postoperative complications and promote faster recovery.[5–7] On the other hand, randomized trials did not confirm the supposed benefits of fluid restriction on recovery after elective surgery.[8,9] Excessive fluid restriction could lead to higher rates of acute kidney injury and renal replacement therapy[9] and more postoperative complications such as anastomotic leaks and surgical site infection.[10]

In fact, the most important point was not the use of the perioperative fluid strategy itself, but rather the use of a goal-directed strategy based on stroke volume,[11–13] oxygen delivery index,[14,15] or cardiac index.[16] In these randomized studies, the volume of intraoperative fluids was decreased,[14,15] unchanged,[16] or increased.[11–13] Nevertheless, in all these studies, postoperative complications or hospital length of stay was decreased. The potential beneficial effects of intraoperative goal-directed fluid therapy in elective major abdominal surgery in terms of morbidity and hospital and ICU length of stay were confirmed in a meta-analysis.[17] Two reviews confirmed that a deliberate perioperative increase in oxygen delivery above supranormal values using fluid infusion and various inotropic drugs (dobutamine, dopamine, epinephrine, dopexamine) in high-risk patients undergoing surgery was associated with a decreased mortality rate and postoperative complications.[18,19] It is important to emphasize that (1) benefits are most pronounced in patients receiving fluid and inotropic therapy as opposed to fluids alone to achieve supranormal values of cardiac index or oxygen delivery with the use of minimally invasive cardiac output monitors,[20] (2) benefits related to the use of an intraoperative goal-directed therapy could also concern low- and moderate-risk patients,[21] and (3) such an early goal-directed therapy (EGDT) is not considered after complications have already developed.[19] However, more recently, the interest of perioperative goal-directed

therapy has been questioned.[22,23] In a pragmatic, multicenter randomized trial in high-risk patients undergoing major gastrointestinal surgery, Pearse and colleagues assessed the clinical effectiveness of a deliberate perioperative strategy including fluid administration and dopexamine to achieve and maintain a maximal stroke volume.[23] When compared with usual care, goal-directed therapy was not associated with a significant reduction in moderate or major postoperative complications.[23] Nevertheless, after incorporating these results into an updated systematic review and meta-analysis, the deliberate perioperative strategy was associated with a significant reduction in the percentage of patients who developed postoperative complications.[23] It is important to note that in the group of usual care, fluid administration was based on central venous pressures and could be considered, in part, as goal-directed therapy.[23] It remains unclear, however, whether potential benefits could be related to the increased oxygen delivery per se or other antiinflammatory effects of catecholamines.[24] In this regard, it has been demonstrated that the increased oxygen delivery per se improved microvascular flow and tissue oxygenation.[25] Nevertheless, an experimental study of murine septic shock has shown that dopexamine infusion per se reduces the systemic inflammatory response, attenuates leukocyte infiltration, and prevents hepatic and renal injury at doses that have no effects on global or regional hemodynamics.[26] The issue of drug dosage is also essential. A recent meta-analysis has suggested that in the setting of major surgery, dopexamine at low doses, but not at high doses, could improve outcome.[27] From all these findings, it is still reasonable to consider the increase in cardiac output and oxygen delivery toward supranormal values during the perioperative period in high-risk patients undergoing elective major surgery and to guide the perioperative management of these high-risk patients by hemodynamic monitoring.[28]

Critically Ill Patients

It was debated whether a supranormal hemodynamic target approach can be applied to patients admitted to the ICU for acute illnesses. On the one hand, a pathologic oxygen consumption/supply dependency, presumably the result of impaired oxygen extraction capacities, has been reported in various categories of acute illnesses such as sepsis[29] and acute respiratory distress syndrome.[30] Such a phenomenon was reported to correlate with the presence of increased blood lactate, to be a marker of global tissue hypoxia,[29] and to be associated with a poor outcome.[31] This so-called *pathologic oxygen consumption/supply dependency* would incite the clinician to increase oxygen delivery toward supranormal values to overpass its critical level. However, such an aggressive therapeutic approach has been seriously questioned since the publication of randomized clinical trials performed in patients with acute illnesses and who did not demonstrate any benefit from the deliberate manipulation of hemodynamic variables toward values higher than physiologic values.[32,33] In one of these studies, the mortality rate was higher in the group of patients assigned to receive an aggressive treatment aimed at achieving supranormal values of oxygen delivery.[32] It was postulated that the deleterious consequences of the use of high doses of dobutamine in patients in the protocol group were responsible for the increased mortality rate. It should be noted that (1) the patients in the protocol group received high doses of the inotropic agent despite no evidence of any deficit of inotropic function and that (2) in most of these patients the aggressive inotropic support failed to achieve the target value of oxygen consumption (170 mL/min/m^2). The later analysis of the subgroup of septic patients in a study showed that survivors were characterized by their ability to increase both oxygen delivery and oxygen consumption, regardless of their group of randomization.[34] Nonsurviving patients were characterized by their inability to increase oxygen consumption despite the increase in oxygen delivery, suggesting a more marked impairment of peripheral oxygen extraction in nonsurvivors than in survivors.[34] In addition, the ability to increase cardiac output and oxygen delivery was also significantly reduced in nonsurvivors than in survivors, suggesting a decrease in cardiac reserve in patients who will die.[34] This is not a surprising finding because the degree of myocardial dysfunction in septic shock correlates with an increased risk of death. In this regard, it has been suggested that the response to a dobutamine challenge has a prognostic value in septic patients because in two prospective studies survivors were able to increase both oxygen consumption and oxygen delivery in response to dobutamine, whereas nonsurvivors were unable to increase either oxygen delivery or oxygen consumption or both.[35,36]

Data from all the results of randomized controlled studies indicate that a deliberative attempt to achieve supranormal hemodynamic targets in the general population of critically ill patients is no longer recommended.[37,38] Nevertheless, in the early phase of septic shock with low blood flow and oxygen delivery, an aggressive hemodynamic therapy, including inotropes, aimed at rapidly normalizing the central venous oxygen saturation ($ScvO_2$) as a surrogate of oxygen delivery, was demonstrated to result in a better outcome in a monocenter, randomized controlled trial.[39] This result has led to the popularity of the concept of EGDT with ($ScvO_2$) as the main hemodynamic target. Nevertheless, three recent multicenter, randomized studies have shown that EGDT using ($ScvO_2$) did not reduce all-cause mortality,[40–42] duration of organ support, or hospital length of stay.[40,41] In addition, compared with usual care, EGDT resulted in higher hospitalization costs[43] and was associated with increased utilization of ICU resources.[44] However, compared with the study by Rivers and colleagues,[39] patients included in the three multicenter, randomized controlled trials[40–42] were fluid resuscitated before randomization, such that the average baseline ($ScvO_2$) was already higher than 70% (the target of the EGDT arm). Such a fact certainly accounted for the absence of superiority of EGDT over the control arms in these studies.[40–42] This clearly cannot rule out the strategy of increasing oxygen delivery and targeting ($ScvO_2$) higher than 70% when ($ScvO_2$) is lower than 70%, as this was the case in the majority of the patients in the study by Rivers et al.[39] Thus in the early phase of septic shock and maybe in other acute illnesses, it could be essential to rapidly restore normal global blood flow conditions to avoid further deleterious consequences of systemic hypoperfusion. In later stages of the disease, with inflammatory processes and organ dysfunction already developed, no evidence of benefit from a further increase in oxygen delivery has been shown in the literature. Nevertheless, it seems likely that cardiac output should be kept in the normal range by using fluids and/or inotropes to prevent worsening of the insult. It should be stressed that even in the EGDT approach, their use should not only be based on $ScvO_2$ but also on the presence of established cardiac dysfunction, which is at best diagnosed on echocardiography,[35,45] and after checking that hypovolemia and hypotension have been already corrected.[37]

PHARMACOLOGIC PROPERTIES OF INOTROPIC AGENTS

Different inotropic drugs are available. Some of them act on adrenergic receptors located at the surface of the cardiomyocytes, whereas others exert their effects into the myocardial cell. The different treatments targeting inotropy and their pharmacologic properties have been summarized in a recent review.[46]

Adrenergic Signalization

Both natural and synthetic catecholamines increase the Ca^{2+} cytosolic concentration, which is directly related to the force of contraction (Fig. 81.1). Ca^{2+} fixes on the troponin C Ca^{2+}-specific binding site,

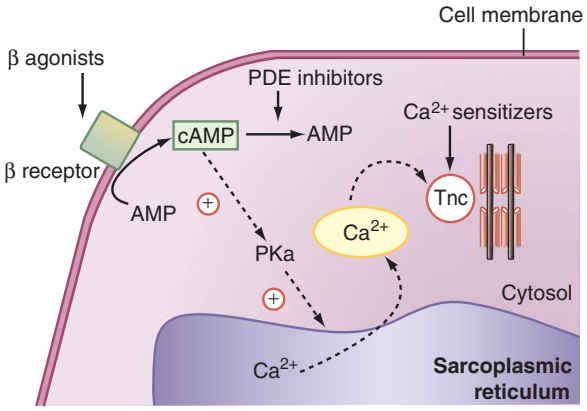

Fig. 81.1 Mechanisms of Action of Inotropic Agents at the Cellular Level. Schematic Representation. Beta-1 agonist agents fix the beta-1 receptor and stimulate the formation of cyclic adenosine monophosphate (*cAMP*) from AMP through adenylate cyclase. cAMP activates protein kinase A (*PKa*), which provokes extrusion of Ca^{2+} from the sarcoplasmic reticulum into the cytosol through phosphorylated ryanodine receptors. Ca^{2+} fixes troponin C (*Tnc*) and finally activates the fixation of actin on myosin filaments. Phosphodiesterase (*PDE*) inhibitors also increase the cAMP concentration by inhibiting its degradation. Ca^{2+} sensitizers increase inotropism through enhancement of troponin C sensitivity for Ca^{2+}. Cardiac myosin activators increase the activity of the ATPase of the myofibrils, increasing the contractile force of the cardiomyocytes without increasing the amount of ATP molecules required for contraction. Istaroxime inhibits the Na^+/K^+-ATPase, increasing the activity of the sarcoplasmic reticulum calcium ATPase pump and increasing the reuptake of Ca^{2+} by the sarcoplasmic reticulum.

inducing a conformational change that leads to the fixation of the myosin head to the actin filament. Hydrolysis of the adenosine triphosphate (ATP) molecule located on the myosin head to adenosine diphosphate (ADP) simultaneously induces the flexion of the myosin neck and the shortening of the contractile apparatus.

A rapid overview of the physiologic response to adrenergic receptor stimulation is essential to understand the pharmacologic properties of these drugs. Receptors of the adrenergic system are classed as alpha-1, alpha-2, beta-1, beta-2, and dopaminergic receptors. Activation of the beta-1 receptors and, to a lesser degree, the alpha-1 receptors, is responsible for the inotropic effect of adrenergic agents.

Beta-1 Adrenergic Receptors

Beta-adrenergic receptors are transmembrane proteins located in the sarcolemma. The beta-1 receptor subtype is mainly represented in the human heart. Its stimulation induces inotropic, lusitropic, chronotropic, and dromotropic effects that result from the enhancement in Ca^{2+} cytosolic concentration. Binding of a beta-1 agonist agent to its receptor stimulates the Gs protein. Guanosine diphosphate, normally fixed to the stimulatory αs subunit of the Gs protein, is replaced by guanosine triphosphate, and the αs–guanosine triphosphate complex binds to adenyl cyclase, which then becomes activated. Cyclic adenosine monophosphate (cAMP) is formed from ATP and activates protein kinase A. Protein kinase A phosphorylates and activates several cellular structures as follows:

- The ryanodine receptors of the sarcoplasmic reticulum, leading to the enhanced extrusion of Ca^{2+} out of the sarcoplasmic reticulum. Indeed, the main part of the Ca^{2+} cytosolic content needed for contraction is provided by the sarcoplasmic Ca^{2+} store. The entry of Ca^{2+} through the membrane L-type channels modifies the molecular conformation of the ryanodine receptor of the sarcoplasmic reticulum. Parts of these ryanodine receptors are Ca^{2+} channels that enable the massive release of Ca^{2+} out of the sarcoplasmic reticulum (see Fig. 81.1).
- The sarcolemmal L-type Ca^{2+} channels, increasing their opening time. This leads to an increased amount of cytosolic Ca^{2+} available for sarcoplasmic reticulum Ca^{2+} release and for contraction. The increase in intracytosolic Ca^{2+} concentration also leads to the activation of calmodulin. This ubiquitous protein enables the phosphorylation of other proteins once it has fixed Ca^{2+}.
- The myosin light chain through the myosin light chain ATPase. This phosphorylation enhances the responsiveness of the cardiac contractile protein to Ca^{2+} and helps increase the affinity of myosin for actin, thus participating in the inotropic effect.
- The phospholamban and the sarcolemmal Na^+/Ca^{2+} exchanger, leading to a faster decrease in Ca^{2+} cytosolic concentration after contraction and accounting for the lusitropic effect. Indeed, relaxation is dependent on Ca^{2+} reuptake by the sarcoplasmic reticulum through the sarcoendoplasmic reticulum Ca^{2+} ATPase pump. The activity of sarcoendoplasmic reticulum Ca^{2+} ATPase is normally inhibited by phospholamban located in the sarcoplasmic reticulum membrane near the Ca^{2+} pump. The phosphorylation of phospholamban relieves this inhibition, and Ca^{2+} uptake by the sarcoplasmic reticulum is thus stimulated.

Beta-2 Adrenergic Receptors

The beta-2 receptor subtype is mainly represented in noncardiac structures. Beta-2 adrenergic stimulation induces arterial and venous relaxation. The effects of beta-2 stimulation in vascular smooth muscle result from a different activation pathway: once the Ca^{2+} intracytosolic concentration increases, it fixes the calmodulin regulatory protein, and the Ca^{2+}–calmodulin complex activates the myosin light chain kinase, leading to the inhibition of phosphorylation of the myosin light chain and finally smooth muscle relaxation.

Alpha-Adrenergic Receptors

When an agonist fixes the alpha-1 receptor, Gh, which is one of the G-protein family, it stimulates phospholipase C, which splits phosphatidyl inositol into inositol triphosphate and 1,2-diacylglycerol. Inositol triphosphate stimulates the release of Ca^{2+} from the sarcoplasmic reticulum. Alpha-2 adrenoreceptor stimulation inhibits adenylate cyclase and reduces cAMP intracellular concentration. Alpha adrenoreceptors are not prominent in the cardiac tissue but are in the vascular wall. Cardiac alpha-1 stimulation induces a positive inotropic effect; alpha-1 and alpha-2 stimulations induce potent arterial and venous constriction.

Pharmacologic Properties of Inotropic Agents Used in Clinical Practice

Epinephrine

Epinephrine is the main physiologic adrenergic hormone of the adrenal medullar gland. It is a potent stimulator of alpha, beta-1, and beta-2 receptors. The alpha-adrenergic effect is responsible for a marked arterial and venous vasoconstriction. Epinephrine increases systolic arterial pressure, but its effect on vasculature is partly counteracted by beta-2–mediated vasodilation. Diastolic blood pressure is thus only slightly affected by epinephrine, and the increase in mean arterial pressure (MAP) is less than that with norepinephrine.

Through cardiac beta-1 stimulation, epinephrine increases heart rate and inotropism. The effects of the combination of the latter, along with the alpha-mediated venous constriction promoting venous return and cardiac preload, results in an increase in cardiac output. Epinephrine

also facilitates ventricular relaxation and enhanced coronary blood flow through the increase in myocardial oxygen consumption.

Norepinephrine

Norepinephrine is the physiologic mediator released by the postganglionic adrenergic nerves. It is a potent alpha and beta-1 adrenergic agonist, but it has little activity on beta-2 receptors. Through its alpha-adrenergic effect, norepinephrine induces potent arterial and venous constriction. It increases systolic and diastolic blood pressure, left ventricular afterload, and cardiac filling pressures. Its alpha-adrenergic effect also induces the reduction of peripheral venous capacitance and thus results in decreased unstressed venous blood volume and increased stressed venous blood volume. This is responsible for increased mean systemic filling pressure, venous return pressure gradient, and venous return.[47,48] Beta-1 stimulation results in a positive inotropic effect and an increase in stroke volume. However, the chronotropic effect is counteracted by baroreflex stimulation after vasoconstriction. Consequently, the heart rate is unchanged or reduced, and the cardiac output can be unchanged. The coronary blood flow is enhanced by norepinephrine because of coronary vasodilation secondary to enhanced cardiac metabolism and the normalization of diastolic blood pressure when low.

Dopamine

Dopamine is the immediate physiologic precursor of norepinephrine and epinephrine. The cardiovascular effects of dopamine are mediated by several types of receptors that are activated at different dopamine concentrations and by norepinephrine produced by the transformation of dopamine.

At low rates of administration (<5 μg/kg/min), dopamine activates D1 receptors located in renal, mesenteric, cerebral, and coronary vessels and induces vasodilation without affecting arterial blood pressure. At higher and intermediate rates of administration (5–10 μg/kg/min), dopamine predominantly stimulates the beta-1 adrenergic receptor and thus enhances inotropism and increases heart rate. At such rates of infusion, dopamine increases systolic blood pressure without altering diastolic blood pressure because stroke volume is enhanced and arterial vascular tone is only slightly altered. Norepinephrine resulting from dopamine transformation contributes to these cardiovascular effects. At higher rates of administration (10–20 μg/kg/min), dopamine predominantly activates vascular alpha-1 adrenergic receptors and induces arterial and venous vasoconstriction, counteracting D1-receptor–mediated vasodilation. This vasoconstriction increases arterial blood pressure, venous return, and cardiac filling pressures. At higher rates of administration, the hemodynamic effects of dopamine are similar to those of norepinephrine.

Dobutamine

Dobutamine is a synthetic adrenergic agonist derived from dopamine. Its effects on adrenergic receptors are complex, but do not result from endogenous transformation to norepinephrine. Dobutamine simultaneously activates different adrenergic receptors with some opposite effects. In fact, the clinically used drug is a racemic mixture of a (−) enantiomer, activating alpha-1 adrenergic receptors, and of a (+) enantiomer, activating beta-1 and beta-2 receptors. The alpha-1 and beta-1 adrenergic stimulation results in inotropic and chronotropic effects. Dobutamine does not exert any intrinsic vascular effect because the vasoconstriction induced by alpha-1 stimulation is counteracted by the beta-2–mediated vasodilating effect. Nevertheless, hypotension caused by a beta-2–induced decreased vascular tone is a potential side effect of dobutamine when this agent is not able to increase stroke volume, as is frequently the case in septic shock, where beta-1 adrenergic receptors can be moderately sensitive to beta-1 adrenergic stimulation.[49]

Dopexamine

Dopexamine is a synthetic catecholamine inducing beta-2 and dopaminergic-receptor activation, with no effect on alpha-adrenergic receptors and a weak direct effect on beta-1 adrenergic receptors. It also exerts indirect effects through the inhibition of the neuronal reuptake of norepinephrine. Its administration induces vasodilation and the inotropic effect with substantially increased stroke volume.

Isoproterenol

Isoproterenol (or isoprenaline) is a potent synthetic beta-adrenergic agonist with a very low affinity for alpha-adrenergic receptors. Through its potent beta-2–mediated vasodilating effect, it induces a fall in diastolic and mean blood pressure, whereas the systolic blood pressure is increased because of the increase in stroke volume related to its beta-1 adrenergic activation. The combination of the latter effect and the marked increase in heart rate leads to an enhanced cardiac output. The resulting increase in myocardial oxygen consumption is not compensated for by coronary blood flow enhancement so that isoproterenol infusion may lead to myocardial ischemia, especially in the case of preexisting coronary artery disease. Because of its proischemic and hypotensive effects, isoproterenol is no longer used as an inotropic agent in clinical practice in the absence of bradycardia.

Phosphodiesterase Inhibitors

Despite the major role of catecholamines in the management of critically ill patients with inadequate cardiac output, problems such as tachycardia, arrhythmias, increased myocardial oxygen consumption, excessive vasoconstriction, or loss of effectiveness with prolonged exposure to beta-agonists may occur. Thus other inotropic drugs such as phosphodiesterase inhibitors (milrinone and enoximone) have been proposed for the management of myocardial dysfunction. These synthetic drugs inhibit the peak III isoform of phosphodiesterase, which catalyzes cAMP (see Fig. 81.1). By increasing intracellular cAMP concentration, they induce a potent vasodilation of the arterial and venous system through the relaxation of vascular smooth muscle. The left ventricular preload is reduced to a greater extent than with dobutamine. At the cardiac level, phosphodiesterase inhibitors induce an inotropic effect similar to that induced by dobutamine. The heart rate is increased only at high rates of administration. The resulting effect is an increase in cardiac output. Because the enhancement of cAMP intracellular concentration also promotes the reuptake of Ca^{2+} by the sarcoplasmic reticulum, phosphodiesterase inhibitors facilitate ventricular relaxation. Finally, because beta-agonists exert their action by increasing the production of cAMP, phosphodiesterase inhibition could enhance their adrenergic effects. This is the pharmacologic basis for the synergic association of beta-agonists and phosphodiesterase inhibitors.

Ca^{2+} Sensitizers

Ca^{2+} sensitizers increase the sensitivity of troponin C for Ca^{2+} and, hence, the force and the duration of cardiomyocyte contraction (see Fig. 81.1). Levosimendan is the leading drug of this therapeutic class. The advantage of levosimendan over classical inotropes is that it increases the force of contraction without enhancing the influx of Ca^{2+} into the cytosol and thus without increasing the risk of arrhythmias related to this ionic alteration. Some degree of phosphodiesterase III inhibitory activity probably also contributes to the inotropic effect of these drugs. It also induces vasodilation by opening ATP-dependent K^+ channels.[50]

Cardiac Myosin Activators

Omecamtiv mecarbil is the leading drug of cardiac myosin activators. These drugs increase the activity of ATPase of the myofibrils, increasing the contractile force of the cardiomyocytes without increasing the concentration of ATP molecules required for contraction (i.e., without increasing the myocardial oxygen consumption).[51] Additionally, these substances increase the cardiac contractile force without the potentially deleterious increase in intracytoplasmic Ca^{2+} concentration. Cardiac myosine activators have been tested in animal studies in which their inotropic properties have been well demonstrated.[51] In humans, two recent studies have demonstrated that cardiac myosin activators are a valuable new class of therapeutic agents in systolic heart failure.[52,53] Cardiac myosin activators are well tolerated,[52,53] including during exercise in patients with ischemic cardiomyopathy.[54] These agents improve cardiac systolic function in a dose- and concentration-related manner,[52,53] without significant changes in diastolic function.[53] In patients hospitalized for acute heart failure with a left ventricular ejection fraction ≤40% (the ATOMIC-AHF study), administration of omecamtiv mecarbil did not improve dyspnea but was well tolerated.[55] In patients with chronic heart failure with a left ventricular ejection fraction ≤40% (the COSMIC-HF study), the oral administration of omecamtiv mecarbil for several weeks improved cardiac function without any adverse effects.[56] An ongoing trial (the GALACTIC-HF study) is evaluating the long-term outcome of patients with chronic heart failure receiving omecamtiv mecarbil (available at www.clinicaltrials.gov, identifier: NCT02929329).

Istaroxime

Istaroxime is a new drug that inhibits Na^+/K^+-ATPase, increasing the activity of the sarcoendoplasmic reticulum Ca^{2+} ATPase pump by relieving phospholamban inhibition.[57] It induces some inotropic and lusitropic effects.[58] In animals, istaroxime was demonstrated to decrease the end-diastolic volume of the left ventricle and increase the left ventricular ejection fraction. In patients with decompensated heart failure without hypotension, istaroxime decreased the pulmonary artery occlusion pressure and improved the diastolic function of the left ventricle.[59] In patients with acute heart failure, istaroxime decreased pulmonary artery occlusion pressure, decreased heart rate in a dose-dependent manner, and increased systolic blood pressure without any effects on neurohormones or troponin levels.[60] A recent randomized controlled trial has shown that istaroxime improved both systolic and diastolic function of patients with heart failure with reduced ejection fraction without significant cardiac adverse effects (arrhythmias and hypotension).[61]

Nitric Oxide Donors

Nitric oxide donors improve cardiac function by direct positive cAMP-independent lusitropic and inotropic effects.[62] These drugs enhance sarcoendoplasmic reticulum Ca^{2+} uptake via modifications of phospholamban, sarcoendoplasmic reticulum Ca^{2+} ATPase pump, and ryanodine receptor. Moreover, nitric oxide donors improve myofilament Ca^{2+} sensitivity.[63] A human study has shown that nitric oxide donors increase cardiac output and decrease both right and left filling pressures in patients with systolic heart failure without any adverse effects.[63]

Ongoing phase I and II trials are testing a new second generation of nitric oxide donors in healthy volunteers (available at www.clinicaltrials.gov, identifier: NCT02819271) and in patients with heart failure (available at www.clinicaltrials.gov, identifier: NCTNCT02157506).

Decrease in Beta-Adrenergic Response

It is well recognized that the response to beta-adrenergic stimulation is decreased in chronic cardiac failure. This may be a response to the increased activity of the sympathetic nervous system, which may itself be a response to the reduced cardiac output. Therefore this negative retrocontrol of the beta-adrenergic response could act as a protection against excessive adrenergic stimulation. The cellular mechanisms involved are a downregulation of beta-1 adrenergic receptors and a stimulation of the Gi protein of the adenyl cyclase system. The decrease in beta-1 adrenergic receptors could result from a decrease in beta-adrenergic receptor mRNA and to an increased internalization and degradation of these receptors. These latter mechanisms are mainly related to the phosphorylation of beta-1 adrenergic receptors by the beta-adrenoreceptor kinase, which is activated. The high level of nitric oxide production during heart failure contributes to the attenuation of the beta-adrenergic response. The effects of exogenous catecholamines during exacerbations of chronic heart failure can thus be reduced.

Similarly, there is evidence for a decreased responsiveness of the myocardium to beta-adrenergic stimulation during septic shock.[49] This phenomenon may be more likely to occur in the later phase (>24 hours) than in the early phase of the septic process.[64] This may be explained by the inhibition of adenyl cyclase activation because of an overexpression of the Gi protein[65] at the gene level.[66]

HEMODYNAMIC EFFECTS OF INOTROPIC AGENTS IN CRITICALLY ILL PATIENTS

Effects on Cardiac Output

Dobutamine

Dobutamine is the beta-adrenergic agent most widely used in critically ill patients when an increase in cardiac output through an increase in myocardial contractility is desired.

In patients with acute heart failure, dobutamine increases cardiac output and heart rate and decreases pulmonary artery occlusion pressure through a dose-response manner (from 0 to 15 μg/kg/min).[67] In patients with cardiogenic shock, dobutamine is also able to increase cardiac output while decreasing pulmonary artery occlusion pressure.[68]

In patients with septic shock and depressed myocardial function, dobutamine is expected to increase stroke volume and heart rate because of its beta-1 adrenergic properties and exert a vasodilatory effect because of its beta-2 adrenergic properties. Accordingly, an increase in cardiac output and a decrease in systemic vascular resistance (SVR) with dobutamine were reported in septic patients.[69,70] This emphasizes the need to give a potent vasopressive agent to patients with septic shock when dobutamine is administered to support cardiac function in the presence of depressed myocardial contractility. One potential advantage of dobutamine is a decrease in cardiac filling pressures that could allow an additional volume infusion to improve further cardiac output when necessary. A change from dopamine to dobutamine was shown to result in lower right and left ventricular filling pressures and an increase in right ventricular ejection fraction for the same pulmonary artery pressure and right ventricular end-diastolic volume, suggesting that dobutamine exerts a more favorable effect on cardiac contractility than dopamine.[71] This has justified the recommendation to administer dobutamine rather than dopamine when the use of inotropic drugs is judged necessary in patients with severe sepsis or septic shock.[37,38] However, because of the alteration of the beta-1 adrenergic pathway in the septic heart, the effect on stroke volume and cardiac output of a beta-1 agonist agent such as dobutamine may be attenuated in patients with sepsis compared with those without sepsis. In this regard, infusion of dobutamine at 5 μg/kg/min, a dose able to increase cardiac output substantially in patients with acute heart failure,[57] has been reported to exert variable effects in the context of

sepsis. For example, dobutamine at 5 μg/kg/min was reported to induce a substantial increase in cardiac output in some studies in patients with severe sepsis[69,72] but to have no significant effect on cardiac output in some studies investigating patients with septic shock.[73–77] It is likely that these differences in response to dobutamine were related to various individual factors, including differences in the vasopressor coadministered and in the degree of myocardial depression and/or beta-receptor downregulation. In this regard, Silverman and colleagues showed that incremental doses of dobutamine (0, 5, 10 μg/kg/min) produced a dose-related increase in cardiac output in patients with sepsis without shock but no increase in cardiac output in patients with septic shock, even for the highest dose.[49] Interestingly, they also found that the post–beta-adrenergic receptor signal transmission was impaired only in patients of the septic shock group and that impairment of beta-adrenergic receptor responsiveness found in both groups was significantly more marked in the septic shock group.[49] These findings, which allow divergent results of numerous studies to be reconciled,[69,72–80] emphasize the unpredictability of the effects of beta-agonist agents in patients with sepsis. It must be stressed that the absence of positive cardiac response to dobutamine seems to be a marker of poor outcome in septic shock patients.[35,36,77] Because dobutamine also has potentially harmful effects (e.g., myocardial ischemia, cardiac arrhythmias), monitoring its effects on cardiac output to check its efficacy is mandatory, especially in patients who are not responding to initial therapy.[37]

Dopamine

In patients with acute heart failure, dopamine increased stroke volume and cardiac output at 4 μg/kg/min, but not at higher doses, presumably because of an increase in left ventricular afterload. It was also reported that pulmonary artery occlusion pressure increased with dopamine, whereas it decreased with dobutamine.[81] Similar results were observed in patients with cardiogenic shock receiving a dose of 15 μg/kg/min of either agent.[68]

In patients with septic shock, it was reported that the restoration of an adequate MAP with dopamine was mainly produced by the increase in cardiac output, whereas minimal effects on SVR were observed despite relatively high doses of this agent.[82] Dopamine was even demonstrated to increase cardiac output markedly, whereas SVR fell in septic patients without shock.[83] Conversely, in another study in patients with severe septic shock, cardiac output did not increase significantly with dopamine at doses of up to 25 μg/kg/min, whereas SVR either did not change or significantly increased.[84] This emphasizes the great heterogeneity of the response to dopamine among patients with sepsis. This also emphasizes the difficulty in predicting clinical hemodynamic effects from pharmacologic properties because of interindividual differences in terms of the severity of the insult, underlying diseases, comorbidities, integrity of the neuro-vegetative status, drugs concomitantly prescribed, and other factors.

Epinephrine and Norepinephrine

Although these agents have beta-1 adrenergic properties and are thus able to increase myocardial contractility, they are used as vasoconstrictive agents in cases of severe hypotension because they also have potent alpha-adrenergic properties. Nevertheless, significant increases in cardiac output with these drugs have been reported in patients with sepsis.[82,85,86] In this regard, norepinephrine was shown to increase cardiac output to the same extent as dopamine for the same increase in MAP.[82] However, the effects of norepinephrine on cardiac output depend on its effect on cardiac preload[87,88] through an increase in mean systemic filling pressure.[89] By contrast, epinephrine appeared as a potent inotropic agent in most studies in patients with sepsis.[75,90]

Dopexamine

The pharmacologic properties of dopexamine should result in a combination of inotropic, afterload-reducing, and renal vasodilating effects, which could be useful for the management of the acute exacerbation of congestive heart failure. In this regard, dopexamine was reported to substantially increase cardiac output in patients with heart failure without altering blood pressure: at doses of up to 4 μg/kg/min, the majority of the effects resulted from an increase in stroke volume. At higher doses, the increase in heart rate made a greater contribution.[91] In cases of human sepsis, dopexamine produced a dose-dependent increase in stroke volume and heart rate but a dose-dependent decrease in SVR.[92] This underlines the marked vasodilating effect of this drug, which should not be administered in severe sepsis in the absence of a potent vasopressor. Under these conditions, dopexamine at doses ranging from 1 to 4 μg/kg/min could still enhance cardiac output without altering blood pressure.[93]

Phosphodiesterase Inhibitors

In patients with heart failure, phosphodiesterase inhibitors significantly increased cardiac output and stroke volume, whereas blood pressure slightly decreased because of a decrease in SVR, confirming the combined inotropic and vasodilating effects of these agents.[94] Because of the ability of beta-agonist agents to increase cAMP levels, thereby providing an increased substrate for phosphodiesterase inhibitors, the combination of these two types of drugs would be attractive. Synergic effects on the cardiac output of dobutamine and enoximone have been observed in patients with heart failure.[95]

Ca^{2+} Sensitizers

It has been well demonstrated that levosimendan induces some beneficial hemodynamic effects in patients with acute heart failure, with an enhanced cardiac output and a decreased pulmonary artery occlusion pressure.[96] In the LIDO study, levosimendan was shown to improve hemodynamic performance more effectively than dobutamine in patients with low-output heart failure.[96] Unlike dobutamine, levosimendan can keep its effects on cardiac performance in patients receiving beta-blockers.[96,97]

Istaroxime

Only a few clinical trials have studied the effect of istaroxime, a new inotropic-lusitropic agent. Two studies demonstrated that in patients with systolic heart failure, istaroxime increased cardiac index[59,98] and decreased pulmonary artery occlusion pressure and heart rate.[59]

Effects on Arterial Oxygen Content

The aim of inotropic therapy in critically ill patients with reduced cardiac contractility is not only to increase cardiac output but also to ultimately improve oxygen delivery to the tissues. Thus attention should be paid to the effects of these drugs on arterial oxygen content. Inotropes may affect arterial oxygen tension through several mechanisms. First, the reduction in lung filtration pressure resulting from an improvement in cardiac function may decrease intrapulmonary shunt fraction and thus improve arterial oxygenation. Second, the increase in cardiac output may result in an increased venous admixture.[99] On the other hand, the increased mixed venous blood oxygen tension resulting from increased cardiac output may improve arterial oxygenation in the presence of ventilation/perfusion mismatching and may thus compensate for the increased venous admixture. Accordingly, when looking at published data, it appears that even if the venous admixture increased with the administration of an inotropic agent, no significant change in arterial oxygen tension was observed.[100,101] Therefore when an inotropic agent increases cardiac output in critically ill patients, it generally increases oxygen delivery to the same extent.[69,82,102,103]

Effects on Tissue Oxygen Utilization

Even though an inotropic agent results in a large increase in oxygen delivery, its effectiveness in reducing oxygen deficit depends on its capacity to provide oxygen in the most hypoxic tissues. This concern is particularly crucial because, first, the redistribution of blood flow is a characteristic pattern of shock states and, second, inotropic drugs may also have vasoactive properties that interact with blood flow distribution.

Cardiogenic Shock

In this setting, the redistribution of blood flow is recognized as a potent compensatory mechanism, which, in response to reduced global oxygen delivery, attempts to redirect blood flow from nonvital organs with a low oxygen extraction ratio toward vital organs with a high oxygen extraction ratio such as the heart or the brain. It must be kept in mind that the administration of drugs with vasoactive properties may interfere with the vasoregulation of regional blood flow. The extent to which this interference is beneficial in increasing oxygen supply and oxygen consumption in hypoxic areas remains speculative. This emphasizes the need to monitor, as far as possible, the perfusion and/or function of critical organs.

Septic Shock

The maldistribution of flow at the macrocirculatory level and the microcirculatory level mainly contributes to defective tissue utilization and eventually to tissue oxygen debt in sepsis, even when systemic oxygen delivery is greater than normal. Besides sepsis-induced microthrombosis, sepsis-induced alteration in vascular reactivity is a major cause of the altered distribution of blood flow between and within organs. In addition, severe sepsis can modify the impact of endogenous catecholamines and adrenergic drugs on regional blood flows, given that a depressed vascular responsiveness to vasoactive agents is likely to occur in this setting. This hypothesis may account for the absence of the reduction of renal blood flow observed during norepinephrine administration in bacteremic animals in comparison with controls.[104]

In cases of human sepsis, numerous studies have examined the effects of adrenergic agents on splanchnic perfusion. Their findings have sometimes varied either because of differences in the methods used for assessing this regional circulation (e.g., gastric tonometry, laser-Doppler flowmetry, indocyanine green dilution) or because of the heterogeneity of the studied populations (e.g., differences in the severity of the septic insult, underlying diseases, or therapy coadministered). However, from the findings of the majority of these studies, some reasonable conclusions can be drawn. First, dobutamine is likely to exert a beneficial effect on gut mucosal perfusion,[70,73,75,79,105] probably via a beta-2 adrenergic effect.[106] Dobutamine may also improve hepatic microcirculation via a beta-1 adrenergic effect.[107] Second, dopamine may have deleterious effects on gut mucosal perfusion,[82] despite its potential vasodilating action through mesenteric dopaminergic receptors. Third, epinephrine is probably the adrenergic agent with the least desirable effects on the splanchnic vasculature, as most studies showed a lower splanchnic blood flow with epinephrine than norepinephrine alone[108] or in combination with dobutamine,[73,75,109] even for similar global hemodynamic effects. Fourth, dopexamine can exert a favorable effect on splanchnic perfusion[110] comparable to that of dobutamine[74] and that is likely to be related to a beta-2 adrenergic effect.

Regarding the effects of inotropic agents on renal circulation in patients with sepsis, two major points must be kept in mind. First, an alpha-adrenergic agent such as norepinephrine is able to increase renal blood flow and urine output,[84,111–113] despite its potential vasoconstricting effect on the afferent glomerular arteries. This is probably because of the beneficial effect of increasing MAP when the renal blood flow is dependent on its perfusion pressure as it occurs in the presence of profound systemic hypotension. Otherwise, the sepsis-induced depressed responsiveness of afferent glomerular arteries to the action of norepinephrine cannot be excluded. Accordingly, there is more evidence that norepinephrine increases, rather than decreases, renal blood flow and urine output when given to patients with sepsis to increase the MAP toward normal values.[84,111,112,114] Moreover, it has been demonstrated in patients with septic shock that elevating the MAP to up to 85 mm Hg with incremental doses of norepinephrine was not associated with a decrease in urine output.[113,115,116] Second, although dopamine at low doses (<5 μg/kg/min) is pharmacologically able to vasodilate renal arteries through its action on dopaminergic receptors, the systematic administration of low doses of dopamine in critically ill patients, including patients with sepsis, does not result in improved outcome[117] and is no longer recommended. Finally, no study focused on the renal effects of levosimendan in patients with septic shock. Nevertheless, a study showed that in postoperative cardiac patients, levosimendan infusion increased both renal blood flow and glomerular filtration, likely via its vasodilatory effects.[118]

Catecholamines can also exert proper effects on the microcirculation. First, the administration of 5 μg/kg/min of dobutamine was shown to improve sublingual microvessel perfusion measured with orthogonal polarizing spectral imaging in patients with septic shock.[119] Interestingly, these changes were independent of changes in systemic hemodynamic variables.[119] The improvement of sublingual microcirculation seems to occur only in patients with severe alterations at baseline.[120] Nevertheless, the effect of dobutamine on microcirculation is still debated. The administration of 5 μg/kg/min in patients with sepsis having hyperlactatemia and a cardiac index of greater than or equal to 2.5 L/min/m^2 failed to improve sublingual perfused vessel density or microvascular flow index in spite of a significant increase in systemic hemodynamics.[102] Compared with the administration of 5 μg/kg/min of dobutamine, an infusion of low doses of levosimendan improved sublingual microcirculatory blood flow patients with septic shock, probably via its vasodilatory effects.[121] Two studies showed no significant effect of increasing MAP with norepinephrine on sublingual microvessels in patients with septic shock who had already been resuscitated.[85,86] However, another study conducted in patients with septic shock requiring norepinephrine for arterial hypotension resistant to fluid administration demonstrated that increasing the MAP from 65 to 85 mm Hg by titrating norepinephrine doses allowed the improvement of sublingual microvessel circulation.[122] Thus at least nonworsening, or even improvement, of microcirculation can result from norepinephrine infusion in patients with septic shock even when a MAP of up to 85 mm Hg is targeted. It is noteworthy that in patients with septic shock who also have a history of chronic hypertension, improved sublingual microcirculation was reported when the usual patient's level (averaged value 93 mm Hg) was targeted compared with 65 mm Hg.[120] This result is in agreement with the results of a multicenter, randomized clinical trial showing that this specific population of patients may benefit from a higher MAP target, at least in terms of renal function, than the population of patients with no chronic hypertension.[123] Nevertheless, a recent study showed that targeting a MAP up to 85–90 mm Hg, as compared with 65 mm Hg, improved sublingual microcirculation in septic shock patients with or without a history of chronic hypertension.[124] Finally, inotropic drugs may also exert nonhemodynamic effects that could affect cellular metabolism and/or organ function.[24,125] For example, the administration of epinephrine in patients with septic shock was demonstrated to increase blood lactate level independently of tissue hypoxia by the stimulation of skeletal muscle cell Na^+/K^+-ATPase, which accelerates aerobic glycolysis and thus the production of pyruvate, and hence of lactate, into the cell.[126]

This metabolic effect is assumed to be related to the activation of the beta-2 adrenergic receptors located at the surface of the skeletal muscle cells.[127] In addition, catecholamines may modulate cytokine response to sepsis, trauma, or major surgery through beta-adrenergic receptor activation.[24] It remains to be evaluated whether this effect (inhibition of proinflammatory cytokines and enhancement of proinflammatory cytokine production) plays a beneficial role in the reversal of tissue hypoxia and organ dysfunction.

MAIN INDICATIONS OF INOTROPIC THERAPY IN PATIENTS WITH CIRCULATORY FAILURE

Acute Heart Failure and Cardiogenic Shock

For the American College of Cardiology Federation/American Heart Association, inotropic agents should be considered in patients with heart failure, in those who are refractory to other therapies, and in those who are suffering consequences from end-organ hypoperfusion.[128,129] In practice, inotropes should be restricted to patients with systolic dysfunction who have a low cardiac index and evidence of systemic hypoperfusion and/or congestion.[128,129] In the European Society of Cardiology guidelines, inotropes should be considered in patients with acute heart failure and in patients having hypotension (systolic blood pressure <90 mm Hg) and/or symptoms of hypoperfusion despite adequate filling status to increase cardiac output, increase blood pressure, and maintain end-organ function.[3] Overall, these indications clearly limit the use of inotropic agents to patients with acute heart failure and low systolic blood pressure, most likely to have increased mortality rates with a strong inverse correlation between systolic blood pressure and survival.[130] For the European Society of Cardiology, dobutamine is currently the first-line inotropic agent in the presence of acute heart failure with low systolic arterial blood pressure.[3] Levosimendan is currently considered the first-choice drug over dobutamine in patients with acute heart failure treated by beta-blocker therapy if beta-blockade is thought to be contributing to hypoperfusion.[3] For the American Heart Association, dobutamine and dopamine are both cited as inotropic agents,[128,129] whereas levosimendan is instead considered as a rescue therapy.[129] Twenty years ago, the SHOCK trial registry (1190 patients) reported that dopamine and dobutamine were used in 89% and 70%, respectively, of patients with cardiogenic shock resulting from massive acute myocardial infarction.[131] However, the use of dopamine is still a matter of debate. In a study comparing dopamine with norepinephrine as the first-line vasopressor agent in the treatment of shock, the use of dopamine was associated with a greater number of cardiac arrhythmias.[132] In addition, in a predefined subgroup analysis, the authors reported that the use of dopamine was associated with an increased risk of death in the subgroup of 280 patients with cardiogenic shock.[132] Finally, a multicenter, placebo-controlled clinical trial demonstrated that the use of low-dose dopamine in patients with acute heart failure and renal dysfunction had no significant effect on the 72-hours' cumulative urine volume and did not improve renal function, assessed by the change in cystatin C levels.[133]

Epinephrine was compared with the combination of norepinephrine and dobutamine in patients with dopamine-resistant cardiogenic shock—for example, with a cardiac index of less than 2.2 L/min/m^2 and a MAP of less than 60 mm Hg.[134] Epinephrine or norepinephrine-dobutamine were titrated to obtain a MAP of greater than 65 mm Hg.[134] Epinephrine infusion was as effective as the combination of norepinephrine and dobutamine to improve cardiac index and oxygen-derived parameters. Nevertheless, epinephrine infusion induced arrhythmia, increased blood lactate level, and impaired splanchnic circulation.[134] More recently, epinephrine was compared with norepinephrine in patients with cardiogenic shock after acute myocardial infarction.[135] Epinephrine or norepinephrine were titrated to obtain a MAP >65 mm Hg. Changes in cardiac index were similar for the first 72 hours with epinephrine and norepinephrine infusion. Nevertheless, epinephrine infusion was associated with tachycardia, increased cardiac double product (an indirect marker of myocardial oxygen consumption), and increased blood lactate level. More importantly, epinephrine infusion was associated with a higher incidence of refractory cardiogenic shock, leading to early termination of the study.[135]

It must be stressed that the intravenous administration of catecholamines such as dobutamine was shown to be associated with an increased risk of death in patients with acute heart failure.[136,137] This emphasizes their restrictive use to patients in whom pump failure results in severe hypotension and peripheral hypoperfusion.[3,128,129]

Phosphodiesterase inhibitors have been proposed as an alternative to beta-adrenergic agents. However, results of trials of long-term oral phosphodiesterase inhibitor therapy in chronic heart failure and of the OPTIME-CHF study in the acute decompensation of congestive heart failure[138] have been disappointing. Thus the use of these agents is limited to a few categories of patients: (1) patients with advanced heart failure awaiting transplantation in whom intravenous milrinone could be better tolerated than dobutamine and its use may allow the continuation of beta-blocker therapy controlling arrhythmias or myocardial ischemia[139]; (2) patients with acute decompensation of chronic heart failure, who are unable to achieve stabilization with the standard treatment; and (3) patients with long-term beta-blocker use, in whom short-term intravenous milrinone may even be preferred to dobutamine.[140] Enoximone, another phosphodiesterase inhibitor, was tested in patients with advanced heart failure. As with milrinone, the results were disappointing. Low doses of enoximone could not improve all-cause mortality or the 6-minute walk test distance.[141] There is now clear evidence that phosphodiesterase inhibitors such as beta-agonists can exert both short-term beneficial hemodynamic effects and serious adverse effects that make them deleterious in terms of long-term outcome. It is likely that their adverse effects (e.g., arrhythmias, increased risk of myocardial ischemia) are related to the increased cAMP concentration in the cytosol of the cardiomyocyte.[142]

The initial enthusiasm in the use of Ca^{2+} sensitizers in patients with heart failure has attenuated in recent years. In the LIDO study, compared with dobutamine, levosimendan significantly decreased mortality rate and improved the hemodynamic condition.[96] Nevertheless, these positive results have been contradicted in two large-scale studies. In the REVIVE study,[143] even though levosimendan improved the composite judgment criteria of clinical signs of heart failure at 5 days compared with placebo, the mortality rate was not significantly changed. In the SURVIVE study,[144] levosimendan was not better than dobutamine in increasing the survival rate in patients with acute heart failure requiring inotropic support. A meta-analysis concluded that in patients with acute severe heart failure, levosimendan improved hemodynamic parameters when compared with placebo, without showing evidence of survival benefit.[145] However, recent meta-analyses demonstrated that levosimendan reduced mortality rate when compared with dobutamine and decreased hospital length of stay in the overall population of cardiologic patients, including but not restricted to patients with heart failure.[146,147] Another indication of levosimendan may be patients with heart failure receiving concomitant use of beta-blocker therapy, a situation where higher doses of dobutamine are usually required to have some efficacy. In such patients, dobutamine was shown to be as effective as levosimendan in the first 24 hours of treatment to increase cardiac index and decrease pulmonary artery occlusion pressure.[148] However, at 48 hours, levosimendan still efficiently improved hemodynamics, whereas dobutamine did not.[148] It must be noted that in a post hoc

analysis of the SURVIVE trial, patients previously receiving beta-blocker therapy had improved short-term survival with levosimendan compared with dobutamine.[148] Moreover, when compared with placebo, levosimendan improved contractility in patients with acute heart failure after myocardial infarction[149] and levosimendan provided rapid and durable symptomatic relief.[150] Nevertheless, levosimendan induced hypotension[149,150] or cardiac arrhythmias.[150] A systematic review found no significant beneficial effects of levosimendan for low cardiac output syndromes in the general population of critically ill patients.[151] A new randomized trial (levoheartShock study) will start soon to compare the effects of an early use of levosimendan with placebo on top of a conventional strategy of inotrope use on a combined morbidity-mortality endpoint in patients with cardiogenic shock (available at www.clinicaltrials.gov, identifier: NCT04020263). In two recent large randomized controlled trials (CHEETAH and LEVO-CTS), levosimendan, as compared with placebo, did not improve the outcome of patients with systolic heart failure undergoing cardiac surgery,[152,153] although levosimendan reduced the use of inotropes after surgery.[153] Finally, a recent meta-analysis of several small trials showed that repeated administration of levosimendan in outpatient settings with advanced heart failure may improve hemodynamics, symptoms, and biomarkers and decrease the rate of rehospitalization of these patients.[154] The recent LION-HEART study[155] confirmed that intermittent intravenous administration of levosimendan in outpatients with advanced heart failure reduced biomarkers, decreased the rate of hospitalization at 12 months, and improved the quality of life of these patients, without any significant adverse effects. Nevertheless, such a strategy of levosimendan use still deserves further studies, such as the ongoing randomized controlled trial (LeoDOR study, available at www.clinicaltrials.gov, identifier: NCT3437226).[156] Currently, all these disappointing results have slowed down the commercialization of levosimendan in many countries. Nevertheless, levosimendan may be an interesting therapeutic option to treat takotsubo syndrome or to facilitate weaning from venoarterial extracorporeal membrane oxygenation.[157]

Nitric oxide synthase inhibitors have been proposed to be used in patients with cardiogenic shock, in whom nitric oxide production is increased, and may exert deleterious effects on cardiac function and vascular tone.[158] Tilarginine is a nonselective nitric oxide synthase inhibitor developed for treating acute heart failure. However, in the TRIUMPH study, tilarginine was unable to improve the survival rate in patients with cardiogenic shock at 3 months in comparison with placebo.[159] These negative results have interrupted the clinical development of this new drug.

Septic Shock

Treating or not treating septic-induced myocardial depression has been a matter of debate. First, it has been thought that left ventricular dilatation and low ventricular ejection fraction denote adaptive mechanisms and then, if so, treating it is questionable. In this regard, left ventricular ejection fraction was reported to be lower and left ventricular end-diastolic volume to be higher in survivors,[160,161] although a meta-analysis showed no difference between survivors for the two parameters. Second, because of the potential, but not constant, hyporesponsiveness of the beta-receptors, the efficacy of beta-agonists is not guaranteed. Third, side effects may occur with these drugs (tachycardia, arrhythmias, and hypotension). It must be stressed that there is an association of inotrope use during septic shock with mortality.[162] For all these reasons, inotropes, and among them dobutamine, should be not systematically administered even when a septic myocardial depression is suspected. It should be reserved for situations where cardiac dysfunction is accompanied by a low or inadequate cardiac output and signs of tissue hypoperfusion in spite of preload optimization.[37] The potential interest of administering dobutamine in patients with septic shock experiencing septic cardiomyopathy in order to reduce tissue hypoperfusion and associated organ dysfunctions will be investigated in a study that will start soon (ADAPT study, available at www.clinicaltrials.gov, identifier: NCT04166331). Bidimensional echocardiography[45,163] is the best tool to diagnose a severe decrease in cardiac contractility. However, bedside echocardiography is not available in all general ICUs; hence, the Surviving Sepsis Campaign recommends the use of dobutamine in patients with septic shock who show evidence of persistent hypoperfusion despite adequate fluid loading and the use of vasopressors.[38] Because dobutamine can exert vasodilatory effects, its use requires the concomitant use of a vasopressor such as norepinephrine. In septic shock, it is clearly recommended to use norepinephrine as the first-choice agent rather than dopamine because the latter is associated with increased mortality.[164] Epinephrine is a potent inotrope with vasopressive properties that could be used as an alternative to the combination of dobutamine and norepinephrine. A randomized study in patients with septic shock and a presumed cardiac dysfunction found no significant difference in patient outcome between epinephrine alone and a combination of norepinephrine and dobutamine.[165] However, this study has been criticized for a lack of statistical power. In the condition of depressed vascular tone and reduced myocardial function, despite similar effects on systemic blood flow and pressure, epinephrine was shown to be inferior to the combination of dobutamine and norepinephrine in terms of splanchnic perfusion[73,75,109] or to norepinephrine alone in terms of myocardial oxygen consumption.[166] A meta-analysis showed that the use of norepinephrine in patients with sepsis reduced the mortality rate, whereas the use of epinephrine did not.[167] For all these reasons, epinephrine is not recommended as the first-choice drug when the treatment of impaired cardiac contractility is considered.[49] The use of levosimendan has been proposed as an alternative to dobutamine in cases of severe septic myocardial depression that no longer responds to dobutamine administration.[168] The rationale for using levosimendan is that the sensitivity of Ca^{2+} to myofilament is reduced during sepsis, probably because of an abnormal phosphorylation of the troponin complex at the site where the Ca^{2+} ion binds to troponin C.[169] Because levosimendan can improve not only left ventricular function but also right ventricular performance through pulmonary vasodilation,[170,171] it might be useful in cases of septic myocardial depression with associated lung injury. Recently, a randomized controlled study (LeoPARDS)[172] showed that systematic levosimendan infusion, when added to standard care, failed to reduce mortality or organ dysfunction at day 28 in patients with septic shock. Importantly, patients receiving levosimendan required a higher dosage of norepinephrine, had more atrial fibrillation, and were less likely to be weaned from mechanical ventilation.[172] A major criticism of this study was that levosimendan was administered in patients without documented cardiac dysfunction in the majority of cases and thus in patients who could have suffered from side effects without getting any benefit in terms of cardiac function. In this regard, dobutamine was administered in less than 10% of the standard care group, suggesting that the incidence of cardiac depression was low in this study.[173] It must be noted that a subgroup analysis of the LeoPARDS study reported no benefit of levosimendan in patients with septic shock and biochemical evidence of myocardial injury or dysfunction, as attested by increased cTnI and Nt-proBNP blood levels.[174] It is important to note that the concept of using beta-blockers in septic conditions to prevent systemic adrenergic activation has recently emerged. In an experimental model, esmolol infusion had no significant effect on cardiac index or systemic arterial pressure and may prevent septic cardiac dysfunction by a preload effect induced by the decrease in heart rate.[175] In patients with septic shock, esmolol infusion was associated with a preserved stroke volume and microcirculation and a decrease in norepinephrine requirement.[176] In this regard, a randomized clinical trial was conducted in patients with septic shock and heart rate of greater than 90 beats/min.[177] Esmolol infusion decreased

heart rate, increased stroke volume and left ventricular stroke work index, and decreased arterial blood lactate level and fluid requirements. Although mortality rate was not the primary endpoint, it should be noted that esmolol infusion was associated with a significant decrease in 28-day mortality.[177] Esmolol infusion also can decrease the arterial elastance of tachycardic patients with septic shock and thus might improve the cardiovascular efficiency in such patients.[178] Nevertheless, patients with severe cardiac dysfunction (i.e., cardiac index ≤2.2 L/min/m^2 in the presence of a pulmonary artery occlusion pressure >18 mm Hg) were excluded.[177,178] As a consequence, the presence of cardiac dysfunction during sepsis cannot be considered as an indication for beta-blockers and should be still considered as a contraindication for their use. The effect of landiolol, a new highly selective beta-blocker with a short-acting effect, is currently tested against placebo in patients with septic shock with cases of tachycardia or tachyarrhythmia.[179]

In summary, given all the available data, it is still recommended to choose the combination of norepinephrine and dobutamine when inotropic therapy is given to reverse cardiac dysfunction in severe sepsis.

KEY POINTS

- Inotropic therapy is considered in patients with cardiogenic shock. In these situations, clinicians expect short-term positive effects of intravenous inotropic drugs, allowing cardiovascular stabilization.
- Inotropic therapy might also be considered in high-risk surgical patients, even in the absence of formally documented myocardial depression, to achieve supranormal levels of oxygen delivery during the perioperative period to prevent tissue hypoxia and organ dysfunction. Such a therapeutic attitude, which is still debated in the perioperative context, is not recommended routinely for critically ill patients with established circulatory shock.
- Most inotropic agents enhance myocardial contractility by increasing the Ca^{2+} concentration in the cytosol of cardiomyocytes after producing an increase in cytosolic cAMP concentration. Synthetic and natural catecholamines enhance cAMP formation after fixing beta-1 adrenergic receptors at the cellular surface, whereas phosphodiesterase inhibitors decrease cAMP degradation.
- Beta-1 adrenergic agents, such as dobutamine, dopamine, and epinephrine, are the most potent inotropic agents.
- Because of the downregulation of beta-1 adrenergic receptors, the myocardial effects of exogenous catecholamines can be attenuated after a few days of administration.
- Sepsis-induced decreased responsiveness of the myocardium to beta-adrenergic stimulation may also result in the attenuation of cardiac effects of exogenous catecholamine administration in patients suffering from septic shock.
- The drugs given to increase cardiac contractility may also exert vasoactive effects that may interfere with the regulation of regional blood flow. The extent to which this interference is beneficial in increasing oxygen supply in hypoxic areas remains speculative. This emphasizes the need to monitor, as far as possible, the perfusion and/or function of critical organs when such agents are given to patients in circulatory shock.

De Backer D, Aldecoa C, Njimi H, et al. Dopamine versus norepinephrine in the treatment of septic shock: a meta-analysis. *Crit Care Med.* 2012; 40(3):725–730.
The objective of this meta-analysis was to compare the effects of norepinephrine and dopamine on outcome and adverse events in patients with septic shock. Six randomized studies (1408 patients) were included. Dopamine administration was associated with greater mortality and a higher incidence of cardiac arrhythmic events compared with norepinephrine administration. This paper is important because it greatly contributed to changing the guidelines of the Surviving Sepsis Campaign, which now recommends the use of norepinephrine as a first-choice vasopressor and to restrict the use of dopamine to highly selected patients (e.g., patients with low risk of tachyarrhythmia and absolute or relative bradycardia).

Hayes MA, Timmins AC, Yau EH, et al. Elevation of systemic oxygen delivery in the treatment of critically ill patients. *N Engl J Med.* 1994;330(24): 1717–1722.
This randomized study showed that attempting to achieve supranormal values of oxygen delivery in patients with an established critical illness may worsen rather than improve outcome.

Levy B, Clere-Jehl R, Legras A, et al. Epinephrine versus norepinephrine for cardiogenic shock after acute myocardial infarction. *J Am Coll Cardiol.* 2018;72(2):173–182.
In this randomized controlled trial, epinephrine and norepinephrine were compared as first-choice vasopressors in cardiogenic shock secondary to acute myocardial infarction. The use of epinephrine was associated with similar effects on arterial pressure and cardiac index but with a higher incidence of refractory shock. This paper confirms the priority place of norepinephrine for reversing hypotension in the majority of shock states.

Mebazaa A, Nieminen MS, Packer M, et al. Levosimendan vs. dobutamine for patients with acute decompensated heart failure: the SURVIVE Randomized Trial. *JAMA.* 2007;297(17):1883–1891.
In 1327 patients with acute decompensated heart failure requiring inotropic support, levosimendan was compared with dobutamine in a randomized double-blind design. Despite an initial reduction in plasma B-type natriuretic peptide level in patients receiving levosimendan, levosimendan did not significantly reduce all-cause mortality at 180 days or affect any secondary clinical outcomes. These disappointing results slowed down commercialization of levosimendan in many countries throughout the world.

Morelli A, De Castro S, Teboul JL, et al. (2005). Effects of levosimendan on systemic and regional hemodynamics in septic myocardial depression. *Intensive Care Med.* 31(5):638–644.
In septic patients with persisting cardiac dysfunction after 48 hours of dobutamine administration, compared with dobutamine continuation, levosimendan improved systemic hemodynamics, improved gastric mucosal perfusion and renal function, and decreased lactate. This study suggested that levosimendan might be an alternative to dobutamine for treating sepsis-induced cardiac dysfunction, especially when dobutamine is no longer effective.

Peake SL, Delaney A, Bailey M, et al. Goal-directed resuscitation for patients with early septic shock. *N Engl J Med.* 2014;371(16):1496–1506.
In this multicenter, randomized controlled trial, 1600 patients presenting to the emergency department with early septic shock were randomly assigned to receive either EGDT or usual care. EGDT did not reduce all-cause mortality at 90 days. This paper contributed to seriously questioning the interest of using EGDT, including $ScvO_2$, in the early phase of septic shock.

Silverman HJ, Penaranda R, Orens JB, et al. Impaired beta-adrenergic receptor stimulation of cyclic adenosine monophosphate in human septic shock: association with myocardial hyporesponsiveness to catecholamines. *Crit Care Med.* 1993;21(1):31–39.
This clinical study demonstrated that patients with septic shock exhibit a decreased hemodynamic response to dobutamine when compared with septic patients without shock. Moreover, the stimulation of circulating lymphocytes of the studied population showed that in patients with septic shock, the degree of impairment of beta-adrenergic receptor responsiveness in addition to that of post–beta-adrenergic receptor signal transmission was greater than in septic patients without shock. This study provides strong evidence of a septic shock–related myocardial hyporesponsiveness to catecholamines that may contribute to the reduced myocardial performance observed in this critical illness.

Mechanical Support in Cardiogenic Shock

Laura M. Seese, Arman Kilic, and Thomas G. Gleason

Heart disease remains the leading cause of death in both men and women among African Americans, Hispanics, and Caucasians in the United States, accounting for nearly 650,000 deaths annually.[1] Significant progress has been made over the past few decades in defining and recognizing cardiogenic shock (CS), and although there are many potential causes of this condition, acute myocardial infarction (AMI) with a large loss of functioning myocardium is the most frequent.[2,3] Despite advances in early reperfusion and mechanical support treatment approaches, CS remains the most common cause of in-hospital mortality after AMI, with rates exceeding 50%.[2]

In 1912 James Herrick was the first to link observations of patients with AMI with autopsy findings of patients who had died from CS.[3] His contention at the time, which was initially rejected by the medical community, was that AMI was not always immediately fatal and that efforts were needed to diagnose and treat the condition while the patient was still alive.[3] It was not until the mid-to-late 20th century when selective coronary angiography became available in humans that DeWood and others reported evidence of coronary occlusion in patients suffering AMIs.[4] These findings laid the foundational basis for developing interventional and medical treatments for AMI to intervene and support patients who were diagnosed with CS. A standard definition of CS was proposed by Binder and colleagues in 1955, which included factors such as a systolic blood pressure less than 80 mm Hg and tachycardia to greater than 100 bpm with signs of peripheral vascular collapse.[5] At the time this definition was developed, the mortality associated with CS after AMI was still close to 100%.[5]

Over the past several decades, the general definition of CS has evolved into a severe impairment of myocardial performance that results in diminished cardiac output (CO), end-organ perfusion, and hypoxia.[6] Despite an updated definition, a level of uncertainty in the outcomes of CS persists, with some contemporary clinical trials lacking uniformity in their definitions for identifying CS. For instance, although the SHOCK (Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock) and Intra-Aortic Balloon Pump (IABP)-SHOCK II trials used systolic blood pressure ≤90 mm Hg for ≥30 minutes, their exact parameters for confirming end-organ hypoperfusion were diverse (Table 82.1).[7,8] Clinically CS is recognized to be on a continuum, but the presence of hypotension refractory to volume resuscitation and features of end-organ hypoperfusion requiring pharmacologic or mechanical support are the crux of this diagnosis.[9] AMI remains the instigator of 81% of CS events.[10] Furthermore, the incidence of CS in myocardial infarction has remained relatively constant in recent decades (,7%) and remains the leading cause of death in patients with AMI.[7]

HISTORY OF MECHANICAL CIRCULATORY SUPPORT

The evolution of mechanical circulatory support (MCS) dates to the early 1950s when Gibbon developed the prototype cardiopulmonary bypass (CPB) apparatus.[11] In the years that followed, Lillehei, Kirklin, and others applied the heart-lung machine to facilitate open heart surgery; their pioneering work and early observations led directly to the development of modern MCS systems.[12–14] Their initial publications introduced the concept that left ventricular (LV) decompression and myocardial rest could afford enhanced cardiac recovery after the insult of open heart surgery. Clinical use of extracorporeal CPB for heart surgery became widespread in the early 1960s. Simultaneously, several groups of investigators were testing means of MCS for use outside the operating room to support patients in CS. The current modes of MCS are derivations of those originally developed.

The decision on the type of MCS used is based on the acuity of the patient's presentation, level of flow or adjunctive CO, and the overall goals of therapy. This decision often changes as the patient's clinical picture evolves. MCS devices include the intraaortic balloon pump (IABP), continuous flow pumps with or without an oxygenator, percutaneous devices, and durable continuous flow pumps. Temporary MCS devices are used in CS as a bridge to recovery (BTR), bridge-to-bridge with a long-term implantable MCS device, bridge to transplant (BTT), or bridge to decision. Some temporary MCS devices can be inserted percutaneously, whereas others require surgical implantation. Long-term MCS devices are used as a BTR, a BTT, or the definitive means of treatment for the patient's remaining lifespan—that is, destination therapy (DT). These devices have been employed for a variety of causes of CS, including AMI, inability to wean from CPB (postcardiotomy CS), acute decompensation of chronic heart failure (HF), acute myocarditis, peripartum cardiomyopathy, HF secondary to acute or chronic valvular heart disease, and congenital heart defects.

History of Aortic Counterpulsation

The concept of arterial counterpulsation was introduced in 1961 by Clauss and coworkers. It involved use of an external "ventricular" chamber that filled with blood from a catheter in the iliac artery and was subsequently compressed by a piston. Compression of the "ventricle" was synchronized to either the QRS complex of an electrocardiogram (ECG) or the impulse of a pacemaker so that a counterpulse of blood was delivered into the arterial system during diastole.[15] It was demonstrated in dogs that cardiac stroke work and LV end-systolic pressures were substantially reduced with the use of a counterpulsation into the aorta. The following year, Moulopoulus and associates adapted the model to create an IABP that could provide a similar

TABLE 82.1 Available Definitions of Cardiogenic Shock

Clinical Definition	SHOCK Trial	IABP-SHOCK II	ESC HF Guidelines
Cardiac disorder that results in both clinical and biochemical evidence of tissue hypoperfusion	Clinical criteria: SBP <90 mm Hg for >30 minutes OR support to maintain SBP >90 mm Hg AND end-organ hypoperfusion (urine output <30 mL/hr or cool extremities) Hemodynamic criteria: CI of <2.2L·m^{-2} AND PCWP >15 mm Hg.	Clinical criteria: SBP <90 mmHg for >30 minutes OR catecholamines to maintain SBP >90 mm Hg AND clinical pulmonary congestion AND impaired organ perfusion (altered mental status, cold/clammy skin and extremities, urine output <30 mL/hr or lactate >2.0 mmol/L)	Clinical criteria: SBP <90 mm Hg with adequate volume and clinical or laboratory signs of hypoperfusion. Clinical hypoperfusion: cold extremities, oliguria, mental confusion, dizziness, narrow pulse pressure. Laboratory hypoperfusion: metabolic acidosis, elevated serum lactate, elevated serum creatinine

counterpulsation without the need for blood reservoirs.[16] The investigators used a balloon that was rapidly inflated and deflated with carbon dioxide during native diastole. The IABP was subsequently adapted and described for clinical use by Kantrowitz and colleagues in 1968.[17] There is little difference in the modern IABP and that originally described, other than the availability of different-sized balloons (30- to 50-mL balloons), the use of helium instead of carbon dioxide, and subtle differences in the materials used to make the catheters.

History of Mechanical Assist Devices

The need for effective MCS devices with more options for greater cardiac flow support became apparent in the 1950s during the development of CPB for open heart surgery. The first attempt at isolated extracorporeal LV support was with a simple roller pump in 1962.[18] Initial attempts with prolonged postoperative CPB demonstrated that the bypass circuit was damaging to both end-organ function and blood constituents after several hours of use.[19] Subsequently, femoral venous–to–femoral arterial CPB was successfully used by Spencer and colleagues in four patients with postcardiotomy cardiac failure.[20] Simultaneous to Spencer and colleagues' work with extracorporeal systems, DeBakey designed the first intracorporeal LV assist device (LVAD), the DeBakey blood pump.[21] A remodeled extracorporeal version was subsequently used for postcardiotomy failure in a 37-year-old woman after aortic and mitral valve replacements. The device was needed for 10 days, and the patient survived.[22]

By 1972 investigators at the Texas Heart Institute had developed a pneumatically driven LVAD designed to be implanted in the abdomen.[23] This device had a blood chamber compressed by pulses of air delivered into the pump by a percutaneous driveline. Modern devices have chamber compression that is electrically powered via percutaneous drivelines. Paracorporeal, pneumatically driven devices were a parallel development. Paramount to the evolution of these devices was the sponsorship of the Artificial Heart Program of the National Heart, Lung, and Blood Institute, which was chartered in 1964.

By the 1960s continuous flow pumps, as compared with pulsatile pumps, were under development.[24,25] Over the subsequent 15 years, continuous flow centrifugal pumps were perfected and introduced into clinical use. These pumps work on the principle of a forced, constrained vortex devised from three magnetic cones.[26,27] They have been shown to be useful in a variety of clinical settings where short-term MCS is needed and an IABP is inadequate. Several types of small, axial-flow, or rotary pumps have also been developed, including some that allow for percutaneous deployment.[28–41] These pumps generally contain a magnetically suspended impeller that rotates at fast rates between 25,000 and 35,000 rpm. The latest generation of rotary pump technology comprises continuous flow devices that use fully magnetically levitated rotors that eliminate the need for seals or bearings. This technology reduces the risk of damage to blood elements and has been shown to lead to lower rates of thromboembolism.[42]

INITIAL MANAGEMENT OF CARDIOGENIC SHOCK

The initial focus in the treatment of CS is to prevent end-organ failure through stabilization of CO and the establishment of hemodynamic stability while simultaneously diagnosing and treating the reversible causes of CS. Fig. 82.1 illustrates an algorithm for the management strategies in CS. Identification of the primary cause of CS can allow for the appropriate pharmacologic or mechanical therapies to be applied. The American Heart Association recommends that patients undergo noninvasive testing with chest x-ray, resting 12-lead ECG, and echocardiography.[6] Suggested laboratory tests include complete blood count, electrolytes, hepatic function tests, serum creatinine, mixed venous oxygen saturation, natriuretic peptides, serial troponin levels, arterial blood gas, and lactate.[6] The mainstay of evidence supports timely reperfusion in patients presenting with CS caused by AMI. The potential revascularization strategies can be noninvasive, with tissue fibrinogen activator or streptokinase, or invasive, with percutaneous coronary interventions (PCI) or coronary artery bypass grafting (CAGB).[7,43,44] Vasoactive medications are often required for support in patients with CS, and the decision for which medication to initiate in CS remains challenging. The SOAP II trial (Sepsis Occurrence in Acutely Ill Patients) evaluated vasopressor selection in a subgroup of patients with CS and found that dopamine was associated with a higher rate of arrhythmias in addition to increased mortality, which may be the result of a tachycardia-induced ischemic propogation.[45] This has led to assertion of using norepinephrine as a first-line agent. Unfortunately, the methodology and clinical definitions of CS used within the SOAP II trial caused major concerns regarding the generalizability and applicability of the findings. Additional studies have suggested that epinephrine should also not be used in the initial management of CS because of its effect in increasing lactate levels, increasing oxygen consumption, lowered arrhythmogenicity thresholds, and association with higher mortality.[46,47] Additionally, in a recent randomized clinical trial (RCT), norepinephrine was found to be superior to epinephrine in achieving hemodynamic stability without increasing lactate levels in patients in CS after AMI.[48] Escalating doses of vasopressors and inotropes in patients with CS are associated with increased mortality.[47] In the setting of refractory CS and impending or worsening end-organ failure, MCS

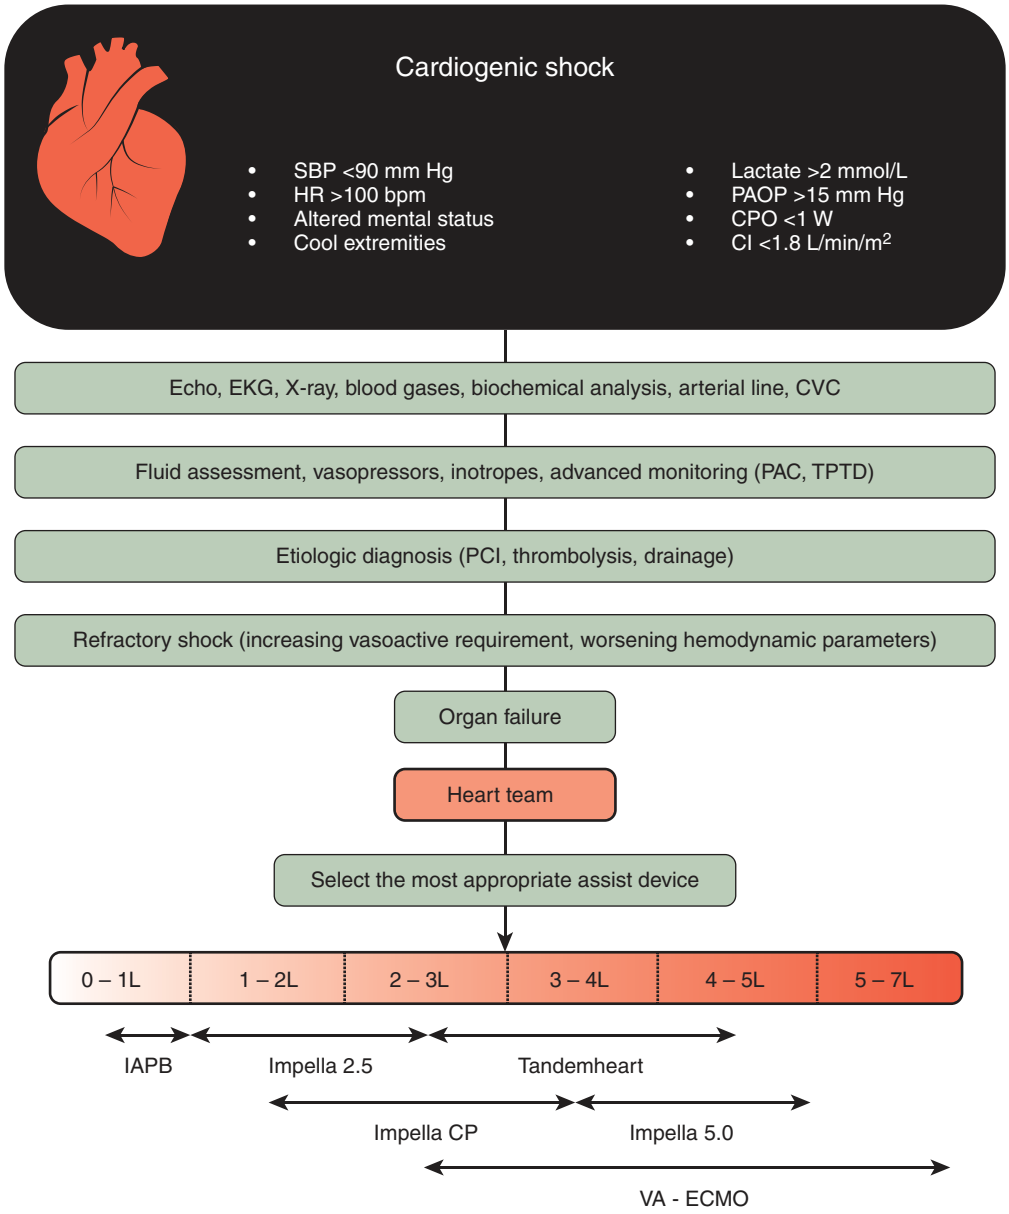

Fig. 82.1 Management schema for cardiogenic shock. (From Hajjar LA, Teboul JL. Mechanical circulatory support devices for cardiogenic shock: State of the art. *Crit Care*. 2019;23[1]:76.)

should be discussed with the multidisciplinary heart team and initiated in appropriate candidates.

The lethality of CS and limited availability of donor hearts for patients with chronic HF has been the impetus for the ongoing search for an ideal form of MCS over the past 60 years. The complexity and heterogeneity of this patient population have led to the development of a vast array of devices, none of which has proven optimal for support in all patients across the spectrum. The decision for which type of MCS device to use is based on the amount of supplemental flow required or CO that the patient requires, the duration of support required, and the patient's candidacy for cardiac transplantation (Figs. 82.2 and 82.3).[49] The biologic barriers to MCS present a constant challenge to clinicians, and the types of MCS devices available are continually evolving. Nonetheless, MCS remains an important adjunct in the treatment of CS and HF, with many devices demonstrating significant improvement in survival and quality of life. Accordingly, the American College of Cardiology Foundation/American Heart Association (ACCF/AHA) guidelines recommend nondurable MCS as a reasonable "bridge to recovery" or "bridge to decision" for patients with acute profound heart failure and a durable MCS for carefully selected patients with stage D heart failure and reduced ejection fraction (class IIa; level B).[50] The current indications, benefits, and limitations of MCS devices are outlined in this chapter.

CURRENT USE OF MECHANICAL CIRCULATORY SUPPORT DEVICES

Temporary Mechanical Circulatory Support

Percutaneous Insertion

Intraaortic balloon pump. The physiologic rationale for the efficacy of the IABP is that balloon deflation provides a rapid, synchronized

reduction in impedance (afterload) during isovolemic LV contraction. This is followed by a rapid, synchronized increase in aortic pressure during isovolemic LV relaxation (diastolic augmentation) caused by balloon inflation. In combination, these events achieve two important goals. First, LV systolic unloading directly reduces stroke work, which in turn reduces myocardial oxygen consumption during the cardiac cycle. Second, diastolic augmentation raises arterial blood pressure and provides better coronary arterial perfusion during diastole, yielding increased oxygen delivery to the myocardium. The IABP does not directly move or redistribute blood flow; however, peak diastolic coronary flow velocity can be increased as much as 87% with IABP augmentation and peak diastolic flow velocity by as much as 117%.[51] Since its introduction into clinical use in 1968, the IABP has remained an important adjunct to supporting patients in CS. Myocardial recovery is promoted

by the reduction of cardiac work and the simultaneous increase in myocardial oxygen supply. However, therapeutic success is dependent on the patient having a minimum degree of LV function that, in combination with IABP support, facilitates an adequate CO to sustain end-organ function. When this minimal CO is not met, alternative MCS must be considered.

The absolute indications for IABP placement include CS, uncontrolled angina pectoris, acute postinfarction ventricular septal defect (VSD), postinfarction mitral regurgitation (MR) secondary to papillary muscle rupture, and postcardiotomy left-sided HF with low CO.[52] In these settings, IABP should be considered as a primary therapy that should not be delayed. It is important to recognize that blood pressure alone is not an adequate indication of hemodynamic or cardiac stability. Limb perfusion, renal function, mental status, and even gastrointestinal function need to be considered in the assessment of adequate resuscitation and homeostasis. Additional measurable indices include arterial (SaO_2) and mixed venous oxygen saturation, acid-base status, urine output, and body temperature. A multivariate analysis of data accrued from 391 postcardiotomy patients requiring an IABP demonstrated that epinephrine requirements greater than 0.5 μg/kg/min, a left atrial pressure greater than 15 mm Hg, urine output less than 100 mL/hr, and mixed venous oxygen saturation less than 60% correlated with mortality.[53] These criteria were used to help predict mortality and the need for subsequent MCS.

Other relative indications for IABP use include (1) high-risk, catheter-based interventional procedures such as left main coronary artery angioplasty, (2) after unsuccessful attempts at catheter-based intervention in patients with poorly controlled ventricular arrhythmias and concomitant poor LV function, and (3) in settings of persistent stunned, ischemic myocardium. These are circumstances in which reduction of LV systolic wall tension and oxygen consumption by the IABP might enhance myocardial recovery after intervention. The Benchmark Counterpulsation Outcomes Registry of IABP use in 22,663 patients from 250 hospitals worldwide demonstrated that CS and high-risk angioplasty were the most common indications for use of the device.[54]

The optimal site of insertion of an IABP is a common femoral artery that can be accessed either percutaneously with the Seldinger technique or by surgical cutdown. Modern intraaortic balloon catheters are available for adults and children, according to the appropriate size and length for a given height and weight of the patient. Adult intraaortic balloons have a range in volume filled between 30 and 50 mL, with a standard balloon size holding 40 mL of helium. IABP catheters placed through the femoral artery are positioned so that the tip is just distal to the takeoff of the left subclavian artery in the proximal descending thoracic aorta. Optimally, the tip of the catheter should be positioned with transesophageal echocardiographic or fluoroscopic guidance.[55] To reduce the diameter of femoral cannulation, the sheathless IABP technique can be used and is our preferred method.[56]

Inflation of the balloon should be timed with closure of the aortic valve (at the dicrotic notch of the aortic pressure tracing) and should be inflated to nearly occlude the descending thoracic aorta. Timing can be synchronized in one of three ways: (1) using an arterial (preferably aortic) pressure tracing in synchrony with the dicrotic notch, (2) using the descent of the R wave on a rhythm tracing, or (3) timed after a ventricular pacing spike when a pacemaker is in use.[56–63] The optimal physiologic benefit of the IABP is significantly improved by proper timing of inflation and deflation, which can be difficult when there is an accelerated heart rate, cardiac rhythm disturbances, atrioventricular dyssynchrony, or low mean arterial pressure. Timing should be adjusted to maximize diastolic augmentation; hence, deflation should be as late as possible but just before opening of the aortic valve. If this cannot be gauged by pressure tracing, it can be timed to the onset of the R wave on ECG tracing or with the use of M-mode echocardiography.[63]

When femoral arterial cannulation is not desirable because of aortoiliac occlusive disease or extensive peripheral vascular disease (PVD), the subclavian artery or the ascending aorta can be used.[64–68] With either technique, the IABP catheter is advanced antegrade down the descending thoracic aorta so that the balloon tip sits above the level of the diaphragmatic hiatus, and the most proximal end of the balloon is distal to the takeoff of the left subclavian artery. These antegrade balloons should always be placed with either fluoroscopic or echocardiographic guidance. They should be removed with open arterial repair in all cases.

IABP catheters should not be left in place after weaning because of the risk of thrombus formation and embolization. An IABP should be weaned stepwise from a rate that is equivalent to heart rate (1:1) down to a ratio of 1:4 just before removal. Balloon catheters placed via the open surgical technique should also be removed surgically. Percutaneous removal of catheters placed in the iliac artery above the inguinal ligament (most common in obese individuals) can result in significant retroperitoneal bleeding. Consideration of operative removal is warranted.

Relative contraindications to IABP use include severe atheromatous disease of the descending thoracic aorta, descending aortic dissection or aneurysm, recent descending thoracic aortic surgery, and mild to moderate aortic insufficiency. Severe aortic insufficiency is an absolute contraindication to use because diastolic augmentation cannot be accomplished, and LV end-diastolic volume and pressure are actually increased rather than decreased.

The overall complication rate of IABP use is between 5% and 10%. Major complications occur at a rate of about 3% and include severe bleeding, major limb ischemia or amputation, infection, visceral or spinal cord ischemia, and attributable IABP mortality.[54,69] In the Benchmark registry, rates of complications were quite low; the most common complications were access site bleeding (4.3%) and limb ischemia (2.3%). The rates of amputation, stroke, visceral or spinal cord ischemia, and IABP-related mortality were all 0.1% or less.[70] Intraaortic balloon entrapment is a rare complication.[70–72] The incidence of major vascular complications according to the STS National Database (1996–1997) and the Benchmark Registry (1997–1999) was 5.4% and 1.4%, respectively.[55,69] Ipsilateral limb ischemia should be immediately addressed after its recognition. This usually requires removal of the IABP with replacement at another location if it is still indicated. The ischemic limb may require thrombectomy with or without revascularization and fasciotomy.[73–79]

The SHOCK trial showed that early revascularization in CS after AMI, often facilitated by IABP use (86%), yielded a lower 6-month mortality rate (50%) than that with medical therapy alone (63%).[7] Additional studies have shown that in patients undergoing urgent or emergent revascularization after an AMI, those supported preoperatively with an IABP had a lower operative mortality than those in whom an IABP was not used (5.3%–8.8% vs. 11.8%–28.2%).[69] These data seem to justify a strategy of aggressive IABP use to facilitate early revascularization in a postinfarction patient. The Second Angioplasty in Myocardial Infarction (PAMI-II) Trial data examined high-risk patients with AMI revascularized by PCI only and demonstrated a modest survival advantage at 6 months with the use of periprocedural IABP support.[54] When evaluating hospital mortality rates among patients undergoing CABG and/or valve surgery who received preoperative IABP or required intraoperative/postoperative IABP support, the mortality rate was significantly lower among patients supported preoperatively, as depicted in Table 82.2.[55,58] Hence, there appears to be a survival advantage to earlier IABP support for

TABLE 82.2 Hospital Mortality (Outcome Parameter) for Patients Undergoing Cardiac Surgery Who Either Received Preoperative IABP or Intra/Postoperative IABP Support

Type of Therapy	Benchmark Registry 1997–1999 Mortality/Total Operations With IABP, N (%)	STS National Database 1996–1997 Mortality/Total Operations With IABP, N (%)	STS National Database 1996–1997 Mortality/Total Operations Without IABP, N (%)

Intraoperative/ postoperative IABP	28.2 (954/3380)	23.6 (3528/14,933)	2.5 (9878/389,954)

From Christenson JT, Cohen M, Ferguson JJ 3rd, et al. Trends in intraaortic balloon counterpulsation: Complications and outcomes in cardiac surgery. *Ann Thorac Surg.* 2002;74:1086–1090.
Based on data from the Benchmark Counterpulsation Registry 1997–1999 and the STS National Database 1996–1997 compared with hospital mortality for patients who had neither preoperative nor intraoperative/postoperative IABP support.

patients with CS after AMI who undergo revascularization. In the setting of an acute VSD or acute MR after an AMI, IABP support can offer a dramatic improvement in the hemodynamic response of the patient.[80–85] It is clear that the mortality rate of patients in CS after AMI remain high. However, these studies suggest that IABP support, combined with revascularization, portends a better prognosis than adjunctive IABP use with medical therapy alone.[54] This benefit is likely greatest in those who are revascularized and present with class 3 or 4 HF.[86] A meta-analysis of 16 studies demonstrated a significant survival benefit for the use of IABP in CS after AMI (relative risk [RR]: 0.78; confidence interval [CI]: 0.60–0.86; $P < 0.0004$).[87] However, no benefit was seen in patients with high-risk AMI that was not complicated by CS.

Conversely, a Cochrane Database meta-analysis of six RCTs reviewed the use of IABP in CS after AMI in 190 patients and found no significant improvement in in-hospital, 30-day, or 6-month all-cause mortality.[88,89] A meta-analysis of cohort studies of IABP use in patients in CS after AMI by Sjauw and colleagues found an 18% decrease in 30-day mortality in patients treated with thrombolysis and IABP. However, in patients treated with PCI, they noted a 6% increase in mortality associated with the additional use of an IABP.[90] In the prospective IABP-SHOCK II trial, 600 patients in CS after AMI were randomized with and without placement of IABP after undergoing revascularization, primarily with PCI (>95%).[91] No difference in the primary endpoint of 30-day, all-cause mortality was seen (39.7% IABP, 41.3% control). However, a 10% crossover to the IABP arm was noted. Additionally, a meta-analysis of 12 RCTs found no improvement in 30-day mortality with the use of IABP in patients with AMI, regardless of whether or not the patients suffered from CS.[92] From this compilation of results, it may be concluded that the use of IABP in CS after AMI has little benefit in any treatment strategy that does not employ the use of early revascularization. Furthermore, improvement in the patient's hemodynamics often seen with the use of IABP does not suffice as a surrogate marker for survival in patients in CS after AMI. An IABP should be placed in the case of acute postinfarction VSD or acute MR without delay.

TandemHeart. The TandemHeart System (Cardiac Assist, Inc., Pittsburgh, PA) is an external centrifugal pump system that allows for percutaneous LV support by pumping blood from the left atrium into the femoral artery (Fig. 82.4).[93] Placement of the 21F venous inflow cannula is performed by accessing the femoral vein percutaneously and positioning the cannula tip in the left atrium via an atrial transseptal puncture. Outflow is established into the contralateral or ipsilateral femoral artery via a 15F or 17F cannula. The centrifugal pump is strapped to the thigh adjacent to the arterial cannula. The device contains a built-in heparin delivery system to decrease thrombin formation. An experienced team

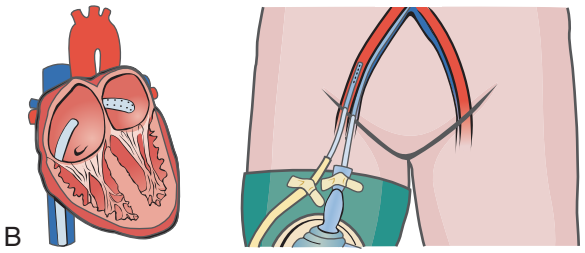

Fig. 82.4 A, Components of the TandemHeart device: 21F left atrial drainage cannula and 15–17F femoral arterial cannula *(left)*; continuous flow centrifugal pump *(right)*. **B,** Schematic demonstrating transseptal left atrial drainage and femoral access points. (From Windecker S. Percutaneous left ventricular assist devices for treatment of patients with cardiogenic shock. *Curr Opin Crit Care.* 2007;13:521–527.)

can establish MCS with TandemHeart in as little as 1 hour.[94] However, this is still longer than required for institution of extracorporeal membrane oxygenation (ECMO) support. Therefore its use may be limited in truly emergent cases and in conditions requiring cardiopulmonary resuscitation (CPR). The TandemHeart does provide more robust left-sided decompression as compared with ECMO.

Contraindications to placement of TandemHeart include severe PVD and isolated right ventricular (RV) failure. It also cannot be used in the presence of a VSD because of the potential for right-to-left shunting.[95] Right-to-left shunting is a known complication that can also occur if the transseptal cannula becomes dislodged into the right atrium (RA). Other complications include limb ischemia and thromboembolism.

TandemHeart has mostly been used as an MCS in CS.[96–98] Support has been employed for various indications, including postcardiotomy failure,[99–101] until corrective valvular surgery is performed,[102–104] until recovery of fulminant myocarditis,[105,106] or as a bridge to LVAD or BTT.[98,107,108] It has also been used successfully for MCS during high-risk PCI.[109–112] TandemHeart has been shown to be a more effective means of improving hemodynamic parameters in CS than IABP; however, no improvement in 30-day mortality has been demonstrated.[113,114]

Impella. The Impella Recover axial flow pump (Abiomed, Inc., Danvers, MA) is an addition to the treatment armamentarium for

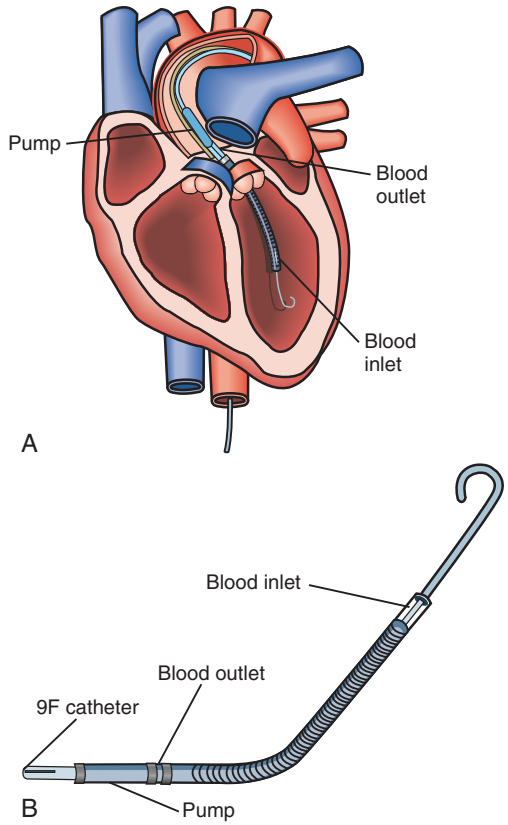

Fig. 82.5 A, Schematic demonstrating retrograde placement of the Impella Recover LP 2.5 device across the aortic valve. **B,** Components of the device. Blood from the ventricle enters the inlet portion of the device and is propelled by a 12F microaxial pump to the outlet portion positioned in the ascending aorta, establishing left ventricular decompression. (From Windecker S. Percutaneous left ventricular assist devices for treatment of patients with cardiogenic shock. *Curr Opin Crit Care.* 2007;13:521–527.)

acute short-term MCS (Fig. 82.5). The device is placed retrograde across the aortic valve with the tip situated in the LV. It can be placed percutaneously or surgically via the femoral artery under fluoroscopic guidance. It may also be placed surgically via an 8-mm T-graft sewn to the subclavian artery[115,116] or directly into the ascending aorta during cardiac surgery. There are several versions of the Impella device, including the 2.5, 5.0, and CP (flow rates of 2.5, 5.0, and 5.0 L/min, respectively). Whereas the 2.5 and the CP can be placed percutaneously or surgically, the larger Impella 5.0 requires surgical placement. Contraindications for the use of Impella include patients with severe aortic stenosis and those who have had a previous mechanical aortic valve replacement. Severe PVD may make percutaneous deployment impossible or mandate a surgical cutdown for placement.

Similar to other devices, Impella has been used for MCS for several indications, including high-risk PCI[117,118]; postcardiotomy failure[119–121]; CS after AMI[97,122–125]; severe allograft rejection after heart transplant[126,127]; myocarditis[128,129]; and as a bridge to placement of a long-term device, BTR, or BTT.[97] RCTs comparing support with Impella 2.5 with IABP in CS AMI have demonstrated improved hemodynamic and laboratory parameters (CI, mean arterial pressure, serum lactate levels) with the use of Impella.[113,114] However, this did not translate into improved 30-day survival. In contrast, the recent PROTECT-II RCT comparing these two devices in high-risk PCI demonstrated lower rates of the two composite endpoints of major adverse events (MAEs) and major adverse cardiac and cerebral events (MACCEs = death, stroke, myocardial infarction, and repeat revascularization).[117] At the 3-month follow-up, the rates of both composite endpoints were lower in the Impella group than in the IABP group (MAE, 37% vs. 49%, $P = 0.014$; MACCE, 22% vs. 31%, $P = 0.034$) at 3 months.

In addition to the Impella devices for LV support, the Impella RP is available for RV support. The Impella RP is a 22F percutaneous, microaxial pump mounted on an 11F catheter. The catheter pump is advanced antegrade through the femoral vein under fluoroscopic guidance and positioned across the tricuspid and pulmonic valves.[130] The pump inflow aspirates blood from the inferior vena cava and ejects it into the pulmonary artery at a rate of up to 4.0 liters per minute. The intended use for the Impella RP is 14 days; however, if there is echocardiographic and hemodynamic evidence of improved RV function, the device can be weaned earlier. During pump operation, an activated clotting time of 160–180 seconds is required. The RECOVER RIGHT study was a prospective, multicenter trial that demonstrated improved hemodynamics and a 73% 30-day survival in patients with RV failure after AMI.[131]

Protek duo. The tandem heart Protek Duo is a device used for isolated RV support accessed via the right internal jugular vein. The device contains two lumens within the 29F or 31F cannula.[130] One serves as the inflow cannula, which is positioned across the superior vena cava and RA, where it removes blood and delivers it to a centrifugal pump. The second lumen is the outflow cannula, which has a multifenestrated tip to deliver blood into the main PA. This system effectively bypasses the RV. The Protek Duo can flow between 2 and 4 liters per minute.[132] The Protek Duo has been reported for use after AMI with RV infarcts, myocarditis, posttransplant RV failure, postcardiotomy RV failure and post-LVAD RV failure.[133]

Extracorporeal membrane oxygenation. Since the 1970s, ECMO has been used in the adult population for short-term MCS when CS is complicated by concomitant pulmonary insufficiency. It provides full cardiopulmonary support to allow reversal of the systemic malperfusion that occurs in CS until definitive surgical correction is performed. It can also serve as a BTR, a BTT, or a bridge-to-bridge to longer-term MCS (i.e., VAD).[134–136] It may be employed for a period of 1–3 days in cases when the neurologic status of a patient is unclear, but longer-term support is generally not appropriate until this status is clarified.

The ECMO circuit consists of inflow and outflow cannulas, a continuous flow centrifugal pump, a hollow-fiber oxygenator, and a heat exchanger. Historically, roller pumps and centrifugal pumps have both been used. Roller pumps remain in widespread use for CPB during cardiac surgery; applications outside the operating room have been virtually abandoned because of higher rates of circuit disruption, particle emboli, and hemolysis.[137] Bio-Medicus Biopump (Medtronic Corp., Minneapolis, MN) and CentriMag (Levitronix LLC, Waltham, MA) are two centrifugal pumps commonly used in ECMO circuits. The Bio-Medicus Biopump generates a constrained vortex within an acrylic shell that houses concentric magnetic cones. The cones rotate as a magnetic rotary motor spins adjacent to the base of the cones and can generate very high flows with less trauma to blood cells than roller pumps.[137–141] The cannulation strategy most often used in acute CS is peripherally via the femoral vessels with either the percutaneous Seldinger or surgical technique. Alternatively, central cannulation via the RA and aorta is used to provide temporary MCS in the case of postcardiotomy failure or in patients who require further ventricular decompression with LV vents in lieu of left thoracotomy drainage approaches or additional percutaneous device therapy. When faced with acute refractory CS, ECMO can facilitate patient stabilization for subsequent transport to a tertiary medical center for VAD evaluation. One particular ECMO system is the CardioHelp (Maquet Cardiopulmonary AG, Hechingen, Germany). It is a miniaturized system that combines the

pump and oxygenator in a single unit. Considering the economical size, it is ideal for patients who require urgent interhospital transport.[142]

Disadvantages in using the peripheral cardiopulmonary support or ECMO include the greater potential for ipsilateral limb complications, higher rates of hemolysis, the requirement for anticoagulation to prevent thrombosis of the oxygenator and circuit, and failure to adequately decompress the left ventricle.[143–149] Inadequate LV decompression with peripheral cardiopulmonary support/ECMO systems may be the mechanism responsible for some treatment failures. Regardless of the etiology of CS, a rested ventricle (i.e., decompressed) has a better chance of recovery than a distended ventricle. Lower extremity ischemia may be resolved or prevented by placing an additional perfusion cannula (8–14F) down the ipsilateral superficial femoral artery.[150] Alternatively, limb ischemia may be prevented with the use of an 8-mm T-graft sutured to the side of the femoral artery.[151] However, this increases the complexity of instituting ECMO and can be impractical in cases of CS with ongoing CPR where efficiency is key.

The use of ECMO in the adult population for reasons other than primary cardiac failure with secondary pulmonary insufficiency has limited advantages over conventional therapies.[151,152] However, a substantial subset of patients who present with CS and are initially resuscitated with cardiopulmonary support/ECMO survive to revascularization, transplantation, or recovery, with survival rates as high as 75%.[153–164] ECMO used as a bridge to VAD placement for profound CS can yield survival rates higher than 40%.[165] This strategy is pragmatic and offers immediate end-organ support while a subsequent definitive treatment plan can be designed. In an outcome study by Combes and colleagues, early predictors of death on ECMO support include hepatic failure, renal failure, or placement of ECMO while undergoing CPR. Of the greater than 40% who did survive to discharge, many reported continued physical and social problems, including the ability to return to work.[166] This underscores the importance of long-term follow-up and the need for continued psychosocial support of these patients.

Improvements in pump and oxygenator technology have made EMCO a relatively simple means to establish MCS, allowing reversal of end-organ malperfusion that inevitably accompanies CS not promptly corrected with medical therapy alone. However, complications of bleeding, infection, stroke, and limb ischemia increase with time on ECMO support.[167] As with any form of MCS, the plan for separation from support or transition to a more permanent means begins upon institution of ECMO. Once end-organ malperfusion has been corrected, the feasibility of ECMO weaning is determined on a daily basis. Weaning trials are guided based on the patient's hemodynamic parameters, oxygenation, and ventilation. Pulmonary and circulatory support can be weaned independently or simultaneously. Pulmonary weaning consists of increasing support from mechanical ventilation while the amount of oxygenation and ventilation provided by ECMO is reduced. Circulatory weaning is done by gradually decreasing the amount of pump flow in a stepwise fashion while assessing hemodynamic and echocardiographic parameters to evaluate the cardiac response to ventricular loading that occurs with decreasing pump flow. Once it is determined that the patient can maintain adequate perfusion and pulmonary function, a plan is made to separate the patient from ECMO and remove the cannulas. The cannulas are most often removed in the operating room with direct vascular repair of the femoral artery. If the patient cannot be successfully weaned from EMCO, the plan for conversion to VAD or transplant is undertaken. This period of support, weaning, and determining the long-term strategy is done with the collaboration of a multidisciplinary heart team, including surgeons, cardiologists, and critical care providers.

Temporary Surgically Inserted Devices

Short-term MCS using continuous flow pumps for CS is a relatively simple means of establishing immediate and complete MCS, requiring no additional equipment other than that needed for standard CPB support during cardiac surgery. As previously discussed, some MCS pumps can be used with percutaneous cannulation for ECMO support. These same pumps may be placed by surgical insertion. The most common indication for temporary MCS where surgical insertion is used is for postcardiotomy CS. This can be achieved by conversion from the CPB circuit used during the primary cardiac operation to a temporary VAD system, using the existing cannulas in the RA and aorta. Temporary VAD support may be required for several days to allow myocardial recovery. If the decision is made to leave the chest open, the cannulas can be brought out through the lower portion of the sternotomy incision and covered with a sealed temporary dressing. Alternatively, they can be brought out through separate incisions inferior to the sternotomy, allowing the sternum to be closed temporarily. The patient can then be brought back to the operating room within several days to explant the cannulas once cardiac recovery has occurred or converted to a long-term LVAD. Under the most recent United Network for Organ Sharing (UNOS) cardiac allocation policy change on October 18, 2018, the priority of patients on nondischargeable, surgically implanted MCS has increased. As such, these devices are frequently considered in patients who are potential candidates for BTT.[168] Temporary, surgically implanted MCS can be withdrawn in cases where severe multiorgan failure ensues despite therapy or conversion to long-term MCS or BTT is not appropriate (advanced age, lack of appropriate psychosocial support). However, it is best to determine candidacy for definitive treatment with the multidisciplinary heart team initially and discuss the goals of treatment before performing any high-risk surgical case.

CentriMag ventricular assist. The CentriMag system uses fully magnetically levitated technology to provide MCS in a fashion similar to the Bio-Medicus Biopump. The CentriMag system has many advantages that make it attractive for temporary MCS in the acute setting.[169] These advantages include ease of implantation, direct outflow cannulation of the ventricle for improved decompression, and less damage to blood elements compared with traditional devices such as the Bio-Medicus pump. It has been used effectively for univentricular or biventricular support in the setting of postcardiotomy failure as a bridge to decision, BTR, BTT, or bridge to a long-term MCS device. For patients with concomitant pulmonary insufficiency, an oxygenator may be spliced into the circuit, effectively converting it to an ECMO system.

Durable Ventricular Assist Devices

Continuous Flow Left Ventricular Assist Devices

In the continued search for smaller, implantable LVADs with increased durability, many advances in technology have led to an array of continuous flow pumps, each with unique features. These axial or centrifugal flow pumps are smaller and more durable than pulsatile devices, making them well suited for long-term support as a BTT, BTR, or DT.[170–172] They are placed within the pericardium or in a preperitoneal pocket, with only an external driveline exposed to provide power and device control. These devices are relatively costly, provide isolated LV support, and require specialized training to implant, although they provide significantly improved survival and quality-of-life outcomes over patients with refractory heart failure treated with optimal medical therapy. In the setting of limited donor organs, these devices continue to be a significant treatment approach for patients with HF.

HeartMate II (HMII). HeartMate II (Abbott Inc., Chicago, IL) is an implantable axial flow LVAD that has been used as a BTT and DT.[171–174] The device is implanted in a preperitoneal pocket with the inflow cannula situated in the LV apex. Outflow is via a graft anastomosed to the ascending aorta. The device was approved for DT by the Food and Drug Administration (FDA) in 2010. A prospective postapproval study confirmed the efficacy of the device and demonstrated a reduction in

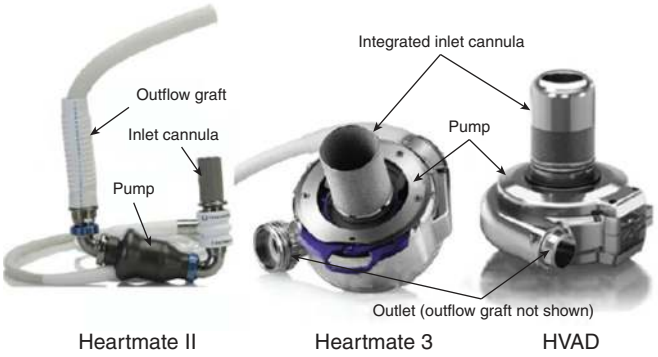

Fig. 82.6 Implantable continuous flow ventricular assist devices currently in commonly in clinical use. (From Stulak JM, Abou El Ela A, Pagani FD. Implantation of a durable left ventricular assist device: How I teach it. *Ann Thorac Surg.* 2017;103[6]:1687–1692.)

the median length of stay by 6 days as compared with the pivotal DT trial.[175] Results of the ROADMAP trial demonstrated that limited HF patients treated with the HeartMate II LVAD had significant improvement in the primary outcome composite of survival and improvement in a 6-minute walk test at 1 year compared with similar patients treated with optimal medical therapy.[176]

Jarvik 2000. Jarvik 2000 (Jarvik Heart, Inc., New York, NY) is an implantable axial flow pump used as a BTT and for DT.[177,178] It is unique in that the pump itself resides within the LV cavity, providing outflow via the LV apex to a graft anastomosed to the ascending or descending thoracic aorta. It is a direct current (DC) battery–powered device, using alternating current (AC) power only to recharge the batteries.

HeartWare ventricular assist device (HVAD). The HVAD (HeartWare, Inc., Framingham, MA) is a centrifugal pump that is implanted within the pericardial space. The pump is attached directly to the LV apex where inflow is provided. Outflow is via a graft sewn to the ascending aorta. Based on results from the ADVANCE clinical trial, the HVAD received FDA approval as a BTT device.[179] Additionally, the ENDURANCE trial found centrifugal flow pumps (HVAD) to be noninferior to axial flow pumps (Heartmate II), with higher rates of strokes (29.7% vs. 12.1%, $P < 0.001$) reported in the HVAD group.[180] The ENDURANCE supplemental study subsequently confirmed the associations between poorly controlled hypertension and strokes in LVAD patients and thus the importance of blood pressure management in the LVAD population.[181]

Heartmate III. The Heartmate III (Abbott, Inc., Chicago, IL) device is a centrifugal flow pump with a bearingless, fully magnetic levitated motor with wide blood-flow passages and no mechanical bearings (Fig. 82.6).[182] Additionally, the Heartmate III is programmed to facilitate rapid changes in rotor speed to create an intrinsic artificial pulse that can potentially reduce stasis and thrombus within the pump.[183] The MOMENTUM 3 trial compared the Heartmate II axial flow pump with the Heartmate III centrifugal flow pump. At 2-year follow-up, the investigators found that the Heartmate III was superior with fewer disabling strokes, reoperations for pump thrombosis, and major bleeding events when compared with the Heartmate II.[184]

TREATMENT OF CARDIOGENIC SHOCK: AN ALGORITHM FOR MECHANICAL CIRCULATORY SUPPORT

The hallmarks of CS are low CO, hypotension, peripheral vasoconstriction, cold extremities, poor urine output, and altered mental status. As the pathophysiologic state progresses, pulmonary insufficiency and pulmonary edema ensue. Extrinsic causes of CS most commonly manifest as circulatory collapse secondary to pericardial tamponade. Acute tamponade is easily diagnosed by echocardiography and requires surgical or percutaneous evacuation and subsequent treatment of that which caused the tamponade (e.g., traumatic injury, aortic dissection, ruptured aneurysm). Extrinsic causes of CS usually require immediate surgical intervention but rarely necessitate mechanical assistance. However, intrinsic causes of CS can be refractory to both medical and surgical therapies and may require MCS. Intrinsic causes can be divided into four pathophysiologic classifications: (1) acute valvular insufficiency, (2) AMI, (3) acute myocarditis, and (4) postcardiotomy cardiac failure. Irrespective of the etiology of CS, the approach toward the initial management of patients should be fairly uniform. Irrespective of the etiology of CS, the approach toward the initial management of patients should be fairly uniform. A suggested management algorithm is outlined in Fig. 82.7.

First, insertion of a pulmonary arterial catheter and echocardiography should be done to help formulate a differential diagnosis. Severe valvular insufficiency or a VSD can usually be effectively excluded at this juncture. If severe aortic insufficiency is present, chronotropic control (heart rate 80–100 beats/min) and afterload reduction with inotropic support should be the initial maneuvers. An IABP is contraindicated because aortic regurgitation will worsen; these patients should be prepared for immediate aortic valve replacement. For patients with acute MR or a VSD, an IABP should be placed immediately in conjunction with inotropic support and afterload reduction. Surgical intervention should proceed emergently. Cardiac catheterization is pursued preoperatively to identify coronary lesions that would require CABG or if PCI is more appropriate.

Acute fulminant myocarditis usually presents in a previously healthy individual with no history of cardiac disease. Patients with presumed myocarditis who do not stabilize after the insertion of an IABP and concomitant inotropic infusion should be diverted to further temporary VAD support expeditiously. A remarkable percentage of these patients will recover if adequately supported during the acute phase of this disease. Short-term to intermediate-term VADs are optimal in these patients because of the ease of their insertion and removal and the anticipation for relatively short-term recovery. Giant cell myocarditis is one exception to this rule, because most patients with this diagnosis will require transplantation or durable MCS.[185–187]

AMI requires pharmacologic support along with emergent cardiac catheterization and PCI as indicated. MCS can be rapidly instituted with IABP placement and should be considered in conjunction with PCI. If a mechanical complication (i.e., severe MR or VSD) has occurred, an IABP should be placed without delay. Urgent surgical intervention is usually required for these mechanical complications. The culprit vessel resulting in the AMI is treated immediately with PCI. The number of diseased arteries remaining and the clinical status usually determine subsequent allocation to further PCI or CABG. This can be accomplished several days later, once the myocardium is recovered and the shock state has resolved. Patients who remain in CS after AMI despite PCI, IABP, and inotropic support should be considered for VAD support.

Postcardiotomy CS should be managed intraoperatively with an initial trial of IABP and inotropic support. If there is persistent shock or an inability to be weaned from CPB, VAD implantation is the next therapeutic step, provided a meaningful recovery is predictable or a plan for transplantation or permanent therapy can be clarified. The general recommendation for implantation of a VAD for postcardiotomy failure is within 1 hour of the first failed attempt to wean from CPB.

The mode of MCS used for CS is determined by a number of factors. First is the degree of pulmonary insufficiency. If there is pulmonary

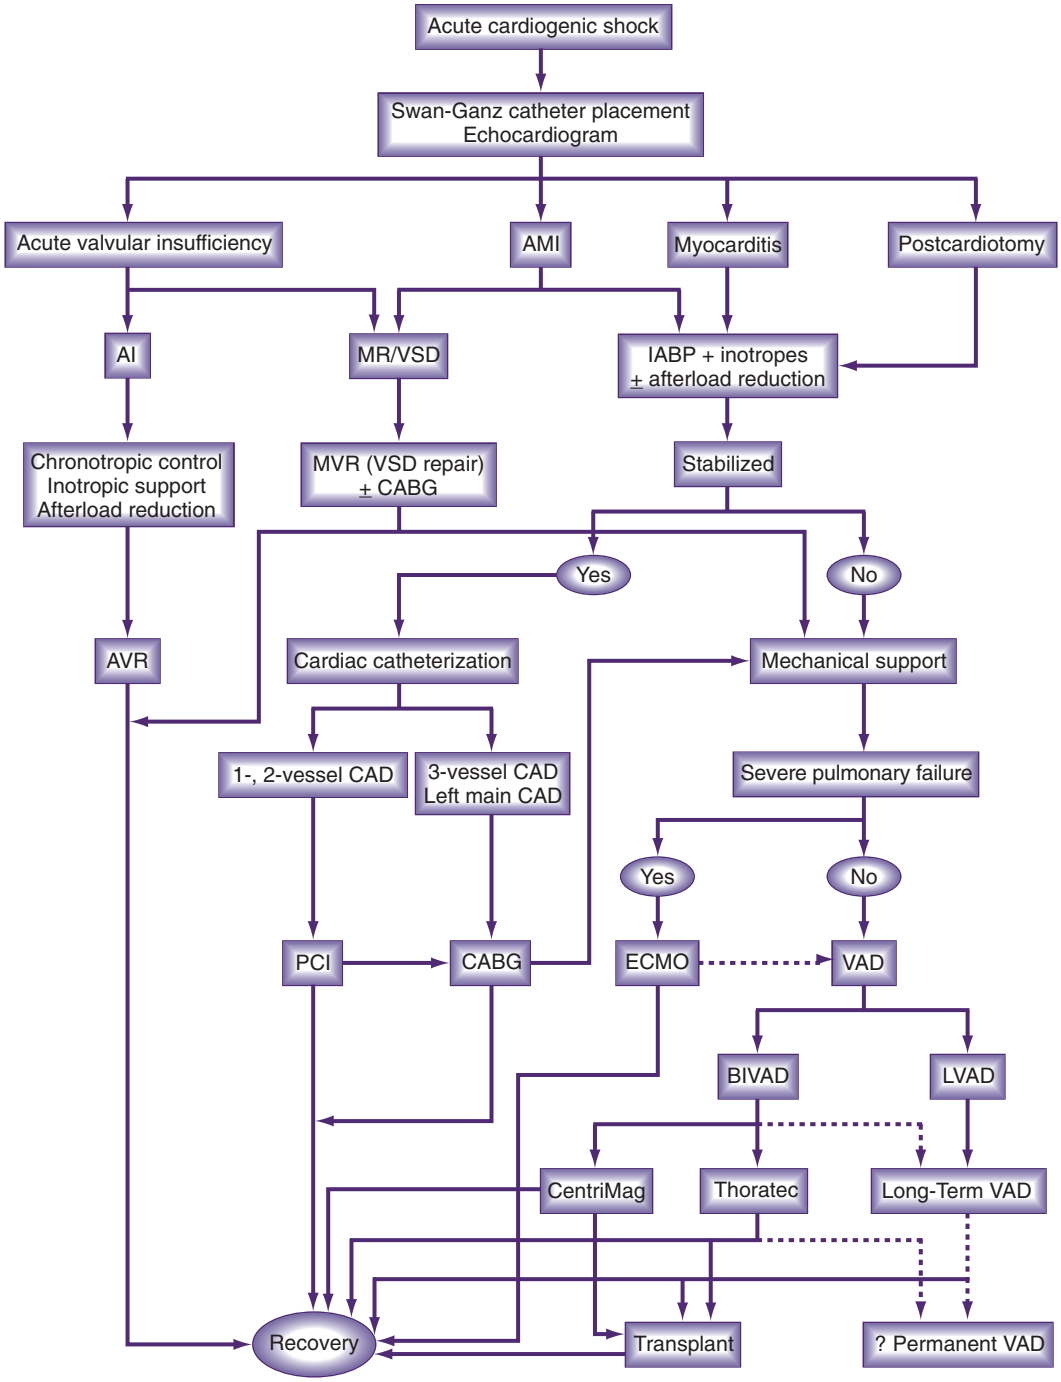

Fig. 82.7 Algorithm for the management of acute cardiogenic shock.

failure with a very large alveolar-to-arterial oxygen gradient on maximal ventilatory support, ECMO support is indicated. A small percentage of ECMO patients in this setting will recover, some will require VAD placement as a BTT, and fewer still will bridge to VAD and then to recovery. If the degree of pulmonary insufficiency is limited to pulmonary edema that is likely to recover with adequate CO, patients should undergo VAD placement directly. The choice of VAD in this situation is also dependent on several factors, including the predicted need for short- or longer-term support, the need for univentricular versus biventricular support, the chance of ventricular recovery, the institutional experience with different devices, device availability, and the relative risks of anticoagulation.[187]

The Levitronix CentriMag system is an attractive option for postcardiotomy cardiac failure in those patients predicted to recover within days to a week of surgery for cases when neurologic function is not known or is markedly compromised but may need a BTR or bridge to a durable device or BTT once stabilized. Both are easy to insert. Therefore in cases of profound CS when operative brevity is paramount, these devices may be beneficial. Additionally, the CentriMag devices allow for arterial cannulation via an inflow graft sewn onto the aorta, which may make conversion to other long-term VAD systems technically easier.

Initial placement of continuous flow VADs (e.g., HeartMate II, Heartmate III or HeartWare HVAD) for MCS in patients with CS is

generally not indicated. These devices may be used as a second bridge ("bridge-to-bridge") toward recovery, BTT, or DT. Typically the only patients with CS who are candidates for direct, durable LVAD placement are those who are more stable without profound end-organ failure, can sustain longer operative times, and are unlikely to achieve myocardial recovery.[188]

OUTCOMES OF CARDIOGENIC SHOCK WITH MCS SUPPORT

As recently as 2017, there were a reported 25,145 adult patients who had undergone MCS implant, with the majority (76.3%) receiving durable, continuous flow LVADs and a minority (2.7%) receiving biventricular support.[189] Although the burden of adverse events remains high for these patients, overall survival at 1 year is >80% and approximately 70% at 2 years.[190] The most commonly encountered adverse events in patients on durable LVAD support, listed in decreasing incidence of hazard, are neurologic dysfunction, multisystem organ failure, infection, device malfunction, and right heart failure.

In adult patients with refractory CS requiring ECMO support, survival to hospital discharge currently ranges from 42% to 66.7%,[191] although patients with chronic renal failure, pre-ECMO end-organ failure, pre-ECMO cardiac arrest, congenital heart disease, lower pulse pressures, and lower serum bicarbonate were at higher risk for mortality.[192] Patients with postcardiotomy CS requiring ECMO have traditionally been poor, with in-hospital mortality rates between 59% and 84%; however, in the modern era, successful weaning from postcardiotomy ECMO has been reported in up to 63.3% of patients, with survival to discharge near 25%.[193]

The evidence surrounding the use of Impella devices is continuing to evolve. A propensity-matched study compared CS patients after an AMI who were supported with an Impella 2.5, Impella CP, IABP or only medical therapy found Impella to be superior to IABP and medical therapy.[194] Furthermore, the IMPRESS (Impella versus IABP Reduces Mortality in STEMI Patients Treated with Primary PCI in Severe Cardiogenic Shock) in Severe Shock trial demonstrated that patients randomized to an Impella CP had similar survival outcomes at 2 years when compared with IABP-supported patients.[195]

HEART TEAM APPROACH TO CS REQUIRING MCS

In the setting of CS, the multidisciplinary heart team, which includes HF cardiologists, interventional cardiologists, HF surgeons, and intensivists, helps evaluate each individual patient and develop a care plan that best suits the individual patient's needs. The hallmarks of a successful heart team approach for CS requiring MCS include early activation, rapid initiation of revascularization and MCS when appropriate, hemodynamic-guided management, and strict protocol adherence.[196] The implementation of a dedicated heart team approach in patients with CS requiring MCS has been shown to improve 30-day survival from 47% to 77%.[197] An example of the heart team approach for CS patients is illustrated in Fig. 82.8.[198] Key aspects include an immediate heart team activation call once CS is suspected. If the patient is within the hospital, they are immediately transferred to the cardiac catheterization laboratory or the cardiac intensive care unit. If the patient is outside of the hospital system, they are emergently transferred by air if available. If the patient is not actively in an arrest situation, hemodynamic, angiographic, and laboratory data are collected and then the decision to pursue MCS is evaluated by the heart team. If an arrest situation is evolving, the heart team will discuss the patient's appropriateness for either ECMO or an alternative percutaneous MCS approach.

CONCLUSION

CS remains a lethal problem with a mortality rate as high as 75%.[3,187,188] Patients who cannot be stabilized with inotropic support and an IABP should be considered for MCS with a VAD. The use of MCS for acute CS has facilitated impressive improvements in survival for certain disease cohorts, such as those with acute myocarditis, with survival rates over 70%.[154] VADs have had less remarkable an impact on patients with postcardiotomy shock or CS after AMI, but results in these patient populations are continuing to improve.[161] Inherent to achieving better results is our understanding that patients who present with CS typically have significant underlying comorbidities with multiple-system organ dysfunction and marked derangements in both coagulation and inflammatory mediators that complicate management. They need to be approached by an integrated multidisciplinary team, including cardiologists, cardiac surgeons, anesthesiologists, critical care specialists, and experienced nursing staff, to implement efficient and decisive treatment plans. These integrated systems offer the greatest chance for salvage.[197,198] The future holds exciting promise with the continued expansion of available devices, both temporary and durable, which will no doubt continue to improve outcomes in this challenging population.

KEY POINTS

- The leading cause of death among hospitalized patients with AMI continues to be CS. Mortality remains high at approximately 40%.
- The hallmarks of CS and low CO are hypotension, peripheral vasoconstriction, cold extremities, poor urine output, and altered mental status.
- Intrinsic causes of CS can be divided into four pathophysiologic classifications: (1) acute valvular insufficiency, (2) AMI, (3) acute myocarditis, and (4) postcardiotomy cardiac failure.
- Echocardiography should be done to help formulate a differential diagnosis, and insertion of a pulmonary artery balloon catheter should be considered.
- CS with AMI requires immediate cardiac catheterization. Concomitant IABP placement or other temporary VAD support may be considered in addition to pharmacologic support for patients with refractory CS.
- Pioneering surgeons recognized by the 1960s that LV decompression and myocardial rest could afford enhanced cardiac recovery.
- The physiologic rationale for the efficacy of the IABP includes (1) LV systolic unloading directly reduces stroke work, which in turn reduces myocardial oxygen consumption during the cardiac cycle, and (2) diastolic augmentation, which raises arterial blood pressure and provides better coronary arterial perfusion during diastole, yielding increased oxygen delivery to the myocardium.
- Relative contraindications to IABP use include severe atheromatous and atherosclerotic descending thoracic aorta, descending aortic aneurysm, recent descending thoracic aortic surgery, and mild to moderate aortic insufficiency.
- Short-term cardiopulmonary support for CS is an important adjunctive therapy. It is a relatively simple means of establishing immediate and complete circulatory support, requiring no additional equipment other than that needed for standard CPB support during cardiac surgery.
- Initial placement of durable VADs for MCS in patients with acute CS is generally not indicated. These devices are best suited as a bridge-to-bridge once the shock state has resolved, often with a temporary MCS device.

Hochman JS, Sleeper LA, Webb JG, et al. Early revascularization in acute myocardial infarction complicated by cardiogenic shock. SHOCK Investigators. Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock. *New Engl J Med* 1999;341:625–634.
Results from the randomized SHOCK trial are reported. Emergency revascularization did not significantly reduce 30-day mortality, but it did reduce mortality at 6 months, and IABP placement helped facilitate early revascularization.

Lauten A, Engström AE, Jung C, et al. Percutaneous left-ventricular support with the Impella-2.5-assist device in acute cardiogenic shock: Results of the Impella-EUROSHOCK-registry. *Circ Heart Fail.* 2013;6:23–30.
Results from this multicenter registry study demonstrated that patients supported with Impella 2.5 devices had improved hemodynamics and reductions in lactate levels, suggesting improved end-organ perfusion. However, the mortality rates of Impella 2.5–supported CS patients remained high at 64.2%. The major complications that were most frequently seen were bleeding, hemolysis, and pericardial tamponade. Age above 65 years and lactate >3.8 mmol/L at admission were identified as predictors of 30-day mortality.

Mehra MR, Uriel N, Naka Y, et al. A fully magnetically levitated left ventricular assist device – Final report. *New Engl J Med.* 2019;380(17):1618–1627.
Results of the MOMENTUM 3 randomized clinical trial demonstrated that patients supported with a HeartMate III centrifugal-flow device, compared with a HeartMate II axial flow device, were less likely to experience disabling strokes or pump thrombosis. Additionally, rates of major bleeding and gastrointestinal bleeding were lower in the HeartMate III group.

Schmidt M, Burrell A, Roberts L, et al. Predicting survival after ECMO for refractory cardiogenic shock: The survival after veno-arterial-ECMO (SAVE)-score. *Eur Heart J.* 2015;36(33):2246–2256.

This retrospective analysis evaluated patients with refractory CS who were supported with venoarterial ECMO and found acceptable survival, with 42% alive at hospital discharge. Chronic renal failure, longer durations of pre-ECMO mechanical ventilation, pre-ECMO end-organ failure, cardiac arrest, and congenital heart disease were all risk factors found to be associated with mortality.

Stone GW, Ohman EM, Miller MF, et al. Contemporary utilization and outcomes of intra-aortic balloon counterpulsation in acute myocardial infarction: the benchmark registry. *J Am Coll Cardiol.* 2003;41:1940–1945.
This study reviews the indications and outcomes for the usage of the intraaortic balloon pump (IABP) from 1996 to 2001. Data were collected prospectively in 250 medical centers with over 22,000 IABPs placed worldwide.

Portal Hypertension: Critical Care Considerations

Paolo Angeli, Marta Tonon, Carmine Gambino, and Alessandra Brocca

THE CHANGE OF A PARADIGM

Portal Hypertension Is Not the Only Driver of Complications of Cirrhosis

Cirrhosis is typically classified as compensated or decompensated, based on the absence or presence (or previous history) of variceal bleeding, ascites, jaundice, or encephalopathy.[1–3] The significantly longer survival—usually symptomless—and better quality of life experienced by patients with compensated cirrhosis compared with those with decompensated cirrhosis have brought about the concept that compensated and decompensated cirrhosis are distinct clinical stages of the disease.[4,5] Further disease stages have been identified according to the presence of esophageal varices and to the presence of only one or more disease complications.[4–10] Four stages were proposed at the Baveno IV Consensus Conference: stage 1, compensated cirrhosis without esophageal varices; stage 2, compensated cirrhosis with varices; stage 3, ascites with or without varices; and stage 4, bleeding with or without ascites. The four stages are characterized by a significant increase in the risk of death.[11] We went on for decades thinking that the only driver in the stage progression of cirrhosis was the progressive increase in portal pressure. In accordance with the theory of splanchnic arterial vasodilation, the progressive impairment of the cardiocirculatory function characterized by arterial vasodilatation and inadequate cardiac output, in addition to the progressive increase in the degree of activation of the endogenous vasoconstrictive and sodium-retaining systems were in fact attributed only to the progressive increase in portal pressure[12,13] (Fig. 83.1). However, today, we can affirm that this is only partially true on the basis of the following, more recent findings.

First, it has not been confirmed in larger cohorts of patients that there is a progressive increase of the grade of activation of the endogenous vasoconstrictive and sodium-retaining systems, at least in the more advanced phases of liver disease.[14] Second, it is possible to reduce significantly the grade of activation of those systems without achieving any clinical result in terms of reduction of the rate of cirrhosis-related complications and/or mortality.[15] Third, during the last 8 years we have learned that another syndrome may develop in any patient with cirrhosis, but particularly in those with decompensated cirrhosis. This syndrome has been called *acute on chronic liver failure* (ACLF)[16]. ACLF is characterized by an acute decompensation (AD) of the liver disease, the development of organ failure, and a 28-day mortality rate >15%. ACLF can develop even in the presence of a normal grade of activation of the endogenous vasoconstrictive and sodium-retaining systems, but never without an increased plasma level of proinflammatory cytokines in absence of systemic inflammation (SI).[17] Taking into account that SI precedes the development of a clinically overt ascites[18] and organ failure[19] and that there is a strong relationship between its grade and both the stage progression of cirrhosis[20] and the severity of ACLF,[16] SI should be considered as another driver of decompensation in patients with cirrhosis.[19] There is some evidence that an SI-related oxidative stress (OS) can be another potential driver of decompensation in these patients.[17] How can we put together these three drivers of decompensation? By proposing a new pathophysiologic theory.[14] We have recently proposed a new theory according to which the main consequence of portal hypertension is thought to be bacterial translocation (BT). BT is the main cause of SI and OS, which, in turn, are the main drivers of the derangement of the cardiovascular function and of the consequent reduction of the effective circulating volume. All these factors together are responsible for the onset of ascites and for other major complications of cirrhosis. In addition, SI and OS can generate a vicious circle whose consequence is a sequential chain of related events, including a further increase in portal pressure and/or in the severity of liver failure and thus in the extent of BT. Thus the final ring of this chain is a further increase in the degree of SI and OS. This may be the most credible, plausible, and acceptable explanation for the possibility of the onset of organ failure in patients with cirrhosis when a precipitating event cannot be detected (Fig. 83.2).[14] In an attempt to quantify, if possible, the relative weight of individual heart failure drivers in the various stages of cirrhosis, it has recently been observed that progression of portal pressure occurs mostly in patients with compensated cirrhosis, whereas SI increases substantially only across the different stages of decompensated cirrhosis.[21] The mechanisms of the effect of SI and OS on organ integrity and function are beyond the aim of this chapter; however they are several and not mutually exclusive. The first mechanism is quite obvious and is an increase in the nitric oxide–mediated vasodilatory effect on arterial splanchnic circulation, resulting in overactivation of the endogenous vasoconstrictor systems, which elicit intense vasoconstriction and hypoperfusion of some organs, in particular, the kidney. The second mechanism is immunopathology, which is an immune-mediated tissue damage that is extremely variable in terms of pathways and impact on the different organs. The third mechanism is related to the relative storage of essential nutrients in several organs because of the fact that SI is energetically quite an expensive process, requiring reallocation of nutrients to fuel immuneactivation.[22]

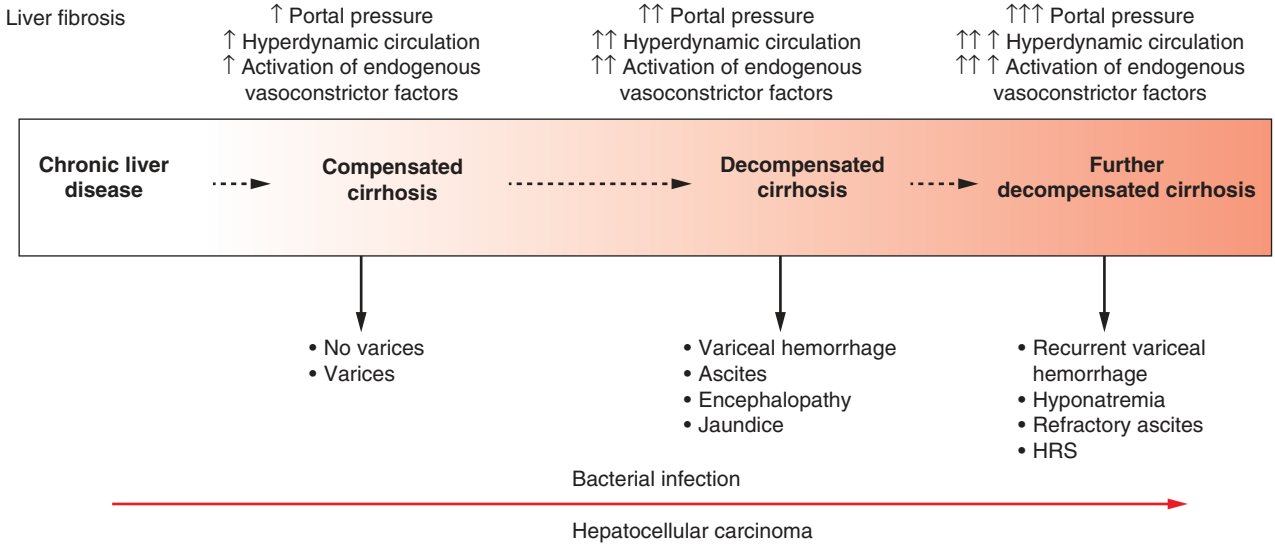

Fig. 83.1 Traditional view of the pathophysiology of the development of decompensation and organ failure in patients with cirrhosis. (Adapted from Albillos A, Garcia-Tsao G. Classification of cirrhosis: The clinical use of HVPG measurements. *Dis Markers*. 2011;31:121–128.)

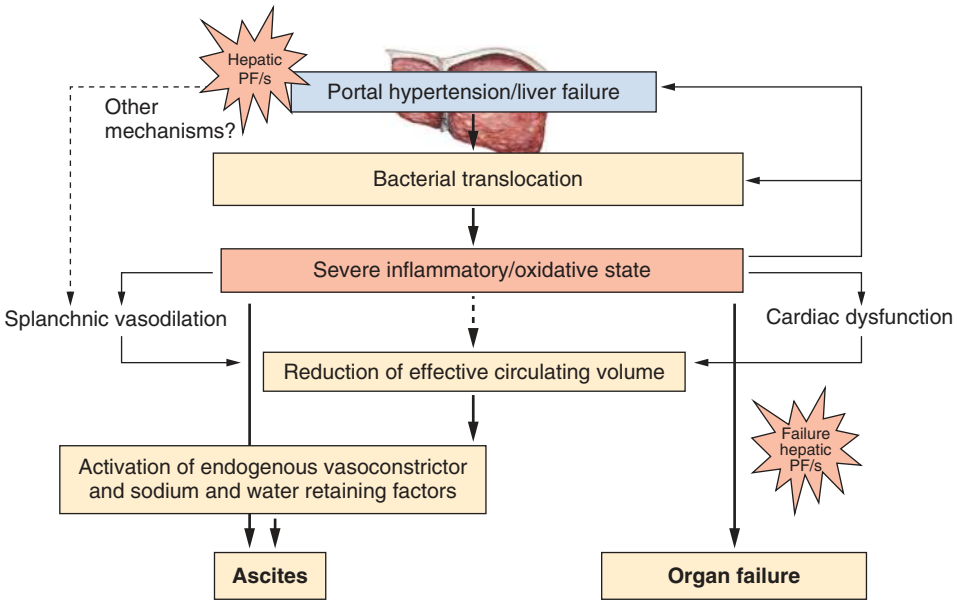

Fig. 83.2 The new systemic inflammation hypothesis on the development of decompensation and organ failure in patients with cirrhosis. Abnormal gut translocation of bacteria and bacterial products induced by portal hypertension and/or liver failure is responsible for systemic inflammation (SI) and oxidative stress (OS). Proinflammatory cytokines and oxidative/nitrosative stress impair effective hypovolemia by enhancing arterial vasodilation, mainly mediated by nitric oxide (NO), and preventing cardiac output to fulfill the needs of the peripheral circulation. SI and OS generate a vicious circle, which is responsible for a progressive increase in the degree of portal pressure and/or the severity of liver failure and of the same intensity of SI and OS. Thus at any time along the course of the liver disease, organ failure can develop, with or without the occurrence of hepatic or extrahepatic precipitating factors (PFs). (Adapted from Bernardi M, Moreau R, Angeli P, et al. Mechanisms of decompensation and organ failure in cirrhosis: From peripheral arterial vasodilation to systemic inflammation hypothesis. *J Hepatol*. 2015;63:1272–1284.)

A New Vision on the Dynamics and Classification of Decompensation in Patients With Cirrhosis

AD has been defined as "the acute development of large ascites, hepatic encephalopathy, gastrointestinal hemorrhage, bacterial infection, or any combination of these requiring an emergent hospitalization."[16] However, the majority of patients with cirrhosis may develop progressive ascites or mild to moderate hepatic encephalopathy (HE) without requiring hospitalization at the first stage of decompensation. This pathway of decompensation can be defined as nonacute decompensation (NAD), and it often precedes AD. Thus focusing on ascites, we

should outline that, in keeping with the new pathophysiologic theory, SI is already present in patients with grade 1 ascites, which is defined as an ascites that can be detected only by abdominal ultrasonography[19] and that ascites of any grade, together with a high Model for End-Stage Liver Disease (MELD) score, a low mean arterial pressure (MAP), and the presence of anemia, is a predictive factor in the development of organ failure and ACLF.[23] Thus we can state that NAD and AD represent the two main ways of transitioning from compensated to decompensated cirrhosis in clinical practice. Patients with NAD may then develop one or more episodes of AD, and when this happens, the subsequent evolution of the liver disease can follow three main trajectories.[24] They may develop ACLF, unstable decompensated cirrhosis (UDC), or stable decompensated cirrhosis (SDC). Patients who develop ACLF have 3-month and 1-year mortality rates of 53.7% and 67.4%, respectively. Those who develop UDC, defined by the absence of organ failure but with a need of at least one hospital readmission during the following 3 months, have a 3-month and 1-year mortality of 21.0% and 35.6%, respectively. Patients with SDC, defined by the absence of both the development of ACLF and the need for hospital readmission during the 3 months after AD, have a 1-year mortality of 9.5%.[24] Therefore this new vision of the dynamics and classification of decompensation can be summarized as shown in Fig. 83.3. Several aspects of decompensation should be further investigated, and thus the new vision is certainly new but also equally certainly partial. In fact, the temporal relationship of the sequence from NAD to AD and the long-term outcome of patients with ACLF, UDC, and SDC are not known. In addition, we do not know the outcome of patients recovering from decompensation. We need a consensus definition on how to define recompensation. It would probably require a symptom-free interval from the previous decompensation and the ability to maintain this stage without treatment. However, this can sometimes occur as a result of effective antiviral treatment in cirrhosis patients with hepatitis B virus (HBV)[25] or hepatitis C virus (HCV)[26] and of abstinence in those with alcohol-related cirrhosis.[27] If recompensation is not taken for granted for etiologic treatments, it is not even expected as a result of disease-modifying agents such as long-term use of human albumin, beta-blockers, and/or statins when exposure to the etiologic agent is still ongoing. However, these treatments may prevent further episodes of decompensation.[28,29]

SOME NEW ACHIEVEMENTS IN THE MANAGEMENT OF COMPLICATIONS OF CIRRHOSIS

Management of Grade 1 Ascites

As previously mentioned, grade 1 ascites has been defined as an ascites that can be detected only by abdominal ultrasonography. For more than 30 years, it has been stated that grade 1 ascites should not be treated by medical therapy (i.e., dietary sodium restriction and/or diuretics). However, this statement was entirely anecdotal and not based on evidence because nothing was known about the clinical course of patients with grade 1 ascites. We have recently proved its correctness because it has been observed that these patients do not have a higher probability of developing an overt ascites than those without any evidence of ascites on ultrasonography. Nonetheless, patients with grade 1 ascites have a higher risk of developing ACLF and dying than those without ascites, and consequently, they should be followed more closely.[19]

The Long-Term Use of Human Albumin Solution in the Treatment of Ascites

An albumin molecule has several biologic properties, oncotic and nononcotic. Albumin represents approximately 75% of plasma oncotic pressure. A large body of evidence exists for its use as a plasma expander in patients with cirrhosis. But with regard to the nononcotic properties, it has been proven that in an experimental model of decompensated cirrhosis, albumin was capable of reducing OS, SI, and inflammation in the cardiac tissue, restoring cardiac contractility. More recently, it has been shown that albumin also attenuates SI even in patients with decompensated cirrhosis. Notably, recent in vitro studies attribute the antiinflammatory properties of albumin to its uptake by immune cells by blocking the endosomal toll-like receptor (TLR) signaling. Thus the long-term use of human albumin solution (HAS) can represent a therapeutic approach in patients with cirrhosis potentially capable of interrupting the pathophysiologic cascade responsible for decompensation. For example, in the ANSWER trial, a nonprofit, multicenter, randomized, open-label study, it was proven that in patients with responsive ascites on diuretic treatment, the long-term administration of HAS on top of the standard medical treatment (SMT) was associated with a significantly better 18-month overall survival as compared with those receiving only the SMT. Furthermore, the cumulative incidence of complications of cirrhosis, including spontaneous bacterial peritonitis (SBP), non-SBP infections, episodes of impairment of renal function, grade III and IV HE, and potential diuretic-induced side effects, was significantly reduced in the group receiving HAS.[28]

The core results of the ANSWER trial were confirmed by a prospective, nonrandomized study that enrolled 70 patients with cirrhosis and refractory ascites. Patients who received SMT + albumin (20 g twice a week) had a significantly lower 24-month mortality than those receiving SMT. Treatment with albumin was the sole independent protective factor against death and was associated with a lower cumulative incidence of rehospitalizations because of any complication of cirrhosis with the exception of gastrointestinal (GI) bleeding.[30]

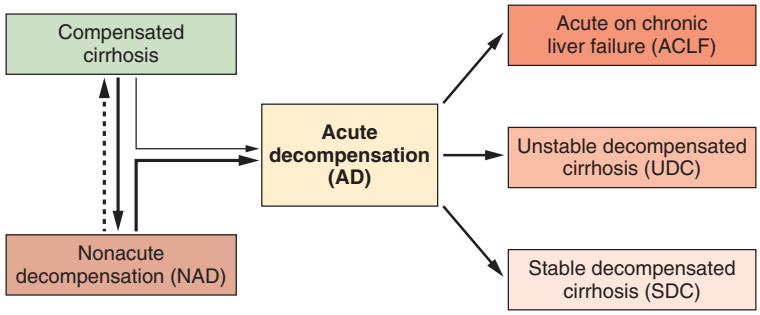

Fig. 83.3 A new vision of the dynamics, classification, and trajectories of decompensation in patients with cirrhosis. AD develops in almost one-third of the cases in patients with compensated cirrhosis and in two-thirds of the cases in patients who have already developed NAD. The dotted line indicates the possibility of recompensation. *AD,* Acute decompensation; *NAD,* nonacute decompensation.

The results of these studies were not confirmed by the MACHT study, which was performed in patients with ascites listed for liver transplantation (LT). Instead, it challenges these results. In this clinical trial, patients were randomized to receive SMT plus 40 g of albumin every 15 days and the alpha-1-receptor agonist midodrine or SMT + placebos. Despite a mild improvement in effective hypovolemia, no difference was observed in either the probability of developing complications or death.[15] The most relevant difference between the ANSWER and MACTH trials is the fact that the amount of albumin administered in the MACHT trial was about half of that administered in the ANSWER trial, so no effect on serum albumin concentration was seen in the MACHT study, whereas a significant and sustained increase by 0.6–0.8 g/L to a median value close to 4 g/dL occurred in the ANSWER study. Interestingly, preliminary results from a post hoc analysis of the ANSWER database showed that the level of serum albumin concentration reached after 1 month of treatment predicts the probability of 18-month overall survival, which was greater than 90% in those patients presenting a level of 4 g/dL. The importance of increasing the serum albumin levels beyond a certain point to obtain the maximal effect of albumin treatment was confirmed by two recent studies.[31,32] In particular, the Spanish study demonstrated that a steady suppression of plasma renin activity and a significant reduction of systemic inflammation were achieved in patients with decompensated cirrhosis receiving high doses (1.5 g/kg per body weight every week) but not low doses (1 g/kg per body weight every 10 days) of albumin.[31] Interestingly, only high doses of albumin were able to normalize serum albumin concentrations.

The Preemptive Use of TIPS in the Treatment of Ascites

Most of the data that compare the effect of a transjugular portosystemic shunt (TIPS) with repeated large-volume paracentesis (LVP) plus albumin have been obtained in the "era" of bare stents in a mixed population of patients with refractory or recurrent ascites.[33–38] Seven different meta-analyses of these studies have been performed,[39–45] but the only definitive and shared conclusion was that TIPS assures better control of ascites but increases the risk of encephalopathy. An advantage in terms of transplant-free survival was evident in only one meta-analysis and seemed more evident in patients with recurrent ascites. In a more recent randomized controlled trial (RCT), the use of a small-diameter covered TIPS in patients with recurrent ascites was associated with better control of ascites and an increased rate of transplant-free survival without any increased risk of developing HE.[46] These results have opened the discussion on the opportunity to anticipate the preemptive use of TIPS before ascites becomes refractory, following the same path used in the treatment of variceal bleeding.[47,48] Accordingly, several experts have mentioned the need to introduce a new diagnostic category (i.e., "difficult-to-treat ascites" or "recurrent ascites"), without almost anyone noticing that a definition of "recurrent ascites" was proposed by International Club of Ascites (ICA) in 1986,[49] in addition to the fact that it has been recently reproposed by the European Association for the Study of the Liver (EASL) clinical practice guidelines (CPGs) on the management of decompensated cirrhosis.[50] According to that definition, recurrent ascites is defined by three episodes of grade 3 ascites during 12 months. By applying this definition, it has recently been observed that recurrent ascites has the same mortality rate as responsive ascites, which is quite lower than that of refractory ascites. This should be taken into account in patients with recurrent ascites when planning the use of TIPS.[19] In the same way, contraindications to the placement of TIPS must be defined. In fact, accurate and reliable indicators predictive of the therapeutic advantage or failure of TIPS are still missing. Patients with severe liver failure have not been included in RCTs. However, the severity of liver failure has arbitrarily been qualified using different parameters and related cutoffs (Child-Pugh score >11, serum bilirubin >5 mg/dL, international normalization ratio [INR] >2). Likewise, a cutoff of serum creatinine >3 mg/dL was used in the RCTs to exclude patients with kidney failure, but without taking into account the nature and the clinical course of this complication. Finally, the impact of other complications such as sarcopenia or syndromes such as ACLF has not been evaluated.

Other Options for the Treatment of Refractory Ascites

Although contraindications to the placement of TIPS should be defined, several patients with cirrhosis and refractory ascites simply are not a candidate for TIPS. What can we offer these patients for a better management of ascites beyond LVP? The automated low-flow pump system (Alfapump) has recently emerged as a potential treatment for refractory ascites in cirrhotic patients. In a small RCT comparing Alfapump with LVP plus albumin infusion in the setting of refractory ascites, Alfapump significantly reduced the need for paracentesis[51] and improved the quality of life[52] in just 6 months. However, patients with the implant had a high risk of renal dysfunction and often needed a reintervention because of technical issues or infections.[51,53,54] Thus after improving both the techniques and the procedure, another RCT was begun. In the near future it will be possible to evaluate the potential role of Alfapump in the management of ascites in patients with cirrhosis.

SOME STILL UNMET OR NEW AIMS IN THE MANAGEMENT OF COMPLICATIONS

Noninvasive Monitoring of the Effect of Nonselective Beta-Blockers

The discovery of the lowering effect on portal pressure of nonselective beta-blockers (NSBBs) represents one of the most important achievements of hepatology research in the last 50 years.[55] The use of NSBBs in the primary and secondary prevention of variceal bleeding has dramatically reduced the rate of this complication and of related mortality in patients with cirrhosis. However, despite all the research done, a noninvasive parameter has not been identified yet to evaluate its effect and therefore to identify patient responders, and even today, the measurement of the hepatic venous pressure gradient (HVPG) represents the only reliable tool in this context.[56] However, it was claimed in the Baveno VI Consensus workshop that the decision to treat with NSBBs should be taken into account when indicated, independent of the possibility to measure HVPG.[56] In the era of precision medicine and/or personalized medicine, this represents a huge vulnerability for their use in clinical practice, in the sense that, in the real world, NSBBs are in fact prescribed without monitoring their effect on portal pressure. Thus in order to follow the current CPGs, what should we do in clinical practice in a patient with cirrhosis who needs NSBBs? Should we prescribe NSBBs and then wait and see if an episode of variceal bleeding occurs or not? Should we wait for an episode of variceal bleeding in order to identify a patient as a nonresponder to NSBBs and thus to change the prophylactic strategy? This would be certainly respectful of the CPGs, but it is unacceptable in clinical practice to such an extent that we want to relate an anecdote. During a recent meeting of the panelists of the GPGs of the Italian Association for the Study of the Liver on the management of portal hypertension, the following request was raised: "Please raise your hand who would monitor a patient with esophageal varices on prophylaxis with NSBBs with an annual upper endoscopy?" All raised their hands. Of course we understand that the strategy of repeating an upper endoscopy every year is not well accepted by patients—it has some potential biases related to interobserver and intraobserver variability and should also be proven to be

cost-effective. Nevertheless, we have some preliminary and still unpublished data showing that this strategy in patients on prophylaxis with NSBBs can reduce the rate of bleeding and the rate of mortality.[57] All this, however, means that in clinical practice, we are deviating from the CPGs, and this is not good for knowledge and science. Therefore the search for a noninvasive, instrumental, or metabolomic tool to monitor the effect on portal pressure of NSBBs represents, in our opinion, an urgent scientific need.

Preventing Bacterial Infections in Patients With Cirrhosis

For many years debate and research on the prevention of infections in patients with cirrhosis have been developed only in reference to a specific type of infection: SBP.[58] This seems today only a partial view of the problem of infections of those patients in light of at least two main considerations: (1) other types of infection besides SBP are extremely dangerous in patients with cirrhosis, particularly when severe, nosocomial, or sustained by multidrug-resistant (MDR) or extensively drug-resistant (XDR) agents, and (2) all types of infections can be complicated by the appearance of organ failure and therefore can precipitate or complicate ACLF. To support the first statement, it is sufficient to consider new epidemiologic data[59] in addition to the fact that the rate of mortality from cirrhosis has decreased over the years for all its major complications with only one exception, sepsis.[60] Regarding the second option, it should be remembered that ACLF is precipitated in about 44% of cases by a bacterial infection[61] or, conversely, that 40%–60% of bacterial infections in cirrhotic patients were complicated by an ACLF with relevant geographic discrepancies.[59] Finally, almost 45%–50% of patients who developed an ACLF not related to a bacterial infection developed bacterial infections during follow-up.[62] Thus the potential candidates for the prevention of infections among patients with cirrhosis should include not only those who experience an episode of SBP or those who are at risk for developing a first episode of SBP but all patients at risk for developing a bacterial infection, all those with AD, and all those with ACLF when not precipitated by a bacterial infection.

Quinolones,[63] and more frequently norfloxacin, have traditionally been used in the primary and secondary prophylaxis of SBP in patients with cirrhosis.[58] In spite of a recent Cochrane meta-analysis,[64] its efficacy has been demonstrated in some RCTs and meta-analyses.[58,65–68] However, some concerns still exist on their use in these patients. First, there is an increasing rate of strains of gram-negative bacteria that are resistant to fluoroquinolones. In fact, their broad spectrum of activity, combined with the high frequency of mutations in the target bacterial enzymes, led to a change in the microbiota of cirrhotic patients with a high prevalence of gram-positive bacteria and extended-spectrum beta-lactamase–producing Enterobacteriaceae.[69] Second, another important point is related to the growing concerns about the fluoroquinolone safety profile. On November 16 2018, the European Medicines Agency released a review on quinolone and fluoroquinolone antibiotics, recommending a restriction in the use of these drugs owing to the possible long-lasting, disabling, and potentially permanent side effects involving tendons, muscles, joints, and the nervous system.[70] In 2016 the Food and Drug Administration coined the term *fluoroquinolone-associated disability* to describe the syndrome related to fluoroquinolone exposure.[7] Moreover, recently published works have shown an increased incidence of aortic aneurysm or dissection in association with the use of oral fluoroquinolone.[71] Taken together, all these data suggest that we have to rethink the use of quinolones and fluoroquinolones for the prevention of infections, including SBP, in patients with cirrhosis. With regard to considering alternative/new antibiotic regimens, a small RCT failed to demonstrate a difference between norfloxacin and trimethoprim-sulfamethoxazole in their effects on preventing infections in patients with liver cirrhosis.[72] Experimental and clinical data showed that rifaximin has a broad-spectrum antibacterial action covering gram-positive and gram-negative aerobic and anaerobic bacteria. Rifaximin has also the advantage of changing the gut microbiome in a limited way, thus inducing a low microbial resistance and also the advantage of having few systemic adverse effects. In addition, rifaximin, with its peculiar pharmacokinetic properties that limit the systemic values of the drug, and thus the side effects, is a promising alternative.[73] Many patients receive rifaximin to prevent recurrent episodes of HE, and rifaximin may also be effective in the prevention of SBP.[73–75] However, large and well-conducted RCTs are needed to establish the efficacy and safety of rifaximin compared with systemic antibiotics for infection prophylaxis in patients with cirrhosis and particularly in those with AD or ACLF.

It is very clear that the main and urgent aim of research in this field is to provide the possibility of a nonantibiotic strategy to prevent bacterial infections in these patients. Thus we are looking forward with great interest to the development of new molecules such as Carbalive, a macroporous carbon of tailored porosity that has a special physical structure that adsorbs both large and small molecules in the gut. Up to now, Carbalive was found to be safe, based on detailed clinical and biochemical assessments compared with placebo. In addition, it was well tolerated with a compliance rate of more than 90%. Preliminary data are quite promising because they showed trends in the improvement of a wide range of biomarkers of systemic inflammation, which is especially notable because Carbalive is not systemically absorbed.[75]

Treating Patients With Acute on Chronic Liver Failure

The short-term prognosis of cirrhotic patients with persistent ACLF 2–3 days after its onset and two or three organs failing is extremely poor. Mortality correlates with the number of organs failing, defined by the chronic liver failure (CLIF) sequential organ failure assessment score and based on the CLIF organ failure scoring system, reaching more than 80% at 30 days in patients with three organs failing. Highly intensive medical treatment and early LT are the only therapeutical options in these patients. However, some aspects of this approach are still controversial and deserve to be discussed. The first is the application of unrestricted intensive care unit (ICU) support, and the second is the feasibility, adequacy, and applicability of an early LT in patients with grade 3 ACLF. Cirrhotic patients with organ failure admitted to the ICU have a mortality rate, ranging from 36% to 89%, depending on the type and number of organ failures.[76–78] These high mortality rates commonly affect the decision not to admit these patients to the ICU, especially when they are not regarded as eligible candidates for LT because of a perception of futility. Notwithstanding that the decision to admit a patient to the ICU is always the result of a multidisciplinary discussion and has to be done on a case-by-case basis, it is beyond question that in some cases there has been—and was particularly during the COVID pandemic—a certain reluctance to give this possibility to patients with ACLF. This is not justified, as a general attitude, by the data available today. A recent study showed that the ICU course and outcome are not different when patients with ACLF are compared with other ICU patients when matched for severity of illness, suggesting that ACLF deserves the same ICU care given to other ICU populations.[79]

In terms of specific therapeutical options in patients with ACLF, it is relevant to underscore, beyond the need for an adequate prevention or treatment of bacterial infections, one aspect related to the treatment of hepatic renal syndrome/acute kidney injury (HRS/AKI). It is well known that according to the algorithm for the management of AKI proposed by the International Club of Ascites in 2015 (Fig. 83.4), once the diagnosis of HRS/AKI stage >1A has been made, patients should

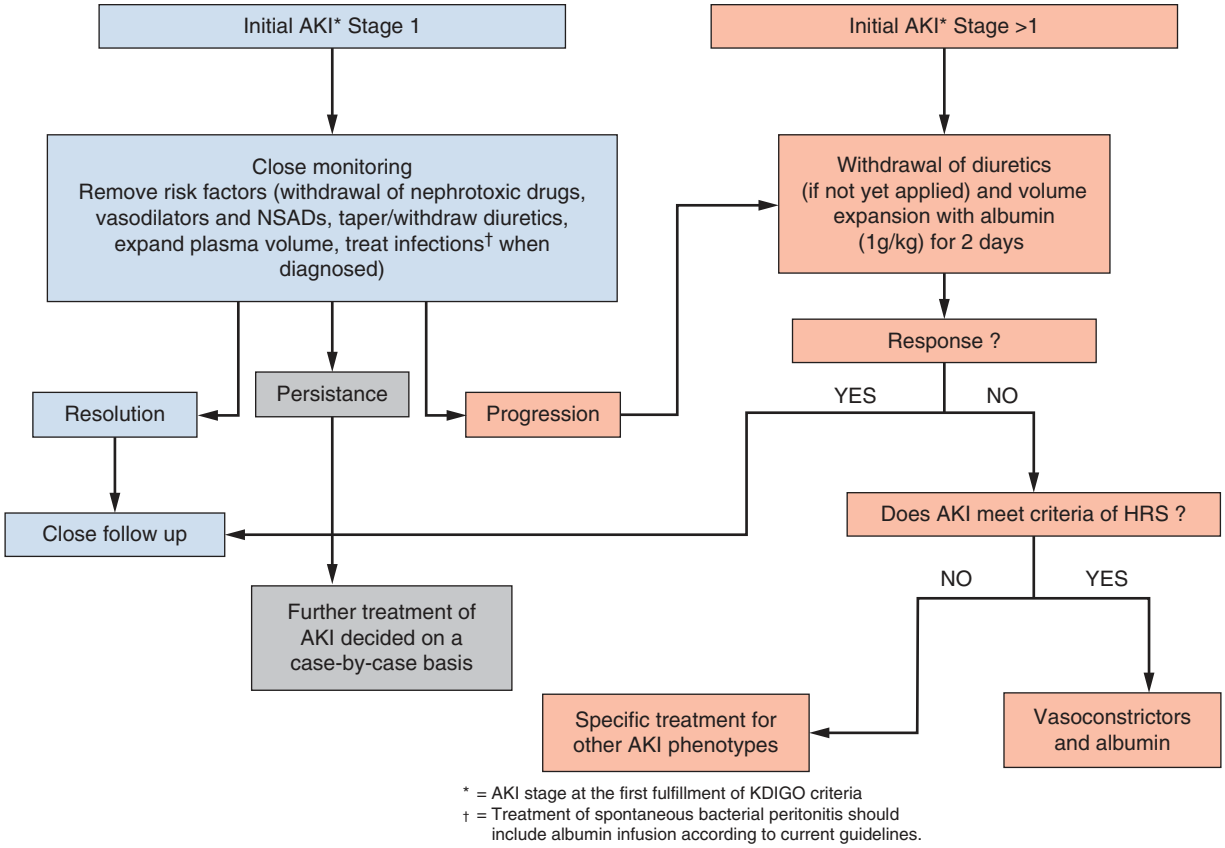

Fig. 83.4 Algorithm for the management of acute kidney injury (AKI) in patients with cirrhosis. (From Angeli P, Gines P, Wong F, et al. Diagnosis and management of acute kidney injury in patients with cirrhosis: Revised consensus recommendations of the International Club of Ascites. *J Hepatol.* 2015;62:968–974.)

promptly receive vasoconstrictive drugs in association with albumin.[80] The rationale for using vasoconstrictors is to counteract the splanchnic arterial vasodilation, thus improving renal perfusion. Terlipressin plus albumin is the first therapeutic option.[81,82] Terlipressin was initially proposed to be given by intravenous boluses at the initial dose of 1 mg every 4–6 hours. However, it was also observed that when terlipressin is given by continuous intravenous infusion at the initial dose of 2 mg/day, it is possible to reduce the total daily dose of the drug and thus the rate of its adverse effects.[83] In case of nonresponse, defined by a decrease in sCr <25% from its peak value within 2 days, the dose of terlipressin should be progressively increased up to a maximum of 12 mg/day. It should be highlighted that the rate of response in patients with ACLF progressively declines moving from those with ACLF grade 1 to those with ACLF grade 3.[84] Noradrenaline is an alternative to terlipressin.[85,86] However, noradrenaline is less effective than terlipressin in patients with HRS/AKI and in patients with ACLF.[87] Both of these observations can be explained by the fact that terlipressin, rather than noradrenalin, is capable of exerting a certain but weak inhibitory effect on inducible nitric oxide synthases and thus reducing the damage related to SI.[88]

With regard to early LT in patients with ACLF grade 3, recent studies suggest that LT is feasible and associated with a clear survival benefit. In particular, we have shown that the 180-day probability of survival of patients with persistent ACLF grade 2 or 3 after 3–7 days from its onset who undergo LT within the 28-day follow-up, was 80.9%, whereas it was only 10% in those who were not transplanted.[89] These results were substantially supported by a French retrospective study, showing that 1-year survival of transplanted patients with ACLF grade 3 was higher than that of nontransplanted controls: 83.9 vs. 7.9%, and not different from that of matched control patients with no ACLF (90%), ACLF grade 1 (82.3%), or ACLF grade 2 (86.2%).[90] All the same, the authors introduced the concept of a "transplantation window" in the debate, showing that a higher rate of complications was observed in patients with ACLF grade 3 at the time of LT (100% vs. 51.2% vs. 76.5% vs. 74.3%, respectively), with a longer hospital stay. The debate has been further fueled by another retrospective study showing that the 90-day and 1-year survival probability in patients with ACLF grade 1 or 2 were 84.5% and 77.2%, respectively, whereas they were 60% and 43.3%, respectively, in patients with ACLF grade 3 and that the presence of ACLF was among the six independent predictors of 90-day mortality after LT together with age, gender, primary diagnosis at listing (end-stage liver disease or hepatocellular carcinoma), and infection during the month prior to LT.[91] The authors also introduced the concept of "potentially inappropriate LT," referring to potential candidates who have a high risk of not surviving LT during the early postoperative period (i.e., 3 months).[92] The debate that follows tries to address this main question: What compromises the outcome of transplantation in patients with ACLF: the number of organs failing and/or the type of organs failing? One of the largest retrospective studies, published by Thuluvath and colleagues, showed that the number of organ failures and the type of organ failures had only a minimal impact on survival after LT and that only mechanical ventilation was identified as an independent negative predictor of survival post-LT.[93] These results were confirmed by Sundaram and colleagues, who showed that mechanical ventilation at LT, donor risk index above 1.7, and LT within 30 days of listing were independently associated

with 1-year survival after LT in patients with ACLF grade 3.[94] Considering the rationing of organs because of shortages, well-designed prospective studies are needed to assess the impact of recipient and donor characteristics on outcome and to define the protocol for quick pre-LT assessment, along with objective criteria for listing and delisting rules in patients with ACLF-3 and multiorgan failure. Nonetheless, there is even a more urgent need, which is to develop a new score in order to prioritize candidates with ACLF on the waiting list because it has been clearly demonstrated that MELD or MELD Na are completely inadequate and should not be used. It has also been proven that their application is associated with a higher rate of death or removal from the waiting list in patients with ACLF than in those without ACLF, a result that cannot be accepted from an ethical point of view.[94,95] Thus further prospective studies are urgently needed to evaluate the optimum timing and selection and prioritization criteria for LT in cirrhotic patients with ACLF.

KEY POINTS

- SI and OS act synergistically with portal hypertension in the pathophysiology of decompensation and organ failure in patients with cirrhosis.
- The clinical course of cirrhosis can be characterized by NAD and/or AD.
- After an episode of AD, patients with cirrhosis can follow three different trajectories: they can develop ACLF, UDC, or SDC.
- The long-term infusion of HAS can reduce the rate of complications and mortality in patients with responsive ascites and in those with refractory ascites.
- The placement of a small-diameter covered TIPS can improve the control of ascites and survival in patients with recurrent ascites.

ANNOTATED REFERENCES

Arroyo V, Angeli P, Moreau R, et al. The systemic inflammation hypothesis: Towards a new paradigm of acute decompensation and multiorgan failure in cirrhosis. J Hepatol. 2021 Mar;74(3):670–685. doi: 10.1016/j.jhep.2020.11.04.
The authors discuss the systemic inflammation hypothesis in detail, suggesting that systemic inflammation acts synergistically with the traditional mechanisms involved in the development of AD. In particular, the authors highlight that systemic inflammation may impair organ system function through different mechanisms, which are not mutually exclusive. The first mechanism is a nitric oxide–mediated accentuation of the preexisting splanchnic vasodilation resulting in the overactivation of the endogenous vasoconstrictor systems, which induces hypoperfusion in vascular beds of different organs, particularly the kidney. Second, systemic inflammation may cause immune-mediated tissue damage, a process that is called immunopathology. Third, systemic inflammation may induce important metabolic changes.

Bernardi M, Moreau R, Angeli P, et al. Mechanisms of decompensation and organ failure in cirrhosis: From peripheral arterial vasodilation to systemic inflammation hypothesis. *J Hepatol* 2015;63:1272–1284.
The authors introduce the systemic inflammation hypothesis of decompensation in patients with cirrhosis. Accordingly, they propose that bacterial translocation progressively affects the natural course of cirrhosis, from the preascitic compensated stage to advanced decompensation and hepatorenal syndrome. An abrupt increase in systemic inflammation represents the pathophysiologic background for ACLF. As with any hypothesis, many, but not all, concepts are demonstrated, and future research on these matters is warranted.

Bureau C, Thabut D, Oberti F, et al. Transjugular intrahepatic portosystemic shunts with covered stents increase transplant-free survival of patients with cirrhosis and recurrent ascites. *Gastroenterology.* 2017;152:157–163.
In this randomized trial, the authors show that covered stents for TIPS can increase the proportion of patients with cirrhosis and recurrent ascites who survive transplantation-free for 1 year, compared with patients given repeated large-volume paracentesis plus albumin. These findings support TIPS as the first-line intervention in such patients.

Caraceni P, Riggio O, Angeli P, et al. Long-term albumin administration in decompensated cirrhosis (ANSWER): An open-label randomised trial. *Lancet.* 2018;391:2417–2429.
In this randomized multicenter trial, long-term HA administration prolongs overall survival and might act as a disease-modifying treatment in patients with decompensated cirrhosis.

Moreau R, Jalan R, Gines P, et al. Acute-on-chronic liver failure is a distinct syndrome that develops in patients with acute decompensation of cirrhosis. *Gastroenterology.* 2013;144:1426–1437.
The authors introduce the definition of AD, organ failure, and ACLF. They analyze data from patients with cirrhosis and AD to establish diagnostic criteria for ACLF and showed that it is distinct from AD, based not only on the presence of organ failure and a high mortality rate but also on age, precipitating events, and systemic inflammation. ACLF mortality is associated with loss of organ function and high leukocyte counts. ACLF is especially severe in patients with no prior history of AD.
In this study the authors show that grade 1 ascites is associated with systemic inflammation and that systemic inflammation progressively increases in those with grade 2 or 3 ascites, particularly when they fit the criteria for recurrent of refractory ascites. In addition, the authors show that patients with grade 1 ascites do not develop grade 2 or 3 ascites more frequently than patients without any evidence of ascites but develop more frequently other complications, including ACLF, and have a higher mortality rate. The authors also show that the mortality rate does not differ significantly between patients with recurrent ascites vs. ascites responsive to medical treatment.

Piano S, Tonon M, Vettore E, et al. Incidence, predictors and outcomes of acute-on-chronic liver failure in outpatients with cirrhosis. *J Hepatol* 2017;67:1177–1184.
In this study, the authors identify four simple predictors of ACLF: MELD score, ascites, mean arterial pressure, and hemoglobin. These variables may help to identify patients with cirrhosis at a high risk of developing ACLF that are candidates for new strategies of surveillance and prevention.

Hepatorenal Syndrome

Brent Ershoff, Colby Tanner, and Anahat Dhillon

An association between advanced liver disease, ascites, and renal failure described in 1861 was named *hepatorenal syndrome* (HRS) by Helvig and Schutz in 1932.[1] Until recently, HRS has been thought of as a purely functional form of renal failure without renal histologic changes.[2] HRS is characterized by intense renal vasoconstriction, impaired renal perfusion, and low glomerular filtration rate (GFR) in the setting of splanchnic and systemic vasodilation.[3] Among individuals with advanced cirrhosis, the incidence of HRS is 18% within 1 year and up to 40% at 5 years.[4,5] The variability in the incidence is related to the degree of liver dysfunction, with higher Model for End-stage Liver Disease (MELD) scores portending an increased risk. HRS heralds a poor prognosis, with nearly half of the patients with HRS type 1 (HRS-1) who do not undergo transplantation dying within 2 weeks.[4,6,7]

RENAL DYSFUNCTION IN CIRRHOSIS

Renal dysfunction in the setting of cirrhosis is common and is associated with adverse outcomes.[8,9] The MELD system was implemented in 2002 to prioritize patients for liver transplantation with renal dysfunction weighted heavily. This has led to an increase in the number of patients with renal dysfunction undergoing liver transplantation.[10] Although HRS is the focus of this chapter; there may be other causes of acute kidney injury (AKI) in patients with cirrhosis. Common causes of prerenal AKI include the use of diuretics, lactulose, and hypovolemia. Intrinsic etiologies of AKI include glomerulonephritis, acute interstitial nephritis, bile cast nephropathy,[11,12] and acute tubular necrosis (ATN).[13] The etiology of renal disease is independently associated with prognosis, with HRS having the lowest 3-month probability of survival.[14]

Several consensus definitions of AKI have been formulated. In 2004, the Acute Dialysis Quality Initiative (ADQI) group proposed the risk, injury, failure, loss of kidney function, and end-stage kidney disease (RIFLE) criteria, which categorized renal dysfunction into grades of increasing severity based on urine output and changes in serum creatinine.[15] Given that even small increases in serum creatinine can reflect kidney injury and adverse outcomes, the Acute Kidney Injury Network (AKIN) criteria were proposed in 2007. In line with new classifications of AKI, in 2015, the International Club of Ascites (ICA) proposed an adjustment to the criteria for a diagnosis of AKI in patients with cirrhosis. The new ICA-AKI criteria propose a move away from a fixed serum creatinine (sCr) cutoff for the diagnosis of AKI in favor of an sCr increase of 0.3 mg/dL or ≥50% from baseline. Further staging of the severity of AKI from grades 1 to 3, corresponding to the magnitude of the elevation of sCr, was also proposed.[16] Follow-up studies on outcomes for patients with cirrhosis complicated by AKI have continued to demonstrate that HRS is the most severe form of AKI with the highest mortality, although no mortality differences among AKI stages 1, 2, and 3 have been noted.[17]

PATHOGENESIS OF HRS

Low blood pressure; a very low GFR (<40 mL/min); and an increase in plasma levels of renin, norepinephrine, and antidiuretic characterize HRS.[2] The increase in sheer stress in the splanchnic vasculature is a result of portal hypertension, leading to the overproduction of nitric oxide and other vasodilators.[18] Other factors contributing to splanchnic vasodilation include increased bacterial translocation, mesenteric angiogenesis, and hyporesponsiveness of the splanchnic vasculature to vasoconstrictors.[19]

Sodium retention, impaired free-water excretion, and decreased renal perfusion and GFR are the main abnormalities in HRS and are progressive. The first abnormality is the reduced ability to excrete sodium secondary to mineralocorticoid effects. As the disease progresses, patients are unable to excrete the sodium ingested in their diet, and ascites develops. When renal sodium avidity is extremely high, the plasma renin activity and the plasma concentrations of aldosterone and norepinephrine are elevated.[20,21] Circulatory dysfunction is greater at this stage, with increased activity of the sympathetic nervous and the renin – angiotensin systems.

Renal perfusion and GFR are dependent on increased renal production of prostaglandins. These lipid mediators are vasodilators that antagonize the vasoconstricting actions of angiotensin II and norepinephrine. A syndrome indistinguishable from HRS can be produced in patients with cirrhosis, ascites, and increased plasma renin activity if prostaglandin synthesis is inhibited by nonsteroidal antiinflammatory drugs.[21,22]

Peripheral arterial vasodilation has been implicated in HRS but primarily affects the splanchnic arterial vascular bed. Doppler ultrasonography studies demonstrate vasoconstriction in renal, brachial, femoral, and cerebral beds.[23,24] Several endogenous vasodilators have been implicated in splanchnic vasodilation, including nitric oxide, carbon monoxide, glucagon, prostacyclin, and endogenous opiates.[25–27]

End-stage liver disease is associated with reduced systolic and diastolic response to stress, enlarged cardiac chambers, and repolarization changes, termed *cirrhotic cardiomyopathy*.[28] The development of HRS has been associated with a lower arterial pressure, a marked decrease in cardiac output, and increases in plasma renin activity and plasma norepinephrine[29] (Fig. 84.1).

Recently, the role of the systemic inflammatory response seen in advanced cirrhosis has been implicated in the pathogenesis of hepatorenal syndrome.[30] The presence of a distinct additional pathophysiologic basis for HRS may explain the lack of response to vasoconstrictors observed in some patients.[31] Further elucidation of the pathophysiology of HRS may lead to novel therapeutic targets in the future. Although HRS has traditionally been viewed as a purely functional form of renal disease, new data suggest that there exists some

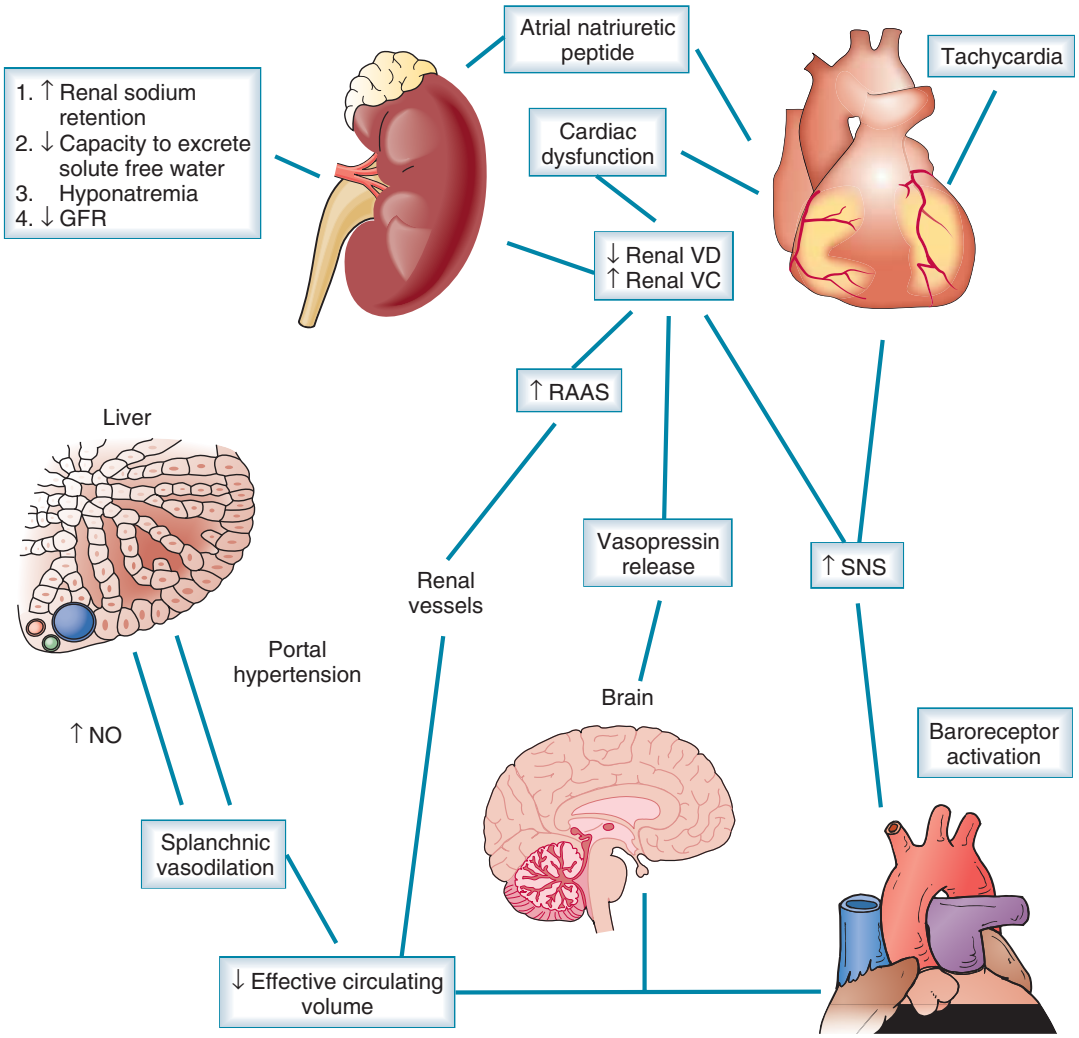

Fig. 84.1 Pathophysiologic Mechanisms of HRS. *GFR,* Glomerular filtration rate; *HRS,* hepatorenal syndrome; *NO,* nitric oxide; *RAAS,* renin–angiotensin–aldosterone system; *renal VC,* renal vasoconstrictors; *renal VD,* renal vasodilators; *SNS,* sympathetic nervous system. (From Wadei HM, Mai ML, Ahsan N, Gonwa TA. Hepatorenal syndrome: pathophysiology and management. *Clin J Am Soc Nephrol.* 2006;1:1066–1079.)

component of parenchymal damage. Neutrophil gelatinase-associated lipocalin (NGAL) is one biomarker reflective of renal structural damage. NGAL is significantly elevated in ATN; however, elevations can be seen in HRS. This suggests a component of structural damage and that ATN and HRS may exist as a spectrum of the same disease rather than as distinct entities.[32,33]

DIAGNOSIS

In 2015, the ICA updated the diagnostic criteria for HRS to include the new definition of AKI, which requires an elevation in serum creatinine of 0.3 mg/dL or ≥50% above baseline in the absence of other potential causes of renal failure (Table 84.1).[16] These criteria are slightly different from previously defined criteria and will be discussed in more detail later. The first step in the diagnosis of HRS is a demonstration of elevated creatinine, which greatly underestimates the decrease in GFR in advanced cirrhosis.[2,34] Similarly, urea is synthesized by the liver, and urea synthesis may be reduced as a consequence of hepatic insufficiency.[35,36] Many patients may not meet the diagnostic criteria for HRS yet have significant renal injury similar to HRS.[37]

TABLE 84.1 Diagnostic Criteria of Hepatorenal Syndrome (HRS) Type of Acute Kidney Injury (AKI) in Patients with Cirrhosis (International Club of Ascites [ICA])

Cirrhosis with ascites
Diagnosis of AKI according to ICA-AKI criteria
No improvement in serum creatinine after at least 2 days with diuretic withdrawal and volume expansion with albumin. The recommended dose of albumin is 1 g/kg of body weight per day up to a maximum of 100 g/day
Absence of shock
No current or recent treatment with nephrotoxic medications
Absence of parenchymal kidney disease as evidenced by proteinuria, microhematuria, and/or abnormal renal ultrasound

From Angeli P, Ginès P, Wong F, et al. Diagnosis and management of acute kidney injury in patients with cirrhosis: revised consensus recommendations of the International Club of Ascites [published correction appears in *J Hepatol.* 2015;63(1):290]. *J Hepatol.* 2015;62(4):968–974. Box 1.

CLINICAL TYPES

HRS has been classified into two types according to the severity and form of presentation of renal failure.[31] Type I HRS (HRS-1) is characterized by a rapid reduction in renal function and is defined by a doubling of the serum creatinine concentration to 2.5 mg/dL in less than 2 weeks. HRS-1 is often precipitated by an infection, hemorrhage, paracentesis, surgery, or acute hepatitis. The association between HRS and spontaneous bacterial peritonitis (SBP) has been carefully investigated.[38–40] HRS-1 develops in approximately 30% of patients with SBP despite rapid and successful treatment. Patients with an intense systemic inflammatory response and high cytokine levels in plasma and ascitic fluid are especially prone to developing HRS-1 after infection. HRS-1 has a 2-week median survival in patients who do not undergo liver transplantation. HRS-2 is characterized by a more moderate and steady decrease in renal function, with a serum creatinine >1.5 mg/dL that fails to satisfy the diagnostic criteria of HRS-1. The dominant clinical feature is severe ascites with poor or no response to diuretics. Patients with HRS-2 are especially predisposed to developing HRS-1 after precipitating events.[38–40] The median survival of patients with HRS-2 is 6 months, which is worse than patients with nonazotemic cirrhosis with ascites.

The ICA has recently recommended reclassifying hepatorenal syndrome into two new categories: HRS-AKI (in place of HRS-1) and HRS-NAKI (in place of HRS-2). Although the changes have caused some confusion and are in some sense semantic in nature, the reclassification is based on the evolving changes in the definition of AKI, recognizing that even small increases in creatinine are suggestive of kidney injury. The original definition of HRS-1 required that an advanced stage of AKI (at least stage 2) be present, which may have limited the efficacy of vasoconstrictor therapy.[41] With this new definition of HRS-AKI, the ICA is encouraging clinicians to initiate treatment of patients quickly, even when increases in sCr are more modest.

The ICA proposes that the diagnosis of HRS-NAKI be made in the context of chronic kidney disease (CKD) or acute kidney disease (AKD) that does not meet the criteria for AKI and lasts for <90 days. HRS-NAKI is characterized by an estimated GFR <60 mL/min but a percent increase in sCr <50% from baseline. It is further broken down into HRS-AKD in patients who have had a decreased estimated GFR (eGFR) for <3 months and HRS-CKD in patients with decreased eGFR for ≥3 months.[31]

TREATMENT

Goals of therapy include improvement of liver function, as in the recovery of alcoholic hepatitis; treatment of decompensated hepatitis B[42]; or medical therapy, including pharmacotherapeutics and renal replacement therapy (RRT), as a bridge to either liver transplantation or simultaneous liver-kidney transplantation (SLK). To date, no single therapeutic agent has been found to permanently reverse HRS. Dopamine, fenoldopam, endothelin antagonists, natriuretic peptides, and angiotensin-converting enzyme inhibitors have been shown to either have no benefit or worsen the outcome of HRS.[43]

Liver Transplantation

Liver transplantation is the treatment of choice for HRS.[44–48] Immediately after transplantation, further impairment in GFR may be observed with the need for RRT.[44] Delay in the administration of nephrotoxic medications for 48–72 hours after transplantation may be considered.[49] GFR improves by 1–2 months postoperatively, but a moderate level of renal dysfunction persists and is more marked than in patients without HRS.[50] The hemodynamic and neurohormonal abnormalities associated with HRS usually resolve within the first month. However, not all patients exhibit renal recovery. Predictors of an HRS-1 reversal after liver transplantation are younger age, lack of CKD, shorter durations of HRS and pretransplant dialysis, and lower preoperative creatinine.[51] There is heterogeneity in the results of studies examining renal recovery posttransplant, with results ranging from 58% to 100%.[52,53]

Patients with HRS who undergo transplantation have more complications, longer intensive care unit stay, and higher in-hospital mortality rates.[44–48] The 3-year probability of survival is 60%,[44–48] which is only slightly less than that for liver transplant recipients without HRS.

SLK

SLK transplant is an option for patients at risk for nonrecovery. SLK should be used only for those who have irreversible kidney injury.[54,55] At this time, however, renal recovery remains difficult to predict. The Organ Procurement and Transplantation Network (OPTN) Liver and Intestine Committee and Kidney Committee proposed listing criteria for SLK candidate selection and allocation. Limitations include the definition and duration of AKI, GFR determination, and timing of initiation and duration of dialysis.[37,56] Whereas some studies suggest that patients on RRT for more than 8–12 weeks have improved survival with SLK compared with liver transplant alone, there is significant variability.[55,57,58] The consensus panel suggested liver transplantation alone in patients with HRS for less than 4 weeks.

Volume Expansion and Vasoconstrictors

Vasoconstrictors and volume expansion to increase splanchnic vasoconstriction and improve circulating volume may be the most promising medical approach for HRS. Over the past decade, many small studies have evaluated vasoconstrictors with and without a volume expander.

Volume administration, particularly with albumin, is an important tenet of therapy, with several studies showing that vasopressors alone are not as effective. It is important to avoid fluid overload. Assessment of intravascular volume is challenging, with physical examination findings or static measurements of filling pressures having poor accuracy in predicting a response to a fluid bolus.[59] The choice of fluid remains controversial,[60] although a consensus panel recommended albumin. The recommended albumin dose is 1 g of albumin/kg for 2 days, up to a maximum of 100 g/day, followed by 20–40 g/day.[16,37] "Chloride liberal" fluid administration may be associated with AKI in critically ill patients and liver transplant recipients.[61,62] Studies in HRS need to be conducted.

Vasopressin is an endogenous hormone with three major identified receptors. The V1 receptor, found on vascular smooth muscle, promotes vasoconstriction. The V2 receptor is involved in the osmoregulation of the kidney, and the V3 receptor affects corticotropin secretion. The V1 receptor has been the target of interest for vasopressin analogs designed to increase splanchnic vasoconstriction.[43,63] The original studies were conducted with ornipressin, but the recent focus has been on terlipressin, which has a greater effect on the V1 receptor and fewer side effects.[64] Complications with vasopressor therapy have been reported in an average of 12% of patients treated and it is contraindicated in patients with ischemic heart disease, peripheral vascular disease, and cerebrovascular disease.[65]

Monotherapy with either albumin or a vasoconstrictor is not as effective as combined therapy. Two randomized trials comparing terlipressin with albumin to either agent alone showed an improved response with combination therapy.[66] Two meta-analyses have shown improved outcomes with the use of terlipressin versus a placebo.[64,67] Fabrizi and colleagues[64] analyzed 10 clinical trials and found a reversal of HRS in 52% of cases. Dobre and colleagues[67] identified eight eligible trials, four of which compared terlipressin with placebo. The

terlipressin group had improved outcomes, including reversal of HRS (odds ratio [OR] of 7.47), improvement in mean arterial pressure (MAP), improvement in urine output, and reduction in serum creatinine. Sanyal and colleagues[68] conducted a randomized controlled trial (RCT), and a subgroup of patients who received terlipressin for more than 3 days had a greater response to therapy compared with the placebo group (52.8% vs. 18%, $P = .002$). These data support the contention that length of therapy may contribute to some of the variability in treatment efficacy. Sanyal and colleagues[69] also showed that earlier therapy increased the probability of reversal. Treatment with terlipressin and albumin may be associated with a survival benefit when including studies other than just placebo control studies.[65]

The terlipressin dose ranges used vary from 1 to 2 mg every 4–6 hours. Incremental increases in dosing while monitoring creatinine have been recommended.[68] Additionally, a maximal dose of 12 mg/day with minimum duration of 3–5 days has been proposed.[63] There are variable data on the rates of recurrence after discontinuation of therapy, ranging from 5.3% to 50%.[43,63,70]

Alpha-adrenergic agonists also have been used to augment renal perfusion. Two RCTs compared norepinephrine with terlipressin.[71,72] In the first study, reversal of HRS occurred in 70% of the patients in the norepinephrine group versus 83% in the terlipressin group. In the second study, norepinephrine was effective in increasing MAP and urine output and decreasing creatinine. A recent meta-analysis found that norepinephrine is as effective as terlipressin when used in conjunction with albumin and that it appears to be associated with fewer adverse events.[73] Although evidence regarding treatment of HRS-2 has historically been scant, an RCT by Ghosh and colleagues found that both terlipressin and norepinephrine are safe and effective, with response rates of 74%.[74]

As treatment with norepinephrine is limited to inpatient and critical care settings, alternative vasopressor regimens, including oral midodrine and octreotide, have emerged. Several studies have shown that oral midodrine used in conjunction with intravenous (IV) albumin and subcutaneous octreotide results in improved renal perfusion, GFR, serum blood urea nitrogen, creatinine, and sodium.[75] Furthermore, the treatment regimen has also been associated with increased survival in both HRS-1 and HRS-2 when compared with untreated controls.[76,77] Studies of monotherapy of octreotide, however, have not shown a benefit over placebo. The combination of midodrine plus octreotide is a promising regimen for HRS-2 as outpatients.

A recent meta-analysis evaluated 10 RCTs that compared terlipressin with other vasopressor regimens, including norepinephrine, dopamine, octreotide, and midodrine, all in conjunction with albumin administration. There was little evidence to support the superiority of terlipressin over alternative vasopressor therapies, including two studies that found it to be inferior in regard to mortality.[78] Additional research has focused on identifying predictors of treatment efficacy with vasoconstrictors. A change in MAP during treatment was the sole independent predictor of patient survival.[79] An increase in MAP of more than 10 mm Hg was associated with better overall survival, with no further improvement despite higher targets. A treat-to-the-target concept by the use of a specific MAP goal may guide management.

In summary, these studies show the following:

1. HRS-1 can be reversible with IV albumin and vasoconstrictors.
2. Both components of the treatment are important.
3. Infusion of vasoconstrictors is associated with ischemic complications.
4. There is a delay between improvement in circulatory function and an increase in GFR.
5. Reversal of HRS improves survival, with a significant number surviving to transplantation.

Transjugular Intrahepatic Portosystemic Shunt

Decreasing portal pressure by portosystemic anastomosis to improve the circulatory compromise of cirrhosis has been targeted as a treatment for HRS. Case reports show that HRS can be reversed after a surgical portosystemic shunt.[80,81]

Transjugular intrahepatic portosystemic shunt (TIPS) in the management of HRS-1 has been evaluated in small-scale studies and may be of benefit in conjunction with vasopressors.[82–84] In one study of patients with HRS-1 who were not candidates for transplantation, it was found that the survival rates at 3, 6, and 12 months after TIPS were 64%, 50%, and 20%, respectively.[82] TIPS may be beneficial in patients with HRS-2 with refractory ascites, with improvements in renal function without improved survival.[85] A more recent meta-analysis by Salerno and colleagues, however, found TIPS significantly improved transplant-free survival of patients with cirrhosis and refractory ascites. Further research is needed to define the role of TIPS in the treatment of HRS.[86]

Other Therapeutic Methods

Hemodialysis and arteriovenous or venovenous hemofiltration are a frequent bridge to liver transplantation or for treating an acute but reversible decompensation.[87] Continuous RRT is often selected in hemodynamically unstable patients, but there are no published studies that allow for evidence-based guidelines on one modality over the other.[88] Given that the prognosis of HRS-1 is poor without transplantation, strong consideration should be had for withholding RRT in patients who are not liver transplant candidates. These decisions should be made within the context of the patient's goals of care and involve shared decision making.

Noncell-based extracorporeal support systems are available that perform detoxifying functions of the liver. One such noncell-based support system uses an albumin-containing dialysate that is recirculated and perfused through charcoal and anion-exchanger columns. This modality has been shown to improve hemodynamics and reduce plasma renin in patients with HRS-1.[89,90] In a small series of patients, improved survival was reported.[91] Modalities such as the Prometheus system and single-pass albumin dialysis have been used in a few patients with some success.[92,93] However, further studies are needed in this area.

PREVENTION

Preventing precipitating factors, such as infections and acute alcoholic hepatitis, may decrease the incidence of HRS-1. Three randomized controlled studies enrolling a large series of patients have shown that HRS can be prevented in specific clinical settings. In the first study,[94] albumin together with cefotaxime was compared with cefotaxime alone in patients with SBP. Treatment with albumin markedly reduced the incidence of impaired circulatory function and the occurrence of HRS-1. The second study showed that oral prophylaxis using norfloxacin decreased the 1-year probability of developing SBP and HRS-1 and improved survival.[95] In a third study,[5] administration of the tumor necrosis factor synthesis inhibitor pentoxifylline to patients with severe acute alcoholic hepatitis reduced the occurrence of HRS (8% vs. 35%) and hospital mortality (24% vs. 46%).

CONCLUSION

The pathophysiology of HRS is characterized by intense vasoconstriction with splanchnic arterial vasodilation. HRS-1, now classified as HRS-AKI, is characterized by rapid and progressive deterioration of circulatory and renal function. It often develops after a precipitating

event and carries a very poor prognosis (median survival rate <2 weeks without liver transplantation). HRS-2, or HRS-NAKI, is characterized by steady deterioration of circulatory and renal function with refractory ascites. Patients with HRS-2 have a median survival of 6 months. The administration of albumin plus a vasoconstrictor is an effective treatment for HRS. These approaches may improve survival and may serve as a bridge to liver transplantation, which is the treatment of choice for these patients.

KEY POINTS

- Portal hypertension leads to the production of vasodilators causing splanchnic vasodilation. This leads to activation of the renin – angiotensin – aldosterone system and the sympathetic nervous system, which causes renal vasoconstriction. Decreased renal perfusion caused by an imbalance between extremely high vasoconstrictor tone and the decreased production of renal vasodilators leads to HRS.
- Criteria of the ICA define HRS-AKI (see Table 84.1) as an increase in sCr >0.3 mg/dL or an increase by ≥50% above baseline.
- HRS is classified into two types:
  - HRS-1 or HRS-AKI: severe and rapidly progressive renal failure, usually after a precipitating event, with a median survival of 2 weeks.
  - HRS-2 or HRS-NAKI: moderate and steady development of renal failure, clinically characterized by refractory ascites, with a median survival of 6 months.
- Liver transplantation is the treatment of choice for HRS. The recovery of renal function neurohumoral physiology may take 1 month.
- The 3-year probability of survival in transplanted patients with HRS is 60%.
- HRS-1 may be reversible after treatment with IV albumin and vasoconstrictors.
- Successful prevention of HRS has been achieved in the setting of SBP and acute alcoholic hepatitis.

Hepatopulmonary Syndrome

Cody D. Turner, Nasim Motayar, and David C. Kaufman

DEFINITION

Hepatopulmonary syndrome (HPS) is defined by an abnormally low arterial oxygen level associated with intrapulmonary vascular dilatations (IPVDs) in patients with liver disease.[1] The presence of coexisting cardiopulmonary disease, which may contribute to impaired gas exchange, should be considered but does not exclude this diagnosis.[2–5] HPS is most commonly associated with cirrhosis[1] and portal hypertension, but neither of these is required for its diagnosis.[6] The correlation between the degree of liver dysfunction and the presence[7,8] and severity[3,4,7,9,10] of this syndrome is debated.

CLINICAL FEATURES

HPS usually presents as dyspnea[6,11] in patients with liver disease. A sensitive but not specific clinical finding is the presence of platypnea, which refers to worsening of dyspnea when going from the supine to upright position (Fig. 85.1). The subsequent drop in arterial oxygenation during this position change is referred to as orthodeoxea.[11,12]

HPS-induced hypoxemia can be corrected with the application of supplemental oxygen;[1,3,4,10,13] unresponsiveness to oxygen therapy should prompt clinicians to search for other causes. Although there are no consistently noted physical examination findings,[6,14] some clinical findings observed include the presence of digital clubbing, cyanosis, and diffuse telangiectasias.[1]

PATHOPHYSIOLOGY

Dilated precapillary vessels and pleural-based arteriovenous (AV) connections are noted at autopsy in cases of HPS.[15] Current thinking suggests that these abnormal vessels develop as a result of an excess of pulmonary vasodilators,[1] which cause hypoxia through ventilation/perfusion (V/Q) mismatching, AV shunting, and the limitation of oxygen diffusion to red blood cells (RBCs) in the center of the vessel.[15–17] The hyperdynamic circulation, which is characteristic of cirrhosis, exacerbates this problem by decreasing RBC transit time through the pulmonary capillaries, further limiting oxygen diffusion.[15,17] Orthodeoxia is caused by a worsening of V/Q mismatch and AV shunting in the standing position.[18]

Nitric oxide (NO) has been implicated as a key vasodilator in HPS. Exhaled NO levels are elevated in patients with cirrhosis compared with healthy controls and in HPS patients compared with cirrhotic patients without HPS. NO levels correlate with the severity of cirrhosis and gas exchange abnormalities.[19] In rat models of HPS induced by common bile duct ligation (CBDL), increased levels of endothelial[20] and inducible NO synthase (eNOS and iNOS) have been observed, and the administration of an NO synthase inhibitor prevents the development of pulmonary vasodilation and HPS.[21]

Excess eNOS, located in the pulmonary arteries and capillaries, is associated with impaired vasoconstriction. Levels of this enzyme correlate with the degree of gas exchange abnormalities.[20] CBDL rats demonstrate increased hepatic production of endothelin-1 (ET-1)[22] and increased vascular expression of the endothelin-B receptor (ET-B)[23] in proportion to the severity of gas exchange abnormalities.[22,24] Interaction between the ET-1 and the ET-B receptor is believed to be the trigger for increased eNOS expression. This theory is supported by data that show a reduction in eNOS expression and an improvement in HPS when CBDL animals are treated with ET-B receptor antagonists.[24]

iNOS is expressed in macrophages found in the lungs of CBDL rats,[21] whereas treatment with norfloxacin is associated with a reduction in the rate of gram-negative bacterial translocation, accumulation of pulmonary macrophages, production of iNOS, and severity of HPS.[25] Pulmonary macrophages in CBDL rats also express elevated levels of heme-oxygenase-1 (HO-1), an enzyme that catalyzes the formation of the vasodilating gas and carbon monoxide (CO).[26] Increased levels of carboxyhemoglobin (COHb) have been observed in rat[26] and human[27] subjects with HPS, and treatment with an HO-1 inhibitor normalizes COHb levels and partially alleviates HPS in CBDL rats.[26] These data suggest that CO also contributes to pulmonary vasodilation in HPS.

Tumor necrosis factor-alpha (TNF-α) rises in CBDL rats in association with ET-1 and endotoxin levels, and it has been proposed to influence the accumulation of the iNOS and HO-1–producing pulmonary macrophages.[28] Administration of pentoxifylline, a phosphodiesterase inhibitor that suppresses the production of TNF-α, is associated with a reduction in pulmonary macrophage accumulation, ET-B receptor and eNOS expression, and the severity of HPS.[29]

More recently, ET-1 and ET-B receptor activation have been shown to increase pulmonary intravascular monocyte adherence through the monocyte chemokine fractalkine.[30,31] Fractalkine promotes angiogenesis directly and through monocyte secretion of vascular endothelial growth factor-A.[31] Angiogenesis is an important feature in experimental models of HPS and may provide new therapeutic targets, in addition to explaining the delay in the resolution of hypoxia in patients posttransplantation.

DIAGNOSIS

HPS should be considered in any patient with liver disease and dyspnea or hypoxemia. Evaluation should begin with the measurement of arterial blood gas (ABG), with the patient in a resting seated position while breathing ambient air.[6,17] A partial pressure of oxygen (PaO_2) <80 mm Hg or an alveolar-arterial oxygen gradient (A-a gradient) ≥ 15 mm Hg (≥ 20 mm Hg for patients over the age of 64)[17] is suggestive of HPS and

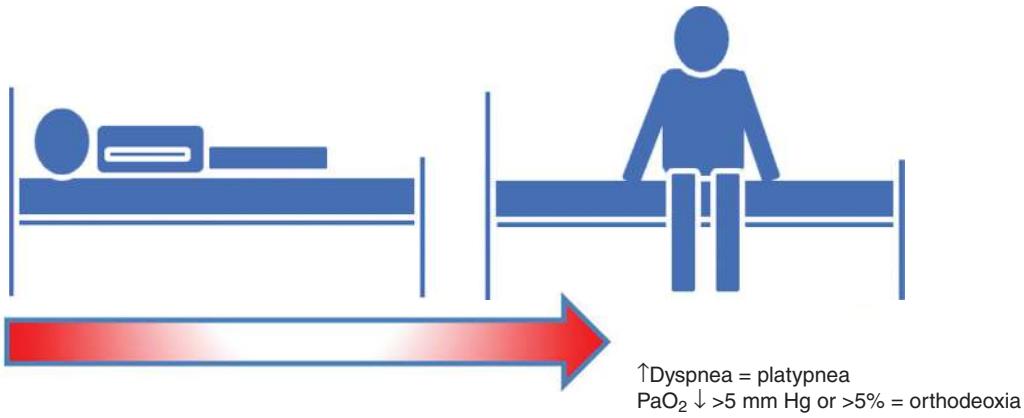

Fig. 85.1 Platypnea Refers to Worsening of Dyspnea when Going from a Supine to Upright Position. The subsequent drop in arterial oxygenation during this position change is referred to as orthodeoxia. Platypnea is a sensitive, but not specific, clinical finding of hepatopulmonary syndrome. *PaO_2*, Partial pressure of oxygen.

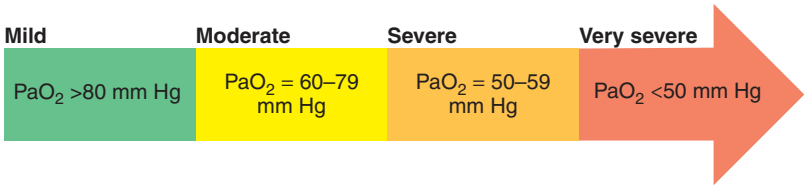

Fig. 85.2 Grading Severity of Hepatopulmonary Syndrome Based on the Measurement of Arterial Blood Gas. *PaO_2*, Partial pressure of oxygen.

should prompt further evaluation. Pulse oximetry has been suggested as a potentially cost-effective and noninvasive screening tool for HPS[1,32]; however, current literature does not support its adequacy.[33] ABG is also preferred because it allows for grading the severity of HPS (Fig. 85.2).

Chest imaging and pulmonary function testing have been used adjunctively to rule out other etiologies for coexisting cardiopulmonary disease that may contribute to abnormal gas exchange, such as chronic obstructive pulmonary disease, congestive heart failure, restrictive lung disease caused by ascites or hepatic hydrothorax, α_1-antitrypsin deficiency, and portopulmonary hypertension.[12] Common but nonspecific findings include increased markings at the lung base on chest x-ray (CXR)[1,6,8] and reduced diffusion capacity for carbon monoxide (DLCO).[3,4,7,14,18] HPS can be distinguished from portopulmonary hypertension by the presence of increased pulmonary artery pressure and vascular resistance.[34]

Contrast-enhanced echocardiography (CEE) is the gold standard for evaluation of HPS once abnormal oxygenation is identified. The benefit of CEE is that it permits concurrent evaluation of cardiac function in addition to evaluating for IPVD, which is required for the diagnosis of HPS.[12] Agitated saline is used as a contrast media, which creates a stream of microbubbles after injection. In healthy subjects, these microbubbles opacify the right heart only as they are filtered through the pulmonary capillary bed because of their size (greater than 15 μm in diameter).[9,35] Intracardiac shunts can be distinguished from intrapulmonary shunts based on the number of cardiac cycles required for agitated saline to pass from the right to the left atrium in the apical four-chamber view (Fig. 85.3). In general, contrast appears in the left atrium within three cycles in intracardiac shunts, whereas it takes four to six cycles in intrapulmonary shunts.[9,35] CEE is highly sensitive for the evaluation of IPVDs[36] and may document them in up to 82% of patients tested.[35] Patients with a positive CEE have a greater incidence of dyspnea[37] and abnormal CXRs,[9,37] in addition to more advanced cirrhosis[9,35,37] and gas exchange abnormalities.[9,37] However, many patients with liver disease and IPVDs demonstrated by CEE do not develop HPS, which additionally requires the presence of impaired gas exchange,[5,8,14,35,37] and so this test is not specific for HPS.[36]

Technetium-99m–labeled macroaggregated albumin (MAA) perfusion lung scanning is an alternative test for IPVDs. It is expensive, requires radiation exposure,[14] and cannot document the site of shunting. However, it can provide a quantitative shunt fraction[14,17,36] that correlates directly with the A-a gradient[3,10,13] and inversely with the room air PaO_2 and oxygen saturation.[3,10,13,38] Perfusion scanning is less sensitive than CEE for IPVD detection but more specific.[5,10,38] These test characteristics have enabled CEE to be advocated as the first line for evaluating patients with liver disease and abnormal gas exchange.[5,10,17] If CEE is positive but the relative contributions of other cardiopulmonary disease and HPS are not clear, perfusion lung scanning can differentiate the degree of hypoxemia from IPVD in comparison to nonvascular pulmonary abnormalities.[5,10,12,17] Recent studies have also demonstrated HPS patients have increased levels of alveolar exhaled NO; however, this has not been validated for HPS screening or diagnosis.[39] Another marker that may be of future interest is von Willebrand factor antigen, which is a surrogate for endothelial dysfunction and was shown to be elevated in patients with HPS in a 2014 prospective study.[40]

PREVALENCE

The prevalence of HPS varies by etiology and has been reported in patients with chronic viral hepatitis (10%), Budd-Chiari syndrome (28%), and cirrhosis (15%–23%)[41–43] and in 5%–30% of patients with cirrhosis being evaluated for liver transplantation.[1]

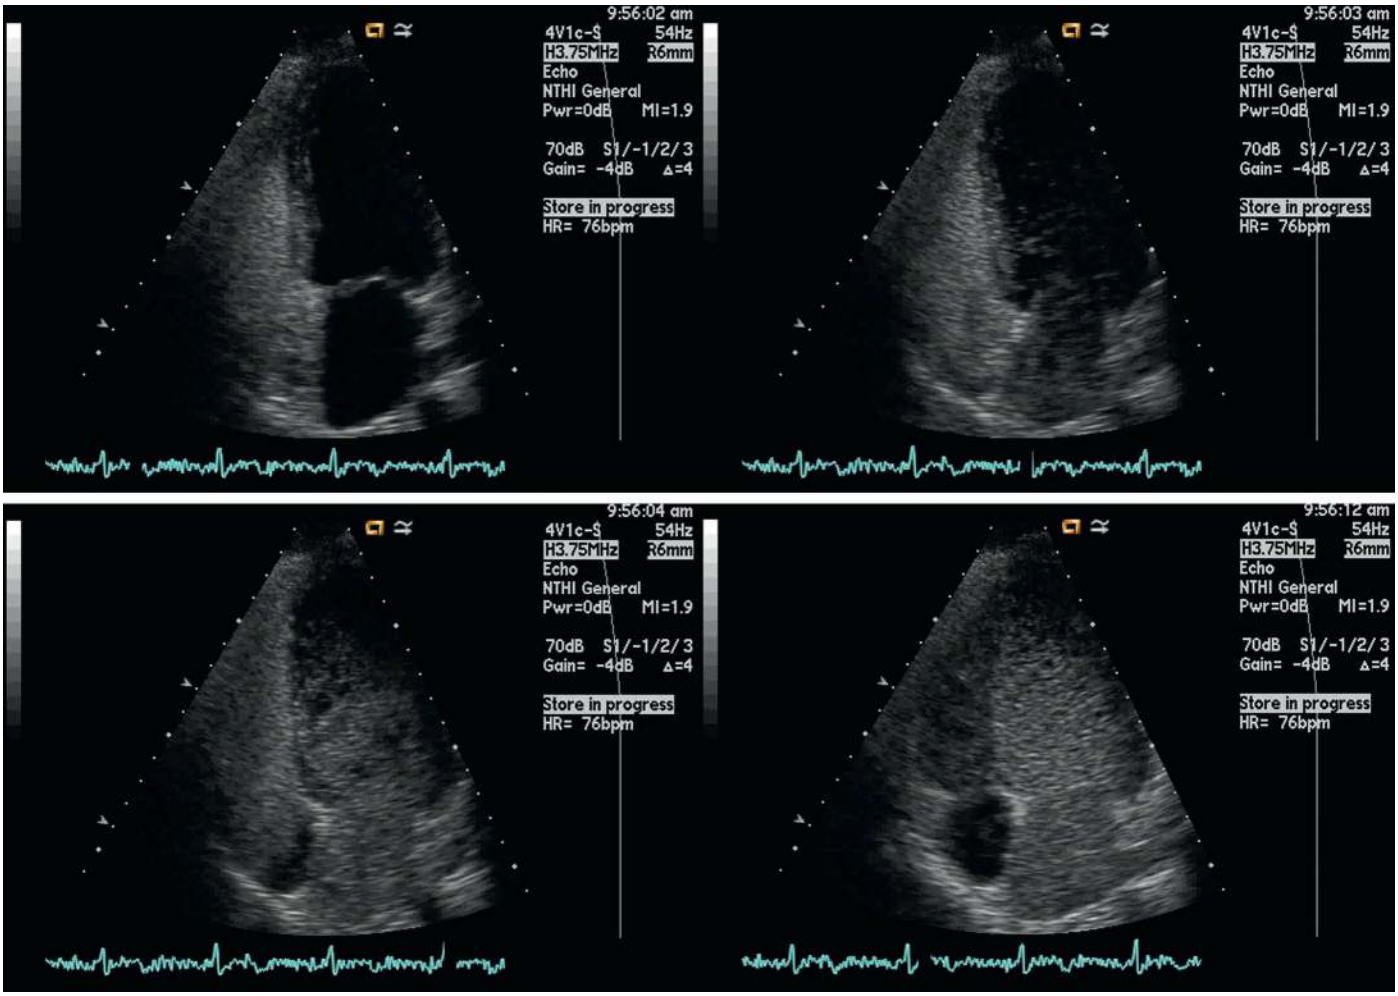

Fig. 85.3 Photos of Contrast-Enhanced Echocardiography. *Top left:* Agitated saline enters the right ventricle. *Top right:* Saline enters the left atrium posteriorly. *Bottom left:* Saline density is equal in the right and left ventricles. *Bottom right:* Saline density in the left ventricle exceeds the right ventricle after multiple cardiac cycles. PROGNOSIS

In the absence of liver transplantation, patients with HPS have a poorer functional status, reduced self-reported quality of life,[8] and twofold increase in mortality[7,8,44] in comparison with non-HPS controls matched for severity of liver disease. HPS patients who die during follow-up have been noted to have greater room air PaO_2 reductions, A-a gradient elevations, and shunt fractions than those who survive,[3,7,44] but this is not a universal finding.[8] Without transplant, HPS patients demonstrate progressive hypoxemia,[44] with a reduction of approximately 5 mm Hg per year.[8,41] Despite this, death is usually caused by complications of liver disease[7,17,44] rather than primary respiratory failure.[44]

THERAPY

Liver transplantation is the only definitive therapy for HPS and should be considered when patients are symptomatic or have a $PaO_2 \leq 60$ mm Hg.[6,17] Multiple therapies have been tried for HPS without clear efficacy, including inhibitors of NO,[45–47] antibiotics,[48] pentoxifylline,[29,49,50] mycophenolate mofetil,[51] transjugular intrahepatic portosystemic shunt,[12,52] the tyrosine kinase inhibitor sorafenib,[53] and pulmonary angiography with embolization of dilated capillaries[54] or AV communications.[55] Oxygen therapy also has been recommended, although clinical benefit has not been confirmed.[1,6,11,12,17,56]

Because of the increased mortality associated with HPS and the lack of other effective therapies, the United Network for Organ Sharing (UNOS) has adjusted organ allocation algorithms to prioritize patients with HPS, using exception points, which increase a potential recipients score to give them a higher priority for transplant.[57] An analysis of the UNOS database demonstrated increased mortality in patients with a $PaO_2 \leq 44$ mm Hg.[57] Among those patients who survive the perioperative period, improvement in or resolution of HPS is noted in the majority of cases, although the amelioration of symptoms may require a year or more to occur.[4,13,44]

KEY POINTS

- HPS consists of a triad of liver disease, abnormally low arterial oxygen level, and IPVD. It most commonly presents as dyspnea or hypoxemia in patients with liver disease.
- HPS is believed to result from excessive pulmonary vasodilation. Pulmonary vasodilatation leads to hypoxemia through ventilation/perfusion mismatching, AV shunting, and limitations to oxygen diffusion.
- The diagnosis of HPS requires a seated, room air ABG to document abnormal gas exchange, in addition to confirmation of an intrapulmonary shunt using echo or lung perfusion scanning. The prevalence of HPS is 5%–30% in patients undergoing evaluation for liver transplantation.
- Patients with liver disease and HPS have an increased risk of death relative to patients with liver disease alone. Liver transplantation is the only effective therapy. Transplant evaluation should be pursued in patients with HPS.

Hepatic Encephalopathy

Alvaro Martinez-Camacho, Brett E. Fortune, and Lisa Forman

Hepatic encephalopathy encompasses a spectrum of neuropsychiatric abnormalities that occur in patients with liver disease in the absence of other brain disease.[1,2] The spectrum includes personality changes, impaired mental function, motor abnormalities (i.e., asterixis, tremors, hyperventilation, hyperactive reflexes), and altered consciousness. A consensus panel of experts proposed the classification of hepatic encephalopathy into *type A,* associated with acute liver failure (ALF); *type B,* associated with portosystemic bypass without intrinsic liver disease; and *type C,* associated with chronic liver disease.[3]

The encephalopathy accompanying ALF (type A) is commonly associated with cerebral edema and increased intracranial pressure (ICP). Patients exhibit an abrupt onset with a short prodrome and rapid sequential progression from drowsiness, delirium, agitation or convulsions, decerebrate rigidity, unresponsiveness, and then deep coma within hours to days of symptom onset.[4,5] Irreversible neurologic damage may occur as a result of brain ischemia or herniation. Patients who develop coma in the setting of ALF have a grave prognosis; less than 20% survive without liver transplantation.[6]

In patients with chronic liver disease, encephalopathy (type C) develops insidiously and is heralded by a change in mental or behavioral status. Encephalopathy may be episodic, persistent, or minimal and subclinical.[3] Episodes are sporadic, characterized by exacerbations and remissions, and are generally precipitated by inciting events.[1,2] Although the initial manifestation of portosystemic encephalopathy (PSE) is usually a subtle change in mentation, neurologic dysfunction may progress and be classified according to confusion, lethargy, and even coma (Table 86.1). Neurologic signs vary and fluctuate but usually include asterixis, hyperreflexia, clonus, and an extensor plantar response. Causes of PSE may not always be apparent but should always be investigated (Box 86.1). Minimal encephalopathy is not clinically obvious and requires psychometric testing for diagnosis. By these tests, about two-thirds of cirrhotic patients with portal hypertension have unsuspected minimal hepatic encephalopathy.[7–9] Patients who undergo portosystemic shunt or bypass procedures, either surgical or transjugular intrahepatic portosystemic shunt (TIPS), are at risk for hepatic encephalopathy (type B), which is similar to type C encephalopathy.

CURRENT CONCEPTS ON THE PATHOPHYSIOLOGY ASSOCIATED WITH HEPATIC ENCEPHALOPATHY

No single abnormality of hepatic or neurologic metabolism adequately explains all of the clinical, biochemical, physiologic, or experimental findings of encephalopathy occurring in patient or animal models.[1,2,5] Abnormalities of multiple neurotransmitters, including glutamate, gamma-aminobutyric acid (GABA), dopamine, serotonin, and opioids, have been described, in addition to increased plasma levels of a wide array of potential neurotoxins (ammonia [NH_3], short-chain fatty acids, and methanethiols).[10,11] Regardless of the mechanism(s) of hepatic encephalopathy, marked changes in central nervous system (CNS) glial cells are noted on neuropathologic examination in patients with hepatic encephalopathy. Encephalopathy associated with ALF is typically characterized by astrocytic swelling, whereas encephalopathy from chronic liver disease is characterized by Alzheimer type II astrocytosis.[11]

Ammonia Hypothesis

The *ammonia hypothesis* states that the major mechanism of hepatic encephalopathy is excessive accumulation of NH_3, which induces neuronal metabolic derangements and promotes astrocytic swelling.[12] In addition, NH_3 perturbs cerebral nitric oxide metabolism, which can mediate some of these effects.[13] Blood NH_3 originates mainly from four sources: intrahepatic deamination of amino acids, extrahepatic metabolism of nucleotides, gut metabolism of glutamine, and bacterial degradation of intestinal protein and urea.[14] More than 50% of blood NH_3 is derived from the latter source.

NH_3 is normally metabolized by the liver to either urea or glutamine by the actions of carbamoyl-phosphate synthetase I and glutamine synthetase, respectively. Patients with hepatic failure have impaired NH_3 metabolism related to liver dysfunction and an increase in portosystemic shunting. Certain clinical and experimental observations link the increase in blood NH_3 concentration to hepatic encephalopathy.[10,11,15,16] Hyperammonemia and elevated concentrations of NH_3 within the cerebrospinal fluid (CSF) are features of acute and chronic hepatic encephalopathy, Reye syndrome, deficiencies of urea cycle enzymes, and sodium valproate toxicity. In patients with cirrhosis or portosystemic shunts, ingestion of NH_3-generating substances (proteins, amino acids, urea, ammonium salts) may precipitate encephalopathy. In animal models, chronic administration of ammonium salts results in Alzheimer type II astrocytosis, a change indistinguishable from that observed in patients with chronic hepatic encephalopathy.[11]

Other clinical and experimental observations refute the link between NH_3 and hepatic encephalopathy. For example, blood levels of NH_3 are frequently elevated in patients with cirrhosis, regardless of the presence or absence of clinical encephalopathy. The grade of hepatic encephalopathy does not correlate with the absolute blood concentration of NH_3. Finally, seizures and hyperexcitability are commonly observed in animal models of NH_3 intoxication and in human congenital hyperammonemia but are rarely observed in patients with chronic hepatic encephalopathy.

Cerebral Blood Flow

In ALF, the brain is potentially subject to hypoxic injury caused by complications such as systemic arterial hypotension, respiratory

failure, and a reduction in cerebral blood flow that accompanies cerebral edema and intracranial hypertension (ICH).[4,5] Clinical data suggest that cerebral blood flow is relatively low initially but subsequently increases with increasing blood concentrations of NH_3.[17–20] Paradoxically, increases in cerebral blood flow may aggravate cerebral edema and worsen neurologic damage. Changes in cerebral blood flow do not appear to play a major role in hepatic encephalopathy related to chronic liver disease.

Cerebral Glucose and Oxygen Metabolism

Brain energy metabolism is unique in that glucose is the only substrate under physiologic conditions, and its uptake by the brain is independent of insulin.[21–25] Ammonia accumulation during hepatic failure is associated with altered cerebral glucose metabolism. In early ALF, before the onset of ICH, cerebral glucose metabolism and oxygen consumption are proportionately diminished.[21] There is no evidence of cerebral hypoxia, implying that reduced glucose and oxygen utilization reflects a diminished metabolic demand by the brain at this early stage. After the development of ICH, oxygen metabolism remains reduced, but measurements of cerebral glucose utilization vary from reduced to increased rates, and glycolysis may be accelerated.[22,23,25] These findings suggest that the progression of ALF and development of ICH are associated with relative cerebral hypoxia and a switch to anaerobic metabolism.

Other Potential Hypotheses for Hepatic Encephalopathy

The glutamine-glutamatergic neurotransmitter system has been implicated in the pathogenesis of hepatic encephalopathy because the glutamatergic excitatory neurotransmitter system in the CNS is markedly altered in patients with both acute and chronic liver disease and in animal models.[6,21,22] Astrocytes are a major regulatory cell in the glutamatergic system and are responsible for the termination of glutamate-induced excitation.[11] When glutamate is taken up by the astrocyte, it is metabolized to glutamine via the action of glutamine synthetase, which uses blood-derived NH_3 (Fig. 86.1). The accumulation of osmotically active glutamine in the astrocyte is associated with cell swelling and can lead to accumulation of glutamate in the extracellular fluid.

The GABA-benzodiazepine receptor hypothesis is another important mechanism that likely plays a role in hepatic encephalopathy.[26] The *GABA hypothesis* states that an excess of GABA or increased sensitivity of GABA receptors to neurosteroids is responsible for hepatic encephalopathy.[26,27] GABA originates from the intestine, and plasma levels increase in hepatic failure caused by inadequate hepatic extraction. During ALF, the blood-brain barrier (BBB) becomes more permeable, and increased amounts of GABA enter the CNS. Once in the brain, GABA binds to its receptor to produce

TABLE 86.1 Stages of Encephalopathy in Chronic Liver Disease (West Haven Criteria)

Stage	Clinical Signs
Stage I	Mental slowness, euphoria or anxiety, shortened attention span, impaired calculating ability
Stage II	Lethargy or apathy, inappropriate behavior, personality change, more obvious problems with calculations
Stage III	Lethargic, somnolent, marked confusion and disorientation but responds to verbal stimuli
Stage IV	Coma, patient may or may not respond to noxious stimuli

Patients with chronic liver disease rarely, if ever, demonstrate cerebral edema, regardless of the stage of encephalopathy.

Box 86.1 Clinical Events Precipitating Hepatic Encephalopathy in Patients With Cirrhosis

Gastrointestinal hemorrhage
Infection (including spontaneous bacterial peritonitis)
Sepsis
Dehydration
Imbalance of electrolytes or acid-base
Renal failure
Drugs, toxins, medications (especially sedative-hypnotics or narcotics)
Illicit substances
Alcohol
Dietary indiscretion (excessive protein intake)

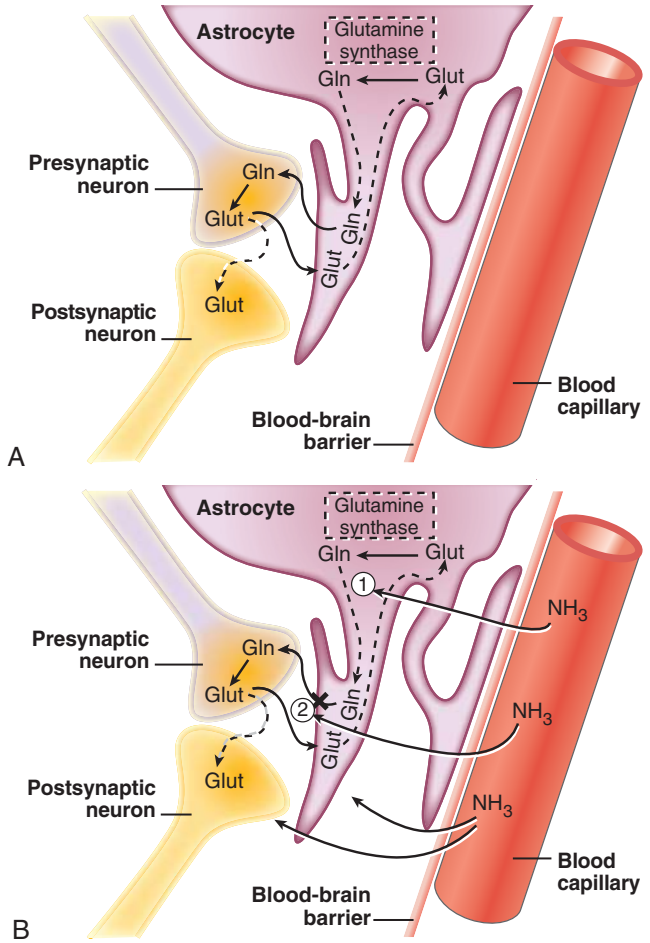

Fig. 86.1 A, Glutamine (*Gln*) forms predominantly in the astrocyte, is pumped out, and is taken up by presynaptic neurons, where it is converted to glutamate (*Glut*). Nerve stimulation releases glutamate from the presynaptic neuron to serve as an excitatory neurotransmitter. Astrocytes avidly take up glutamate from the synaptic cleft to abolish neuronal stimulation. **B,** Ammonia (NH_3) freely diffuses across the blood-brain barrier and stimulates formation of glutamine by the astrocyte via the action of glutamine synthase *(1)*. Ammonia also blocks the export of glutamine from the astrocyte at the synaptic cleft *(2)*. The net effect of these two actions is increased concentration of glutamine within astrocytes, which promotes astrocyte swelling.

neuroinhibition. A key component to understanding the relationship of GABA and benzodiazepines was the recognition that the GABA receptor was tightly linked to and modulated by the benzodiazepine receptor.[27–31] The GABA hypothesis predicts that benzodiazepines would increase the severity of hepatic encephalopathy and that benzodiazepine antagonists such as flumazenil might ameliorate hepatic encephalopathy. Recent studies demonstrated that patients with hepatic encephalopathy had increased plasma levels of benzodiazepines or "natural" benzodiazepine-like compounds that may act as "false neurotransmitters."[32,33] Clinical experience suggests that cirrhotic patients, especially those with encephalopathy, are particularly sensitive to the amnesic and sedative effects of benzodiazepines.

Previously Studied Agents Associated With Hepatic Encephalopathy

Numerous clinical studies reported alterations in levels of other agents or pathways in patients with hepatic encephalopathy. These agents or pathways include the dopaminergic and serotonergic systems, taurine, methanethiols, short-chain fatty acids, manganese, and zinc. However, conclusive evidence to support or refute their association with hepatic encephalopathy is lacking, and clinical and bench research of these agents as causative or therapeutic targets has been abandoned.

Fig. 86.2 Magnetic resonance image (MRI) of a T1-weighted sagittal view of the brain demonstrating hyperintensity of the globus pallidus (whitish area) that may be related to manganese deposition.

ENCEPHALOPATHY IN THE SETTING OF ACUTE LIVER FAILURE

Definition

ALF, also referred to as *fulminant hepatic failure,* is defined by the development of coagulopathy (prothrombin time [PT] >20 seconds prolonged with an international normalized ratio [INR] >1.5) and hepatic encephalopathy in a patient who lacks underlying chronic liver disease (except in Wilson disease).[34–37] Patients with ALF usually have extreme elevations of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) with the initial injury (e.g., 1000–5000 IU/L), are often jaundiced, and exhibit constitutional symptoms. They are at risk of encephalopathy, although most recover uneventfully. Progressive hepatic encephalopathy is a poor prognostic sign and signals the need for emergent liver transplantation.

Prognosis

A major determinant of prognosis is the level of encephalopathy (see Table 86.1). Patients with ALF who have progressed to higher stages of encephalopathy (i.e., stage III or IV) have the worst prognosis. The King's College Criteria and Glasgow Coma Scale are useful in assessing the need for transplantation.[36,38] Cerebral edema on computed tomography (CT) scan of the brain is a late feature of progressive encephalopathy (Fig. 86.2). Additional clinical features that indicate a poor prognosis include metabolic acidosis, renal failure, severe jaundice, or markedly prolonged PT.[37]

General Clinical Management

Once recognized, patients with acute liver injury and encephalopathy should be quickly transferred to a liver transplant center. Further recommendations on intensive care management of the patient with ALF are addressed elsewhere (see Chapter 96).

Use of Intracranial Pressure Monitoring

Use of ICP monitoring is controversial, and it remains unclear which patients would most benefit from such monitoring. Even though the incidence of ICH has recently decreased, it affects up to one-third of patients with significant hepatic encephalopathy (grades III and IV).[37] Preference in ICP monitoring device will depend on institutional expertise.

Advantages

Patients with ALF often do not have classic findings of cerebral edema (decerebration, dilated pupils, Cushing triad), and CT findings can be discordant. An ICP monitor is the gold standard for measuring and following ICP and therefore may be quite helpful in this patient population. It allows direct continuous measurements of ICP in real time. Several studies advocate ICP monitoring for its ability to provide important prognostic information about neurologic recovery after liver transplantation and in managing ICH while awaiting transplantation.[38–40] Changes in ICP can quickly be acted upon and may affect the decision to proceed with liver transplant. For example, ICP >20 mm Hg would indicate treatment with mannitol, whereas sustained ICP >40 mm Hg for >2 hours may preclude liver transplantation. Additionally, ICP monitoring may reveal unsuspected sustained ICH, which would require intervention.[40] Therefore ICP monitoring could be considered for patients with high risk for the development of ICH (young age, kidney failure, shorter jaundice-to-hepatic encephalopathy interval, etc.) who are under consideration for liver transplantation. Also, centers could consider ICP monitoring in nontransplant candidates if there is a reasonable likelihood of spontaneous recovery, such as in acetaminophen-induced ALF. In addition to helping with the management of ICH, ICP devices assist with close monitoring during the perioperative period of liver transplantation, because a transient increase in ICP that can last up to 12 hours postoperatively has been reported.[38]

Disadvantages

The use of ICP monitoring may lead to severe complications such as ICH in these critically ill patients with coagulopathy, in addition to infection. A recent multicenter retrospective study of 629 patients (140 with ICP monitors) did not demonstrate any 21-day mortality

difference (33% vs. 38%, P =.24), and subgroup analysis of the nonacetaminophen ALF group actually demonstrated an increased mortality (odds ratio [OR] 3.04, P = .014).[39] Moreover, improved management, as mentioned previously, is not necessarily synonymous with improved survival. It is important to note that studies were limited by the heterogeneity of ICP monitor use, variability in transducers (subdural vs. intraparenchymal), and level of center experience. One prospective study of 92 patients with ALF, high-grade encephalopathy, and ICP monitoring found a 10.3% rate of ICH that likely contributed to the death of two patients.[41] However, nearly half of the cases of intracranial bleeding were incidental radiographic findings without clinical consequence. Regardless of ICP monitor usage, 30-day survival posttransplant was approximately 85% in this study. Other reports confirm that bleeding complications from the placement of ICP monitoring devices in patients with ALF are mostly mild and without clinical significance.[41,42] And one study demonstrated the effectiveness of recombinant factor VIIa in preventing intracranial bleeding in 11 patients with ALF who required ICP monitoring.[43] Overall, use of ICP monitoring remains controversial, but experts agree that these devices should not be used in patients with mild hepatic encephalopathy (i.e., stage I or II) or in patients with evidence of cerebral herniation, hypotension, or imminent death. Ideally it should be performed only in centers vastly experienced with ALF and ICP monitoring and in patients with high risk of ICH.[44,45]

MANAGEMENT OF ENCEPHALOPATHY AND INTRACRANIAL HYPERTENSION

Encephalopathy is a hallmark of ALF. The encephalopathy of ALF is related to both metabolic factors, such as progressive elevation in blood NH_3 concentration, and cerebral edema. Progressively worsening encephalopathy is an ominous clinical feature in ALF; development of grade III or IV encephalopathy may herald the death of the patient as a result of cerebral edema, increased ICP, and central herniation of the brain. Efforts to control the encephalopathy of ALF are directed at preventing or resolving cerebral edema (Box 86.2).[46–49] Arterial hyperammonemia at the time of admission was associated with higher rates of hepatic encephalopathy, ICH, and mortality in patients with ALF cared for at liver transplant centers.[50,51] Therefore most liver transplant centers recommend that lactulose (20–40 g/day in divided doses) be administered enterally to purge the bowel. Exact threshold values of at-risk hyperammonemia are not clear, but usually values greater than 124 μmol/L warrant attention. However, one must exercise caution when using lactulose in the setting of ALF; dosing should be monitored carefully and adjusted to avoid excessive diarrhea, alterations in electrolytes, and volume depletion. If oral (PO) lactulose is given simultaneously with intravenous (IV) mannitol, marked deficits of free water can develop, inducing severe hypernatremia. Alternatively, continuous renal replacement therapy (CRRT) initiated early during admission for ALF demonstrated appreciable reductions in ammonia values over 5 days of therapy.[52] Reduction of hyperammonemia was independent of the type of CRRT (continuous venovenous hemodiafiltration vs. continuous venovenous hemofiltration) or intensity (i.e., ultrafiltration volume) but was associated with a longer duration of CRRT. Although one recent study suggested that infusion of hypertonic (3%) saline to maintain serum sodium concentration between 145 and 155 mEq/L is beneficial to reduce ICH,[53] rapid shifts in sodium concentration have been associated with central pontine myelinolysis (CPM). Further discussion of hypertonic saline is provided later in this chapter. Administration of terlipressin or vasopressin may worsen ICH and should be avoided.[54]

Reversal of coagulopathy before placement of ICP transducers is recommended, but exact targets (INR <1.5–1.9) vary from center to center. Caution should be used, as reversal of coagulopathy may be difficult and require large volumes of fresh frozen plasma (FFP), potentially contributing to volume overload and worsening of cerebral

Box 86.2 Measures Used to Monitor and Control Cerebral Edema Caused by Acute Liver Failure

1. Correction of metabolic abnormalities.
   - Electrolytes (Na, K, Cl, HCO_3).
   - Acid-base (if patient is on mechanical ventilation, induce mild respiratory alkalosis).
   - Glucose (maintenance intravenous glucose infusion).
2. Avoid overtransfusion or overhydration.
   - Carefully match intake and output once patient is euvolemic.
   - Daily weight.
   - Avoid use of blood products unless indicated for ongoing bleeding and correction of coagulopathy or to maintain hemostasis when intracranial monitor has been placed. In the latter circumstance, the patient may require diuresis to avoid an excess in intravascular volume, especially from plasma.
3. Institute dialysis in patients in renal failure.
   - Continuous arteriovenous or venovenous hemodialysis is preferred over standard hemodialysis.
   - Avoid severe volume shifts, stabilize blood pressure, maintain euvolemia, correct electrolyte and acid-base abnormalities.
4. Mechanical ventilation (worsening encephalopathy, >grade II).
   - Main indication in liver failure is airway protection to prevent aspiration pneumonia.
   - Induce mild respiratory alkalosis (pH 7.45–7.50, Pco_2 20–30 mm Hg).
   - Elevate head of bed 15–30 degrees.
   - Use sedation to avoid having the patient "fight the endotracheal (ET) tube."
5. Consider placement of intracranial pressure (ICP) monitor in the epidural space.
   - Should be considered when patients evolve from stage II (agitated confusion) to stage III (stuporous) encephalopathy.
   - Maintain adequate platelet count (>60,000) with platelet transfusions and INR <1.5 with fresh frozen plasma if necessary.
   - Mannitol is used to control ICP in patients with intact renal function or in those on dialysis. Mannitol is given in 0.5–1 g/kg doses. Serum electrolytes, glucose, and osmolarity should be checked every 4–6 hours. If ICP is elevated, osmolarity <310, and Na <145, then give mannitol. Mannitol should be withheld if the patient has excessive serum osmolarity or significant hypernatremia.

edema. Recombinant human factor VIIa infusion (40 to 90 μg/kg bolus, repeated as needed every 4 hours to correct INR) may be preferred over FFP in this setting for limiting volume infusion and rapidly correcting the PT/INR.

Hepatic glycogen, the main storage supply of glucose, is depleted early in the course of ALF, predisposing to severe, potentially life-threatening hypoglycemia and worsening of cerebral energy metabolism. All patients with ALF should be treated with glucose infusions, and blood glucose concentration must be monitored frequently.

Second-Line Therapies for Treatment of Mannitol-Refractory Intracranial Hypertension

Hypothermia in Acute Liver Failure

Therapeutic hypothermia, or intentional reduction of core body temperatures, has been increasingly used to treat hypoxic brain injury after cardiac arrest. Animal models of ALF suggest that hypothermia may be effective in the prevention of cerebral edema.[55,56] Several case series suggest that therapeutic hypothermia may show efficacy in patients awaiting liver transplantation.[57–59] However, a multicenter retrospective cohort study from the US Acute Liver Failure Study Group revealed that hypothermia (body temperature target 32°C–35°C) improved 21-day overall and transplant-free survival in only a subset of young (<25 years) patients with acetaminophen-associated ALF and high-grade encephalopathy, but not for the entire cohort of 97 patients.[60] Based on this analysis, physicians must wait for a prospective trial to further elucidate the use of hypothermia in this clinical setting.

Hypertonic Saline in Acute Liver Failure

Another possible method for treating refractory ICH during ALF is the use of hypertonic saline. Hypertonic saline infusion requires extreme caution because of the potential consequence of osmotic shifts across the BBB. However, a presumed advantage of hypertonic saline for the treatment of ICH is a higher osmotic reflection coefficient across the BBB.[61–63] Thus hypertonic saline could potentially lead to a reduction in cerebral edema, lower ICPs, and improved perfusion by developing a higher osmotic gradient in the cerebral vascular compartment. In a randomized placebo-controlled study, Murphy and colleagues studied the effect of hypertonic saline infusion on the induction of hypernatremia in patients with ICP and clinical outcomes among intensive care unit (ICU) patients with ALF.[64] Fifteen patients were treated with 30% hypertonic saline (5–20 mL/h) to maintain serum sodium levels between 145 and 155 mmol/L. After 24–72 hours, ICP reduction was significantly greater in the treatment group compared with the standard care group. However, high osmolar loads and continuous hemofiltration were required. Nevertheless, mortality was similar between both treatment and standard care groups. The use of hypertonic saline in the management of ICH in ALF warrants further investigation, but its use is accepted as prophylactic therapy by societal guidelines for patients with the highest risk of developing cerebral edema.[65]

Other Options for Refractory ICH

Other potential therapies that can be considered in ALF patients with refractory ICH include barbiturates such as pentobarbital or thiopental and indomethacin. By inducing a comatose state and reducing cerebral edema, pentobarbital (3–5 mg/kg IV load, then 1–3 mg/kg/h infusion) or thiopental (5–10 mg/kg load, then 3–5 mg/kg/h infusion) showed some benefit in refractory ICH.[66] However, severe side effects such as arterial hypotension, hypokalemia, and prolonged coma limit their use and often necessitate the coadministration of vasopressors in order to maintain cerebral perfusion pressure (CPP) above 50 mm Hg. Indomethacin (dosed at 25 mg IV over 1 minute) also has the potential to cause an acute decrease in ICP and an acute increase in CPP by causing cerebral vasoconstriction but has not been validated in a trial.[67,68] Therefore these medications may play a role as second- or third-line options for patients with persistent refractory ICH.

Experimental Therapies

Several other methods were tested in ALF: exchange blood transfusion, plasmapheresis, cross-circulation with human and baboon donors, hemoperfusion through isolated human or animal livers, hemodialysis (conventional and polyacrylonitrate), and column hemoperfusion (microencapsulated charcoal, albumin-covered Amberlite XAD-7 resin). Because none of these techniques were demonstrated to improve survival, their use in the management of ALF is not currently recommended.

Promising strategies that were investigated in the management of patients with high-grade encephalopathy in the setting of ALF include an extracorporeal liver assist device based on albumin dialysis (molecular adsorbent recirculation system [MARS]). However, its use did not yield clear survival benefit.[69] Bioartificial liver (BAL) machines have also emerged as a potential therapeutic intervention. To date, there was only one large randomized multicenter trial of the use of BAL in ALF, and it did not conclude a survival benefit.[70] Finally, the use of human hepatocyte transplantation in the setting of ALF as a bridge to transplantation is in persistent development.[71,72]

Liver Transplantation

Liver transplantation is the only treatment that was proven to improve survival in patients with ALF and high-grade encephalopathy.[6,73] Survival without transplantation is 10%–20% in this patient subset. Survival increases to 60%–80% with liver transplantation. In the largest series of living donor liver transplants for ALF, Lee and colleagues reported patient survival as 82.3% at 5 years after transplantation.[74] These results are similar to those of deceased donor liver transplantation for ALF and demonstrated the durability of living donor allografts.

At some stage cerebral edema becomes irreversible and patients, despite transplantation, will experience brain death or irreversible brain injury.[75] The risk of irreversible neurologic injury is greatest in those with CPP less than 40 mm Hg for more than 4 hours. Lesser increases in ICP may be associated with neurologic injury, but usually cerebral edema resolves in the posttransplant period, and complete or partial neurologic recovery may be expected. In most cases of ALF, all the manifestations of neurologic illness (cerebral edema, encephalopathy, and coma) reverse without sequelae after successful liver transplantation. One complication, CPM, may occur in the absence of cerebral edema and may be related to fluctuations in plasma sodium during resuscitative measures in the ICU, such as IV fluids, transfusions, antibiotics, sedatives, narcotics, invasive procedures, and ventilatory support. Despite the serious nature of CPM, significant neurologic recovery can occur.

ENCEPHALOPATHY IN THE SETTING OF CHRONIC LIVER DISEASE

Patients with cirrhosis of any cause and chronic PSE may present with a host of neuropsychiatric symptoms, ranging from subtle changes in mental status to coma. Fetor hepaticus (a peculiar odor to

the breath in people with severe liver disease) is common but not invariable. Asterixis, the "flapping tremor," is caused by involuntary intermittent relaxation of sustained motor activity but is less specific than fetor hepaticus for hepatic encephalopathy and is usually only present during the late stages of encephalopathy. Although reported, cerebral edema rarely occurs in patients with encephalopathy in the setting of chronic liver disease. As the patient recovers from hepatic encephalopathy, asterixis and other manifestations of encephalopathy resolve.

Risk Factors and Precipitating Events: Implications for Diagnostic Testing and Treatment

Flares of chronic encephalopathy may occur spontaneously without an identifiable precipitant in patients with very severe hepatic impairment and/or extensive portosystemic shunting. However, in the majority of cases, acute worsening of chronic encephalopathy is precipitated by one or more of a number of common events.

Gastrointestinal Hemorrhage

Hemodynamically significant gastrointestinal (GI) hemorrhage is a major precipitant of hepatic encephalopathy. Delivery of a large protein load to the GI tract via hemorrhage stimulates bacterial metabolism of luminal blood and release of NH_3, GABA, and other chemicals or compounds that may inhibit neurotransmission. Poor hepatic function or shunting of portal blood via portosystemic collaterals impairs hepatic clearance and enhances delivery of these molecules to the brain.

Infection

Infection—in particular, sepsis—may precipitate hepatic encephalopathy in patients with chronic liver disease. Spontaneous bacterial peritonitis (SBP) always should be considered in the differential diagnosis of patients with ascites and new-onset encephalopathy. Fever may be absent, and clinical signs (abdominal pain, ileus) are lacking. SBP is presumptively diagnosed if the absolute neutrophil count in ascitic fluid exceeds 250 cells/mL. Patients with cirrhosis and malnutrition are susceptible to infections as a result of reduced leukocyte migration, decreased serum bactericidal activity, depressed white cell mobilization, and impaired phagocytosis. Infection increases protein catabolism, releasing aromatic amino acids that may contribute to the encephalopathy.

Medications (Sedatives)

There are no safe sedatives for administration in cirrhotic patients who have hepatic encephalopathy. Because liver metabolism is usually severely impaired in these patients, the clearance of benzodiazepines, barbiturates, chlorpromazine, morphine, and opioid derivatives such as methadone, meperidine, and codeine are reduced. With repeated dosing, all these compounds tend to accumulate in cirrhotic patients, increasing the degree and prolonging the duration of sedation.

Renal Failure

A common precipitant of hepatic encephalopathy is excessive diuresis, resulting in relative depletion of intravascular volume and prerenal azotemia. Factors contributing to the encephalopathy include electrolyte imbalances; disordered acid-base metabolism; reduced fluid volume; and impaired renal clearance of metabolites, drugs, and toxins.

Fluid, Electrolyte, and Acid-Base Imbalance

Hepatic encephalopathy may be precipitated by dehydration, hypokalemia, and alkalosis. Metabolic alkalosis promotes an increase in levels of nonionic NH_3, which diffuses very rapidly into the CNS. Diffusion of NH_3 into the brain and enhanced glutamine production may precipitate encephalopathy as a result of either astrocyte swelling and dysfunction or impairment of glutamatergic neurotransmission. With hepatic impairment, the kidneys produce glucose from branched-chain amino acids (gluconeogenesis) in an attempt to maintain peripheral energy supply. This process results in decreased circulating levels of branched-chain amino acids and an increase in circulating levels of the relatively more toxic aromatic amino acids, which may diffuse into the brain.

Surgical Shunt Procedure or Tips

Hepatic encephalopathy is a common complication of portal diversion after surgical portosystemic shunts or TIPS.[76] Predictors of postshunt encephalopathy include preshunt encephalopathy, severe liver disease (Child-Pugh score >10 or Model-for-End-Stage-Liver-Disease [MELD] score >16), renal failure, and elderly age. The mechanisms of hepatic encephalopathy after placement of a portosystemic shunt include lack of compensatory dilatation of the hepatic artery, lack of perfusion of the liver via the portal vein, and reduction in hepatocyte function. Clinically apparent encephalopathy after placement of a shunt usually responds to medical treatment. In rare circumstances, narrowing of the shunt with a flow-reducing stent or occlusion of the shunt may be necessary to control encephalopathy.[77]

Portosystemic Shunting from Collaterals

In cases of refractory encephalopathy, patients should undergo contrast-enhanced abdominal imaging to visualize the presence of prominent portosystemic collateral vessels. If large collaterals are seen, selected patients may benefit from embolization of these collaterals.[78,79]

Noncompliance with Therapy

One of the most common factors precipitating encephalopathy is noncompliance with prescribed outpatient medical treatments (e.g., lactulose). A careful history, focusing on adherence to medical therapy, is necessary in the evaluation of encephalopathic patients.

Microbiota Dysbiosis

Research regarding gut microbiota dysbiosis has gained recent interest. Dysbiosis in chronic liver disease was associated with increased intestinal permeability, systemic inflammation and endotoxemia, and increased impairment of cognition and rates of hepatic encephalopathy.[80] Clinical improvement in patients with recurrent hepatic encephalopathy treated with fecal microbiota transplant supports the role of gut dysbiosis as a potential mechanism of disease.[81]

Diagnosis

The diagnosis of PSE is based upon clinical suspicion in patients with chronic liver disease, and the impression is confirmed by resolution after medical therapy.[82] Occasionally, it may be necessary to employ additional testing to confirm a diagnosis of PSE. Additional testing is particularly useful when encephalopathy is the primary clinical manifestation of otherwise unsuspected liver disease or if the manifestations of encephalopathy are predominantly a change in behavior or an unusual neurologic syndrome (seizures, focal neurologic deficits). Rarely, cerebral edema complicates chronic liver disease.[83]

Plasma Ammonia

An elevated blood NH_3 level is common in cirrhotic patients, especially those with encephalopathy. Some studies have demonstrated a correlation between blood NH_3 levels and the presence and grade of encephalopathy, whereas others have not. In general, blood NH_3 levels might be useful as a marker of liver disease but are of little diagnostic or clinical value in managing the cirrhotic patient with hepatic encephalopathy.

Electroencephalography

Electroencephalographic (EEG) abnormalities are relatively nonspecific in hepatic encephalopathy. Two findings have some specificity with regard to hepatic encephalopathy: reduced brainstem auditory-evoked potentials and diminished visual-evoked potentials. In various studies, the percentage of encephalopathic cirrhotics with EEG abnormalities is highly variable, ranging from 14% to 78% of patients.

Radiologic Imaging

Standard CT scans or nuclear brain scans exhibit little or no specific distinguishing features, although loss of cortical volume may be common in patients with Laënnec cirrhosis and chronic encephalopathy. CT may be used to document cerebral edema or to exclude CNS complications such as tumor, infection, or hemorrhage. Magnetic resonance imaging (MRI) studies have revealed a few features relatively unique to hepatic encephalopathy. One feature, hyperintensity on T1-weighted images of the globus pallidus (Fig. 86.3), correlates with (extrapyramidal) motor disorders and excess accumulation of manganese.

Neuropsychiatric Testing

In general, neuropsychiatric testing is used primarily to monitor efficacy of treatment or diagnose subclinical or minimal encephalopathy. A battery of tests is employed to distinguish hepatic encephalopathy and organic brain syndrome from other causes of encephalopathy and underlying psychiatric disease. These tests are itemized in Table 86.2. Poor performance on number connection tests correlates reasonably well with severity of encephalopathy and Child-Pugh and/or MELD classifications.

Therapeutic Options

Past thoughts on the treatment of hepatic encephalopathy included a protein-restricted diet of 40 grams or less per day.[84,85] However, cirrhotic patients often develop severe muscle wasting; thus in patients with advanced disease, unnecessary protein restriction might further worsen the poor nutritional state. Therefore hepatologists currently avoid the use of protein restriction in the management of chronic hepatic encephalopathy.

Lactulose

The mainstay of therapy in the treatment of hepatic encephalopathy is lactulose, a nonabsorbable disaccharide that is fermented by bacteria in the intestine to yield acetic, butyric, propionic, and lactic acids.[85–88] The fermentation of lactulose produces an acidic milieu that alters the composition of gut bacterial flora, lowers colonic pH, and produces an osmotic diarrhea. Each of these effects may be responsible for the ameliorative effects of lactulose on hepatic encephalopathy. Changing the composition of the bacterial flora may alter the metabolism of fecal contents and reduce the production of toxins, NH_3, and methanethiols that are responsible for encephalopathy. The acidic luminal milieu creates an environment capable of trapping NH_3:

$$NH_3 + H^+ \Rightarrow NH_4^+$$

Ammonia is neutral and freely diffuses across the mucosal barrier of the colon, where it can enter the portal circulation for delivery to the rest of the body. In contrast, the ammonium ion (NH_4^+) produced from the reaction of NH_3 with hydrogen ions is ionized, highly polar, and unable to diffuse readily across the lipid bilayer of mucosal cells.

Fig. 86.3 Computed tomography (CT) scan of the brain of a patient with acute liver failure, stage IV hepatic coma, and cerebral edema. Note the diminished sulci and lack of distinction between white and gray matter. This patient's cerebral edema resolved with medical management, and she subsequently underwent transplantation. She achieved complete neurologic recovery posttransplant.

TABLE 86.2 Neuropsychiatric Tests Used to Evaluate Hepatic Encephalopathy

Cerebral Function	Test
Learning and delayed recall	Story Memory Test
	Figure Memory Test
Concentration	Digit Vigilance Test
Fine motor coordination	Grooved Pegboard
Sequential procedures	Trail Making Test
Problem solving	Wisconsin Card Sorting Test
Attention	WAIS-R* Digit Symbol Subtest
Vocabulary	WAIS-R Vocabulary Subtest
Verbal fluency skills	Controlled Oral Word Association
	Animal Naming
Auditory comprehension	Complex Material
Visual-spatial analysis	WAIS-R Block Design Subtest
Psychological function	MMPI-2†

*WAIS-R, Wechsler Adult Intelligence Scale–Revised.
†MMPI-2, Minnesota Multiphasic Personality Inventory.

This ammonium ion is "trapped" in the fecal effluent and eliminated with passage of the bowel movement. In addition to these properties, the breakdown of each molecule of lactulose produces at least four osmotically active particles. Water diffuses into the lumen and down the osmotic gradient, increasing fecal water content, and if enough lactulose is given, a dose-dependent osmotic diarrhea results. The purgative effect of lactulose may also be responsible for altering the composition of colonic bacteria and helping to eliminate toxins and waste that might otherwise accumulate. The usual recommendation is that enough lactulose be given to produce two to three loose, semiformed stools each day. Excessive dosing with lactulose will produce severe diarrhea with large volume losses and electrolyte imbalances and should be avoided.

Rifaximin

Rifaximin is a nonabsorbable antibiotic derivative of rifamycin with broad antimicrobial activity and has become an important adjunct agent along with lactulose for the treatment of hepatic encephalopathy. A randomized controlled trial of 299 patients demonstrated a reduction of recurrent hepatic encephalopathy episodes and number of hospitalizations resulting from hepatic encephalopathy.[89] In comparison studies of rifaximin with lactulose versus lactulose monotherapy, patients treated with rifaximin showed greater improvement in the degree of hepatic encephalopathy, had lower NH_3 levels, and had lower PSE index scores.[90]

Branched-Chain Amino Acids

Early studies demonstrated that cirrhotic patients had an increase in aromatic amino acids and a decrease in branched-chain amino acids in blood samples. Subsequent clinical work suggested that patients with the greatest imbalance in plasma amino acids were more likely to be encephalopathic and to experience early and higher mortality. For this reason, there were at least 14 controlled trials of the use of branched-chain amino acids in the treatment of cirrhotic patients with chronic encephalopathy. However, results of these trials have been inconsistent, and separate meta-analyses yielded opposite conclusions.[91] A trial of branched-chain amino acids might be considered in patients who develop encephalopathy on standard protein diets and manifest protein-calorie malnutrition.

Benzodiazepine Antagonists

There were several randomized controlled trials of short-term administration of flumazenil in the treatment of hepatic encephalopathy.[92–94] In some studies, flumazenil was superior to placebo in improving the grade of encephalopathy; 30%–60% of encephalopathic patients improved after administration of flumazenil, and EEG changes paralleled this improvement. In other studies, however, flumazenil was no better than placebo in ameliorating the symptoms of encephalopathy, and EEGs did not improve. Overall, flumazenil has a limited role in the treatment of hepatic encephalopathy.

L-Ornithine-L-Aspartate and Ammonia Scavengers

l-ornithine-l-aspartate (LOLA) is a compound salt that was shown to reduce NH_3 levels by increasing NH_3 disposal through enhanced peripheral metabolism. LOLA increases the activity of hepatic urea cycle enzymes and increases the rate of glutamine production within skeletal muscle. Although a large randomized controlled study using LOLA in ALF did not find significant changes in survival,[95] other studies investigated its potential use in hepatic encephalopathy from chronic liver disease. A meta-analysis consisting of three randomized trials and a pool of 212 patients found an overall significant improvement in chronic hepatic encephalopathy symptoms, although lower-grade encephalopathic patients had the greatest benefit.[96]

Additional agents (i.e., glycerol phenylbutyrate and ornithine phenylacetate) that were initially developed for ammonia reduction in patients with inborn urea cycle defects are also being tested in clinical trials for the management of chronic hepatic encephalopathy.[97,98]

Neomycin and Metronidazole

The systemic antibiotics neomycin and metronidazole are used as second-line therapy of chronic hepatic encephalopathy with the goal of therapy being alteration of the colonic bacterial composition. Neomycin's advantage over metronidazole is its limited entrance to the circulation.[99] The main disadvantage is that nephrotoxicity may occur despite its poor absorption.

Some studies demonstrated that oral metronidazole was as effective as neomycin or lactulose in controlling encephalopathy.[100] Other studies did not observe similar efficacy and measured little effect of metronidazole on NH_3 levels. The main disadvantages of metronidazole are that many patients complain of epigastric discomfort (leading to poor compliance with long-term treatment) and development of ototoxicity and neurotoxicity that can be irreversible. Maintenance therapy with metronidazole can be expected to cause peripheral neuropathy (already a problem in patients with advanced liver disease) and was reported to cause the "disulfiram reaction" when alcohol was consumed. The physician prescribing metronidazole to cirrhotic patients should be aware that this drug undergoes extensive hepatic metabolism. Given the establishment of rifaximin, neomycin and metronidazole are now rarely used. If these antibiotics are used in selected cases, it is recommended to give only short courses lasting 2–8 weeks.

Liver Transplantation

The development of encephalopathy in a patient with chronic liver disease indicates the presence of portosystemic shunting and hepatic dysfunction. The prognosis for patients who develop this complication is grim; one recent study indicated that the 1-year survival rate is 42% and the 3-year survival rate is 23%.[101] In addition, there are numerous comorbidities in encephalopathic patients, including the inability to continue gainful employment, poor function at home, nursing strains on spouse or family, inability to drive a vehicle, and inability to handle personal finances. Although medical therapies can ameliorate the major symptoms of encephalopathy, they are rarely effective enough to return the patient to full function. Often the patient with encephalopathy is at risk of other life-threatening complications of liver disease such as variceal hemorrhage and SBP. For all of these reasons, any patient with hepatic encephalopathy should be considered for liver transplantation.

CONCLUSION

This chapter discussed several key issues regarding hepatic encephalopathy, including definitions, clinical syndromes, diagnostic tests, precipitants, prognosis, and outcomes with therapy, including liver transplantation. The section on pathogenesis defines current knowledge regarding mechanisms of encephalopathy in both ALF and chronic liver disease. The clinician faced with neuropsychiatric syndromes in patients with liver disease must differentiate the nature of the underlying liver disorder (ALF versus chronic liver disease), evaluate diagnostic tests, and institute appropriate therapy. Overall outcomes of patients with encephalopathy depend on the general condition of the patient, severity of underlying liver disease, comorbid conditions, and, when in ALF, the presence of cerebral edema and ICH. Liver transplantation, including the option of living donor liver transplantation, may yield favorable outcomes without neurologic sequelae if instituted before excessive and prolonged ICH in the case of ALF, or before multiorgan failure in the case of chronic liver disease.

ACKNOWLEDGMENT

We thank Gregory T. Everson, MD, for assistance with manuscript preparation and Jasmohan S. Bajaj, MD, for comments that greatly improved the manuscript.

KEY POINTS

- Clinical presentation and prognosis of hepatic encephalopathy vary by presence of ALF or chronic liver disease.
- Patients with hepatic encephalopathy and ALF should urgently be referred to a liver transplant center.
- The routine use of ICP monitors in patients with ALF is controversial.
- Mannitol and hypertonic saline are common therapies for ICH in the setting of ALF.
- Precipitants of hepatic encephalopathy should be assessed with each episode in the setting of chronic liver disease.
- Lactulose is the mainstay of therapy in patients with hepatic encephalopathy and chronic liver disease.
- Rifaximin has become an important therapy to prevent recurrent episodes of hepatic encephalopathy in the setting of chronic liver disease.

Acute Liver Failure

Stephen Warrillow and Caleb Fisher

INTRODUCTION

Acute liver failure (ALF), also known as *fulminant hepatic failure,* is a compelling example of complex critical illness. The initiating event is extreme liver injury from a variety of possible causes. Thereafter, a severe multisystem critical illness rapidly develops, involving disruption of function in virtually all organ systems (Fig. 87.1). Although ALF is a relatively rare cause of admission to the intensive care unit (ICU),[1] it is important because it predominately affects those who are young and have few comorbidities, yet it has a high mortality. Management challenges include hepatic encephalopathy, cerebral edema, disordered hemostatic parameters, hemodynamic instability, metabolic abnormalities, renal failure, and vulnerability to infection. Although some causes of ALF have etiology-specific treatments, most ICU management involves supportive care and prevention of complications, with the hope that life can be sustained until either hepatic regeneration takes place or emergency liver transplantation can occur. As with any complex or rare condition, a systematic and coordinated approach is required so as to ensure that all problems are anticipated and addressed.

Definition

Despite a lack of a consensus definition,[2] it is generally accepted that the diagnosis of ALF requires the triad of encephalopathy (regardless of severity), abnormal measures of hemostasis (generally elevation of the international normalized ratio [INR] or prolongation of the prothrombin time [PT]), and the development of overt liver failure over a short interval in the absence of previously known liver disease. A number of classification systems have sought to define the cardinal features of ALF and patterns of presentation. In particular, the duration of illness before the onset of encephalopathy is strongly associated with specific underlying etiologies and associated outcomes.[3] Hyperacute patients develop an altered mental state within a week of first becoming unwell and are often critically ill at initial presentation. Acute presentations are those with an illness duration of 7–21 days before encephalopathy, whereas subacute presentations involve the onset of encephalopathy up to 26 weeks after initial symptoms occur. Paradoxically, hyperacute patients have the highest spontaneous survival rate.

Etiology

Although the causes of ALF are myriad (Box 87.1), there is marked variation in etiology across regions, with a relatively small number of underlying causes being responsible in any given locality.[4] This has important implications for management and outcomes.

Drug-Induced Liver Injury

Drugs, traditional remedies, and toxins are important causes of ALF in most countries. There are two broad types of drug-induced liver injury: direct hepatotoxicity and idiosyncratic hepatotoxicity.

Direct Hepatotoxicity

Severe liver injury from exposure to a known hepatotoxin that produces dose-related liver damage is the most common single cause of ALF in many countries. The typical onset of ALF after ingestion of a supratherapeutic or toxic dose is abrupt for most drugs, and the usual pattern is of major hepatic necrosis.

Acetaminophen (Paracetamol)

Acetaminophen is the most common cause of ALF in most anglophone countries, where it may account for more than half of all ALF cases.[1] A single major overdose (often with delayed presentation) is typical; however, some result from staggered supratherapeutic ingestion that may be deliberate, inadvertent, or iatrogenic. Poor nutrition, low body mass, and cytochrome P-450 enzyme–inducing medications may predispose to toxicity. The link between chronic alcohol excess and vulnerability to acetaminophen poisoning has not been fully elucidated.[5] A thorough history (including from family members) may identify the timing and amount ingested; however, information may be unreliable, limiting the utility of nomograms to determine risk and guide treatment decisions. Acetaminophen usually undergoes glucuronidation and is then excreted into the bile. The toxicity of acetaminophen overdose occurs through the generation of a toxic metabolite (*N*-acetyl-*p*-benzoquinone imine [NAPQI]) by cytochrome P-450 enzymes. If the ability to metabolize acetaminophen via glucuronidation is overwhelmed and the capacity to detoxify NAPQI through conjugation with glutathione is exceeded, massive hepatic necrosis will follow. The early initiation of n-acetylcysteine (NAC) may prevent the development of serious liver injury and attenuate it if hepatic necrosis has already commenced.

Nonacetaminophen Direct Hepatotoxins

A range of other medications can also cause liver injury via direct mechanisms (see Box 87.1). Patterns of acute hepatic injury vary from hepatic necrosis, to sinusoidal obstruction syndrome, to microvesicular steatosis.

Idiosyncratic Drug-Induced Liver Injury

Idiosyncratic liver injury usually takes the form of acute hepatocellular hepatitis, with a period of latency that typically extends to several weeks. Other less common forms include cholestatic hepatitis and mixed hepatitis. Antiinfectives, psychotropics, and nonsteroidal antiinflammatory drugs are commonly implicated. Idiosyncratic drug-induced hepatitis may variably be accompanied by hypersensitivity features, such as rash, fever, and eosinophilia.

Herbal Remedies, Nutritional Supplements, Traditional Medicines, and Illicit Drugs

Nonprescription alternative therapies and illicit drugs are widely used in many populations and represent an important cause of ALF.

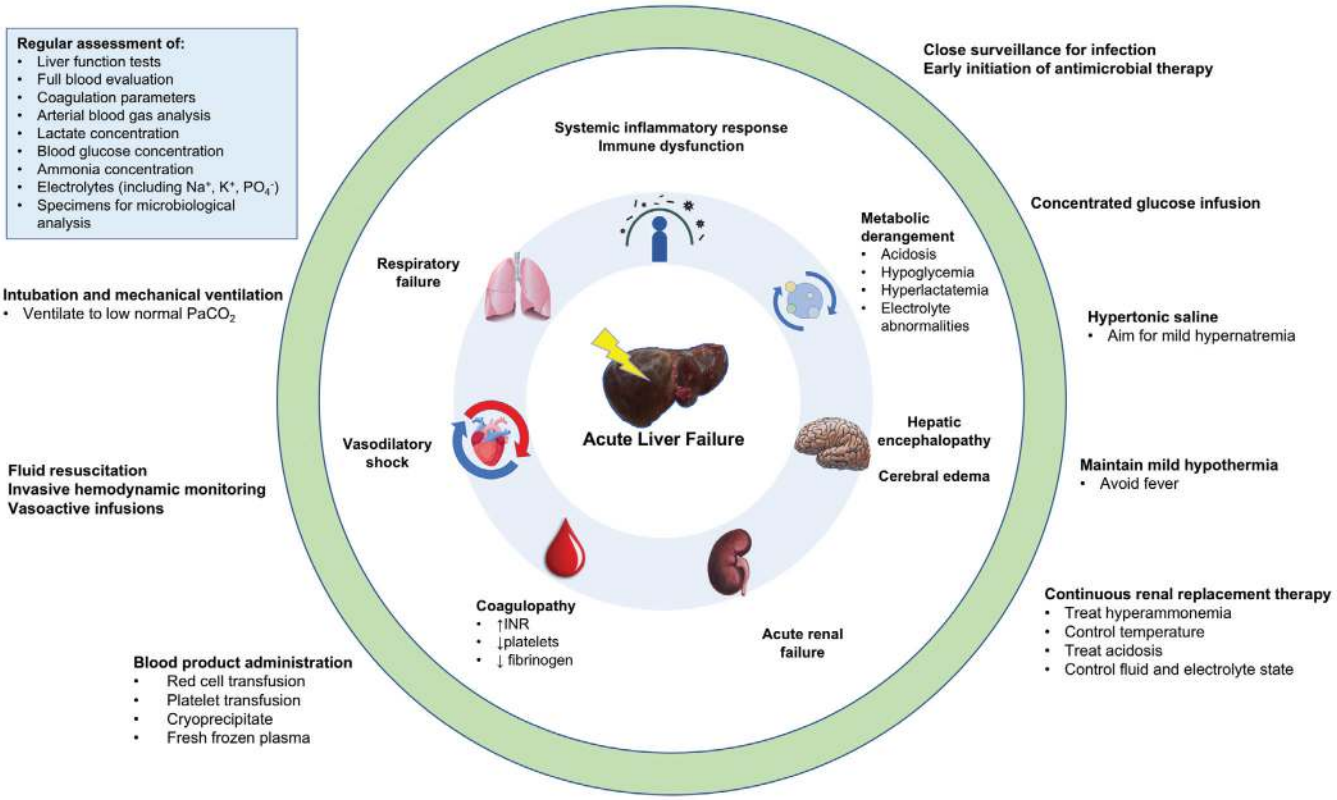

Fig. 87.1 Key management challenges in acute liver failure.

BOX 87.1 Causes of Acute Liver Failure

Drugs

Dose related (predictable):
- Acetaminophen
- Aspirin
- Niacin

Idiosyncratic (unpredictable and individually rare):
- Isoniazid
- β-lactams
- NSAIDs
- Herbal remedies
- 3,4-Methylenedioxymethamphetamine (ecstasy)

Toxins
- *Amanita* mushroom
- Carbon tetrachloride
- Yellow phosphorous

Viral

Hepatotropic:
- HAV
- HBV
- HDV
- HEV

Nonhepatotropic:
- HSV
- CMV
- EBV
- Parvovirus B19

Vascular Thrombosis
- Budd-Chiari syndrome

Inherited Metabolic Disorders
- Wilson disease

Pregnancy-Related
- Acute fatty liver of pregnancy

Other
- Autoimmune hepatitis
- Reye syndrome
- Cryptogenic

CMV, Cytomegalovirus; *EBV,* Epstein-Barr virus; *HAV,* hepatitis A virus; *HBV,* hepatitis B virus; *HDV,* hepatitis D virus; *HEV,* hepatitis E virus; *HSV,* herpes simplex virus; *NSAID,* nonsteroidal antiinflammatory drug.

Patients may not disclose the use of such agents, and direct enquiry is necessary.

Viral Hepatitis

Hepatotropic Viruses

Four out of the five generally recognized hepatotropic viruses are established causes of ALF. Hepatitis C virus (HCV) is a prominent cause of chronic liver disease, but almost never results in ALF.[6]

Hepatitis A

Most cases of hepatitis A virus (HAV) follow a relatively benign course, but occasional cases lead to life-threatening ALF, especially for adults with preexisting liver disease. The virus is spread via the fecal-oral route (usually ingestion of contaminated food or drinking water), and vaccination is protective when traveling to endemic regions. Serologic diagnosis is generally made on detection of anti-HAV immunoglobulin M (IgM) antibodies.

Hepatitis B

Hepatitis B virus (HBV) can cause ALF at the time of initial acquisition, through reactivation of a latent infection, or with coinfection by hepatitis D virus (HDV). The virus may be vertically transmitted during pregnancy or acquired through either blood exposure or unprotected sexual activity. Detection of IgM antibodies against hepatitis B core antigen (HbcAg) is the key serologic marker indicator of active disease. Immunosuppression may reactivate HBV in chronic carriers, resulting in a subacute presentation that is associated with a poor prognosis.[7]

Hepatitis D

HDV is a defective virus that can only replicate in circumstances of coinfection with HBV, and its acquisition in chronic HBV carriers has been reported to occasionally result in ALF.[6] Diagnosis of acute infection by HDV may be determined through the detection of HDV RNA or the presence of HDV antigen and anti-HDV IgM antibody.

Hepatitis E

Whereas hepatitis E virus (HEV) is rare in developed regions, it is a common cause of ALF in some resource-limited countries, with pregnant women being disproportionally affected. ALF from HEV is associated with high maternal and fetal mortality. Instances of HEV being transmitted by travelers returning from endemic regions have been reported. Similar to HAV, the virus is spread via the fecal-oral route and is diagnosed through the detection of anti-HEV IgM antibodies.

Other Viral Causes of ALF

Several nonhepatotropic viruses, especially Herpesviridae, are recognized to cause sporadic ALF and should especially be considered in situations where there are typical features of a specific infective agent (e.g., mucocutaneous lesions from varicella) in the absence of another clear cause.

Cryptogenic Acute Liver Failure

No clear cause can be found for ALF in up to a fifth of cases.[1] These may represent infection with as yet unidentified viral pathogens, unusual manifestations of autoimmune hepatitis (AIH), or unrecognized idiosyncratic drug reactions.

Other Causes of ALF

Ischemic Hepatitis

Cases of severe shock, especially if associated with hepatic congestion (e.g., cardiac tamponade), can result in ALF. The underlying cause of circulatory failure is the main determinant of outcome, rather than the extent of liver injury per se. If effective resuscitation and reversal of the primary problem occur, hepatic recovery usually follows, and specific liver-directed therapies are rarely required.

Autoimmune Hepatitis

Although AIH usually manifests as a chronic disorder, an important minority of cases may present with a subacute progression to ALF. Women are most commonly affected, and autoimmune markers in addition to liver biopsy are usually required for diagnosis. Corticosteroids for immunosuppression may achieve effective disease control in some patients, occasionally preventing deterioration and need for emergency liver transplantation (ELT).

Amanita Mushroom Poisoning

Amanita phalloides has a wide geographic spread and an appearance similar to several common edible mushrooms. Amatoxins are heat stable, and a single large mushroom may contain sufficient amounts to cause ALF. Many patients will experience early gastrointestinal upset that resolves before subsequent overt liver failure occurring several days later.

Wilson Disease

Wilson disease is a rare inherited disorder of copper accumulation that is typically diagnosed before the onset of overt liver failure, but may occasionally present with ALF, hemolysis, and thrombocytopenia as the first presentation. The prognosis without ELT is extremely poor, and treatment is focused on supportive measures until transplantation can occur.

Budd-Chiari Syndrome

Thrombosis of the hepatic vein is a rare cause of ALF and is usually associated with an underlying prothrombotic state, such as malignancy (especially myeloproliferative disorders). The overall prognosis is poor, especially if occurring in the context of malignancy.[8]

Acute Fatty Liver of Pregnancy

This catastrophic illness occurs exclusively in the third trimester of pregnancy and is characterized by microvesicular fatty infiltration of hepatocytes causing ALF. Fetal defects in fatty acid oxidation appear to be the underlying trigger. Urgent recognition and delivery are essential to prevent fetal and maternal death.[9]

Reye Syndrome

Reye syndrome is a rare pediatric condition strongly linked to aspirin use in the setting of a viral illness. Clinical features, rather than specific investigations, are key to making the diagnosis. Supportive care achieves full recovery in the majority of those affected.[10]

Predictive Scoring Systems

ELT is the only intervention proven to improve survival in ALF, yet many patients may achieve ELT-free survival with supportive care alone. The decision to proceed with ELT can therefore be extremely challenging. Several systems to guide clinical decision making have been developed in order to differentiate patients at high risk of death without ELT from those who may be reasonably expected to survive with supportive care alone. It is clear that in addition to the severity of liver damage and associated complications, important determining factors for outcome include the underlying etiology and patient age.[11] Several of the main predictive criteria are summarized in Box 87.2. The

BOX 87.2 Predictive Criteria for Death Without Emergency Liver Transplantation

King's College Criteria[14]

Acetaminophen Overdose

- Arterial pH <7.3 (irrespective of grade of encephalopathy)

or

- PT >100 seconds (INR >6.5) and
- Serum creatinine >3.4 mg/dL (>300 μmol/L) and
- Patients with West Haven grade III and IV hepatic encephalopathy

Nonacetaminophen-Induced Liver Injury

Acute form (delayed jaundice-encephalopathy <7 days):

- PT >100 seconds (INR >6.5) (irrespective of grade of encephalopathy)

or any three of the following variables:

- Aged <10 or >40 years
- Non-A, non-B hepatitis, halothane hepatitis, idiosyncratic drug reactions

Subacute form: delayed encephalopathy >7 days

- Serum bilirubin 17.4 mg/dL (300 μmol/L)
- PT >50 seconds

Clichy Criteria[15]

- Grade III or IV encephalopathy

and

- Factor V <20% in patients <30 years

or

- Factor V <30% in patients >30 years

Liver Biopsy[13]

- ≤60% necrosis on transjugular biopsy associated with ELT-free survival

Computed Tomography[12]

- Liver volume <1000 cm^3 predicts failure to achieve ELT-free survival for nonacetaminophen ALF

ELT, Emergency liver transplantation; *INR,* international normalized ratio; *PT,* prothrombin time.

utility of such scoring systems has been questioned, as some elements may be subjective (e.g., grade of encephalopathy) and many others are inevitably altered by various critical care interventions (e.g., use of continuous renal replacement therapy [CRRT]). Although they remain in widespread use, improvements in outcome (especially for the hyperacute pattern of ALF such as acetaminophen related) justify concerns that none demonstrate sufficient precision to be the sole determinant for selecting ELT candidates.[11] Imaging with computed tomography (CT) to ascertain residual liver volume may assist prognostically.[12] Liver biopsy may be safer via a transjugular route than the percutaneous approach and can be diagnostically useful in some circumstances.[13]

Although acetaminophen often presents as hyperacute liver failure with extreme physiologic and biochemical derangement, ELT-free survival is considerably more common than for other causes of ALF.[1] Similar findings apply to HAV and acute fatty liver of pregnancy (AFLP), where patients generally achieve ELT-free survival with optimal supportive care. This is often not the case for patients with ALF caused by idiosyncratic drug reactions, HBV, AIH, Wilson disease, or Budd-Chiari syndrome (BCS). Paradoxically, patients with hyperacute ALF presentations often have higher initial illness severity, yet are more likely to survive through spontaneous hepatic regeneration and supportive care, whereas patients with a subacute ALF pattern may be less dramatically unwell at presentation, but relentlessly deteriorate and die without ELT. Regardless of etiology, given the high risk of death and the potential for rapid deterioration, transfer to a center capable of providing ELT should be considered in all ALF patients where this is feasible.

CLINICAL FEATURES OF ACUTE LIVER FAILURE

Regardless of etiology, ALF has a characteristic pattern of critical illness. Patients may complain of constitutional symptoms such as fatigue, nausea, and anorexia. Consistent with diagnostic definitions, derangement in hemostatic parameters (especially of INR) are always evident, as are jaundice and hepatic encephalopathy (HE). It is this latter finding that differentiates ALF from the less severe acute liver injury (ALI), in which there is no neurologic impairment.[16] Laboratory tests are confirmatory, with elevations in amino acid transaminase levels (up to 25 times the normal upper limit) and bilirubin, in addition to a tendency to hypoglycemia and hyperlactatemia. Hyperammonemia is a cardinal feature, especially in the setting of significant HE. In addition to an elevated INR, thrombocytopenia and hypofibrinogenemia frequently occur and suggest a likely bleeding tendency. Arterial blood gas analysis typically reveals a combination of respiratory alkalosis and metabolic acidosis.[17] Spontaneous improvement of the INR indicates recovery, whereas progressive worsening, even in the setting of reductions in transaminase levels, portend deterioration. The absolute values of elevated amino acid transaminase levels do not reflect prognosis.

Management Challenges in ALF

Hepatic Encephalopathy, Cerebral Edema, and Intracranial Hypertension

HE is the result of a complex pathophysiologic process that reflects serious underlying liver failure. A combination of metabolic toxins, false neurotransmitters, benzodiazepine-like compounds, and inflammatory mediators accumulate in liver failure, resulting in a metabolic delirium that can proceed to drowsiness and overt coma.

Whereas HE occurs in both decompensated chronic liver disease and ALF, cerebral edema occurs almost exclusively in the latter. Hyperammonemia develops in hepatic failure because of the major role the liver plays in its detoxification via the urea cycle. Ammonia is a neurotoxic by-product of protein metabolism that is converted to less toxic urea, which becomes the vehicle for excreting nitrogenous waste in the urine. Although some conversion of ammonia to urea occurs in other organs, severe liver failure will invariably result in ammonia accumulation and low blood urea concentrations. Cytotoxic cerebral edema occurs when ammonia crosses the blood-brain barrier (BBB), leading to increasing concentrations in brain tissue that cause glutamine-mediated astrocyte swelling, neuroexcitation, and disruption of many neuronal metabolic and signaling processes. In cases of severe HE and progressive cerebral edema, normal autoregulation of cerebral blood flow and the integrity of the BBB are lost, leading to cerebral hyperemia and vasogenic edema. Up to 80% of patients with high-grade HE may develop cerebral edema, and ammonia concentrations of more than 150 μmol/L are associated with intracranial hypertension that may be complicated by neurologic injury and death from brainstem herniation.[18] Progressive neurologic deterioration can be difficult to detect on clinical assessment of critically ill patients, and early intracranial hypertension may not be obvious on neuroimaging.[19] Monitoring strategies such as near-infrared spectroscopy, jugular venous bulb saturation monitoring, electroencephalogram (EEG), Doppler ultrasound, and intracranial pressure (ICP) monitoring all have significant limitations and none has been shown to improve patient outcomes. Invasive ICP monitoring in particular has associated risks of bleeding and infection.[20] Although it is used routinely in many specialist centers,[21] the technique has been abandoned by many in favor of other strategies. For most patients who recover either through ELT or spontaneous liver regeneration, resolution of HE and full neurologic recovery is the usual outcome.[22]

Deranged Hemostatic Parameters

Abnormalities of hemostatic parameters are part of the definition of ALF. Reduced hepatic synthesis of factors II, V, VII, IX, and X results in prolongation of the PT (and INR) and, later on, the activated partial thromboplastin time (aPTT). Although this results in a pattern of hemostatic derangement suggestive of high bleeding risk, the situation is complicated, with simultaneous reductions in the hepatic synthesis of anticoagulant factors such as proteins S and C, the accumulation of microparticles, and generalized inflammation that combine to promote a prothrombotic state.[23] For many patients, neither overt bleeding nor thrombosis occur,[24] suggesting that although routine measures of clotting appear markedly deranged, hemostasis remains functionally balanced and intact. The INR is a poor predictor of bleeding risk in ALF, whereas thrombocytopenia and hypofibrinogenemia may be more strongly associated with haemorrhage.[24]

Vasodilatory Shock

A vasodilated, hyperdynamic systemic circulation occurs in most patients with ALF, with the pattern of hemodynamic instability strongly resembling septic shock. Severe inflammation, endothelial injury, and abnormal neurohormonal control are all important factors leading to circulatory dysfunction. Relative or absolute hypovolemia may be present as a result of poor fluid intake before presentation, gastrointestinal losses, and capillary leakage. After appropriate fluid resuscitation, vasopressor therapy with agents such as norepinephrine administered by continuous infusion according to similar treatment principles for managing septic shock is recommended. Occasionally, patients may develop a low cardiac output state caused by preexisting cardiovascular disease or overwhelming critical illness such that inotropic support becomes necessary. In circumstances of advanced circulatory failure, general malperfusion ensues, contributing to multiple organ failure.

Metabolic Abnormalities

Severe metabolic derangement is a hallmark of ALF. Hyperlactatemia can develop secondary to generalized malperfusion combined with

high circulating catecholamine levels. Reduced hepatic clearance and direct impairment of mitochondrial function by toxic levels of acetaminophen may also contribute.[25]

Hypoglycemia is a serious development and suggests extreme liver injury. Failure of gluconeogenesis and loss of glycogen stores may lead to refractory hypoglycemia unless concentrated intravenous dextrose is administered.

Hyponatremia is occasionally present early on and is associated with worse outcomes in acute liver dysfunction.[26] Hypokalemia and hypophosphatemia may also occur, especially if high-dose CRRT is undertaken.

Relative or absolute adrenal insufficiency has been described in acute liver failure,[27] and steroid replacement therapy should be considered in the setting of refractory shock.[28]

Renal Failure

Acute renal failure occurs commonly in ALF, either secondary to the primary insult that caused liver injury (e.g., acetaminophen overdose) or from the systemic inflammatory response and associated shocked state. Uremia is notably rare because of reduced hepatic synthesis of urea; however, fluid accumulation, acidosis, and electrolyte derangement may all develop and cause complications. The initiation of CRRT should not be delayed until overt renal failure is evident, as it plays a key neuroprotective role by removing ammonia and other water-soluble toxins that contribute to HE and cerebral edema.

Respiratory Failure

Respiratory failure is rarely a prominent feature of ALF at initial presentation. ALF patients have a tendency to hyperventilation and develop a respiratory alkalosis; hypoxia is relatively uncommon. Over time, however, complications such as pulmonary edema, aspiration pneumonitis, atelectasis, and pneumonia are common, and severe hypoxic respiratory failure may develop. Hepatopulmonary syndrome is rare in ALF, but has been reported.[29]

Susceptibility to Infection and Sepsis

Severe susceptibility to bacterial and fungal infection is a hallmark of ALF and a major contributor to poor outcomes.[30] Contributing factors include compromised reticuloendothelial function, reduced complement levels, impaired phagocytosis, and the presence of vascular access catheters. Common sites for infection are the lower respiratory tract, urinary tract, and vascular access devices with associated bacteremia, and common pathogens include gram-positive cocci, gram-negative bacilli, and fungal species such as *Candida*. Infection may arise from the patient's own microbiome or from the hospital environment.

Fluid and Electrolyte Abnormalities

Critically ill patients with shock and multiple organ failure often receive considerable amounts of intravenous fluids, and this is also true for ALF. A strongly positive fluid balance is undesirable in patients at high risk of cerebral edema, and a strategy that aims to avoid excessive fluid accumulation is appropriate. Abnormalities of potassium and phosphate also occur frequently and need to be tested for and supplemented as necessary.[31]

Initial Assessment and Management

After initial resuscitation, a comprehensive history (either first person or from family members) is the most important part of initial assessment. Essential details include previous overall health, past history of liver disease, family history of liver disease, and risk factors for hepatotropic viruses (especially intravenous drug use, blood exposure, sexual history, and travel). All recent medications, alternative therapies, nutritional supplements, alcohol intake, use of illicit drugs, and possible mushroom ingestion must be evaluated. Female patients should be asked about the possibility of pregnancy.

A thorough clinical examination should also be completed. In addition to a general appraisal of vital systems, a directed search for signs of chronic liver disease (e.g., generalized sarcopenia, clubbing, leukonychia, spider nevi, gynecomastia, prominent abdominal wall veins, and significant ascites) in order to differentiate ALF from decompensated cirrhosis is essential. The presence of HE is a defining element of ALF but may be subtle early on. The West Haven criteria are often used to grade HE severity; however, critical care clinicians may be more familiar with using the Glasgow Coma Scale (GCS) to make an initial assessment and follow progress. Cutaneous lesions such as herpetic vesicles, tattoos, and needle marks may suggest the possibility of a viral etiology, and ophthalmic review may assist in checking for Kayser-Fleischer rings that are diagnostic of Wilson disease. Abdominal examination should evaluate liver and spleen size and for the presence of ascites.

INVESTIGATIONS

All ALF patients require a panel of investigations, as outlined in Table 87.1. Hemostatic parameters (INR, fibrinogen, platelet count) and blood concentrations of bilirubin, transaminases, albumin, glucose, and lactate can reveal the extent of liver injury and assist in detecting deterioration. Point-of-care arterial blood gas analysis is extremely helpful to assess oxygenation, ventilation, metabolic profile, and acid-base status. Blood ammonia concentrations should be checked in all patients with high-grade encephalopathy and any patient who is intubated. The persistence of extreme elevations is associated with neurologic complications. Pancreatitis is easily missed in a critically ill ALF patient, and serum lipase should be checked. All of these investigations should be repeated regularly to guide ongoing management. All female patients should be tested for pregnancy. Acetaminophen levels must be performed in every patient presenting with acute liver injury, even in the absence of a clear evidence for overdose. Interpreting the results may be difficult in the absence of a reliable history regarding the timing of and nature of ingestion (e.g., single overdose versus staggered supratherapeutic doses over time); empiric treatment with NAC is wise when there is any doubt regarding the significance of test results. A screen for illicit drugs may be appropriate if circumstances are suggestive. Tests for relevant hepatotropic viruses (HAV, HBV, HEV) in addition to Epstein-Barr virus (EBV), cytomegalovirus (CMV), and herpes simplex virus (HSV) are essential, as are copper studies and an autoimmune screen. Abdominal ultrasound with Doppler evaluation of vascular integrity (especially of the hepatic vein) should occur early during assessment and may also be helpful in detecting ascites. For patients with focal neurologic deficits, a history of trauma, or other concerns for intracranial pathology, neuroimaging with CT should be arranged. A focused hemodynamic assessment with echocardiography may guide treatment for patients with progressive hemodynamic compromise and shock who do not respond to vasoactive infusions and fluid resuscitation.

MANAGEMENT

Patients with ALF almost always develop a severe critical illness. They often follow an unpredictable, rapidly progressive clinical course with high risk of complications and require admission to the ICU in all circumstances where this is possible. Ward-based care will rarely suffice.

TABLE 87.1 Investigations in Acute Liver Failure

Investigation	Purpose	Suggested Frequency
Hematology		
Full blood examination	Anemia and thrombocytopenia for bleeding risk	Daily
Hemostatic parameters:		Daily
INR	Measure of hepatic insufficiency	Daily
Fibrinogen	Measure of hepatic insufficiency and bleeding risk	Daily
Blood film	Assess for hemolysis in Wilson disease and AIH	At presentation
Biochemistry		
Serum electrolytes	Management of Na^+, K^+	6-hourly
Liver function tests		Daily
AST, ALT	Assess hepatocyte injury and necrosis	Daily
Bilirubin, ALP, GGT	Assess hepatic insufficiency and cholestasis	Daily
Phosphate	Often low with liver failure, especially with CRRT	Daily
Creatinine	Measure of renal function	
Urea	Usually low in liver failure	Daily
Ammonia	Hyperammonemia associated with neurologic injury	Daily (at least)
Lactate	Measure of hepatic and circulatory failure	6-hourly
Blood glucose	Measure of hepatic insufficiency	6-hourly
Arterial blood gas analysis	Assess ventilation, oxygenation, and acid-base status	6-hourly
Acetaminophen concentration	Check for acetaminophen overdose in all ALF patients	At presentation
Copper studies	Ceruloplasmin low in Wilson disease	At presentation
β-hCG	Screen for pregnancy in female patients	At presentation
Lipase	Assess for pancreatitis	As indicated
Toxicologic screen	Assess for illicit drug use according to local practice	As indicated
Microbiology		
Serology		
Hepatotropic viruses	HAV, HBV, HDV, HEV as causes of ALF	At presentation
Nonhepatotropic viruses	EBV, CMV, HSV, VZV, parvovirus B19	At presentation
Microscopy and culture	Low threshold to assess for sepsis: blood, sputum, etc.	As indicated
Autoimmune markers		**At presentation**
ANA, ANCA, AMA, anti-LKM, anti-SM	Varying patterns in AIH	At presentation
Imaging		
Liver ultrasound with Doppler	Assess liver size, parenchyma, vascular integrity for Budd-Chiari	At presentation
Chest x-ray	Assess for pulmonary complications	Daily
CT brain	If evidence of trauma or focal neurologic deficits	As indicated
CT abdomen	Volumetric assessment of liver for prognosis	As indicated
Other		
ECG	Assess for toxidromes, arrhythmia, ischemia	Daily
EEG	Assess for possible seizure activity	As indicated
Liver biopsy	Assess for AIH or possible underlying cirrhosis	As indicated

ABG, Arterial blood gas; *ALP,* alkaline phosphatase; *ALT,* alanine transaminase; *ANA,* antinuclear antibody; *ANCA,* antineutrophil cytoplasmic antibody; *anti-LKM,* anti–liver kidney microsomal antibody; *anti-SM,* anti–Smith antibody; *APTT,* activated partial thromboplastin time; *ARDS,* acute respiratory distress syndrome; *AST,* aspartate transaminase; β-hCG, beta human chorionic gonadotrophin; *CMV,* cytomegalovirus; *EBV,* Epstein-Barr virus; *ECG,* electrocardiograph; *EEG,* electroencephalograph; *GGT,* gamma glutamyl transpeptidase; *HAV,* hepatitis A virus; *HBV,* hepatitis B virus; *HDV,* hepatitis D virus; *HEV,* hepatitis E virus; *HSV,* herpes simplex virus.

Treatment Directed at Specific Causes of ALF

Although supportive care is the most important aspect of management for most ALF patients, some etiologies have specific treatments that may limit further injury or reverse the underlying process.

NAC by intravenous infusion should be started immediately for all known or suspected cases of acetaminophen overdose. Delays must be avoided, and it should be continued until critical illness has resolved. There may also be a role for its use in other causes of ALF,[32,33] even though a survival benefit has not been clearly demonstrated.[34] Given its favorable safety profile, NAC is recommended by several guidelines in such circumstances.[35,36]

Specific antiviral therapies may occasionally have a role, such as nucleoside analogues for HBV or acyclovir for HSV. Emergency delivery is the definitive treatment for AFLP, and an expedited approach achieves the best outcomes. For BCS, an attempt at catheter-directed thrombolysis or shunt placement (e.g., transjugular portosystemic shunt [TIPS]), may be worthwhile. AIH-induced ALF may variably respond to high-dose steroids; however, it should be anticipated that ELT may prove necessary in many affected patients, especially those with high-grade encephalopathy.[37] Evidence for antidotes is limited, but high-dose penicillin (as a continuous infusion) or silibinin may be considered for *Amanita* mushroom poisoning.

Neurologic Care

Patients with high-grade HE from ALF can develop severe cerebral edema and intracranial hypertension. Although the incidence of cerebral edema in this setting may be falling,[38,39] affected patients are at high risk of neurologic complications and death.[40] Intubation is recommended for all patients with progressive HE to ensure airway protection and facilitate other elements of care. The head should remain elevated to 30 degrees at all times and maintained in a neutral position. Except for ELT, no individual intervention has been demonstrated to improve outcomes, so a coordinated approach is required to ensure that the various underlying processes may be simultaneously addressed. A combination of early CRRT, osmotherapy with hypertonic saline, optimized ventilation, and careful temperature management is recommended (Table 87.2).[41]

Hemofiltration

Intubated ALF patients should commence renal replacement therapy to treat hyperammonemia as soon as possible, rather than waiting for overt acute renal failure to manifest.[42,43] Continuous modalities are preferred, as they offer benefits that include continuously titratable fluid management, effective thermoregulation, control of pH, management of electrolyte abnormalities, minimal hemodynamic impact, and a lower risk of exacerbating intracranial hypertension.[44] A dual-lumen vascular access catheter can be safely inserted with ultrasound guidance, and only extreme derangement of hemostatic parameters necessitates prophylaxis with clotting factors. Bicarbonate buffered replacement fluid is preferred to avoid exogenous lactate loading. Although there is little evidence on which to recommend a specific mode of CRRT, a strategy that incorporates a diffusive component may improve ammonia clearance. Most CRRT machines incorporate an integrated heater that may be turned off in order to allow the patient's temperature to be lowered. High blood flows (e.g., >250 mL/min) with effective vascular access help lower the risk of clotting within the circuit, and anticoagulation may not be required. If anticoagulation proves necessary, low-dose heparin or epoprostenol may be tried, whereas citrate regional anticoagulation should generally be avoided in the setting of severe hepatic insufficiency. Ammonia exhibits similar kinetics to urea and is effectively cleared in a similar manner, especially at an hourly exchange dose of 40 mL/kg/hr or more. Early initiation and continuity of therapy are essential to ensure ammonia concentrations are rapidly lowered and then maintained at a safe level.[43] Serial monitoring of ammonia levels is recommended, and failure to achieve reductions down to near the normal range or frequent interruptions to therapy should prompt efforts to optimize the application of CRRT. This approach may result in electrolyte abnormalities such as hypokalemia and hypophosphatemia, so diligent testing and preemptive supplementation are required. A strategy to avoid a strongly cumulative fluid balance is advisable in order to avoid potentiating cerebral edema.

TABLE 87.2 Management of Intubated ALF Patients With High-Grade Hepatic Encephalopathy at Risk of Cerebral Edema and Intracranial Hypertension

Neuroprotective Intervention[41]	Therapeutic Target	Method of Therapy	Mechanism
Hemodiafiltration	Blood ammonia <60 μmol/L and even daily fluid balance	High-volume CRRT using dialysis and filtration	Treats hyperammonemia and allows precise metabolic, electrolyte, and fluid management and provides a cooling effect
Hypernatremia	Serum sodium 145–155 mmol/L	Continuous infusion of concentrated saline via central venous catheter	Increases serum tonicity and reduces cerebral edema
mild Hyperventilation	Lower of $PaCO_2$ = 35 mm Hg or that achieved by the patient before intubation	Set ventilator to provide minute ventilation sufficient to achieve target	Attenuates cerebral hyperemia and lowers intracranial pressure
mild Hypothermia	Core temperature 35°C Always prevent fever	CRRT Active cooling device	Reduces ammonia production and CNS uptake, attenuates cerebral hyperemia, reduces cerebral metabolic rate, reduces neuroexcitation and, has anti-inflammatory effects

After Warrillow SJ, Bellomo R. Preventing cerebral oedema in acute liver failure: The case for quadruple-H therapy. *Anaesth Intensive Care.* 2014;42:78–88.

CNS, Central nervous system; *CRRT,* continuous renal replacement therapy.

General measures include sedation, elevation of head to 30 degrees, avoidance of hypotension and hypertension, and avoidance of hypoxemia. "Rescue" measures for refractory intracranial hypertension include deep sedation, hyperventilation, moderate hypothermia, bolus hypertonic saline or mannitol, indomethacin, and advanced blood purification (e.g., plasmapheresis).

Hypertonic Saline

Osmotherapy is an established treatment for cerebral edema. The two major therapeutic options are mannitol and hypertonic saline. Although mannitol is often used in many regions, there is a theoretical risk of rebound cerebral edema after repeated use, as it may leech into the brain parenchyma and induce a "reverse" osmotic gradient. Hypertonic saline (HTS) is at least as effective as mannitol[45] and has been suggested both as a prophylactic strategy for cerebral edema in ALF and as treatment for associated intracranial hypertension.[46–49] Either bolus dosing or continuous infusion of HTS via a central venous catheter may be used, with the latter having the advantage of being titratable as guided by point-of-care testing. Other proposed advantages of HTS for the brain include antiinflammatory effects, reduced hyperemia, improved microcirculation, and maintenance of intravascular volume without excessive fluid loading.[50] A target serum sodium concentration of 145–155 mmol/L is recommended,[48] and achieving this goal is more important than the method of administration (bolus or continuous infusion) or the absolute dose given.[46] The serum sodium should not be permitted to exceed 160 mmol/L,[51] and it is important to avoid rapid increases in patients who are hyponatremic at presentation and therefore at risk of central nervous system (CNS) demyelination syndromes.

Mechanical Ventilation

Spontaneous hyperventilation is typical of ALF, even in patients who are obtunded.[52,53] Patients with high-grade HE should be intubated. The arterial carbon dioxide tension exerts considerable influence over cerebral vascular resistance, which in turn is a major determinant of cerebral perfusion. Cerebral blood flow is reduced by approximately 3% per 1 mm Hg reduction in partial pressure of carbon dioxide ($PaCO_2$).[54] Although perfusion and cerebral metabolic requirements are usually well matched (including in patients with early HE), autoregulation may be lost in patients with severe HE who are at the highest risk of cerebral edema and intracranial hypertension.[53] Whether relative or absolute, cerebral hyperemia exacerbates cerebral edema and intracranial hypertension. Careful control of $PaCO_2$ can restore cerebral blood flow autoregulation in ALF, and a target $PaCO_2$ similar to that achieved by the patient before intubation or at the lower end of the normal physiologic range is recommended.[35,55] Adjustments to minute volume can be guided by end-tidal CO_2 monitoring and regular arterial blood gas analysis. Hypercapnia must be avoided, especially during vulnerable periods such as during intubation and patient transport. More aggressive deliberate hyperventilation provides no clear benefit when applied routinely, and the associated reductions in ICP are transient. It should be reserved for situations where, despite other measures, severe cerebral edema is complicated by intracranial hypertension and it is necessary to achieve an urgent reduction so that a definitive intervention such as ELT can proceed.[56] Consistent with current recommendations, an approach that targets safe tidal volumes and plateau pressures, uses positive expiratory-end pressure (PEEP) effectively, and achieves satisfactory oxygenation is a fundamental element of respiratory care.

Targeted Temperature Management

It is widely accepted that fever is especially detrimental to patients with cerebral edema, who are prone to intracranial hypertension.[57] Evidence suggests a range of potential benefits from mild therapeutic hypothermia, especially for younger patients with acetaminophen overdose, and it can be safely undertaken with low risk of complications.[58] More aggressive lowering of temperature provides no additional benefit, and it is therefore appropriate to reserve cooling lower than 34°C for situations of severe cerebral edema where ELT is planned.[59] Many of the benefits from therapeutic hypothermia are obtained by targeting a temperature of 35°C (i.e., slightly subphysiologic) and ensuring that fever never occurs.[60] This approach also minimizes theoretical risks of exacerbating coagulopathy, immunosuppression, or arrythmias.

Other Potential Neuroprotective Therapies

Other therapies may be tried in the setting of refractory intracranial hypertension in instances where it is necessary to support a patient for sufficient time to undertake a definitive intervention, such as ELT. Most of these have little evidence and often entail a risk of complications. Deep sedation with barbiturates may lower ICP but risks cardiovascular compromise. Indomethacin has been shown to be helpful in models of ALF-associated cerebral edema, but evidence in humans is limited.[61] Anticonvulsants should only be used in the setting of clinically evident or EEG-proven seizure activity. Lactulose is often used in the setting of HE complicating chronic liver disease; however, it has little evidence for use in ALF, and it causes diarrhea and bowel distension, which may be problematic. Similarly, enteral antibiotics such as rifaximin are often administered to cirrhotic patients with HE but have not been well-studied in ALF patients. l-ornithine-l-aspartate and l-ornithine phenylacetate may provide a novel means of enhancing ammonia detoxification but have not shown benefit in human studies. Complex blood purification techniques such as coupled plasma filtration adsorption (CPFA), molecular adsorbent recirculation system (MARS), and bioartificial devices have not been shown to improve survival and have a limited role outside of clinical trials.[62]

Other Care

Circulatory Support

An approach similar to the resuscitation and ongoing circulatory support for septic shock is appropriate for the hemodynamic abnormalities resulting from ALF. The early placement of an indwelling arterial catheter and multilumen central venous catheter permits continuous hemodynamic monitoring, regular blood sampling, and the administration of essential infusions. Routine administration of clotting factors is not necessary; however, extreme derangement of hemostatic parameters should be corrected before the insertion of invasive monitoring lines. Pulse contour analysis and bedside echocardiography may guide the selection of hemodynamic supports with minimal additional risk to the patient. After hypovolemia has been addressed with fluid resuscitation, most patients will require vasopressor support. Norepinephrine via continuous infusion is a common approach, and if high doses are required (e.g., >0.5 μg/kg/min), additional agents such as vasopressin by continuous infusion and corticosteroids may improve vasomotor tone. Similar to other critically ill patients, ALF patients often accrue a positive fluid balance and are at risk of generalized edema. This may increase their risk of complications such as cerebral and pulmonary edema. After the initial resuscitation phase, it is prudent to avoid excessive fluid loading and consider strategies such as concentrated albumin (e.g., 20% human albumin or similar) to maintain intravascular volume while minimizing the volume of fluid administration.

Management of Deranged Hemostatic Parameters

Although measures of hemostasis in ALF suggest a high risk of bleeding, this does not eventuate in most patients. INR is not a reliable guide to bleeding tendency, and isolated elevations should not prompt administration of clotting factors such as fresh frozen plasma. Similarly, it is not necessary to routinely administer clotting factors on the basis of INR before most invasive procedures.[35] Thrombocytopenia and hypofibrinogenemia are clearly associated with bleeding risk, however, and extreme derangements should be corrected.[24] Daily assessment of

TABLE 87.3 General ICU Care of Acute Liver Failure Patients

Intervention	Suggested Target/Approach	Method/Examples
Treatment for specific underlying etiology	Reversal of pathologic process and minimization of ongoing injury	• N-acetyl cysteine infusion for acetaminophen overdose • Withdrawal of hepatotoxic drugs • Nucleoside analogues for HBV • Penicillin or silibinin for *Amanita* mushroom poisoning • Urgent delivery of fetus for AFLP
Hemodynamic support	Hemodynamic parameters according to patient's clinical progress: • CVP 6–10 mm Hg • MAP 65–70 mm Hg • Even daily fluid balance	• Fluid administration • Vasoactive infusions (e.g., norepinephrine) • Low-dose corticosteroid administration if persisting shock
Sepsis care	• Low threshold for empiric broad-spectrum antibiotics if clinical suspicion of infection • Consider antifungal therapy if deterioration after several days of critical illness • Regular cultures of blood, urine, and sputum • Daily CXR	• Extended-spectrum β-lactams • Liposomal amphotericin or echinocandin antifungal therapy if deterioration after several days of critical illness
Respiratory support	See hyperventilation section of Table 87.2	• Intubate patients with high-grade encephalopathy • Avoid hypoventilation, especially during vulnerable periods such as during intubation, neuroimaging, and transfers
Renal support	See hemodiafiltration section of Table 87.2	• Ensure blood flow >200 mL/min • Use high exchange rates of lactate-free replacement fluid (40–50 mL/kg/hr) • Turn off heater • Aim for blood ammonia within normal range • Monitor electrolytes (especially phosphate, potassium, magnesium) • Administer hypertonic saline by continuous infusion to avoid reduced serum osmolarity while on CRRT
Hematologic support	• Hb >7.0 g/dL • INR <6 • Platelet count >75 × 10^9/L • Fibrinogen >1.5 g/L	• Avoid treating isolated derangements in hemostatic parameters • Prophylactic FFP is not recommended before most procedures • Avoid extreme hypofibrinogenemia and thrombocytopenia • Administer vitamin K 10 mg IV daily • Use FFP, platelets, and cryoprecipitate if factor support is required
Metabolic/gastrointestinal/nutritional care	• Blood glucose 6–10 mmol/L • Stress ulcer prophylaxis • Enteral feeding	• Concentrated dextrose infusion via central line • H_2 blocker or PPI therapy • Enteral feeding via nasogastric tube

AFLP, Acute fatty liver of pregnancy; *CVP,* central venous pressure; *CXR,* chest x-ray; *FFP,* fresh frozen plasma; *Hb,* hemoglobin; *HBV,* hepatitis B virus; *INR,* international normalized ratio; *MAP,* mean arterial pressure; *PPI,* proton pump inhibitor.

all hemostatic parameters is recommended to assess for possible hepatic recovery and to preempt potential bleeding complications. Recommended targets are outlined in Table 87.3. Intravenous vitamin K is appropriate for all ALF patients and can be given on a daily basis. Although the evidence that clotting factor administration may precipitate a prothrombotic state is limited, it is sensible to limit therapy to situations where there is a clear indication, such as active bleeding in the setting of abnormal hemostatic test results.

Sepsis

Immune paresis is an important complication of ALF, and infection with bacterial or fungal pathogens is a common cause of death. Prophylactic antibiotics seem to offer no clear benefit, and there are concerns that resistance may be facilitated by their unnecessary use.[63] Vigilance with a low threshold to investigate for and empirically treat infection with broad-spectrum antimicrobials is a reasonable strategy. A typical septic workup should include imaging (e.g., chest x-rays) and surveillance cultures of blood, urine, and sputum. Standard markers of infection such as fever, leukocytosis, and biomarkers (e.g., C-reactive protein [CRP]) may not follow a typical pattern and should not be wholly relied upon.[64] There may be a role for empiric antifungal therapy if a patient remains critically ill or is deteriorating after several days of critical care support. Antimicrobial selection should be guided by knowledge of local resistance patterns and the avoidance of potential hepatotoxins.

Metabolic, Gastrointestinal, and Nutritional Support

Hypoglycemia is common in ALF patients with extreme hepatic insufficiency. It must be immediately corrected and a continuous infusion of concentrated dextrose (e.g., 25% dextrose via a central line) may be required, with a target blood glucose of between 6 and 10 mmol/L. Hyperglycemia is common during the recovery phase, and an insulin infusion may then be required to control elevations in blood glucose. Upper gastrointestinal bleeding may occur in ALF patients,[24] especially those with hypofibrinogenemia and thrombocytopenia, and use of H2 blockers or proton pump inhibitors is appropriate.

Nutritional support via the enteral route is preferred, and intubated patients will require a nasogastric feeding tube. There is scant evidence

on which to base recommendations for specific formulations; branched-chain amino acid–enriched preparations offer few additional benefits beyond standard options.

Emergency Liver Transplantation

ELT is the only single intervention proven to reduce mortality in ALF; however, it accounts for only a small proportion of liver transplants undertaken in jurisdictions where it is available. Although ELT for ALF has a slightly higher early mortality than transplantation undertaken for chronic liver disease, the outcomes are otherwise very good,[65] with rapid improvement in all aspects of critical illness over a short period after a successful procedure.[22] Developing reliable and generalizable selection criteria has proven challenging. The survival benefit of ELT in nonacetaminophen ALF seems clear; however, there is less certainty in the setting of ALF from acetaminophen overdose.[1,66,67] Other issues that require careful consideration include judging whether the patient has become too critically ill to survive major surgery and also complex ethical issues such as whether or not a patient who has deliberately overdosed in an act of self-harm should proceed to ELT.[68] Contraindications to ELT include known malignancy, irreversible neurologic injury, and uncontrolled sepsis. The most common surgical approach is orthotopic transplantation of a whole cadaveric organ; however, cadaveric split livers, living related partial donations, and the increasing use of marginal donors (including donation after circulatory death) increase the options available when organs are scarce. Another interesting approach is the use of auxiliary partial orthotopic liver transplantation (APOLT) in which a cut-down donor liver is transplanted orthotopically after partial hepatectomy of the native liver.[69] The transplanted donor tissue provides effective function for a bridging period until sufficient regeneration of the native liver can occur. When convincing evidence of recovered native liver function is evident, immunosuppression can be tapered to cessation, and a controlled chronic rejection of the transplanted tissue causes gradual atrophy.

The optimal approach to decision making uses predictive criteria as a preliminary screening assessment, which then informs the clinical interpretation of dynamic measures (such as INR, lactate, and indicators of shock and organ failure). It is usual practice to proceed to ELT in situations where death is likely in the absence of ELT, an organ is available, and there are no absolute contraindications. Frequent assessment and consultation between intensive care clinicians and transplant teams at the bedside are essential in order to make the best decisions possible under circumstances where certainty is so often impossible.

CONCLUSION

Although rare, ALF causes extreme critical illness to which patients often succumb. With optimal care, ELT-free survival is possible for many of those patients with favorable etiologies, and transplantation may be lifesaving for others.[70] Clinicians should be aware of the common causes in their region and know etiology-specific therapy and how to coordinate the complex supportive care that is often necessary. Early consultation with a liver transplant service is recommended so that transfer can be considered, even if ELT does not seem necessary on preliminary assessment. As with any complex critical illness, a proactive, coordinated approach to care is required, and frequent re-evaluation to assess the clinical course and detect complications is essential.

KEY POINTS

- ALF is defined by the triad of overt liver failure with jaundice occurring over a period of weeks, with encephalopathy and deranged hemostatic measures (usually INR or PT) in the absence of known chronic liver disease.
- Causes of ALF vary considerably by region, with acetaminophen and other drugs common in most developed countries, whereas viral hepatitis is much more frequent in many resource-limited and developing regions.
- Mortality is high, and ELT is the only single intervention proven to reduce mortality. Some etiologies have a more favorable outcome (e.g., acetaminophen overdose), whereas some are usually lethal without ELT (e.g., Wilson disease).
- Cerebral edema as a complication of hepatic encephalopathy is unique to ALF and rarely occurs in encephalopathic cirrhotic patients. The pathophysiology is complex, but hyperammonemia is a potent neurotoxin that drives many of the contributing processes and is a readily measured surrogate for other unmeasured toxins that accumulate in liver failure.
- For patients with high-grade hepatic encephalopathy, the early initiation of CRRT (e.g., with hemodiafiltration at an effluent dose of ≥40 mL/kg/hr), HTS administration (to achieve a serum sodium of 145–155 mmol/L), optimized mechanical ventilation ($PaCO_2$ lower of either low normal or that achieved by the patient before intubation), and targeted temperature management (core temperature 35°C and strict avoidance of fever) may limit the risk of intracranial hypertension. These interventions should be applied to all patients intubated for high-grade encephalopathy and continue until recovery is evident. Although it is widely used, invasive ICP monitoring does not improve outcomes, and its role remains unclear.
- The initiation of CRRT is neuroprotective and should not be delayed until overt renal failure is apparent. It effectively treats hyperammonemia and reduces levels to near normal, thereby reducing the risk of neurologic complications. Ammonia levels should be checked at least daily while encephalopathy persists. HTS should be used in conjunction with CRRT to avoid inadvertent reductions in serum osmolarity. Intermittent dialysis risks exacerbating cerebral edema and has an adverse impact on the systemic circulation.
- Elevations in the INR, although indicative of liver injury, are not especially predictive of bleeding risk. Administration of fresh frozen plasma to treat an isolated INR result or routinely before most procedures is not recommended. Hypofibrinogenemia and thrombocytopenia are associated with bleeding tendency, and the administration of cryoprecipitate and platelet transfusion is recommended for extremely low levels. Hemostatic parameters (especially INR, fibrinogen, and platelet count) should be checked at least daily.
- Various predictive scoring systems have been developed, and although they may assist with identifying many patients at high risk of death without ELT, none of the criteria developed so far should be wholly relied upon to determine listing for ELT. Clinicians must apply their own expertise and engage in repeated clinical assessment to ensure that patients capable of spontaneous recovery avoid ELT, whereas those who will likely die without it undergo transplantation.
- ELT should be considered early during the course of management for patients with unfavorable etiologies who are unlikely to achieve ELT-free survival (e.g., Wilson disease, idiosyncratic drug reactions, cryptogenic ALF).

Calculous and Acalculous Cholecystitis

Samuel A. Tisherman

Evaluating the patient with a possible acute abdomen and intraabdominal sepsis in the intensive care unit (ICU) can be challenging. Patients frequently have multiple potential sources of sepsis and are often unable to describe symptoms or localize tenderness on physical examination. In addition, many imaging studies require transporting the patient to the radiology suite, which can be risky. These issues are especially troublesome for patients with the potential for acute cholecystitis.

Acute cholecystitis, frequently without gallstones, has long been recognized as a complication of surgery or acute critical illness.[1] The pathophysiology of cholecystitis in critically ill patients is different from that in the general population, as at least half of the patients have no gallstones.[2] Understanding the risk factors and pathogenesis of acute cholecystitis in the ICU can help increase the index of suspicion and lead to early diagnosis and treatment, which is necessary for good outcomes in the already critically ill patient.

RISK FACTORS AND PATHOPHYSIOLOGY

In the general population, acute cholecystitis is associated with the presence of gallstones, which develop as a result of decreased solubility of cholesterol and bile salts in bile. Risk factors for gallstones include age, female sex, recent pregnancy, positive family history for gallstones, and hemolysis. Patients with gallstones may develop acute cholecystitis at any time. Rarely, acute calculous cholecystitis can occur during hospitalization for other reasons.

Acalculous cholecystitis can occur spontaneously under certain circumstances. In outpatients, risk factors for acalculous cholecystitis include diabetes mellitus, vasculitis, older age, and male sex.[3]

Acute cholecystitis has been described as a complication of a variety of surgical procedures,[4,5] burns,[6] sepsis,[7] cardiovascular diseases, and malignancy.[8] Trauma patients are also at increased risk, perhaps because of the development of sludge over time, which may also increase the risk for pancreatitis.[9,10]

There is an association between total parenteral nutrition and biliary stasis.[11] Though lack of enteral feeding may play a significant role, parenteral nutrition can directly decrease bile production, worsening biliary stasis. Biliary sludge can be found in almost all patients on long-term parenteral nutrition.[11] Many go on to form gallstones. The fatty acid derivatives of lipid emulsions, large amounts of dextrose, and specific deficiencies, such as choline and taurine, may also play a role.[12]

Theories regarding the pathogenesis of acalculous cholecystitis in critically ill and postoperative patients have evolved over the years. Presumptive causes have included gastrointestinal hypomotility, biliary stasis, and lack of enteral feeding in the postoperative period, leading to increased concentrations of bile salts and cholesterol in bile.[13] The rarely observed acute onset of cholecystitis with refeeding suggests impaction of stones or viscous bile in the cystic duct with gallbladder contractions.

Gallbladder mucosal necrosis, arterial thrombosis, gangrene, and perforation suggest that hypoperfusion may be another critical mechanism for acalculous cholecystitis. Histopathologic studies confirm microvascular changes and ischemic cholecystitis histologically.[14] Hypoperfusion, particularly of the splanchnic circulation, is common in critically ill patients because of hemorrhage, dehydration, heart failure, and sepsis. Vasopressors can exacerbate the situation. Mechanical ventilation with positive end-expiratory pressure can increase hepatic venous pressure and thereby decrease portal perfusion.[15]

In addition to hypoperfusion, increased intraluminal pressure from biliary stasis secondary to fasting and narcotics may be a critical factor.[16] The combination of hypoperfusion and increased intraluminal pressure leads to a decrease in gallbladder perfusion pressure, wall ischemia, bacterial invasion, and cholecystitis.

INCIDENCE

The incidence of acute cholecystitis in the ICU is difficult to determine, given the great diversity in ICU patient populations and illness severity. Visceral hypoperfusion related to left ventricular dysfunction has been implicated as an etiologic factor, particularly in the cardiac surgery population. Early predictors of acute cholecystitis in these patients include arterial occlusive disease, low preoperative oxygen delivery, longer cardiopulmonary bypass times, need for surgical reexploration, cardiac arrhythmias, mechanical ventilation for $\geq$3 days, bacteremia, and nosocomial infections.[4] The common threads among these factors include decreased tissue perfusion and oxygenation, significant surgical trauma with the expected inflammatory response, and perhaps bacterial translocation from the gut lumen. Because of high risk, some have suggested ultrasound screening of patients who have had complicated courses after cardiovascular surgical procedures.[5]

In the general population of postoperative patients, acute cholecystitis appears to occur with or without gallstones. Among trauma patients, about 90% of the acute cholecystitis cases are acalculous.[9] Because the incidence of the disease is low but the many risk factors for the disease are common, it is difficult to identify specific groups of ICU patients who might benefit from selective screening for acute cholecystitis.

CLINICAL PRESENTATION

The signs and symptoms of acute cholecystitis do not generally differ between calculous and acalculous disease. Typically, patients with acute cholecystitis present with right upper quadrant or epigastric pain, often after ingesting a fatty meal. The pain may radiate to the back. Anorexia, nausea, and vomiting are common findings, as are fever and chills. If the patient is receiving enteral nutrition, the symptoms may be related to meals or tube feedings.

On examination, the most consistent finding is fever. Focal tenderness in the right upper quadrant or epigastrium is typically found, often with evidence of peritoneal irritation. Rarely, the gallbladder is palpable. There may be abdominal distention and loss of bowel sounds. In critically ill patients, symptoms and physical examination findings are frequently difficult to assess or absent because of alterations in the patient's mental status and concurrent disease.

The most consistent laboratory finding is a leukocytosis. Serum levels of liver enzymes and bilirubin are usually normal unless choledocholithiasis, Mirizzi syndrome (external compression of the common hepatic duct by a stone impacted in the cystic duct), or liver dysfunction from sepsis is present. Thus jaundice is rare. Clinical findings and laboratory studies are not very sensitive or specific for cholecystitis, even in the general population,[17] and are less so in critically ill patients.

Given that the underlying pathophysiology of cholecystitis in the ICU often involves gallbladder wall ischemia, there is significant risk for rapid progression to gangrene and perforation. Consequently, even though other causes of sepsis in the ICU are more common, one needs to have a low threshold for considering cholecystitis in the differential diagnosis of patients who may have intraabdominal sepsis. Imaging of the gallbladder should be the next step.

IMAGING STUDIES

Ultrasonography is usually the first test of choice for acute cholecystitis in the general population and in critically ill patients. In the ICU, the presence or absence of gallstones does not help with the diagnosis. The most useful ultrasonographic findings are thickening of the gallbladder wall and pericholecystic fluid (Fig. 88.1). These findings correlate well with operative findings. False-positive findings may occur with sludge, nonshadowing stones, cholesterolosis, ascites, hypoalbuminemia, and portal hypertension. Other ultrasonographic findings indicative of acute cholecystitis include the following: the "double wall sign," representing edema of the gallbladder wall; the "halo sign," representing sloughed gallbladder mucosa; intramural gas; distention of the gallbladder; and the "sonographic Murphy sign," demonstrating point tenderness by pressing the ultrasound probe directly over the gallbladder. The sensitivity of ultrasound for detecting acalculous cholecystitis is 81%–92%. The specificity is 60%–96%,[17,18] but these results are operator dependent.

One problem in the ICU is that the typical ultrasonographic findings of cholecystitis can be seen in ICU patients without the condition. For example, Boland and colleagues performed ultrasound examinations of the gallbladder twice a week in a variety of ICU patients.[18] Half of the patients without calculi developed at least one ultrasonographic finding of acute cholecystitis. Patients with several findings should undergo more aggressive diagnostic evaluation and, perhaps, therapeutic interventions. In equivocal cases, serial examinations may demonstrate increasing wall thickness, which should increase the suspicion for cholecystitis.[19]

Fig. 88.1 Ultrasound of the gallbladder demonstrating wall thickening *(double arrows)* and sludge *(black arrow)*.

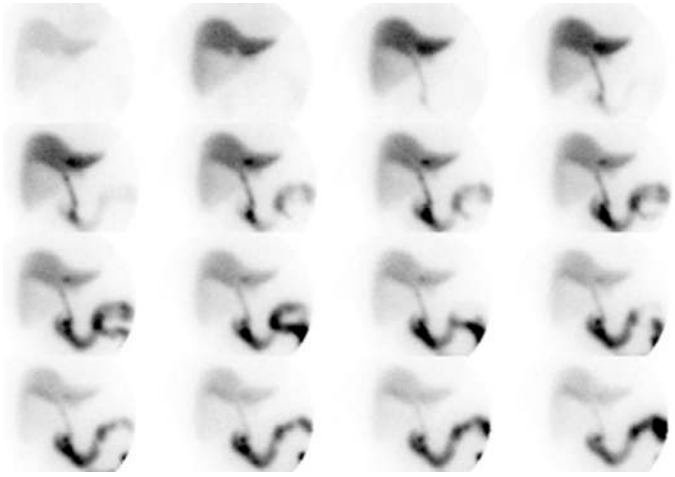

Fig. 88.2 Scintigraphy of the biliary tree demonstrating concentration of the tracer in the liver followed by flow into the biliary tree and small bowel. The gallbladder is not visualized.

Computed tomography (CT) of the abdomen can be used to make the diagnosis of acute cholecystitis.[20] The criteria for a positive study include wall thickness >4 mm, pericholecystic fluid, intramural gas, sloughed mucosa, or subserosal edema without ascites (Fig. 88.2). If intravenous contrast is administered, enhancement of the gallbladder wall may be seen. Although CT may not be as sensitive as ultrasound for determining the presence of gallstones or acute cholecystitis, it can help to detect or rule out other causes of intraabdominal sepsis. A great disadvantage of CT for critically ill patients, however, is the need to transport the patient to the scanner. In critically ill patients with suspected cholecystitis, ultrasound remains the first test of choice. Frequently, however, additional studies are necessary.

Scintigraphy of the gallbladder has been used when acute cholecystitis is suspected but findings from other tests such as ultrasound or CT are inconclusive or contradictory. Gallbladder scintigraphy is performed by administering technetium-labeled iminodiacetic acid (IDA). Cholecystitis is diagnosed if the radioactive tracer is visualized in the small bowel without visualization of the gallbladder within 4 hours, suggesting occlusion of the cystic duct (Fig. 88.3). Delayed visualization of the gallbladder may represent chronic cholecystitis. The rate of false-positive tests is significant in fasting patients, particularly those receiving parenteral nutrition, as the gallbladder may already be maximally filled. The use of intravenous morphine to increase tone in the sphincter of Oddi and thereby increase pressure within the biliary system can decrease the risk of a false-positive test.[21] In patients with severe liver disease, there may be inadequate uptake and excretion of the tracer to provide visualization of the biliary tree. Also, if a patient has had a biliary sphincterotomy, the tracer may pass too quickly through the biliary tree. Overall, the sensitivity of scintigraphy is 91%–97% and the specificity is 38%–99%.[21] Scintigraphy is a useful complement to ultrasonography for early decision making regarding intervention.

DIAGNOSIS

The differential diagnosis for patients with potential cholecystitis in the ICU includes peptic ulcer disease (particularly perforation), acute

Fig. 88.3 Computed tomographic study of the abdomen demonstrating thickening of the gallbladder wall with infiltration of the pericholecystic fat *(black arrow)* and gallstones *(white arrow)*.

pancreatitis, hepatic or subphrenic abscess, pyelonephritis, right lower lobe pneumonia (although right lower lobe atelectasis is common with a subdiaphragmatic process), and practically any cause of sepsis. The clinical presentation, laboratory studies, and imaging studies all should be considered when making clinical decisions.

To help with confirming the diagnosis of acute cholecystitis, the Tokyo Guidelines for the management of cholecystitis from 2018 (TG18) include specific criteria.[22] Patients have suspected cholecystitis if they have signs of local inflammation (right upper quadrant pain, tenderness or mass, or a positive Murphy sign) and signs of systemic inflammation (fever, elevated C-reactive protein, leukocytosis). The diagnosis is definitive if the patient has positive imaging studies. The severity of cholecystitis is defined as grade I (mild: without any of the grade II or III criteria), grade II (moderate: white blood cell count $>18{,}000/mm^3$, palpable tender mass in the right upper quadrant, duration of symptoms >72 hours, or marked local inflammation), and grade III (severe: end-organ dysfunction). Markers of inflammation, such as Ôªøneutrophil-to-lymphocyte ratio, the Glasgow Prognostic Score (original or modified), and the C-reactive protein/albumin ratio, also correlate with severity and may complement the Tokyo guidelines severity grade.[23] The American Association for the Surgery of Trauma Emergency General Surgery grading system may also perform at least as well as the Tokyo guidelines.[24]

MANAGEMENT

The management of a patient with acute cholecystitis involves supportive care, antibiotics, and either drainage or removal of the gallbladder (Fig. 88.4). Even in equivocal cases, drainage of the gallbladder may be appropriate in critically ill patients.

The standard initial medical treatment for acute cholecystitis includes antibiotics, analgesia, and, at least during the early phase, bowel rest. For patients who are septic from cholecystitis, it is appropriate to follow the Surviving Sepsis Campaign guidelines regarding fluid resuscitation, use of vasopressors, and initiation of broad-spectrum antibiotics.[25]

Antibiotics for uncomplicated cholecystitis should cover enterococcal species and gram-negative rods, particularly *Escherichia coli* and *Klebsiella* spp.[26] Cultures are positive in about half of the cases, particularly beyond 72 hours after the onset of symptoms—more so if empyema of the gallbladder is present. In patients who have more severe illness, have previously received antibiotics, or are older, more resistant and unusual organisms may be cultured from gallbladder bile. These organisms can include *Staphylococcus* spp., resistant gram-negative bacilli, anaerobic bacteria, and fungi. Broader coverage may be required initially until cultures are obtained and coverage can be more tailored. Local antibiograms, particularly the proportion of extended-spectrum beta-lactamase–producing organisms can be helpful.

Optimal duration of antibiotic coverage for cholecystitis remains unclear. If patients undergo early cholecystectomy, continuing antibiotic coverage postoperatively may not be necessary. For patients who undergo cholecystostomy, 7 days or less of antibiotics seems to be as good as more prolonged courses.[27]

Nonsteroidal antiinflammatory drugs can be very effective for controlling the pain from cholecystitis. When narcotics are needed, the choice of narcotic analgesic is probably not as important as was once believed. All narcotics can increase the pressure of the sphincter of Oddi, potentially increasing pressure in the biliary tree.

The next question is whether to drain or remove the gallbladder acutely. For patients with septic shock, severity of illness and delay in source control, particularly greater than 16 hours after presentation, are associated with increased mortality.[28] There is a lack of prospective, randomized trials to help clarify this issue. Early surgical consultation is critical. The decision regarding drainage or removal of the gallbladder must be made with consideration of both the critical care and general surgical issues. If the patient can tolerate transport to the operating room and a general anesthetic, cholecystectomy remains the most definitive therapy, particularly in light of the risk of gallbladder gangrene and perforation. Patients with grade I or II cholecystitis and with good performance status based upon the Charlson Comorbidity

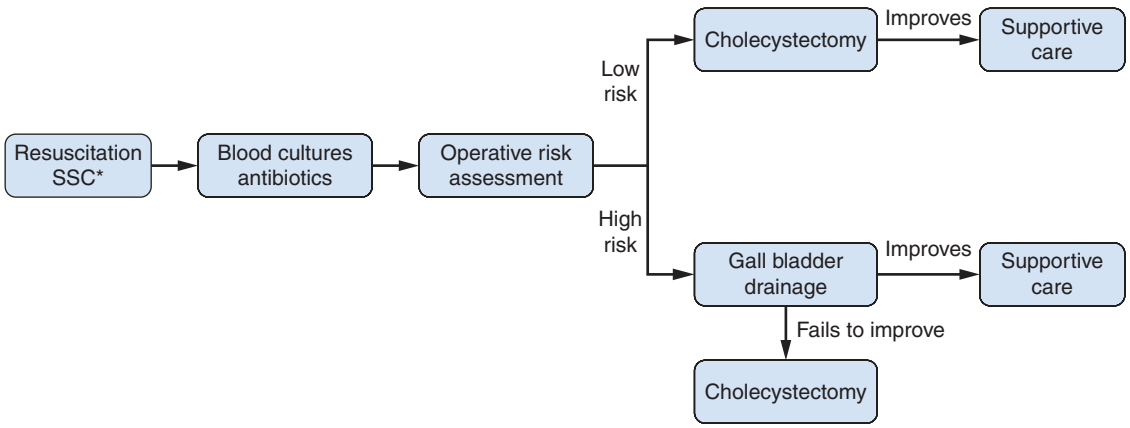

Fig. 88.4 Management of cholecystitis. **SSC,* Surviving Sepsis Campaign.

Index and American Society of Anesthesiologists physical status should undergo cholecystectomy.[29] Frequently, however, critically ill patients with acute cholecystitis, particularly those with significant respiratory dysfunction or hemodynamic instability, may be too ill for cholecystectomy. Patients with grade II cholecystitis and poor performance status or with grade III disease may be better managed with image-guided or endoscopic drainage to obtain source control.

Image-Directed Drainage

Image-directed cholecystostomy has become a relatively low-risk procedure for patients with acute cholecystitis.[30] Some physicians have used percutaneous cholecystostomy as a diagnostic and therapeutic maneuver in ICU patients with persistent, unexplained sepsis, though its role in this setting remains unclear. Because the risk of this procedure is low, percutaneous cholecystostomy should be considered when the index of suspicion for acute cholecystitis is high enough in a critically ill patient.

Percutaneous cholecystostomy is contraindicated if the patient has evidence of diffuse peritonitis, suggesting gallbladder perforation. On the other hand, if imaging studies suggest a pericholecystic abscess, concomitant drainage of the abscess or surgical exploration is indicated.

Percutaneous cholecystostomy is performed under ultrasound or CT guidance. A needle is inserted into the gallbladder, usually via a transhepatic approach. The tract is dilated using a standard Seldinger technique. A pigtail catheter is advanced over the wire into the gallbladder. Some use a trocar technique instead. The catheter is then attached to a drainage bag.

Studies suggest up to 100% success with tube placement and clinical improvement, but mortality remains high, particularly with multiple comorbidities.[31] Given the risk for catheter-related complications over time, interval cholecystectomy or removal of the catheter should be considered once safe to do so, which can be considered once symptoms have resolved.[32,33]

There has been concern that the presence of ascites may increase the risk of complications, such as bile peritonitis or catheter dislodgement, from percutaneous cholecystostomies. Duncan and colleagues found no difference in procedural complications between patients with or without ascites, though patients with ascites underwent fewer delayed cholecystectomies and had greater mortality.[34]

Overall mortality for percutaneous cholecystostomy is variable depending on the presence of shock and other comorbidities.[32,35] The limiting factor for success of percutaneous drainage is the viability of the gallbladder. Focal ischemia or necrosis is unlikely to improve without cholecystectomy and predisposes the patient to perforation. Cholecystectomy should be considered in patients who do not improve with cholecystostomy.

In many cases, cholecystostomy may provide definitive management without the need for interval cholecystectomy, particularly with acalculous disease and with elderly patients.[36,37] Patients with calculous disease should generally undergo interval cholecystectomy. Optimal timing is unclear. Performing the interval cholecystectomy too early (perhaps $<$10 days after cholecystostomy placement) may be associated with greater difficulty and more frequent complications.[38] Others have found that early cholecystectomy (within 5 days of drainage) after percutaneous cholecystostomy can be safe and even advantageous.[39]

In some cases, percutaneous, transhepatic gallbladder aspiration in elderly or otherwise high-risk patients can provide clinical improvement with few complications and allow safe, delayed cholecystectomy.[40,41] On the other hand, some patients, particularly those with calculous disease and/or purulence in the gallbladder, seem to be at higher risk for recurrent cholecystitis before cholecystectomy.[42]

Whether or not percutaneous cholecystostomy is superior to cholecystectomy has been difficult to determine. One systematic review did not demonstrate benefit and, in fact, suggested worse outcomes with cholecystostomy.[43] Patients who undergo a percutaneous cholecystostomy may have a more prolonged inflammatory response and higher mortality.[44]

ENDOSCOPIC DRAINAGE

A novel technique for drainage of the gallbladder involves a transpapillary endoscopic approach.[45] This approach may be helpful if other indications for endoscopic evaluation or intervention are present. It seems that the intervention is more successful if the ultrasound demonstrates that the gallbladder is not severely distended or thick. Endoscopic ultrasound can also be used for transgastric or transduodenal placement of a stent into the gallbladder. The success rate for this approach seems to be similar to that of percutaneous cholecystomy,[46] possibly with fewer complications and need for fewer repeat procedures.[47,48]

Surgical Management

Surgical options include cholecystostomy and cholecystectomy. Surgical cholecystostomy can be accomplished via a small right subcostal incision using local anesthesia or via laparoscopy. This procedure largely has been supplanted by image-guided, percutaneous or endoscopic drainage.

Cholecystectomy may be advantageous compared with cholecystostomy, because it allows one to examine the entire right upper quadrant for other pathology and to completely drain any fluid collections around the gallbladder. It also alleviates the risk of gallbladder perforation. When cholecystectomy is performed, a laparoscopic approach can usually be attempted, recognizing that one may need to convert to an open procedure because of difficulty with the dissection. The timing of cholecystectomy for acute cholecystitis remains controversial, but cholecystectomy within the first 3 days, even in patients with severe cholecystitis, seems to be safe if the patient does not have other risk factors for mortality.[49] In a study of patients over 65 years of age with cholecystitis in the National Inpatient Sample, cholecystostomy was associated with greater mortality and morbidity than cholecystectomy, suggesting that unless the risk of cholecystectomy is clearly prohibitive, cholecystectomy is indicated.[50] On the other hand, age alone may not be an independent risk factor for complications after cholecystectomy.[51] If the patient is not responding to nonoperative management, cholecystectomy needs to be considered.

Though rarely done, bedside laparoscopy can be performed for evaluation of the acute abdomen in critically ill patients. If acute cholecystitis is identified, a cholecystostomy can be performed readily, or the patient can be taken to the operating room for a cholecystectomy.[52] If the diagnosis of cholecystitis is excluded, the patient may be spared an unnecessary operation.

Summary of Management

The TG18 guidelines include management bundles for patients with acute cholecystitis.[53] The diagnosis should be made expeditiously with imaging. If the findings are equivocal, repeat assessment is indicated every 6–12 hours until cholecystitis or an alternative diagnosis is confirmed. Early supportive care for critically ill patients with cholecystitis should focus on fluid resuscitation, bowel rest, analgesia, and antibiotics. The next steps are based upon the severity of cholecystitis (see Fig. 88.4). For patients at low risk for an operation, early laparoscopic cholecystectomy is recommended. For patients at high risk, urgent gallbladder drainage is more appropriate, though it has been difficult to prove this.[43] If the patient fails to improve after drainage, operative intervention should be considered. Transfer to a higher level of care should be considered in appropriate cases.

COMPLICATIONS AND OUTCOME

Complications of acute cholecystitis are much more common in critically ill patients than in the general population. Elderly patients are particularly at risk. Among patients with acalculous cholecystitis, gangrene is common.[9,17] Compared with patients without gangrene, those with gangrene are at greater risk of perforation or of failure of percutaneous drainage. Some of these patients have emphysematous cholecystitis, a diagnosis that carries an even greater risk of perforation. Emphysema can be identified by plain abdominal radiographs, CT, or ultrasound. In these cases, antibiotics should cover gas-forming anaerobic organisms. Although percutaneous drainage may be effective, early cholecystectomy is indicated if the patient does not improve promptly.

Perforation of the gallbladder occurs in up to 10% of cases.[54] Usually, the resulting fluid collection is localized and amenable to percutaneous drainage. Free perforation also can occur, and when it does, the risk of mortality is markedly increased. The clinical problem, however, is that preoperative imaging may not demonstrate evidence of perforation. The risk of perforation increases with delay in drainage or operation. Cholecystectomy is indicated for free perforation.

Empyema of the gallbladder also greatly increases mortality. This complication may be amenable to percutaneous drainage, but the risks of failure or perforation are substantial.

The risk of mortality from cholecystitis in the ICU mainly reflects the underlying disease processes and comorbidities, but may be as high as around 30%.[7,9]

PREVENTION

No intervention has been shown conclusively to prevent development of cholecystitis in ICU patients. If the theories regarding the pathophysiologic mechanisms are correct, the incidence of the disease should be reduced by aggressively resuscitating patients with shock, avoiding biliary stasis by implementing early enteral feeding, and minimizing the use of narcotics.

SUMMARY

The diagnosis of acute cholecystitis in critically ill patients is difficult because patients frequently do not present with the usual symptoms and signs. Laboratory tests are nonspecific. The best initial radiographic study is ultrasound. Scintigraphy and CT also may be helpful. Management includes antibiotics and bowel rest. Image-guided or endoscopic gallbladder drainage may be performed in unstable patients, although cholecystectomy remains the most definitive treatment if this intervention can be accomplished safely.

KEY POINTS

- Critically ill patients frequently do not present with the usual symptoms and signs of cholecystitis.
- Laboratory tests for cholecystitis are not specific.
- The best initial imaging study is ultrasound, but scintigraphy or CT may be needed as well.
- Management begins with antibiotics and bowel rest.
- Although cholecystectomy is the most definitive procedure, image-guided or endoscopic gallbladder drainage is indicated for patients too unstable to undergo cholecystectomy.

Acute Pancreatitis

Lillian L. Tsai and Pamela A. Lipsett

Acute pancreatitis is an inflammatory condition of the exocrine pancreas, the severity of which can range from mild edematous changes to severe acute necrotizing pancreatitis. Pancreatitis is one of the most common diseases requiring inpatient hospitalization with an incidence of 34 per 100,000 people worldwide.[1,2] In the United States the annual cost associated with treatment of acute pancreatitis has increased by 365% from 1997 to 2012, now accounting for more than $9.2 billion.[1,3] Mild acute pancreatitis is a self-limited process that usually resolves within several days to 1 week, rarely causes mortality, and is not associated with organ dysfunction or necrosis.[4,5] By definition, transient organ failure and local complications occur in moderately severe acute pancreatitis. Although 80% of patients have mild disease, 15%–20% develop severe pancreatitis, which is characterized by persistent organ failure.[5] Although the overall mortality rate for all patients with acute pancreatitis is very low, the mortality rate for severe acute pancreatitis can be over 30%.[1,6–9]

In the early phase of pancreatitis, which typically lasts about 1 week, pancreatic inflammation triggers cytokine cascades, which result in a systemic inflammatory response syndrome (SIRS). The late phase can last for many weeks to many months with persistence of multiple organ failure, local complications, and ongoing inflammation. A compensatory antiinflammatory response syndrome (CARS) is thought to contribute to the increased risk of infection.[4,9] There has been limited success in attempting to modify the course of the disease using agents such as protease inhibitors.[10,11]

Since the early 2000s, mortality associated with acute pancreatitis has decreased from 1.6% to 0.8%.[1,8] Most cases of pancreatitis that result in patient death are caused by infection of necrotic pancreatic tissue. Although there have been many improvements in management of pancreatitis, there remain many long-term sequelae of the disease. After an episode of acute pancreatitis, 40% of patients develop new-onset prediabetes or diabetes. Up to 25% develop exocrine pancreatic insufficiency and 8% chronic pancreatitis.[1] Therefore it is critical to optimize the prevention, diagnosis, and treatment of pancreatitis to improve patient outcomes.

This chapter delineates the etiology, pathophysiology, severity and staging, and current management of patients with acute pancreatitis.

ETIOLOGY AND EPIDEMIOLOGY

In the United States alone, pancreatitis accounts for over 270,000 hospital admissions annually.[12] It is the most common gastrointestinal discharge diagnosis and fifth leading cause of in-hospital mortality.[13] From 2002 to 2012 there has been a 16% increase in pancreatitis-related admissions.[8] The increasing incidence of pancreatitis, particularly in western countries, is conventionally thought to be associated with a rise in obesity and thus gallstone-related pancreatitis. To this point, recent studies have discovered more than a threefold increase in aspects of metabolic syndrome and morbid obesity among patients with pancreatitis.[8] However, in recent years the prevalence of chronic pancreatitis has increased markedly, suggesting that increasing hospitalization may be the result of recurrent flares of chronic pancreatitis.[8] Epidemiologically, the subgroup of acute pancreatitis patients with associated chronic pancreatitis had higher odds of alcohol and tobacco use, African American race, and lower socioeconomic background.[8] A greater proportion of these patients were admitted to urban teaching hospitals in the United States.

Risk factors for acute pancreatitis include smoking, alcohol use, age, family history, obesity, diabetes, inflammatory bowel disease, end-stage renal disease (ESRD), and possibly cannabis use.[13–18] Interestingly, there is a differential dose-response relationship between alcohol consumption and pancreatitis in women versus men. In men, the relationship between alcohol consumption and pancreatitis is linear, monotonically increasing with no threshold, whereas in women, the relationship is nonlinear and J shaped in which the risk of pancreatitis is increased only above 40 g per day of alcohol consumption.[13,16]

The most common etiology of acute pancreatitis is the result of gallstones, causing 40%–70% of cases.[5,8] Alcohol abuse accounts for 25%–35%, and hypertriglyceridemia causes 9% of cases of acute pancreatitis. The majority of alcoholic pancreatitis occurs in males.[19] Other causes of pancreatitis fall into several categories and are widely varied. These include trauma, medications, infectious agents, metabolic disorders, pancreaticobiliary tumors, genetic factors, autoimmune factors, and idiopathic factors. Traumatic insults to the pancreas can occur during procedures such as endoscopic retrograde cholangiopancreatography (ERCP), endoscopic ultrasound (EUS) with fine needle aspiration, aortic surgery, and pancreatic resection.[20] Medications known to cause pancreatitis include mercaptopurine, azathioprine, mesalamine, furosemide, and losartan.[1,5,21] Bacterial, viral, and parasitic infections can all trigger pancreatitis. Metabolic disorders of hypercalcemia and hyperparathyroidism are rare causes. In hypertriglyceridemia, only a triglyceride level above 1000 mg/dL has been found to be significant.[5] Tumors obstructing pancreatic drainage, including intraductal papillary mucinous neoplasms (IPMNs) and adenocarcinoma, also can cause pancreatitis. Genetic mutations in *PRSS1, SPINK, CFTR, CTRC,* and *CASR* have all been linked as well. Finally, anatomic anomalies of the pancreas such as pancreas divisum and sphincter of Oddi dysfunction predispose to pancreatitis. Identifying the etiology of acute pancreatitis is important to tailor diagnostic and treatment strategies.

PATHOGENESIS AND GENETIC SUSCEPTIBILITY

The main function of the exocrine pancreas is carried out by acinar cells, which are responsible for synthesizing, storing, and secreting digestive enzymes.[2] These enzymes are then transported to the small

intestine via ductal cells that secrete 2.5 L of alkaline, bicarbonate-rich fluid each day.[2,22] Although the pathogenesis of acute pancreatitis is complex and remains under active investigation, it is known that derangements in the molecular processes of these cells contribute to dysregulation. Normally, acinar cells secrete trypsinogen in an inactive precursor form that becomes activated to trypsin by serine protease enteropeptidases in the duodenum.[23,24] In turn, trypsin then activates chymotrypsinogens, proelastases, and carboxypeptidases and autoactivates additional trypsinogen. This process relies on normal functioning of cellular organelles.

Theoretically, premature activation of digestive enzymes is the inciting event that leads to pancreatitis.[25] Calcium signaling is tightly regulated by the endoplasmic reticulum of acinar cells because it serves as a messenger for the release of digestive enzymes.[2,23] Pathologic stimuli to the cell causes a transient spike in cytoplasmic calcium that becomes a sustained, global increase in calcium levels, replacing physiologic oscillations.[2,24,25] This calcium signal then activates calcineurin, which mediates activation of trypsinogen.[24] Simultaneously, the elevated calcium level affects mitochondrial membrane permeability, resulting in inability to produce adenosine triphosphate (ATP), increased reactive oxygen species, and triggering of apoptosis.[2]

Abnormal calcium signaling also precedes colocalization, or fusion, of lysosomal and zymogen components.[24] Trypsinogen is activated by the lysosomal enzyme cathepsin B in these intracellular vacuoles.[24,25] Impaired autophagy additionally leads to an imbalance between cathepsin B, which activates trypsinogen, and cathepsin L, which degrades trypsin.[2,24] The inappropriate activation of these digestive enzymes induces up-regulation and release of cytokines that contribute to local and systemic inflammation. Furthermore, activation of the NFκB pathway in acinar cells has recently been found to cause many downstream inflammatory effects.[22,25]

Certain proteins act to regulate trypsinogen and, when mutated, can predispose to pancreatitis. For instance, in normal pancreatic cells SPINK1 inhibits trypsin and CTRC mediates trypsinogen degradation.[23] Mutations in *PRSS1* prevent CTRC from functioning and thus cause hereditary pancreatitis. Although SPINK1 mutations have been found in many patients with pancreatitis, the expression and function of the protein do not seem to be affected in all variants.[23] Therefore the mechanism for predisposition to pancreatitis remains unclear.[26]

DIAGNOSIS

The diagnosis of pancreatitis can be made when two of the following three criteria are met: (1) abdominal pain, (2) serum amylase and/or lipase level over three times the upper limit of normal, and (3) imaging consistent with pancreatitis.[1,18,27] Symptoms of severe, persistent epigastric pain radiating to the back are most characteristic of pancreatitis. Oftentimes, this pain is associated with nausea and vomiting. Dull, colicky pain and lower abdominal pain are generally not consistent with pancreatitis and alternative diagnoses should be considered.[5]

On physical examination, upper abdominal tenderness is perceived and can be associated with guarding. Although not specific, Cullen and Grey Turner signs portend severe pancreatitis and high mortality rates up to 37%.[28,29] In both signs, pancreatic enzymes cause diffusion of fat necrosis that leads to inflammation and retroperitoneal hemorrhage. In Cullen sign, ecchymoses are seen in the periumbilical region via the round ligament, whereas in Grey Turner sign, ecchymoses are seen in the flanks via subcutaneous tissues.

Serum amylase and lipase are the most commonly used laboratory markers of acute pancreatitis. The upper limit of normal for amylase ranges from 100 to 300 U/L, and for lipase it ranges from 50 to 160 U/L.[1] Amylase levels usually elevate within the first few hours after onset of symptoms and return to normal in 3–5 days. However, serum amylase may remain normal in up to one-fifth of patients with pancreatitis and can be normal in those with alcohol abuse or hypertriglyceridemia.[5] Serum lipase is a more specific marker of pancreatitis and remains elevated for a longer period than does amylase.[5,27] After diagnosis, daily measurement of amylase or lipase has limited value.[27] Other disease processes that cause increased serum amylase include intestinal perforation or infarction, bowel obstruction, abdominal aortic aneurysm, appendicitis, cholecystitis, peptic ulcer disease, biliary obstruction, salivary gland diseases, and gynecologic conditions.[1,5] Serum lipase can also be elevated in intestinal pathologies, cholecystitis, peptic ulcer disease, and renal disease.[1,5] Additional laboratory values that can be useful in the clinical evaluation of acute pancreatitis include a complete blood count, electrolytes, blood urea nitrogen (BUN), creatinine, liver enzymes, coagulation tests, albumin, calcium, and triglycerides.[18,27]

Some studies have investigated the ability of urinary trypsinogen-2 to diagnose acute pancreatitis. Overall, dipstick urinary trypsinogen-2 has been found to rule out acute pancreatitis with high probability and identify patients who should be further evaluated. It may be useful as a screening test because of its reported high negative predictive value.[30–33]

SEVERITY AND SCORING

The ability to distinguish patients at high risk of morbidity and mortality from pancreatitis is important to guide management decisions. To this end, over 20 different scoring systems for acute pancreatitis have been developed.[34] One of the most commonly described scoring systems is the Ranson criteria, which have a sensitivity of 75%, specificity of 77%, positive predictive value of 49%, and negative predictive value of 91% for predicting severe acute pancreatitis (Table 89.1).[35] Ranson criteria assesses 11 factors (2 clinical components and 9 laboratory values) at the time of patient presentation and at 48 hours after admission. The score ranges from 0 to 11, with a score of <3 associated with a mortality of 0%–3%, a score of ≥ 3 associated with a mortality of 11%–15%, and a score of ≥ 6 conferring a 40% chance of mortality.[34,36] One major weakness of Ranson criteria is that the score can

TABLE 89.1 Pancreatitis Scoring Systems

Name of Scoring System	Number of Variables	Sensitivity	Specificity	PPV	NPV
Ranson Criteria	11	75%–82%	74%–77%	48%	93%
APACHE II	12	58%–81%	72%–78%	43%–63%	84%–86%
BISAP	5	51%–62%	72%–91%	25%	93%

From Refs. 35,37,38–40.
NPV, Negative predictive value; *PPV,* positive predictive value.

only be calculated after 48 hours, when many early interventions have already been determined.

The Acute Physiologic and Chronic Health Evaluation (APACHE) score originated as an intensive care unit (ICU) scoring method. Early iterations, APACHE II and III, have been used as established prognostic indicators in acute pancreatitis. The latest version, APACHE IV, is highly accurate in predicting ICU mortality. It takes 52 variables into consideration, including bilirubin, albumin, sedation status, and chronic health problems. Limited studies have validated APACHE IV as a valuable system to predict mortality associated with acute pancreatitis.[35,37] However, further investigation is needed, and the latest version is proprietary.

The Bedside Index for Severity in Acute Pancreatitis (BISAP) is a tool that evaluates and identifies patients who are at high risk of mortality within the first 24 hours of hospital admission.[38] It is scored out of 5 points, with each of the following variables conferring 1 point: BUN >25 mg/dL, impaired mental status, SIRS, age >60, and presence of a pleural effusion.[39] When compared with Ranson criteria and APACHE II, BISAP had higher specificity but lower sensitivity for mortality and severe acute pancreatitis.[39] BISAP is able to predict poor outcomes before the onset of organ failure.[38]

An imaging-based scoring system is Balthazar's computed tomography (CT) index that uses early scan characteristics such as pancreatic necrosis and peripancreatic inflammation to predict the severity of pancreatitis. A high index of 7–10 points confers a 92% morbidity and 17% mortality rate, whereas a low index of 0–2 points only had a 2% morbidity and no mortality.[40]

Various serum biomarkers have been suggested as predictors of severity for pancreatitis. In particular, increased admission hematocrit (≥44) and failure of hematocrit to decrease after 24 hours is thought to be associated with necrotizing pancreatitis. The third spacing of fluids caused by inflammation reduces intravascular volume and is reflected by the hematocrit.[36] Additionally, C-reactive protein (CRP) levels greater than 150 mg/L in the first 72 hours are associated with pancreatic necrosis, with a sensitivity and specificity of over 80%. Other laboratory values such as procalcitonin, trypsinogen-2, amyloid A, and urinary trypsinogen have also been investigated as predictive markers.[36]

The 2012 revision to the Atlanta Classification changed the definition of acute pancreatitis severity. In the updated version, pancreatitis is divided into mild, moderately severe, and severe.[4,9,18] Mild pancreatitis has no organ failure or complications, a self-limited course, and usually results in discharge within 7 days. Moderately severe pancreatitis shows transient organ failure, may have local and systemic complications, and has a greater risk of mortality. Severe acute pancreatitis is characterized by persistent organ failure (>48 hours), local and systemic complications, and a mortality of greater than 30%.[4,18] This classification recommends the modified Marshall scoring system to assess organ failure, which evaluates the respiratory, cardiovascular, and renal systems. Persistent organ failure is defined as a score of 2 or higher in any of the three organ systems for longer than 48 hours. The score is determined using laboratory and physiologic variables.[4,9] Although there are numerous scores aimed at identifying pancreatitis patients who are at high risk of mortality, early clinical recognition and treatment remains the cornerstone of prudent management.

IMAGING

Ultrasonography and Endoscopic Ultrasonography

Because of its noninvasive nature, transabdominal ultrasound is recommended in the first 24 hours for all patients with acute pancreatitis.[5,44–46] In acute pancreatitis, ultrasound examination can show diffuse enlargement and a hypoechoic echotexture from glandular edema. However, assessment of the pancreas is often limited as a result of overlying bowel gas. Therefore the primary function of ultrasound is in identification of gallstones and biliary ductal dilatation or choledocholithiasis. Ultrasound has a 70% sensitivity in detecting gallstones for patients with acute biliary pancreatitis, whereas it only has a 20% sensitivity in detecting choledocholithiasis. CT and magnetic resonance cholangiopancreatography (MRCP) have sensitivities of 40% and 80%, respectively.[45]

EUS is highly sensitive for the identification of choledocholithiasis, with accuracy similar to that of ERCP.[47] As a bedside procedure, EUS can be used to determine the need for ERCP in high-risk, pregnant, or critically ill patients and those with coagulopathy or unusual anatomy.[36]

COMPUTED TOMOGRAPHY

CT is the gold standard in the diagnosis of acute pancreatitis and its complications. When contrast is used, CT has over a 90% sensitivity and specificity for acute pancreatitis.[5] CT can reliably identify interstitial pancreatitis, necrotizing pancreatitis (Fig. 89.1), acute peripancreatic fluid collections, acute necrotic collections, walled-off necrosis (Fig. 89.2), and pseudocysts.[44] Interstitial pancreatitis

Fig. 89.1 Pancreatic necrosis.

Fig. 89.2 Walled-off necrosis and perisplenic fluid.

shows uniform enhancement of the pancreas because of intact microcirculation, whereas necrotizing pancreatitis shows devitalized areas that do not enhance as a result of disturbances in the microcirculation.[36] Other complications visualized by CT include portal or splenic vein thrombus, abscess, pseudoaneurysm, colonic inflammation, and gastrointestinal (GI) tract obstruction from strictures or compression.[36,44]

Although CT is valuable in the assessment of acute pancreatitis, routine use is not recommended.[5,18,36,46] CT should be performed when the diagnosis is unclear to distinguish acute pancreatitis from other conditions causing abdominal pain, or when patients fail to clinically improve in the first 48–72 hours.[18,36,48] The best time for CT is after 72 hours to evaluate for local complications with additional scans if there is a change in clinical status.[21,47] CT is also recommended when patients older than 40 years present with a first episode of acute pancreatitis to exclude neoplasm. Patients exhibiting alarm signs of weight loss, recent diabetes diagnosis, and a history of tobacco use may also warrant a CT scan.[46]

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

ERCP is used in acute pancreatitis to treat common bile duct stones. Patients with acute cholangitis and severe pancreatitis should undergo ERCP in the first 24 hours. ERCP is also used in patients who are poor surgical candidates for cholecystectomy, certain cases post-cholecystectomy, and those with persistent biliary obstruction.[36] It is unnecessary to perform ERCP routinely before cholecystectomy. Because most gallstones causing pancreatitis pass naturally, ERCP is not recommended in biliary pancreatitis patients without laboratory and clinical evidence of ongoing obstruction.[5] Three recognized interventions decrease the risk of post-ERCP pancreatitis. The first is guidewire cannulation of the bile and pancreatic ducts to avoid hydrostatic injury from radiocontrast administration.[5] Other studied measures to reduce post-ERCP pancreatitis rates are insertion of pancreatic duct stents and rectal nonsteroidal antiinflammatory drugs (NSAIDs).

MAGNETIC RESONANCE CHOLANGIOPANCREATOGRAPHY

Magnetic resonance imaging (MRI) and cholangiopancreatography (MRCP) are comparable to CT when evaluating pancreatitis and offer certain advantages. MRCP has a sensitivity of 89%–100% and specificity of 83%–100% for gallstones, with an ability to detect choledocholithiasis down to a size of 3 mm.[5,44] Selective use of MRCP can thus decrease the need for ERCP. In addition, MRCP is excellent in delineation of fluid collection composition. MRCP has 100% sensitivity for the detection of solid debris and therefore can reliably distinguish between pseudocysts and necrotic or superinfected collections.[36,45,47,48] MRI is also more effective than CT in detecting pancreatic hemorrhage and pancreatic ductal anomalies, including anatomic variations, strictures, and disruptions.[46,49] MRCP with secretin administration improves image quality and allows for assessment of pancreatic excretory function.[50]

Further benefits of MRI include no radiation exposure and lack of nephrotoxicity from use of gadolinium. Patients who are pregnant, have a contrast allergy, or have renal insufficiency can undergo MRI safely.[5,36,44,45] However, there are disadvantages to MRI as well. There is a greater variation in image quality among different centers, difficulty managing critically ill patients during MRI, and relative lack of availability.

MANAGEMENT

General Support

Monitoring and Resuscitation

Upon admission for acute pancreatitis, hemodynamic and clinical status should be assessed for risk stratification.[5] Patients who meet one or more of the following parameters defined by the Society of Critical Care Medicine (SCCM) should be admitted to the ICU: heart rate <40 or >150 beats/minute, systolic arterial blood pressure <80 mm Hg, mean arterial pressure <60 mm Hg, diastolic arterial pressure >120 mm Hg, respiratory rate >35 breaths/minute, sodium <110 mmol/L or >170 mmol/L, potassium <2 mmol/L or >7 mmol/L, PaO_2 <50 mm Hg, pH <7.1 or >7.7, glucose >800 mg/dL, calcium >15 mg/dL, anuria, or coma.[12] Patients with persistent organ failure and thus severe acute pancreatitis as defined by the revised Atlanta Classification should also be admitted to the ICU.[5,12] Management in a high-volume institution with intensive care facilities, ability to carry out organ replacement therapy, daily access to interventional radiology, performance of EUS/ERCP, and surgical expertise is recommended for patients who may need those specialties and for those with severe acute pancreatitis.[12]

Fluid resuscitation is the foundation of acute pancreatitis management. Pancreatitis causes a state of hypovolemia caused by third spacing, emesis, reduced oral intake, and increased respiratory losses.[5,51] This leads to microangiopathic effects and glandular edema, which reduce blood flow and impair microcirculatory perfusion of the pancreas.[5,51,52] Tissue ischemia then triggers release of cytokines, increased capillary permeability, and endothelial damage, all ultimately resulting in cell death and necrosis.[5,52] Therefore the hypovolemic state is thought to play a major role in the transition from mild to severe acute pancreatitis with SIRS and organ failure.[52]

Early, goal-directed intravenous (IV) fluid resuscitation at a rate of 5–10 mL/kg/hr should be given initially.[12,21] In most patients, a total of 2.5–4 L in the first 24 hours will be sufficient to accomplish resuscitation goals. Fluid needs should be frequently assessed in the first 6 hours and for 24–48 hours after admission.[5,12,52] Patients with severe volume depletion who are tachycardic or hypotensive may need additional fluid boluses. Response to resuscitation should be monitored with noninvasive clinical parameters, including heart rate <120 beats/minute, mean arterial pressure of 65–85 mm Hg, and urine output >0.5–1 mL/kg/hr. Invasive clinical targets include stroke volume variation and intrathoracic blood volume assessment. Biochemical measurements should also be considered, with a hematocrit goal of 35%–44%, decreasing BUN, and normalizing creatinine as positive signs.[5,12,52] In elderly patients and those with cardiac or renal disease, fluid should be given more cautiously to avoid adverse effects of volume overload such as abdominal compartment syndrome and pulmonary edema.[5]

Although fluid resuscitation is vital and associated with decreased rates of organ failure and in-hospital mortality, overly aggressive therapy can be detrimental. One study compared fluid rates of 5–10 mL/kg/hr with 10–15 mL/kg/hr and found higher rates of infectious complications and mortality in the latter group.[12,53,54] Another study found that rapid hemodilution with a hematocrit of less than 35% was also more frequently associated with infection and mortality.[54,55]

Finally, there has been debate on the optimal fluid that should be used for resuscitation. The International Association of Pancreatology (IAP) and American Pancreatic Association (APA) recommend lactated Ringer's (LR), whereas the American Gastroenterological Association (AGA) makes no recommendation on normal saline versus LR.[12,21] Several studies suggest that LR may be preferred over normal saline.[5,56,57] A randomized controlled trial of 40 patients with acute pancreatitis showed that patients resuscitated with LR had a significantly

lower prevalence of SIRS and lower CRP levels (mean CRP 51 mg/L versus 104 mg/L) compared with those resuscitated with normal saline. Use of LR was associated with a smaller decrease in serum bicarbonate, suggesting a pH-mediated reduction of inflammation.[56] Other studies have suggested that LR has direct antiinflammatory properties via inhibition of macrophages and NFκB.[51,58] Hydroxyethyl starch is discouraged as a resuscitative fluid because of increased mortality and higher rates of renal failure.[12]

In a general critical care patient population, there is a theoretical concern that the high chloride level in normal saline may cause a greater risk of acute kidney injury. However, the SPLIT trial was a randomized double-crossover trial that showed no difference in acute kidney injury, failure, or mortality among patients receiving normal saline compared with buffered crystalloid.[59] The subsequent SALT trial similarly found no overall difference in acute kidney injury between critically ill patients receiving normal saline versus balanced crystalloids.[60] Interestingly, patients who required larger volumes of saline had an increased risk of major adverse kidney events, suggesting a possible dose-response relationship.

PULMONARY DYSFUNCTION

Acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) occur in 10%–25% of acute pancreatitis cases and are responsible for up to 60% of pancreatitis-associated mortality.[61–63] Pulmonary complications of acute pancreatitis are the most common and potentially the most perilous.[63,64] SIRS in acute pancreatitis causes increased pulmonary endothelial permeability, with leakage of exudate into the alveolar space and interstitial tissues.[61,62] This leads to alveolar damage, type I pneumocyte necrosis, release of cytokines, and leukocyte infiltration, all of which injure the lung parenchyma and compromise gas exchange.[61] Furthermore, pancreatic autodigestion releases phospholipase A2 into the circulation, where it travels to the lung and degrades surfactant.[62,64] Acute pancreatitis also increases production of platelet-activating factor, pancreatic elastase, and proteases that damage lung tissue. These multifactorial effects of acute pancreatitis on the lung cause hypoxia from a ventilation perfusion mismatch via right-to-left intrapulmonary shunting.[64]

In this setting of ALI, the addition of a secondary gram-negative infection serves as a predisposing factor for the development of ARDS. The compromised intestinal barrier in acute pancreatitis allows for translocation of gut bacteria and endotoxins.[61,62] Severe respiratory compromise and multiple organ failure can then occur. Other pulmonary complications include atelectasis, pleural effusion particularly on the left side from lymphatic obstruction, and pancreaticopleural fistulae from pancreatic duct disruption.[64]

PULMONARY MANAGEMENT

It is imperative to monitor oxygenation status and diligently observe for signs of respiratory failure in patients with acute pancreatitis. Supplemental oxygen should be provided as needed. Treatment of pleural effusions should be conservative unless symptomatic, in which case thoracentesis or tube thoracotomy may become necessary.[64] Some patients, particularly those who have developed ARDS, will require endotracheal intubation and mechanical ventilation.

Limited studies have shown that noninvasive positive-pressure ventilation (NIPPV) can be an effective option for the treatment of ARDS in the setting of acute pancreatitis.[65,66] One retrospective cohort study found that NIPPV was successful in all pancreatitis patients with mild ARDS, 49 of 64 patients with moderate ARDS, and 10 of 19 patients with severe ARDS.[65] There were significant improvements in oxygenation and decreases in heart rate and respiratory rate after NIPPV use in patients who did not require ventilation. Another study similarly suggested that NIPPV increases lung volume by re-expanding collapsed alveoli and redistributing extravascular fluid in the lung.[66] Together, these results suggest that NIPPV may decrease the need for intubation if administered early in the clinical course of respiratory distress. Success of NIPPV is dependent on clinician experience and patient compliance. In particular, one should cautiously use NIPPV in patients with nausea and vomiting for fear of aspiration. The positive pressure of NIPPV can also cause gastric distension, which reduces functional residual capacity of the lung.[67]

PAIN RELIEF

Pain is one of the main symptoms of acute pancreatitis and should be effectively controlled. There is very limited evidence to support the use of one type of analgesic over another. In a systematic review, buprenorphine, pentazocine, and metamizole showed relatively superior efficacy.[68] Buprenorphine was able to specifically reduce pain in acute pancreatitis. Morphine theoretically may cause spasms in the sphincter of Oddi, but there is no clinical evidence to recommend avoiding its usage.[54] NSAIDs have a favorable safety and efficacy profile. In a comparison of nine randomized controlled trials, there was no evidence to support the use of parenterally administered local anesthetics.[54] Patients with severe pain should be given IV analgesia. Patient-controlled analgesia and epidural analgesia are both viable options as well. A Cochrane review assessed multiple agents and concluded that opioids may decrease the need for supplementary analgesia. There was no difference in complications or adverse events between opioids and nonopioids.[51,69] One study found that opioid analgesia was associated with a significantly increased risk of GI dysmotility and cautioned overuse to prevent delays in oral intake.[51,70] Overall, there is no consensus on the optimal analgesic regimen, agent, or method of administration. Pain in acute pancreatitis should be treated adequately, with adjustments made as needed for patient comfort.[71]

SPECIFIC SUPPORT

Nutrition

Traditionally, it was thought that patients with pancreatitis should remain nil per os to allow for the inflamed organ to recover. However, recent studies suggest that maintenance of enteral nutrition can help protect the intestinal mucosal barrier. Current guidelines recommend early feeding in acute pancreatitis. The IAP/APA state that oral feeding can be started in mild pancreatitis once abdominal pain improves and inflammatory markers are down-trending, without a need to wait for normalization.[12,72] In mild pancreatitis, instituting a normal, solid diet is safe and has been shown to correlate with shorter hospitalizations.[73–75] The AGA recommends feeding within 24 hours of admission. Their review analyzed 11 randomized controlled trials comparing early versus delayed feeding and found a 2.5-fold increase in risk of interventions for necrosis in the delayed feeding group. There were also trends towards higher rates of organ failure and necrotizing pancreatitis.[76]

Multiple studies have shown that patients who initiate early enteral nutrition have improved outcomes.[77] In one study, delayed enteral nutrition was found to be associated with increased mortality and rates of infected necrosis, fluid collections, respiratory failure, and ICU admission.[78] Another study examined inflammatory markers in severe acute pancreatitis patients receiving enteral nutrition within 48 hours versus 8 days after admission. Laboratory CRP levels and CD4+

T-lymphocyte percentages were lower in the early feeding group, suggesting a moderating effect on the immune response. Clinical outcomes, including organ dysfunction, SIRS, and pancreatic infection, were all lower in the early enteral nutrition group.[79] A meta-analysis of 11 studies with 775 total patients similarly indicated that enteral feeding within 48 hours reduced the risk of infectious complications, catheter-related septic complications, hyperglycemia, length of stay, and mortality. A stratified analysis based on severity showed that early feeding was superior in severe pancreatitis as well.[80] Further, three additional studies showed gastrointestinal symptoms of feeding intolerance, nausea, and vomiting occurred at a lower rate among patients who received early feeding.[75]

Despite these studies, the recent Dutch PYTHON trial results do not support the current guidelines recommending early initiation of enteral feeding.[81] This was a multicenter randomized controlled trial of 208 patients at high risk for complications according to APACHE II, Imrie score, or CRP level. Patients were randomized to receive nasoenteric tube feeding within 24 hours or an oral diet 72 hours after presentation, with tube feeding if intolerant of an oral diet. There was no difference between the two groups in rates of major infection or death. A later study compared enteral nutrition within 24 hours with no nutritional support and found no reduction in SIRS, organ failure, or mortality.[82] There are many possible explanations for this discrepancy, and further studies may be needed to clarify the extent to which early feeding affects infection rates.

In pancreatitis patients who need nutritional support, enteral is recommended over parenteral feeding.[12,76,83] Parenteral nutrition causes gut atrophy and increased intestinal permeability. The lack of peristaltic action also leads to disturbances in the microflora.[77] All reviews and meta-analyses comparing enteral versus parenteral nutrition show that enteral feeding decreases rates of organ failure and infection.[12,71,76,77,84–87] Additionally, some studies showed a marked reduction in mortality, with a 4% rate in patients receiving enteral and 15.9% in those receiving parenteral nutrition.[77,85] A Cochrane review of eight trials comprising 348 patients showed reduced mortality, organ failure, systemic infection, need for operative intervention, and a trend towards shorter length of stay for pancreatitis patients receiving enteral nutrition.[71,84] Similar results are seen in the subset of critically ill patients with severe pancreatitis as well.[86] If oral and enteral tube feeding are not tolerated, parenteral nutrition should be used.

When enteral feeding is given, it may be administered using either a nasogastric (NG) or nasojejunal (NJ) route.[12,16,76] There have been three notable randomized controlled trials comparing NG and NJ feeds.[71,88–91] All of these have found that enteral nutrition is well tolerated via both NG and NJ routes in severe acute pancreatitis with no significant clinical differences. Neither route is associated with differences in pain, infectious complications, discharge, surgical need, or mortality.[89,90] A meta-analysis examining these three trials compiled a total of 157 patients and found no difference in tracheal aspiration, diarrhea, pain level, achievement of energy goals, or mortality.[88] One study showed that NG delivery of enteral feeds was efficacious, with 90% receiving only NG nutrition and 92% reaching nutritional targets. Patients receiving feeds via NG and NJ had similar rates of changing to parenteral nutrition. Vomiting and diarrhea were the most common adverse effects of NG feeds.[92] Caution should be taken in pancreatitis patients with delayed gastric emptying and intolerance of feeds to avoid aspiration risk.

PATHOGENESIS OF PANCREATIC INFECTION AND ANTIBIOTIC PROPHYLAXIS

Secondary infections cause over 80% of pancreatitis-related deaths.[93] Patients with infected pancreatic necrosis have double the risk of death, three times higher rate of organ failure, and are four times as likely to require ICU admission compared with patients with sterile necrosis.[94] The large majority of pathogens involved in pancreatic infection are gram-negative enteric bacteria such as *Escherichia coli, Pseudomonas, Proteus,* and *Klebseilla*.[93,95] Infection with gram-positive organisms, including *Staphylococcus aureus, Streptococcus faecalis,* and *Enterococcus,* anaerobes, and fungi have also been identified.

The pathogenesis of secondary infection is thought to occur either hematogenously, ascending from the duodenum and biliary system through the pancreatic duct, or via translocation of GI bacteria.[93] Impairment of the gut barrier from reduced intestinal blood flow, mucosal damage, and epithelial atrophy during acute pancreatitis leads to greater mucosal permeability.[95] In patients with severe acute pancreatitis, there are significant increases in intestinal permeability to both macromolecules and micromolecules. This change was found within 72 hours of onset and was correlated with poor clinical outcomes. In addition to facilitating bacterial translocation, intestinal permeability corresponded with systemic endotoxin levels. Endotoxin exposure has negative effects on immune function and causes release of cytokines. Together, these processes predispose patients to fatal secondary pancreatic infections.

There has been much debate and many conflicting studies on the use of prophylactic antibiotics to prevent infectious complications during acute pancreatitis. Currently, the guidelines from multiple organizations and studies do not recommend the routine use of antibiotic prophylaxis.[12,16,76] Some studies have found that early use of antibiotics, within 72 hours of symptom onset, reduces mortality and secondary infection.[96] However, multiple meta-analyses over the years have found no difference in outcomes.[97] One meta-analysis of 14 randomized controlled trials with a total of 841 patients showed that antibiotic prophylaxis was not associated with reduction in mortality, incidence of infected necrosis, nonpancreatic infections, or surgical interventions.[98] A more recent review examined 18 meta-analyses of randomized controlled trials between 1998 and 2015.[93] The authors found that 6 of 18 studies showed reduced mortality with prophylactic antibiotics, and 12 of 18 studies had no change in mortality. Based on these results, use of antibiotics is recommended only once there are clinical signs of infection or elevated inflammatory markers on laboratory testing.[93] Interestingly, a Cochrane meta-analysis of seven studies found that when imipenem specifically was used, there was a significant decrease in rates of pancreatic infection. When beta-lactams in general were used, there was a trend towards lower mortality (9.4% versus 15%) and infected pancreatic necrosis (16.8% versus 24.2%), but the results were not statistically significant.[99]

Overall, prophylactic antibiotics have no impact on mortality, risk of infection in pancreatic necrosis or nonpancreatic sites, rate of organ failure, and hospital length of stay.[76] When infection is suspected, antibiotics should be given promptly. Selective gut decontamination may be promising in preventing infectious complications, but further characterization is needed.[12] Probiotic prophylaxis is also not recommended.[12,100,101]

MANAGEMENT OF PANCREATIC NECROSIS AND ABSCESS

Infected pancreatic necrosis is suspected based on clinical and imaging signs. The demonstration of gas in pancreatic or peripancreatic collections on contrast-enhanced CT scan is the strongest indicator of infection.[102,103] Clinical deterioration, persistent fevers, elevated inflammatory markers, and bacteremia are all signs of infected necrosis as well.[12] When these elements are identified, broad-spectrum IV antibiotics

should be initiated. Agents with adequate pancreatic penetration include quinolones, metronidazole, carbapenems, and third-generation or higher cephalosporins.[103] Fine needle aspiration (FNA) can also be used to diagnose infected necrosis or to tailor antibiotic therapy to specific bacteria. However, routine use of FNA is unnecessary and not recommended. There is a high false-negative rate and a small risk of contaminating a previously sterile fluid collection.[102,103]

LABORATORY MARKERS OF INFECTED NECROSIS

Several laboratory values have been shown to provide prognostic value in pancreatic necrosis. CRP at 48 hours after admission is an indicator of severe acute pancreatitis, pancreatic necrosis, and in-hospital mortality.[104] Daily measurement of procalcitonin is used to predict infected pancreatic necrosis. The highest value, in addition to a sustained increase in procalcitonin on serial measurements, are able to identify patients who are likely to develop infected necrosis.[105] One study found that procalcitonin, hematocrit, BUN, and CRP all independently served as risk factors for infected pancreatic necrosis. Individually, these markers had high specificity but low sensitivity. When taken together, the maximum level at 48 hours of these four values had a sensitivity of 67.8% and specificity of 77.3% for infected pancreatic necrosis.[106]

INDICATION AND TIMING OF INTERVENTION

In necrotizing pancreatitis, intervention is indicated when there is suspicion or evidence of infected tissue and a decline in clinical status. Intervention may also be necessary in the absence of documented infection when there is prolonged organ failure.[12,102] In sterile necrotizing pancreatitis, intervention is warranted with (1) ongoing gastric, intestinal, or biliary obstruction; (2) persistent systemic symptoms such as weight loss, anorexia, and pain; and (3) disconnected pancreatic duct syndrome. Other rarer indications for intervention include abdominal compartment syndrome, bowel ischemia, and acute hemorrhage.

Generally, invasive measures should ideally be delayed until 4 weeks after initial onset of pancreatitis to allow for necrotic collections to liquefy and become encapsulated or walled off.[12,102,103,107] This reduces the risk of adverse events and has been shown to decrease morbidity and mortality.[103,107]

INTERVENTIONAL PROCEDURES

When intervention for infected necrosis becomes necessary, the step-up approach is currently the standard of care.[12] The optimal initial strategy is percutaneous catheter drainage followed by minimally invasive retroperitoneal necrosectomy if catheter drainage fails. In the landmark PANTER trial, 88 patients with suspected or confirmed infected necrotizing pancreatitis were randomized to receive either an open necrosectomy or the step-up approach.[108] The composite endpoint of major complications or death was lower in the step-up group (40% versus 69%). Patients in the step-up group also had a lower rate of multiple organ failure (12% versus 40%), incisional hernia (7% versus 24%), and new-onset diabetes (16% versus 38%). Notably, of the patients randomized to the step-up group, 35% were adequately treated with percutaneous drainage alone.[103,108]

A long-term follow up study of the PANTER trial reassessed all 73 patients who were alive at an average of 86 months after admission. At this time, the rate of death or major complications was 44% in the step-up group and 73% in the open necrosectomy group.[109] In the step-up group there was a lower incidence of incisional hernias (23% versus 53%), pancreatic exocrine insufficiency (29% versus 56%), and endocrine insufficiency (40% versus 64%). There was no significant difference in incidence of patients requiring pancreatic surgery, additional procedures, chronic pancreatitis, recurrent acute pancreatitis, pain scores, or medical costs. Thus the step-up approach with supportive management and percutaneous catheter drainage is recommended as the initial intervention for infected necrotizing pancreatitis.

When catheter drainage is unsuccessful, the tract can guide entry for video-assisted retroperitoneal debridement (VARD). In this procedure, laparoscopic instruments are used to access the retroperitoneal space and debride necrotic tissue under direct visualization. Minimally invasive necrosectomy has been found to decrease the incidence of multiple organ failure, complications, and mortality compared with open necrosectomy.[107]

NECROSECTOMY

The overarching goals of operative debridement in necrotizing pancreatitis are to achieve source control and to reduce the burden of necrotic tissue.[103] Classically, open surgical necrosectomy is performed via midline laparotomy or bilateral subcostal incisions. The greater omentum is opened to gain entry into the lesser sac and expose the pancreas. Blunt fragmentation is then used to remove necrotic tissue.[110] Cholecystectomy can be performed concurrently in cases of biliary pancreatitis. Large-bore drains are then left before closure.[103] Open necrosectomy has a complication rate of 34%–95% and a mortality rate of 11%–39%.[107] Patients undergoing this procedure often have more severe disease and a large amount of necrosis. Indications for open surgical intervention include failure of the step-up approach, abdominal compartment syndrome, bowel ischemia, and perforation.[102]

Endoscopic interventions can be done to drain collections transduodenally or transgastrically. Endoscopic ultrasound is used to guide transmural entry. Self-expandable metal stents or plastic stents may be placed into the necrotic cavity. Direct endoscopic necrosectomy involves using an endoscope to mechanically debride infected tissue.[103] Disadvantages to this approach include the risk of intracavitary bleeding, perforation, and air embolism. Antibiotic lavage and hydrogen peroxide irrigation are complementary therapies that can be used during endoscopic intervention as well.

In the recently conducted TENSION trial, 98 patients with suspected or confirmed pancreatic necrosis were randomized to a surgical or endoscopic step-up approach.[111] The endoscopic arm started with EUS-guided transluminal drainage followed by endoscopic necrosectomy. The surgical group received percutaneous catheter drainage followed by VARD. No patients underwent open necrosectomy. The primary endpoint of major complications or death occurred in 43% of the endoscopic group and 45% of the surgical group. The rate of pancreatic fistulae and hospital length of stay were lower in the endoscopic group. This study concluded that the endoscopic step-up approach was not superior to the surgical step-up approach. However, because of their less invasive nature, endoscopic approaches may be reasonable to consider as initial treatment options if local expertise is available to safely perform these interventions.

OUTCOME

With the increasing survival of acute pancreatitis patients, it has become important to analyze long-term outcomes and quality of life. One study examined 91 patients at 14 months after admission for acute pancreatitis.[112] Physical health–related quality of life was

significantly impaired after acute pancreatitis compared with control patients, independent of factors including age, gender, race, smoking status, alcohol consumption, body mass index (BMI), and comorbidities. The decrease in mental health–related quality of life normalized within 1 year of follow-up. Multiple organ failure during admission along with abdominal pain, analgesic use, and smoking at follow-up were all associated with decreased physical health–related quality of life.[112] Another study analyzed 113 patients with acute pancreatitis and found that 59% developed diabetes or impaired glucose tolerance. A smaller proportion developed exocrine pancreatic insufficiency, 6% severe and 29% mild to moderate.[113] These studies suggest that modifiable factors should be identified and optimized to improve long-term outcomes of acute pancreatitis.

SUMMARY

Acute pancreatitis is a disease of increasing incidence and cost. Although most cases of acute pancreatitis are mild and self-limited, the mortality in severe acute pancreatitis can be over 30%. Patients with severe acute pancreatitis often require intensive care, including aggressive fluid resuscitation, nutritional support, respiratory management, and therapy for multiple organ failure. In patients with declining clinical status, persistent fevers, and signs of SIRS, infected pancreatic necrosis should be suspected. The step-up approach should be used with percutaneous catheter drainage as initial treatment and escalation to minimally invasive debridement as needed. Endoscopic techniques have shown promise and may be considered in expert centers.

KEY POINTS

- Severe acute pancreatitis accounts for 15%–20% of patients with acute pancreatitis and has a mortality of over 30%.
- The early phase of severe acute pancreatitis is characterized by a pronounced SIRS response followed by organ failure, often requiring intensive support.
- The most common etiologies of acute pancreatitis are gallstones (40%–70%), alcohol abuse (25%–35%), and hypertriglyceridemia (9%).
- Acute pancreatitis is diagnosed when two of the following three criteria are met: (1) abdominal pain, (2) serum amylase and/or lipase level over three times the upper limit of normal, and (3) imaging consistent with pancreatitis.
- Ultrasound is recommended in all patients with acute pancreatitis. Contrast enhanced CT is the gold standard for the diagnosis of pancreatitis and its complications. However, its routine use is not recommended and should be performed in patients with unclear diagnoses or clinical worsening. ERCP should be performed in patients with acute cholangitis or evidence of ongoing obstruction. MRCP is useful in particular patient populations and for detailed imaging of the ductal system and for distinguishing composition of fluid collections.
- Fluid resuscitation is the cornerstone of acute pancreatitis management. Early, goal-oriented IV fluid resuscitation at a rate of 5–10 mL/kg/hr should be given, with heart rate, mean arterial pressure, and urine output used to measure adequacy of response.
- Early feeding should be instituted to protect the intestinal mucosal barrier once abdominal pain is improving and inflammatory markers are downtrending. Enteral feeding is recommended over parenteral feeding and may be administered via NG or NJ routes.
- Over 80% of pancreatitis-related deaths are attributable to secondary infections. Prophylactic antibiotics are not recommended because they do not improve mortality, risk of infection, or other clinical outcomes.
- When infected pancreatic necrosis is suspected or confirmed, IV antibiotics should be promptly initiated. Interventions should be delayed for 4 weeks after initial onset to allow for collections to become walled off. The step-up approach is standard of care, with percutaneous drainage as the initial therapy and minimally invasive retroperitoneal necrosectomy to follow as needed. Endoscopic interventions can also be performed in skilled centers and are being investigated as a safe alternative to classical surgical interventions.

Abdominal Sepsis

Scott Brakenridge and Ashley Thompson

INTRODUCTION

Sepsis is defined as life-threatening organ dysfunction caused by a dysregulated host response to infection and accounts for approximately 20% of deaths worldwide.[1] Despite tremendous advancements in early diagnosis and both surgical and antimicrobial therapies, it remains a leading cause of in-hospital and intensive care unit (ICU) mortality.[2,3] Intraabdominal sepsis is the second most prevalent infectious etiology after pneumonia.[4,5] Similar to other etiologies of sepsis, early recognition, initiation of antimicrobial therapy, and expedient volume resuscitation are crucial components of initial management of intraabdominal sepsis. Uniquely, rapid and definitive source control is an additional early management priority that differentiates intraabdominal sepsis from other infectious etiologies and is crucial to survival. Failure to achieve early source control is more likely to cause death than refractory infection by a multidrug-resistant pathogen. Independent risk factors for 30-day mortality in severe intraabdominal sepsis include the extent of peritonitis, type of exudate (purulent, fecal or bile), and a nonappendiceal source of infection.[6] In those who require intensive care, studies have shown a mortality rate that exceeds 25%.[7] Recent trends indicate that although inpatient mortality after abdominal sepsis is declining, a large number of "sepsis survivors" develop a clinical trajectory of chronic critical illness (CCI) and suffer dismal long-term outcomes.

DEFINITIONS AND CLASSIFICATIONS

Intraabdominal infection (IAI) occurs when bacteria or yeast invade the normally sterile peritoneal cavity. This condition encompasses a variety of pathologic processes ranging from localized appendicitis to feculent peritonitis after colonic perforation. Both bacterial factors and the host innate immune response contribute to the subsequent clinical course and influence the transition from initial infection to sepsis. There is a wide range of disease severity based on the physiologic response of the patient, including systemic inflammatory response syndrome (SIRS), sepsis, and septic shock. These represent a physiologic continuum with a progressively worsening balance of proinflammatory and antiinflammatory responses. Multiple organ dysfunction syndrome (MODS) and multisystem organ failure (MOF) are terms used to describe the development of end-organ dysfunction in septic patients that leads to physiologic imbalances that are not maintainable without organ support interventions.[8]

Several classification systems exist to describe IAIs. These include (1) community acquired versus hospital acquired and (2) complicated versus uncomplicated infections. Complicated infections can be categorized as localized (such as an abscess) or diffuse (peritonitis). Diffuse peritonitis is further classified as primary, secondary, and tertiary. Each of these has a distinct spectrum of infectious organisms (Table 90.1). Therefore treatment regimens vary based on the etiology and extent of infection. Most IAIs (e.g., appendicitis, colitis) are community acquired and, if identified and treated promptly, do not require intensive care. However, some patients will go on to develop sepsis and become critically ill, usually because of delayed presentation or recognition, immunosuppression, or advanced age/frailty. The majority of these patients have polymicrobial intraabdominal infections as a result of inflammatory or ischemic bowel perforation or postoperative complications (i.e., enteric anastomotic leak).

Uncomplicated IAIs are those contained within a single organ (e.g., appendicitis, cholecystitis) and rarely lead to critical illness if addressed in a timely fashion. Definitive management is surgical, and antibiotics are not warranted after source control has been achieved. If the infection is contained by the initial host inflammatory response, an intraabdominal abscess will form, which depending on the size, accessibility, and patient status is best treated with abdominal-spectrum antibiotic therapy and image-guided percutaneous drain placement. Abscesses that are not amenable to percutaneous drainage and fail to resolve (or progress) on antibiotic therapy alone may require operative washout and drainage.

In contrast, complicated IAIs extend beyond the source organ into the peritoneal cavity, resulting in a much greater systemic inflammatory response. Complicated infections causing peritonitis can be classified as primary, secondary, or tertiary. In primary peritonitis, formerly referred to as "spontaneous" bacterial peritonitis, the infection does not arise from direct gastrointestinal (GI) tract spillage or contamination and rarely causes critical illness. Primary peritonitis most commonly occurs in patients with ascites caused by advanced cirrhosis, but can also be associated with collagen vascular disease or glomerulopathies. The diagnosis is made with a positive ascites bacterial culture and elevated fluid absolute polymorphonuclear leukocyte (PMN) count.[9] These cases are almost always monomicrobial (most commonly *Escherichia coli* [~70%] or *Klebsiella* [~10%]).[10] Treatment consists of antibiotic therapy, and there is no role for operative intervention. Drainage of diffuse ascites as a means of source control is not warranted unless loculated peritoneal fluid collections develop. Device-associated primary peritonitis can occur in patients on peritoneal dialysis. The incidence of these infections is relatively high, at approximately one episode per year of peritoneal dialysis. Peritoneal catheter-related infections are usually monomicrobial, and the most common pathogens are *Staphylococcus aureus, Pseudomonas,* and *Candida*. Although rare, these patients can develop methicillin-resistant *S. aureus* (MRSA), and vancomycin-resistant pathogens are emerging.[11] Treatment includes catheter removal and antibiotics.

Secondary peritonitis is by far the most common presentation in clinical practice and describes infections with an intraabdominal pathology. Causes of secondary peritonitis include perforation of a hollow viscus, bowel ischemic/necrosis, leak of surgical bowel anastomoses, and

TABLE 90.1 Microbiology of Intraabdominal Infection

Primary Peritonitis	Secondary Peritonitis	Tertiary Peritonitis
Escherichia coli	*Bacteroides fragilis*	*Enterobacter* spp.
Enterococcus spp.	*Escherichia coli*	*Enterococcus* spp.
Klebsiella spp.	*Klebsiella* spp.	*Acinetobacter* spp.
Streptococcus pneumoniae	*Clostridium* spp.	*Pseudomonas* spp.
	Other anaerobe spp.	*Staphylococcus* spp.
		Candida spp.

bowel injury after penetrating trauma. These infections are polymicrobial with, on average, five distinct organisms identified in a peritoneal fluid sample. Not surprisingly, common gut flora are the most frequently encountered bacteria (e.g., *E. coli, Klebsiella, Bacteroides*). Treatment includes percutaneous or operative source control and antibiotic therapy.

An infection that recurs or persists after a source control procedure has been performed is considered tertiary peritonitis. These infections are also polymicrobial, but can present an additional management challenge, as there is an increased likelihood of multidrug-resistant organisms (e.g., *S. aureus*/MRSA, *Enterococcus*/vancomycin-resistant *Enterococcus* [VRE], *Candida, Pseudomonas*). These patients may have an acute or chronic host defense impairment that has resulted in an inability to clear the index infection. Whether tertiary peritonitis represents a persistent invasive infection versus peritoneal cavity colonization remains controversial.

Regardless of the etiology of peritonitis, clinicians should be aware of the presence of adjuvant substances that decrease the bacterial threshold inoculum necessary to cause an infection and often require removal in order to clear the infection. The most common adjuvant is blood, but other examples include ascites, fibrin, bile, urine, chyle, pancreatic fluid, and platelets. Evacuation and ongoing drainage of these fluid adjuvants (via percutaneous or surgical drainage) are often required for adequate source control. Fibrin promotes bacterial trapping and can isolate bacteria from neutrophils. Iron present in hemoglobin is essential for bacterial growth and reduces phagocyte function. Foreign bodies are also a nidus for persistent infection and may be present in IAIs in the form of prosthetic mesh or nonabsorbable sutures. Clearance of infection most often requires explant of the infected material, especially when the formation of biofilms is suspected.

ENTERIC MICROBIOTA

Most of the bacteria in the gut are commensal flora that generally do not contribute to the pathogenesis of IAI. They play a fundamental role in immunomodulation, maintenance of barrier function, metabolism (enterohepatic circulation), and overgrowth prevention of pathogenic microbes. Loss of intestinal homeostasis, whether by disruption of the gut mucosal barrier or by depleting the normal flora with long-term antibiotic use, is the first step in the development of abdominal sepsis. The vast majority of cases of IAI are bacterial, although intraabdominal candidiasis is not uncommon in critically ill patients and those who are immunocompromised. The microbial density and composition vary across the digestive tract. Therefore the offending pathogens in an IAI can, to some degree, be anticipated if the inciting pathology is known.

The stomach was initially considered to be a "sterile organ" because of its high intraluminal acidity. *Helicobacter pylori* was discovered in 1982, and for the next few decades, it was believed to be the only bacteria capable of survival in such a low pH secondary to its ability to produce neutralizing urease. The development of culture-independent molecular methods has facilitated the identification and classification of additional gastric bacteria.[12] Although most gastric microbes originate from and are in transit from the oropharynx, the most abundant inhabitants are *Streptococcus, Propionibacterium,* and *Lactobacillus*.[13] These bacteria are more prevalent in patients with reduced gastric acidity. In addition to bacteria, *Candida* commonly colonizes the GI tract and has been associated with the development of gastric ulcers. However, there are relatively small numbers of gastric microbes ($<10^4$ colony-forming units [CFU]/mL) in healthy subjects.[14]

The proximal small bowel, because of the nearness to the stomach and outflowing acidic juices, contains many of the same bacteria in relatively small numbers. Duodenal bile and pancreatic secretions have additional antibacterial properties. Forward propulsion (peristalsis) also plays a key role in suppressing the flora of the upper GI tract. In the distal small bowel, the more alkaline conditions allow for the growth of enteric gram-negative rods. The terminal ileum represents a transition zone from the jejunum, containing predominantly aerobes, to the colon, containing predominantly anaerobes. There are typically $<10^9$ CFU/mL of microorganisms immediately proximal to the ileocecal valve.

In the colon, the concentration and variety of enteric flora changes dramatically. The number of anaerobic bacteria outnumber aerobic by a factor of up to 1000:1,[15] with the most abundant being members of the *Bacteroides* genus. As many as 10^{12} CFU/mL can be found, which contribute to 60% of fecal mass. The stability of the normal flora discourages infection by exogenous microbes and helps prevent overgrowth of pathogenic bacteria already present.

PATHOGENESIS

In general, the pathophysiology of intraabdominal sepsis is described as an initial hyperinflammatory phase that lasts several days followed by an immunosuppressive phase (Fig. 90.1). This pathophysiologic state is the result of opposing influences of the host defense and pathogen virulence. Multiple factors contribute to the inflammatory response. Host factors include patient age, functional status, comorbidities, medications (e.g., steroids, immunosuppressants), environment, and genetics.[16] Pathogen factors include the microbial load, virulence, and pathogen-associated molecular patterns (PAMPs). PAMPs are highly conserved molecules essential for bacterial survival that can be detected by the host innate immune response. Examples of PAMPs include lipopolysaccharide (LPS) and porins from gram-negative cell walls, peptidoglycans, lipoteichoic acids, flagellin in bacterial flagella, and bacterial/viral nucleic acids. PAMPs are recognized by Toll-like receptors (TLRs) and other pattern recognition receptors (PRRs) and trigger a robust innate immune response which can be beneficial to the host. However, this response can later be counterproductive if it is overly robust or fails to resolve and return to immunologic homeostasis.

Resident flora bacteria occupy the bowel lumen and adhere to the mucosa. Direct penetration of organisms through the mucosa is an abnormal event. However, pathogens such as *Shigella, Salmonella,* and *Campylobacter* can invade in this manner.[17] More commonly, bacteria are released in the peritoneal cavity as the result of a perforation of the GI tract. When this occurs, the bacteria must proliferate to cause a clinical infection. To assist with this process, they express specific adherence factors that ultimately make their eradication much more difficult. Adherence factors are one of the many mechanisms bacteria

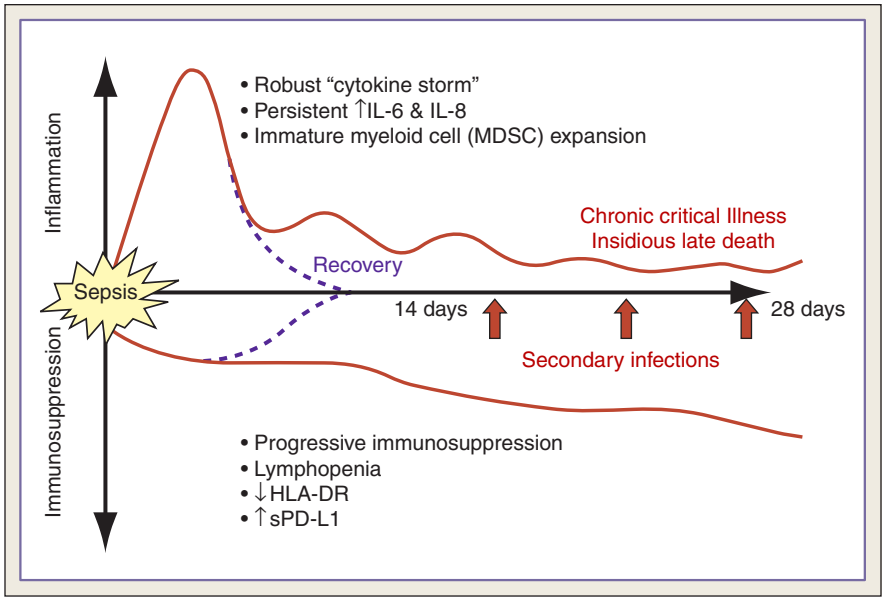

Fig. 90.1 Intraabdominal sepsis is driven by a dysfunctional host innate immune response to infection, with an early "cytokine storm" causing shock and organ dysfunction. Persistent inflammation and progressive immunosuppression lead to immune incompetence and recurrent infections. *HLA,* Human leukocyte antigen; *IL,* interleukin; *MDSC,* myeloid-derived suppressor cell.

use to achieve increased virulence. Endotoxins are LPSs in the outer membrane of gram-negative bacteria. They are large molecules that provide structural integrity and protect invading organisms from the host immune response. The lipid A domain of LPS is primarily responsible for the initial systemic toxicity in gram-negative bacterial infections. When bacterial cells are lysed, fragments containing lipid A are released into the host's circulation, causing systemic symptoms such as fever and potentially septic shock. In gram-positive bacteria, lipoteichoic acid and peptidoglycans in the cell walls play an important role in initiating the host innate immune response; however, they can cause an excessive response resulting in the inflammatory sequelae involved in sepsis.[18]

Once the inflammatory response has been initiated, proinflammatory cytokines (e.g., tumor necrosis factor alpha [TNF-α], interleukin [IL]-1, IL-6) are released, which have a multitude of effects. They cause production of toxic mediators such as prostaglandins, phospholipase A_2, platelet-activating factor, and others, which damage the endothelial lining and subsequently lead to increased capillary leakage.[19] They lead to increased production of adhesion molecules on neutrophils and endothelial cells, resulting in further endothelial injury from release of neutrophil components. These activated neutrophils release nitric oxide, a vasodilator that plays a key role in the development of septic shock. Proinflammatory cytokines from innate immune effector cells also disrupt activated protein C and antithrombin, modulators of coagulation. The culmination of these effects can result in extensive "third-spacing" of intravascular fluid, vasodilatory shock, and MODS/MOF.[20]

After the initial "cytokine storm" triggered by infection, there is a subsequent phase of profound and persistent immunosuppression, which manifests as secondary infections and "sepsis recidivism." This state of host immunoparalysis is the result of several mechanisms, including apoptotic depletion of immune cells, endotoxin tolerance/impaired cytokine response, the expansion of immature myeloid lineage cells (myeloid-derived stem cells [MDSCs]), and compromised T-cell function and exhaustion (see Fig. 90.1).[21–23] Apoptosis of lymphocytes and antigen-presenting cells (T cells, B cells, and dendritic cells) is considered a hallmark of immunosuppression in sepsis[24] and has shown promise as a new target for sepsis treatment in animal models.[25] Endotoxin tolerance is the severely reduced capacity of a cell to respond to LPS in a second exposure to a toxic stimulus and represents an immune amnesia instead of an antiinflammatory response.[26] T-cell exhaustion develops in the face of persistent antigen exposure and/or inflammation. This prolonged exposure leads to decreased expression of major histocompatibility complex (MHC) class II molecules (human leukocyte antigen [HLA]-DR) on antigen-presenting cells and increased expression of cell surface inhibitory receptors (such as programmed cell death-1 [PD-1]) on $CD4^+$ and $CD8^+$ T lymphocytes.[27] Studies have shown that increased expression of PD-1 in circulating T cells from patients with sepsis correlated with decreased T-cell proliferative capacity and mortality.[28]

More specific to abdominal sepsis is the concept of peritoneal compartmentalization. Based on findings of high concentrations of cytokines (IL-1, TNF-α, IL-6, IL10, interferon-gamma [IFN-γ]) in the peritoneal fluid of patients with peritonitis, studies have suggested that intraabdominal sepsis may result in a cytokine-mediated proinflammatory response that is initially localized to the abdominal compartment[29] and that plasma levels may increase only after saturation of tissues within the peritoneal cavity.[30]

SPECTRUM OF DISEASE CAUSING CRITICAL ILLNESS

Perforated Hollow Viscus

Loss of integrity of the GI tract is the most common cause of IAI and abdominal sepsis. Inciting disease processes range from perforated gastric ulcers to acute appendicitis, diverticulitis, and traumatic injuries. Each of these clinical conditions is discussed in further detail in their respective chapters; however, their significance as common etiologies of abdominal sepsis should be noted. The basic tenets of sepsis management should be applied regardless of the specific cause: timely identification, rapid intravascular volume resuscitation, early initiation of antimicrobial therapy, and definitive source control.

Solid Organ Abscess

Abscesses of solid organs are rare but can progress to expansive, potentially lethal IAIs if not diagnosed promptly. Most cases arise from bacterial translocation from another infected system. The most common site of solid organ abscess is the liver, followed by the spleen and kidney.

Pyogenic liver abscesses can develop from direct injury to the liver or from a disseminated IAI. The most common cause—approximately half of the cases—are secondary to cholangitis and direct extension from an infected biliary tract.[31] Less common causes include portal vein bacteremia from an enteric infection (usually diverticulitis), hepatic artery bacteremia, and devitalized liver secondary to trauma or angioembolization or ablation of neoplasms. The most common organisms identified in these lesions are *Klebsiella, E. coli, Streptococcus, Staphylococcus,* and anaerobic organisms, but they are usually polymicrobial. If *Staphylococcus* or *Streptococcus* are the sole isolates, there should be a high suspicion for another source of infection (endocarditis) that has spread hematogenously. *Entamoeba histolytica* is the most common anaerobic source and is acquired via ingestion of food or water contaminated by human feces. Ingestion initially causes an amebic colitis and seeds the portal system, ultimately resulting in an amebic liver abscess. Although these are quite rare in the United States, they are not uncommon among those who live or have recently traveled to developing countries. *Echinococcus granulosus* is a parasitic organism that causes hydatid cysts of the liver. These are most often acquired from dogs and are usually discovered incidentally or in the late stages.[32]

Patients with liver abscesses may present with a wide range of symptoms. Fever is present in 90%, and abdominal pain is present in 50%–75% of patients.[33] Approximately half of patients will have elevated liver transaminases and 90% will have elevated alkaline phosphatase.[34] An abdominal ultrasound is the initial test of choice, but computed tomography (CT) imaging of the abdomen is slightly more sensitive. Drainage of the abscess and antibiotics are the cornerstones of treatment. If the abscess is less than 5 cm, ultrasound or CT-guided needle aspiration may suffice. If the abscess is larger than 5 cm, consider percutaneous drainage with a pigtail catheter placement. Although rarely encountered, indications for surgical intervention include ruptured abscess with generalized peritonitis, thick-walled or multiple abscesses, and previously failed percutaneous drainage procedures. Antibiotics should be administered and may require up to 6 weeks of coverage. Metronidazole should be used for *E. histolytica.* Echinococcal treatment involves injection of the hydatid cysts before drainage, as rupture of the abscess may cause shock in addition to albendazole therapy, which may last for several years. In-hospital mortality of pyrogenic liver abscesses is estimated at 2.5%–19%.[35]

Abscesses of the spleen most commonly arise from hematologic seeding of bacteremia (most often from endocarditis) or as a result of devitalized tissue. Devitalization can result from trauma, angioembolization, or infarction secondary to systemic disorders such as hemoglobinopathies or sickle cell disease. Direct extension of an adjacent infection, such as from a gastric or colonic perforation, may also occur. The most commonly encountered pathogen is hematogenously spread *Staphylococcus*. CT imaging is the gold standard for diagnosis. Treatment includes empiric antibiotic therapy and abscess drainage. Percutaneous aspiration can be attempted as a temporary solution as a bridge to surgery, but splenectomy is often required as definitive treatment.[36]

Renal abscesses are the rarest solid organ abscess. They most commonly develop from obstruction and ascending infection from the lower urinary tract and, not surprisingly, are caused by the same pathogens as a urinary tract infection (*E. coli, Klebsiella,* and *Enterococcus*). Treatment includes urinary tract decompression and broad-spectrum antibiotics until speciation and susceptibility data are available.

Acute Acalculous Cholecystitis

Acute acalculous cholecystitis is inflammation of the gallbladder secondary to ischemia without evidence of gallstones or cystic duct obstruction. It is the cause of approximately 5%–10% of all cases of acute cholecystitis and occurs most commonly in critically ill patients after a major physiologic insult such as sepsis, severe burns, cardiopulmonary bypass, emergent aortic surgery, or significant trauma.[37,38] The etiology of this disease is thought to be biliary stasis. Critically ill patients and those on total parenteral nutrition (TPN) are more predisposed because of fever, dehydration, and prolonged absence of oral feeding resulting in a decrease of cholecystokinin-induced contraction of the gallbladder. The gallbladder becomes distended with increased wall tension and subsequent impaired lymphatic/venous drainage, progressive edema, and ultimately ischemic necrosis.

As patients with this condition are commonly intubated and sedated, pinpointing a diagnosis of acalculous cholecystitis can be challenging. Clinicians must carry a high index of suspicion and consider this possibility in any critically ill patient with fever or sepsis of unclear origin. Transaminases, bilirubin, and alkaline phosphatase may be elevated. Abdominal ultrasound is the imaging modality of choice,[39] and diagnosis can be confirmed by a gallbladder wall thickness greater than 3.5 mm and the presence of pericholecystic fluid.[40] Abdominal CT imaging is equally accurate, but hepatobiliary iminodiacetic acid (HIDA) imaging has a poor positive predictive value in this patient population, as patients are not generally receiving adequate alimentary stimuli for gallbladder contraction.

Once a diagnosis has been established, treatment most often includes antibiotics and percutaneous cholecystostomy. Although surgical evaluation is warranted, most of these critically ill patients are not candidates for definitive cholecystectomy, and temporizing percutaneous drainage is necessary. Percutaneous cholecystostomy has a >90% success rate for source control. Failure of cholecystostomy placement is usually secondary to catheter malposition or gallbladder necrosis and perforation. Once the patient has recovered from acute illness, interval cholecystectomy is the definitive treatment. However, many of these patients remain high-risk surgical candidates because of underlying comorbidities. In these cases, if a cholecystostomy tube study confirms the absence of gallstones and a patent biliary tree, the drain can simply be removed. Transpapillary drainage through an endoscopic retrograde cholangiopancreatography (ERCP) has been used with variable success but has high recurrence rates.[41] An emerging alternative for drainage is endoscopic placement of a lumen-apposing fully covered metal stent (LAMS) through the GI tract into the gallbladder. This procedure obviates the need for percutaneous drain placement, and studies are showing success rates similar to percutaneous cholecystostomy with few adverse events.[42,43]

Mesenteric Ischemia

Intestinal ischemia occurs when a patient has inadequate blood flow through the mesenteric vessels, resulting in ischemia and eventual gangrene of the bowel. If this condition occurs acutely, it can be a life-threatening surgical emergency that requires immediate intervention. Chronic mesenteric ischemia typically presents with vague, postprandial abdominal pain and rarely leads to bowel necrosis and abdominal sepsis unless a patient develops acute-on-chronic disease.

Acute mesenteric ischemia (AMI) can be subdivided into four categories based on the etiology: acute mesenteric arterial embolism (AMAE), acute mesenteric arterial thrombosis (AMAT), mesenteric venous thrombosis (MVT), and nonocclusive mesenteric ischemia (NOMI). An additional cause of acute bowel ischemia is that which occurs as a result of mechanical obstruction (e.g., intussusception, volvulus, internal hernia with strangulation). Each of these types of

Fig. 90.2 Computed tomography with oral and intravenous contrast in a patient with embolic occlusion of the superior mesenteric artery and segmental ischemia of the small bowel and right colon *(arrows).* Bowel ischemia is evident from the marked thickening of the intestinal wall.

AMI has somewhat different predisposing factors and prognoses, but all share a final common pathway to bowel infarction and necrosis if not treated expeditiously.

Mesenteric ischemia caused by an arterial embolism is the most common subtype accounting for up to 50% of AMI cases.[44] In this type of AMI, an embolus (usually from a cardiac source) lodges in the mesenteric vasculature. Large emboli lodge in the superior mesenteric artery (SMA), most often 6–8 cm from the origin and distal to the middle colic artery.[45] Blood flow distal to the embolism will be interrupted, resulting in bowel ischemia (Fig. 90.2). If the entirety of flow through the SMA is compromised, the patient may have the devastating outcome of entire midgut necrosis. Smaller emboli are more likely to lodge in the more distal mesenteric circulation, resulting in smaller segments of affected bowel with a generally better prognosis.

AMAT is a similar phenomena, but abrupt cessation of flow is secondary to in situ thrombosis of the vessel rather than an embolus. This occurs in patients with underlying atherosclerotic disease who may have had progressively worsening abdominal pain over the weeks preceding presentation. Mesenteric (or portal) venous thrombosis occurs when a blood clot forms in one of the major veins carrying blood from the intestine and is usually in patients with either a hypercoagulable state or a local inflammatory process such as pancreatitis. Mesenteric or portal vein thrombosis is rarely associated with bowel necrosis and is usually successfully managed with systemic anticoagulation and bowel rest.

NOMI is a common complication of severe critical illness and is the result of a low-flow state to the splanchnic circulation, most notably when the cardiac index is less than 2 L/min/m^2.[46] There are numerous potential causes of the decreased flow, including hypovolemia, shock, and prolonged high-dose vasopressor use. Any segment of bowel can be affected; however, the most frequently affected are the cecum and splenic flexure. The cecum is the farthest from the inferior mesenteric artery (IMA) collaterals, and the splenic flexure is a watershed region of the superior and inferior mesenteric arteries. Of note, in patients with prior abdominal aortic operations, the IMA may have been ligated, and therefore the left colon is at higher risk for NOMI.

In patients that are communicative, abdominal pain out of proportion to examination is the hallmark symptom of AMI. In intubated, sedated patients, the diagnosis can be more challenging. Clinical features may include abdominal distention and a progressively worsening metabolic acidosis. Hematochezia can be seen as the vasculature to the mucosa is more vulnerable and the mucosa will begin to slough. Patients may develop sepsis or septic shock before transmural gangrene and perforation because of the compromised integrity of the mucosa leading to bacterial translocation and bacteremia. Blood per rectum after an abdominal aortic surgery is strongly suggestive of colonic ischemia.

Aortic angiography has traditionally been the most reliable method to diagnose AMI, but is now superseded by CT angiographic (CTA) imaging.[47] Bedside lower endoscopy can be used for a diagnosis of colonic ischemia, but may underestimate the extent of disease (Fig. 90.3). When AMI is suspected, goals of management are resuscitation, rapid diagnosis, early revascularization, and reassessment of the bowel.[48] Revascularization is generally performed via several endovascular strategies, including percutaneous aspiration embolectomy, balloon thrombectomy, catheter-directed thrombolysis, and stenting.[49] An exploratory laparotomy is generally performed in conjunction with revascularization to evaluate the bowel. Necrotic bowel is resected, but potentially viable bowel should be left for at least 30 minutes once perfusion has been established or reassessed at an interval repeat laparotomy 24 hours later. These patients are at risk for short bowel syndrome if a large resection is performed. Depending on the patient's physiologic status, the surgeon may consider a second-look laparotomy in 12–48 hours if there is questionable bowel viability or if a massive enterectomy would be needed.

Clostridium difficile Colitis

Clostridium difficile is a gram-positive, anaerobic, spore-forming bacteria that is the most common pathogen causing healthcare-associated infection in the United States, accounting for 15% of all such infections.[50] The incidence of *C. difficile* infections (CDIs) continues to rise, and cases of antibiotic resistance are becoming more common.[51–53] Risk factors for colonic CDI include advanced age, hospitalization, and antibiotic exposure. The prevalence of *C. difficile* spores in the environment is relatively high among hospitals and long-term care facilities. As such, it is not surprising that patients in these facilities carry a higher colonization rate (10%–25% among hospitalized patients,

Fig. 90.3 Colonoscopy is the preferred modality to assess for colonic ischemia, but visualizes only the mucosa and may underestimate the extent of disease.

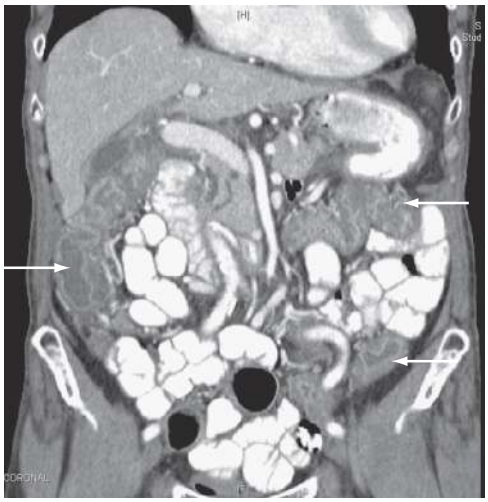

Fig. 90.4 Computed tomography with oral and intravenous contrast in a patient with *Clostridium difficile* colitis. Typical findings include colonic wall thickening *(arrows),* dilation, and thickened/edematous colonic wall.

4%–20% among residents of long-term care facilities) than healthy adults in the general population (2%–3% colonization rate).[54]

Clinical features of active CDI infection include crampy abdominal pain, diarrhea, fever, and leukocytosis in the setting of recent antibiotic use, generally within the previous 8 weeks. Peritonitis is generally not seen until advanced stages of infection with megacolon and/or perforation. The diagnosis is confirmed with a stool sample. Multiple tests are available, including polymerase chain reaction (PCR) assays, antigen detection tests, tissue culture cytotoxicity assays, enzyme immunoassays, and stool culture. PCR assays are the most effective diagnostic method for accurate and early diagnosis of CDI.[55] Imaging is not needed for diagnosis, but CT imaging may reveal colonic wall thickening, dilation, ascites, pericolonic stranding, and a characteristic "accordion sign" of thickened haustral folds containing trapped contrast material (Fig. 90.4). Visualization of colonic pseudomembranes on endoscopy is also diagnostic, though this procedure is not commonly used because of the risk of perforation in fulminant colitis.

Recommended treatment of CDI includes a 10-day course of oral vancomycin or fidaxomicin.[56] Metronidazole, previously the first-line drug for CDI, may be used as an alternative for an initial, nonsevere episode or in intravenous (IV) form as a secondary agent in a fulminant infection. Rectal vancomycin enemas may also be added, but are cumbersome, and their additional yield is unclear. Fecal microbiota transplantation is perhaps the most promising emerging therapy for refractory CDI, but there are logistical changes regarding stool donation, storage, and dissemination that remain problematic at this time.[57] Fulminant colitis has been broadly defined as *C. difficile* colitis with significant systemic toxic effects and shock and occurs in 3%–5% of patients with *C. difficile.* These patients develop a severely dilated toxic megacolon, which may progress to perforation. Treatment includes aggressive sepsis resuscitation and source control with a total abdominal colectomy. In-hospital mortality for fulminant *C. difficile* colitis is >30%.[58]

Acute Necrotizing Pancreatitis

Acute pancreatitis is an inflammatory condition of the pancreas that is characterized by premature activation of digestive enzymes within the pancreatic acinar cells resulting in autodigestion. There are many underlying causes of pancreatitis, but 60%–75% of all cases are caused by gallstone disease or alcohol abuse.[59] Most patients develop a mild, self-limited disease, but up to 30% develop a severe, life-threatening form that is associated with a mortality rate as high as 25%.[60] Severe pancreatitis is defined by single or multiple organ failure lasting >48 hours and can be complicated by the development of parenchymal/peripancreatic fluid collections and necrosis. Acute necrotizing pancreatitis is diagnosed when more than 30% of the gland is necrotic (Fig. 90.5). Two-thirds of necrotic pancreatic collections are sterile and will resolve with conservative management. The remaining minority that become infected or mature to a pancreatic pseudocyst require further intervention.[61]

The initial assessment of a patient with acute pancreatitis includes determining the etiology of the disease, as this may help direct management (e.g., ERCP for an obstructing gallstone). These patients generally require aggressive IV fluid resuscitation. Prophylactic antibiotics have no role in preventing infection of pancreatic necrosis, are associated with the development of antibiotic resistance, and do not improve clinical outcomes.[62] The timing of infection in pancreatic necrosis is variable and unpredictable, with peaks in the second to fourth week after the onset of pancreatitis.[63] Diagnosis of infected pancreatic necrosis remains a significant clinical challenge. The presence of retroperitoneal gas on contrast-enhanced CT imaging is considered indicative of infected pancreatitis but is only present in a limited number of patients. Fine-needle aspiration (FNA) culture remains the diagnostic "gold standard" but has largely been abandoned because of its high false-negative rate. Serum biomarkers such as procalcitonin may offer some diagnostic yield, but overall infected necrosis remains a clinical diagnosis.

Treatment for infected necrosis includes an appropriate antibiotic regimen, source control, and early enteral feeding. The antibiotic selected must provide both aerobic and anaerobic gram-negative and gram-positive coverage and provide adequate pancreatic penetration. Current treatment guidelines include use of a carbapenem, piperacillin/tazobactam, or a third-generation cephalosporin or fluoroquinolone combined with an antianaerobic drug such as metronidazole.[64,65] A Cochrane meta-analysis revealed enteral nutrition to be superior to TPN in severe acute pancreatitis, with reduction in infectious complications, length of hospital stay, and overall mortality.[66] Early institution of feeding (within 48 hours) is preferred, though the exact timing remains controversial.[67]

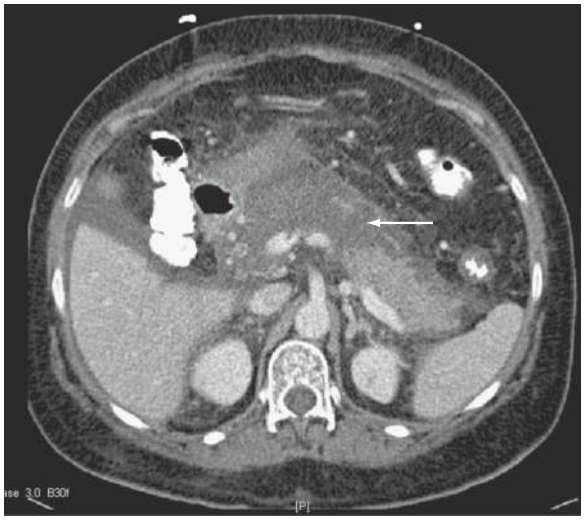

Fig. 90.5 Computed tomography with oral and intravenous contrast in a patient with necrotizing pancreatitis. There is significant peripancreatic inflammation, and the hypodense area in the body of the pancreas is an area of pancreatic necrosis *(arrow).*

The three well-established approaches for drainage of infected pancreatic necrosis are radiographically guided percutaneous, endoscopic, and surgical. Over the last two decades, the paradigm has shifted away from surgical intervention to less invasive approaches. Open necrosectomy is associated with high morbidity and mortality rates and the development of complications such as enterocutaneous and pancreatico-cutaneous fistula formation.[68] Percutaneous drain placement under ultrasound or CT guidance via a retroperitoneal approach is preferable to a transperitoneal approach and has fewer complications. Additionally, this facilitates a "step-up" approach in which the drain can be upsized and eventually used as a tract for laparoscopic-assisted retroperitoneal necrosectomy if necessary. The drain should be irrigated multiple times daily with sterile water. Endoscopic drainage and debridement is usually reserved after the formation of a defined pancreatic pseudocyst. The necrotic collection is punctured through the gastric wall under ultrasound guidance. The tract is then dilated and stented, allowing drainage of necrotic material into the GI tract.

DIAGNOSIS

The diagnosis of abdominal sepsis is based primarily on clinical assessment. The patient may present with abdominal pain or other GI complaints and show signs of a systemic inflammatory response such as fever, tachycardia, and tachypnea. In advanced cases, peritonitis may be present with abdominal distention or rigidity. Altered mental status, hypotension, and oliguria are signs that a patient is transitioning from sepsis to septic shock.

Recommended laboratory tests include a complete blood count with differential, basic metabolic panel, measurement of lactate and liver enzyme levels, coagulation studies, and blood cultures. Leukocytosis is often seen because of an early leukemoid reaction. However, leukopenia can also result secondary to an overwhelming infection causing bone marrow suppression. Cytokine production triggers the release of immature granulocytes from the bone marrow, resulting in a "left shift" or "bandemia" in the cell differential analysis.[69] Serum lactate is a sensitive but nonspecific indicator of metabolic stress.[70] As a product of anaerobic glycolysis, lactate is increased in hypoxia, systemic malperfusion, and many critical illnesses.[71] There is a clear association between higher lactate levels and increased mortality. Different thresholds have been recommended as an early aggressive resuscitation predictor and, as a result, early identification of elevated serum lactate can potentially lead to early identification of patients who are at high risk for poor outcomes.[72–74] Lastly, procalcitonin is a biomarker that has been evaluated for early detection of sepsis in addition to monitoring the antimicrobial treatment regimen but is limited because of its nonspecific nature in the setting of inflammation.

Radiographic imaging yields a definitive diagnosis in most patients with IAIs. Upright plain films may reveal intestinal obstruction, ischemia, or pneumoperitoneum (Fig. 90.6). They may also be used with water-soluble contrast injection to evaluate drains and/or fistulas. Ultrasound can be performed at the bedside and is useful in patients that are too unstable to leave the ICU. It is the imaging modality of choice for biliary sepsis and can also be used to detect and drain intraabdominal abscesses, particularly in the pelvis using transvaginal or transrectal probes. However, ultrasound is dependent on operator experience and patient body habitus. CT with IV (± oral [PO]) contrast is the test of choice in stable patients. Findings concerning for IAI include extraluminal air (Fig. 90.7), contrast extravasation, free fluid, mesenteric stranding, and the presence of a contrast-enhancing rim that is characteristic of an abscess (Fig. 90.8). In a patient with mesenteric ischemia, vascular thrombus may be identified in addition to pneumatosis or portal venous gas suggesting bowel ischemia. Obtaining CT imaging

requires transport, which can be challenging in an unstable patient and also carries the risk of contrast-induced nephropathy.

MANAGEMENT

Sepsis Resuscitation

Regardless of etiology, initial treatment principles are the same for all sepsis patients and include timely recognition, initiation of antimicrobial therapy, volume resuscitation to restore end-organ perfusion, and prompt source control. Sepsis is characterized by a state of systemic malperfusion caused by vasoregulatory dysfunction and myocardial depression. Increased venous capacitance and capillary leakage result in an overall hypovolemic state with decreased venous return to the heart. The resultant diminished cardiac function leads to tissue hypoxia, which causes overstimulated endothelial cell activity leading to a systemic inflammatory cascade.[20] The key contributor to the high morbidity and mortality rates associated with sepsis is the development of MOF driven by malperfusion and systemic inflammation.

Although the efficacy of individual components can be debated, the use of early goal-directed therapy protocols clearly reduce in-hospital mortality from sepsis.[75] Fluid resuscitation should be initiated as early as possible if clinical evidence of organ dysfunction exists, regardless of lactate level. There is no clear evidence from randomized controlled trials that support colloids over crystalloid solutions to reduce the risk of death in patients with trauma, burns, or sepsis.[76] Because of the increased expense of colloids, crystalloid solutions are recommended.[77] Intravascular volume status can be monitored and optimized during the initial resuscitation with point-of-care echocardiography. Pulmonary artery catheters have been shown to not improve outcomes and increase cost.[78] Experimental studies have correlated a positive fluid balance with more severe organ dysfunction and overall worse outcomes.[79] Volume overload can cause increased intraabdominal pressure, resulting in splanchnic hypoperfusion and increased bowel edema leading to bacterial translocation, cytokine release, and perpetuation of the inflammatory cascade. Patients should be monitored for the development of intraabdominal hypertension with repeated intravesical measurements of intraabdominal pressure.

Vasopressor support should be added when hypotension persists with restoration of adequate intravascular volume. Norepinephrine is recommended as the first-line vasoactive agent in septic shock.[77] Compared with dopamine, norepinephrine causes less tachycardia and is less arrhythmogenic. Vasopressin increases vasculature responsiveness to catecholamines and can be added as a second-line agent, if needed.[80] Epinephrine is a potent adrenergic agent that increases cardiac index and peripheral vascular tone through both alpha and beta stimulation. Because of its potential to reduce splanchnic blood flow, there are concerns regarding its use in septic shock, though no trials have shown worse outcomes with epinephrine compared with norepinephrine.[81] Dobutamine is rarely used in septic shock but may be considered only if the patient has a simultaneous myocardial dysfunction. The Surviving Sepsis Campaign (SSC) is a global initiative created in 2004 that designed evidence-based guidelines and bundles to help improve outcomes in sepsis. Resuscitation goals from SSC include central venous pressure (CVP) >8 mm Hg, mean arterial pressure (MAP) >65 mm Hg, central venous oxygen saturation ($ScvO_2$) of >70%, and urine output (UOP) of >0.5 mL/kg/h.

Empiric Broad-Spectrum Antibiotics

Timely antimicrobial administration is a key factor in the management of sepsis.[82,83] Initial empiric therapy used in abdominal sepsis should be broad spectrum but, if possible, take into account the presumed source, as the etiologic distribution varies according to the source site (Table 90.2). The upper GI tract has a prevalence of gram-positive

TABLE 90.2 Empiric Antimicrobial Regimens for Critically Ill Patients With Intraabdominal Infection

Hospital-Acquired IAI		Community-Acquired IAI	
Meropenem 1 g q8h or Doripenem 500 mg q8h or Imipenem/cilastatin 1 g q8h		Piperacillin/tazobactam 4.5 g q6h or Cefepime 2 g q8h + Metronidazole 500 mg q6h	
Carbapenem-sparing regimen:	Ceftolozane/tazobactam 1.5 g q6h + Metronidazole 500 mg q6h or Ceftazidime/avibactam 2.5 g q6h + Metronidazole 500 mg q6h + Vancomycin 25–30 mg/kg loading dose, then 15–20 mg/kg/dose q6h or Teicoplanin 12 mg/kg q12h × 3 loading dose, then 12 mg/kg q24h	If at risk for community-acquired ESBL-producing Enterobacteriaceae:	Meropenem 1 g q8h or Doripenem 500 mg q8h or Imipenem/cilastatin 1 g q8h
If at risk for vancomycin-resistant enterococci (VRE):	Linezolid 600 mg q24h or Daptomycin 6 mg/kg q24h	If at high risk for infection with enterococci:	Ampicillin 2 g q6h* *If not on piperacillin/tazobactam or imipenem/cilastatin
If at high risk for invasive candidiasis:	Caspofungin 70 mg loading dose, then 50 daily Or Micafungin 100 mg daily Or Amphotericin B liposomal 3 mg/kg/dose q24h		

ESBL, Extended-spectrum beta-lactamase; *IAI,* intraabdominal infection.

bacteria and *Candida* with a progressive increase of anaerobes and gram negatives in the lower GI tract. The patient should be reassessed when the results of microbiologic testing are available. Antibiotic de-escalation has been associated with lower mortality rates in ICU patients and is considered a key practice for antimicrobial stewardship.[84]

For patients with community-acquired IAI, a narrower spectrum of activity is recommended. There is an increased likelihood in hospital-acquired IAI to encounter pathogens with reduced susceptibility to traditional antibiotic regimens. With increasing prevalence of MRSA and extended-spectrum beta-lactamase (ESBL)–producing Enterobacteriaceae because of selection pressures related to cephalosporin overuse, their routine use is discouraged.[85] Carbapenem use has increased in recent years with the rise in ESBL infections; however, there is now an emergence of carbapenem resistance in *Pseudomonas aeruginosa.* With regard to gram-positive bacteria, enterococci play a significant role in IAIs, and hospitalized, critically ill patients are at risk of vancomycin-resistant enterococci (VRE) infection.[86] Options for treating VRE are linezolid or tigecycline.

Empiric antifungal therapy should be considered in patients with intraabdominal septic shock from community-acquired infections or in patients with postoperative infections where the presence of yeast is associated with a poor prognosis.[87] An echinocandin should be used as empirical antifungal therapy in critically ill patients having either community-acquired or hospital-acquired IAI.

In uncomplicated IAIs, once the source of infection (e.g., appendix or gallbladder) has been effectively treated by surgical therapy, postoperative antibiotics are not necessary.[88,89] In complicated IAIs in patients who are not severely ill and where source control has been obtained, a short course (3–5 days) of postoperative antibiotic therapy is suggested.[90] For severe bacterial hospital-acquired IAI in those who were severely ill, a duration of antibacterial therapy between 7 and 15 days may be necessary.[91] In a patient with intraabdominal candidiasis, a longer duration of antifungal coverage is recommended, up to 2–3 weeks, because of the high rates of recurrence.[92] For complicated patients with persistent IAIs, the decision to continue, revise, or stop antimicrobial therapy should be made based on the patient's clinical picture, available laboratory data, and clinician judgment.

Source Control

Early intervention and adequate source control are tenets to surviving intraabdominal sepsis. Source control encompasses all measures taken to reduce the bacterial load, including drainage of fluid collections, debridement of necrotic tissue, and resection or repair of perforated viscus. If the patient is stable and a fluid collection/abscess is accessible by percutaneous means, CT- or ultrasound-guided drain placement may be the optimal approach. Surgical intervention is indicated in the hemodynamically unstable patient with diffuse peritonitis, suspected perforated viscera, uncontrolled enteric spillage, or infected fluid collections not amenable to percutaneous drainage.

Objectives of surgical intervention include determination of the cause of peritonitis, drainage of fluid collections, and controlling the origin of abdominal sepsis. Intraoperatively, the entirety of the GI tract should be evaluated. Blood, purulent fluid, and any other contaminants should be removed to reduce the infectious burden and to help prevent or reduce fibrin formation. Careful attention should be given to the pelvis, paracolic gutters, and subphrenic spaces, as these are the most dependent areas of the abdomen and are therefore prone to fluid pooling and abscess development. Peritoneal lavage may help with removal of and dilution of contaminants by irrigating with large volumes of saline; however, its use remains controversial.

Damage control laparotomy was introduced in 1993 in the severely injured trauma population.[93] This technique involves performing a midline laparotomy to obtain initial control of contamination or hemorrhage in an unstable patient. The fascia of the abdomen is left open with a temporary closure device placed, and the patient is transferred to the ICU to facilitate the prioritization of resuscitation to normal physiology (Fig. 90.9). Once stabilized, patients are taken back to the operating room within 24–48 hours for re-exploration, definitive repair, and abdominal closure. The principle of damage control or "staged" laparotomy has since been applied to many other patient populations, including those with abdominal sepsis. The abdomen may be left open to prevent the development of abdominal compartment syndrome, allow for re-evaluation of adequate source control, and optimize conditions for definitive surgical reconstruction (e.g., bowel anastomosis or ostomy creation).[94,95] The patient managed by temporary abdominal closure should return to the operating room every 24 hours for re-evaluation and attempt at sequential or completion fascial closure. Failure to achieve primary fascial closure as a result of bowel edema and retracted fascia requires temporization with absorbable mesh and split-thickness skin grafting of the granulated exposed bowel. This commits the patient to a large planned ventral hernia, carries significant risk of enteroatmospheric fistula formation, and commits the patient to a 6- to 12-month course to definitive surgical repair.

Fig. 90.9 Management of the open abdomen after damage control surgery. A nonadherent plastic layer is placed over the abdominal contents below towels or commercial sponge dressings. Negative pressure is applied to the closure to drain fluid, prevent evisceration, and facilitate subsequent abdominal closure.

Adjunctive Therapies

Corticosteroids should only be considered for patients with clinical suspicion of relative adrenal insufficiency in the setting of vasopressor refractory shock.[77] If steroids are used, hydrocortisone 200 mg/day IV in four divided doses or as a 100-mg bolus followed by a continuous infusion of 10 mg/h is the recommended regimen.[96] The optimal duration of steroid taper remains unknown and therefore should be tailored to the physiologic status of the individual patient.

Nutritional support, preferably via the enteral route, should be initiated once initial resuscitation is complete and adequate perfusion pressure has been achieved.[97] Enteral nutrition maintains the integrity of the gut mucosa and helps prevent bacterial translocation. Some studies have shown early enteral feeding reduces the length of mechanical ventilation, ICU length of stay, and hospital length of stay but with no consistent mortality benefit.[98]

COMPLICATIONS

Outcomes after abdominal sepsis are directly related to early diagnosis, timely sepsis resuscitation, early source control, and contributing comorbidities. Most complications are a result of failed source control or the overwhelming physiologic response to sepsis. Abscess formation, anastomotic dehiscence, abdominal compartment syndrome, surgical site infection, "frozen" abdomen hindering return to the operating room, fistula formation, postoperative secondary nosocomial infection, MOF, and development of CCI are just a few of the potential complications that can arise. However, refractory or nonresolving MOF remains the leading cause of inpatient death.[99]

Enterocutaneous fistula is a dreaded complication of abdominal sepsis and can be significantly life-altering for the patient. After an IAI, this may be an occult source of sepsis before the tract drains through the skin. The tract can also contain an abscess cavity that requires drainage. Initial treatment is primarily supportive care with bowel rest, nutritional support, and skin care. The output should be monitored and controlled to avoid dehydration. Data on spontaneous closure rates are variable but most studies demonstrate 20%–30% of fistulas will close without operative intervention, usually within 3–4 weeks.[100] An elective fistula take-down procedure can be considered months later once the peritoneal cavity is less hostile.

The understanding of long-term outcomes after critical illness from abdominal sepsis has substantially evolved. Because of advances in sepsis detection, management, and critical care organ support, inpatient mortality rates have significantly declined over the past 20 years. However, there is an increasingly recognized cohort of "sepsis survivors" that overcome the initial septic insult to develop into a state of CCI.[101] Patients that develop CCI have an underlying pathophysiologic state of a persistent inflammation, immunosuppression, and catabolism syndrome (PICS), which manifests clinically as the development of recurrent nosocomial infections and multiple hospital readmissions because of "sepsis recidivism," and approximately 40% are dead at 1 year (see Fig. 90.1).[102–107] Risk factors for PICS-CCI include advanced age, severe comorbidities, and severity of shock. Therefore the prompt identification and treatment of intraabdominal sepsis of at-risk patients should be prioritized in order to improve the post-ICU outcomes for these patients.

KEY POINTS

- Timely diagnosis, initiation of antimicrobial therapy, volume resuscitation to restore end-organ perfusion, and definitive source control are essential in decreasing the mortality of intraabdominal sepsis.
- CT imaging of the abdomen/pelvis with IV (± PO) contrast is generally the imaging modality of choice in evaluating intraabdominal sepsis.
- The Surviving Sepsis initiative has helped improve outcomes in sepsis. Norepinephrine is recommended as the first-line vasoactive drug in septic shock.
- Empiric antimicrobial therapy in abdominal sepsis should be broad and include coverage for aerobic gram-negative bacilli, anaerobes, and possibly fungi. Antibiotics should be de-escalated after source control has been obtained and results of microbiologic testing are available.
- Source control encompasses all measures taken to reduce the bacterial load, including drainage of fluid collections, debridement of necrotic tissue, and resection or repair of perforated viscus.
- Studies have shown a cohort of "sepsis survivors" who overcome an initial septic insult but go on to develop into a state of CCI. These patients have an underlying pathophysiologic state of PICS, which manifests clinically as the development of recurrent nosocomial infections and multiple hospital readmissions because of "sepsis recidivism," and approximately 40% are dead at 1 year.

The recommended treatment of an initial episode of Clostridium difficile *infection (CDI) is a 10-day course of oral vancomycin or fidaxomicin. These agents have been shown to be superior to metronidazole; however, in settings where access to vancomycin or fidaxomicin is limited, metronidazole may be used for an initial episode of nonsevere CDI only.*

Rhodes A, Evans LE, Alhazzani W, et al. Surviving sepsis campaign: International guidelines for management of sepsis and septic shock: 2016. *Intensive Care Med.* 2017;43:304–377.
Administration of IV antimicrobials should be initiated as soon as possible after recognition and within 1 hour for both sepsis and septic shock. Routine microbiologic cultures (including blood) should be obtained before starting antimicrobial therapy in patients with suspected sepsis or septic shock as long as doing so results in no substantial delay in the initiation of antimicrobials.

Sartelli M, Chichom-Mefire A, Labricciosa FM, et al. The management of intra-abdominal infections from a global perspective: 2017 WSES Guidelines for management of intra-abdominal infections. *World J Emerg Surg.* 2017;12:29.
Key aspects of the management of intraabdominal infections include early and accurate diagnosis, prompt resuscitation, early and effective source control, and initiation of appropriate antimicrobial therapy.

Sawyer RG, Claridge JA, Nathens AB, et al. Trial of short-course antimicrobial therapy for intraabdominal infection. *N Engl J Med.* 2015;372:1996–2005.
For complicated intraabdominal infections in patients who are not severely ill and where source control has been obtained, a short course (3–5 days) of postoperative antibiotic therapy is recommended.

Solomkin J, Mazuski J, Bradley JS, et al. Diagnosis and management of complicated intra-abdominal infection in adults and children: Guidelines by the Surgical Infection Society and the Infectious Diseases Society of America. *Clin Infect Dis.* 2010;50:133–164.
In patients with pancreatic necrosis, broad-spectrum antimicrobial therapy is recommended only if clinical or culture evidence of an established infection is present. Appropriate treatment regimens include single-agent therapy such as a carbapenem or piperacillin/tazobactam or combination therapy using a third-generation cephalosporin or fluoroquinolone combined with an antianaerobic drug such as metronidazole.

Waibel B, Rotondo M. Damage control in trauma and abdominal sepsis. *Crit Care Med.* 2010;38(Suppl. 9):S421–S430.
Damage control and open abdomen techniques from trauma have been adopted for emergency surgery. If repeat operations are needed for debridement or source control, significant visceral edema is present preventing closure without development of abdominal compartment syndrome (ACS), or patient instability requiring further resuscitation would have high risk of creating ACS, a temporary abdominal closure may be used.
