Foreword

How can health care providers respond to the new model of consumerism in medicine, in which patients are encouraged to question everything, are bombarded with health care information in the media, and are targeted by direct advertising campaigns marketing everything from weight loss programs to therapies for erectile dysfunction? In today's information- and technology-driven environment, staying on the leading edge of ever-changing medical information can be overwhelming. The reality of contemporary medical economics and regulation of medical practice is driving many clinicians to see greater numbers of patients each day, each with more complex illnesses. This has resulted in less time spent with the patient, less time to perform detailed literature searches for complex conditions, and more time devoted to medical record completion, negotiating with medical insurance companies and other administrative representatives and justifying the medical necessity for many orders. In this environment there's a need for a well-organized and comprehensive summary of a wide variety of illnesses to help the busy clinician.

This 11th edition of *Professional Guide to Diseases* features well-organized chapters coordinated around disease clusters. The data in this edition are accurate, updated in terms of original research and practice guidelines, and designed to provide a brief yet comprehensive overview of a large array of disease processes and new sections for a quick pathophysiology review. Readers ranging from the trainee preparing for a board certification examination to the senior faculty member or other health care provider needing a ready reference will find that this book provides a clear and concise overview of hundreds of diseases and conditions.

This edition features improved sections focused on health promotion, disease prevention, and special focuses on elderly patients. Additionally, there is an updated section on bioterrorism and a new section on approaches to care of LGBTQ individuals—topics that have been receiving added emphasis in health care circles in recent years. Complications associated with different diseases are also included. This edition also updates information on many conditions for which a variety of clinical treatment guidelines have been published recently by major professional medical and surgical organizations. The content of clinical practice guidelines typically includes a detailed review of the literature for the specific topic.

For the variety of health care providers for whom this book has been created, the organizational format allows the option of reviewing an entire topic, such as clinical genetics and genomics, or narrowing the focus to one aspect of disease, such as the details of treatment or special considerations of emerging illnesses. The text is written clearly and includes graphic data

displays that make it useful as a quick reference, but it also contains comprehensive material that allows for more complete coverage of a group of similar disease entities. In this edition of the book are artwork and figures that illustrate the pathophysiology of many conditions in a full-color format. These images can not only be used to better understand the topic on a professional level, but can also be leveraged for patient teaching while in the office or hospital. This book continues to feature information on efficient health care delivery for routine conditions seen almost daily, as well as cultural considerations in patient care, information on potential bioterrorism agents, updates on rare diseases, and a revised section discussing complementary and alternative therapies for specific conditions.

As the practice of medicine continues to evolve, providers must face the challenges of achieving correct diagnoses using more targeted and cost-effective testing in a more constricted time frame. The 11th edition of *Professional Guide to Diseases* offers a strong background of successful editions combined with the latest updates and recommendations that will help you provide accurate information to your patients.

Enjoy this book!

Cardiovascular Disorders

Introduction

The cardiovascular system begins its activity when the fetus is barely a month old and is the last body system to cease activity at the end of life. This system is so vital that its activity defines the presence of life.

LIFE-GIVING TRANSPORT SYSTEM

The heart, arteries, veins, and lymphatics form the cardiovascular network that serves as the body's transport system, bringing life-supporting oxygen and nutrients to cells, removing metabolic waste products, and carrying hormones from one part of the body to another. Often called the *circulatory system,* it may be divided into two branches: *pulmonary circulation,* in which blood picks up new oxygen and liberates the waste product carbon dioxide; and *systemic circulation* (including coronary circulation), in which blood carries oxygen and nutrients to all active cells while transporting waste products to the kidneys, liver, and skin for excretion.

Circulation requires normal functioning of the heart, which propels blood through the system by continuous rhythmic contractions. Located behind the sternum, the heart is a muscular organ the size of a man's fist. It has three layers: the *endocardium*—the smooth inner layer; the *myocardium*—the thick, muscular middle layer that contracts in rhythmic beats; and the *epicardium*—the thin, serous membrane, or outer surface of the heart. Covering the entire heart is a saclike membrane called the *pericardium,* which has two layers: a *visceral* layer that's in contact with the heart and a *parietal,* or outer, layer. To prevent irritation when the heart moves against this layer during contraction, fluid lubricates the parietal pericardium.

The heart has four chambers: two thin-walled chambers called *atria* and two thick-walled chambers called *ventricles.* The atria serve as reservoirs during ventricular contraction (systole) and as booster pumps during ventricular relaxation (diastole). The left ventricle propels blood through the systemic circulation. The right ventricle, which forces blood through the pulmonary circulation, is much thinner than the left because it meets only one sixth the resistance.

ELDER TIP As a person's body ages, the ventricular and aortic walls stiffen, decreasing the heart's pumping action.

HEART VALVES

Two kinds of valves work inside the heart: *atrioventricular* (AV) and *semilunar*. The AV valve between the right atrium and the ventricle has three leaflets, or cusps, and three papillary muscles; hence, it's called the *tricuspid valve*. The AV valve between the left atrium and the ventricle consists of two cusps shaped like a bishop's hat, or miter, and two papillary muscles and is called the *mitral valve*. The tricuspid and mitral valves prevent blood backflow from the ventricles to the atria during ventricular contraction. The leaflets of both valves are attached to the ventricles' papillary muscles by thin, fibrous bands called *chordae tendineae*; the leaflets separate and descend funnel-like into the ventricles during diastole and are pushed upward and together during systole to occlude the mitral and tricuspid orifices. The valves' action isn't entirely passive because papillary muscles contract during systole and prevent the leaflets from prolapsing into the atria during ventricular contraction.

The two semilunar valves, which resemble half-moons, prevent blood backflow from the aorta and pulmonary arteries into the ventricles when those chambers relax and fill with blood from the atria. They're referred to as the *aortic valve* and *pulmonic valve* for their respective arteries.

ELDER TIP *In elderly people, fibrotic and sclerotic changes thicken heart valves and reduce their flexibility. These changes lead to rigidity and incomplete closure of the valves, which may result in systolic or diastolic murmurs.*

THE CARDIAC CYCLE

Diastole is the phase of ventricular relaxation and filling. As diastole begins, ventricular pressure falls below arterial pressure, and the aortic and pulmonic valves close. As ventricular pressure continues to fall below atrial pressure, the mitral and tricuspid valves open, and blood flows rapidly into the ventricles. Atrial contraction then increases the volume of ventricular filling by pumping 15% to 25% more blood into the ventricles. When *systole* begins, the ventricular muscle contracts, raising ventricular pressure above atrial pressure and closing the mitral and tricuspid valves. When ventricular pressure finally becomes greater than that in the aorta and pulmonary artery, the aortic and pulmonic valves open, and the ventricles eject blood. Ventricular pressure continues to rise as blood is expelled from the heart. As systole ends, the ventricles relax and stop ejecting blood, and ventricular pressure falls, closing both valves.

S_1 (the first heart sound) is heard as the ventricles contract and the AV valves close. S_1 is loudest at the heart's apex, over the mitral area. S_2 (the second heart sound), which is normally rapid and sharp, occurs when the aortic and pulmonic valves close. S_2 is loudest at the heart's base (second intercostal space [ICS] on both sides of the sternum).

Ventricular distention during diastole, which can occur in systolic heart failure, creates low-frequency vibrations that may be heard as a third heart sound (S_3), or ventricular gallop. An atrial gallop (S_4) may appear at the end of diastole, just before S_1, if atrial filling is forced into a ventricle that has become less compliant or overdistended or has a decreased ability to contract. A pressure rise and ventricular vibrations cause this sound.

CARDIAC CONDUCTION

The heart's conduction system is composed of specialized cells capable of generating and conducting rhythmic electrical impulses to stimulate heart contraction. This system includes the sinoatrial (SA) node, the AV junction, the bundle of His and its bundle branches, and the ventricular conduction tissue and Purkinje fibers.

Normally, the SA node controls the heart rate and rhythm at 60 to 100 beats/minute. Because

the SA node has the lowest resting potential, it's the heart's pacemaker. If it defaults, another part of the system takes over. The AV junction may emerge at 40 to 60 beats/minute; the bundle of His and bundle branches at 30 to 40 beats/minute; and ventricular conduction tissue at 20 to 30 beats/minute.

ELDER TIP *As the myocardium of the aging heart becomes more irritable, extrasystoles may occur along with sinus arrhythmias and sinus bradycardias. In addition, increased fibrous tissue infiltrates the SA nodes and internodal atrial tracts, which may cause atrial fibrillation and flutter.*

CARDIAC OUTPUT

Cardiac output—the amount of blood pumped by the left ventricle into the aorta each minute—is calculated by multiplying the *stroke volume* (the amount of blood the left ventricle ejects during each contraction) by the *heart rate* (number of beats/minute). When cellular demands increase, stroke volume or heart rate must increase.

Many factors affect the heart rate, including exercise, pregnancy, and stress. When the sympathetic nervous system releases norepinephrine, the heart rate increases; when the parasympathetic system releases acetylcholine, it slows. As a person ages, the heart rate takes longer to normalize after exercise.

Stroke volume depends on the ventricular blood volume and pressure at the end of diastole (preload), resistance to ejection (afterload), and the myocardium's contractile strength (inotropy). Changes in preload, afterload, or inotropic state can alter the stroke volume.

ELDER TIP *Exercise cardiac output declines slightly with age. A decrease in maximum heart rate and contractility may cause this change.*

CIRCULATION AND PULSES

Blood circulates through three types of vessels: *arteries, veins,* and *capillaries.* The sturdy, pliable walls of the arteries adjust to the volume of blood leaving the heart. The major artery branching out of the left ventricle is the aorta. Its segments and subbranches ultimately divide into minute, thin-walled (one-cell thick) capillaries. Capillaries pass the blood to the veins, which return it to the heart. In the veins, valves prevent blood backflow.

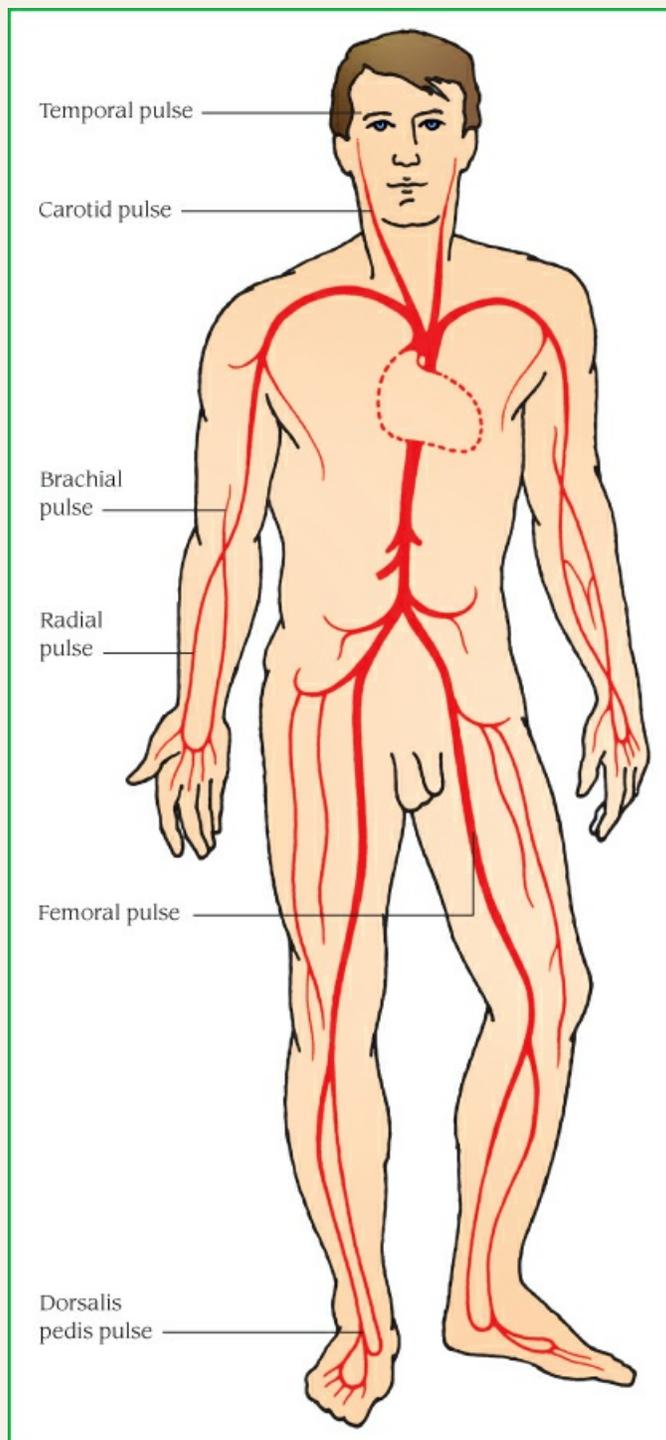
ELDER TIP *Aging contributes to arterial and venous insufficiency as the strength and elasticity of blood vessels decrease.*

Pulses are felt best wherever an artery runs near the skin and over a hard structure. (See *Pulse points*.) Easily found pulses are:

Pulse Points

Peripheral pulse rhythm should correspond exactly to the auscultatory heart rhythm. The pulse's character may offer useful information. For example, *pulsus alternans,* a strong beat followed by a weak one, can mean myocardial weakness. A *water-hammer* (or *Corrigan*) *pulse,* a forceful bounding pulse best felt in the carotid arteries or in the forearm, accompanies increased pulse pressure—commonly with capillary pulsations of the fingernails (*Quincke sign*). This pulse usually indicates aortic valve regurgitation.

Pulsus bisferiens, a double peripheral pulse for every apical beat, can signal aortic

regurgitation or hypertrophic obstructive cardiomyopathy. *Pulsus bigeminus* is a coupled rhythm; you feel its beat in pairs. *Pulsus paradoxus* is exaggerated waxing and waning of the arterial pressure (≥15 mm Hg decrease in systolic blood pressure during inspiration), often seen in cardiac tamponade.


- *radial artery*—anterolateral aspect of the wrist
- *temporal artery*—in front of the ear, above and lateral to the eye
- *common carotid artery*—neck (side)
- *femoral artery*—groin

The lymphatic system also plays a role in the cardiovascular network. Originating in tissue spaces, the lymphatic system drains fluid and other plasma components that build up in extravascular spaces and reroutes them back to the circulatory system as lymph, a plasmalike fluid. Lymphatics also extract bacteria and foreign bodies.

CARDIOVASCULAR ASSESSMENT

Physical assessment provides vital information about cardiovascular status.

- Check for underlying cardiovascular disorders, such as central cyanosis (impaired gas exchange), edema (heart failure or valvular disease), and clubbing (congenital cardiovascular disease).
- Palpate the peripheral pulses bilaterally and evaluate their rate, equality, and quality on a scale of 0 (absent) to +4 (bounding). (See *Pulse amplitude scale*.)

Pulse amplitude scale

To record your patient's pulse amplitude, use this standard scale:
- **0:** Pulse isn't palpable.
- **+1:** Pulse is thready, weak, difficult to find, may fade in and out, and disappears easily with pressure.
- **+2:** Pulse is constant but not strong; light pressure must be applied or pulse will disappear.
- **+3:** Pulse considered normal. Is easily palpable, doesn't disappear with pressure.
- **+4:** Pulse is strong, bounding, and doesn't disappear with pressure.

- Inspect the carotid arteries for equal appearance. Auscultate for bruits; then palpate the arteries individually, one side at a time, for *thrills* (fine vibrations due to irregular blood flow).
- Check for pulsations in the jugular veins (more easily seen than felt). Watch for jugular vein distention (JVD)—a possible sign of right-sided heart failure, valvular stenosis, cardiac tamponade, or pulmonary embolism. Take blood pressure readings in both arms while the patient is lying, sitting, and standing.
- Palpate the precordium for any abnormal pulsations, such as lifts, heaves, or thrills. Use the palms (at the base of the fingertips) or the fingertips. The normal apex will be felt as a light tap and extends over 1″ (2.5 cm) or less.
- Systematically auscultate the anterior chest wall for each of the four heart sounds in the aortic area (second ICS at the right sternal border), pulmonic area (second ICS at the left sternal border), right ventricular area (lower half of the left sternal border), and mitral area (fifth ICS at the midclavicular line). However, don't limit your auscultation to these four areas. Valvular sounds may be heard all over the precordium. Therefore, inch your stethoscope in a Z pattern, from the base of the heart across and down and then over to the apex, or start at the apex and

work your way up. For low-pitched sounds, use the bell of the stethoscope; for high-pitched sounds, the diaphragm. Carefully inspect each area for pulsations, and palpate for thrills. Check the location of apical pulsation for deviations in normal size ($^3/_8''$ to $^3/_4''$ [1 to 2 cm]) and position (in the mitral area)—possible signs of left ventricular hypertrophy, left-sided valvular disease, or right ventricular disease.

◆ Listen for the vibrating sound of turbulent blood flow through a stenotic or incompetent valve. Time the murmur to determine where it occurs in the cardiac cycle—between S_1 and S_2 (systolic), between S_2 and the following S_1 (diastolic), or throughout systole (holosystolic). Finally, listen for the scratching or squeaking of a pericardial friction rub.

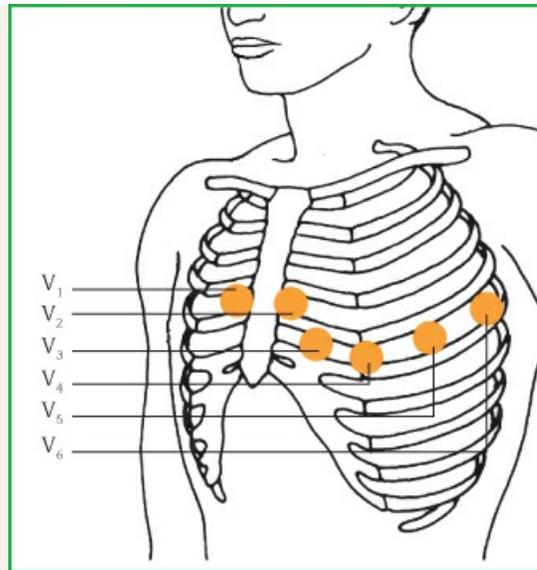
SPECIAL CARDIOVASCULAR TESTS

Electrocardiography (ECG) measures electrical activity by recording currents transmitted by the heart. It can detect ischemia, injury, necrosis, bundle branch blocks, fascicular blocks, conduction delay, chamber enlargement, and arrhythmias. In Holter monitoring, a tape recording tracks as many as 100,000 cardiac cycles over a 12- or 24-hour period. This test may be used to assess the effectiveness of antiarrhythmic drugs or to evaluate arrhythmia symptoms. A signal-averaged ECG will identify afterpotentials, which are associated with a risk of ventricular arrhythmias. (See *Positioning chest electrodes,* page 5.)

Positioning chest electrodes

To record the 12-lead electrocardiogram, place electrodes on the patient's arms and legs (with the ground lead on the patient's right leg). The three standard limb leads (I, II, III) and the three augmented leads (aV_R, aV_L, aV_F) are recorded using these electrodes.

To record the precordial (chest) leads, place the electrodes as follows:

◆ V_1—fourth ICS, right sternal border
◆ V_2—fourth ICS, left sternal border
◆ V_3—midway between V_2 and V_4
◆ V_4—fifth ICS, left midclavicular line
◆ V_5—fifth ICS, left anterior axillary line
◆ V_6—fifth ICS, left midaxillary line


Chest X-rays may reveal cardiac enlargement and aortic dilation. They also assess pulmonary circulation. When pulmonary venous and arterial pressures rise, characteristic changes appear, such as dilation of the pulmonary venous shadows. When pulmonary venous pressure exceeds oncotic pressure of the blood, capillary fluid leaks into lung tissues, causing pulmonary edema. This fluid may settle in the alveoli, producing a butterfly pattern, or the lungs may appear cloudy or hazy; in the interlobular septa, sharp linear densities (Kerley lines) may appear.

Exercise testing intra-aortic balloon pump (IABP) treadmill determines the heart's response to physical stress. This test measures blood pressure and ECG changes during increasingly rigorous exercises. Myocardial ischemia, abnormal blood pressure response, or arrhythmias indicate the circulatory system's failure to adapt to exercise.

Cardiac catheterization evaluates chest pain, the need for coronary artery surgery or angioplasty, congenital heart defects, and valvular heart disease and determines the extent of heart failure. Right-sided catheterization involves threading a pulmonary artery thermodilution catheter, which can measure cardiac output, through a vein into the right side of the heart, pulmonary artery, and its branches in the lungs to measure right atrial, right ventricular, pulmonary artery, and pulmonary artery wedge pressures (PAWPs). Left-sided catheterization entails retrograde catheterization of the left ventricle or transseptal catheterization of the left atrium. Ventriculography during left-sided catheterization involves injecting radiopaque dye into the left ventricle to measure ejection fraction and to disclose abnormal heart wall motion or mitral valve incompetence.

In coronary angiography, radiopaque material injected into coronary arteries allows cineangiographic visualization of coronary arterial narrowing or occlusion.

Echocardiography uses echoes from pulsed high-frequency sound waves (ultrasound) to evaluate cardiac structures. Two-dimensional echocardiography (most common), in which an ultrasound beam rapidly sweeps through an arc, produces a cross-sectional or fan-shaped view of cardiac structures. Contrast agents may be used for image enhancement. Doppler echocardiography records blood flow within the cardiovascular system. Color Doppler echocardiography shows the direction of blood flow, which provides information about the

degree of valvular insufficiency. Transesophageal echocardiography combines ultrasound with endoscopy to better view the heart's structures. This procedure allows images to be taken from the heart's posterior aspect.

Echocardiography provides information about valve leaflets, size and dimensions of heart chambers, and thickness and motion of the septum and the ventricular walls. It can also reveal intracardiac masses, detect pericardial effusion, diagnose hypertrophic cardiomyopathy, and estimate cardiac output and ejection fraction. This test can also evaluate possible aortic dissection when it involves the ascending aorta.

In multiple-gated acquisition scanning (MUGA), a radioactive isotope in the intravascular compartment allows measurement of stroke volume, wall motion, and ventricular ejection fraction. Myocardial imaging uses a radioactive isotope to detect abnormalities in myocardial perfusion. This agent concentrates in normally perfused areas of the myocardium but not in ischemic areas ("cold spots"), which may be permanent (scar tissue) or temporary (from transient ischemia). These tests can be done as exercise studies or can be combined with drugs (nuclear stress test), in patients unable to exercise.

Peripheral arteriography consists of a fluoroscopic X-ray after arterial injection of a contrast medium. Similarly, phlebography defines the venous system after injection of a contrast medium into a vein.

Doppler ultrasonography evaluates the peripheral vascular system and assesses peripheral artery disease (PAD) when combined with sequential systolic blood pressure readings.

Endomyocardial biopsy can detect cardiomyopathy, infiltrative myocardial diseases, and, most often, transplant rejection.

Electrophysiologic studies help diagnose conduction system disease and serious arrhythmias. Electronic induction and termination of arrhythmias aid drug selection. Endocardial mapping detects an arrhythmia's focus using a finger electrode. Epicardial mapping uses a computer and a device containing electrodes that's slipped over the heart to detect arrhythmias.

Magnetic resonance imaging (MRI) can investigate cardiac structure and function. Positron emission tomography and magnetic resonance spectroscopy are used to assess myocardial metabolism.

Electron-beam computed tomography, also known as ultrafast computed tomography, is used to detect microcalcifications in the coronary arteries and can give a coronary calcium score. This test is useful for identifying early coronary artery disease (CAD).

Blood tests

Cardiac enzymes (cellular proteins released into blood after cell membrane injury) confirm acute myocardial infarction (MI) or severe cardiac trauma. All cardiac enzymes—creatine kinase (CK), lactate dehydrogenase, and aspartate aminotransferase, for example—are also found in other cells. Fractionation of enzymes can determine the source of damaged cells. For example, three fractions of CK are isolated, one of which (an isoenzyme called *CK-MB*) is found only in cardiac cells. CK-MB in the blood indicates injury to myocardial cells.

Measurement of a cardiac protein called *troponin* is the most precise way to determine whether a patient has experienced an MI. Some 6 hours after an MI, a blood test can detect two forms of troponin: T and I. Troponin T levels peak about 2 days after an MI and return to normal about 16 days later. Troponin I levels reach their peak in less than 1 day after an MI and return to normal in about 7 days.

MANAGING CARDIOVASCULAR DISEASE

Patients with cardiovascular disease pose a tremendous challenge. Their sheer numbers alone compel a thorough understanding of cardiovascular anatomy, physiology, and pathophysiology. Anticipate a high anxiety level in cardiac patients, and provide support and reassurance, especially during procedures such as cardiac catheterization.

Cardiac rehabilitation programs are widely prescribed and offer education and support along with exercise instruction. Rehabilitation programs begin in healthcare facilities and continue on an outpatient basis. Helping the patient resume a satisfying lifestyle requires planning and comprehensive teaching. Inform the patient about healthcare facilities and organizations that offer cardiac rehabilitation programs.

Congenital Acyanotic Defects

VENTRICULAR SEPTAL DEFECT

Causes and Incidence

In ventricular septal defect (VSD), the most common congenital heart disorder, an opening in the septum between the ventricles allows blood to shunt between the left and the right ventricles. This disease accounts for up to 30% of all congenital heart defects. Although most children with congenital heart defects are otherwise normal, in some, VSD coexists with additional birth defects, especially Down syndrome and other autosomal trisomies, renal anomalies, and such cardiac defects as patent ductus arteriosus (PDA) and coarctation of the aorta. VSDs are located in the membranous or muscular portion of the ventricular septum and vary in size. Some defects close spontaneously; in other defects, the entire septum is absent, creating a single ventricle. The prognosis is good for defects that close spontaneously or are correctable surgically but poor for untreated defects, which are sometimes fatal by age 1, usually from secondary complications. Less than 1% of neonates are born with VSD. In 80% to 90% of neonates who are born with this disorder, the hole is small and will usually close spontaneously. In the remaining 10% to 20% of neonates, surgery is needed to close the hole. (See *Understanding ventricular septal defect*, page 7.)

Understanding Ventricular Septal Defect

A ventricular septal defect (VSD), the most common type of congenital disorder, is an abnormal opening between the right and left ventricles that allows blood to shunt between them. Not always readily apparent at birth, the defect can be small and may close spontaneously. The septum may be entirely absent, resulting in a single ventricle. A large, untreated defect can cause right ventricular hypertrophy, pulmonary hypertension, and heart failure. VSD is classified as an increased pulmonary blood flow defect.

Aorta

To right lung

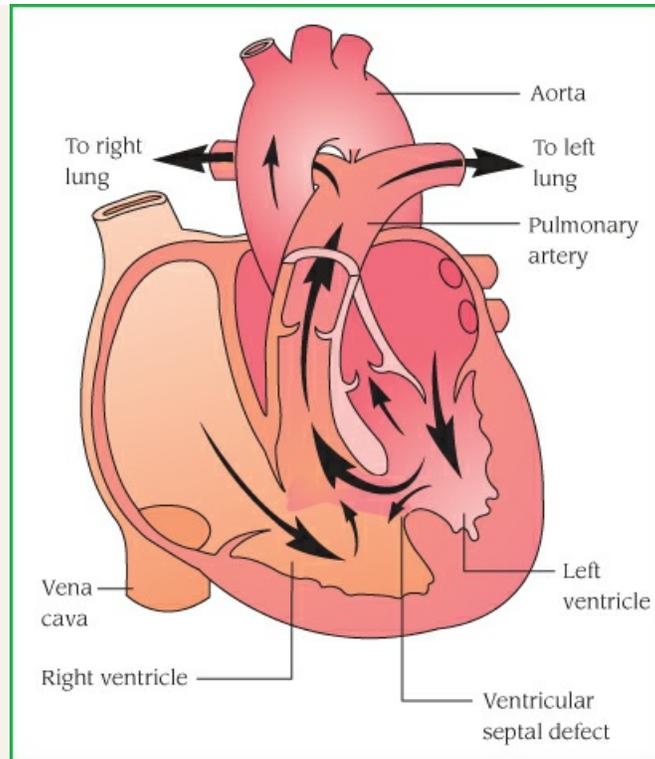
To left lung

Pulmonary artery

Vena cava

Left ventricle

Right ventricle

Ventricular septal defect


Pathophysiology

In neonates with VSD, the ventricular septum fails to close completely by the eighth week of gestation, as it would normally.

VSD isn't readily apparent at birth, because right and left ventricular pressures are about equal, so blood doesn't shunt through the defect. As the pulmonary vasculature gradually relaxes, 4 to 8 weeks after birth, right ventricular pressure decreases, allowing blood to shunt from the left to the right ventricle. In small or restrictive defects, right ventricle pressure is only slightly elevated, while pulmonary artery pressures (PAPs) and peripheral vascular resistance (PVR) remain normal. In moderate defects, the size of the defect determines the magnitude of the shunt. When right ventricular pressure decreases, the left atrium and ventricle may become fluid overloaded. Because large defects do not meet a lot of flow resistance, the pressure of the ventricles is equal at first. As PVR decreases, volume increases to the pulmonary system, in turn increasing the volume of the left ventricle. This, in turn, can create left ventricular dilation, followed by increased left atrial pressure and pulmonary venous pressure.

Complications

- Right arterial and ventricular hypertrophy
- Heart failure
- Pulmonary hypertension

Signs and Symptoms

Clinical features of VSD vary with the defect's size, the shunting's effect on the pulmonary

vasculature, and the infant's age. In a small VSD, shunting is minimal, and PAP and heart size remain normal. Such defects may eventually close spontaneously without ever causing symptoms.

Initially, large VSD shunts cause left atrial and left ventricular hypertrophy. Later, an uncorrected VSD will cause right ventricular hypertrophy due to increasing pulmonary vascular resistance. Eventually, biventricular heart failure and cyanosis (from reversal of shunt direction) occur. Resulting cardiac hypertrophy may make the anterior chest wall prominent. A large VSD increases the risk of pneumonia.

Infants with large VSDs are thin and small and gain weight slowly. They may develop heart failure with dusky skin; liver, heart, and spleen enlargement because of systemic venous congestion; diaphoresis; feeding difficulties; rapid, grunting respirations; and increased heart rate. They may also develop severe pulmonary hypertension. Fixed pulmonary hypertension may occur much later in life with right-to-left shunt (Eisenmenger syndrome), causing cyanosis and clubbing of the nail beds.

The typical murmur associated with a VSD is blowing or rumbling and varies in frequency. In the neonate, a moderately loud early systolic murmur may be heard along the lower left sternal border. About the second or third day after birth, the murmur may become louder and longer. In infants, the murmur may be loudest near the heart's base and may suggest pulmonary stenosis (PS). A small VSD may produce a functional murmur or a characteristic loud, harsh systolic murmur. Larger VSDs produce audible murmurs (at least a grade 3 pansystolic), loudest at the fourth ICS, usually with a thrill; however, a large VSD with minimal pressure gradient may have no audible murmur. In addition, the pulmonic component of S_2 sounds loud and is widely split. Palpation reveals displacement of the point of maximal impulse to the left. When fixed pulmonary hypertension is present, a diastolic murmur may be audible on auscultation, the systolic murmur becomes quieter, and S_2 is greatly accentuated.

Diagnosis

Diagnostic findings include:

- Chest X-ray is normal in small defects; in large VSDs, it shows cardiomegaly, left atrial and left ventricular enlargement, and prominent pulmonary vascular markings.
- ECG is normal in children with small VSDs; in large VSDs, it shows left and right ventricular hypertrophy, suggesting pulmonary hypertension.
- Echocardiography may detect a large VSD and its location in the septum, estimate the size of a left-to-right shunt, suggest pulmonary hypertension, and identify associated lesions and complications.

CONFIRMING DIAGNOSIS *Cardiac catheterization determines the VSD's size and exact location, calculates the degree of shunting by comparing the blood oxygen saturation in each ventricle, determines the extent of pulmonary hypertension, and detects associated defects.*

Treatment

In mild cases, no treatment is needed, although the infant should be closely followed to make sure that the hole closes properly as the infant grows. Large defects usually require early surgical correction before heart failure and irreversible pulmonary vascular disease develop.

For small defects, surgery consists of simple suture closure. Moderate to large defects require insertion of a patch graft, using cardiopulmonary bypass. In patients with heart failure, digoxin

and diuretics may be prescribed to control symptoms. In patients who develop increased pulmonary resistance and irreversible pulmonary vascular changes that produce a reversible right-to-left shunt (Eisenmenger syndrome), a heart–lung transplant may be required.

If the child has other defects and will benefit from delaying surgery, pulmonary artery banding normalizes pressures and flow distal to the band and prevents pulmonary vascular disease, allowing postponement of surgery. (Pulmonary artery banding is done only when the child has other complications.) A rare complication of VSD repair is complete heart block from interference with the bundle of His during surgery. (Heart block may require temporary or permanent pacemaker implantation.)

Before surgery, treatment consists of:

◆ digoxin, sodium restriction, and diuretics to prevent heart failure
◆ careful monitoring by physical examination, X-ray, and ECG to detect increased pulmonary hypertension, which indicates a need for early surgery
◆ measures to prevent infection (prophylactic antibiotics, e.g., to prevent infective endocarditis)

Generally, postoperative treatment includes a brief period of mechanical ventilation. The patient will need analgesics and may also require diuretics to increase urine output, continuous infusions of nitroprusside or adrenergic agents to regulate blood pressure and cardiac output and, in rare cases, a temporary pacemaker.

Special Considerations

Although the parents of an infant with VSD often suspect something is wrong with their child before diagnosis, they need psychological support to help them accept the reality of a serious cardiac disorder. Because surgery may take place months after diagnosis, parent teaching is vital to prevent complications until the child is scheduled for surgery or the defect closes. Thorough explanations of all tests are also essential.

◆ Instruct parents to watch for signs of heart failure, such as poor feeding, sweating, and heavy breathing.
◆ If the child is receiving digoxin or other medications, tell the parents how to give it and how to recognize adverse effects. Caution them to keep medications out of the reach of all children.
◆ Teach parents to recognize and report early signs of infection and to avoid exposing the child to people with obvious infections.
◆ Encourage parents to let the child engage in normal activities.
◆ Tell parents to follow up with their pediatrician. Also tell them that child life therapy may be appropriate if their child displays delayed growth and development or failure to thrive.
◆ Stress the importance of prophylactic antibiotics before and after surgery.

After surgery to correct VSD:

◆ Monitor vital signs and intake and output. Maintain the infant's body temperature with an overbed warmer. Give catecholamines, nitroprusside, and diuretics, as ordered; analgesics as needed.
◆ Monitor central venous pressure (CVP), intra-arterial blood pressure, and left atrial or PAP readings. Assess heart rate and rhythm for signs of conduction block.
◆ Check oxygenation, particularly in a child who requires mechanical ventilation. Suction to maintain a patent airway and to prevent atelectasis and pneumonia, as needed.

- Monitor pacemaker effectiveness if needed. Watch for signs of failure, such as bradycardia and hypotension.
- Reassure parents and allow them to participate in their child's care.

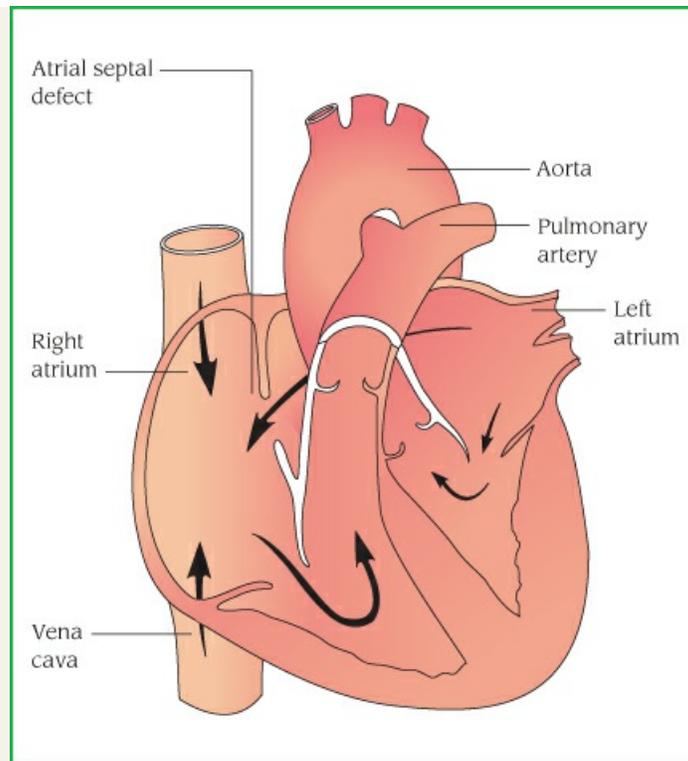
ATRIAL SEPTAL DEFECT

Causes and Incidence

In an atrial septal defect (ASD), an opening between the left and the right atria allows shunting of blood between the chambers. *Ostium secundum defect* (most common) occurs in the region of the fossa ovalis and occasionally extends inferiorly, close to the vena cava; *sinus venosus defect* occurs in the superior–posterior portion of the atrial septum, sometimes extending into the vena cava, and is almost always associated with abnormal drainage of pulmonary veins into the right atrium; *ostium primum defect* occurs in the inferior portion of the septum primum and is usually associated with AV valve abnormalities (cleft mitral valve) and conduction defects. The cause of ASD is unknown.

ASD accounts for about 6% to 8% of congenital heart defects and appears almost twice as often in females as in males, with a strong familial tendency. Although ASD is usually a benign defect during infancy and childhood, delayed development of symptoms and complications makes it one of the most common congenital heart defects diagnosed in adults. ASD is present in 4 of every 100,000 people. Symptoms usually develop before age 30. When no other congenital defect exists, the patient—especially if a child—may be asymptomatic. The prognosis is excellent in asymptomatic patients but poor in those with cyanosis caused by large, untreated defects. (See *Understanding atrial septal defect*.)

Understanding Atrial Septal Defect

An atrial septal defect (ASD) is an abnormal opening between the left and the right atria. A small opening may cause few symptoms. However, if the opening is large, higher pressure in the left atrium can shunt large amounts of blood into the right atrium, which can result in right heart volume overload, right atrial and ventricular enlargement, and pulmonary hypertension. ASD is classified as an increased pulmonary blood flow defect and is one of the most common congenital heart defects.


Pathophysiology

In this condition, blood shunts from left to right because left atrial pressure normally is slightly higher than right atrial pressure; this pressure difference forces large amounts of blood through a defect. The left-to-right shunt results in right heart volume overload, affecting the right atrium, right ventricle, and pulmonary arteries. Eventually, the right atrium enlarges, and the right ventricle dilates to accommodate the increased blood volume. If pulmonary artery hypertension develops because of the shunt (rare in children), increased pulmonary vascular resistance and right ventricular hypertrophy will follow. In some adult patients, irreversible (fixed) pulmonary artery hypertension causes reversal of the shunt direction, which results in unoxygenated blood entering the systemic circulation, causing cyanosis.

Complications

- Unoxygenated blood in systemic circulation
- Right and left ventricular hypertrophy
- Atrial arrhythmias
- Heart failure
- Emboli

Signs and Symptoms

ASD commonly goes undetected in preschoolers; such children may complain about feeling tired only after extreme exertion and may have frequent respiratory tract infections but otherwise appear normal and healthy. However, children with large shunts may show growth retardation.

Children with ASD seldom develop heart failure, pulmonary hypertension, infective endocarditis, or other complications. However, as adults, they usually manifest pronounced symptoms, such as fatigability and dyspnea on exertion, frequently to the point of severe limitation of activity (especially after age 40).

In children, auscultation reveals an early to midsystolic murmur, superficial in quality, heard at the second or third left ICS. In patients with large shunts (resulting from increased tricuspid valve flow), a low-pitched diastolic murmur is heard at the lower left sternal border, which becomes more pronounced on inspiration. Although the murmur's intensity is a rough indicator of the size of the left-to-right shunt, its low pitch sometimes makes it difficult to hear and, if the pressure gradient is relatively low, a murmur may not be detectable. Other signs include a fixed, widely split S_2, caused by delayed closure of the pulmonic valve, and a systolic click or late systolic murmur at the apex, resulting from mitral valve prolapse (MVP), which occasionally affects older children with ASD.

In older patients with large, uncorrected defects and fixed pulmonary artery hypertension, auscultation reveals an accentuated S_2. A pulmonary ejection click and an audible S_4 may also be present. Clubbing and cyanosis become evident; syncope and hemoptysis may occur with severe pulmonary vascular disease.

Diagnosis

A history of increasing fatigue and characteristic physical features suggest ASD. The following findings confirm it:

- Chest X-ray shows an enlarged right atrium and right ventricle, a prominent pulmonary artery, and increased pulmonary vascular markings.
- ECG may be normal but usually shows right axis deviation, prolonged PR interval, varying degrees of right bundle branch block, right ventricular hypertrophy, atrial fibrillation (particularly in severe cases after age 30) and, in ostium primum defect, left axis deviation.
- Echocardiography measures right ventricular enlargement, may locate the defect, and shows volume overload in the right side of the heart. (Other causes of right ventricular enlargement must be ruled out.)

CONFIRMING DIAGNOSIS *Two-dimensional echocardiography with color Doppler flow, contrast echocardiography, or both have supplanted cardiac catheterization as the confirming tests for ASD. Cardiac catheterization is used if inconsistencies exist in the clinical data or if significant pulmonary hypertension is suspected.*

Treatment

Operative repair is advised for all patients with uncomplicated ASD with evidence of significant left-to-right shunting. Ideally, this is performed when the patient is between ages 2 and 4. Operative treatment shouldn't be performed in patients with small defects and trivial left-to-right shunts. Because ASD seldom produces complications in infants and toddlers, surgery can be delayed until they reach preschool or early school age. A large defect may need immediate surgical closure with sutures or a patch graft.

Physicians have developed a new procedure, referred to as catheter closure or transcatheter closure of the ASD, that uses wires or catheters to close ASD without surgery. In this procedure, the surgeon makes a tiny incision in the groin to introduce the catheters, then advances the catheters into the heart, and places the closure device across the ASD. This procedure may not be

applicable to all patients.

Special Considerations

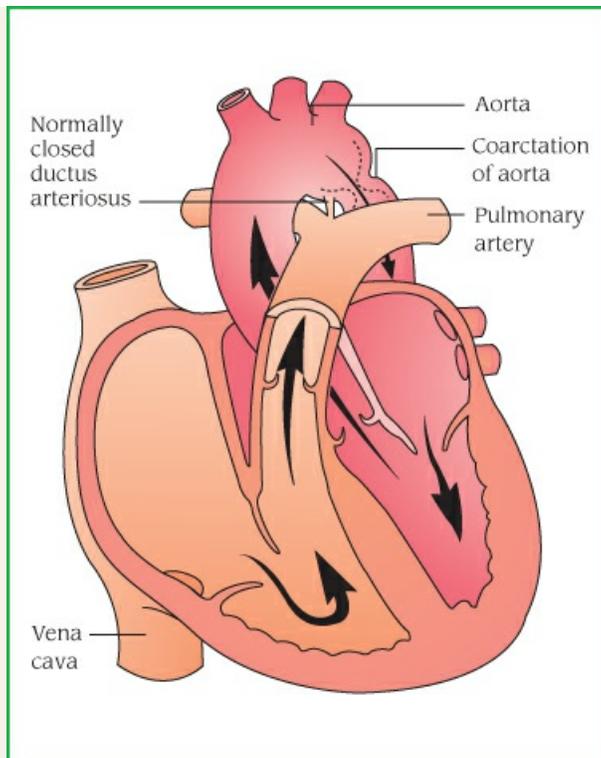
- Before cardiac catheterization, explain pretest and posttest procedures to the child and her parents. If possible, use drawings or other visual aids to explain it to the child.
- As needed, teach the patient about prophylactic antibiotics to prevent infective endocarditis. (They may be administered before dental or other invasive procedures.)
- If surgery is scheduled, teach the child and his or her parents about the intensive care unit (ICU) and introduce them to the staff. Show parents where they can wait during the operation. Explain postoperative procedures, tubes, dressings, and monitoring equipment.
- After surgery, closely monitor the patient's vital signs, central venous and intra-arterial pressures, and intake and output. Watch for atrial arrhythmias, which may remain uncorrected.

COARCTATION OF THE AORTA

Causes and Incidence

Coarctation is a narrowing of the aorta, usually just below the left subclavian artery, near the site where the ligamentum arteriosum (the remnant of the ductus arteriosus, a fetal blood vessel) joins the pulmonary artery to the aorta. Coarctation may occur with aortic valve stenosis (usually of a bicuspid aortic valve) and with severe cases of hypoplasia of the aortic arch, PDA, and VSD. This is typically sporadic and without clear cause before this condition induces severe systemic hypertension or degenerative changes in the aorta. (See *Understanding coarctation of the aorta*.)

Understanding Coarctation of the Aorta

Coarctation is a narrowing of the aorta, usually just below the left subclavian artery, near the site where the ligamentum arteriosum joins the pulmonary artery to the aorta. It can result from spasm and constriction of the smooth muscle in the ductus arteriosus as it closes. Restricted blood flow through the narrow aorta increases the pressure load on the left ventricle, resulting in dilation of the proximal aorta, left ventricular hypertrophy, elevated upper body blood pressures, and diminished blood flow to the lower body. The ductus arteriosus may be open or closed. Coarctation of the aorta is more common in boys and is the leading cause of heart failure in the first few months of life. It's classified as an obstruction to blood flow leaving the heart.


Coarctation of the aorta occurs in 4 of every 10,000 people born each year in the United States and is usually diagnosed in children or adults younger than age 40. It accounts for about 4% to 6% of all congenital heart defects in children and is twice as common in males as in females. When it occurs in females, it's commonly associated with Turner syndrome, a chromosomal disorder that causes ovarian dysgenesis. Generally, the prognosis for coarctation of the aorta depends on the severity of associated cardiac anomalies; the prognosis for isolated coarctation is good if corrective surgery is performed.

Pathophysiology

Coarctation of the aorta may develop as a result of spasm and constriction of the smooth muscle in the ductus arteriosus as it closes. Possibly, this contractile tissue extends into the aortic wall, causing narrowing. The obstructive process causes hypertension in the aortic branches above the constriction (arteries that supply the arms, neck, and head) and diminished pressure in the vessels below the constriction.

Restricted blood flow through the narrowed aorta increases the pressure load on the left ventricle and causes dilation of the proximal aorta and ventricular hypertrophy. Untreated, this condition may lead to left-sided heart failure and, rarely, to cerebral hemorrhage and aortic rupture. If VSD accompanies coarctation, blood shunts left to right, straining the right side of the heart. This leads to pulmonary hypertension and, eventually, right-sided heart hypertrophy and failure.

Complications

◆ Infective endocarditis

- Pulmonary hypertension
- Right ventricular hypertrophy
- Right-sided heart failure

Signs and Symptoms

Clinical features vary with age. During the first year of life, when aortic coarctation may cause heart failure, the infant displays tachypnea, dyspnea, pulmonary edema, pallor, tachycardia, failure to thrive, cardiomegaly, and hepatomegaly. In most cases, heart sounds are normal unless a coexisting cardiac defect is present. Femoral pulses are absent or diminished.

If coarctation is asymptomatic in infancy, it usually remains so throughout adolescence, as collateral circulation develops to bypass the narrowed segment. During adolescence, this defect may produce dyspnea, claudication, headaches, epistaxis, and hypertension in the upper extremities despite collateral circulation. It commonly causes resting systolic hypertension and wide pulse pressure; high diastolic pressure readings are the same in both the arms and the legs. Coarctation may also produce a visible aortic pulsation in the suprasternal notch, a continuous systolic murmur, an accentuated S_2, and an S_4.

Diagnosis

℞ **CONFIRMING DIAGNOSIS** *The cardinal signs of coarctation of the aorta are resting systolic hypertension, absent or diminished femoral pulses, and wide pulse pressure.*

The following tests support this diagnosis:

- Chest X-ray may demonstrate left ventricular hypertrophy, heart failure, a wide ascending and descending aorta, and notching of the undersurfaces of the ribs, due to extensive collateral circulation.
- ECG may eventually reveal left ventricular hypertrophy.
- Echocardiography may show increased left ventricular muscle thickness, coexisting aortic valve abnormalities, and the coarctation site.
- Doppler ultrasound and cardiac catheterization evaluate collateral circulation and measure pressure in the right and left ventricles and in the ascending and descending aortas (on both sides of the obstruction).
- MRI enables assessment of the anatomy and function of aortic abnormalities.

Treatment

For an infant with heart failure caused by coarctation of the aorta, treatment consists of medical management with digoxin, diuretics, oxygen, and sedatives. If medical management fails, surgery may be needed.

The child's condition usually determines the timing of surgery. Signs of heart failure or hypertension may call for early surgery. If these signs don't appear, surgery usually occurs during the preschool years.

Before the operation, the child may require endocarditis prophylaxis or, if he or she is older and has previously undetected coarctation, antihypertensive therapy. During surgery, the surgeon uses a flap of the left subclavian artery to reconstruct an unobstructed aorta.

Balloon angioplasty with possible stent placement may also be indicated for some patients as an alternative to surgical repair. It uses a technique similar to that used to open the coronary

arteries, but is performed on the aorta.

Special considerations

- Palpate the pulses in the legs in newborns and at well-baby visits to detect absent or diminished pulses.
- When coarctation in an infant requires rapid digitalization, monitor vital signs closely and watch for digoxin toxicity (poor feeding and vomiting).
- Balance intake and output carefully, especially if the infant is receiving diuretics with fluid restriction.
- Because the infant may not be able to maintain proper body temperature, regulate environmental temperature with an overbed warmer if needed.
- Monitor blood glucose levels to detect possible hypoglycemia, which may occur as glycogen stores become depleted.
- Offer the parents emotional support and an explanation of the disorder. Also explain diagnostic procedures, surgery, and drug therapy. Tell parents what to expect postoperatively.
- For an older child, assess the blood pressure in extremities regularly, explain any exercise restrictions, stress the need to take medications properly and to watch for adverse effects, and teach about tests and other procedures.

  After corrective surgery:

- Monitor blood pressure closely, using an intra-arterial line. Measure blood pressure in arms and legs. Monitor intake and output.
- If the patient develops hypertension and requires a medication such as nitroprusside, administer it, as ordered, using an infusion pump. Watch for severe hypotension and regulate the dosage carefully.
- Provide pain relief and encourage a gradual increase in activity.
- Promote adequate respiratory functioning through turning, coughing, and deep breathing.
- Watch for abdominal pain or rigidity and signs of gastrointestinal (GI) or urinary bleeding.
- If an older child needs to continue antihypertensives after surgery, teach the patient and his parents about them.
- Stress the importance of continued endocarditis prophylaxis as appropriate.

PATENT DUCTUS ARTERIOSUS

Causes and Incidence

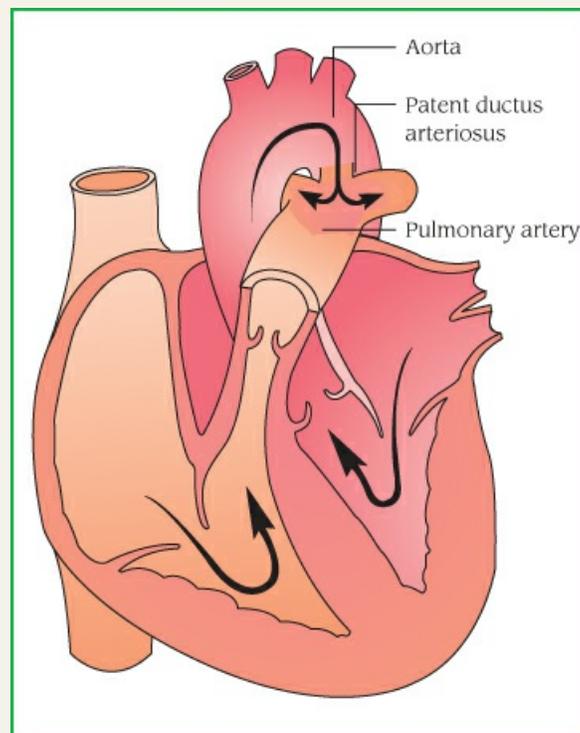
The ductus arteriosus is a fetal blood vessel that connects the pulmonary artery to the descending aorta. In PDA, the lumen of the ductus remains open after birth. This creates a left-to-right shunt of blood from the aorta to the pulmonary artery and results in recirculation of arterial blood through the lungs. Normally, the ductus closes within days to weeks after birth. Failure to close is most prevalent in premature neonates, probably as a result of abnormalities in oxygenation or the relaxant action of prostaglandin E, which prevents ductal spasm and contracture necessary for closure. However, most of the time, the cause of this condition is unknown. PDA commonly accompanies rubella syndrome and may be associated with other congenital defects, such as coarctation of the aorta, VSD, and pulmonary and aortic stenoses.

Initially, PDA may produce no clinical effects, but in time it can precipitate pulmonary vascular disease, causing symptoms to appear by age 40. PDA is found in 1 of every 2,000

infants and is the most common congenital heart defect found in adults. It affects twice as many females as males. Additionally, babies born at above 10,000 feet in altitude are more affected.

The prognosis is good if the shunt is small or surgical repair is effective. Otherwise, PDA may advance to intractable heart failure, which may be fatal. (See *Understanding patent ductus arteriosus*.)

Understanding Patent Ductus Arteriosus

The ductus arteriosus is a fetal blood vessel that connects the pulmonary artery to the descending aorta. Normally, the ductus closes within weeks after birth. However, with patent ductus arteriosus (PDA), it remains open, creating a left-to-right shunt of blood from the aorta to the pulmonary artery and resulting in recirculation of arterial blood through the lungs. PDA is classified as an increased pulmonary blood flow defect.


Pathophysiology

In PDA, relative resistances in pulmonary and systemic vasculature and the size of the ductus determine the amount of left-to-right shunting. The left atrium and left ventricle must accommodate the increased pulmonary venous return, in turn increasing filling pressure and workload on the left side of the heart and possibly causing heart failure. In the final stages of untreated PDA, the left-to-right shunt leads to chronic pulmonary artery hypertension that becomes fixed and unreactive. This causes the shunt to reverse; unoxygenated blood thus enters systemic circulation, causing cyanosis.

Complications

- Left-sided heart failure
- Pulmonary artery hypertension
- Respiratory distress (children)

Signs and Symptoms

In neonates, especially those who are premature, a large PDA usually produces respiratory distress, with signs of heart failure due to the tremendous volume of blood shunted to the lungs through a patent ductus and the increased workload on the left side of the heart. Other characteristic features may include heightened susceptibility to respiratory tract infections, slow motor development, and failure to thrive. Most children with PDA have no symptoms except cardiac ones. Others may exhibit signs of heart disease, such as physical underdevelopment, fatigability, and frequent respiratory tract infections. Adults with undetected PDA may develop pulmonary vascular disease and, by age 40, may display fatigability and dyspnea on exertion. About 10% of them also develop infective endocarditis.

Auscultation reveals the classic machinery murmur (Gibson murmur): a continuous murmur (during systole and diastole) best heard at the heart's base, at the second left ICS under the left clavicle in 85% of children with PDA. This murmur may obscure S_2. However, with a right-to-left shunt, such a murmur may be absent. Palpation may reveal a thrill at the left sternal border and a prominent left ventricular impulse. Peripheral arterial pulses are bounding (Corrigan pulse); pulse pressure is widened because of an elevation in systolic blood pressure and, primarily, a drop in diastolic pressure.

Diagnosis

- Chest X-ray may show increased pulmonary vascular markings, prominent pulmonary arteries, and left ventricle and aorta enlargement.
- ECG may be normal or may indicate left atrial or ventricular hypertrophy and, in pulmonary vascular disease, biventricular hypertrophy.
- Echocardiography confirms the diagnosis, detecting and helping to estimate the size of a PDA. It also reveals an enlarged left atrium and left ventricle or right ventricular hypertrophy from pulmonary vascular disease.

CONFIRMING DIAGNOSIS *Cardiac catheterization can also be performed and shows pulmonary arterial oxygen content higher than right ventricular content because of the influx of aortic blood. Increased PAP indicates a large shunt or, if it exceeds systemic arterial pressure, severe pulmonary vascular disease. Catheterization allows calculation of blood volume crossing the ductus and can rule out associated cardiac defects. Dye injection definitively demonstrates PDA.*

Treatment

Asymptomatic infants with PDA require no immediate treatment. Those with heart failure require fluid restriction, diuretics, and cardiac glycosides to minimize or control symptoms. If these measures can't control heart failure, surgery is necessary to ligate the ductus. If symptoms are mild, surgical correction is usually delayed until the infant is between ages 6 months and 3 years, unless problems develop. Before surgery, children with PDA require antibiotics to protect

against infective endocarditis.

Other forms of therapy include cardiac catheterization to deposit a plug or coil in the ductus to stop shunting or administration of indomethacin I.V. (a prostaglandin inhibitor that's an alternative to surgery in premature neonates) to induce ductus spasm and closure.

Special Considerations

PDA necessitates careful monitoring, patient and family teaching, and emotional support.

- Watch carefully for signs of PDA in all premature neonates.
- Be alert for respiratory distress symptoms resulting from heart failure, which may develop rapidly in a premature neonate. Frequently assess vital signs, ECG, electrolyte levels, and intake and output. Record response to diuretics and other therapy. Watch for signs of digoxin toxicity (poor feeding and vomiting).
- If the infant receives indomethacin for ductus closure, watch for possible adverse effects, such as diarrhea, jaundice, bleeding, and renal dysfunction.
- Before surgery, carefully explain all treatments and tests to parents. Include the child in your explanations. Arrange for the child and her parents to meet the ICU staff. Tell them about expected I.V. lines, monitoring equipment, and postoperative procedures.
- Immediately after surgery, the child may have a CVP catheter and an arterial line in place. Carefully assess vital signs, intake and output, and arterial and venous pressures. Provide pain relief as needed.
- Before discharge, review instructions to the parents about activity restrictions based on the child's tolerance and energy levels. Advise parents not to become overprotective as their child's tolerance for physical activity increases.
- Stress the need for regular follow-up examinations. Advise parents to inform any practitioner who treats their child about the history of surgery for PDA—even if the child is being treated for an unrelated medical problem.

Congenital Cyanotic Defects

TETRALOGY OF FALLOT

Causes and Incidence

Tetralogy of Fallot is a combination of four cardiac defects: VSD, right ventricular outflow tract obstruction (PS), right ventricular hypertrophy, and dextroposition of the aorta, with overriding of the VSD. Blood shunts right to left through the VSD, permitting unoxygenated blood to mix with oxygenated blood, resulting in cyanosis. Tetralogy of Fallot sometimes coexists with other congenital heart defects, such as PDA or ASD.

The cause of tetralogy of Fallot is unknown, but it results from embryologic hypoplasia of the outflow tract of the right ventricle. Multiple factors, such as Down syndrome, have been associated with its presence. Prenatal risk factors include maternal rubella or other viral illnesses, poor prenatal nutrition, maternal alcoholism, mother older than age 40, and diabetes.

Tetralogy of Fallot occurs in about 5 of every 10,000 infants and accounts for about 10% of all congenital heart diseases. It occurs equally in boys and girls. Before surgical advances made correction possible, about one third of these children died in infancy.

Pathophysiology

Tetralogy of Fallot is present at birth.

Pathophysiology depends on the degree of right ventricular outflow obstruction. A mild obstruction may result in a net left-to-right shunt through the VSD; a severe obstruction causes a right-to-left shunt, resulting in low systemic arterial saturation (cyanosis) that is unresponsive to supplemental oxygen.

Each patient may have a varying degree of defect.

Complications

- Cerebral abscess
- Pulmonary thrombosis
- Venous thrombosis
- Cerebral embolism
- Infective endocarditis

Signs and Symptoms

Generally, the hallmark of the disorder is cyanosis, which usually becomes evident within several months after birth but may be present at birth if the neonate has severe PS. Between ages 2 months and 2 years, children with tetralogy of Fallot may experience cyanotic or "tet" spells. Such spells result from increased right-to-left shunting, possibly caused by spasm of the right ventricular outflow tract, increased systemic venous return, or decreased systemic arterial resistance.

Exercise, crying, straining, infection, or fever can precipitate blue spells. Blue spells are characterized by dyspnea; deep, sighing respirations; bradycardia; fainting; seizures; and loss of consciousness. Older children may also develop other signs of poor oxygenation, such as clubbing, diminished exercise tolerance, increasing dyspnea on exertion, growth retardation, and eating difficulties. These children habitually squat when they feel short of breath; this is thought to decrease venous return of unoxygenated blood from the legs and increase systemic arterial resistance.

Children with tetralogy of Fallot also risk developing cerebral abscesses, pulmonary thrombosis, venous thrombosis or cerebral embolism, and infective endocarditis.

In females with tetralogy of Fallot who live to childbearing age, the incidence of spontaneous abortion, premature births, and low birth weight rises.

Diagnosis

In a patient with tetralogy of Fallot, auscultation detects a loud systolic heart murmur (best heard along the left sternal border), which may diminish or obscure the pulmonic component of S_2. In a patient with a large PDA, the continuous murmur of the ductus obscures the systolic murmur. Palpation may reveal a cardiac thrill at the left sternal border and an obvious right ventricular impulse. The inferior sternum appears prominent.

The results of special tests also support the diagnosis:

- Chest X-ray may demonstrate decreased pulmonary vascular marking, depending on the pulmonary obstruction's severity, and a boot-shaped cardiac silhouette.
- ECG shows right ventricular hypertrophy, right axis deviation, and, possibly, right atrial hypertrophy.

- Echocardiography identifies septal overriding of the aorta, the VSD, and PS and detects the hypertrophied walls of the right ventricle.
- Pulse oximetry shows a decrease in oxygen saturation.

℞ CONFIRMING DIAGNOSIS *Cardiac catheterization confirms the diagnosis by visualizing PS, the VSD, and the overriding aorta and ruling out other cyanotic heart defects. This test also measures the degree of oxygen saturation in aortic blood.*

Treatment

Effective management of tetralogy of Fallot necessitates prevention and treatment of complications, measures to relieve cyanosis, and palliative or corrective surgery. During cyanotic spells, the knee–chest position and administration of oxygen and morphine improve oxygenation. Propranolol (a beta-adrenergic blocking agent) may prevent blue spells.

Palliative surgery is performed in infants with potentially fatal hypoxic spells or occasionally needed prior to final correction. The goal of surgery is to enhance blood flow to the lungs to reduce hypoxia; this is often accomplished by joining the subclavian artery to the pulmonary artery (modified Blalock–Taussig procedure). Supportive measures include prophylactic antibiotics to prevent infective endocarditis or cerebral abscess administered before, during, and after bowel, bladder, or any other surgery or dental treatments. Management may also include phlebotomy in children with polycythemia.

Complete corrective surgery to relieve PS and close the VSD, directing left ventricular outflow to the aorta, requires cardiopulmonary bypass with hypothermia to decrease oxygen utilization during surgery, especially in young children. An infant may have this corrective surgery without prior palliative surgery. It's usually done when progressive hypoxia and polycythemia impair the quality of life, rather than at a specific age. However, most children require surgery, some as young as 6 months old as long as oxygen levels remain adequate.

Special Considerations

- Explain tetralogy of Fallot to the parents. Inform them that their child will set their own exercise limits and will know when to rest. Make sure they understand that their child can engage in physical activity, and advise them not to be overprotective.
- Teach the parents to recognize serious hypoxic spells, which can dramatically increase cyanosis; deep, sighing respirations; and loss of consciousness. Tell them to place their child in the knee–chest position and to report such spells immediately. Emergency treatment may be necessary.
- Instruct the parents on ways to prevent overexerting their child, such as feeding slowly and providing smaller and more frequent meals. Tell them that remaining calm may decrease anxiety and that anticipating needs may minimize crying. Encourage the parents to recruit other family members in the care of the child to help prevent their own exhaustion.
- To prevent infective endocarditis and other infections, warn the parents to keep their child away from people with infections. Urge them to encourage good dental hygiene, and tell them to watch for ear, nose, and throat infections and dental caries, all of which necessitate immediate treatment. When dental care, infections, or surgery requires prophylactic antibiotics, tell the parents to make sure the child completes the prescribed regimen.
- If the child requires medical attention for an unrelated problem, advise the parents to inform the practitioner immediately of the child's history of tetralogy of Fallot because any treatment

must take this serious heart defect into consideration.

◆ During hospitalization, alert the staff to the child's condition. Because of the right-to-left shunt through the VSD, treat I.V. lines like arterial lines. A clot dislodged from a catheter tip in a vein can cross the VSD and cause cerebral embolism. The same thing can happen if air enters the venous lines.

After palliative surgery:

◆ Monitor oxygenation and arterial blood gas (ABG) values closely in the ICU.
◆ If the child has undergone the modified Blalock–Taussig procedure, don't use the arm on the operative side for measuring blood pressure, inserting I.V. lines, or drawing blood samples, because blood perfusion on this side diminishes greatly until collateral circulation develops. Note this on the child's chart and at the bedside.

After corrective surgery:

◆ Watch for right bundle branch block or more serious disturbances of AV conduction and for ventricular ectopic beats.
◆ Be alert for other postoperative complications, such as bleeding, right-sided heart failure, and respiratory failure. After surgery, transient heart failure is common and may require treatment with digoxin and diuretics.
◆ Monitor left atrial pressure directly. A pulmonary artery catheter may also be used to check central venous and PAPs.
◆ Frequently check color and vital signs. Obtain ABG measurements regularly to assess oxygenation. Suction to prevent atelectasis and pneumonia, as needed. Monitor mechanical ventilation.
◆ Monitor and record intake and output accurately.
◆ If AV block develops with a low heart rate, a temporary external pacemaker may be necessary.
◆ If blood pressure or cardiac output is inadequate, catecholamines may be ordered by continuous I.V. infusion. To decrease left ventricular workload, administer nitroprusside, if ordered, and provide analgesics, as needed.
◆ Keep the parents informed about their child's progress. After discharge, the child may require digoxin, diuretics, and other drugs. Stress the importance of complying with the prescribed regimen, and make sure the parents know how and when to administer these medications. Teach the parents to watch for signs of digoxin toxicity (anorexia, nausea, and vomiting). Prophylactic antibiotics to prevent infective endocarditis will still be required. Advise the parents to avoid becoming overprotective as the child's tolerance for physical activity rises.

TRANSPOSITION OF THE GREAT ARTERIES

Causes and Incidence

In this congenital heart defect, the great arteries are reversed: the aorta arises from the right ventricle and the pulmonary artery from the left ventricle, producing two noncommunicating circulatory systems (pulmonary and systemic). Transposition accounts for about 3% of all congenital heart defects and often coexists with other congenital heart defects, such as VSD, VSD with PS, ASD, and PDA. It affects two to three times more males than females. Transposition of the great arteries results from faulty embryonic development, but the cause of such development is unknown. Transposition of the great arteries occurs in about 30 of every

100,000 infants.

Pathophysiology

In transposition, oxygenated blood returning to the left side of the heart is carried back to the lungs by a transposed pulmonary artery; unoxygenated blood returning to the right side of the heart is carried to the systemic circulation by a transposed aorta.

Communication between the pulmonary and systemic circulations is necessary for survival. In infants with isolated transposition, blood mixes only at the patent foramen ovale and at the PDA, resulting in slight mixing of unoxygenated systemic blood and oxygenated pulmonary blood. In infants with concurrent cardiac defects, greater mixing of blood occurs.

Complications

- Chronic heart failure
- Poor oxygenation
- Arrhythmias
- Right-sided heart failure

Signs and Symptoms

Within the first few hours after birth, neonates with transposition of the great arteries and no other heart defects generally show cyanosis and tachypnea, which worsen with crying. After several days or weeks, such neonates usually develop signs of heart failure (gallop rhythm, tachycardia, dyspnea, hepatomegaly, and cardiomegaly). S_2 is louder than normal because the anteriorly transposed aorta is directly behind the sternum; in many cases, however, no murmur can be heard during the first few days of life. Associated defects (ASD, VSD, or PDA) cause their typical murmurs and may minimize cyanosis but may also cause other complications (especially severe heart failure). VSD with PS produces a characteristic murmur and severe cyanosis.

As infants with this defect grow older, cyanosis is their most prominent abnormality. However, they also develop diminished exercise tolerance, fatigability, coughing, clubbing, and more pronounced murmurs if ASD, VSD, PDA, or PS is present.

Diagnosis

- Chest X-rays are normal in the first days of life. Within days to weeks, right atrial and right ventricular enlargement characteristically cause the heart to appear oblong. X-rays also show increased pulmonary vascular markings, except when PS coexists.
- ECG typically reveals right axis deviation and right ventricular hypertrophy but may be normal in a neonate.

> **CONFIRMING DIAGNOSIS** *Echocardiography demonstrates the reversed position of the aorta and pulmonary artery and records echoes from both semilunar valves simultaneously, due to aortic valve displacement. It also detects other cardiac defects. Cardiac catheterization reveals decreased oxygen saturation in left ventricular blood and aortic blood; increased right atrial, right ventricular, and pulmonary artery oxygen saturation; and right ventricular systolic pressure equal to systemic pressure. Dye injection reveals the transposed vessels and the presence of any other cardiac defects.*

- ABG measurements indicate hypoxia and secondary metabolic acidosis.

Treatment

An infant with transposition may undergo atrial balloon septostomy (Rashkind procedure) during cardiac catheterization. This procedure enlarges the patent foramen ovale, which improves oxygenation by allowing greater mixing of the pulmonary and systemic circulations. Atrial balloon septostomy requires passage of a balloon-tipped catheter through the foramen ovale and subsequent inflation and withdrawal across the atrial septum. This procedure alleviates hypoxia to a certain degree. Afterward, digoxin and diuretics can lessen heart failure until the infant is ready to withstand corrective surgery (usually by 1 to 2 weeks of age).

One of three surgical procedures can correct transposition, depending on the defect's physiology. The Mustard procedure replaces the atrial septum with a Dacron or pericardial partition that allows systemic venous blood to be channeled to the pulmonary artery—which carries the blood to the lungs for oxygenation—and oxygenated blood returning to the heart to be channeled from the pulmonary veins into the aorta. The Senning procedure accomplishes the same result, using the atrial septum to create partitions to redirect blood flow. In the arterial switch, or Jantene procedure, transposed arteries are surgically anastomosed to the correct ventricle. For this procedure to be successful, the left ventricle must be used to pump at systemic pressure, as it does in neonates or in children with a left ventricular outflow obstruction or a large VSD. The Jantene procedure is the procedure of choice; however, the Mustard and Senning procedures may be used when specific anatomic conditions exist.

Special Considerations

- Explain cardiac catheterization and all necessary procedures to the parents. Offer emotional support.
- Monitor vital signs, ABG values, urine output, and CVP, watching for signs of heart failure. Give digoxin and I.V. fluids, being careful to avoid fluid overload.
- Teach the parents to recognize signs of heart failure and digoxin toxicity (poor feeding and vomiting). Stress the importance of regular checkups to monitor cardiovascular status.
- Teach the parents to protect their infant from infection and to give antibiotics.
- Tell the parents to let their child develop normally. They need not restrict activities; let the child set his or her own limits.
- If the patient is scheduled for surgery, explain the procedure to the parents and child, if old enough. Teach them about the ICU and introduce them to the staff. Also explain postoperative care.
- Preoperatively, monitor ABG values, acid–base balance, intake and output, and vital signs.

  After corrective surgery:

- Monitor cardiac output by checking blood pressure, skin color, heart rate, urine output, central venous and left atrial pressures, and level of consciousness (LOC). Report abnormalities or changes.
- Carefully monitor ABG levels and report changes in trends.
- To detect supraventricular conduction blocks and arrhythmias, monitor the patient closely. Watch for signs of AV blocks, atrial arrhythmias, and faulty SA function.
- After the Mustard or Senning procedure, watch for signs of baffle obstruction such as marked facial edema.

- Encourage parents to help their child assume new activity levels and independence. Teach them about postoperative antibiotic prophylaxis for endocarditis.

Acquired Inflammatory Heart Disease

MYOCARDITIS

Causes and Incidence

Myocarditis is focal or diffuse inflammation of the cardiac muscle (myocardium). It may be acute or chronic and can occur at any age. In many cases, myocarditis fails to produce specific cardiovascular symptoms or electrocardiogram (ECG) abnormalities, and recovery is usually spontaneous, without residual defects. Occasionally, myocarditis is complicated by heart failure; in rare cases, it leads to cardiomyopathy.

Myocarditis may result from:

- bacterial infections—diphtheria; tuberculosis; typhoid fever; tetanus; and staphylococcal, pneumococcal, and gonococcal infections
- chemical poisons—such as chronic alcoholism
- helminthic infections—such as trichinosis
- hypersensitive immune reactions—acute rheumatic fever and postcardiotomy syndrome
- parasitic infections—especially South American trypanosomiasis (Chagas disease) in infants and immunosuppressed adults; also toxoplasmosis
- radiation therapy—large doses of radiation to the chest in treating lung or breast cancer
- viral infections (most common cause in the United States and Western Europe)— coxsackievirus A and B strains and, possibly, poliomyelitis, influenza, rubeola, rubella, and adenoviruses and echoviruses

Myocarditis occurs in 1 to 10 of every 100,000 people in the United States. The median age for this disorder is 42, and incidence is equal between males and females. Children, especially neonates, and persons who are immunocompromised or pregnant (especially pregnant black women) are at higher risk for developing this disorder.

Pathophysiology

The pathophysiology of myocarditis is still being researched, but it is usually caused by a virus, as already mentioned. It results in necrosis of myocardial cells either through direct injury or as a result of an autoimmune reaction of an infectious or toxic process. The extent of the involvement depends on the magnitude of the insult; if it extends to the pericardium, myopericarditis occurs.

Complications

- Arrhythmias
- Thromboembolism
- Chronic valvulitis (when disease results from rheumatic fever)
- Recurrence of disease
- Left-sided heart failure (occasional)
- Cardiomyopathy (rare)

Signs and symptoms

Myocarditis usually causes nonspecific symptoms—such as fatigue, dyspnea, palpitations, and fever—that reflect the accompanying systemic infection. Occasionally, it may produce mild, continuous pressure or soreness in the chest (unlike the recurring, stress-related pain of angina pectoris). Although myocarditis is usually self-limiting, it may induce myofibril degeneration that results in right- and left-sided heart failure, with cardiomegaly, JVD, dyspnea, persistent fever with resting or exertional tachycardia disproportionate to the degree of fever, and supraventricular and ventricular arrhythmias. Sometimes myocarditis recurs or produces chronic valvulitis (when it results from rheumatic fever), cardiomyopathy, arrhythmias, and thromboembolism.

Diagnosis

Patient history commonly reveals recent febrile upper respiratory tract infection, viral pharyngitis, or tonsillitis. Physical examination shows supraventricular and ventricular arrhythmias, S_3 and S_4 gallops, a faint S_1, possibly a murmur of mitral insufficiency (from papillary muscle dysfunction) and, if pericarditis is present, a pericardial friction rub.

Laboratory tests can't unequivocally confirm myocarditis, but the following findings support this diagnosis:

- cardiac enzymes: elevated CK, CK-MB, aspartate aminotransferase, and lactate dehydrogenase levels
- increased white blood cell count and erythrocyte sedimentation rate
- elevated antibody titers (such as antistreptolysin-O titer in rheumatic fever)

CONFIRMING DIAGNOSIS *Endomyocardial biopsy is rarely performed to diagnose myocarditis; the procedure is invasive and costly. A negative biopsy doesn't exclude the diagnosis, and a repeat biopsy may be needed.*

ECG typically shows diffuse ST-segment and T-wave abnormalities as in pericarditis, conduction defects (prolonged PR interval), and other supraventricular arrhythmias. Echocardiography demonstrates some degree of left ventricular dysfunction, and radionuclide scanning may identify inflammatory and necrotic changes characteristic of myocarditis.

Stool and throat cultures may identify bacteria.

Treatment

While myositis is usually self-limiting, treatment may include antibiotics for bacterial infection, modified bed rest to decrease cardiac workload, and careful management of complications. Inotropic support of cardiac function with amrinone, dopamine, or dobutamine may be needed. Heart failure requires restriction of activity to minimize myocardial oxygen consumption, supplemental oxygen therapy, sodium restriction, diuretics to decrease fluid retention, and cardiac glycosides to increase myocardial contractility. However, cardiac glycosides should be administered cautiously because some patients with myocarditis may show a paradoxical sensitivity to even small doses. Arrhythmias necessitate prompt but cautious administration of antiarrhythmics because these drugs depress myocardial contractility. Thromboembolism requires anticoagulation therapy. Treatment with corticosteroids or other immunosuppressants may be used to reduce inflammation, but they haven't been shown to change the progression of myocarditis. Nonsteroidal anti-inflammatory drugs are contraindicated during the acute phase

(first 2 weeks) because they increase myocardial damage.

Surgical treatment may include left ventricular assistive devices and extracorporeal membrane oxygenation for support of cardiogenic shock. Cardiac transplantation has been beneficial for giant cell myocarditis.

Special Considerations

- Assess cardiovascular status frequently, watching for signs of heart failure, such as dyspnea, hypotension, and tachycardia. Check for changes in cardiac rhythm or conduction.
- Observe for signs of digoxin toxicity (anorexia, nausea, vomiting, blurred vision, and cardiac arrhythmias) and for complicating factors that may potentiate toxicity, such as electrolyte imbalance or hypoxia.
- Stress the importance of bed rest. Assist with bathing, as necessary; provide a bedside commode because this stresses the heart less than using a bedpan. Reassure the patient that activity limitations are temporary. Offer diversional activities that are physically undemanding.
- During recovery, recommend that the patient resume normal activities slowly and avoid competitive sports.

PREVENTION

- *Instruct patient to obtain prompt treatment of causative disorders.*
- *Instruct patient to practice good hygiene, including thorough handwashing.*
- *Tell patient to thoroughly wash and cook food.*

ENDOCARDITIS

Causes and Incidence

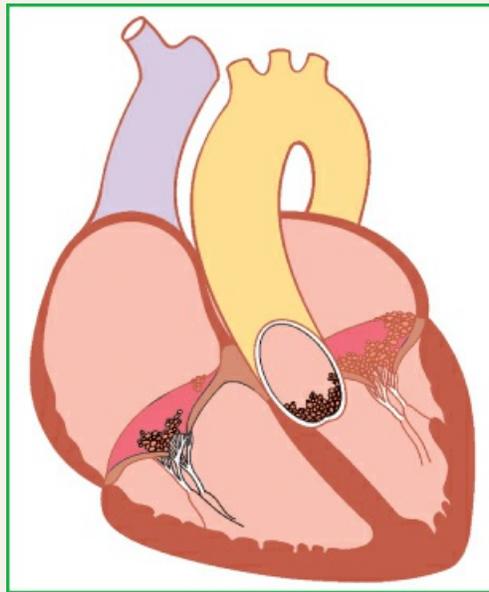
Endocarditis (also known as *infective* or *bacterial endocarditis*) is an infection of the endocardium, heart valves, or cardiac prostheses resulting from bacterial or fungal invasion. Most cases of endocarditis occur in I.V. drug abusers, patients with prosthetic heart valves, and those with MVP (especially males with a systolic murmur). These conditions have surpassed rheumatic heart disease as the leading risk factor. Other predisposing conditions include coarctation of the aorta, tetralogy of Fallot, subaortic and valvular aortic stenosis, VSDs, PS, Marfan syndrome, degenerative heart disease (especially calcific aortic stenosis), and, rarely, syphilitic aortic valve. However, some patients with endocarditis have no underlying heart disease. In the United States, endocarditis affects 2 to 6 people out of every 100,000. Males are twice as likely as females to acquire this infection, and the mean age of onset is 50. Mortality is associated with increased age, infection of the aortic valve, heart failure and underlying heart disease, and central nervous system complications; mortality rates vary with the infecting organism. Untreated endocarditis is usually fatal, but with proper treatment, 70% of patients recover. The prognosis is worst when endocarditis causes severe valvular damage, leading to insufficiency and heart failure, or when it involves a prosthetic valve.

Pathophysiology

The invasion of bacteria or fungi produces vegetative growths on the heart valves, endocardial lining of a heart chamber, or endothelium of a blood vessel that may embolize to the spleen,

kidneys, central nervous system, and lungs. In endocarditis, fibrin and platelets aggregate on the valve tissue and engulf circulating bacteria or fungi that flourish and produce friable verrucous vegetations. (See *Degenerative changes in endocarditis*.) Such vegetations may cover the valve surfaces, causing ulceration and necrosis; they may also extend to the chordae tendineae, leading to their rupture and subsequent valvular insufficiency.

Degenerative Changes in Endocarditis

This illustration shows typical vegetations on the endocardium produced by fibrin and platelet deposits on infection sites.


Infecting organisms differ depending on the cause of endocarditis. In patients with native valve endocarditis who aren't I.V. drug abusers, causative organisms usually include—in the order of frequency—streptococci (especially *Streptococcus viridans*), staphylococci, or enterococci. Although many other bacteria occasionally cause the disorder, fungal causes are rare in this group. The mitral valve is involved most commonly, followed by the aortic valve.

In patients who are I.V. drug abusers, *Staphylococcus aureus* is the most common infecting organism. Less commonly, streptococci, enterococci, gram-negative bacilli, or fungi cause the disorder. The tricuspid valve is involved most commonly, followed by the aortic and then the mitral valve.

In patients with prosthetic valve endocarditis, early cases (those that develop within 60 days of valve insertion) are usually due to staphylococcal infection. However, gram-negative aerobic organisms, fungi, streptococci, enterococci, or diphtheroids may also cause the disorder. The course is usually fulminant and is associated with a high mortality. Late cases (occurring after 60 days) present similar to native valve endocarditis.

Complications

- Left-sided heart failure
- Valvular stenosis or insufficiency
- Myocardial erosion

Signs and Symptoms

Early clinical features of endocarditis are usually nonspecific and include malaise, weakness, fatigue, weight loss, anorexia, arthralgia, night sweats, chills, valvular insufficiency and, in 90% of patients, an intermittent fever that may recur for weeks. A more acute onset is associated with organisms of high pathogenicity such as *S. aureus.* Endocarditis commonly causes a loud, regurgitant murmur typical of the underlying heart lesion. A suddenly changing murmur or the discovery of a new murmur in the presence of fever is a classic physical sign of endocarditis.

In about 30% of patients, embolization from vegetating lesions or diseased valvular tissue may produce typical features of splenic, renal, cerebral, or pulmonary infarction or of peripheral vascular occlusion:

- splenic infarction—pain in the left upper quadrant, radiating to the left shoulder, and abdominal rigidity
- renal infarction—hematuria, pyuria, flank pain, and decreased urine output
- cerebral infarction—hemiparesis, aphasia, or other neurologic deficits
- pulmonary infarction (most common in right-sided endocarditis, which commonly occurs among I.V. drug abusers and after cardiac surgery)—cough, pleuritic pain, pleural friction rub, dyspnea, and hemoptysis
- peripheral vascular occlusion—numbness and tingling in an arm, leg, finger, or toe, or signs of impending peripheral gangrene

Other signs may include splenomegaly; petechiae of the skin (especially common on the upper anterior trunk) and the buccal, pharyngeal, or conjunctival mucosa; and splinter hemorrhages under the nails. Rarely, endocarditis produces Osler nodes (tender, raised, subcutaneous lesions on the fingers or toes), Roth spots (hemorrhagic areas with white centers on the retina), and Janeway lesions (purplish macules on the palms or soles).

Diagnosis

CONFIRMING DIAGNOSIS *Three or more blood cultures in a 24- to 48-hour period (each from a separate venipuncture) identify the causative organism in up to 90% of patients. Blood cultures should be drawn from three different sites with 1 hour between each draw.*

The remaining 10% may have negative blood cultures, possibly suggesting fungal infection or infections that are difficult to diagnose, such as *Haemophilus parainfluenzae.*

Other abnormal but nonspecific laboratory test results include:

- normal or elevated white blood cell count
- abnormal histiocytes (macrophages)
- elevated erythrocyte sedimentation rate
- normocytic, normochromic anemia (in 70% to 90% of patients)
- proteinuria and microscopic hematuria (in about 50% of patients)
- positive serum rheumatoid factor (in about 50% of patients after endocarditis is present for 3 to 6 weeks)

Echocardiography (particularly, transesophageal) may identify valvular damage; ECG may show atrial fibrillation and other arrhythmias that accompany valvular disease.

Treatment

The goal of treatment is to eradicate the infecting organism with appropriate antimicrobial therapy, which should start promptly and continue over 4 to 6 weeks. Selection of an antibiotic is based on identification of the infecting organism and on sensitivity studies. While awaiting results, or if blood cultures are negative, empiric antimicrobial therapy is based on the likely infecting organism.

Supportive treatment includes bed rest, aspirin for fever and aches, and sufficient fluid intake. Severe valvular damage, especially aortic or mitral insufficiency, may require corrective surgery if refractory heart failure develops, or in cases requiring that an infected prosthetic valve be replaced.

Special considerations

- Before giving antibiotics, obtain a patient history of allergies. Administer antibiotics on time to maintain consistent antibiotic blood levels.
- Observe for signs of infiltration or inflammation at the venipuncture site, possible complications of long-term I.V. drug administration. To reduce the risk of these complications, rotate venous access sites.
- Watch for signs of embolization (hematuria, pleuritic chest pain, left upper quadrant pain, or paresis), a common occurrence during the first 3 months of treatment. Tell the patient to watch for and report these signs, which may indicate impending peripheral vascular occlusion or splenic, renal, cerebral, or pulmonary infarction.
- Monitor the patient's renal status (blood urea nitrogen [BUN] levels, creatinine clearance, and urine output) to check for signs of renal emboli or evidence of drug toxicity.
- Observe for signs of heart failure, such as dyspnea, tachypnea, tachycardia, crackles, JVD, edema, and weight gain.
- Provide reassurance by teaching the patient and family about this disease and the need for prolonged treatment. Tell them to watch closely for fever, anorexia, and other signs of relapse about 2 weeks after treatment stops. Suggest quiet diversionary activities to prevent excessive physical exertion.
- Make sure susceptible patients understand the need for prophylactic antibiotics before, during, and after dental work, childbirth, and genitourinary, GI, or gynecologic procedures.
- Teach patients how to recognize symptoms of endocarditis and tell them to notify the practitioner at once if such symptoms occur. (See *Preventing endocarditis*.)

PREVENTION
PREVENTING ENDOCARDITIS

Any patient who is at risk for or susceptible to endocarditis, such as those with artificial heart valves or other predisposing factors, should have prophylactic antibiotics before dental or other invasive procedures.

In addition, the patient should practice good hygiene, including thoroughly washing hands and washing fruits and vegetables and thoroughly cooking all food to prevent

introducing organisms into the system. Maintaining good oral health by daily brushing and flossing and having regular dental checkups can also prevent infection. Be sure to advise the patient to notify the family practitioner as well as the dentist or another specialist that they have a condition that places them at high risk for endocarditis.

PERICARDITIS

Causes and Incidence

Pericarditis is an inflammation of the pericardium, the fibroserous sac that envelops, supports, and protects the heart. Common causes of this disease include:

- bacterial, fungal, or viral infection (infectious pericarditis)
- neoplasms (primary or metastatic from lungs, breasts, or other organs)
- high-dose radiation to the chest
- uremia
- hypersensitivity or autoimmune disease, such as acute rheumatic fever (most common cause of pericarditis in children), systemic lupus erythematosus (SLE), and rheumatoid arthritis
- postcardiac injury such as MI, which later causes an autoimmune reaction (Dressler syndrome) in the pericardium; trauma; or surgery that leaves the pericardium intact but causes blood to leak into the pericardial cavity
- drugs, such as hydralazine or procainamide
- idiopathic factors (most common in acute pericarditis)

Less common causes include aortic aneurysm with pericardial leakage and myxedema with cholesterol deposits in the pericardium.

Pericarditis most commonly affects men 20 to 50 years old, but it can also occur in children after infection with an adenovirus or coxsackievirus.

The prognosis depends on the underlying cause but is generally good in acute pericarditis, unless constriction occurs.

Pathophysiology

The pericardium protects the heart mechanically and reduces friction of the surrounding structures through a small amount of pericardial fluid (25 to 50 mL). Inflammation of the layers of the pericardium leads to an increase in the production of this fluid in the form of exudate. Pericarditis occurs in both acute and chronic forms. Acute pericarditis can be fibrinous or effusive, with purulent serous or hemorrhagic exudate; chronic constrictive pericarditis is characterized by dense fibrous pericardial thickening.

Complications

- Pericardial effusion
- Cardiac tamponade
- Shock
- Cardiovascular collapse
- Death

Signs and symptoms

Acute pericarditis typically produces a sharp and often sudden pain that usually starts over the sternum and radiates to the neck, shoulders, back, and arms. However, unlike the pain of MI, pericardial pain is often pleuritic, increasing with deep inspiration and decreasing when the patient sits up and leans forward, pulling the heart away from the diaphragmatic pleurae of the lungs.

Pericardial effusion, the major complication of acute pericarditis, may produce effects of heart failure (such as dyspnea, orthopnea, and tachycardia), ill-defined substernal chest pain, and a feeling of fullness in the chest. (See *Patterns of cardiac pain*.)

Patterns of cardiac pain

Although pain perception is individualistic, specific characteristics are associated with different types of cardiac pain, as shown below.

Pericarditis	*Angina*	*Myocardial infarction*
Onset and duration	**Onset and duration**	**Onset and duration**
◆ Sudden onset; continuous pain lasting for days; residual soreness	◆ Gradual or sudden onset; pain usually lasts <15 minutes and not >30 minutes (average: 3 minutes)	◆ Sudden onset; pain lasts 30 minutes to 2 hours; waxes and wanes; residual soreness 1 to 3 days
Location and radiation		**Location and radiation**
◆ Substernal pain to left of midline; radiation to back or subclavicular area	**Location and radiation**	◆ Substernal, midline, or anterior chest pain; radiation to jaws, neck, back, shoulders, or one or both arms
Quality and intensity	◆ Substernal or anterior chest pain, not sharply localized; radiation to back, neck, arms, jaws, even upper abdomen or fingers	**Quality and intensity**
◆ Mild ache to severe pain, deep or superficial; "stabbing," "knifelike"		◆ Persistent, severe pressure; deep sensation; "crushing," "squeezing," "heavy," "oppressive"
Signs and symptoms	**Quality and intensity**	**Signs and symptoms**
◆ Precordial friction rub; increased pain with movement, inspiration, laughing, coughing; decreased pain with sitting or leaning forward (sitting up pulls heart away from diaphragm)	◆ Mild-to-moderate pressure; deep sensation; varied pattern of attacks; "tightness," "squeezing," "crushing," "pressure"	◆ Nausea, vomiting, apprehension, dyspnea, diaphoresis, increased or decreased blood pressure; gallop heart sound, "sensation of impending doom"
Precipitating factors	**Signs and symptoms**	**Precipitating factors**
◆ Myocardial infarction or upper respiratory tract infection; invasive cardiac trauma	◆ Dyspnea, diaphoresis, nausea, desire to void, belching, apprehension	◆ Occurrence at rest or during physical exertion or emotional stress
	Precipitating factors	
	◆ Exertion, stress, eating, cold or hot and humid weather	

ALERT *If the fluid accumulates rapidly, cardiac tamponade may occur, resulting in pallor, clammy skin, hypotension, pulsus paradoxus (a decrease in systolic blood pressure of 15 mm Hg or more during slow inspiration), JVD and, eventually, cardiovascular collapse and death.*

Chronic constrictive pericarditis causes a gradual increase in systemic venous pressure and produces symptoms similar to those of chronic right-sided heart failure (fluid retention, ascites, and hepatomegaly).

Diagnosis

Because pericarditis commonly coexists with other conditions, the diagnosis of acute pericarditis depends on typical clinical features and elimination of other possible causes. The pericardial friction rub, a classic symptom, is a grating sound heard as the heart moves. It can usually be auscultated best during forced expiration, while the patient leans forward or is on hands and knees in bed. It may have up to three components, corresponding to the timing of atrial systole, ventricular systole, and the rapid-filling phase of ventricular diastole. Occasionally, this friction rub is heard only briefly or not at all. Nevertheless, its presence, together with other characteristic features, is diagnostic of acute pericarditis. In addition, if acute pericarditis has caused very large pericardial effusions, physical examination reveals increased cardiac dullness and diminished or absent apical impulse and distant heart sounds.

Chest X-ray, echocardiogram, chest MRI, heart MRI, heart computed tomography scan, and radionuclide scanning can detect fluid that has accumulated in the pericardial sac. They may also show enlargement of the heart and signs of inflammation or scarring, depending on the cause of pericarditis.

In patients with chronic pericarditis, acute inflammation or effusions don't occur—only restricted cardiac filling.

Laboratory results reflect inflammation and may identify its cause:

- normal or elevated white blood cell count, especially in infectious pericarditis
- elevated erythrocyte sedimentation rate
- slightly elevated cardiac enzyme levels with associated myocarditis
- culture of pericardial fluid obtained by open surgical drainage or cardiocentesis (sometimes identifies a causative organism in bacterial or fungal pericarditis)
- ECG showing the following changes in acute pericarditis: elevation of ST segments in the standard limb leads and most precordial leads without the significant changes in QRS morphology that occur with MI, atrial ectopic rhythms such as atrial fibrillation and, in pericardial effusion, diminished QRS voltage

Other pertinent laboratory data include BUN levels to check for uremia, antistreptolysin-O titers to detect rheumatic fever, and a purified protein derivative skin test to check for tuberculosis. In pericardial effusion, echocardiography is diagnostic when it shows an echo-free space between the ventricular wall and the pericardium.

Treatment

The goal of treatment is to relieve symptoms and manage the underlying systemic disease. In acute idiopathic pericarditis and postthoracotomy pericarditis, treatment consists of bed rest as long as fever and pain persist, and nonsteroidal drugs, such as aspirin and indomethacin, to relieve pain and reduce inflammation. Post-MI patients should avoid nonsteroidal anti-inflammatory drugs and steroids because they may interfere with myocardial scar formation. If these drugs fail to relieve symptoms, corticosteroids may be used. Although corticosteroids produce rapid and effective relief, they must be used cautiously because episodes may recur when therapy is discontinued.

Infectious pericarditis that results from disease of the left pleural space, mediastinal abscesses, or septicemia requires antibiotics (possibly by direct pericardial injection), surgical drainage, or both. Cardiac tamponade may require pericardiocentesis. Signs of tamponade include pulsus paradoxus, JVD, dyspnea, and shock.

Recurrent pericarditis may necessitate partial pericardectomy, which creates a "window" that allows fluid to drain into the pleural space. In constrictive pericarditis, total pericardectomy to permit adequate filling and contraction of the heart may be necessary. Treatment must also include management of rheumatic fever, uremia, tuberculosis, and other underlying disorders.

Special considerations

A patient with pericarditis needs complete bed rest. In addition, healthcare includes:

- assessing pain in relation to respiration and body position to distinguish pericardial pain from myocardial ischemic pain
- placing the patient in an upright position to relieve dyspnea and chest pain; providing analgesics and oxygen; and reassuring the patient with acute pericarditis that the condition is temporary and treatable
- monitoring for signs of cardiac compression or cardiac tamponade, possible complications of pericardial effusion (Signs include decreased blood pressure, increased CVP, and pulsus paradoxus. Because cardiac tamponade requires immediate treatment, keep a pericardiocentesis set handy whenever pericardial effusion is suspected.)
- explaining tests and treatments to the patient (If surgery is necessary, the patient should learn deep breathing and coughing exercises beforehand. Postoperative care is similar to that given after cardiothoracic surgery.)

RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

Causes and Incidence

Acute rheumatic fever is a systemic inflammatory disease of childhood, in many cases recurrent, that follows a group A beta-hemolytic streptococcal infection. Rheumatic heart disease refers to the cardiac manifestations of rheumatic fever and includes pancarditis (myocarditis, pericarditis, and endocarditis) during the early acute phase and chronic valvular disease later. Although rheumatic fever tends to be familial, this may merely reflect contributing environmental factors. For example, in lower socioeconomic groups, incidence is highest in children between 5 and 15 years old, probably as a result of malnutrition and crowded living conditions. This disease strikes generally during cool, damp weather in the winter and early spring. In the United States, it's most common in the northern states. Long-term antibiotic therapy can minimize the recurrence of rheumatic fever, reducing the risk of permanent cardiac damage and eventual valvular deformity. However, severe pancarditis occasionally produces fatal heart failure during the acute phase. Of the patients who survive this complication, about 20% die within 10 years.

Pathophysiology

Rheumatic fever appears to be a hypersensitivity reaction to a group A beta-hemolytic streptococcal infection, in which antibodies manufactured to combat streptococci react and produce characteristic lesions at specific tissue sites, especially in the heart and joints. Because very few persons (0.3%) with streptococcal infections ever contract rheumatic fever, altered host resistance must be involved in its development or recurrence.

Complications

- Destruction of mitral and aortic valves

- Severe pancarditis
- Pericardial effusion
- Fatal heart failure

Signs and symptoms

In 95% of patients, rheumatic fever characteristically follows a streptococcal infection that appeared a few days to 6 weeks earlier. A temperature of at least 100.4° F (38° C) occurs, and most patients complain of migratory joint pain or polyarthritis. Swelling, redness, and signs of effusion usually accompany such pain, which most commonly affects the knees, ankles, elbows, or hips. In 5% of patients (generally those with carditis), rheumatic fever causes skin lesions such as erythema marginatum, a nonpruritic, macular, transient rash that gives rise to red lesions with blanched centers. Rheumatic fever may also produce firm, movable, nontender, subcutaneous nodules about 3 mm to 2 cm in diameter, usually near tendons or bony prominences of joints (especially the elbows, knuckles, wrists, and knees) and less often on the scalp and backs of the hands. These nodules persist for a few days to several weeks and, like erythema marginatum, often accompany carditis.

Later, rheumatic fever may cause transient chorea, which develops up to 6 months after the original streptococcal infection. Mild chorea may produce hyperirritability, a deterioration in handwriting, or an inability to concentrate. Severe chorea (Sydenham chorea) causes purposeless, nonrepetitive, involuntary muscle spasms; poor muscle coordination; and weakness. Chorea always resolves without residual neurologic damage.

The most destructive effect of rheumatic fever is carditis, which develops in up to 50% of patients and may affect the endocardium, myocardium, pericardium, or the heart valves. Pericarditis causes a pericardial friction rub and, occasionally, pain and effusion. Myocarditis produces characteristic lesions called Aschoff bodies (in the acute stages) and cellular swelling and fragmentation of interstitial collagen, leading to the formation of a progressively fibrotic nodule and interstitial scars. Endocarditis causes valve leaflet swelling; erosion along the lines of leaflet closure; and blood, platelet, and fibrin deposits, which form beadlike vegetations. Endocarditis affects the mitral valve most often in females and the aortic valve most often in males. In both females and males, endocarditis affects the tricuspid valves occasionally and the pulmonic valve only rarely.

Severe rheumatic carditis may cause heart failure with dyspnea; right upper quadrant pain; tachycardia; tachypnea; a hacking, nonproductive cough; edema; and significant mitral and aortic murmurs. The most common of such murmurs include:

- a systolic murmur of mitral insufficiency (high-pitched, blowing, holosystolic, loudest at apex, possibly radiating to the anterior axillary line)
- a midsystolic murmur due to stiffening and swelling of the mitral leaflet
- occasionally, a diastolic murmur of aortic insufficiency (low-pitched, rumbling, almost inaudible). Valvular disease may eventually result in chronic valvular stenosis and insufficiency, including mitral stenosis and insufficiency, and aortic insufficiency. In children, mitral insufficiency remains the major sequela of rheumatic heart disease.

Diagnosis

Diagnosis depends on recognition of one or more of the classic symptoms (carditis, rheumatic fever without carditis, polyarthritis, chorea, erythema marginatum, or subcutaneous nodules) and a detailed patient history. Laboratory data support the diagnosis:

- White blood cell count and erythrocyte sedimentation rate may be elevated (during the acute phase); blood studies show slight anemia due to suppressed erythropoiesis during inflammation.
- C-reactive protein is positive (especially during the acute phase).
- Cardiac enzyme levels may be increased in severe carditis.
- Antistreptolysin-O titer is elevated in 95% of patients within 2 months of onset.
- Electrocardiogram changes aren't diagnostic, but PR interval is prolonged in 20% of patients.
- Chest X-rays show normal heart size (except with myocarditis, heart failure, or pericardial effusion).
- Echocardiography helps evaluate valvular damage, chamber size, and ventricular function.
- Cardiac catheterization evaluates valvular damage and left ventricular function in severe cardiac dysfunction.

Treatment

Effective management eradicates the streptococcal infection, relieves symptoms, and prevents recurrence, reducing the chance of permanent cardiac damage. During the acute phase, treatment includes penicillin, sulfadiazine, or erythromycin. Salicylates such as aspirin relieve fever and minimize joint swelling and pain; if carditis is present or salicylates fail to relieve pain and inflammation, corticosteroids may be used. Supportive treatment requires strict bed rest for about 5 weeks during the acute phase with active carditis, followed by a progressive increase in physical activity, depending on clinical and laboratory findings and the response to treatment.

After the acute phase subsides, low-dose antibiotics may be used to prevent recurrence. Such preventive treatment usually continues for 5 years or until age 21 (whichever is longer). Heart failure necessitates continued bed rest and diuretics. Severe mitral or aortic valve dysfunction that causes persistent heart failure requires corrective valvular surgery, including commissurotomy (separation of the adherent, thickened leaflets of the mitral valve), valvuloplasty (inflation of a balloon within a valve), or valve replacement (with prosthetic valve). Such surgery is seldom necessary before late adolescence.

Special Considerations

Because rheumatic fever and rheumatic heart disease require prolonged treatment, the care plan should include comprehensive patient teaching to promote compliance with the prescribed therapy.

- Before giving penicillin, ask the patient or parents if the patient has ever had a hypersensitivity reaction to it. If not, warn that such a reaction is possible. Tell them to stop the drug and call the practitioner immediately if the patient develops a rash, fever, chills, or other signs of allergy *at any time* during penicillin therapy.
- Instruct the patient and family to watch for and report early signs of heart failure, such as dyspnea and a hacking, nonproductive cough.
- Stress the need for bed rest during the acute phase, and suggest appropriate, physically undemanding diversions. After the acute phase, encourage family and friends to spend as much time as possible with the patient to minimize boredom. Advise parents to secure tutorial services to help the child keep up with schoolwork during the long convalescence.
- Help the child's parents overcome any guilt feelings they may have about the illness. Tell them that failure to seek treatment for streptococcal infection is common because this illness often seems no worse than a cold. Encourage the child and his or her parents to vent their

frustrations during the long, tedious recovery. If the child has severe carditis, help them prepare for permanent changes in lifestyle.

- Teach the patient and his or her family about this disease and its treatment. Warn parents to watch for and immediately report signs of recurrent streptococcal infection—sudden sore throat, diffuse throat redness and oropharyngeal exudate, swollen and tender cervical lymph glands, pain on swallowing, temperature of 101° to 104° F (38.3° to 40° C), headache, and nausea. Urge them to keep the child away from people with respiratory tract infections.
- Promote good dental hygiene to prevent gingival infection. Make sure the patient and his or her family understand the need to comply with prolonged antibiotic therapy and follow-up care and the need for additional antibiotics during dental surgery or procedures. Arrange for a home health nurse to oversee home care if necessary.
- Teach the patient to follow current recommendations of the American Heart Association for prevention of bacterial endocarditis. Antibiotic regimens used to prevent recurrence of acute rheumatic fever are inadequate for preventing bacterial endocarditis.

Valve Disorders

VALVULAR HEART DISEASE

Causes and Incidence

More than 5 million people in the United States are diagnosed with some form of valvular disease each year. The mitral and aortic valves are most commonly affected. Common causes of each type can be found in *Types of valvular heart disease.*

Types of valvular heart disease

Causes and incidence	*Signs and symptoms*	*Diagnostic measures*
Aortic insufficiency		
• Results from rheumatic fever, syphilis, hypertension, endocarditis, or may be idiopathic • Associated with Marfan syndrome • Most common in males • Associated with ventricular septal defect, even after surgical closure	• Dyspnea, cough, fatigue, palpitations, angina, syncope • Pulmonary venous congestion, heart failure, pulmonary edema (left-sided heart failure), "pulsating" nail beds • Rapidly rising and collapsing pulses (pulsus bisferiens), cardiac arrhythmias, wide pulse pressure in severe insufficiency • Auscultation: reveals S_3 and diastolic blowing murmur at left sternal border • Palpation and visualization of apical impulse in chronic disease	• Cardiac catheterization: reduction in arterial diastolic pressures, aortic insufficiency, other valvular abnormalities, and increased left ventricular end-diastolic pressure • X-ray: left ventricular enlargement, pulmonary vein congestion • Echocardiography: left ventricular enlargement, alterations in mitral valve movement (indirect indication of aortic valve disease), and mitral thickening • Electrocardiography (ECG): sinus tachycardia, left ventricular hypertrophy, and left atrial hypertrophy in severe disease

Aortic stenosis

• Results from congenital aortic bicuspid valve (associated with coarctation of the aorta), congenital stenosis of valve cusps, rheumatic fever, or atherosclerosis in elderly persons • Most common in males	• Dyspnea on exertion, paroxysmal nocturnal dyspnea, fatigue, syncope, angina, palpitations • Pulmonary venous congestion, heart failure, pulmonary edema • Diminished carotid pulses, decreased cardiac output, cardiac arrhythmias; may have pulsus alternans • Auscultation: reveals systolic murmur at base or in carotids and, possibly, S_4	• Cardiac catheterization: pressure gradient across valve (indicating obstruction), increased left ventricular end-diastolic pressures • X-ray: valvular calcification, left ventricular enlargement, and pulmonary venous congestion • Echocardiography: thickened aortic valve and left ventricular wall • ECG: left ventricular hypertrophy

Mitral insufficiency

• Results from rheumatic fever, hypertrophic cardiomyopathy, mitral valve prolapse, myocardial infarction, severe left-sided heart failure, or ruptured chordae tendineae • Associated with other congenital anomalies such as transposition of the great arteries • Rare in children without other congenital anomalies	• Orthopnea, dyspnea, fatigue, angina, palpitations • Peripheral edema, jugular vein distention (JVD), hepatomegaly (right-sided heart failure) • Tachycardia, crackles, pulmonary edema • Auscultation: reveals holosystolic murmur at apex, possible split S_2, and S_3	• Cardiac catheterization: mitral insufficiency with increased left ventricular end-diastolic volume and pressure, increased atrial pressure and pulmonary artery wedge pressure (PAWP); and decreased cardiac output • X-ray: left atrial and ventricular enlargement, pulmonary venous congestion • Echocardiography: abnormal valve leaflet motion, left atrial enlargement • ECG: left atrial and ventricular hypertrophy, sinus tachycardia, and atrial fibrillation

Mitral stenosis

• Results from rheumatic fever (most common cause) • Most common in females • May be associated with other congenital anomalies	• Dyspnea on exertion, paroxysmal nocturnal dyspnea, orthopnea, weakness, fatigue, palpitations • Peripheral edema, JVD, ascites, hepatomegaly (right-sided heart failure in severe pulmonary hypertension) • Crackles, cardiac arrhythmias (atrial fibrillation), signs of systemic emboli • Auscultation: reveals loud S_1 or opening snap and diastolic murmur at apex	• Cardiac catheterization: diastolic pressure gradient across valve; elevated left atrial pressure and PAWP (>15 mm Hg) with severe pulmonary hypertension and pulmonary artery pressures (PAPs); elevated right-sided heart pressure; decreased cardiac output; and abnormal contraction of the left ventricle • X-ray: left atrial and ventricular enlargement, enlarged pulmonary arteries, and mitral valve calcification • Echocardiography: thickened mitral valve leaflets, left atrial enlargement • ECG: left atrial hypertrophy, atrial fibrillation, right ventricular hypertrophy, and right axis deviation

Mitral valve prolapse syndrome

• Can be genetic or associated with conditions such as Ehlers–Danlos syndrome, Marfan	• May produce no signs • Chest pain, palpitations, headache, fatigue,	• Two-dimensional echocardiography: prolapse of mitral valve leaflets into left atrium • Color-flow Doppler studies: mitral insufficiency • Resting ECG: ST-segment changes, biphasic or

syndrome, Graves disease, and muscular dystrophy ♦ Most commonly affects young women but may occur in both sexes and in all age groups	exercise intolerance, dyspnea, light-headedness, syncope, mood swings, anxiety, panic attacks ♦ Auscultation: typically reveals mobile, midsystolic click, with or without mid-to-late systolic murmur	inverted T waves in leads II, III, or AV ♦ Exercise ECG: evaluates chest pain and arrhythmias

Pulmonic insufficiency

♦ May be congenital or may result from pulmonary hypertension ♦ May rarely result from prolonged use of pressure-monitoring catheter in the pulmonary artery	♦ Dyspnea, weakness, fatigue, chest pain ♦ Peripheral edema, JVD, hepatomegaly (right-sided heart failure) ♦ Auscultation: reveals diastolic murmur in pulmonic area	♦ Cardiac catheterization: pulmonic insufficiency, increased right ventricular pressure, and associated cardiac defects ♦ X-ray: right ventricular and pulmonary arterial enlargement ♦ ECG: right ventricular or right atrial enlargement

Pulmonic stenosis

♦ Results from congenital stenosis of valve cusp or rheumatic heart disease (infrequent) ♦ Associated with other congenital heart defects such as tetralogy of Fallot	♦ Asymptomatic or symptomatic with dyspnea on exertion, fatigue, chest pain, syncope ♦ May lead to peripheral edema, JVD, hepatomegaly (right-sided heart failure) ♦ Auscultation: reveals systolic murmur at left sternal border, split S_2 with delayed or absent pulmonic component	♦ Cardiac catheterization: increased right ventricular pressure, decreased PAP, and abnormal valve orifice ♦ ECG: may show right ventricular hypertrophy, right axis deviation, right atrial hypertrophy, and atrial fibrillation

Tricuspid insufficiency

♦ Results from right-sided heart failure, rheumatic fever and, rarely, trauma and endocarditis ♦ Associated with congenital disorders ♦ Associated with I.V. drug abuse and infective endocarditis manifesting as tricuspid valve disease	♦ Dyspnea and fatigue ♦ May lead to peripheral edema, JVD, hepatomegaly, and ascites (right-sided heart failure) ♦ Auscultation: reveals possible S_3 and systolic murmur at lower left sternal border that increases with inspiration	♦ Right-sided heart catheterization: high atrial pressure, tricuspid insufficiency, decreased or normal cardiac output ♦ X-ray: right atrial dilation, right ventricular enlargement ♦ Echocardiography: shows systolic prolapse of tricuspid valve, right atrial enlargement ♦ ECG: right atrial or right ventricular hypertrophy, atrial fibrillation

Tricuspid stenosis

♦ Results from rheumatic fever ♦ May be congenital ♦ Associated with mitral or aortic valve disease ♦ Most common in women	♦ May be symptomatic with dyspnea, fatigue, syncope ♦ Possibly peripheral edema, JVD, hepatomegaly, and ascites (right-sided heart failure) ♦ Auscultation: reveals diastolic murmur at	♦ Cardiac catheterization: increased pressure gradient across valve, increased right atrial pressure, decreased cardiac output ♦ X-ray: right atrial enlargement ♦ Echocardiography: leaflet abnormality, right atrial enlargement ♦ ECG: right atrial hypertrophy, right or left ventricular hypertrophy, and atrial fibrillation

lower left sternal

with inspiration

Pathophysiology

In valvular heart disease, three types of mechanical disruption can occur: stenosis, or narrowing, of the valve opening; incomplete closure of the valve; and prolapse of the valve. A combination of these three in the same valve may also occur. They can result from such disorders as endocarditis (most common), congenital defects, and inflammation, and they can lead to heart failure.

Valvular heart disease occurs in varying forms, described in the following.

- Mitral insufficiency: In this form, blood from the left ventricle flows back into the left atrium during systole, causing the atrium to enlarge to accommodate the backflow. As a result, the left ventricle also dilates to accommodate the increased volume of blood from the atrium and to compensate for diminishing cardiac output. Ventricular hypertrophy and increased end-diastolic pressure result in increased PAP, eventually leading to left- and right-sided heart failure.
- Mitral stenosis: Narrowing of the valve by valvular abnormalities, fibrosis, or calcification obstructs blood flow from the left atrium to the left ventricle. Consequently, left atrial volume and pressure rise and the chamber dilates. Greater resistance to blood flow causes pulmonary hypertension, right ventricular hypertrophy, and right-sided heart failure. Also, inadequate filling of the left ventricle produces low cardiac output.
- Mitral valve prolapse: One or both valve leaflets protrude into the left atrium. *MVP* is the term used when the anatomic prolapse is accompanied by signs and symptoms unrelated to the valvular abnormality.
- Aortic insufficiency: Blood flows back into the left ventricle during diastole, causing fluid overload in the ventricle, which dilates and hypertrophies. The excess volume causes fluid overload in the left atrium, and, finally, the pulmonary system. Left-sided heart failure and pulmonary edema eventually result.
- Aortic stenosis: Increased left ventricular pressure tries to overcome the resistance of the narrowed valvular opening. The added workload increases the demand for oxygen, whereas diminished cardiac output causes poor coronary artery perfusion, ischemia of the left ventricle, and left-sided heart failure.
- Pulmonic insufficiency: Blood ejected into the pulmonary artery during systole flows back into the right ventricle during diastole, causing fluid overload in the ventricle, ventricular hypertrophy and, finally, right-sided heart failure.
- Pulmonic stenosis: Obstructed right ventricular outflow causes right ventricular hypertrophy, eventually resulting in right-sided heart failure.
- Tricuspid insufficiency: Blood flows back into the right atrium during systole, decreasing blood flow to the lungs and the left side of the heart. Cardiac output also lessens. Fluid overload in the right side of the heart can eventually lead to right-sided heart failure.
- Tricuspid stenosis: Obstructed blood flow from the right atrium to the right ventricle causes the right atrium to dilate and hypertrophy. Eventually, this leads to right-sided heart failure and increases pressure in the vena cava.

Treatment

Treatment depends on the nature and severity of associated symptoms. For example, heart failure requires diuretics, a sodium-restricted diet, and, in acute cases, oxygen. Other measures may include anticoagulant therapy or antiplatelet medications to prevent thrombus formation around diseased or replaced valves, prophylactic antibiotics before and after surgery, and valvuloplasty. An IABP may be used temporarily to reduce backflow by enhancing forward blood flow into the aorta.

If the patient has severe signs and symptoms that can't be managed medically, open heart surgery using cardiopulmonary bypass for valve repair or replacement is indicated. Newer procedures are available, such as transcatheter aortic valve replacement, and may be an option, as well. This is a minimally invasive procedure that wedges a replacement valve in the position of the old valve. This valve begins to take over the duties of the old valve while pushing the leaflets of the old valve away.

Special considerations

- Watch closely for signs of heart failure or pulmonary edema and for adverse effects of drug therapy.
- Teach the patient about diet restrictions, medications, and the importance of consistent follow-up care.
- If the patient undergoes surgery, watch for hypotension, arrhythmias, and thrombus formation. Monitor vital signs, ABG values, intake, output, daily weight, blood chemistries, chest X-rays, and pulmonary artery catheter readings.

Degenerative Cardiovascular Disorders

HYPERTENSION

Causes and Incidence

Hypertension, an intermittent or sustained elevation in diastolic or systolic blood pressure, occurs as two major types: essential (idiopathic) hypertension, the most common, and secondary hypertension, which results from renal disease or another identifiable cause. Malignant hypertension is a severe, fulminant form of hypertension common to both types. Hypertension is a major cause of stroke, cardiac disease, and renal failure. Hypertension affects 25% of adults in the United States. If untreated, it carries a high mortality. Risk factors for hypertension include family history, race (most common in blacks), stress, obesity, a diet high in saturated fats or sodium, tobacco use, sedentary lifestyle, and aging.

Secondary hypertension may result from renal vascular disease; pheochromocytoma; primary hyperaldosteronism; Cushing syndrome; thyroid, pituitary, or parathyroid dysfunction; coarctation of the aorta; pregnancy; neurologic disorders; and use of hormonal contraceptives or other drugs, such as cocaine, epoetin alfa (erythropoietin), and cyclosporine.

The prognosis is good if this disorder is detected early and treatment begins before complications develop. Severely elevated blood pressure (hypertensive crisis) may be fatal. (See *What happens in a hypertensive crisis*, page 31.)

PATHOPHYSIOLOGY

WHAT HAPPENS IN A HYPERTENSIVE CRISIS

   Hypertensive crisis is a severe rise in arterial blood pressure caused by a disturbance in one or more of the regulating mechanisms. If left untreated, hypertensive crisis may result in renal, cardiac, or cerebral complications and, possibly, death.

Causes of hypertensive crisis

- Abnormal renal function
- Hypertensive encephalopathy
- Intracerebral hemorrhage
- Heart failure
- Withdrawal of anti-hypertensive drugs (abrupt)
- Myocardial ischemia
- Eclampsia
- Pheochromocytoma
- Monoamine oxidase inhibitor interactions

↓

Prolonged hypertension

↓

Inflammation and necrosis of arterioles

↓

Narrowing of blood vessels

↓

Restriction of blood flow to major organs

↓

Organ damage

↓

Renal
- Decreased renal perfusion
- Progressive deterioration of nephrons
- Decreased ability to concentrate urine
- Increased serum creatinine and blood urea nitrogen levels
- Increased renal tubule permeability with protein leakage into tubules
- Renal insufficiency
- Uremia
- Renal failure

Cardiac
- Decreased cardiac perfusion
- Coronary artery disease
- Angina or myocardial infarction
- Increased cardiac workload
- Left ventricular hypertrophy
- Heart failure

Cerebral
- Decreased cerebral perfusion
- Increased stress on vessel wall
- Arterial spasm
- Ischemia
- Transient ischemic attacks
- Weakening of vessel intima
- Aneurysm formation
- Intracranial hemorrhage

Pathophysiology

Cardiac output and PVR determine blood pressure. Increased blood volume, cardiac rate, and stroke volume as well as arteriolar vasoconstriction can raise blood pressure. The link to sustained hypertension, however, is unclear. Hypertension may also result from failure of intrinsic regulatory mechanisms:

- Renal hypoperfusion causes release of renin, which is converted by angiotensinogen, a liver enzyme, to angiotensin I. Angiotensin I is converted to angiotensin II, a powerful vasoconstrictor. The resulting vasoconstriction increases afterload. Angiotensin II stimulates adrenal secretion of aldosterone, which increases sodium reabsorption. Hypertonic-stimulated release of antidiuretic hormone from the pituitary gland follows, increasing water reabsorption, plasma volume, cardiac output, and blood pressure.
- Autoregulation changes an artery's diameter to maintain perfusion despite fluctuations in systemic blood pressure. The intrinsic mechanisms responsible include stress relaxation (vessels gradually dilate when blood pressure rises to reduce peripheral resistance) and capillary fluid shift (plasma moves between vessels and extravascular spaces to maintain intravascular volume).
- When the blood pressure drops, baroreceptors in the aortic arch and carotid sinuses decrease their inhibition of the medulla's vasomotor center, which increases sympathetic stimulation of the heart by norepinephrine. This, in turn, increases cardiac output by strengthening the contractile force, increasing the heart rate, and augmenting peripheral resistance by vasoconstriction. Stress can also stimulate the sympathetic nervous system to increase cardiac output and PVR.

Complications

- Stroke
- Coronary artery disease
- Angina
- Myocardial infarction
- Heart failure
- Arrhythmias
- Sudden death
- Cerebral infarction
- Hypertensive encephalopathy
- Hypertensive retinopathy
- Renal failure

Signs and Symptoms

Hypertension usually doesn't produce clinical effects until vascular changes in the heart, brain, or kidneys occur. Severely elevated blood pressure damages the intima of small vessels, resulting in fibrin accumulation in the vessels, development of local edema and, possibly, intravascular clotting. Symptoms produced by this process depend on the location of the damaged vessels:

- brain—stroke
- retina—blindness
- heart—myocardial infarction
- kidneys—proteinuria, edema, and, eventually, renal failure

Hypertension increases the heart's workload, causing left ventricular hypertrophy and, later, left- and right-sided heart failure and pulmonary edema.

Diagnosis

Serial blood pressure measurements are obtained and compared to previous readings and trends to reveal an increase in diastolic and systolic pressures. (See *Classifying blood pressure readings*, page 32.)

Classifying Blood Pressure Readings

The Eighth Joint National Committee (JNC8) released updated guidelines in 2014 for classifying and treating hypertension.

The following categories are based on the average of two or more readings taken on separate visits after an initial screening. They apply to adults 18 years old and older.

Normal blood pressure with respect to cardiovascular risk is a systolic reading below 120 mm Hg and a diastolic reading below 80 mm Hg. Historically, hypertension was defined as a systolic blood pressure of 140 mm Hg or higher or a diastolic pressure above 90 mm Hg. The latest guidelines, however, classify hypertension as a systolic reading of 130 mm Hg or higher, or a diastolic pressure above 90 mm Hg.

In addition to classifying stages of hypertension based on average blood pressure readings, clinicians should also take note of target organ disease and any additional risk factors.

Category	Systolic (mm Hg)		Diastolic (mm Hg)
Normal	<120	and	<80
Elevated	120 to 129	and	<80
Hypertension			
Stage 1	130 to 139	or	80 to 89
Stage 2	≥140	or	≥90
Hypertensive crisis	≥180	and/or	≥120

Auscultation may reveal bruits over the abdominal aorta and the carotid, renal, and femoral arteries; ophthalmoscopy reveals arteriovenous nicking and, in hypertensive encephalopathy, papilledema. Patient history and the following additional tests may show predisposing factors and help identify an underlying cause such as renal disease:

- Urinalysis: Protein levels and red and white blood cell counts may indicate glomerulonephritis.
- Excretory urography: Renal atrophy indicates chronic renal disease; one kidney more than 5/8″ (1.5 cm) shorter than the other suggests unilateral renal disease.
- Serum potassium: Levels less than 3.5 mEq/L may indicate adrenal dysfunction (primary hyperaldosteronism).
- BUN and serum creatinine: BUN level that's normal or elevated to more than 20 mg/dL and serum creatinine level that's normal or elevated to more than 1.5 mg/dL suggest renal disease.

Other tests help detect cardiovascular damage and other complications:

- ECG may show left ventricular hypertrophy or ischemia.
- Chest X-ray may show cardiomegaly.
- Echocardiography may show left ventricular hypertrophy.

Treatment

The JNC8 recommends the following approach for treating primary hypertension:

- First, help the patient start needed lifestyle modifications, including weight reduction, moderation of alcohol intake, regular physical exercise, reduction in sodium intake, and smoking cessation.
- If the patient fails to achieve the desired blood pressure or make significant progress, continue lifestyle modifications and begin drug therapy.
- Pharmacologic therapy should begin when blood pressure is 140/90 in patients less than 60, and 150/90 in those 60 and older.
- If the patient has comorbid conditions such as diabetes mellitus or chronic kidney disease (CKD), the goal should be to achieve blood pressure less than 140/90 regardless of age.
- In nonblack patients without CKD, consider using a thiazide diuretic, an angiotensin-converting enzyme (ACE) inhibitor, an angiotensin receptor blocker (ARB), or a calcium channel blocker (CCB), alone or in combination.
- In black patients without CKD, consider using a thiazide diuretic or a CCB, alone or in combination.
- In all patients with CKD, consider initiating an ACE or ARB, alone or in combination with another class.
- If the patient has one or more compelling indications, base drug treatment on benefits from outcome studies or existing clinical guidelines. Treatment may include the following, depending on indication:

  - Heart failure—ACE/ARB + beta-adrenergic blocker (BB) + diuretic + spironolactone
  - CAD—ACE, BB, diuretic, CCB
  - Diabetes—ACE/ARB, CCB, diuretic
  - CKD—ACE inhibitor or ARB
  - Postmyocardial infarction/clinical CAD—ACE/ARB + BB
  - Recurrent stroke prevention—ACE, diuretic
  - Pregnancy—labetalol (first line), nifedipine, methyldopa

  Give other antihypertensive drugs as needed.

- If the patient fails to achieve the desired blood pressure, continue lifestyle modifications and optimize drug dosages or add drugs until the goal blood pressure is achieved. Also, consider consultation with a hypertension specialist.

Treatment of secondary hypertension focuses on correcting the underlying cause and controlling hypertensive effects.

Typically, hypertensive emergencies require parenteral administration of a vasodilator or an adrenergic inhibitor. Oral administration of a selected drug, such as nicardipine, hydralazine, or esmolol to rapidly reduces blood pressure. The initial goal is to reduce mean arterial blood pressure by no more than 25% (within minutes to hours) and then to 160/110 mm Hg within 2 hours while avoiding excessive falls in blood pressure that can precipitate renal, cerebral, or myocardial ischemia.

Examples of hypertensive emergencies include hypertensive encephalopathy, intracranial hemorrhage, acute left-sided heart failure with pulmonary edema, and dissecting aortic aneurysm. Hypertensive emergencies are also associated with eclampsia or severe gestational hypertension, unstable angina, and acute MI.

Hypertension without accompanying symptoms or target organ disease seldom requires emergency drug therapy.

Special Considerations

- To encourage adherence to antihypertensive therapy, suggest that the patient establish a daily routine for taking medication. Warn that uncontrolled hypertension may cause stroke and heart attack. Tell the patient to report adverse drug effects. Also, advise the patient to avoid high-sodium antacids and over-the-counter cold and sinus medications, which contain harmful vasoconstrictors.
- Encourage a change in dietary habits. Help the obese patient plan a weight-reduction diet; tell the patient to avoid high-sodium foods (pickles, potato chips, canned soups, and cold cuts) and table salt.
- Help the patient examine and modify lifestyle (e.g., by reducing stress and exercising regularly).
- If a patient is hospitalized with hypertension, find out if the patient was taking his or her prescribed medication. If not, ask why. If the patient can't afford the medication, refer to appropriate social service agencies. Tell the patient and family to keep a record of drugs used in the past, noting especially those that were or weren't effective. Suggest that the patient record this information on a card and show it to his or her practitioner.
- When routine blood pressure screening reveals elevated pressure, first make sure the cuff size is appropriate for the patient's upper arm circumference. Take the pressure in both arms in lying, sitting, and standing positions. Ask the patient if he or she smoked, drank a beverage containing caffeine, or was emotionally upset before the test. Advise the patient to return for blood pressure testing at frequent and regular intervals.
- To help identify hypertension and prevent untreated hypertension, participate in public education programs dealing with hypertension and ways to reduce risk factors. Encourage public participation in blood pressure screening programs. Routinely screen all patients, especially those at risk (blacks and people with family histories of hypertension, stroke, or heart attack). (See *Preventing hypertension*, page 34.)

PREVENTION
PREVENTING HYPERTENSION

Certain risk factors for hypertension can't be changed, such as family history, race, and aging, but lifestyle modifications can help prevent hypertension. Based on American Heart Association recommendations, advise your patient to do the following:

Maintain A Healthy Weight
Maintain a normal weight or lose weight if overweight. Weight loss lowers blood pressure.

Reduce Salt

Salt intake should be reduced to about 1.5 g/day. Reducing salt intake can lower blood pressure in individuals with and without hypertension.

Increase Potassium

Patients should eat 8 to 10 servings of fruits and vegetables per day to increase potassium intake. Potassium reduces blood pressure in individuals with and without hypertension. Those with kidney disease or heart failure should contact their practitioner before increasing their potassium intake.

Limit Alcohol Intake

Studies have shown a correlation between alcohol intake and increased blood pressure, especially in individuals who drink >2 drinks/day.

Include Exercise

Regular physical activity is defined by the American Heart Association as moderate-intensity exercise such as brisk walking for 150 minutes each week. A lack of physical activity can lead to obesity and increase the risk of hypertension, heart attack, and stroke.

Manage Stress

Stress can lead to increased alcohol consumption, smoking, overeating, and other activities that increase the risk of heart attack or stroke. Daily relaxation for short periods during the workday and on weekends can also lower blood pressure.

Stop Smoking

Smoking even filtered and light or ultra cigarettes can lead to atherosclerosis. Quitting or not starting is the only way to prevent this major risk factor for heart attack and stroke.

Follow The Dash Diet

The Dietary Approaches to Stop Hypertension (DASH) diet encourages vegetables, fruits, and low-fat dairy as well as whole grains, fish, poultry, and nuts. Discourage the eating of fats, red meat, sweets, and sugar-containing beverages. However, individuals with reduced kidney function should always consult their practitioners before starting this diet; it's rich in potassium, which isn't recommended for individuals with these disorders.

CORONARY ARTERY DISEASE

Causes and Incidence

CAD occurs when the arteries that supply blood to the heart muscle harden and narrow, usually as a result of atherosclerosis. The result is the loss of oxygen and nutrients to myocardial tissue because of diminished coronary blood flow. This reduction in blood flow can also lead to coronary syndrome (angina or MI). (See *Understanding coronary artery disease.*)

Understanding Coronary Artery Disease

Coronary artery disease (CAD) results as atherosclerotic plaque fills the lumens of the

coronary arteries and obstructs blood flow. The primary effect of CAD is a diminished supply of oxygen and nutrients to myocardial tissues.

CAD has been linked to many risk factors: family history, male gender, age (risk increased in those 65 years old or older), hypertension, obesity, smoking, diabetes mellitus, stress, sedentary lifestyle, high serum cholesterol (particularly high low-density lipoprotein cholesterol) or triglyceride levels, low high-density lipoprotein cholesterol levels, high blood homocysteine levels, menopause and, possibly, infections producing inflammatory responses in the artery walls.

Uncommon causes of reduced coronary artery blood flow include dissecting aneurysms, infectious vasculitis, syphilis, and congenital defects in the coronary vascular system. Coronary artery spasms may also impede blood flow. (See *Coronary artery spasm*, page 36.)

Coronary Artery Spasm

In coronary artery spasm, a spontaneous, sustained contraction of one or more coronary arteries causes ischemia and dysfunction of the heart muscle. This disorder also causes Prinzmetal angina and even myocardial infarction in patients with unoccluded coronary arteries. Its cause is unknown but possible contributing factors include:
- altered flow of calcium into the cell
- intimal hemorrhage into the medial layer of the blood vessel
- hyperventilation
- elevated catecholamine levels
- fatty buildup in lumen

Signs and Symptoms
The major symptom of coronary artery spasm is angina. However, unlike classic angina, this pain often occurs spontaneously and may not be related to physical exertion or emotional stress; it's also more severe, usually lasts longer, and may be cyclic, frequently recurring every day at the same time. Such ischemic episodes may cause arrhythmias, altered heart rate, lower blood pressure and, occasionally, fainting due to diminished cardiac output. Spasm in the left coronary artery may result in mitral insufficiency, producing a loud systolic murmur and, possibly, pulmonary edema, with dyspnea, crackles, hemoptysis, or sudden death.

CAD is the leading cause of death in the United States. According to the American Heart Association, 1 in 3 deaths is due to cardiovascular disease, and someone dies from such an event about every 40 seconds.

Pathophysiology

In atherosclerosis, a form of arteriosclerosis, fatty, fibrous plaques, possibly including calcium deposits, narrow the lumen of the coronary arteries and reduce the volume of blood that can flow through them, and leading to myocardial ischemia. Plaque formation also predisposes to thrombosis, which can provoke MI.

Atherosclerosis usually develops in high-flow, high-pressure arteries, such as those in the heart, brain, kidneys, and in the aorta, especially at bifurcation points.

Signs and Symptoms

The classic symptom of CAD is angina, the direct result of inadequate oxygen flow to the myocardium. Anginal pain is usually described as a burning, squeezing, or tight feeling in the substernal or precordial chest that may radiate to the left arm, neck, jaw, or shoulder blade. Typically, the patient clenches a fist over his chest or rubs the left arm when describing the pain, which may be accompanied by nausea, vomiting, fainting, sweating, and cool extremities. Anginal episodes most often follow physical exertion but may also follow emotional excitement, exposure to cold, or a large meal. Some patients, particularly those with diabetes, may not experience typical anginal pain but may have dyspnea, fatigue, diaphoresis, or more vague symptoms.

Angina has four major forms: *stable* (pain is predictable in frequency and duration and can be relieved with nitrates and rest), *unstable* (pain increases in frequency and duration and is more easily induced), *Prinzmetal* or *variant* (from unpredictable coronary artery spasm), and *microvascular* (in which impairment of vasodilator reserve causes angina-like chest pain in a patient with normal coronary arteries). Severe and prolonged anginal pain generally suggests MI, with potentially fatal arrhythmias and mechanical failure.

Diagnosis

The patient history—including the frequency and duration of angina and the presence of

associated risk factors—is crucial in evaluating CAD. Additional diagnostic measures include the following:

- Electrocardiogram (ECG) during angina may show ischemia and, possibly, arrhythmias such as premature ventricular contractions. ECG is apt to be normal when the patient is pain-free. Arrhythmias may occur without infarction, secondary to ischemia.
- Treadmill or exercise stress test may provoke chest pain and ECG signs of myocardial ischemia.
- Coronary angiography reveals coronary artery stenosis or obstruction, possible collateral circulation, and the arteries' condition beyond the narrowing.
- Myocardial perfusion imaging with thallium-201, Cardiolite, or Myoview during treadmill exercise detects ischemic areas of the myocardium, visualized as "cold spots."
- Stress echocardiography may show wall motion abnormalities.
- Electron-beam computed tomography identifies calcium within arterial plaque; the more calcium seen, the higher the likelihood of CAD.

Treatment

The goal of treatment in patients with angina is to either reduce myocardial oxygen demand or increase oxygen supply. Therapy consists primarily of nitrates such as nitroglycerin (given sublingually, orally, transdermally, or topically in ointment form) to dilate coronary arteries and improve blood supply to the heart. Glycoprotein IIb to IIIa inhibitors and antithrombin drugs may be used to reduce the risk of blood clots. BBs may be used to decrease heart rate and lower the heart's oxygen use. CCBs may be used to relax the coronary arteries and all systemic arteries, reducing the heart's workload. ACE inhibitors, diuretics, or other medications may be used to lower blood pressure.

Percutaneous transluminal coronary angioplasty (PTCA) may be performed during cardiac catheterization to compress fatty deposits and relieve occlusion in patients with no calcification and partial occlusion. PTCA carries a certain risk, but the morbidity associated with it is lower than that for surgery. (See *Relieving occlusions with angioplasty*, pages 38 and 39.)

Relieving Occlusions With Angioplasty

Percutaneous transluminal coronary angioplasty can open an occluded coronary artery without opening the chest—an important advantage over bypass surgery. First, coronary angiography must confirm the presence and location of the arterial occlusion. Then, the physician threads a guide catheter through the patient's femoral or radial artery into the coronary artery under fluoroscopic guidance, as shown at right.

When angiography shows the guide catheter positioned at the occlusion site, the physician carefully inserts a smaller double-lumen balloon catheter through the guide catheter and directs the balloon through the occlusion (opposite page, left). A marked pressure gradient will be obvious.

The physician alternately inflates and deflates the balloon until an angiogram verifies successful arterial dilation (opposite page, right) and the pressure gradient has decreased.

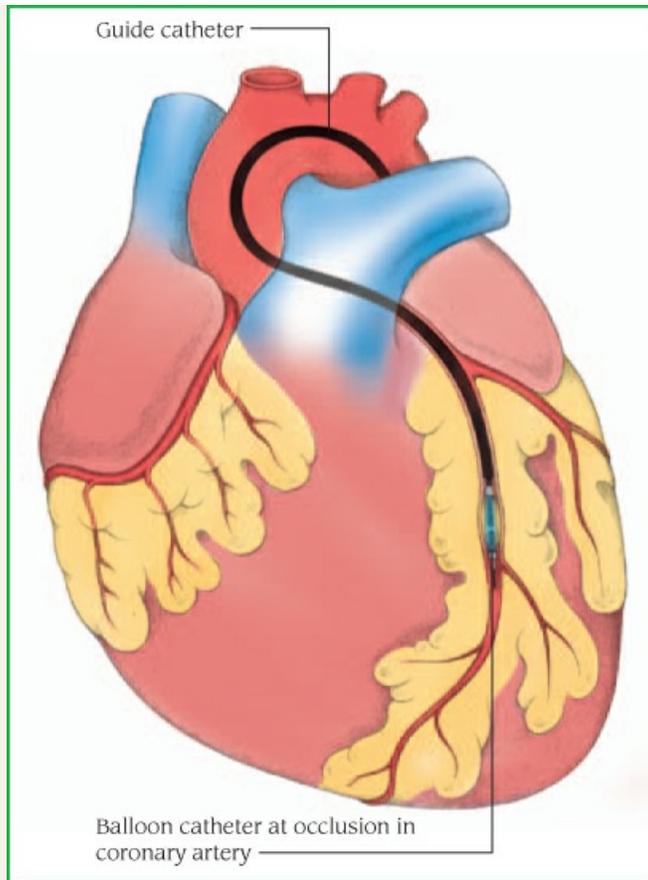
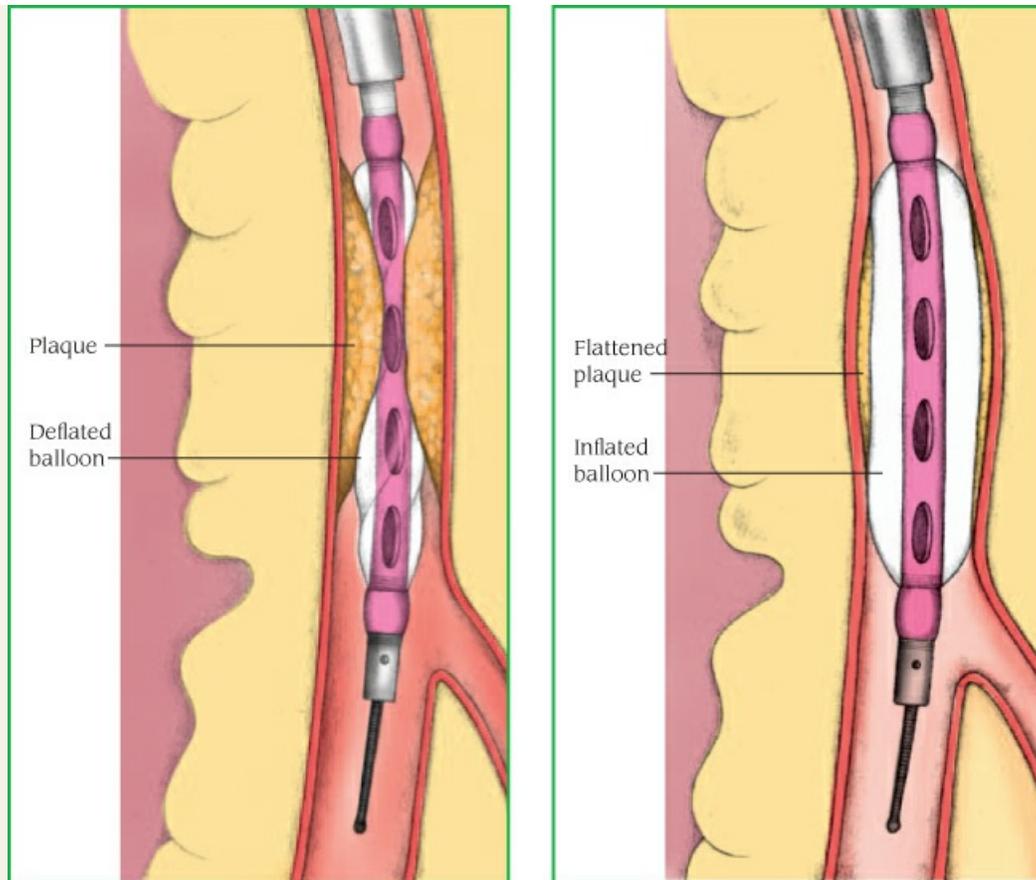
Flattened plaque

Inflated balloon




PTCA is an alternative to grafting in elderly patients or others who can't tolerate cardiac surgery. However, patients who have a left main coronary artery occlusion, lesions in extremely tortuous vessels, or occlusions older than 3 months aren't candidates for PTCA.

PTCA can be done along with coronary stenting, or stents may be placed alone. Stents provide a framework to hold an artery open by securing the flaps of the tunica media against an artery wall. Intravascular coronary artery stenting is done to reduce the incidence of restenosis. Prosthetic cylindrical stents made of stainless steel coil are positioned at the site of occlusion. Drug-eluting stents have proven to be safe and effective and have a lower rate of restenosis when compared with bare-metal stents.

Laser angioplasty corrects occlusion by vaporizing fatty deposits with the excimer, or hot-tipped laser device. Percutaneous myocardial revascularization uses a laser to create channels in the heart muscle to improve perfusion to the myocardium. A carbon dioxide laser is used to create transmural channels from the epicardium to the myocardium, extending into the left ventricle. This technique is also known as transmyocardial revascularization and appears to be effective for severe symptoms. In addition, a stent may be placed in the artery to act as a scaffold to hold the artery open. Obstructive lesions may necessitate coronary artery bypass graft (CABG) surgery and the use of vein grafts.

A surgical technique available as an alternative to traditional CABG surgery is minimally invasive coronary artery bypass surgery, also known as *laparoscopic surgery*. This procedure requires a shorter recovery period and has fewer postoperative complications. Instead of sawing

open the patient's sternum and spreading the ribs apart, several small cuts are made in the torso through which small surgical instruments and fiber-optic cameras are inserted. This procedure was initially designed to correct blockages in just one or two easily reached arteries; it may not be suitable for more complicated cases.

Coronary brachytherapy, which involves delivering beta or gamma radiation into the coronary arteries, may be used in patients who've undergone stent implantation in a coronary artery but then developed such problems as diffuse in-stent restenosis. Brachytherapy is a promising technique, but its use is restricted to the treatment of stent-related problems because of complications and the unknown long-term effects of the radiation. However, in some facilities, brachytherapy is being studied as a first-line treatment of CAD.

PREVENTION *Because CAD is so widespread, prevention is of great importance. Encourage dietary restrictions aimed at reducing intake of calories (in obesity) and salt, saturated fats, and cholesterol, in order to minimize the risk, especially when supplemented with regular exercise. Also, encourage the patient to stop smoking and to reduce stress. Other preventive actions to encourage include control of hypertension, control of elevated serum cholesterol or triglyceride levels (with antilipemics), and measures to minimize platelet aggregation and the danger of blood clots (with aspirin or other antiplatelet drugs).*

Special Considerations

- During anginal episodes, monitor blood pressure and heart rate. Take an ECG during anginal episodes and before administering nitroglycerin or other nitrates. Record duration of pain, amount of medication required to relieve it, and accompanying symptoms.
- Keep nitroglycerin available for immediate use. Instruct the patient to call immediately whenever feeling chest, arm, or neck pain.
- Before cardiac catheterization, explain the procedure to the patient. Make sure the patient knows why it's necessary, understands the risks, and realizes that it may indicate a need for surgery.
- After catheterization, review the expected course of treatment with the patient and family. Monitor the catheter site for bleeding. Also, check for distal pulses. To counter the dye's diuretic effect, make sure the patient drinks plenty of fluids. Assess potassium levels.
- If the patient is scheduled for surgery, explain the procedure to the patient and family. Give them a tour of the ICU and introduce them to the staff.
- After surgery, monitor blood pressure, intake and output, breath sounds, chest tube drainage, and ECG, watching for signs of ischemia and arrhythmias. Also, observe for and treat chest pain and possible dye reactions. Give vigorous chest physiotherapy and guide the patient in removal of secretions through deep breathing, coughing, and expectoration of mucus.
- Before discharge, stress the need to follow the prescribed drug regimen (e.g., antihypertensives, nitrates, and antilipemics), exercise program, and diet. Encourage regular, moderate exercise. Refer the patient to a self-help program to stop smoking.

MYOCARDIAL INFARCTION

Causes and Incidence

MI, commonly known as a *heart attack* and part of a broader category of disease known as *acute coronary syndrome,* results from prolonged myocardial ischemia due to reduced blood flow

through one of the coronary arteries. (See *Tissue destruction in myocardial infarction*, page 40.) In cardiovascular disease, the leading cause of death in the United States and Western Europe, death usually results from the cardiac damage or complications of MI. (See *Complications of myocardial infarction*, page 41.)

Tissue Destruction In Myocardial Infarction

A myocardial infarction results from prolonged myocardial ischemia due to reduced blood flow through one or more of the coronary arteries.

Superior vena cava

Arch of aorta

Right atrium

Pulmonary trunk

Left atrium

Right coronary artery

Circumflex branch of left coronary artery

Left anterior descending artery

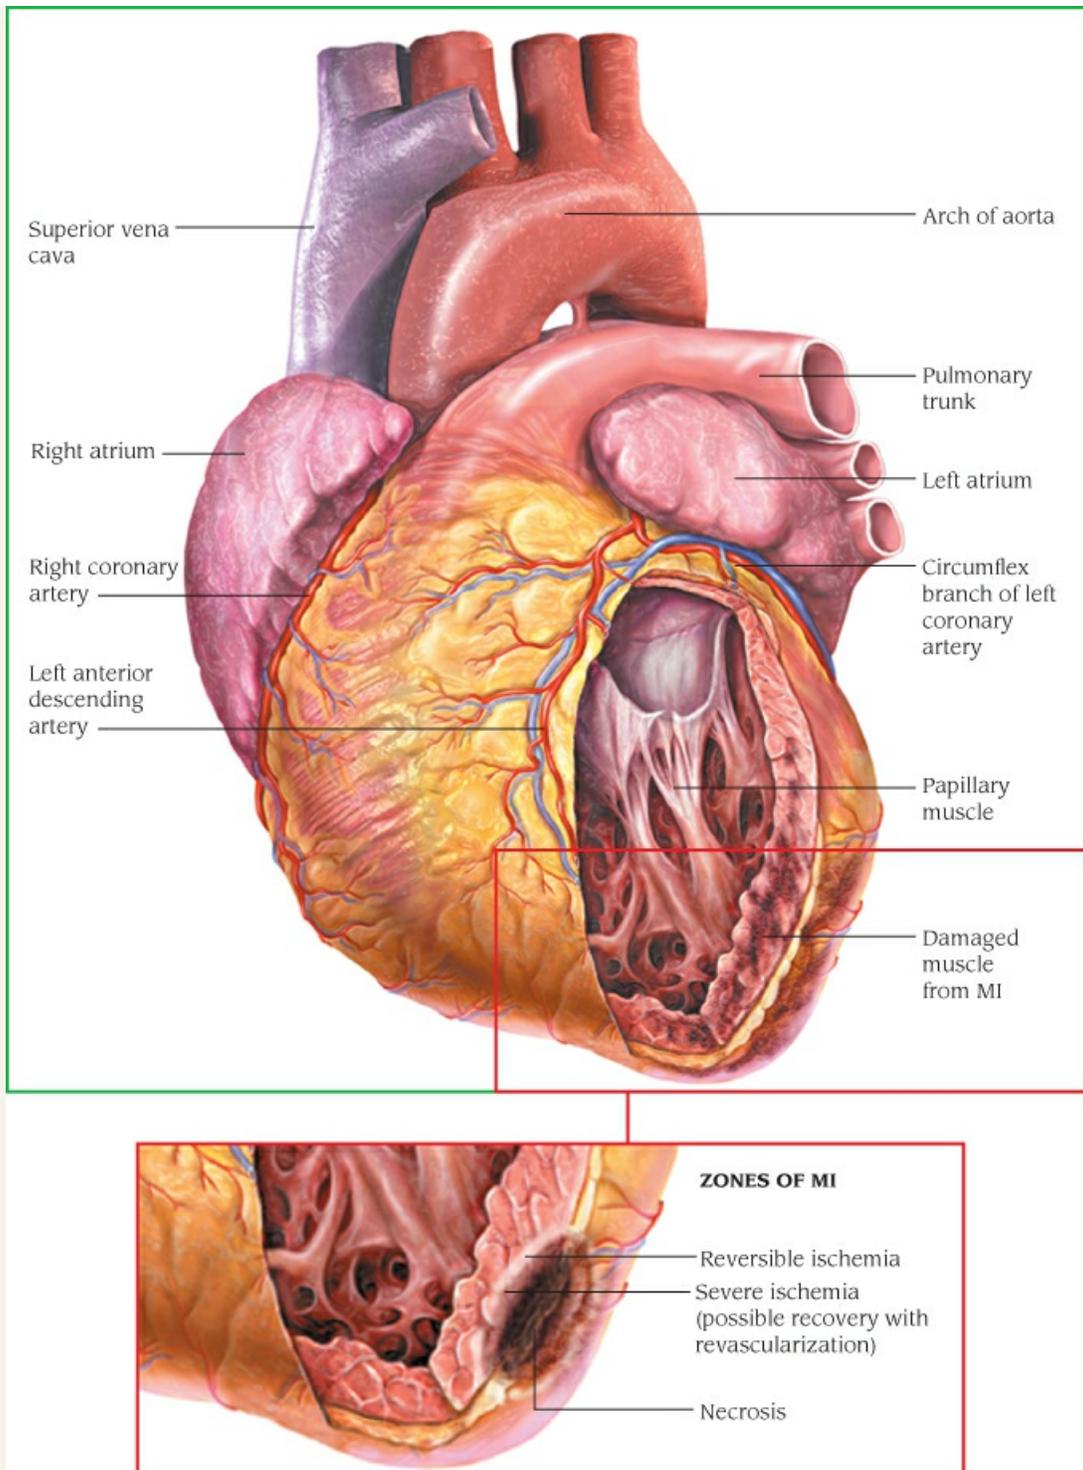
Papillary muscle

Damaged muscle from MI

ZONES OF MI

Reversible ischemia

Severe ischemia (possible recovery with revascularization)

Necrosis


Complications of Myocardial Infarction

Complication	Diagnosis	Treatment

Arrhythmias	Electrocardiogram (ECG) shows premature ventricular contractions, ventricular tachycardia, or ventricular fibrillation; in inferior wall myocardial infarction (MI), bradycardia and junctional rhythms or atrioventricular block; in anterior wall MI, tachycardia or heart block	Antiarrhythmics, atropine, and pacemaker; cardioversion for tachycardia
Heart failure	In left-sided heart failure, chest X-rays show venous congestion, cardiomegaly, and Kerley B lines Catheterization shows increased pulmonary artery pressure (PAP) and central venous pressure	Diuretics, angiotensin-converting enzyme inhibitors, vasodilators, inotropic agents, cardiac glycosides, and beta-adrenergic blockers
Cardiogenic shock	Catheterization shows decreased cardiac output and increased PAP and pulmonary artery wedge pressure (PAWP) Signs include hypertension, tachycardia, S_3, S_4, decreased levels of consciousness, decreased urine output, jugular vein distention, and cool, pale skin	I.V. fluids, vasodilators, diuretics, cardiac glycosides, intra-aortic balloon pump (IABP), and beta-adrenergic stimulants
Rupture of left ventricular papillary muscle	Auscultation reveals an apical holosystolic murmur. Inspection of jugular vein pulse or hemodynamic monitoring shows increased v waves Dyspnea is prominent Color-flow and Doppler echocardiogram show mitral insufficiency. Pulmonary artery catheterization shows increased PAP and PAWP	Nitroprusside (Nitropress) IABP Surgical replacement of the mitral valve with possible concomitant myocardial revascularization (in patients with significant coronary artery disease)
Ventricular septal rupture	In left-to-right shunt, auscultation reveals a holosystolic murmur and thrill Catheterization shows increased PAP and PAWP Confirmation is by increased oxygen saturation of the right ventricle and pulmonary artery	Surgical correction, IABP, nitroglycerin, nitroprusside, low-dose inotropic agents, or pacemaker
Pericarditis or Dressler syndrome	Auscultation reveals a friction rub Chest pain is relieved by sitting up	Aspirin or NSAIDs
	Chest X-ray may show cardiomegaly ECG may show arrhythmias and persistent ST-segment elevation Left ventriculography shows altered or paradoxical left ventricular motion	Cardioversion, defibrillation, antiarrhythmics, vasodilators, anticoagulants, cardiac glycosides, and diuretics (if conservative treatment fails, surgical resection is necessary)
Thromboembolism	Severe dyspnea and chest pain or neurologic changes Nuclear scan shows ventilation–perfusion mismatch Angiography shows arterial blockage	Oxygen and heparin

Incidence is high: About 1 million patients visit the hospital each year with an MI, and another 120,000 people die from MI-related complications without seeking medical care. Men and postmenopausal women are more susceptible to MI than premenopausal women, although incidence is rising among females, especially those who smoke and take hormonal contraceptives.

Mortality is high when treatment is delayed, and almost one half of sudden deaths due to an MI occur before hospitalization, within 1 hour of the onset of symptoms. The prognosis improves if vigorous treatment begins immediately.

Predisposing risk factors include:

- diabetes mellitus
- drug use, especially cocaine

- elevated serum triglyceride, total cholesterol, and low-density lipoprotein levels
- hypertension
- obesity or excessive intake of saturated fats, carbohydrates, or salt
- positive family history
- sedentary lifestyle
- smoking
- stress or a type A personality

Pathophysiology

The site of the MI depends on the vessels involved. Occlusion of the circumflex branch of the left coronary artery causes a lateral wall infarction; occlusion of the anterior descending branch of the left coronary artery, an anterior wall infarction. True posterior or inferior wall infarctions generally result from occlusion of the right coronary artery or one of its branches. Right ventricular infarctions can also result from right coronary artery occlusion, can accompany inferior infarctions, and may cause right-sided heart failure.

Signs and Symptoms

The cardinal symptom of MI is persistent, crushing substernal pain that may radiate to the left arm, jaw, neck, or shoulder blades. Such pain is usually described as heavy, squeezing, or crushing, and may persist for 12 hours or more. However, in some MI patients—particularly elderly people or those with diabetes—pain may not occur at all; in others, it may be mild and confused with indigestion. In patients with CAD, angina of increasing frequency, severity, or duration (especially if not provoked by exertion, a heavy meal, or cold and wind) may signal impending infarction.

Other clinical effects include a feeling of impending doom, fatigue, nausea, vomiting, and shortness of breath. Some patients may have no symptoms. The patient may experience catecholamine responses, such as coolness in extremities, perspiration, anxiety, and restlessness. Fever is unusual at the onset of an MI, but a low-grade temperature elevation may develop during the next few days. Blood pressure varies; hypotension or hypertension may be present.

The most common post-MI complications include recurrent or persistent chest pain, arrhythmias, left-sided heart failure (resulting in heart failure or acute pulmonary edema), and cardiogenic shock. Unusual but potentially lethal complications that may develop soon after infarction include thromboembolism; papillary muscle dysfunction or rupture, causing mitral insufficiency; rupture of the ventricular septum, causing VSD; rupture of the myocardium; and ventricular aneurysm. Up to several months after infarction, Dressler syndrome (pericarditis, pericardial friction rub, chest pain, fever, leukocytosis and, possibly, pleurisy or pneumonitis) may develop.

Diagnosis

℞ **CONFIRMING DIAGNOSIS** *Persistent chest pain, elevated ST segment on ECG, and elevated total CK and CK-MB levels over a 72-hour period are consistent with ST-elevation MI (STEMI). Troponin T or troponin I is also used in the diagnosis because both are specific to cardiac necrosis, and levels rise 6 to 8 hours after onset of ischemia. These labs are also useful when no ST-segment elevation occurs, as in non–ST elevation MI (NSTEMI).*

Auscultation may reveal diminished heart sounds, gallops, and, in papillary dysfunction, the

apical systolic murmur of mitral insufficiency over the mitral valve area.

When clinical features are equivocal, assume that the patient had an MI until tests rule it out. Diagnostic laboratory results include:

- serial 12-lead ECG—ECG abnormalities may be absent or inconclusive during the first few hours after an MI. When present, characteristic abnormalities include serial ST-segment depression NSTEMI and STEMI.
- serial serum enzyme levels—CK levels are elevated, specifically, the CK-MB isoenzyme.
- echocardiography—may show ventricular wall motion abnormalities.
- nuclear ventriculography scans (MUGA or radionuclide ventriculography)—using I.V. radioactive substance, can identify acutely damaged muscle by picking up radioactive nucleotide, which appears as a "hot spot" on the film; useful in localizing a recent MI.

Treatment

The goals of treatment are to relieve chest pain, stabilize heart rhythm, reduce cardiac workload, revascularize the coronary artery, and preserve myocardial tissue. Arrhythmias, the predominant problem during the first 48 hours after the infarction, may require antiarrhythmics, possibly a pacemaker, and, rarely, cardioversion. Arrhythmias are best detected using a 12-lead ECG.

To preserve myocardial tissue is primary percutaneous coronary intervention (PCI) (mechanical reperfusion). PCI has been shown in many studies to be superior to fibrinolysis in the combined end points of death, stroke, and reinfarction when it is performed within 90 minutes of patient arrival. When primary PCI cannot be performed within 90 minutes, thrombolysis is the treatment of choice in STEMI. (See *Comparing thrombolytics,* page 43.)

Comparing Thrombolytics

If your patient has suffered a myocardial infarction (MI), you must intervene promptly to minimize cardiac damage and avert death. If appropriate, prepare the patient for thrombolytic therapy as ordered.

Thrombolytic drugs enhance the body's natural ability to dispose of blood clots. To lyse (dissolve) fibrin, the essential component of a clot, tissue activators convert plasminogen to plasmin. A nonspecific protease, plasmin, degrades fibrin, fibrinogen, and procoagulant factors (such as factors V, VII, and XII).

Candidates for thrombolytic therapy include patients with acute ST-segment elevation and chest pain that has lasted no more than 6 hours and who have no access to cardiac catheterization. Timely use of thrombolytic agents can restore myocardial perfusion and prevent further injury. When effective, thrombolytic agents relieve chest pain, restore the ST segment to baseline, and induce reperfusion arrhythmias within 30 to 45 minutes.

Contraindications to thrombolytic therapy include surgery within the past 2 months, active bleeding, a history of stroke, intracranial neoplasm, arteriovenous malformation, aneurysm, or uncontrolled hypertension.

Here's how selected thrombolytics open occluded coronary arteries in patients with an acute MI.

Alteplase (Activase)

This naturally occurring enzyme has been cloned and produced as a drug, alteplase (tissue

plasminogen activator). Binding to plasminogen, it catalyzes the conversion of plasminogen to plasmin in the presence of fibrin. Because of its strong affinity for fibrin, alteplase concentrates at the clot site, resulting in a minimal decrease in the fibrinogen level.

This thrombolytic has a half-life of 5 minutes, so maintaining coronary artery patency depends on continued anticoagulation with heparin. Alteplase doesn't induce antigenic responses; doses may be repeated at any time.

Reteplase (Retavase)

Reteplase, recombinant plasminogen activator, has a half-life of 13 to 16 minutes. Its longer half-life allows it to be administered as a bolus. Two boluses are required.

Streptokinase (Streptase)

Streptokinase, a thrombolytic, is a bacterial protein that binds to circulating plasminogen and catalyzes plasmin formation. Its low specificity for fibrin induces a systemic lytic state and increases the risk of bleeding.

The half-life is ~20 minutes. Like anistreplase, streptokinase is antigenic.

Tenecteplase (Tnkase)

Tenecteplase is a modified form of human tissue plasminogen activator that binds to fibrin and converts plasminogen to plasmin. It's given as a single bolus dose.

Urokinase (Abbokinase)

Naturally produced by the human kidney, urokinase promotes thrombolysis by directly activating the conversion of plasminogen to plasmin.

With a serum half-life of 10 to 20 minutes, urokinase is rapidly cleared by the kidneys and liver. Unlike streptokinase, it doesn't induce an antigenic response. Urokinase isn't given through a peripheral I.V. line to treat an acute MI, but patients who undergo cardiac catheterization may receive it directly in a coronary artery.

Other treatments consist of:

- lidocaine, vasopressin, or amiodarone for ventricular arrhythmias, or other drugs, such as procainamide, quinidine, or disopyramide
- antiplatelet therapy with glycoprotein IIb to IIIa inhibitors, such as clopidogrel for non-STEMI
- atropine I.V. or a temporary pacemaker for heart block or bradycardia
- nitroglycerin (sublingual, topical, transdermal, or I.V.); CCBs, such as nifedipine, verapamil, or diltiazem (sublingual, oral, or I.V.); or isosorbide dinitrate (sublingual, oral, or I.V.) to relieve pain by redistributing blood to ischemic areas of the myocardium, increasing cardiac output, and reducing myocardial workload
- heparin I.V. (usually follows thrombolytic therapy)
- morphine I.V. for pain and sedation
- bed rest with bedside commode to decrease cardiac workload
- oxygen administration at a modest flow rate for 2 to 3 hours (a lower concentration is necessary if the patient has chronic obstructive pulmonary disease)
- ACE inhibitors for patients with large anterior wall MIs and for those with an MI and a left

ventricular ejection fraction less than 40%

- drugs to increase myocardial contractility or blood pressure
- BBs, such as carvedilol or atenolol, after acute MI to help prevent reinfarction by reducing the heart's workload
- aspirin to inhibit platelet aggregation (should be initiated immediately and continued for years)
- pulmonary artery catheterization to detect left- or right-sided heart failure and to monitor the patient's response to treatment.

Special Considerations

Care for patients who have suffered an MI is directed toward detecting complications; preventing further myocardial damage; and promoting comfort, rest, and emotional well-being. Most MI patients receive treatment in the ICU or on a telemetry unit, where they're under constant observation for complications.

- On admission, monitor and record the patient's ECG, blood pressure, temperature, and heart and breath sounds.
- Assess and record the severity and duration of pain, and administer analgesics. Avoid I.M. injections; absorption from the muscle is unpredictable, and bleeding is likely if the patient is receiving thrombolytic therapy.
- Check the patient's blood pressure after giving nitroglycerin, especially the first dose.
- Frequently monitor the ECG to detect rate changes or arrhythmias. Place rhythm strips in the patient's chart periodically for evaluation.
- During episodes of chest pain, obtain 12-lead ECG (before and after nitroglycerin therapy as well), blood pressure, and pulmonary artery catheter measurements, and monitor them for changes.
- Watch for signs and symptoms of fluid retention (crackles, cough, tachypnea, and edema), which may indicate impending heart failure. Carefully monitor daily weight, intake and output, respirations, serum enzyme levels, and blood pressure. Auscultate for adventitious breath sounds periodically (patients on bed rest frequently have atelectatic crackles, which disappear after coughing), for S_3 or S_4 gallops, and for new-onset heart murmurs.

- Organize patient care and activities to maximize periods of uninterrupted rest.
- Initiate a cardiac rehabilitation program. This usually includes education regarding heart disease, exercise, and emotional support for the patient and family.
- Ask the dietary department to provide a clear liquid diet until nausea subsides. A low-cholesterol, low-sodium, low-fat, high-fiber diet may be prescribed.
- Provide a stool softener to prevent straining during defecation, because this causes vagal stimulation and may slow the heart rate. Allow use of a bedside commode and provide as much privacy as possible.
- Assist with range-of-motion exercises. If the patient is completely immobilized by a severe MI, turn often. Antiembolism stockings help prevent venostasis and thrombophlebitis.
- Provide emotional support and help reduce stress and anxiety. Explain procedures and answer questions. Explaining the ICU environment and routine can ease anxiety. Involve the patient's family in the care as much as possible.

  To prepare the patient for discharge:

- Thoroughly explain dosages and therapy to promote compliance with the prescribed medication regimen and other treatment measures. Warn about drug adverse effects, and advise the patient to watch for and report signs of toxicity (anorexia, nausea, vomiting, and yellow vision, e.g., if the patient is receiving digoxin).
- Review dietary restrictions with the patient. If the patient must follow a low-sodium or low-fat and low-cholesterol diet, provide a list of foods that the patient should avoid. Ask the dietitian to speak to the patient and family.
- Counsel the patient to resume sexual activity progressively.
- Advise the patient to report typical or atypical chest pain. Postinfarction syndrome may develop, producing chest pain that must be differentiated from recurrent MI, pulmonary infarct, or heart failure.
- If the patient has a Holter monitor in place, explain its purpose and use.
- Stress the need to stop smoking.
- Encourage participation in a cardiac rehabilitation program.
- Review follow-up procedures and office visits with the patient.

PREVENTION

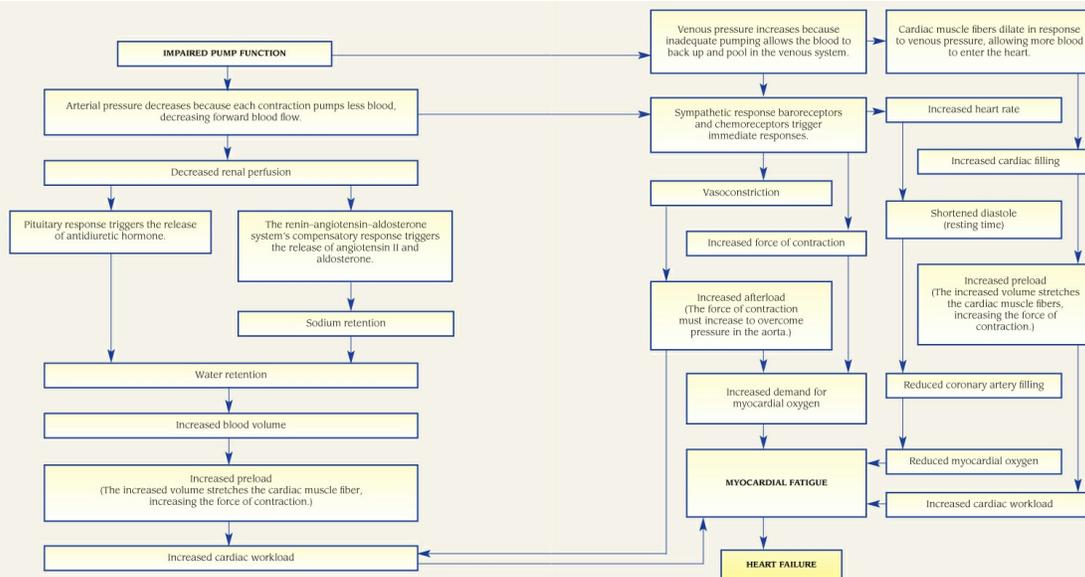
- *Instruct patient to practice heart-healthy living, with a heart-healthy diet, regular exercise, stress reduction and preventive care, maintenance of a healthy weight, smoking cessation, and abstinence from alcohol and illegal drugs, especially cocaine.*
- *Suggest a daily aspirin regimen for patients with CAD or history of an MI.*

HEART FAILURE

Causes and Incidence

Heart failure is a syndrome characterized by myocardial dysfunction that leads to impaired pump performance (diminished cardiac output) or to frank heart failure and abnormal circulatory congestion. Congestion of systemic venous circulation may result in peripheral edema or hepatomegaly; congestion of pulmonary circulation may cause pulmonary edema, an acute life-threatening emergency. Pump failure usually occurs in a damaged left ventricle (left-sided heart failure) but may occur in the right ventricle (right-sided heart failure) either as a primary disorder or secondary to left-sided heart failure. Sometimes, left- and right-sided heart failure develop simultaneously. (See *What happens in heart failure*, pages 44 and 45.)

PATHOPHYSIOLOGY
WHAT HAPPENS IN HEART FAILURE

Heart failure occurs when cardiac output is inadequate to meet the body's needs. The pathophysiology of heart failure is shown in the flow chart below.


Heart failure may result from a primary abnormality of the heart muscle such as an infarction, inadequate myocardial perfusion due to CAD, or cardiomyopathy. Other causes include:

- diastolic dysfunction with preserved ejection fraction, impairment of ventricular filling by diminished relaxation or reduced compliance seen with hypertrophic cardiomyopathy, myocardial hypertrophy, and pericardial restriction
- mechanical disturbances in ventricular filling during diastole when there's too little blood for the ventricle to pump, as in mitral stenosis secondary to rheumatic heart disease or constrictive pericarditis and atrial fibrillation
- systolic hemodynamic disturbances, such as excessive cardiac workload due to volume overload or pressure overload that limit the heart's pumping ability. These disturbances can result from mitral or aortic insufficiency, which causes volume overloading, and aortic stenosis or systemic hypertension, which result in increased resistance to ventricular emptying.

Heart failure affects 5.7 million people in the United States. It becomes more common with advancing age. Although heart failure may be acute (as a direct result of MI), it's generally a chronic disorder associated with sodium and water retention by the kidneys. Advances in diagnostic and therapeutic techniques have greatly improved the outlook for patients with heart failure, but the prognosis still depends on the underlying cause and its response to treatment. Fifty percent will diet within 5 years of diagnosis.

Pathophysiology

Reduced cardiac output triggers compensatory mechanisms, such as ventricular dilation, hypertrophy, increased sympathetic activity, and activation of the renin–angiotensin–aldosterone system. These mechanisms improve cardiac output at the expense of increased ventricular work. In cardiac dilation, an increase in end-diastolic ventricular volume (preload) causes increased stroke work and stroke volume during contraction, stretching cardiac muscle fibers beyond optimum limits and producing pulmonary congestion and pulmonary hypertension, which in turn

lead to right-sided heart failure.

In ventricular hypertrophy, an increase in muscle mass or diameter of the left ventricle allows the heart to pump against increased resistance (impedance) to the outflow of blood. An increase in ventricular diastolic pressure necessary to fill the enlarged ventricle may compromise diastolic coronary blood flow, limiting oxygen supply to the ventricle and causing ischemia and impaired muscle contractility.

Increased sympathetic activity occurs as a response to decreased cardiac output and blood pressure by enhancing PVR, contractility, heart rate, and venous return. Signs of increased sympathetic activity, such as cool extremities and clamminess, may indicate impending heart failure. Increased sympathetic activity also restricts blood flow to the kidneys, which respond by reducing the glomerular filtration rate and increasing tubular reabsorption of salt and water, in turn expanding the circulating blood volume. This renal mechanism, if unchecked, can aggravate congestion and produce overt edema.

Chronic heart failure may worsen as a result of respiratory tract infections, pulmonary embolism, stress, increased sodium or water intake, or failure to adhere to the prescribed treatment regimen.

Complications

- ◆ Pulmonary edema
- ◆ Multiorgan failure
- ◆ Myocardial infarction

Signs and Symptoms

Left-sided heart failure primarily produces pulmonary signs and symptoms; right-sided heart failure, primarily systemic signs and symptoms. However, heart failure often affects both sides of the heart.

Clinical signs of left-sided heart failure include dyspnea, orthopnea, crackles, possibly wheezing, hypoxia, respiratory acidosis, cough, cyanosis or pallor, palpitations, arrhythmias, elevated blood pressure, and pulsus alternans.

Clinical signs of right-sided heart failure include dependent peripheral edema, hepatomegaly, splenomegaly, JVD, ascites, slow weight gain, arrhythmias, positive hepatojugular reflex, abdominal distention, nausea, vomiting, anorexia, weakness, fatigue, dizziness, and syncope.

ALERT *Excessive fluid can accumulate in the pericardium, requiring removal through pericardiocentesis.*

Diagnosis

- ◆ ECG may reflect heart strain or enlargement, ischemia, or old MI. It may also reveal atrial enlargement, tachycardia, and extrasystoles.
- ◆ Chest X-ray shows increased pulmonary vascular markings, interstitial edema, or pleural effusion and cardiomegaly.
- ◆ PAP monitoring typically demonstrates elevated pulmonary artery and PAWPs elevated; left ventricular end-diastolic pressure in left-sided heart failure; and elevated right atrial pressure or CVP in right-sided heart failure.
- ◆ B-type natriuretic peptide (BNP) is a neurohormone produced predominantly by the ventricles and released in response to blood volume expansion or pressure overload. Blood

concentrations greater than 100 pg/mL can be an accurate predictor of acute heart failure.
- ◆ Echocardiogram may demonstrate wall motion abnormalities and chamber dilation.

Other tests that may also demonstrate enlargement of the heart or decreased functioning include chest computed tomography scan, cardiac MRI, or nuclear scans, such as MUGA and radionuclide ventriculography.

Treatment

The goal of therapy is to improve pump function by reversing the compensatory mechanisms producing the clinical effects, underlying disorders, and precipitating factors. Heart failure can be quickly controlled by treatment consisting of:

- ◆ ACE inhibitors to decrease PVR
- ◆ antiembolism stockings to reduce the risk of venostasis and thromboembolus formation
- ◆ bed rest for acute heart failure
- ◆ carvedilol, a nonselective BB with alpha-receptor blockade to reduce mortality and improve quality of life
- ◆ digoxin or dopamine to strengthen myocardial contractility
- ◆ diuresis to reduce total blood volume and circulatory congestion
- ◆ inotropic agents, such as dobutamine and milrinone, given I.V. to improve the heart's ability to pump
- ◆ nesiritide, a recombinant form of endogenous human BNP, to reduce sodium through its diuretic action
- ◆ vasodilators to increase cardiac output by reducing the impedance to ventricular outflow (afterload).

Excess fluid can be removed through dialysis if necessary. Circulatory assistance can be provided by implanted devices, such as the IABP and the left ventricular assist device (LVAD), but they're only temporary solutions.

A LVAD may be an option for those with refractory heart failure who are not eligible for transplant. This procedure may increase the patient's quality of life.

Watch for and treat complications, which typically may include pulmonary edema (See *Pulmonary edema: How to intervene*, pages 48 and 49); venostasis, with predisposition to thromboembolism (associated primarily with prolonged bed rest); cerebral insufficiency; and renal insufficiency, with severe electrolyte imbalance.

Pulmonary Edema: How To Intervene

Obtain the patient history; assist with diagnostic tests; and assess respiratory, mental, and cardiovascular status.

RESPIRATORY STATUS		MENTAL STATUS		CARDIOVASCULAR STATUS	
Signs and symptoms include orthopnea, dyspnea, cough, frothy sputum, crackles, and wheezing.	Unremarkable → Observe	Signs and symptoms include restlessness, anxiety, shortness of breath, and confusion.	Unremarkable → Observe	Signs and symptoms include hypotension; cold, clammy skin; irregular pulse; and S3 heart sound.	Unremarkable → Observe

Notify the physician and administer oxygen, place the patient in the upright position with his legs dangling, monitor arterial blood gas levels, administer bronchodilators as indicated, and auscultate for breath sounds frequently.

Notify the physician and provide emotional support. Remain with the patient and explain procedures.

Notify the physician and administer cardiopulmonary treatment as ordered: digoxin, diuretics, and aminophylline. Apply rotating tourniquets as ordered.

Administer I.V. morphine sulfate, as indicated.

Monitor vital signs, fluid intake and output, and serum electrolyte levels. Document findings.

Resolution of acute phase

Deteriorating condition

Prepare the patient for transfer to the intensive care unit.

Special Considerations

During the acute phase of heart failure:

- Give supplemental oxygen to help make breathing easier.
- Weigh the patient daily and check for peripheral edema. Carefully monitor I.V. intake and urine output, vital signs, and mental status. Auscultate the heart for abnormal sounds (S_3 gallop) and the lungs for crackles or rhonchi. Report changes at once.
- Give the patient a fluid restriction of less than 2 L/day from all sources.
- Frequently monitor BUN, creatinine, and serum potassium, sodium, chloride, and magnesium levels.
- Make sure the patient has continuous cardiac monitoring during acute and advanced stages to identify and treat arrhythmias promptly.
- To reduce the risk of deep vein thrombosis (DVT) due to vascular congestion, assist the patient with range-of-motion exercises. Enforce bed rest and apply antiembolism stockings.
- Allow adequate rest periods.

To prepare the patient for discharge:

- Advise the patient to avoid foods high in sodium, such as canned or commercially prepared foods and dairy products, to curb fluid overload.
- Encourage participation in an outpatient cardiac rehabilitation program.
- Explain to the patient that the potassium lost through diuretic therapy may need to be replaced by taking a prescribed potassium supplement and eating high-potassium foods, such as bananas and apricots.
- Stress the need for regular checkups.

- Stress the importance of taking digoxin exactly as prescribed. Tell the patient to watch for and immediately report signs of toxicity, such as anorexia, vomiting, and yellow vision.
- Tell the patient to notify the practitioner promptly if his or her pulse is unusually irregular or measures less than 60 beats/minute; if experiencing dizziness, blurred vision, shortness of breath, a persistent dry cough, palpitations, increased fatigue, paroxysmal nocturnal dyspnea, swollen ankles, or decreased urine output; or if he notices rapid weight gain (3 to 5 lb [1.4 to 2.3 kg] in 1 week).

PREVENTION

- *Instruct patient to make lifestyle modifications, including regular exercise, weight loss, smoking cessation, stress reduction, and reduced sodium, alcohol, and fat intake.*
- *Instruct patient to practice compliance with and timely administration of maintenance doses of diuretics and cardiac drugs.*

DILATED CARDIOMYOPATHY

Causes and Incidence

Dilated cardiomyopathy results from extensively damaged myocardial muscle fibers. It is the most common type of cardiomyopathy. This disorder interferes with myocardial metabolism and grossly dilates all four chambers of the heart, giving the heart a globular appearance and shape. In this disorder, hypertrophy may be present. Dilated cardiomyopathy leads to intractable heart failure, arrhythmias, and emboli. Because this disease isn't usually diagnosed until it's in the advanced stages, the patient's prognosis is generally poor.

The cause of most cardiomyopathies is unknown. Occasionally, dilated cardiomyopathy results from myocardial destruction by toxic, infectious, or metabolic agents, such as certain viruses, endocrine and electrolyte disorders, nutritional deficiencies, and certain cardiotoxic anticancer drugs (e.g., doxorubicin). Other causes include muscle disorders (myasthenia gravis, progressive muscular dystrophy, and myotonic dystrophy), infiltrative disorders (hemochromatosis and amyloidosis), and sarcoidosis.

Cardiomyopathy may also be a complication of alcoholism. In such cases, it may improve with abstinence from alcohol but recurs when the patient resumes drinking.

Dilated cardiomyopathy occurs in 1 in 2,500 people and affects all ages and both sexes. It's most common in adult men between the ages of 30 and 40.

Pathophysiology

How viruses induce cardiomyopathy is unclear, but researchers suspect a link between viral myocarditis and subsequent dilated cardiomyopathy, especially after infection with poliovirus, coxsackievirus B, influenza virus, or human immunodeficiency virus.

Metabolic cardiomyopathies are related to endocrine and electrolyte disorders and nutritional deficiencies. Thus, dilated cardiomyopathy may develop in patients with hyperthyroidism, pheochromocytoma, beriberi (thiamine deficiency), or kwashiorkor (protein deficiency). Cardiomyopathy may also result from rheumatic fever, especially among children with myocarditis.

Antepartal or postpartal cardiomyopathy may develop during the last trimester or within months after delivery. Its cause is unknown, but it occurs most frequently in multiparous women

older than 30, particularly those with malnutrition or preeclampsia. In these patients, cardiomegaly and heart failure may reverse with treatment, allowing a subsequent normal pregnancy. If cardiomegaly persists despite treatment, the prognosis is poor.

Complications

- Heart failure
- Arrhythmias
- Emboli
- Ventricular arrhythmias
- Syncope
- Sudden death

Signs and Symptoms

In dilated cardiomyopathy, the heart ejects blood less efficiently than normal. Consequently, a large volume of blood remains in the left ventricle after systole, causing signs of heart failure—both left-sided (shortness of breath, orthopnea, dyspnea on exertion, paroxysmal nocturnal dyspnea, fatigue, and an irritating dry cough at night) and right-sided (edema, liver engorgement, and JVD). Dilated cardiomyopathy also produces peripheral cyanosis and sinus tachycardia or atrial fibrillation at rest in some patients secondary to low cardiac output. Auscultation reveals diffuse apical impulses, pansystolic murmur (mitral and tricuspid insufficiency secondary to cardiomegaly and weak papillary muscles), and S_3 and S_4 gallop rhythms.

Diagnosis

Diagnosis of dilated cardiomyopathy requires elimination of other possible causes of heart failure and arrhythmias.

- ECG and angiography rule out ischemic heart disease; ECG may also show biventricular hypertrophy, sinus tachycardia, atrial enlargement, and, in 20% of patients, atrial fibrillation and bundle branch block.
- Chest X-ray shows cardiomegaly—usually affecting all heart chambers—and may demonstrate pulmonary congestion, pleural or pericardial effusion, or pulmonary venous hypertension.
- Chest computed tomography scan or echocardiography identifies left ventricular thrombi, global hypokinesia, and degree of left ventricular dilation.
- Nuclear heart scans, such as MUGA and ventriculography, show heart enlargement, lung congestion, heart failure, and decreased movement or functioning of the heart.

Treatment

Therapeutic goals include correcting the underlying causes and improving the heart's pumping ability with digoxin, diuretics, oxygen, and a sodium-restricted diet. Other options include an ACE inhibitor or ARB, a beta-blocker, aspirin, and, potentially, other blood-thinning medications. Vasodilators reduce preload and afterload, thereby decreasing congestion and increasing cardiac output. Acute heart failure requires vasodilation with nitroprusside or nitroglycerin I.V.

When these treatments fail, therapy may require pacemakers, implantable cardiac defibrillations, LVADs, or, as a last resort, a heart transplant for carefully selected patients.

Special Considerations

In the patient with acute failure:

- Monitor for signs of progressive failure (increasing crackles and dyspnea and increased JVD) and compromised renal perfusion (oliguria, elevated BUN and creatinine levels, and electrolyte imbalances). Weigh the patient daily.
- If the patient is receiving vasodilators, check blood pressure and heart rate. If the patient becomes hypotensive, stop the infusion and place in a supine position, with legs elevated to increase venous return and to ensure cerebral blood flow.
- If the patient is receiving diuretics, monitor for signs of resolving congestion (decreased crackles and dyspnea) or too-vigorous diuresis. Check serum potassium level for hypokalemia, especially if therapy includes digoxin.
- Therapeutic restrictions and an uncertain prognosis usually cause profound anxiety and depression, so offer support and let the patient express his or her feelings. Be flexible with visiting hours.
- Before discharge, teach the patient about their illness and its treatment. Emphasize the need to avoid alcohol and smoking, to restrict sodium intake, to watch for weight gain (a weight gain of 3 lb [1.4 kg] over 1 to 2 days indicates fluid accumulation), and to take digoxin as prescribed, watching for its adverse effects (anorexia, nausea, vomiting, and yellow vision).
- Encourage family members to learn cardiopulmonary resuscitation (CPR).

HYPERTROPHIC CARDIOMYOPATHY

Causes and Incidence

This primary disease of cardiac muscle, also called *idiopathic hypertrophic subaortic stenosis*, is characterized by disproportionate, asymmetrical thickening of the interventricular septum, particularly in the left ventricle's free wall. In hypertrophic cardiomyopathy, cardiac output may be low, normal, or high, depending on whether the stenosis is obstructive or nonobstructive. If cardiac output is normal or high, the disorder may go undetected for years; but low cardiac output may lead to potentially fatal heart failure. The disease course varies; some patients progressively deteriorate; others remain stable for years. (See *Looking at hypertrophic cardiomyopathy*, pages 50 to 52.)

Looking At Hypertrophic Cardiomyopathy

1. The left ventricle and interventricular septum hypertrophy and become stiff, noncompliant, and unable to relax during ventricular filling.

RESPIRATORY STATUS		MENTAL STATUS		CARDIOVASCULAR STATUS	
Signs and symptoms include orthopnea, dyspnea, cough, frothy sputum, crackles, and wheezing.	Unremarkable → Observe	Signs and symptoms include restlessness, anxiety, shortness of breath, and confusion.	Unremarkable → Observe	Signs and symptoms include hypotension; cold, clammy skin; irregular pulse; and S3 heart sound.	Unremarkable → Observe

Notify the physician and administer oxygen, place the patient in the upright position with his legs dangling, monitor arterial blood gas levels, administer bronchodilators as indicated, and auscultate for breath sounds frequently.

Notify the physician and provide emotional support. Remain with the patient and explain procedures.

Notify the physician and administer cardiopulmonary treatment and diuretics as ordered.

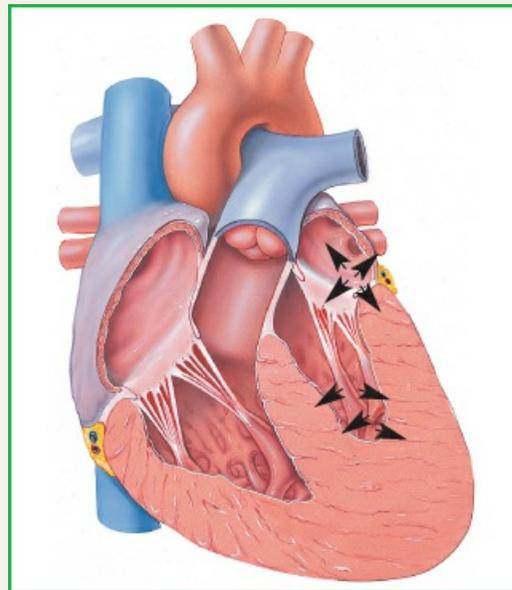
Possible administration of I.V. morphine sulfate, if indicated.

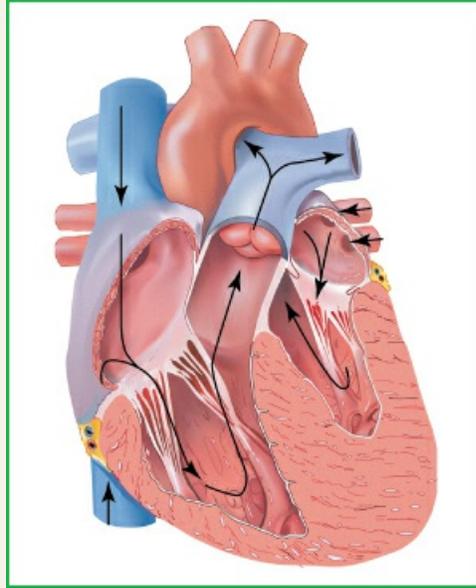
Monitor vital signs, fluid intake and output, and serum electrolyte levels. Document findings.

Resolution of acute phase

Deteriorating condition

Prepare the patient for transfer to the intensive care unit.

2. As the ventricle's ability to fill decreases, the pressure increases, and left atrial and pulmonary venous pressures rise.


3. The left ventricle forcefully contracts but can't sufficiently relax.


4. The anterior leaflet of the mitral valve is drawn toward the interventricular septum as the blood is forcefully ejected. Early closure of the outflow tract results because of the decreasing ejection fraction.

This disorder affects 1 in 500 people and is more common in men than in women and more so in blacks than in whites. It is also usually the cause of sudden death, particularly in otherwise healthy athletes.

Pathophysiology

Despite being designated as idiopathic, hypertrophic cardiomyopathy may be inherited as a non–sex-linked autosomal dominant trait in almost all cases. Most patients have obstructive disease,

resulting from effects of ventricular septal hypertrophy and the movement of the anterior mitral valve leaflet into the outflow tract during systole. Eventually, left ventricular dysfunction, from rigidity and decreased compliance, causes pump failure.

Complications

- Pulmonary hypertension
- Heart failure
- Ventricular arrhythmias
- Sudden death

Signs and Symptoms

Clinical features of the disorder may not appear until it's well advanced, when atrial dilation and, possibly, atrial fibrillation abruptly reduce blood flow to the left ventricle. Reduced inflow and subsequent low output may produce angina pectoris, arrhythmias, dyspnea, orthopnea, syncope, heart failure, and death. Auscultation reveals a medium-pitched systolic ejection murmur along the left sternal border and at the apex; palpation reveals a peripheral pulse with a characteristic double impulse (pulsus bisferiens) and, with atrial fibrillation, an irregular pulse.

Diagnosis

Diagnosis depends on typical clinical findings and these test results:

- Echocardiography (most useful) shows increased thickness of the intraventricular septum and abnormal motion of the anterior mitral leaflet during systole, occluding left ventricular outflow in obstructive disease.
- Cardiac catheterization reveals elevated left ventricular end-diastolic pressure and, possibly, mitral insufficiency.
- ECG usually shows left ventricular hypertrophy, T-wave inversion, left anterior hemiblock, Q waves in precordial and inferior leads, ventricular arrhythmias, and, possibly, atrial fibrillation.
- Auscultation confirms an early systolic murmur.

Treatment

The goals of treatment are to relax the ventricle and to relieve outflow tract obstruction. Agents such as metoprolol, a BB, slow heart rate and increase ventricular filling by relaxing the obstructing muscle, thereby reducing angina, syncope, dyspnea, and arrhythmias. Atrial fibrillation necessitates cardioversion to treat the arrhythmia and, because of the high risk of systemic embolism, anticoagulant therapy until fibrillation subsides. Because vasodilators such as nitroglycerin reduce venous return by permitting pooling of blood in the periphery, decreasing ventricular volume and chamber size, and may cause further obstruction, they're contraindicated in patients with hypertrophic cardiomyopathy. Also contraindicated are ACE inhibitors and ARBs because they can also worsen the obstruction. Disopyramide is preferred because of its negative inotropic properties. Patients with potentially lethal arrhythmias may need an implantable cardioverter–defibrillator to prevent sudden death.

If drug therapy fails, surgery is indicated. Septal myectomy reduces the thickness of the septum through removal of a portion of the proximal septum. This can be performed alone or in combination with mitral valve replacement, which may ease outflow tract obstruction and relieve

symptoms. However, complications, such as complete heart block and VSD, can occur, requiring pacemaker implantation.

Special Considerations

- Because syncope or sudden death may follow well-tolerated exercise, warn such patients against strenuous physical activity such as running.
- Administer medications as prescribed. *Caution:* Avoid nitroglycerin, digoxin, and diuretics because they can worsen obstruction. Warn the patient not to stop taking their beta-blocker abruptly, because doing so may increase myocardial demands. To determine the patient's tolerance for an increased dosage of the beta-blocker, take his or her pulse to check for bradycardia. Also take a blood pressure reading while the patient is supine and while standing (a drop in blood pressure [>10 mm Hg] when standing may indicate orthostatic hypotension).
- Before dental work or surgery, tell the patient to discuss prophylaxis for subacute infective endocarditis with his or her healthcare provider.
- Provide psychological support. If the patient is hospitalized for a long time, be flexible with visiting hours and encourage occasional weekends away from the hospital, if possible. Refer the patient for psychosocial counseling to help the patient and family accept restricted lifestyle and poor prognosis.
- If the patient is a child, have the parents arrange for them to continue school work or studies in the healthcare facility.
- Because sudden cardiac arrest is possible, urge the patient's family to learn cardiopulmonary resuscitation.

Cardiac Complications

HYPOVOLEMIC SHOCK

Causes and Incidence

In hypovolemic shock, reduced intravascular blood volume causes circulatory dysfunction and inadequate tissue perfusion. Without sufficient blood or fluid replacement, hypovolemic shock syndrome may lead to irreversible cerebral and renal damage, cardiac arrest, and, ultimately, death. Hypovolemic shock requires early recognition of signs and symptoms and prompt, aggressive treatment to improve the prognosis. (See *What happens in hypovolemic shock,* page 55.)

PATHOPHYSIOLOGY
WHAT HAPPENS IN HYPOVOLEMIC SHOCK

In hypovolemic shock, vascular fluid volume loss causes extreme tissue hypoperfusion. Internal fluid losses can result from hemorrhage or third-space fluid shifting. External fluid loss can result from severe bleeding or from severe diarrhea, diuresis, or vomiting. Inadequate vascular volume leads to decreased venous return and cardiac output. The resulting drop in arterial blood pressure activates the body's compensatory mechanisms in an attempt to increase vascular volume. If compensation is unsuccessful, decompensation and

death may occur.

Internal or external fluid loss

↓

Decreased intravascular fluid volume

↓

Diminished venous return

↓

Reduced preload (filling pressure)

↓

Decreased stroke volume

↓

Lowered cardiac output

↓

Reduced mean arterial blood pressure

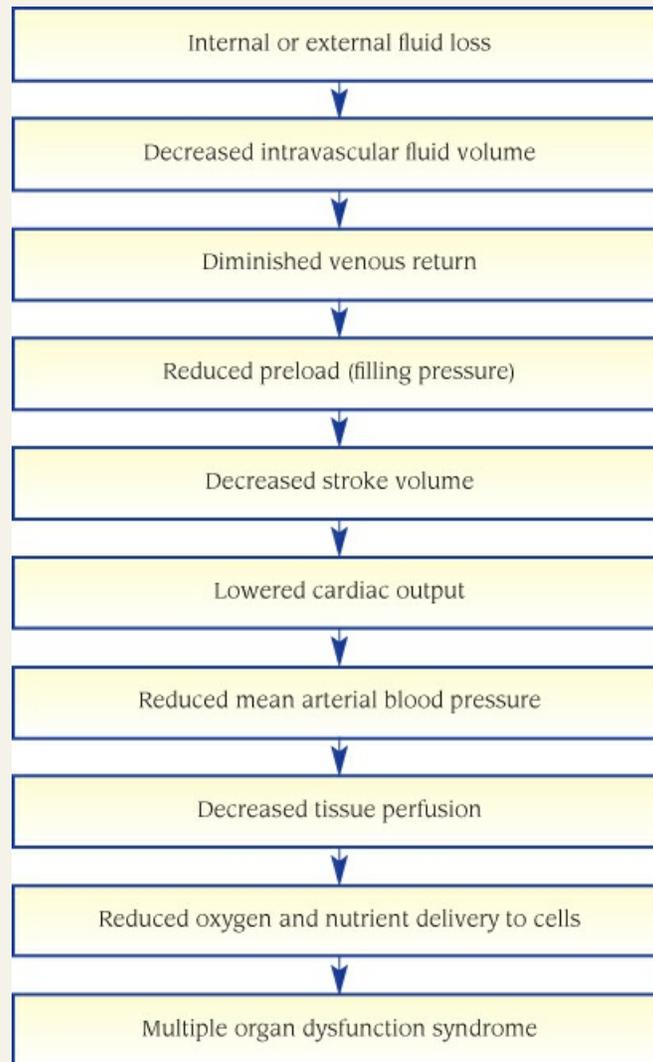
↓

Decreased tissue perfusion

↓

Reduced oxygen and nutrient delivery to cells

↓

Multiple organ dysfunction syndrome


Hypovolemic shock usually results from acute blood loss—about one fifth of total volume. Such massive blood loss may result from GI bleeding, internal hemorrhage (hemothorax and hemoperitoneum), external hemorrhage (accidental or surgical trauma), or from any condition that reduces circulating intravascular plasma volume or other body fluids such as in severe burns. Other underlying causes of hypovolemic shock include intestinal obstruction, peritonitis, acute pancreatitis, ascites and dehydration from excessive perspiration, severe diarrhea or protracted vomiting, diabetes insipidus, diuresis, or inadequate fluid intake.

Pathophysiology

Hypovolemic shock occurs when there is not enough intravascular volume to maintain tissue perfusion. At first, the body responds by stimulating thirst and reducing the amount of fluid filtered through the kidneys. Additionally, heart rate becomes elevated to increase cardiac output, contractility increases to maintain stroke volume, and increased systemic vascular resistance

shunts blood away from the periphery and toward the heart and central nervous system. Hypotension is a late sign since blood pressure can be maintained initially through compensatory vasoconstriction, which decreases tissue perfusion. Cardiac arrest may occur soon after.

Complications

- Acute respiratory distress syndrome
- Acute tubular necrosis
- Disseminated intravascular coagulation (DIC)
- Multiple-organ-dysfunction syndrome

Signs and Symptoms

Hypovolemic shock produces a syndrome of hypotension, with narrowing pulse pressure; decreased sensorium; tachycardia; rapid, shallow respirations; reduced urine output (<25 mL/hour); and cold, pale, clammy skin. Metabolic acidosis with an accumulation of lactic acid develops as a result of tissue anoxia, as cellular metabolism shifts from aerobic to anaerobic pathways. DIC is a possible complication of hypovolemic shock.

Diagnosis

No single symptom or diagnostic test establishes the diagnosis or severity of shock. Characteristic laboratory findings include:

- elevated potassium, serum lactate, and BUN levels
- increased urine specific gravity (>1.020) and urine osmolality
- decreased blood pH and partial pressure of arterial oxygen and increased partial pressure of arterial carbon dioxide.

In addition, gastroscopy, aspiration of gastric contents through a nasogastric (NG) tube, computed tomography scan, and X-rays identify internal bleeding sites; coagulation studies may detect coagulopathy from DIC. Echocardiography or right heart catheterization can help differentiate between hypovolemic and cardiogenic shock.

Treatment

Emergency treatment measures must include prompt and adequate blood and fluid replacement to restore intravascular volume and raise blood pressure. Saline solution or lactated Ringer solution, then possibly plasma proteins (albumin) or other plasma expanders, may produce adequate volume expansion until whole blood can be matched. A rapid solution infusion system of 1 to 2 L of isotonic crystalloids can be used and continued if hypotension persists. Measuring CVP can assist in directing therapy. Treatment may also include oxygen administration, identification of bleeding site, control of bleeding by direct measures (such as application of pressure and elevation of a limb) and, possibly, surgery.

Special Considerations

Management of hypovolemic shock necessitates prompt, aggressive supportive measures and careful assessment and monitoring of vital signs. Follow these priorities:

- Check for a patent airway and adequate circulation. If blood pressure and heart rate are absent, start CPR.

- Record blood pressure, pulse rate, peripheral pulses, respiratory rate, and other vital signs every 15 minutes and the electrocardiograph continuously. Systolic blood pressure lower than 80 mm Hg usually results in inadequate coronary artery blood flow, cardiac ischemia, arrhythmias, and further complications of low cardiac output. When blood pressure drops below 80 mm Hg, increase the oxygen flow rate and notify the practitioner immediately. A progressive drop in blood pressure, accompanied by a thready pulse, generally signals inadequate cardiac output from reduced intravascular volume. Notify the practitioner and increase the infusion rate.
- Start I.V. lines with normal saline or lactated Ringer solution, using a large-bore catheter (14G), which allows easier administration of later blood transfusions. (*Caution:* Don't start I.V. lines in the legs of a patient in shock who has suffered abdominal trauma, because infused fluid may escape through the ruptured vessel into the abdomen.)
- An indwelling urinary catheter may be inserted to measure hourly urine output. If output is less than 30 mL/hour in adults, increase the fluid infusion rate, but watch for signs of fluid overload such as an increase in PAWP. Notify the practitioner if urine output doesn't improve. An osmotic diuretic such as mannitol may be ordered to increase renal blood flow and urine output. Determine how much fluid to give by checking blood pressure, urine output, CVP, or PAWP. (To increase accuracy, CVP should be measured at the level of the right atrium, using the same reference point on the chest each time.)
- Draw an arterial blood sample to measure blood gas levels. Administer oxygen by face mask or airway to ensure adequate oxygenation of tissues. Adjust the oxygen flow rate to a higher or lower level, as blood gas measurements indicate.
- Draw venous blood for complete blood count and electrolyte, type and crossmatch, and coagulation studies.
- During therapy, assess skin color and temperature, and note changes. Cold, clammy skin may be a sign of continuing peripheral vascular constriction, indicating progressive shock.
- Watch for signs of impending coagulopathy (petechiae, bruising, and bleeding or oozing from gums or venipuncture sites).
- Explain procedures and their purpose. Throughout these emergency measures, provide emotional support to the patient and family.

PREVENTION

- *Recognize patients with conditions that reduce blood volume as at-risk patients.*
- *Estimate fluid loss and replace, as necessary, to prevent hypovolemic shock.*

CARDIOGENIC SHOCK

Causes and Incidence

Sometimes called *pump failure,* cardiogenic shock is a condition of diminished cardiac output that severely impairs tissue perfusion. It reflects severe left-sided heart failure and occurs as a serious complication in 5% to 10% of all patients hospitalized with acute MI. Cardiogenic shock can result from any condition that causes significant left ventricular dysfunction with reduced cardiac output, such as MI (most common), myocardial ischemia, papillary muscle dysfunction, or end-stage cardiomyopathy. The incidence of cardiogenic shock is higher those with an elevated body mass index, and also higher in men than in women because of their higher

incidence of CAD. Historically, mortality for cardiogenic shock had been 80% to 90%, but recent studies indicate that the rate has dropped to 40% to 50% due to improved interventional procedures and better therapies. Mortality is expected to decline even further.

Pathophysiology

Regardless of the underlying cause, left ventricular dysfunction sets into motion a series of compensatory mechanisms that attempt to increase cardiac output and, in turn, maintain vital organ function. (See *What happens in cardiogenic shock*, page 57.) As cardiac output falls in left ventricular dysfunction, aortic and carotid baroreceptors initiate sympathetic nervous responses, which increase heart rate, left ventricular filling pressure, and peripheral resistance to flow, to enhance venous return to the heart. These compensatory responses initially stabilize the patient but later cause deterioration with the rising oxygen demands of the already compromised myocardium. These events comprise a vicious circle of low cardiac output, sympathetic compensation, myocardial ischemia, and even lower cardiac output.

PATHOPHYSIOLOGY
WHAT HAPPENS IN CARDIOGENIC SHOCK

When the myocardium can't contract sufficiently to maintain adequate cardiac output, stroke volume decreases, and the heart can't eject an adequate volume of blood with each contraction. The blood backs up behind the weakened left ventricle, increasing preload and causing pulmonary congestion. In addition, to compensate for the drop in stroke volume, the heart rate increases in an attempt to maintain cardiac output. As a result of the diminished stroke volume, coronary artery perfusion and collateral blood flow decrease. All of these mechanisms increase the heart's workload and enhance left-sided heart failure. The result is myocardial hypoxia, further decreased cardiac output, and a triggering of compensatory mechanisms to prevent decompensation and death.

```

Signs and Symptoms

Cardiogenic shock produces signs of poor tissue perfusion: cold, pale, clammy skin; a decrease in systolic blood pressure to 30 mm Hg below baseline, or a sustained reading below 80 mm Hg not attributable to medication; tachycardia; rapid, shallow respirations; oliguria (<20 mL/hour); restlessness; mental confusion and obtundation; narrowing pulse pressure; and cyanosis. Although many of these clinical features also occur in heart failure and other shock syndromes, they're usually more profound in cardiogenic shock.

Diagnosis

Auscultation may detect gallop rhythm, faint heart sounds, and, possibly, if the shock results from rupture of the ventricular septum or papillary muscles, a holosystolic murmur.

- PAP monitoring may show increased PAP and increased PAWP, reflecting a rise in left ventricular end-diastolic pressure (preload) and increased resistance to left ventricular

emptying (afterload) due to ineffective pumping and increased PVR. Thermodilution technique measures decreased cardiac output.

- Invasive arterial pressure monitoring may indicate hypotension due to impaired ventricular ejection.
- ABG analysis may show metabolic acidosis and hypoxia.
- ECG may show possible evidence of acute MI, ischemia, or ventricular aneurysm.
- Echocardiography can determine left ventricular function and reveal valvular abnormalities.
- Enzyme levels may show elevated CK, lactate dehydrogenase, aspartate aminotransferase, and alanine aminotransferase, which point to MI or ischemia and suggest heart failure or shock. Troponin I, troponin T, and CK may confirm acute MI.

Additional tests determine other conditions that can lead to pump dysfunction and failure, such as cardiac arrhythmias, cardiac tamponade, papillary muscle infarct or rupture, ventricular septal rupture, pulmonary emboli, venous pooling (associated with vasodilators and continuous intermittent positive-pressure breathing), and hypovolemia.

Treatment

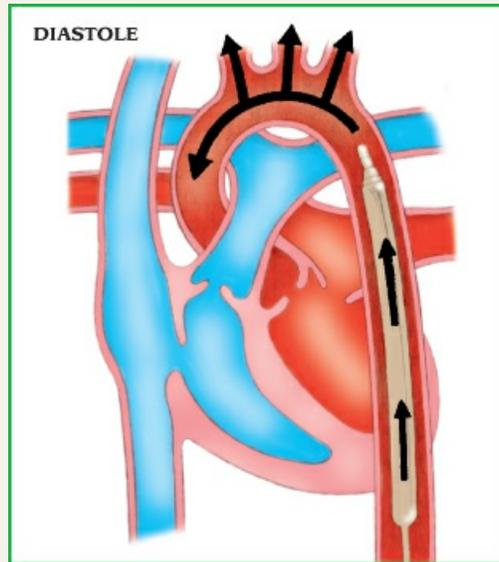
The aim of treatment is to enhance cardiovascular status by increasing cardiac output, improving myocardial perfusion, and decreasing cardiac workload with combinations of various cardiovascular drugs and mechanical-assist techniques. Myocardial reperfusion can be accomplished by PTCA, stents, thrombolytic therapy, or bypass grafting. Drug therapy may include dopamine I.V., a vasopressor that increases cardiac output, blood pressure, and renal blood flow; milrinone or dobutamine I.V., inotropic agents that increase myocardial contractility; norepinephrine, when a more potent vasoconstrictor is necessary; and nitroprusside I.V., a vasodilator that may be used with a vasopressor to further improve cardiac output by decreasing PVR (afterload) and reducing left ventricular end-diastolic pressure (preload). However, the patient's blood pressure must be adequate to support nitroprusside therapy and must be monitored closely.

The IABP is a mechanical-assist device that attempts to improve coronary artery perfusion and decrease cardiac workload. (See *Understanding the IABP*, page 58.) The inflatable balloon pump is percutaneously or surgically inserted through the femoral artery into the descending thoracic aorta. The balloon inflates during diastole to increase coronary artery perfusion pressure and deflates before systole (before the aortic valve opens) to reduce resistance to ejection (afterload) and reduce cardiac workload. Improved ventricular ejection, which significantly improves cardiac output, and a subsequent vasodilation in the peripheral vasculature lead to lower preload volume.

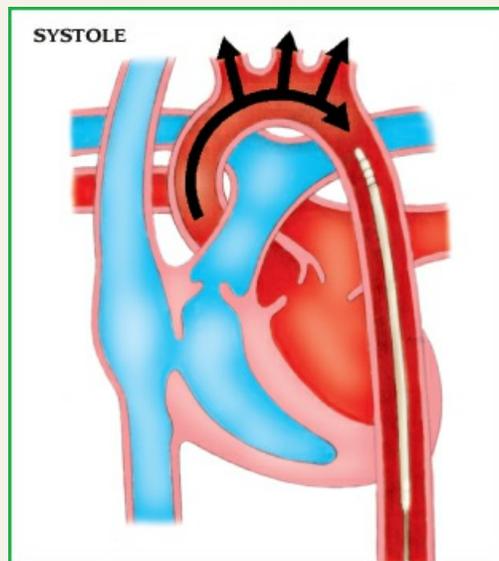
Understanding The IABP

An intra-aortic balloon pump (IABP) consists of a polyurethane balloon attached to an external pump console by means of a large-lumen catheter. It is inserted percutaneously through the femoral artery and positioned in the descending aorta, just distal to the left subclavian artery and above the renal arteries.

Push...
This external pump works in precise counterpoint to the left ventricle, inflating the balloon

with helium early in diastole and deflating it just before systole. As the balloon inflates, it forces blood toward the aortic valve, thereby raising pressure in the aortic root and augmenting diastolic pressure to improve coronary perfusion. It also improves peripheral circulation by forcing blood through the brachiocephalic, common carotid, and subclavian arteries arising from the aortic trunk.


...and Pull

The balloon deflates rapidly at the end of diastole, creating a vacuum in the aorta. This reduces aortic volume and pressure, thereby decreasing the resistance to left ventricular ejection (afterload). This decreased workload, in turn, reduces the heart's oxygen requirements and, combined with the improved myocardial perfusion, helps prevent or diminish myocardial ischemia.


When drug therapy and IABP insertion fail, treatment may require the use of a ventricular assist device. This device (which may be either temporary or permanent) diverts systemic blood flow from a diseased ventricle into a centrifugal pump. It assists the heart's pumping action rather than replacing it.

Special Considerations

- At the first sign of cardiogenic shock, check the patient's blood pressure and heart rate. If the patient is hypotensive or is having difficulty breathing, ensure a patent I.V. line and a patent airway, and provide oxygen to promote tissue oxygenation. Notify the practitioner immediately.
- Monitor ABG values to measure oxygenation and detect acidosis from poor tissue perfusion. Increase oxygen delivery as indicated. Check complete blood count and electrolyte levels.
- After diagnosis, monitor cardiac rhythm continuously and assess skin color, temperature, and other vital signs often. Watch for a drop in systolic blood pressure to less than 80 mm Hg (usually compromising cardiac output further). Report hypotension immediately.
- An indwelling urinary catheter may be inserted to measure urine output. Notify the practitioner if output drops below 30 mL/hour.
- Using a pulmonary artery catheter, closely monitor PAP, PAWP, and, if equipment is available, cardiac output. A high PAWP indicates heart failure and should be reported.
- When a patient is on the IABP, reposition the patient often and perform passive range-of-motion exercises to prevent skin breakdown. However, don't flex the patient's "ballooned" leg at the hip because this may displace or fracture the catheter. Assess pedal pulses and skin temperature and color to make sure circulation to the leg is adequate. Check the dressing on the insertion site frequently for bleeding, and change it according to facility protocol. Also, check the site for hematoma or signs of infection, and culture any drainage.
- After the patient becomes hemodynamically stable, the frequency of balloon inflation is gradually reduced to wean from the IABP. During weaning, carefully watch for monitor changes, chest pain, and other signs of recurring cardiac ischemia and shock.
- Provide psychological support and reassurance because the patient and family may be anxious about the ICU, IABP, and other tubes and devices. To ease emotional stress, plan your care to allow frequent rest periods, and provide as much privacy as possible.

PREVENTION *Emphasize the fact that prevention requires timely, thorough, and aggressive identification and treatment of causative disorders.*

VENTRICULAR ANEURYSM

Causes and Incidence

A ventricular aneurysm is an outpouching, almost always of the left ventricle, that produces ventricular wall dysfunction in about 25% of patients after MI. Ventricular aneurysm may develop within weeks after MI. Untreated ventricular aneurysm can lead to arrhythmias, systemic embolization, or heart failure and may cause sudden death. Resection improves the prognosis in patients with heart failure or refractory patients who have developed ventricular arrhythmias.

Pathophysiology

When MI destroys a large muscular section of the left ventricle, necrosis reduces the ventricular wall to a thin sheath of fibrous tissue. Under intracardiac pressure, this thin layer stretches and forms a separate noncontractile sac (aneurysm). Abnormal muscular wall movement accompanies ventricular aneurysm and includes akinesia (lack of movement), dyskinesia (paradoxical movement), asynergia (decreased and inadequate movement), and asynchrony (uncoordinated movement). During systolic ejection, the abnormal muscular wall movements associated with the aneurysm cause the remaining normally functioning myocardial fibers to increase the force of contraction to maintain stroke volume and cardiac output. At the same time, a portion of the stroke volume is lost to passive distention of the noncontractile sac.

Complications

- Ventricular arrhythmias
- Cerebral embolism
- Heart failure
- Death

Signs and Symptoms

Ventricular aneurysm may cause arrhythmias—such as premature ventricular contractions or ventricular tachycardia—palpitations, signs of cardiac dysfunction (weakness on exertion, fatigue, and angina) and, occasionally, a visible or palpable systolic precordial bulge. This condition may also lead to left ventricular dysfunction, with chronic heart failure (dyspnea, fatigue, edema, crackles, gallop rhythm, and JVD); pulmonary edema; systemic embolization; and, with left-sided heart failure, pulsus alternans. Ventricular aneurysms enlarge but seldom rupture.

Diagnosis

Persistent ventricular arrhythmias, onset of heart failure, or systemic embolization in a patient with left-sided heart failure and a history of MI strongly suggest ventricular aneurysm. Indicative tests include the following:

- Left ventriculography during catheterization reveals left ventricular enlargement, with an area of akinesia or dyskinesia and diminished cardiac function.
- ECG may show persistent ST–T wave elevations after infarction.
- Chest X-ray may demonstrate an abnormal bulge distorting the heart's contour if the aneurysm is large; the X-ray may be normal if the aneurysm is small.
- Noninvasive nuclear cardiology scan may indicate the site of infarction and suggest the area of aneurysm.
- Echocardiography shows abnormal motion in the left ventricular wall.
- MRI gives excellent visualization of the heart's apex.

Treatment

Depending on the aneurysm's size and the complications, treatment may necessitate only routine medical examination to follow the patient's condition or aggressive measures for intractable ventricular arrhythmias, heart failure, and emboli.

Emergency treatment of ventricular arrhythmia includes antiarrhythmics I.V. or cardioversion. Preventive treatment continues with medications that decrease afterload to increase left

ventricular function such as ACE inhibitors, anti-ischemic medications for angina, and anticoagulation if thrombus formation.

Emergency treatment for heart failure with pulmonary edema includes oxygen, cardiac glycosides I.V., furosemide I.V., morphine I.V., and, when necessary, nitroprusside I.V. and intubation. Maintenance therapy may include nitrates, prazosin, and oral hydralazine. Systemic embolization requires anticoagulation therapy or embolectomy. Refractory ventricular tachycardia, heart failure, recurrent arterial embolization, and persistent angina with coronary artery occlusion may necessitate surgery, of which the most effective procedure is aneurysmectomy with myocardial revascularization.

Special Considerations

- If ventricular tachycardia occurs, administer a prescribed antiarrhythmic such as lidocaine. Monitor blood pressure and heart rate. If cardiac arrest develops, initiate CPR and call for assistance, resuscitative equipment, and medication.
- In a patient with heart failure, closely monitor vital signs, heart sounds, intake and output, fluid and electrolyte balances, and BUN and creatinine levels. Because of the threat of systemic embolization, frequently check peripheral pulses and the color and temperature of extremities. Be alert for sudden changes in sensorium that indicate cerebral embolization and for any signs that suggest renal failure or progressive MI.

If the patient is scheduled to undergo resection:

- Before surgery, explain expected postoperative care in the ICU (including use of such things as endotracheal [ET] tube, ventilator, hemodynamic monitoring, chest tubes, and drainage bottle).
- After surgery, monitor vital signs, intake and output, heart sounds, and pulmonary artery catheter. Watch for signs of infection, such as fever and drainage.

To prepare the patient for discharge:

- Teach how to check for pulse irregularity and rate changes. Encourage the patient to follow the prescribed medication regimen—even during the night—and to watch for adverse effects.
- Because arrhythmias can cause sudden death, refer the family to a community-based CPR training program.
- Provide psychological support for the patient and family.

CARDIAC TAMPONADE

Causes and Incidence

In cardiac tamponade, a rapid, unchecked rise in intrapericardial pressure impairs diastolic filling of the heart. The rise in pressure usually results from blood or fluid accumulation in the pericardial sac. If fluid accumulates rapidly, this condition requires emergency lifesaving measures to prevent death. A slow accumulation and rise in pressure, as in pericardial effusion associated with malignant tumors, may not produce immediate symptoms, because the fibrous wall of the pericardial sac can gradually stretch to accommodate as much as 1 to 2 L of fluid.

Increased intrapericardial pressure and cardiac tamponade may be idiopathic (Dressler syndrome) or may result from:

- effusion (in cancer, bacterial infections, tuberculosis, and, rarely, acute rheumatic fever)

- hemorrhage from trauma (such as gunshot or stab wounds of the chest and perforation by catheter during cardiac or central venous catheterization or postcardiac surgery)
- hemorrhage from nontraumatic causes (such as rupture of the heart or great vessels or anticoagulant therapy in a patient with pericarditis)
- acute MI
- end-stage lung cancer
- heart tumors
- radiation therapy
- hypothyroidism
- systemic lupus erythematosus
- uremia.

Cardiac tamponade occurs in 2 of every 10,000 people.

Pathophysiology

Increased fluid in the pericardial space leads to increased pressure. The right ventricle is unable to expand adequately, and so pressure shifts the interventricular septum to the left. This decreases the left ventricle end-diastolic volume, resulting in decreased cardiac output and hypotension.

Complications

- Cardiogenic shock
- Death

Signs and Symptoms

Cardiac tamponade classically produces increased venous pressure with JVD, reduced arterial blood pressure, muffled heart sounds on auscultation, and pulsus paradoxus (an abnormal inspiratory drop in systemic blood pressure >15 mm Hg). The absence of a preexisting pericardial friction rub may suggest an increase in fluid in the pericardial space. These classic symptoms represent failure of physiologic compensatory mechanisms to override the effects of rapidly rising pericardial pressure, which limits diastolic filling of the ventricles and reduces stroke volume to a critically low level. Generally, ventricular end-systolic volume may drop because of inadequate preload. The increasing pericardial pressure is transmitted equally across the heart cavities, producing a matching rise in intracardiac pressure, especially atrial and end-diastolic ventricular pressures. Cardiac tamponade may also cause dyspnea, diaphoresis, pallor or cyanosis, anxiety, tachycardia, narrow pulse pressure, restlessness, and hepatomegaly, but the lung fields will be clear. The patient typically sits upright and leans forward.

Diagnosis

- Chest X-ray shows slightly widened mediastinum and cardiomegaly.
- ECG is rarely diagnostic of tamponade but is useful in ruling out other cardiac disorders. It may reveal changes produced by acute pericarditis.
- Pulmonary artery catheterization detects increased right atrial pressure, right ventricular diastolic pressure, and CVP.
- Echocardiography, computed tomography scan, or MRI shows pericardial effusion with signs of right ventricular and atrial compression.

Treatment

The goal of treatment is to relieve intrapericardial pressure and cardiac compression by removing accumulated blood or fluid. Pericardiocentesis (needle aspiration of the pericardial cavity) or surgical creation of an opening (pericardiectomy or pericardial window) dramatically improves systemic arterial pressure and cardiac output with aspiration of as little as 25 mL of fluid. Such treatment necessitates continuous hemodynamic and ECG monitoring in the ICU. Trial volume loading with temporary I.V. normal saline solution and perhaps an inotropic drug, such as isoproterenol or dopamine, may be necessary in the hypotensive patient to maintain cardiac output. Although these drugs normally improve myocardial function, they may further compromise an ischemic myocardium after MI.

Depending on the cause of tamponade, additional treatment may include:

- in traumatic injury—blood transfusion or a thoracotomy to drain reaccumulating fluid or to repair bleeding sites
- in heparin-induced tamponade (not often used)—the heparin antagonist protamine sulfate
- in warfarin-induced tamponade—vitamin K.

Resection of a portion or all of the pericardium to allow full communication with the pleura may be needed if repeated pericardiocentesis fails to prevent recurrence.

Special Considerations

If the patient needs pericardiocentesis:

- Explain the procedure to him. Keep a pericardial aspiration needle attached to a 50-mL syringe by a three-way stopcock, an ECG machine, and an emergency cart with a defibrillator at the bedside. Make sure the equipment is turned on and ready for immediate use. Position the patient at a 45- to 60-degree angle. Connect the precordial ECG lead to the hub of the aspiration needle with an alligator clamp and connecting wire, and assist with fluid aspiration. When the needle touches the myocardium, you'll see an ST-segment elevation or premature ventricular contractions.
- Monitor blood pressure and CVP during and after pericardiocentesis. Infuse I.V. solutions, as prescribed, to maintain blood pressure. Watch for a decrease in CVP and a concomitant rise in blood pressure, which indicate relief of cardiac compression.
- Watch for complications of pericardiocentesis, such as ventricular fibrillation, vasovagal response, or coronary artery or cardiac chamber puncture. Closely monitor ECG changes, blood pressure, pulse rate, LOC, and urine output.

If the patient needs thoracotomy:

- Explain the procedure to him. Tell the patient what to expect postoperatively (chest tubes, drainage bottles, and oxygen administration). Teach the patient how to turn, deep breathe, and cough.
- Give antibiotics, protamine sulfate, or vitamin K, as ordered.
- Postoperatively, monitor critical parameters, such as vital signs and ABG values, and assess heart and breath sounds. Give pain medication as ordered. Maintain the chest drainage system and be alert for complications, such as hemorrhage and arrhythmias.

PREVENTION *Instruct patient to practice heart-healthy living, with a heart-healthy diet,*

stress reduction, regular exercise and preventive care, maintenance of a healthy weight, smoking cessation, and abstinence from alcohol.

CARDIAC ARRHYTHMIAS

Causes and Incidence

Arrhythmias may be congenital or may result from one of several factors, including myocardial ischemia, MI, or organic heart disease. Drug ingestion (cocaine, amphetamines, caffeine, BBs, psychotropics, sympathomimetics), drug toxicity, or degeneration of the conductive tissue necessary to maintain normal heart rhythm (sick sinus syndrome) can sometimes precipitate arrhythmias. People with imbalances of blood chemistries or those with a history of cardiac conditions (CAD or heart valve disorders) are at higher risk for developing arrhythmias.

Pathophysiology

In cardiac arrhythmias (sometimes called *cardiac dysrhythmias*), abnormal electrical conduction or automaticity changes heart rate and rhythm. (See *Normal cardiac conduction,* page 61.) Arrhythmias vary in severity, from those that are mild, asymptomatic, and require no treatment (such as sinus arrhythmia, in which heart rate increases and decreases with respiration) to catastrophic ventricular fibrillation, which necessitates immediate resuscitation. Arrhythmias are generally classified according to their origin (ventricular or supraventricular). Their effect on cardiac output and blood pressure, partially influenced by the site of origin, determines their clinical significance. (See *Types of cardiac arrhythmias*, pages 65 to 71.)

Normal Cardiac Conduction

The conduction system of the heart begins with the heart's pacemaker: the sinoatrial (SA) node. When an impulse leaves the SA node, it travels through the atria along the Bachmann bundle and the internodal tracts on its way to the atrioventricular (AV) node. After the impulse passes through the AV node, it travels to the ventricles, first down the bundle of His, then along the bundle branches and, finally, down the Purkinje fibers.

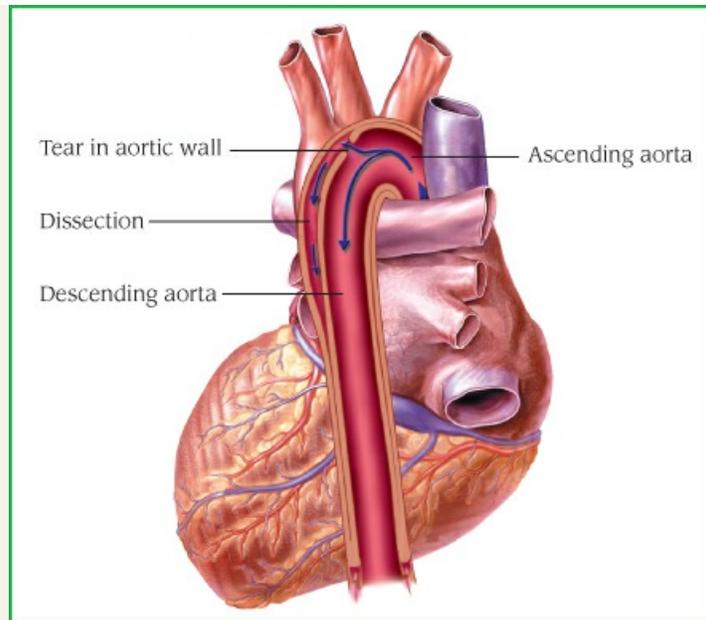
Types of Aortic Aneurysms

Dissecting Aneurysm
A hemorrhagic separation of the medial layer of the vessel wall, which creates a false lumen


Saccular Aneurysm

Unilateral pouchlike bulge with a narrow neck

Fusiform Aneurysm

A spindle-shaped bulge encompassing the vessel's entire diameter

- syphilis, usually of the ascending aorta (uncommon because of antibiotics)
- hypertension (in dissecting aneurysm).

False Aneurysm

A pulsating hematoma resulting from trauma; usually seen in the femoral artery after catheterization

Types of Cardiac Arrhythmias

This chart reviews many common cardiac arrhythmias and outlines their features, causes, and treatments. Use a normal electrocardiogram strip, if available, to compare normal cardiac rhythm configurations with the rhythm strips below. Characteristics of normal rhythm include:
- ventricular and atrial rates of 60 to 100 beats/minute
- regular and uniform QRS complexes and P waves
- PR interval of 0.12 to 0.2 second
- QRS duration <0.12 second
- identical atrial and ventricular rates, with constant PR interval.

Arrhythmia and features	Causes	Treatment
Sinus arrhythmia • Irregular atrial and ventricular rhythms • Normal P wave preceding each QRS complex	• A normal variation of normal sinus rhythm in athletes, children, and elderly people • Also seen in digoxin toxicity and inferior wall myocardial infarction (MI)	• Atropine if rate decreases below 40 beats/minute and patient is symptomatic (e.g., has hypotension)
Sinus tachycardia • Atrial and ventricular rhythms regular • Rate > 100 beats/minute; rarely, >160 beats/minute • Normal P wave preceding each QRS complex	• Normal physiologic response to fever, exercise, anxiety, pain, dehydration; may also accompany shock, left-sided heart failure, cardiac tamponade, hyperthyroidism, anemia, hypovolemia, pulmonary embolism, and anterior wall MI • May also occur with atropine, epinephrine, isoproterenol, quinidine, caffeine, alcohol, and nicotine use	• Correction of underlying cause • Beta-adrenergic blockers or calcium channel blockers for symptomatic patients
Sinus bradycardia		

Characteristics	Causes	Treatment
 • Regular atrial and ventricular rhythms • Rate < 60 beats/minute • Normal P wave preceding each QRS complex	• Normal in well-conditioned heart, as in an athlete • Increased intracranial pressure; increased vagal tone due to straining during defecation, vomiting, intubation, mechanical ventilation; sick sinus syndrome; hypothyroidism; inferior wall MI • May also occur with anticholinesterase, beta-adrenergic blocker, digoxin, and morphine use	• For low cardiac output, dizziness, weakness, altered level of consciousness, or low blood pressure: follow advanced cardiac life support (ACLS) protocol for administration of atropine • Temporary pacemaker; may need to be evaluated for permanent pacemaker at a later time

Sinoatrial (SA) arrest or block (sinus arrest)

Characteristics	Causes	Treatment
 • Atrial and ventricular rhythms normal except for missing complex • Normal P wave preceding each QRS complex • Pause not equal to a multiple of the previous sinus rhythm	• Acute infection • Coronary artery disease, degenerative heart disease, and acute inferior wall MI • Vagal stimulation, Valsalva maneuver, or carotid sinus massage • Digoxin, quinidine, or salicylate toxicity • Pesticide poisoning • Pharyngeal irritation caused by endotracheal (ET) intubation • Sick sinus syndrome	• Treat symptoms with atropine I.V. • Temporary pacemaker; consider permanent pacemaker for repeated episodes

Wandering atrial pacemaker

Characteristics	Causes	Treatment
 • Atrial and ventricular rhythms vary slightly • Irregular PR interval • P waves irregular with changing configuration, indicating that they aren't all from SA node or single atrial focus; may appear after the QRS complex • QRS complexes uniform in shape but irregular in rhythm	• Rheumatic carditis due to inflammation involving the SA node • Digoxin toxicity • Sick sinus syndrome	• No treatment if patient is asymptomatic • Treatment of underlying cause if patient is symptomatic

Premature atrial contraction (PAC)

Characteristics	Causes	Treatment
 • Premature, abnormal-looking P waves that differ in configuration from normal P waves • QRS complexes after P waves, except in very early or blocked PACs • P wave often buried in the preceding T wave or identified in the preceding T wave	• Coronary or valvular heart disease, atrial ischemia, coronary atherosclerosis, heart failure, acute respiratory failure, chronic obstructive pulmonary disease (COPD), electrolyte imbalance, and hypoxia • Digoxin toxicity; use of aminophylline, adrenergics, or caffeine • Anxiety	• Usually no treatment needed • Treatment of underlying cause if patient is symptomatic

Paroxysmal supraventricular tachycardia

- Atrial and ventricular rhythms regular
- Heart rate >160 beats/minute; rarely exceeds 250 beats/minute
- P waves regular but aberrant; difficult to differentiate from preceding T wave
- P wave preceding each QRS complex
- Sudden onset and termination of arrhythmia
- When a normal P wave is present, it's called *paroxysmal atrial tachycardia*; when a normal P wave isn't present, it's called *paroxysmal junctional tachycardia*

- Intrinsic abnormality of atrioventricular (AV) conduction system
- Physical or psychological stress, hypoxia, hypokalemia, cardiomyopathy, congenital heart disease, MI, valvular disease, Wolff–Parkinson–White syndrome, cor pulmonale, hyperthyroidism, and systemic hypertension
- Digoxin toxicity; use of caffeine, marijuana, or central nervous system stimulants

- If patient is unstable, prepare for immediate cardioversion
- If patient is stable, vagal stimulation, Valsalva maneuver, or carotid sinus massage
- Adenosine by rapid I.V. bolus injection to rapidly convert arrhythmia
- If patient has a normal ejection fraction, consider calcium channel blockers, beta-adrenergic blockers, or amiodarone
- If patient has an ejection fraction <40%, consider amiodarone

Atrial flutter

- Atrial rhythm regular; rate, 250 to 400 beats/minute
- Ventricular rate variable, depending on degree of AV block (usually 60 to 100 beats/minute)
- Sawtooth P-wave configuration possible (F waves)
- QRS complexes uniform in shape but often irregular in rate

- Heart failure, tricuspid or mitral valve disease, pulmonary embolism, cor pulmonale, inferior wall MI, and carditis
- Digoxin toxicity

- If patient is unstable with a ventricular rate >150 beats/minute, prepare for immediate cardioversion
- If patient is stable, drug therapy may include calcium channel blockers, beta-adrenergic blockers, or antiarrhythmics
- Anticoagulation therapy may be necessary
- Catheter ablation using radiofrequency energy to eliminate cardiac tissue causing the rapid heartbeat

Atrial fibrillation

- Atrial rhythm grossly irregular; rate >400 beats/minute
- Ventricular rhythm grossly irregular
- QRS complexes of uniform configuration and duration

- Heart failure, COPD, thyrotoxicosis, constrictive pericarditis, ischemic heart disease, sepsis, pulmonary embolus, rheumatic heart disease, hypertension, mitral stenosis, and atrial irritation; complication of coronary bypass or valve replacement surgery

- If patient is unstable with a ventricular rate >150 beats/minute, prepare for immediate cardioversion
- If patient is stable, drug therapy may include calcium channel blockers, beta-adrenergic blockers, digoxin, procainamide, quinidine, ibutilide, or amiodarone
- Consider anticoagulation to prevent emboli
- Dual-chamber atrial pacing, implantable atrial pacemaker, or

• PR interval indiscernible • No P waves, or P waves that appear as erratic, irregular, baseline fibrillatory waves		• surgical maze procedure may also be used • Catheter ablation

Junctional rhythm

 • Atrial and ventricular rhythms regular • Atrial rate 40 to 60 beats/minute • Ventricular rate usually 40 to 60 beats/minute (60 to 100 beats/minute is accelerated junctional rhythm) • P waves preceding, hidden within (absent), or after QRS complex; usually inverted if visible • PR interval (when present) <0.12 second • QRS complex configuration and duration normal, except in aberrant conduction	• Inferior wall MI or ischemia, hypoxia, vagal stimulation, and sick sinus syndrome • Acute rheumatic fever • Valve surgery • Digoxin toxicity	• Correction of underlying cause • Atropine for symptomatic slow rate • Pacemaker insertion if patient is refractory to drugs • Discontinuation of digoxin if appropriate

Premature junctional contractions

 • Atrial and ventricular rhythms irregular • P waves inverted; may precede, be hidden within, or follow QRS complex • PR interval <0.12 second if P wave precedes QRS complex • QRS complex configuration and duration normal	• MI or ischemia • Digoxin toxicity and excessive caffeine or amphetamine use	• Correction of underlying cause • Discontinuation of digoxin if appropriate

Junctional tachycardia

 • Atrial rate >100 beats/minute; however, P wave may be absent, hidden in QRS complex, or preceding T wave	• Myocarditis, cardiomyopathy, inferior wall MI or ischemia, and acute rheumatic fever; complication of valve replacement surgery • Digoxin toxicity	• Cardioversion if ventricular rate is >150 beats/minute or if patient is symptomatic • Amiodarone, beta-adrenergic blockers, or calcium channel blockers if patient is stable • Discontinuation of digoxin if appropriate

- Ventricular rate >100 beats/minute
- P wave inverted
- QRS complex configuration and duration normal
- Onset of rhythm often sudden, occurring in bursts

First-degree AV block

- Atrial and ventricular rhythms regular
- PR interval >0.20 second
- P wave preceding each QRS complex
- QRS complex normal

- Inferior wall MI or ischemia or infarction, hypothyroidism, hypokalemia, and hyperkalemia
- Digoxin toxicity; use of quinidine, procainamide, beta-adrenergic blockers, calcium channel blockers, or amiodarone

- Correction of underlying cause
- No treatment is typically required

Second-degree AV block Mobitz I (Wenckebach)

- Atrial rhythm regular
- Ventricular rhythm irregular
- Atrial rate exceeds ventricular rate
- PR interval progressively, but only slightly, longer with each cycle until QRS complex disappears (dropped beat); PR interval shorter after dropped beat

- Inferior wall MI, cardiac surgery, acute rheumatic fever, and vagal stimulation
- Digoxin toxicity; use of propranolol, quinidine, or procainamide

- No specific treatment is required if asymptomatic
- Treatment of underlying cause
- Atropine or temporary pacemaker for symptomatic bradycardia
- Discontinuation of digoxin if appropriate

Second-degree AV block Mobitz II

- Atrial rhythm regular
- Ventricular rhythm regular or irregular, with varying degree of block
- P-P interval constant
- QRS complexes periodically absent

- Severe coronary artery disease, anterior wall MI, and acute myocarditis
- Digoxin toxicity

- Atropine, for symptomatic bradycardia
- Dopamine for hypotension
- Dobutamine for heart failure symptoms
- Temporary or permanent pacemaker for symptomatic bradycardia
- Discontinuation of digoxin if appropriate

Third-degree AV block (complete heart block)

- Atrial rhythm regular
- Ventricular rhythm regular and rate slower

- Inferior or anterior wall MI, congenital abnormality, rheumatic fever, hypoxia, postoperative complication of mitral valve replacement, Lev disease (fibrosis and calcification that spreads from cardiac structures to the conductive tissue), and Lenegre disease (conductive tissue fibrosis)
- Digoxin toxicity

- Atropine, for symptomatic bradycardia
- Dopamine for hypotension
- Dobutamine for heart failure symptoms
- Temporary or permanent pacemaker for symptomatic bradycardia

• than atrial rate • No relation between P waves and QRS complexes • No constant PR interval • QRS interval normal (nodal pacemaker) or wide and bizarre (ventricular pacemaker)		

Premature ventricular contraction (PVC)

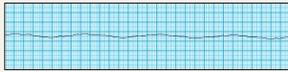
  • Atrial rhythm regular • Ventricular rhythm irregular • QRS complex premature, usually followed by a complete compensatory pause • QRS complex wide and distorted, usually >0.14 second • Premature QRS complexes occurring singly, in pairs, or in threes; alternating with normal beats; focus from one or more sites • Ominous when clustered, multifocal, with R wave on T pattern	• Heart failure; old or acute myocardial ischemia, infarction, or contusion; myocardial irritation by ventricular catheter such as a pacemaker; hypercapnia; hypokalemia; and hypocalcemia • Drug toxicity (cardiac glycosides, aminophylline, tricyclic antidepressants, beta-adrenergics [isoproterenol or dopamine]) • Caffeine, tobacco, or alcohol use • Psychological stress, anxiety, pain, exercise	• Treatment of underlying cause • Discontinuation of drug causing toxicity • Correction of electrolyte imbalances • Beta-blockers, calcium channel blockers, or antiarrhythmics may be used to treat symptoms

Ventricular tachycardia (VT)

  • Ventricular rate 140 to 220 beats/minute, regular or irregular • QRS complexes wide, bizarre, and independent of P waves • P waves not discernible • May start and stop suddenly	• Myocardial ischemia, infarction, or aneurysm; coronary artery disease; rheumatic heart disease; mitral valve prolapse; heart failure; cardiomyopathy; ventricular catheters; hypokalemia; hypercalcemia; and pulmonary embolism • Digoxin, procainamide, epinephrine, or quinidine toxicity • Anxiety	• Pulseless: Initiate cardiopulmonary resuscitation (CPR); follow ACLS protocol for defibrillation, ET intubation, and administration of epinephrine by amiodarone or lidocaine; if ineffective, consider magnesium sulfate • With pulse: If hemodynamically stable, follow ACLS protocol for administration of amiodarone; if ineffective, initiate synchronized cardioversion • If polymorphic VT, consult an expert in arrhythmia management

Ventricular fibrillation

  • Ventricular rhythm and rate rapid and chaotic • QRS complexes wide and irregular; no visible P waves	• Myocardial ischemia or infarction, R-on-T phenomenon, untreated ventricular tachycardia, hypokalemia, hyperkalemia, hypercalcemia, alkalosis, electric shock, and hypothermia • Digoxin, epinephrine, or quinidine toxicity	• Pulseless: Start CPR; follow ACLS protocol for defibrillation, ET intubation, and administration of epinephrine, lidocaine, or amiodarone; if ineffective, consider magnesium sulfate

Asystole


- No atrial or ventricular rate or rhythm
- No discernible P waves, QRS complexes, or T waves

- Myocardial ischemia or infarction, aortic valve disease, heart failure, hypoxemia, hypokalemia, severe acidosis, electric shock, ventricular arrhythmias, AV block, pulmonary embolism, heart rupture, cardiac tamponade, hyperkalemia, and electromechanical dissociation
- Cocaine overdose

- Start CPR; follow ACLS protocol for ET intubation, transcutaneous pacing, and administration of epinephrine

Complications

◆ Impaired cardiac output

Signs and Symptoms

Signs and symptoms of cardiac arrhythmias include palpitations, fainting, light-headedness, dizziness, chest pain, shortness of breath, changes in pulse patterns, paleness, and the temporary absence of breathing. However, the patient with a cardiac arrhythmia may be asymptomatic until the development of sudden cardiac arrest.

Diagnosis

Diagnosis is made by tests that reveal the arrhythmia, such as 12-lead ECG. Ambulatory cardiac monitoring (Holter monitoring), echocardiography, electrophysiology studies, and coronary angiography may also confirm or rule out suspected causes of arrhythmias and help determine treatment.

Special Considerations

- Assess an unmonitored patient for rhythm disturbances.
- If the patient's pulse is abnormally rapid, slow, or irregular, watch for signs of hypoperfusion, such as altered LOC, hypotension, and diminished urine output.
- Document arrhythmias in a monitored patient, and assess for possible causes and effects.
- When life-threatening arrhythmias develop, rapidly assess LOC, respirations, and pulse rate.
- Initiate CPR if indicated.
- Evaluate the patient for altered cardiac output resulting from arrhythmias.
- Administer medications as ordered and prepare to assist with medical procedures (e.g., cardioversion), if indicated.
- Monitor patient for predisposing factors—such as fluid and electrolyte imbalance—and signs of drug toxicity, especially with digoxin. If you suspect drug toxicity, report such signs to the practitioner immediately and withhold the next dose.
- To prevent arrhythmias in a postoperative cardiac patient, provide adequate oxygen and reduce the heart's workload while carefully maintaining metabolic, neurologic, respiratory, and hemodynamic status.
- Consider sedation for transcutaneous pacing if appropriate.
- To avoid temporary pacemaker malfunction, install a fresh battery before each insertion. Carefully secure the external catheter wires and the pacemaker box. Assess the threshold daily. Watch closely for premature contractions, a sign of myocardial irritation.
- To avert permanent pacemaker malfunction, restrict the patient's activity after insertion as

ordered. Monitor the pulse rate regularly and watch for signs of decreased cardiac output.
- If the patient has a permanent pacemaker, warn about environmental hazards, as indicated by the pacemaker manufacturer. Although hazards may not present a problem, in doubtful situations, 24-hour Holter monitoring may be helpful. Tell the patient to report light-headedness or syncope, and stress the importance of regular checkups.
- Compare the patient's cardiac status (pulse, blood pressure, and cardiac output) with the cardiac rhythm before and after treatments.

PREVENTION

- *Maintain adequate oxygenation.*
- *Maintain normal fluid, acid–base, and electrolyte (especially potassium, magnesium, and calcium) balance.*
- *Maintain normal drug levels.*

Vascular Disorders

THORACIC AORTIC ANEURYSM

Causes and Incidence

Thoracic aortic aneurysm is an abnormal widening of the ascending, transverse, or descending part of the aorta. Aneurysm of the ascending aorta is the most common type and has the highest mortality. Aneurysms may be *dissecting,* a hemorrhagic separation in the aortic wall, usually within the medial layer; *saccular,* an outpouching of the arterial wall, with a narrow neck; or *fusiform,* a spindle-shaped enlargement encompassing the entire aortic circumference. (See *Types of aortic aneurysms,* page 64.) Some aneurysms progress to serious and, eventually, lethal complications, such as rupture of an untreated thoracic dissecting aneurysm into the pericardium, with resulting tamponade.

Thoracic aortic aneurysms commonly result from atherosclerosis, which weakens the aortic wall and gradually distends the lumen. An intimal tear in the ascending aorta initiates dissecting aneurysm in about 65% of patients. Regardless of causation, these aneurysms affect 6 out of every 100,000 people.

ELDER TIP Ascending aortic aneurysms, the most common type, are usually seen in hypertensive men younger than 60 years old. Descending aortic aneurysms, usually found just below the origin of the subclavian artery, are most common in elderly men who are hypertensive.

Descending aortic aneurysms are also seen in younger patients with a history of traumatic chest injury less often in those with infection. Transverse aortic aneurysms are the least common type.

Other causes include:

- fungal infection (mycotic aneurysms) of the aortic arch and descending segments
- congenital disorders, such as coarctation of the aorta and Marfan syndrome
- trauma, usually of the descending thoracic aorta, from an accident that shears the aorta transversely (acceleration–deceleration injuries)

Pathophysiology

Most aneurysms result from changes to the vascular wall of arteries caused by failure of important proteins, elastin and collagen, leading to dilation. This eventually affects the structural stability and strength of the vessel. The location of the aneurysm, its diameter, the cause, and its morphologyall assist in determining rate of expansion per year. Saccular aneurysms are thought to rupture more readily than other types, such as fusiform.

Complications

- Rupture into pericardium
- Cardiac tamponade

Signs and Symptoms

The most common symptom of thoracic aortic aneurysm is pain. With ascending aneurysm, the pain is described as severe, boring, and ripping and extends to the neck, shoulders, lower back, or abdomen but seldom radiates to the jaw and arms. Pain is more severe on the right side.

   Other signs of ascending aneurysm may include bradycardia, aortic insufficiency, pericardial friction rub caused by a hemopericardium, unequal intensities of the right carotid and left radial pulses, and a difference in blood pressure between the right and the left arms. These signs are absent in descending aneurysm. If dissection involves the carotids, an abrupt onset of neurologic deficits may occur.

   With descending aneurysm, pain usually starts suddenly between the shoulder blades and may radiate to the chest; it's described as sharp and tearing. Transverse aneurysm causes a sudden, sharp, tearing pain radiating to the shoulders. It may also cause hoarseness, dyspnea, dysphagia, and a dry cough because of compression of surrounding structures in this area. (See *Clinical characteristics of thoracic dissection,* page 72.)

Clinical Characteristics of Thoracic Dissection

Ascending aorta	Descending aorta	Transverse aorta
Character of pain		
Severe, boring, ripping; extending to neck, shoulders, lower back, or abdomen (rarely to jaw and arms); more severe on right side	Sudden onset; sharp, tearing; usually between the shoulder blades; may radiate to the chest; most diagnostic feature	Sudden onset; sharp, boring, tearing; radiates to shoulders
Other symptoms and effects		
If dissection involves carotids, abrupt onset of neurologic deficit (usually intermittent); bradycardia, aortic insufficiency, and hemopericardium detected by pericardial friction rub; unequal intensity of right and left carotid pulses and radial pulses; difference in blood pressure, especially systolic, between right and left arms	Aortic insufficiency without murmur, hemopericardium, or pleural friction rub; carotid and radial pulses and blood pressure in both arms tend to stay equal	Hoarseness, dyspnea, pain, dysphagia, and dry cough resulting from compression of surrounding structures
Diagnostic features		
Chest X-ray		
Best diagnostic tool; shows widening of mediastinum, enlargement of ascending aorta	Shows widening of mediastinum, descending aorta larger than ascending	Shows widening of mediastinum, descending aorta larger than ascending, widened transverse arch

Computerized tomography		
Shows false lumen; narrowing of lumen of aorta in ascending section. Also good for visualizing anatomic details to help determine the extent of the aneurysm, and to assist in preparing for repair	Shows false lumen; narrowing of lumen of aorta in descending section. Also good for visualizing anatomic details to help determine the extent of the aneurysm, and to assist in preparing for repair	Shows false lumen, narrowing of lumen of aorta in transverse arch. Also good for visualizing anatomic details to help determine the extent of the aneurysm, and to assist in preparing for repair
Treatment		
This is a medical emergency requiring immediate, aggressive treatment to reduce blood pressure (usually with labetalol or verapamil). Nitroprusside may be required if there is persistent hypertension. Surgical repair is also required	Surgical repair is required but less urgent than for the ascending dissection	Immediate surgical repair (mortality as high as 50%) and control of hypertension are required

Diagnosis

Diagnosis relies on patient history, clinical features, and appropriate tests. In an asymptomatic patient, diagnosis often occurs accidentally when chest X-rays show widening of the aorta. Other tests help confirm aneurysm:

- Aortography can show the lumen of the aneurysm, its size and location, and the false lumen in dissecting aneurysm.
- ECG helps distinguish thoracic aneurysm from MI.
- Echocardiography may help identify dissecting aneurysm of the aortic root.
- Hemoglobin levels may be normal or low, due to blood loss from a leaking aneurysm.
- Computed tomography scan is considered the gold standard and can confirm and locate the aneurysm and may be used to monitor its progression.
- MRI may aid diagnosis.
- Transesophageal echocardiography is used to diagnose and size an aneurysm in either the ascending or the descending aorta.
- Ultrasound is frequently used for screening purposes in high-risk patients.

Treatment

Dissecting aortic aneurysm is an emergency that requires prompt surgery and stabilizing measures: antihypertensives such as nitroprusside; negative inotropic agents that decrease contractility force such as propranolol; oxygen for respiratory distress; opioids for pain; I.V. fluids and, possibly, whole blood transfusions.

Surgery consists of resecting the aneurysm, restoring normal blood flow through a graft replacement, and, with aortic valve insufficiency, replacing the aortic valve. Groin catheter placement may be used for aortic stenting. This procedure, which may be used for aneurysms of the descending aorta, eliminates the need for a chest incision.

Postoperative measures include careful monitoring and continuous assessment in the ICU, antibiotics, placement of ET and chest tubes, ECG monitoring, and pulmonary artery catheterization.

Long-term management includes treatment of underlying conditions, such as heart disease and diabetes.

Special Considerations

- Monitor blood pressure, PAWP, and CVP. Assess pain; breathing; and carotid, radial, and femoral pulses.
- Make sure laboratory tests include complete blood count, differential, electrolyte levels, type and crossmatching for whole blood, ABG studies, and urinalysis.
- Insert an indwelling urinary catheter. Administer dextrose 5% in water or lactated Ringer solution, and antibiotics, as ordered. Carefully monitor nitroprusside I.V., if ordered; use a separate I.V. line for infusion. Adjust the dose by slowly increasing the infusion rate. Meanwhile, check blood pressure every 5 minutes until it stabilizes. With suspected bleeding from aneurysm, give whole blood transfusion.
- Explain diagnostic tests. If surgery is scheduled, explain the procedure and expected postoperative care (I.V. lines, ET and drainage tubes, cardiac monitoring, and ventilation).

  After repair of thoracic aneurysm:

- Assess LOC. Monitor vital signs; PAP, PAWP, and CVP; pulse rate; urine output; and pain.
- Check respiratory function. Carefully observe and record type and amount of chest tube drainage, and frequently assess heart and breath sounds.
- Monitor I.V. therapy.
- Give medications as appropriate.
- Watch for signs of infection, especially fever, and excessive wound drainage.
- Assist with range-of-motion exercises of legs to prevent thromboembolic phenomenon due to venostasis during prolonged bed rest.
- After stabilization of vital signs and respiration, encourage and assist the patient in turning, coughing, and deep breathing. If necessary, provide intermittent positive-pressure breathing to promote lung expansion. Help the patient walk as soon as he or she is able.
- Before discharge, ensure compliance with antihypertensive therapy by explaining the need for such drugs and the expected adverse effects. Teach the patient how to monitor blood pressure. Refer to community agencies for continued support and assistance, as needed.
- Throughout hospitalization, offer the patient and family psychological support. Answer all of their questions honestly and provide reassurance.

ABDOMINAL ANEURYSM

Causes and Incidence

Abdominal aneurysm, an abnormal dilation in the arterial wall, generally occurs in the aorta between the renal arteries and the iliac branches. Rupture—in which the aneurysm breaks open, resulting in profuse bleeding—is a common complication that occurs in larger aneurysms. Dissection occurs when the artery's lining tears, and blood leaks into the walls.

Abdominal aortic aneurysms (AAAs) result from arteriosclerosis, hypertension, congenital weakening, cystic medial necrosis, trauma, syphilis, and other infections. In children, this disorder can result from blunt abdominal injury or Marfan syndrome.

This disorder is four times more common in men than in women and is most prevalent in whites 40 to 70 years old. It is especially prevalent in male smokers who are 65 and older. Less than 50% of people with a ruptured AAA survive.

Pathophysiology

These aneurysms develop slowly. First, a focal weakness in the muscular layer of the aorta

(tunica media), due to degenerative changes, allows the inner layer (tunica intima) and outer layer (tunica adventitia) to stretch outward. Blood pressure within the aorta progressively weakens the vessel walls and enlarges the aneurysm.

Complications

- Rupture
- Hemorrhage
- Shock

Signs and Symptoms

Although abdominal aneurysms usually don't produce symptoms, most are evident (unless the patient is obese) as a pulsating mass in the periumbilical area, accompanied by a systolic bruit over the aorta. Some tenderness may be present on deep palpation. A large aneurysm may produce symptoms that mimic renal calculi, lumbar disk disease, and duodenal compression. Abdominal aneurysms rarely cause diminished peripheral pulses or claudication, unless embolization occurs.

Lumbar pain that radiates to the flank and groin from pressure on lumbar nerves may signify enlargement and imminent rupture. A rare but recognized symptom is unrelenting testicular pain with no other cause. If the aneurysm ruptures into the peritoneal cavity, it causes severe, persistent abdominal and back pain, mimicking renal or ureteral colic. Signs of hemorrhage— such as weakness, sweating, tachycardia, and hypotension—may be subtle because rupture into the retroperitoneal space produces a tamponade effect that prevents continued hemorrhage. Patients with such rupture may remain stable for hours before shock and death occur, although 20% die immediately.

Diagnosis

Because abdominal aneurysms seldom produce symptoms, they're commonly detected accidentally as the result of an X-ray or a routine physical examination.

℞ **CONFIRMING DIAGNOSIS** *Several tests can confirm a suspected abdominal aneurysm. Serial ultrasound (sonography) can accurately determine the aneurysm's size, shape, and location. Anteroposterior and lateral X-rays of the abdomen can detect aortic calcification, which outlines the mass, at least 75% of the time. Aortography shows the condition of vessels proximal and distal to the aneurysm and the aneurysm's extent but may underestimate aneurysm diameter because it visualizes only the flow channel and not the surrounding clot. Computed tomography scan is used to diagnose and size the aneurysm. MRI can be used as an alternative to aortography.*

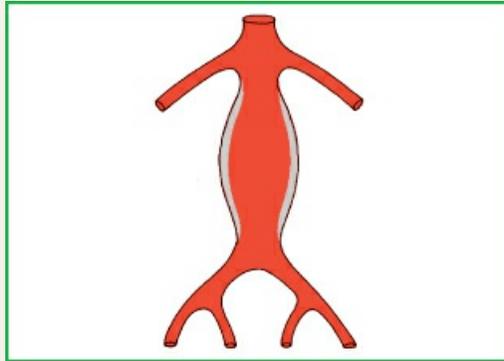
Treatment

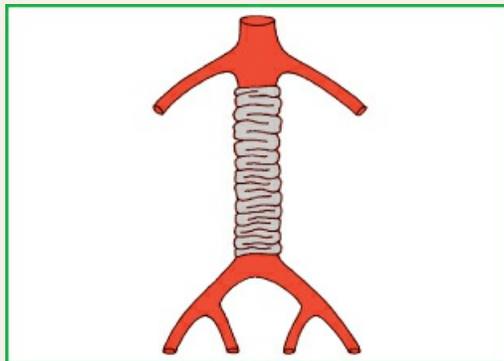
Usually, abdominal aneurysm requires resection of the aneurysm and replacement of the damaged aortic section with a Dacron graft. (See *Abdominal aneurysms: Before and after surgery*, page 75. Also see *Endovascular grafting for repair of an AAA*, page 76.) If the aneurysm is small and asymptomatic, surgery may be delayed, and the aneurysm may be followed and allowed to expand to a certain size because of possible surgical complications; however, small aneurysms may also rupture. Because of this risk, surgical repair or replacement is recommended for symptomatic patients or for patients with aneurysms greater than 5 cm in

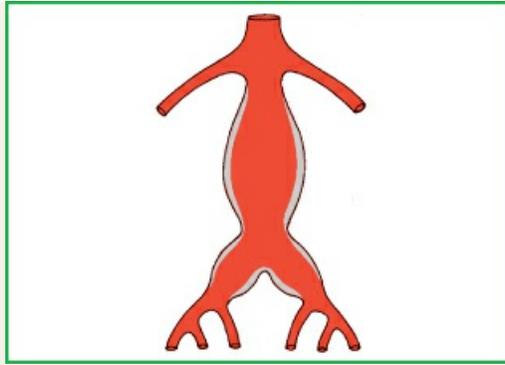
diameter.

Abdominal Aneurysms: Before and After Surgery

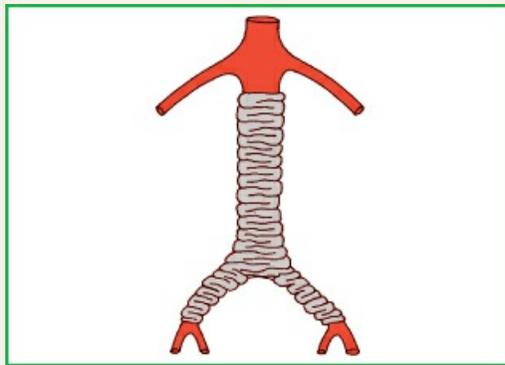
During surgery, a prosthetic graft replaces or encloses the weakened area.

Before Surgery
Aneurysm below renal arteries and above bifurcation


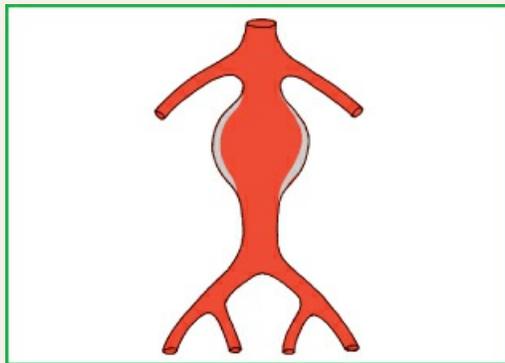
Before Surgery
Aneurysm below renal arteries involving the iliac branches


Before Surgery
Small aneurysm in a patient with poor distal runoff (poor risk)


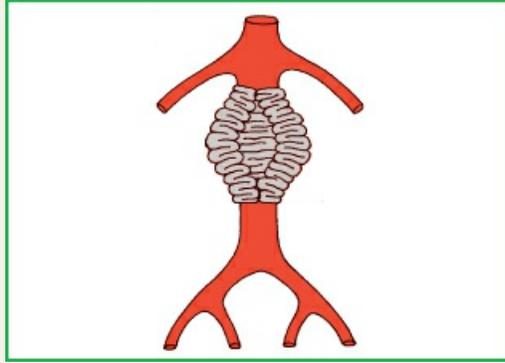
After Surgery

The prosthesis extends distal to the renal arteries to above the aortic bifurcation.


After Surgery

The prosthesis extends to the common femoral arteries.


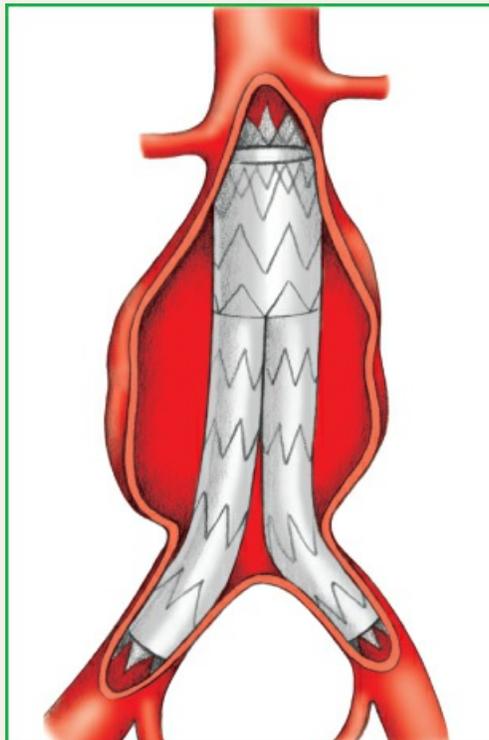
After Surgery

The external prosthesis encircles the aneurysm and is held in place with sutures.


Endovascular Grafting For Repair of An AAA

Endovascular grafting is a minimally invasive procedure for the repair of an abdominal aortic aneurysm (AAA). This procedure reinforces the walls of the aorta to prevent rupture and prevent expansion of the aneurysm.

Endovascular grafting is performed with fluoroscopic guidance: Using a guide wire, a delivery catheter with an attached compressed graft is inserted through a small incision into the femoral or iliac artery. The delivery catheter is advanced into the aorta, where it's positioned across the aneurysm. A balloon on the catheter expands the graft and affixes it to the vessel wall.

The procedure generally takes 2 to 3 hours to perform. Patients are instructed to walk the first day after surgery and are generally discharged from the facility in 1 to 3 days.


Stenting is also a treatment option. It can be performed without an abdominal incision by introducing the catheters through arteries in the groin. However, not all patients with AAAs are candidates for this treatment.

Regular physical examination and ultrasound checks are necessary to detect enlargement, which may forewarn rupture. Large aneurysms or those that produce symptoms pose a significant risk of rupture and necessitate immediate repair. In patients with poor distal runoff, external grafting may be done.

Risk factor modification is fundamental in the medical management of abdominal aneurysm, including control of hypocholesterolemia and hypertension. BBs are commonly prescribed to reduce the risk of aneurysm expansion and rupture.

Special Considerations

Abdominal aneurysm requires meticulous preoperative and postoperative care, psychological support, and comprehensive patient teaching. Following diagnosis, if rupture isn't imminent, elective surgery allows time for additional preoperative tests to evaluate the patient's clinical status.

- Monitor vital signs, and type and crossmatch blood.
- Use only gentle abdominal palpation.
- As ordered, obtain renal function tests (BUN, creatinine, and electrolyte levels), blood samples (complete blood count with differential), electrocardiogram and cardiac evaluation, baseline pulmonary function tests, and ABG analysis.
- Be alert for signs of rupture, which may be immediately fatal. Watch closely for signs of acute blood loss (decreasing blood pressure; increasing pulse and respiratory rate; cool, clammy skin; restlessness; and decreased sensorium).
- If rupture does occur, the first priority is to get the patient to surgery immediately. Surgery allows direct compression of the aorta to control hemorrhage. Large amounts of blood may be needed during the resuscitative period to replace blood loss. In such a patient, renal failure caused by ischemia is a major postoperative complication, possibly requiring hemodialysis.
- Before elective surgery, weigh the patient, insert an indwelling urinary catheter and an I.V. line, and assist with insertion of an arterial line and pulmonary artery catheter to monitor fluid and hemodynamic balance. Give prophylactic antibiotics as ordered.
- Explain the surgical procedure and the expected postoperative care in the ICU for patients undergoing complex abdominal surgery (I.V. lines, ET and NG intubation, and mechanical ventilation).
- After surgery, in the ICU, closely monitor vital signs, intake and hourly output, neurologic status (LOC, pupil size, and sensation in arms and legs), and ABG values. Assess the depth, rate, and character of respirations and breath sounds at least every hour.
- Watch for signs of bleeding (increased pulse and respiratory rates and hypotension) and back pain, which may indicate that the graft is tearing. Check abdominal dressings for excessive bleeding or drainage. Be alert for temperature elevations and other signs of infection. After NG intubation for intestinal decompression, irrigate the tube frequently to ensure patency. Record the amount and type of drainage.
- Suction the ET tube often. If the patient can breathe unassisted and has good breath sounds and adequate ABG values, tidal volume, and vital capacity 24 hours after surgery, it is likely

he or she will be extubated and will require oxygen by mask.

◆ Weigh the patient daily to evaluate fluid balance.

◆ Help the patient walk as soon as able (generally the second day after surgery).
◆ Provide psychological support for the patient and family. Help ease their fears about the ICU, the threat of impending rupture, and surgery by providing appropriate explanations and answering all questions.

FEMORAL AND POPLITEAL ANEURYSMS

Causes and Incidence

Femoral and popliteal aneurysms (sometimes called *peripheral arterial aneurysms*) are the end result of progressive atherosclerotic changes occurring in the walls (medial layer) of these major peripheral arteries. These aneurysmal formations may be *fusiform* (spindle-shaped) or *saccular* (pouchlike); the fusiform type is three times more common. They may be singular or multiple segmental lesions, often affecting both legs, and may accompany other arterial aneurysms located in the abdominal aorta or iliac arteries.

Femoral and popliteal aneurysms are usually secondary to atherosclerosis. Rarely, they result from congenital weakness in the arterial wall. They may also result from trauma (blunt or penetrating), bacterial infection, or peripheral vascular reconstructive surgery (which causes "suture line" aneurysms, or false aneurysms, in which a blood clot forms a second lumen).

This condition occurs most frequently in men older than 50. The clinical course is usually progressive, eventually ending in thrombosis, embolization, and gangrene. Elective surgery before complications arise greatly improves the prognosis.

Pathophysiology

As with other aneurysms, a weakening of the vessel wall caused by inflammation, proteolysis, and changes in the matrix result in the outpouching seen in this condition.

Complications

◆ Amputation of thrombosis
◆ Emboli
◆ Gangrene

Signs and Symptoms

Popliteal aneurysms may cause pain in the popliteal space when they're large enough to compress the medial popliteal nerve and edema and venous distention if the vein is compressed. Femoral and popliteal aneurysms can produce symptoms of severe ischemia in the leg or foot due to acute thrombosis within the aneurysmal sac, embolization of mural thrombus fragments and, rarely, rupture. Symptoms of acute aneurysmal thrombosis include severe pain, loss of pulse and color, coldness in the affected leg or foot, and gangrene. Distal petechial hemorrhages may develop from aneurysmal emboli.

Diagnosis

Diagnosis is usually confirmed by bilateral palpation that reveals a pulsating mass above or below the inguinal ligament in femoral aneurysm. When thrombosis has occurred, palpation

detects a firm, nonpulsating mass. Arteriography or ultrasound may be indicated in doubtful situations. Arteriography may also detect associated aneurysms, especially those in the abdominal aorta and the iliac arteries. Ultrasound may be helpful in determining the size of the popliteal or femoral artery.

Treatment

Femoral and popliteal aneurysms require surgical bypass and reconstruction of the artery, usually with an autogenous saphenous vein graft replacement. Arterial occlusion that causes severe ischemia and gangrene may require leg amputation.

Special Considerations

Before corrective surgery:

- Assess and record circulatory status, noting the location and quality of peripheral pulses in the affected arm or leg.
- Administer prophylactic antibiotics or anticoagulants, as ordered.
- Discuss postoperative procedures and review the explanation of the surgery.

  After arterial surgery:

- Monitor carefully for early signs of thrombosis or graft occlusion (loss of pulse, decreased skin temperature and sensation, and severe pain) and infection (fever).
- Palpate distal pulses at least every hour for the first 24 hours and then as frequently as ordered. Correlate these findings with preoperative circulatory assessment. Mark the sites on the patient's skin where pulses are palpable to facilitate repeated checks.
- Help the patient walk soon after surgery to prevent venostasis and possible thrombus formation.

  To prepare the patient for discharge:

- Tell the patient to immediately report any recurrence of symptoms because the saphenous vein graft replacement can fail or another aneurysm may develop.
- Explain to the patient with popliteal artery resection that swelling may persist for some time. If antiembolism stockings are ordered, make sure they fit properly and teach the patient how to apply them. Warn against wearing constrictive apparel.
- If the patient is receiving anticoagulants, suggest measures to prevent bleeding, such as using an electric razor. Tell the patient to report any signs of bleeding (bleeding gums, tarry stools, and easy bruising) immediately. Explain the importance of follow-up blood studies to monitor anticoagulant therapy. Warn the patient to avoid trauma, tobacco, and aspirin.

THROMBOPHLEBITIS

Causes and Incidence

An acute condition characterized by inflammation and thrombus formation, thrombophlebitis may occur in deep (intermuscular or intramuscular) or superficial (subcutaneous) veins. DVT or thrombophlebitis affects small veins, such as the soleal venous sinuses, or large veins, such as the vena cava and the femoral, iliac, and subclavian veins, causing venous insufficiency. (See *Chronic venous insufficiency*, page 78.) This disorder is typically progressive, leading to pulmonary embolism, a potentially lethal complication. Superficial thrombophlebitis is usually

self-limiting and seldom leads to pulmonary embolism. Thrombophlebitis often begins with localized inflammation alone (phlebitis), but such inflammation rapidly provokes thrombus formation. Rarely, venous thrombosis develops without associated inflammation of the vein (phlebothrombosis).

Chronic Venous Insufficiency

Chronic venous insufficiency results from the valvular destruction of deep vein thrombophlebitis, usually in the iliac and femoral veins, and occasionally the saphenous veins. It's often accompanied by incompetence of the communicating veins at the ankle, causing increased venous pressure and fluid migration into the interstitial tissue. Clinical effects include chronic swelling of the affected leg from edema, leading to tissue fibrosis, and induration; skin discoloration from extravasation of blood in subcutaneous tissue; and stasis ulcers around the ankle.

Treatment of small ulcers includes bed rest, elevation of the legs, warm soaks, and antimicrobial therapy for infection. Treatment to counteract increased venous pressure, the result of reflux from the deep venous system to surface veins, may include compression dressings, such as a sponge rubber pressure dressing or a zinc gelatin boot (Unna boot). This therapy begins after massive swelling subsides with leg elevation and bed rest.

Large stasis ulcers unresponsive to conservative treatment may require excision and skin grafting. Patient care includes daily inspection to assess healing. Other care measures are the same as for varicose veins.

DVT may be idiopathic, but it usually results from endothelial damage, accelerated blood clotting, and reduced blood flow, known as the *Virchow triad*. Predisposing factors are prolonged bed rest, trauma, surgery, childbirth, and use of hormonal contraceptives such as estrogens. It occurs in about 80 of every 100,000 people; 1 of every 20 persons is affected at some point during their lifetime. Males are at slightly greater risk than females. People older than 40 are also at increased risk.

Causes of superficial thrombophlebitis include trauma, infection, I.V. drug abuse, and chemical irritation due to extensive use of the I.V. route for medications and diagnostic tests.

Pathophysiology

A thrombus occurs when an alteration in the epithelial lining causes platelet aggregation and consequent fibrin entrapment of red and white blood cells and additional platelets. Thrombus formation is more rapid in areas where blood flow is slower, due to greater contact between platelet and thrombin accumulation. The rapidly expanding thrombus initiates a chemical inflammatory process in the vessel epithelium, which leads to fibrosis. The enlarging clot may occlude the vessel lumen partially or totally, or it may detach and embolize to lodge elsewhere in the systemic circulation.

Complications

- Pulmonary embolism
- Chronic venous insufficiency

Signs and Symptoms

In both types of thrombophlebitis, clinical features vary with the site and length of the affected vein. Although DVT may occur asymptomatically, it may also produce severe pain, fever, chills, malaise and, possibly, swelling and cyanosis of the affected arm or leg. Superficial thrombophlebitis produces visible and palpable signs, such as heat, pain, swelling, rubor, tenderness, and induration along the length of the affected vein. Varicose veins may also be present. (See *Varicose veins*, page 79.) Extensive vein involvement may cause lymphadenitis.

Varicose Veins

Varicose veins are dilated, tortuous veins, usually affecting the subcutaneous leg veins—the saphenous veins and their branches. They can result from congenital weakness of the valves or venous wall, diseases of the venous system such as deep vein thrombophlebitis, conditions that produce prolonged venostasis such as pregnancy, or occupations that necessitate standing for an extended period.

Varicose veins may be asymptomatic or may produce mild to severe leg symptoms, including a feeling of heaviness; cramps at night; diffuse, dull aching after prolonged standing or walking; aching during menses; fatigability; palpable nodules, and, with deep vein incompetency, orthostatic edema and stasis pigmentation of the calves and ankles.

Treatment

In mild-to-moderate varicose veins, antiembolism stockings or elastic bandages counteract pedal and ankle swelling by supporting the veins and improving circulation. An exercise program such as walking promotes muscular contraction and forces blood through the veins, thereby minimizing venous pooling. Severe varicose veins may necessitate stripping and ligation or, as an alternative to surgery, injection of a sclerosing agent into small affected vein segments.

To promote comfort and minimize worsening of varicosities:

- Discourage the patient from wearing constrictive clothing.
- Advise the patient to elevate the legs above heart level whenever possible and to avoid prolonged standing or sitting.

After stripping and ligation or after injection of a sclerosing agent:

- To relieve pain, administer analgesics as ordered.
- Frequently check circulation in toes (color and temperature) and observe elastic bandages for bleeding. When ordered, rewrap bandages at least once a shift, wrapping from toe to thigh, with the leg elevated.
- Watch for signs of complications, such as sensory loss in the leg (which could indicate saphenous nerve damage), calf pain (thrombophlebitis), and fever (infection).

Diagnosis

Findings are usually nonspecific and are not reliable for making the diagnosis of DVT. Essential laboratory tests include:

- Duplex Doppler is most commonly performed; this makes it possible to noninvasively examine the major veins (but not calf veins).

CONFIRMING DIAGNOSIS *Compression ultrasonography with Doppler is the diagnostic test of choice in the evaluation of DVT.*

Diagnosis must also rule out PAD, lymphangitis, cellulitis, and myositis.

Diagnosis of superficial thrombophlebitis is based on physical examination (redness and warmth over the affected area, palpable vein, and pain during palpation or compression).

Treatment

The goals of treatment are to control thrombus development, prevent complications, relieve pain, and prevent recurrence of the disorder. Symptomatic measures include bed rest, with elevation of the affected arm or leg; warm, moist soaks to the affected area; and analgesics. After the acute episode of DVT subsides, the patient may resume activity while wearing antiembolism stockings that were applied before getting out of bed.

Treatment also includes anticoagulants to prolong clotting time. While warfarin is still an option for the treatment of DVT, new medications are now available that are safer, as effective, and do not require monitoring of blood levels through frequent lab draws. These medications are called direct factor Xa inhibitors and include rivaroxaban and apixaban. If the patient is not a candidate for these novel medications, low-molecular-weight (LMW) heparin has been shown to be effective in treating DVT or can be used as bridge therapy until a therapeutic level of warfarin is achieved. Although LMW heparin is more expensive, it doesn't require monitoring for its anticoagulant effect, either. Full anticoagulant doses must be discontinued during any operative period because of the risk of hemorrhage. After some types of surgery, especially major abdominal or pelvic operations, prophylactic doses of anticoagulants may reduce the risk of DVT and pulmonary embolism. For lysis of acute, extensive DVT, treatment may include thrombolysis with or without thrombectomy. Rarely, DVT may cause complete venous occlusion, which necessitates venous interruption through simple ligation to vein plication, or clipping. Embolectomy and insertion of a vena caval umbrella or filter may also be done.

Therapy for severe superficial thrombophlebitis may include an anti-inflammatory drug such as indomethacin, antiembolism stockings, warm soaks, and elevation of the leg.

Special Considerations

Patient teaching, identification of high-risk patients, and measures to prevent venostasis can prevent DVT; close monitoring of anticoagulant therapy can prevent serious complications such as internal hemorrhage.

- Enforce bed rest as ordered, and elevate the patient's affected arm or leg. If you plan to use pillows for elevating the leg, place them so they support the entire length of the affected extremity to prevent possible compression of the popliteal space.
- Apply warm soaks to increase circulation to the affected area and to relieve pain and inflammation. Give analgesics to relieve pain, as ordered.
- Measure and record the affected arm or leg's circumference daily, and compare this measurement to the other arm or leg. To ensure accuracy and consistency of serial measurements, mark the skin over the area and measure at the same spot daily.
- Administer heparin I.V., as ordered, with an infusion monitor or pump to control the flow rate if necessary. Remember that this medication is not being used as often with the growing popularity of direct factor Xa inhibitors.
- Measure partial thromboplastin time regularly for the patient on heparin therapy; prothrombin

time and international normalized ratio (INR) for the patient on warfarin (therapeutic anticoagulation values are 1½ to 2 times control values for prothrombin time and an INR of 2 to 3). Watch for signs and symptoms of bleeding, such as dark, tarry stools; coffee-ground vomitus; and ecchymosis. Encourage the patient to use an electric razor and to avoid medications that contain aspirin.

◆ Be alert for signs of pulmonary emboli (crackles, dyspnea, hemoptysis, sudden changes in mental status, restlessness, and hypotension).

To prepare the patient with thrombophlebitis for discharge:

◆ Emphasize the importance of follow-up blood studies to monitor anticoagulant therapy, if necessary.
◆ If the patient is being discharged on heparin therapy, teach the patient or family how to give subcutaneous injections. If the patient requires further assistance, arrange for a home health nurse.
◆ Tell the patient to avoid prolonged sitting or standing to help prevent recurrence.
◆ Teach the patient how to properly apply and use antiembolism stockings. Tell the patient to report any complications such as cold, blue toes. (See *Preventing thrombophlebitis*.)

PREVENTION
PREVENTING THROMBOPHLEBITIS

To prevent thrombophlebitis in a high-risk patient, perform range-of-motion exercise while the patient is on bed rest, use intermittent pneumatic calf massage during lengthy surgical or diagnostic procedures, apply antiembolism stockings postoperatively, and encourage early ambulation.

After some types of surgery, especially major abdominal or pelvic operations, prophylactic doses of anticoagulants may reduce the risk of deep vein thrombosis and pulmonary embolism.

RAYNAUD DISEASE

Causes and Incidence

Raynaud disease is one of several primary arteriospastic disorders characterized by episodic vasospasm in the small peripheral arteries and arterioles, precipitated by exposure to cold or stress. This condition occurs bilaterally and usually affects the hands or, less often, the feet. Raynaud disease is most prevalent in females, particularly those between puberty and 40 years old. It's a benign condition, requiring no specific treatment and causing no serious sequelae.

Although the cause is unknown, several theories account for the reduced digital blood flow: intrinsic vascular wall hyperactivity to cold, increased vasomotor tone due to sympathetic stimulation, and antigen–antibody immune response (the most likely theory because abnormal immunologic test results accompany Raynaud phenomenon). Risk factors include associated diseases (Buerger disease, atherosclerosis, rheumatoid arthritis, scleroderma, and SLE) and smoking.

This disorder affects females more often than males.

Raynaud phenomenon, however, a condition commonly associated with several connective

tissue disorders—such as scleroderma, SLE, or polymyositis—has a progressive course, leading to ischemia, gangrene, and amputation. Distinguishing between the two disorders is difficult because some patients who experience mild symptoms of Raynaud disease for several years may later develop overt connective tissue disease—especially scleroderma.

Pathophysiology

Complications

- Ischemia
- Gangrene
- Amputation

Signs and Symptoms

After exposure to cold or stress, the skin on the fingers typically blanches and then becomes cyanotic before changing to red and before changing from cold to normal temperature. Numbness and tingling may also occur. These symptoms are relieved by warmth. In long-standing disease, trophic changes, such as sclerodactyly, ulcerations, or chronic paronychia, may result. Although it's extremely uncommon, minimal cutaneous gangrene necessitates amputation of one or more phalanges.

Diagnosis

Clinical criteria that establish Raynaud disease include skin color changes induced by cold or stress; bilateral involvement; absence of gangrene or, if present, minimal cutaneous gangrene; normal arterial pulses; and patient history of clinical symptoms of longer than 2 years' duration. Diagnosis must also rule out secondary disease processes, such as chronic arterial occlusive or connective tissue disease.

Treatment

Initially, treatment consists of avoidance of cold, mechanical, or chemical injury; cessation of smoking; and reassurance that symptoms are benign. Because adverse drug effects, especially from vasodilators, may be more bothersome than the disease itself, drug therapy is reserved for unusually severe symptoms. Such therapy may include low doses of nifedipine. Sympathectomy may be helpful when conservative modalities fail to prevent ischemic ulcers and becomes necessary in less than 25% of patients.

Special Considerations

- Warn the patient against exposure to the cold. Tell the patient to wear mittens or gloves in cold weather or when handling cold items or defrosting the freezer.
- Advise the patient to avoid stressful situations and to stop smoking.
- Instruct the patient to inspect the skin frequently and to seek immediate care for signs of skin breakdown or infection.
- Teach the patient about drugs, their use, and their adverse effects.
- Provide psychological support and reassurance to allay the patient's fear of amputation and disfigurement.

BUERGER DISEASE

Causes and Incidence

Buerger disease (sometimes called *thromboangiitis obliterans*)—an inflammatory, nonatheromatous occlusive condition—causes segmental lesions and subsequent thrombus formation in the small and medium arteries (and sometimes the veins), resulting in decreased blood flow to the feet and legs. This disorder may produce ulceration and, eventually, gangrene.

Buerger disease is caused by vasculitis, an inflammation of blood vessels, primarily of the hands and feet. The vessels become constricted or totally blocked, reducing blood flow to the tissues and resulting in pain and, eventually, damage.

This disorder occurs in 12 to 20 of every 100,000 people. Incidence is highest among males 20 to 40 years old who have a history of smoking or chewing tobacco. It may be associated with a history of Raynaud disease and may occur in people with autoimmune disease.

Pathophysiology

The pathophysiology of Buerger disease is not well understood. In the acute phase, occlusive thrombi develop in arteries and veins of distal extremities. Next, thrombi start to organize into larger vessels. Over time, inflammation resides but fibrosis and organized thrombi remain.

There is also evidence that dysfunction of the endothelial layer of the vessels occurs, as well as the possibility of issues with prothrombin.

Complications

- Gangrene
- Muscle atrophy
- Ulceration

Signs and Symptoms

Buerger disease typically produces intermittent claudication of the instep, which is aggravated by exercise and relieved by rest. During exposure to low temperature, the feet initially become cold, cyanotic, and numb; later, they redden, become hot, and tingle. Occasionally, Buerger disease also affects the hands, possibly resulting in painful fingertip ulcerations. Associated signs and symptoms may include impaired peripheral pulses, migratory superficial thrombophlebitis and, in later stages, ulceration, muscle atrophy, and gangrene.

Diagnosis

Patient history and physical examination strongly suggest Buerger disease. Supportive diagnostic tests include:

- Doppler ultrasonography to show diminished circulation in the peripheral vessels
- angiography or arteriography to locate lesions and rule out atherosclerosis.

Treatment

The primary goals of treatment are to relieve symptoms and prevent complications. Such therapy may include an exercise program that uses gravity to fill and drain the blood vessels or, in severe disease, a lumbar sympathectomy to increase blood supply to the skin. Aspirin and vasodilators may also be used. Amputation may be necessary for nonhealing ulcers, intractable pain, or gangrene.

Special Considerations

- Strongly urge the patient to stop smoking to enhance the treatment's effectiveness. Symptoms may disappear if the patient stops tobacco use. If necessary, refer the patient to a self-help group to stop smoking.
- Warn the patient to avoid precipitating factors, such as emotional stress, exposure to extreme temperatures, and trauma.
- Teach the patient proper foot care, especially the importance of wearing well-fitting shoes and cotton or wool socks. Show the patient how to inspect feet daily for cuts, abrasions, and signs of skin breakdown, such as redness and soreness. Remind the patient to seek medical attention at once after any trauma.
- If the patient has ulcers and gangrene, enforce bed rest and use a padded footboard or bed cradle to prevent pressure from bed linens. Protect the feet with soft padding. Wash them gently with a mild soap and tepid water, rinse thoroughly, and pat dry with a soft towel.
- Provide emotional support. If necessary, refer the patient for psychological counseling to help the patient cope with restrictions imposed by this chronic disease. If the patient has undergone amputation, assess rehabilitative needs, especially regarding changes in body image. Refer the patient to physical therapists, occupational therapists, and social service agencies, as needed.

PERIPHERAL ARTERY DISEASE

Causes and Incidence

PAD, referred to as *arterial occlusive disease,* is the obstruction or narrowing of the lumen of the aorta and its major branches, causing an interruption of blood flow, usually to the legs and feet. PAD may affect the carotid, vertebral, innominate, subclavian, mesenteric, and celiac arteries. Occlusions may be acute or chronic and commonly cause severe ischemia, skin ulceration, and gangrene.

The prognosis depends on the occlusion's location, the development of collateral circulation to counteract reduced blood flow, and, in acute disease, the time elapsed between occlusion and its removal.

Predisposing factors include smoking; aging; such conditions as hypertension, hyperlipidemia, and diabetes; and a family history of vascular disorders, MI, or stroke. PAD has no racial predilection. Men older than 50 are at increased risk for intermittent claudication, a common sign of PAD.

Pathophysiology

PAD is a common complication of atherosclerosis. The occlusive mechanism may be endogenous, due to emboli formation or thrombosis, or exogenous, due to trauma or fracture.

Complications

- Severe ischemia
- Skin ulceration
- Gangrene
- Limb loss

Signs and Symptoms

The signs and symptoms of PAD depend on the site of the occlusion. (See *Types of peripheral artery disease,* page 81.)

Types of Peripheral Artery Disease

Site of occlusion	Signs and symptoms
Carotid arterial system	
Internal carotids External carotids	• Absent or decreased pulsation with an auscultatory bruit over the affected vessels • Neurologic dysfunction: transient ischemic attacks (TIAs) due to reduced cerebral circulation producing unilateral sensory or motor dysfunction (transient monocular blindness, hemiparesis), possible aphasia or dysarthria, confusion, decreased mentation, and headache (These are recurrent features that usually last 5 to 10 minutes but may persist up to 24 hours and may herald a stroke)
Vertebrobasilar system	
Vertebral arteries Basilar arteries	• Neurologic dysfunction: TIAs of the brainstem and cerebellum producing binocular vision disturbances, vertigo, dysarthria, and "drop attacks" (falling down without loss of consciousness); less common than carotid TIA
Innominate	
Brachiocephalic artery	• Indications of ischemia (claudication) of the right arm • Neurologic dysfunction: signs and symptoms of vertebrobasilar occlusion • Possible bruit over the right side of the neck
Subclavian artery	
	• Clinical effects of vertebrobasilar occlusion and exercise-induced arm claudication • Subclavian steal syndrome (characterized by the backflow of blood from the brain through the vertebral artery on the same side as the occlusion, into the subclavian artery distal to the occlusion) • Possibly gangrene (usually limited to the digits)
Mesenteric artery	
Superior (most commonly affected) Celiac axis Inferior	• Bowel ischemia, infarct necrosis, and gangrene • Diarrhea • Leukocytosis • Nausea and vomiting • Shock due to massive intraluminal fluid and plasma loss • Sudden, acute abdominal pain
Aortic bifurcation	
(Saddle block occlusion, a medical emergency associated with cardiac embolization)	• Sensory and motor deficits (muscle weakness, numbness, paresthesias, and paralysis) in both legs • Signs of ischemia (sudden pain and cold, pale legs with decreased or absent peripheral pulses) in both legs
Iliac artery	
(Leriche syndrome)	• Absent or reduced femoral or distal pulses • Impotence • Intermittent claudication of the lower back, buttocks, and thighs, relieved by rest • Possible bruit over femoral arteries
Femoral and popliteal artery	
(Associated with aneurysm formation)	• Gangrene • Intermittent claudication of the calves on exertion • Ischemic pain in feet • Leg pallor and coolness; blanching of the feet on elevation • No palpable pulses in the ankles and feet • Pretrophic pain (heralds necrosis and ulceration)

Diagnosis

Diagnosis of PAD is usually indicated by patient history and physical examination. Pertinent supportive diagnostic tests include the following:

- Arteriography demonstrates the type (thrombus or embolus), location, and degree of obstruction and the collateral circulation. It's particularly useful in chronic disease or for evaluating candidates for reconstructive surgery.
- Doppler ultrasonography and plethysmography are noninvasive tests that show decreased blood flow distal to the occlusion in acute disease.
- EEG and computed tomography scan may be necessary to rule out brain lesions.
- Ankle-brachial indices compare the systolic blood pressures between the upper and lower extremities and have been shown to be sensitive in detecting PAD.

Treatment

Treatment depends on the obstruction's cause, location, and size. For mild chronic disease, supportive measures include elimination of smoking, hypertension control, and walking exercise. For carotid artery occlusion, antiplatelet therapy may begin with clopidogrel and aspirin. For intermittent claudication of chronic occlusive disease, cilostazol may improve blood flow through the capillaries, particularly for patients who are poor candidates for surgery. Statin medications are used frequently, as well, to lessen the progression of atherosclerosis.

Acute PAD usually requires surgery to restore circulation to the affected area, for example:

- Atherectomy—Excision of plaque using a drill or slicing mechanism.
- Balloon angioplasty—Compression of the obstruction using balloon inflation.
- Bypass graft—Blood flow is diverted through an anastomosed autogenous or Dacron graft past the thrombosed segment.
- Combined therapy—Concomitant use of any of the above treatments.
- Embolectomy—A balloon-tipped Fogarty catheter is used to remove thrombotic material from the artery. Embolectomy is used mainly for mesenteric, femoral, or popliteal artery occlusion.
- Laser angioplasty—Use of excision and hot-tipped lasers to vaporize the obstruction.
- Lumbar sympathectomy—An adjunct to surgery, depending on the sympathetic nervous system's condition.
- Patch grafting—Removal of the thrombosed arterial segment and replacement with an autogenous vein or Dacron graft.
- Stents—Insertion of a mesh of wires that stretch and mold to the arterial wall to prevent reocclusion. This follows laser angioplasty or atherectomy.
- Thromboendarterectomy—Opening of the occluded artery and direct removal of the obstructing thrombus and the medial layer of the arterial wall; usually performed after angiography and commonly used with autogenous vein or Dacron bypass surgery (femoral-popliteal or aortofemoral).
- Thrombolytic therapy—Lysis of any clot around or in the plaque by urokinase, streptokinase, or alteplase.

Amputation becomes necessary with failure of arterial reconstructive surgery or with the development of gangrene, persistent infection, or intractable pain.

Other therapy includes heparin to prevent emboli (for embolic occlusion) and bowel resection after restoration of blood flow (for mesenteric artery occlusion).

Special Considerations

◆ Provide comprehensive patient teaching, including proper foot care. Explain diagnostic tests and procedures. Advise the patient to stop smoking and to follow the prescribed medical regimen.

Preoperatively, during an acute episode:

◆ Assess the patient's circulatory status by checking for the most distal pulses and by inspecting skin color and temperature.
◆ Provide pain relief as needed.
◆ Administer heparin by continuous I.V. drip as ordered. Use an infusion monitor or pump to ensure the proper flow rate.
◆ Wrap the patient's affected foot in soft cotton batting, and reposition it frequently to prevent pressure on any one area. Strictly avoid elevating or applying heat to the affected leg.
◆ Watch for signs of fluid and electrolyte imbalance, and monitor intake and output for signs of renal failure (urine output <30 mL/hour).
◆ If the patient has carotid, innominate, vertebral, or subclavian artery occlusion, monitor for signs of stroke, such as numbness in an arm or leg and intermittent blindness.

Postoperatively:

◆ Monitor the patient's vital signs. Continuously assess circulatory function by inspecting skin color and temperature and by checking for distal pulses. In charting, compare earlier assessments and observations. Watch closely for signs of hemorrhage (tachycardia and hypotension) and check dressings for excessive bleeding.
◆ In carotid, innominate, vertebral, or subclavian artery occlusion, assess neurologic status frequently for changes in LOC or muscle strength and pupil size.
◆ In mesenteric artery occlusion, connect the NG tube to low intermittent suction. Monitor intake and output (low urine output may indicate damage to renal arteries during surgery). Check bowel sounds for return of peristalsis. Increasing abdominal distention and tenderness may indicate extension of bowel ischemia with resulting gangrene, necessitating further excision, or it may indicate peritonitis.
◆ In saddle block occlusion, check distal pulses for adequate circulation. Watch for signs of renal failure and mesenteric artery occlusion (severe abdominal pain), and for cardiac arrhythmias, which may precipitate embolus formation.
◆ In iliac artery occlusion, monitor urine output for signs of renal failure from decreased perfusion to the kidneys as a result of surgery. Provide meticulous catheter care.
◆ In both femoral and popliteal artery occlusions, assist with early ambulation, but discourage prolonged sitting.
◆ After amputation, check the patient's stump carefully for drainage; record the color and amount of damage, and the time. Elevate the stump as ordered, and administer adequate analgesic medication. Because phantom limb pain is common, explain this phenomenon to the patient.
◆ When preparing the patient for discharge, instruct the patient to watch for signs of recurrence (pain, pallor, numbness, paralysis, and absence of pulse) that can result from graft occlusion or occlusion at another site. Warn the patient against wearing constrictive clothing.

Respiratory Disorders

Introduction

The respiratory system distributes air to the alveoli, where gas exchange—the addition of oxygen (O_2) and the removal of carbon dioxide (CO_2) from pulmonary capillary blood—takes place. Certain specialized structures within this system play a vital role in preparing air for use by the body. The nose, for example, contains vestibular hairs that filter the air and an extensive vascular network that warms it. The nose also contains a layer of goblet cells and a moist mucosal surface; water vapor enters the airstream from this mucosal surface to saturate inspired air as it's warmed in the upper airways. Ciliated mucosa in the posterior portion of the nose and nasopharynx as well as major portions of the tracheobronchial tree propel particles deposited by impaction or gravity to the oropharynx, where the particles are swallowed.

EXTERNAL RESPIRATION

The external component of respiration—ventilation or breathing—delivers inspired air to the lower respiratory tract and alveoli. Contraction and relaxation of the respiratory muscles move air into and out of the lungs. Ventilation begins with the contraction of the inspiratory muscles: the diaphragm (the major muscle of respiration) descends, while external intercostal muscles move the rib cage upward and outward.

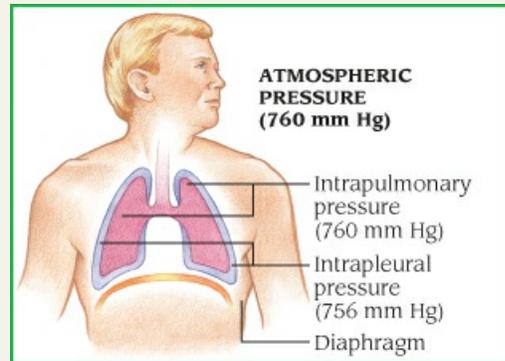
Air then enters the lungs in response to the pressure gradient between the atmosphere and the lungs. The lungs adhere to the chest wall and diaphragm because of the vacuum created within the pleural space. As the thorax expands, negative pressure is created in the intrapleural space, causing the lungs to also expand and draw in the warmed, humidified air. The accessory muscles of inspiration, which include the scalene and sternocleidomastoid muscles, raise the clavicles, upper ribs, and sternum. The accessory muscles aren't used in normal inspiration but may be used in some pathologic conditions.

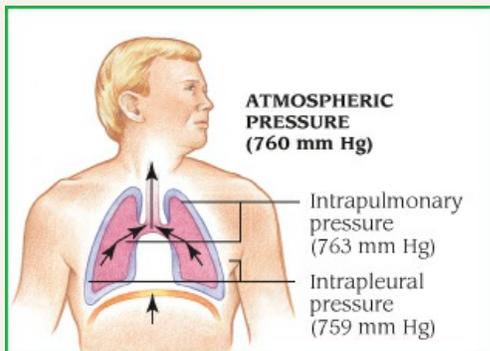
Normal expiration is passive; the inspiratory muscles cease to contract, the diaphragm rises, and the elastic recoil of the lungs causes the lungs to contract. These actions raise the pressure within the lungs above atmospheric pressure, moving air from the lungs to the atmosphere. Active expiration causes pleural pressure to become less negative. (See *Mechanics of ventilation*, page 87.)

Mechanics of Ventilation

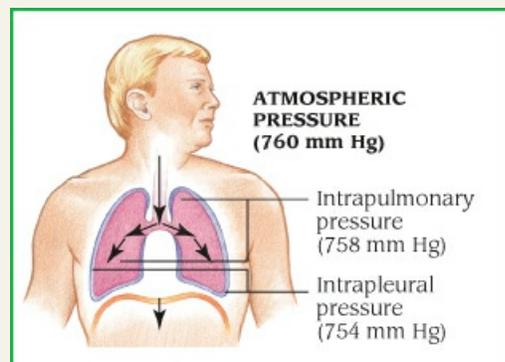
Breathing results from differences between atmospheric and intrapulmonary pressures, as described below.

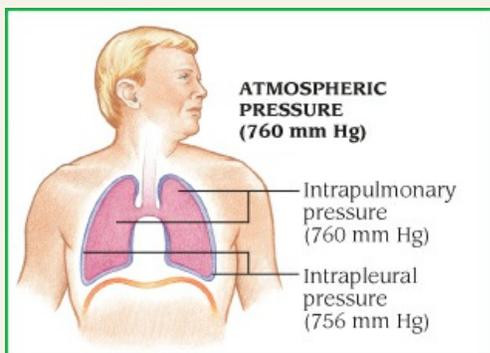
Before inspiration, intrapulmonary pressure equals atmospheric pressure (~760 mm Hg). Intrapleural pressure is 756 mm Hg.

The intrapulmonary atmospheric pressure gradient pulls air into the lungs until the two pressures are equal.




During inspiration, the diaphragm and external intercostal muscles contract, enlarging the thorax vertically and horizontally. As the thorax expands, intrapleural pressure decreases and the lungs expand to fill the enlarging thoracic cavity.

During normal expiration, the diaphragm slowly relaxes and the lungs and thorax passively return to resting size and position. During deep or forced expiration, contraction of internal intercostal and abdominal muscles reduces thoracic volume. Lung and thorax compression raises intrapulmonary pressure above atmospheric pressure.




An adult lung contains an estimated 300 million alveoli; each alveolus is supplied by many capillaries. To reach the capillary lumen, O_2 must cross the alveolocapillary membrane, which consists of an alveolar epithelial cell, a thin interstitial space, the capillary basement membrane, and the capillary endothelial cell membrane. The O_2 tension of air entering the respiratory tract is

approximately 150 mm Hg. In the alveoli, inspired air mixes with CO_2 and water vapor, lowering the O_2 pressure to approximately 100 mm Hg. Because alveolar partial pressure of O_2 is higher than that present in mixed venous blood entering the pulmonary capillaries (~40 mm Hg), O_2 diffuses across the alveolocapillary membrane into the blood.

O_2 AND CO_2 TRANSPORT AND INTERNAL RESPIRATION

Circulating blood delivers O_2 to the cells of the body for metabolism and transports metabolic wastes and CO_2 from the tissues back to the lungs. When oxygenated arterial blood reaches tissue capillaries, O_2 diffuses from the blood into the cells because of the O_2 tension gradient. The amount of O_2 available is determined by the concentration of hemoglobin (Hb; the principal carrier of O_2), the percentage of O_2 saturation of the Hb, regional blood flow, arterial O_2 content, and cardiac output.

Internal (cellular) respiration occurs as a part of cellular metabolism, which can take place with O_2 (aerobic) or without O_2 (anaerobic). The most efficient method for providing fuel (high-energy compounds such as adenosine triphosphate [ATP]) for cellular reactions is aerobic metabolism, which produces CO_2 and water in addition to ATP. Anaerobic metabolism is less efficient because a cell produces only a limited amount of ATP and yields lactic acid as well as CO_2 as a metabolic by-product.

Because circulation is continuous, CO_2 doesn't normally accumulate in tissues. CO_2 produced during cellular respiration diffuses from tissues into regional capillaries and is transported by systemic venous circulation. When CO_2 reaches the alveolar capillaries, it diffuses into the alveoli, where the partial pressure of CO_2 is lower; CO_2 is removed from the alveoli during exhalation.

MECHANISMS OF CONTROL

The central nervous system's (CNS) control of respiration lies in the respiratory center, located in the lateral medulla oblongata of the brainstem. Impulses travel down the phrenic nerves to the diaphragm, and down the intercostal nerves to the intercostal muscles, where the impulses change the rate and depth of respiration. The inspiratory and expiratory centers, located in the posterior medulla, establish the involuntary rhythm of the breathing pattern.

Apneustic and pneumotaxic centers in the pons influence the pattern of breathing. Stimulation of the lower pontine apneustic center (e.g., by trauma, tumor, or stroke) produces forceful inspiratory gasps alternating with weak expiration. The apneustic center continually excites the medullary inspiratory center and thus facilitates inspiration. Signals from the pneumotaxic center as well as afferent impulses from the vagus nerve inhibit the apneustic center and "turn off" inspiration. The apneustic pattern doesn't occur if the vagus nerves are intact.

Partial pressure of arterial oxygen (Pa_{O_2}), pH, and pH of cerebrospinal fluid (CSF) influence output from the respiratory center. When CO_2 enters the CSF, the pH of CSF falls, stimulating central chemoreceptors to increase ventilation.

The respiratory center also receives information from peripheral chemoreceptors in the carotid and aortic bodies. These chemoreceptors respond primarily to decreased Pa_{O_2} but also to decreased pH. The peripheral chemoreceptors have little control over respirations until the Pa_{O_2} is less than 60 mm Hg.

During exercise, stretch receptors in lung tissue and the diaphragm prevent overexpansion of

the lungs. During swallowing, the cortex can interrupt automatic control of ventilation. During sleep, respiratory drive may fluctuate, producing hypoventilation and periods of apnea. External sensations, drugs, chronic hypercapnia, and changes in body temperature can also alter the respiratory pattern.

DIAGNOSTIC TESTS

Diagnostic tests evaluate physiologic characteristics and pathologic states within the respiratory tract.

Noninvasive tests include:

- Chest X-ray shows such conditions as atelectasis, pleural effusion, infiltrates, pneumothorax, lesions, mediastinal shifts, pulmonary edema, and chronic obstructive pulmonary disease (COPD).
- Computed tomography (or CT) scan provides a three-dimensional picture that's 100 times more sensitive than a chest X-ray.
- Magnetic resonance imaging identifies obstructed arteries and tissue perfusion, but movement of the heart and lungs reduces the image's clarity.
- Sputum specimen analysis assesses sputum quantity, color, viscosity, and odor; microbiological stains and culture of sputum can identify infectious organisms; and cytologic preparations can detect respiratory tract neoplasms. Sensitivity tests determine antibiotic sensitivity and resistance.
- Pulmonary function tests (or PFTs) measure lung volume, flow rates, and compliance. Normal values, individualized by body stature, ethnicity, and age, are reported in percentage of the normal predicted value. Static measurements are volume measurements that include tidal volume, volume of air contained in a normal breath; functional residual capacity, volume of air remaining in the lungs after normal expiration; vital capacity, volume of air that can be exhaled after maximal inspiration; residual volume, air remaining in the lungs after maximal expiration; and total lung capacity (TLC), volume of air in the lungs after maximal inspiration. Dynamic measurements characterize the movement of air into and out of the lungs and show changes in lung mechanics. They include measurement of forced expiratory volume in 1 second (FEV_1), maximum volume of air that can be expired in 1 second from TLC; maximal voluntary ventilation, volume of air that can be expired in 1 minute with the patient's maximum voluntary effort; and forced vital capacity (FVC), maximal volume of air that the patient can exhale from TLC. (Peak flow rate, which can be obtained at the bedside, is also a dynamic measurement of pulmonary function.)
- Methacholine challenge is one method of assessing airway responsiveness and is used to determine a diagnosis of asthma.
- Exercise stress test evaluates the ability to transport O_2 and remove CO_2 with increasing metabolic demands.
- Polysomnography can diagnose sleep disorders.
- Lung scan (ventilation–perfusion or scintiphotography scan) demonstrates ventilation and perfusion patterns. It's used primarily to evaluate pulmonary embolus.
- Arterial blood gas (ABG) analysis assesses gas exchange. Decreased Pa_{O_2} may indicate hypoventilation, ventilation–perfusion mismatch, or shunting of blood away from gas exchange sites. Increased partial pressure of arterial carbon dioxide (Pa_{CO_2}) reflects marked ventilation–perfusion mismatch or hypoventilation; decreased Pa_{CO_2} reflects increased

alveolar ventilation. Changes in pH may reflect metabolic or respiratory dysfunction.

◆ Pulse oximetry is a noninvasive assessment of arterial oxygen saturation.
◆ Capnography may be used either transcutaneously or in ventilator circuit to determine Pa_{CO_2} trends.

Invasive tests include:

◆ Bronchoscopy permits direct visualization of the trachea and mainstem, lobar, segmental, and subsegmental bronchi. It may be used to localize the site of lung hemorrhage, visualize masses in these airways, and collect respiratory tract secretions. Brush biopsy may be used to obtain specimens from the lungs for microbiological stains, culture, and cytology. Lesion biopsies may be performed by using small forceps under direct visualization (when present in the proximal airways) or with the aid of fluoroscopy (when present distal to regions of direct visualization). Bronchoscopy can also be used to clear secretions and remove foreign bodies.
◆ Thoracentesis permits removal of pleural fluid for analysis.
◆ Pleural biopsy obtains pleural tissue for histologic examination and culture.
◆ Pulmonary artery angiography, the injection of dye into the pulmonary artery, can locate pulmonary embolism. This is considered the gold standard for diagnosing pulmonary emboli.
◆ Positron emission tomography scan uses a short-life radionuclide. Increased uptake of the substance is seen in malignant cells.

ASSESSMENT

Assessment of the respiratory system begins with a thorough patient history. Ask the patient to describe his or her respiratory problem. How long has he or she had it? How long does each attack last? Does one attack differ from another? Does any activity in particular bring on an attack or make it worse? What relieves the symptoms? Always ask whether the patient was or is a smoker, what and how often he or she smoked or smokes, and how long he or she smoked or has been smoking. Record this information in *pack years*—the number of packs of cigarettes per day multiplied by the number of smoking years. Remember to ask about the patient's occupation, hobbies, and travel; some of these activities may involve exposure to toxic or allergenic substances.

If the patient has dyspnea, ask if it occurs during activity or at rest. What position is the patient in when dyspnea occurs? How far can he or she walk? How many flights of stairs can he or she climb? Has his or her exercise tolerance been decreasing? Can he or she relate dyspnea to allergies or environmental conditions? Does it occur only at night, during sleep? If the patient has a cough, ask about its severity, persistence, and duration; ask if it produces sputum and, if so, how much and what kind. Have the patient's cough habits and character of sputum changed recently?

PHYSICAL EXAMINATION

Use inspection skills to check for clues to respiratory disease, beginning with the patient's general appearance. If he or she is frail or cachectic, he or she may have a chronic disease that has impaired his or her appetite. If he or she is diaphoretic, restless, or irritable or protective of a painful body part, he or she may be in acute distress. Also, look for behavior changes that may indicate hypoxemia or hypercapnia. Confusion, lethargy, bizarre behavior, or quiet sleep from which the patient can't be aroused may point to hypercapnia. Watch for marked cyanosis, indicated by bluish or ashen skin (usually best seen on the lips, tongue, earlobes, and nail beds),

which may be due to hypoxemia or poor tissue perfusion.

Assess chest shape and symmetry at rest and during ventilation. Increased anteroposterior diameter ("barrel chest") characterizes emphysema. Kyphoscoliosis also alters chest configuration, which in turn restricts breathing. Assess respiratory excursion and observe for accessory muscle use during breathing. The use of upper chest and neck muscles is normal only during physical stress.

Observe the rate and pattern of breathing because certain disorders produce characteristic changes in breathing patterns. For example, an acute respiratory disorder can produce tachypnea (rapid, shallow breathing) or hyperpnea (increased rate and depth of breathing); intracranial lesions can produce Cheyne–Stokes and Biot's respirations; increased intracranial pressure can result in central hyperventilation and apneustic or ataxic breathing; metabolic disorders can cause Kussmaul's respirations; and airway obstruction can lead to prolonged forceful expiration and pursed-lip breathing.

Also observe posture and carriage. A patient with COPD, for example, usually supports rib cage movement by placing his or her arms on the sides of a chair to increase expansion and lean forward during exhalation to help expel air.

Palpation of the chest wall detects areas of tenderness, masses, changes in fremitus (palpable vocal vibrations), or crepitus (air in subcutaneous tissues). To assess chest excursion and symmetry, place your hands in a horizontal position, bilaterally on the posterior chest, with your thumbs pressed lightly against the spine, creating folds in the skin. As the patient takes a deep breath, your thumbs should move quickly and equally away from the spine. Repeat this with your hands placed anteriorly, at the costal margins (lower lobes) and clavicles (apices). Unequal movement indicates differences in expansion, seen in atelectasis, diaphragm or chest wall muscle disease, or splinting due to pain.

Percussion should detect resonance over lung fields that aren't covered by bony structures or the heart. A dull sound on percussion may mean consolidation or pleural disease. (See *Characterizing and interpreting percussion sounds*.)

Characterizing and Interpreting Percussion Sounds

Percussion may produce several kinds of sounds. Known as flat, dull, resonant, hyperresonant, or tympanic, these sounds indicate the location and density of various structures. During percussion, determining other tonal characteristics, such as pitch, intensity, and quality, also will help identify respiratory structure. Use this chart as a guide to interpreting percussion sounds.

Characteristic

Sound	Pitch	Intensity	Quality	Implications
Flatness	High	Soft	Extremely dull	These sounds are normal over the sternum. Over the lung, they may indicate atelectasis or pleural effusion.
Dullness	Medium	Medium	Thudlike	Normal over the liver, heart, and diaphragm, these sounds over the lung may point to pneumonia, tumor, atelectasis, or pleural effusion.
Resonance	Low	Moderate to loud	Hollow	When percussed over the lung, these sounds are normal.
Hyperresonance	Lower	Very loud	Booming	These are normal findings with percussion over a child's lung.

	than resonance			Over an adult's lung, these findings may indicate emphysema, chronic bronchitis, asthma, or pneumothorax.
Tympany	High	Loud	Musical, drumlike	Over the stomach, these are normal findings; over the lung, they suggest tension pneumothorax.

Auscultation normally detects soft, vesicular breath sounds throughout most of the lung fields. Absent or adventitious breath sounds may indicate fluid in small airways or interstitial lung disease (crackles), secretions in moderate and large airways (rhonchi), and airflow obstruction (wheezes).

SPECIAL RESPIRATORY CARE

The hospitalized patient with respiratory disease may require an artificial upper airway, chest tubes, chest physiotherapy, and supervision of mechanical ventilation. In cardiopulmonary arrest, establishing an airway always takes precedence. In a patient with this condition, airway obstruction usually results when the tongue slides back and blocks the posterior pharynx. The head-tilt method or, in suspected or confirmed cervical fracture or arthritis, the jaw-thrust maneuver can immediately push the tongue forward, relieving such obstruction. Endotracheal (ET) intubation and, sometimes, a tracheotomy may be necessary.

CHEST TUBES

An important procedure in patients with respiratory disease is chest tube drainage, which removes air or fluid from the pleural space. This allows the collapsed lung to re-expand to fill the evacuated pleural space. Chest drainage also allows removal of pleural fluid for culture. Chest tubes are commonly used after thoracic surgery, penetrating chest wounds, pleural effusion, and empyema. They're also used for evacuation of pneumothorax, hydrothorax, or hemothorax. Sometimes chest tubes are used to instill sclerosing drugs into the pleural space to prevent recurrent malignant pleural effusions.

Commonly, the chest tube is placed in the sixth or seventh intercostal space, in the axillary region. Occasionally, in pneumothorax, the tube is placed in the second or third intercostal space, in the midclavicular region.

Follow these guidelines when caring for a patient with a chest tube:

◆ Monitor changes in suction pressure.
◆ Make sure that all connections in the system are tight and secured with tape.
◆ Never clamp the chest tube unless checking for air leaks or changing the drainage system.
◆ Record the amount, color, and consistency of drainage. Watch for signs of shock, such as tachycardia and hypotension, if drainage is excessive.
◆ Encourage the patient to cough and breathe deeply every hour to enhance lung expansion.

Additionally, if a water seal–wet suction system is in place:

◆ Check for fluctuation in the water-seal chamber as the patient breathes. Normal fluctuations of 2″ to 4″ (about 5 to 10 cm) reflect pressure changes in the pleural space during respiration.
◆ Watch for intermittent bubbling in the water-seal chamber. This bubbling occurs normally when the system is removing air from the pleural cavity. Absence of bubbling indicates that the pleural space has sealed.
◆ Check the water level in the suction-control chamber. If necessary, add sterile water to bring the level to the ordered level.

- Check for gentle bubbling in the suction-control chamber, which indicates that the proper suction level has been reached.

If a dry-suction system is in place, check that the rotary dry-suction control dial is turned to the ordered suction mark and verify that the appropriate indicator is present, indicating that the desired amount of suction is applied.

VENTILATOR METHODS

Mechanical ventilators are typically used for CNS problems, hypoxemia, or failure of the normal bellows action provided by the diaphragm and rib cage. Positive-pressure ventilators cause inspiration while increasing tidal volume (V_T). The inspiratory cycles of these ventilators may vary in volume, pressure, time, or frequency. For example, a volume-cycled ventilator—the type most commonly used—delivers a preset volume of air each time, regardless of the amount of lung resistance. A pressure-cycled ventilator generates flow until the machine reaches a preset pressure regardless of the volume delivered or the time required to achieve the pressure. A time-cycled ventilator generates flow for a preset amount of time. A high-frequency ventilator uses high respiratory rates and low V_T to maintain alveolar ventilation. Positive end-expiratory pressure (PEEP) is used to retain a certain amount of pressure in the lungs at the end of expiration. By keeping small airways and alveoli open with this method, functional residual capacity is increased and oxygenation is improved.

Implement strategies to prevent ventilator-associated pneumonia (VAP) and plan to remove the patient from ventilator support as soon as the cause of respiratory failure has resolved. (See *Preventing ventilator-associated pneumonia,* page 92.) Several weaning methods are used. The patient may be taken off the ventilator and supplied with a T-piece (ET tube O_2 adapter) that provides O_2 and humidification. The patient then breathes spontaneously without the ventilator for gradually increasing periods.

PREVENTION
PREVENTING VENTILATOR-ASSOCIATED PNEUMONIA

Ventilator-associated pneumonia (VAP) is the leading cause of death among all hospital-acquired infections. VAP also prolongs time spent on the ventilator, length of critical care unit (CCU) stay, and length of hospital stay after discharge from the CCU. Research has shown that the mortality rate due to VAP can be reduced by early recognition of pneumonia and consistent application of evidence-based practices. The Ventilator Bundle is a group of interventions related to ventilator care that, when implemented together, achieve significantly better outcomes than when implemented individually. The key components of the Ventilator Bundle include:

- elevating the head of the bed 30 to 45 degrees
- interrupting sedation daily and assessing the readiness to extubate
- instituting peptic ulcer disease prophylaxis
- instituting deep vein thrombosis prophylaxis
- providing daily oral care with chlorhexidine

Various other best practices can be combined with the bundle to prevent VAP. They

include:

- adhering to Centers for Disease Control and Prevention or World Health Organization hand hygiene guidelines to prevent the spread of infection
- using noninvasive ventilatory support, such as bilevel positive-airway ventilation instead of endotracheal (ET) intubation and mechanical ventilation, to eliminate the risk of VAP
- using the oral route instead of the nasal route for ET intubation to prevent sinusitis
- maintaining ET tube cuff pressure at 20 cm or more to prevent aspiration
- using a cuffed ET tube with in-line and subglottic suctioning to prevent secretion aspiration
- avoiding gastric distention to reduce the risk for aspiration
- avoiding unexplained extubation and reintubation to prevent secretion aspiration
- minimizing equipment contamination (by removing condensate from ventilator circuits, keeping the circuit closed during removal, changing the ventilator circuit only when visibly soiled or malfunctioning, and disinfecting and storing respiratory equipment properly) to prevent airway contamination
- teaching the patient and family about measures to prevent VAP and involving them in monitoring

With intermittent mandatory ventilation, the ventilator provides a specific number of breaths, and the patient is able to breathe spontaneously between ventilator breaths. The frequency of ventilator breaths is gradually decreased until the patient can breathe on his or her own. Pressure support ventilation, in which the patient receives a preset pressure boost with each spontaneous breath, has proved effective. Vital signs, ABG levels, physical findings, and subjective symptoms should be monitored periodically during weaning to assess respiratory status.

Chest Physiotherapy

In respiratory conditions marked by excessive accumulation of secretions in the lungs, chest physiotherapy may enhance removal of secretions. Chest physiotherapy includes chest assessment, effective breathing and coughing exercises, postural drainage, percussion, vibration, and evaluation of the therapy's effectiveness. Before initiating treatment, review X-rays and physical assessment findings to locate areas of secretions.

- Deep breathing maintains diaphragm use, increases negative intrathoracic pressure, and promotes venous return; it's especially important when pain or dressings restrict chest movement. An incentive spirometer can provide positive visual reinforcement to promote deep breathing.
- Pursed-lip breathing is used primarily in obstructive disease to slow expiration and prevent small airway collapse. Such breathing slows air through smaller bronchi, maintaining positive pressure and preventing collapse of small airways and resultant air trapping.
- Segmental breathing or lateral costal breathing is used after lung resection and for localized disorders. Place your hand over the lung area on the affected side. Instruct the patient to try to push that portion of the chest against your hand on deep inspiration. You should be able to feel this with your hand.
- Coughing that's controlled and staged gradually increases intrathoracic pressure, reducing pain and bronchospasm of explosive coughing. When wound pain prevents effective

coughing, splint the wound with a pillow, towel, or your hand during coughing exercises.

- ◆ Postural drainage uses gravity to drain secretions into larger airways, where they can be expectorated. This technique is used in the patient with copious or tenacious secretions. Before performing postural drainage, auscultate the patient's chest and review chest X-rays to determine the best position for maximum drainage. To prevent vomiting, schedule postural drainage at least 1 hour after meals.
- ◆ Percussion moves air against the chest wall, enhancing the effectiveness of postural drainage by loosening lung secretions. Percussion is contraindicated in severe pain, extreme obesity, cancer that has metastasized to the ribs, crushing chest injuries, bleeding disorders, spontaneous pneumothorax, spinal compression fractures, and in patients with temporary pacemakers.
- ◆ Vibration can be used with percussion or alone when percussion is contraindicated.
- ◆ PEEP therapy maintains positive pressure in airways, preventing small airway collapse.

Before and after chest physiotherapy, auscultate the patient's lung fields and assess for sputum production to evaluate the effectiveness of therapy.

Congenital and Pediatric Disorders

RESPIRATORY DISTRESS SYNDROME

Respiratory distress syndrome (RDS), also called *hyaline membrane disease*, is the most common cause of neonatal mortality. In the United States alone, it kills 40,000 neonates every year. RDS occurs in premature neonates and, if untreated, is fatal within 72 hours of birth in up to 14% of neonates weighing less than 5½ lb (2.5 kg). Aggressive management using mechanical ventilation can improve the prognosis, but some surviving neonates may develop some degree of bronchopulmonary dysplasia (BPD).

Causes and Incidence

Although airways and alveoli of a neonate's respiratory system are present by 27 weeks' gestation, the intercostal muscles are weak, and the alveolar capillary system is immature. The preterm neonate with RDS develops widespread alveolar collapse because of a lack of surfactant, a lipoprotein present in alveoli and respiratory bronchioles. The surfactant lowers surface tension and helps prevent alveolar collapse. This surfactant deficiency results in widespread atelectasis, which leads to inadequate alveolar ventilation with shunting of blood through collapsed areas of lung, causing hypoxemia and acidosis.

RDS occurs almost exclusively in neonates born before 37 weeks' gestation (in 60% of those born before the 28th week). The incidence is greatest in those with birth weights of 1,000 to 1,500 g. Infants of diabetic mothers, those born by cesarean delivery, second-born twins, infants with perinatal asphyxia, and those delivered suddenly after antepartum hemorrhage are more commonly affected.

Pathophysiology

The lack of surfactant coating the alveoli reduces the available pulmonary surface and decreases the area for gas exchange. Worsening hypercapnia and hypoxia cause metabolic and respiratory acidosis leading to pulmonary vasoconstriction and peripheral vasodilation. Damage to the

endothelial and alveolar cells results from the ongoing hypoxia. The subsequent vascular disruption leads to plasma leakage into the alveolar spaces, layering of fibrin and necrotic cells creating hyaline membranes. These membranes impede the exchange of gases across the alveolar surface.

Complications

- Pneumothorax
- Pneumomediastinum
- Pneumopericardium
- BPD
- Intraventricular bleed
- Hemorrhage into lungs after surfactant use
- Retinopathy of prematurity (or ROP)
- Delayed mental development or mental retardation

Signs and Symptoms

Although a neonate with RDS may breathe normally at first, they usually develop rapid, shallow respirations within minutes or hours of birth, with intercostal, subcostal, or sternal retractions; nasal flaring; and audible expiratory grunting. This grunting is a natural compensatory mechanism designed to produce PEEP and prevent further alveolar collapse.

Severe disease is marked by apnea, bradycardia, and cyanosis (from hypoxemia, left-to-right shunting through the foramen ovale, or right-to-left intrapulmonary shunting through atelectatic regions of the lung). Other clinical features include pallor, frothy sputum, and low body temperature as a result of an immature nervous system and the absence of subcutaneous fat.

Diagnosis

CONFIRMING DIAGNOSIS *Signs of respiratory distress in a premature neonate during the first few hours of life strongly suggest RDS, but a chest X-ray and ABG analysis are needed to confirm the diagnosis.*

- Chest X-ray may be normal for the first 6 to 12 hours (in 50% of neonates with RDS), but 24 hours after birth it will show the characteristic ground-glass appearance and air bronchograms.
- ABG analysis shows decreased Pa_{O_2}; normal, decreased, or increased Pa_{CO_2}; and decreased pH (from respiratory or metabolic acidosis or both).
- Chest auscultation reveals normal or diminished air entry and crackles (rare in early stages).

When a cesarean birth is necessary before 36 weeks' gestation, amniocentesis enables the determination of the lecithin/sphingomyelin (L/S) ratio and the presence of phosphatidylglycerol. An L/S ratio of more than 2:1 and the presence of phosphatidylglycerol decrease the likelihood of RDS.

Treatment

Treatment of an infant with RDS requires vigorous respiratory support. Warm, humidified, oxygen-enriched gases are administered by oxygen hood or, if such treatment fails, by mechanical ventilation. Severe cases may require mechanical ventilation with PEEP or

continuous positive-airway pressure (CPAP), administered by nasal prongs or, when necessary, ET intubation. Special ventilation techniques are now used on the patient's refractory to conventional mechanical ventilation. These include high-frequency jet ventilation and high-frequency oscillatory ventilation. Extracorporeal membrane oxygenation is the last choice for ventilation and is only available in certain specialized facilities. Treatment of RDS also includes:

- a radiant warmer or isolette for thermoregulation
- I.V. fluids and sodium bicarbonate to control acidosis and maintain fluid and electrolyte balance
- tube feedings or total parenteral nutrition if the neonate is too weak to eat
- administration of surfactant by an ET tube (Studies show that this treatment can prevent or improve the course of RDS as well as reduce mortality.)

Special Considerations

- Neonates with RDS require continual assessment and monitoring in an intensive care nursery.
- Closely monitor ABGs as well as fluid intake and output. If the neonate has an umbilical catheter (arterial or venous), check for arterial hypotension or abnormal central venous pressure. Watch for complications, such as infection, thrombosis, or decreased circulation to the legs. If the neonate has a transcutaneous oxygen monitor, change the site of the lead placement every 2 to 4 hours.
- To evaluate progress, assess skin color, rate and depth of respirations, severity of retractions, nostril flaring, frequency of expiratory grunting, frothing at the lips, and restlessness.
- Regularly assess the effectiveness of oxygen or ventilator therapy. Evaluate every change in fraction of inspired oxygen and PEEP or CPAP by monitoring arterial oxygen saturation or ABG levels. Adjust the PEEP or CPAP as indicated, on the basis of findings.
- Mechanical ventilation in neonates is usually done in a pressure-limited mode rather than in the volume-limited mode used in adults.
- When the neonate is on mechanical ventilation, watch carefully for signs of barotrauma (an increase in respiratory distress and subcutaneous emphysema) and accidental disconnection from the ventilator. Check ventilator settings frequently. Be alert for signs of complications of PEEP or CPAP therapy, such as decreased cardiac output, pneumothorax, and pneumomediastinum. Mechanical ventilation increases the risk of infection in the preterm neonate, so preventive measures are essential.
- As needed, arrange for follow-up care with a neonatal ophthalmologist to check for retinal damage. Preterm neonates in an oxygen-rich environment are at increased risk for developing ROP.
- Teach the parents about their neonate's condition and, if possible, let them participate in their care (using sterile technique), to encourage normal parent–infant bonding. Advise parents that full recovery may take up to 12 months. When the prognosis is poor, prepare the parents for the neonate's impending death and offer emotional support.
- Help reduce mortality in the neonate with RDS by detecting respiratory distress early. Recognize intercostal retractions and grunting, especially in a premature neonate, as signs of RDS; make sure the neonate receives immediate treatment.

PREVENTION

- *Prenatal care can help prevent prematurity.*
- *Give corticosteroids to the mother 2 to 3 days before delivery to help the infant's lungs mature in preterm deliveries.*

SUDDEN INFANT DEATH SYNDROME

A medical mystery of early infancy, sudden infant death syndrome (SIDS), also called *crib death*, is the unexpected, sudden death of an infant or child younger than age 1 year. Reasons for the death remain unexplained even after an autopsy. Typically, parents put the infant to bed and later find him or her dead, commonly with no indications of a struggle or distress of any kind. Incidence has decreased with the practice of teaching parents to place an infant on their back to sleep.

Causes and Incidence

SIDS is the third leading cause of death in infants between 1 month and 1 year old. It occurs more commonly in winter months. The incidence is higher in males, preterm neonates, and those who sleep on their stomachs or in cribs with soft bedding. Incidence is also higher among neonates born in conditions of poverty and to those who were one of a single multiple birth, such as twins and triplets, and to mothers who smoke, take drugs, or failed to seek prenatal care until late in the pregnancy. SIDS may also result from an abnormality in the control of ventilation that allows CO_2 to build up in the blood, thereby causing prolonged apneic periods with profound hypoxemia and serious cardiac arrhythmias. It's also thought to be associated with problems in sleep arousal.

Pathophysiology

Although the exact pathophysiology of SIDS is not known, there is a common theory. Abnormalities of the autoimmune nervous system and brainstem cause dysfunctions of breathing. Episodes of hypoxia contribute to delaying the arousal response when oxygen availability is decreased and potentially leading to death.

Signs and Symptoms

Although parents find some victims wedged in crib corners or with blankets wrapped around their heads, autopsies rule out suffocation as the cause of death. Autopsy shows a patent airway, so aspiration of vomitus isn't the cause of death. Typically, SIDS babies don't cry out and show no signs of having been disturbed in their sleep. However, their positions or tangled blankets may suggest movement just before death, perhaps due to terminal spasm.

Depending on how long the infant has been dead, a SIDS baby may have a mottled complexion with extreme cyanosis of the lips and fingertips or pooling of blood in the legs and feet that may be mistaken for bruises. Pulse and respirations are absent, and the diaper is wet and full of stool.

Diagnosis

Diagnosis of SIDS requires an autopsy to rule out other causes of death. Characteristic histologic findings on autopsy include small or normal adrenal glands and petechiae over the visceral surfaces of the pleura, within the thymus, and in the epicardium. Autopsy also reveals extremely well-preserved lymphoid structures and certain pathologic characteristics that suggest chronic hypoxemia such as increased pulmonary artery smooth muscle. Examination also shows

edematous, congestive lungs fully expanded in the pleural cavities, liquid (not clotted) blood in the heart, and curd from the stomach inside the trachea.

Treatment

If the parents bring the infant to the emergency department (ED), the physician will decide whether to try to resuscitate him. An "aborted SIDS" infant is one who's found apneic and is successfully resuscitated. Such an infant, or any infant who had a sibling stricken by SIDS, should be tested for infantile apnea. If tests are positive, a home apnea monitor may be recommended. Because the infant usually can't be resuscitated, however, treatment focuses on providing emotional support for the family.

Special Considerations

- Make sure that parents are present when the child's death is announced. They may lash out at ED personnel, the babysitter, or anyone else involved in the child's care—even each other. Stay calm and let them express their feelings. Reassure them that they weren't to blame.
- Let the parents see the baby in a private room. Allow them to express their grief in their own way. Stay in the room with them if appropriate. Offer to call clergy, friends, or relatives.
- After the parents and family have recovered from their initial shock, explain the necessity for an autopsy to confirm the diagnosis of SIDS (in some states, this is mandatory). At this time, provide the family with some basic facts about SIDS and encourage them to give their consent for the autopsy. Make sure that they receive the autopsy report promptly.
- Find out whether your community has a local counseling and information program for SIDS parents. Participants in such a program will contact the parents, ensure that they receive the autopsy report promptly, put them in touch with a professional counselor, and maintain supportive telephone contact. Also, find out whether there's a local SIDS parent group; such a group can provide significant emotional support. Contact the National Sudden Infant Death Foundation for information about such local groups.
- If your facility's policy is to assign a public health nurse to the family, they will provide the continuing reassurance and assistance the parents will need.
- If the parents decide to have another child, they'll need information and counseling to help them through the pregnancy and the first year of the new infant's life.
- Infants at high risk for SIDS may be placed on apnea monitoring at home.
- All new parents should be informed of the American Academy of Pediatrics' recommendation that infants be positioned on their back, not on their stomach or side, for sleeping.

PREVENTION

- *Tell parents to place infants on their backs to sleep.*
- *Tell parents infants should sleep on a firm mattress and shouldn't have soft objects in the crib; like stuffed toys and blankets.*
- *Tell parents infants shouldn't sleep in the same bed as their parents.*
- *Tell parents to give infants pacifiers at bedtime.*
- *Tell parents infants shouldn't be exposed to secondhand smoke.*

CROUP

Croup is a severe inflammation and obstruction of the upper airway, occurring as acute

laryngotracheobronchitis (most common), laryngitis, and acute spasmodic laryngitis; it must always be distinguished from epiglottitis. It's derived from an old German word for "voice box" and refers to swelling around the larynx or vocal cords. Recovery is usually complete.

Causes and Incidence

Croup usually results from a viral infection but can also be caused by bacteria, allergens, and inhaled irritants. Parainfluenza viruses cause 75% of such infections; adenoviruses, respiratory syncytial virus (RSV), influenza, and measles viruses account for the rest.

Croup is a childhood disease affecting more boys than girls (typically between 3 months and 5 years old) that usually occurs during the winter. Up to 15% of patients have a strong family history of croup.

Pathophysiology

Infection of the laryngeal mucosa leads to edema and inflammation of the epiglottal area. This swelling leads to a narrowing of the airway and increasingly deep respirations. The ongoing effort to breath as the narrowing progresses becomes more difficult and the air flowing through the upper airway becomes turbulent. During inspiration, the flexible chest wall caves in slightly and causing paradoxical breathing.

Complications

- Respiratory distress
- Respiratory arrest
- Epiglottitis
- Bacterial tracheitis
- Atelectasis
- Dehydration

Signs and Symptoms

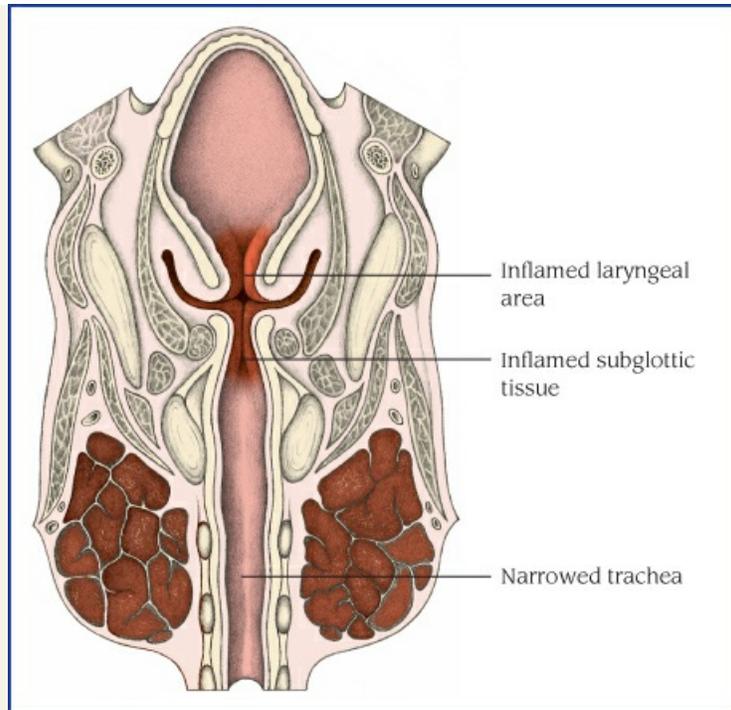
The onset of croup usually follows an upper respiratory tract infection. Clinical features include inspiratory stridor, hoarse or muffled vocal sounds, varying degrees of laryngeal obstruction and respiratory distress, and a characteristic sharp, barking, seal-like cough. These symptoms may last only a few hours or persist for a day or two. As it progresses, croup causes inflammatory edema and, possibly, spasm, which can obstruct the upper airway and severely compromise ventilation. (See *How croup affects the upper airway*.)

PATHOPHYSIOLOGY
HOW CROUP AFFECTS THE UPPER AIRWAY

In croup, inflammatory swelling and spasms constrict the larynx, thereby reducing airflow. This cross-sectional drawing (from chin to chest) shows the upper airway changes caused by croup. Inflammatory changes almost completely obstruct the larynx (which includes the epiglottis) and significantly narrow the trachea.

Inflamed laryngeal area

Inflamed subglottic tissue

Narrowed trachea


Each form of croup has additional characteristics:

In *laryngotracheobronchitis,* the symptoms seem to worsen at night. Inflammation causes edema of the bronchi and bronchioles as well as increasingly difficult expiration that frightens the child. Other characteristic features include fever, diffusely decreased breath sounds, expiratory rhonchi, and scattered crackles.

Laryngitis, which results from vocal cord edema, is usually mild and produces no respiratory distress except in infants. Early signs include a sore throat and cough, which, rarely, may progress to marked hoarseness, suprasternal and intercostal retractions, inspiratory stridor, dyspnea, diminished breath sounds, restlessness and, in later stages, severe dyspnea and exhaustion.

Acute spasmodic laryngitis affects a child between 1 and 3 years old, particularly one with allergies and a family history of croup. It typically begins with mild to moderate hoarseness and nasal discharge, followed by the characteristic cough and noisy inspiration (that usually awaken the child at night), labored breathing with retractions, rapid pulse, and clammy skin. The child understandably becomes anxious, which may lead to increasing dyspnea and transient cyanosis. These severe symptoms diminish after several hours but reappear in a milder form on the next one or two nights.

Diagnosis

The clinical picture is very characteristic, so the diagnosis should be suspected immediately. When bacterial infection is the cause, throat cultures may identify the organisms and their sensitivity to antibiotics and rule out diphtheria. On a posterior–anterior X-ray of the chest, narrowing of the upper airway ("steeple sign") may be apparent. Laryngoscopy may reveal inflammation and obstruction in epiglottal and laryngeal areas. In evaluating the patient, assess

for foreign body obstruction (a common cause of crouplike cough in a young child) as well as masses and cysts.

Treatment

For most children with croup, home care with rest, cool mist humidification during sleep, and antipyretics, such as acetaminophen, relieve symptoms. However, respiratory distress that's severe or interferes with oral hydration requires hospitalization and parenteral fluid replacement to prevent dehydration. If bacterial infection is the cause, antibiotic therapy is necessary. Oxygen therapy may also be required. Increasing obstruction of the airway requires intubation and mechanical ventilation.

Inhaled racemic epinephrine and corticosteroids may be used to alleviate respiratory distress.

Special Considerations

Monitor and support respiration, and control fever. Because croup is so frightening to the child and family, you must also provide support and reassurance.

- Carefully monitor cough and breath sounds, hoarseness, severity of retractions, inspiratory stridor, cyanosis, respiratory rate and character (especially prolonged and labored respirations), restlessness, fever, and cardiac rate.
- Keep the child as quiet as possible. However, avoid sedation because it may depress respiration. If the patient is an infant, position them in an infant seat or propped up with a pillow; place an older child in Fowler's position. If an older child requires a cool mist tent to help them breathe, explain why it's needed.
- Isolate patients suspected of having RSV and parainfluenza infections if possible. Wash your hands carefully before leaving the room, to avoid transmission to other children, particularly infants. Instruct parents and others involved in the care of these children to take similar precautions.
- Control fever with sponge baths and antipyretics. Keep a hypothermia blanket on hand for temperatures above 102° F (38.9° C). Watch for seizures in infants and young children with high fevers. Give I.V. antibiotics as ordered.
- Relieve sore throat with soothing, water-based ices, such as fruit sherbet and ice pops. Avoid thicker, milk-based fluids if the child is producing heavy mucus or has great difficulty in swallowing. Apply petroleum jelly or another ointment around the nose and lips to soothe irritation from nasal discharge and mouth breathing.
- Maintain a calm, quiet environment and offer reassurance. Explain all procedures and answer any questions.

When croup doesn't require hospitalization:

- Teach the parents effective home care. Suggest the use of a cool mist humidifier (vaporizer). To relieve croupy spells, tell parents to carry the child into the bathroom, shut the door, and turn on the hot water. Breathing in warm, moist air quickly eases an acute spell of croup.
- Warn parents that ear infections and pneumonia are complications of croup, which may appear about 5 days after recovery. Stress the importance of immediately reporting earache, productive cough, high fever, or increased shortness of breath.

PREVENTION

- *Perform hand hygiene frequently to prevent a respiratory infection.*
- *Give diphtheria, tetanus, and pertussis (DpT); Haemophilus influenzae B (Hib); and measles, mumps, and rubella (MMR) vaccines to children.*

EPIGLOTTITIS

Acute epiglottitis is an acute inflammation of the epiglottis that tends to cause airway obstruction. A critical emergency, epiglottitis can prove fatal unless it's recognized and treated promptly.

Causes and Incidence

Epiglottitis usually results from infection with Hib and, occasionally, pneumococci and group A streptococci. It typically strikes children between 2 and 6 years old. (However, immunosuppression can predispose adults to epiglottitis.) Since the advent of the Hib vaccine, epiglottitis is becoming more rare.

Pathophysiology

The causative bacteria invade the mucosa and into the bloodstream causing bacteremia and infection of the epiglottis as well as surrounding tissues. Acute inflammation and edema begin in the epiglottic area and progressing to the epiglottic folds, arytenoids, and entire supraglottic larynx. The aggressive swelling and edema greatly reduces the available airway and quickly increasing the risk for a respiratory crisis.

Complications

- Respiratory failure
- Pneumonia
- Meningitis
- Death
- Pericarditis

Signs And Symptoms

Sometimes preceded by an upper respiratory infection, epiglottitis may rapidly progress to complete upper airway obstruction within 2 to 5 hours. Laryngeal obstruction results from inflammation and edema of the epiglottis. Accompanying symptoms include high fever, stridor, sore throat, dysphagia, irritability, restlessness, and drooling. To relieve severe respiratory distress, the child with epiglottitis may hyperextend his or her neck, sit up, and lean forward with his or her mouth open, tongue protruding, and nostrils flaring as he or she tries to breathe. The child may develop inspiratory retractions and rhonchi.

Diagnosis

In acute epiglottitis, throat examination reveals a large, edematous, bright red epiglottis. Such examination should follow lateral neck X-rays and, generally, *shouldn't* be performed if the suspected obstruction is great. Special equipment (laryngoscope and ET tubes) should be available because a tongue blade can cause sudden complete airway obstruction. Trained personnel (such as an anesthesiologist) should be on hand during the throat examination to secure an emergency airway. On the lateral soft-tissue X-ray of the neck, a large, thick but

indistinct ("thumbprint") epiglottis will be seen. Blood or throat culture may show *H. influenzae* or other bacteria.

Treatment

A child with acute epiglottitis and airway obstruction requires emergency hospitalization; the child may need emergency ET intubation or a tracheotomy with subsequent monitoring in an intensive care unit. Respiratory distress that interferes with swallowing necessitates parenteral fluid administration to prevent dehydration. A patient with acute epiglottitis should always receive a complete course of parenteral antibiotics—usually a second- or third-generation cephalosporin. (If the child is allergic to penicillin, a quinolone or sulfa drug may be substituted.) Corticosteroids should be used to decrease swelling of the throat.

Special Considerations

- Keep equipment available in case of sudden complete airway obstruction to secure an airway. Be prepared to assist with intubation or tracheotomy, as necessary.

ALERT *Watch for increasing restlessness, rising cardiac rate, fever, dyspnea, and retractions, which may indicate the need for an emergency tracheotomy. Monitor blood gases for hypoxemia and hypercapnia.*

- After a tracheotomy, anticipate the patient's needs because they won't be able to cry or call out; provide emotional support. Reassure the patient and their family that the tracheotomy is a short-term intervention (usually from 4 to 7 days). Monitor the patient for rising temperature and pulse rate and hypotension—signs of secondary infection.
- The bacterial infection causing epiglottitis is contagious, and airborne or droplet precautions should be followed. Family members should be screened.

PREVENTION

- *Perform hand hygiene frequently to prevent infections.*
- *Administer the Hib vaccine to children.*

Acute Disorders

ACUTE RESPIRATORY DISTRESS SYNDROME

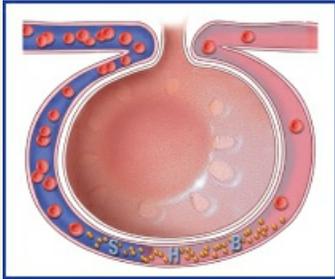
A form of noncardiogenic pulmonary edema that causes acute respiratory failure (ARF), acute respiratory distress syndrome (ARDS), also called *shock lung* or *adult respiratory distress syndrome,* results from increased permeability of the alveolocapillary membrane. Fluid accumulates in the lung interstitium, alveolar spaces, and small airways, causing the lung to stiffen. Effective ventilation is thus impaired, prohibiting adequate oxygenation of pulmonary capillary blood. Severe ARDS can cause intractable and fatal hypoxemia. However, patients who recover may have little or no permanent lung damage. (See *Alveolar changes in ARDS.*)

PATHOPHYSIOLOGY

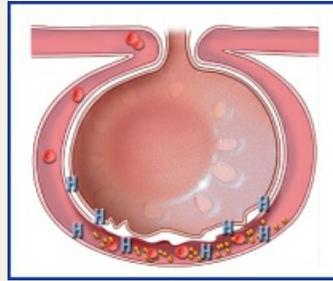
ALVEOLAR CHANGES IN ARDS

The alveoli undergo major changes in each phase of ARDS.

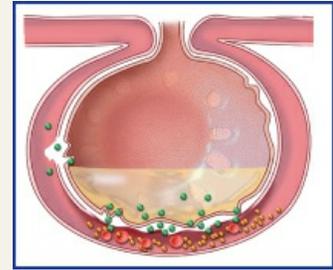
Phase 1

In *phase 1*, injury reduces normal blood flow to the lungs. Platelets aggregate and release histamine (H), serotonin (S), and bradykinin (B).


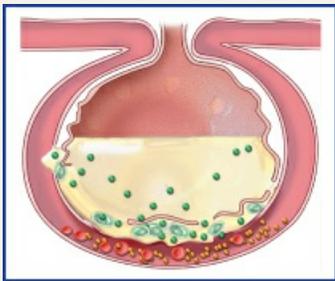
Phase 2

In *phase 2*, those substances—especially histamine—inflame and damage the alveolocapillary membrane, increasing capillary permeability. Fluids then shift into the interstitial


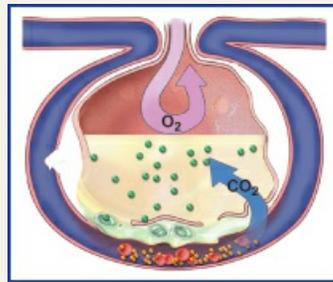
Phase 3

In *phase 3*, as capillary permeability increases, proteins and fluids leak out, increasing interstitial osmotic pressure and causing pulmonary edema.


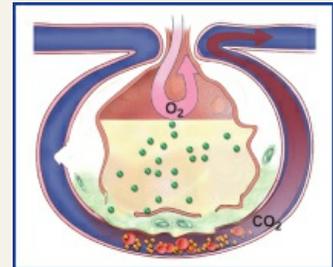
Phase 4

In *phase 4*, decreased blood flow and fluids in the alveoli damage surfactant and impair the cell's ability to produce more. As a result, alveoli collapse, impeding gas exchange and decreasing lung compliance.


Phase 5

In *phase 5*, sufficient oxygen can't cross the alveolocapillary membrane, but carbon dioxide (CO_2) can and is lost with every exhalation. Oxygen (O_2) and CO_2 levels decrease in the blood.


Phase 6

In *phase 6*, pulmonary edema worsens, inflammation leads to fibrosis, and gas exchange is further impeded.


Causes and Incidence

ARDS results from many respiratory and nonrespiratory insults, such as:

- aspiration of gastric contents
- sepsis (primarily gram-negative), trauma, or oxygen toxicity
- shock
- viral, bacterial, or fungal pneumonia or microemboli (fat or air emboli or disseminated intravascular coagulation)
- drug overdose (barbiturates, glutethimide, or opioids)
- blood transfusion
- smoke or chemical inhalation (nitrous oxide, chlorine, or ammonia)
- hydrocarbon and paraquat ingestion

- pancreatitis, uremia, or miliary tuberculosis (TB; rare)
- near drowning
- severe traumatic injuries, such as head injury or pulmonary contusions

Altered permeability of the alveolocapillary membrane causes fluid to accumulate in the interstitial space. If the pulmonary lymphatic glands can't remove this fluid, interstitial edema develops. The fluid collects in the peribronchial and peribronchiolar spaces, producing bronchiolar narrowing. Hypoxemia occurs as a result of fluid accumulation in alveoli and subsequent alveolar collapse, causing the shunting of blood through nonventilated lung regions. In addition, alveolar collapse causes a dramatic increase in lung compliance, which makes it more difficult to achieve adequate ventilation.

ARDS affects 10 to 14 people per 100,000, with a mortality rate of 36% to 52%.

Pathophysiology

An acute lung injury can begin the cascade of alveolar damage resulting in an altered permeability of the epithelial barrier and subsequent pulmonary edema. Diffuse alveolar damage progresses and granulation tissue forms in the alveolar spaces creating fibrosis. This fibrotic phase inhibits lung compliance and effective respiration.

Complications

- Multisystem failure
- Pulmonary fibrosis
- Pneumothorax

Signs and Symptoms

ARDS initially produces rapid, shallow breathing and dyspnea within hours to days of the initial injury (sometimes after the patient's condition appears to have stabilized). Hypoxemia develops, causing an increased drive for ventilation. Because of the effort required to expand the stiff lung, intercostal and suprasternal retractions result. Fluid accumulation produces crackles and rhonchi; worsening hypoxemia causes restlessness, apprehension, mental sluggishness, motor dysfunction, and tachycardia (possibly with transient increased arterial blood pressure).

ELDER TIP The older patient may appear to do well following an initial episode of ARDS. Symptoms commonly appear 2 to 3 days later.

Severe ARDS causes overwhelming hypoxemia. If uncorrected, this results in hypotension, decreasing urine output, respiratory and metabolic acidosis, and eventually ventricular fibrillation or standstill.

Diagnosis

On room air, ABG analysis initially shows decreased Pao_2 (less than 60 mm Hg) and $Paco_2$ (less than 35 mm Hg). The resulting pH usually reflects respiratory alkalosis. As ARDS becomes more severe, ABG analysis shows respiratory acidosis (increasing $Paco_2$ [more than 45 mm Hg]), metabolic acidosis (decreasing bicarbonate [less than 22 mEq/L]), and a decreasing Pao_2 despite oxygen therapy.

Other diagnostic tests include the following:

- Pulmonary artery catheterization helps identify the cause of pulmonary edema (cardiac versus

noncardiac) by evaluating pulmonary artery wedge pressure (PAWP); allows collection of pulmonary artery blood, which shows decreased oxygen saturation, reflecting tissue hypoxia; measures pulmonary artery pressure (PAP); measures cardiac output by thermodilution techniques; and provides information to allow calculation of the percentage of blood shunted through the lungs.

◆ Serial chest X-rays initially show bilateral infiltrates. In later stages, a ground-glass appearance and eventually (as hypoxemia becomes irreversible), "whiteouts" of both lung fields are apparent. Medical personnel can differentiate ARDS from heart failure by noting the following on serial chest X-rays:

  ◆ normal cardiac silhouette
  ◆ diffuse bilateral infiltrates that tend to be more peripheral and patchy, as opposed to the usual perihilar "bat wing" appearance of cardiogenic pulmonary edema
  ◆ fewer pleural effusions

Differential diagnosis must rule out cardiogenic pulmonary edema, pulmonary vasculitis, and diffuse pulmonary hemorrhage. To establish the etiology, laboratory work should include sputum Gram stain, culture and sensitivity tests, and blood cultures to detect infections; a toxicology screen for drug ingestion; and, when pancreatitis is a consideration, a serum amylase determination.

Treatment

When possible, treatment is designed to correct the underlying cause of ARDS as well as to prevent progression and the potentially fatal complications of hypoxemia and respiratory acidosis. Supportive medical care consists of administering humidified oxygen with CPAP. Hypoxemia that doesn't respond adequately to these measures requires ventilatory support with intubation, volume ventilation, and PEEP. Other supportive measures include fluid restriction, diuretics, and correction of electrolyte and acid–base abnormalities.

When ARDS requires mechanical ventilation, sedatives, opioids, or neuromuscular blocking agents may be ordered to optimize ventilation. Treatment to reverse severe metabolic acidosis with sodium bicarbonate may be necessary, although in severe cases this may worsen the acidosis if CO_2 can't be cleared adequately. Use of fluids and vasopressors may be required to maintain blood pressure. Infections require appropriate anti-infective therapy.

Special Considerations

ARDS requires careful monitoring and supportive care.

◆ Frequently assess the patient's respiratory status. Be alert for retractions on inspiration. Note the rate, rhythm, and depth of respirations; watch for dyspnea and the use of accessory muscles of respiration. On auscultation, listen for adventitious or diminished breath sounds. Check for clear, frothy sputum, which may indicate pulmonary edema.

◆ Observe and document the hypoxemic patient's neurologic status (level of consciousness and mental status).

◆ Maintain a patent airway by suctioning, using sterile, nontraumatic technique. Ensure adequate humidification to help liquefy tenacious secretions.

◆ Closely monitor heart rate and blood pressure. Watch for arrhythmias that may result from hypoxemia, acid–base disturbances, or electrolyte imbalance. With pulmonary artery catheterization, know the desired pressure levels. Check readings often and watch for

decreasing mixed venous oxygen saturation.

- Monitor serum electrolytes and correct imbalances. Measure intake and output; weigh the patient daily.
- Check ventilator settings frequently, and empty condensate from tubing promptly to ensure maximum oxygen delivery. Monitor ABG studies and pulse oximetry. The patient with severe hypoxemia may need controlled mechanical ventilation with positive pressure. Give sedatives, as needed, to reduce restlessness.
- Because PEEP may decrease cardiac output, check for hypotension, tachycardia, and decreased urine output. Suction only as needed to maintain PEEP or use an in-line suctioning apparatus. Reposition the patient often and record an increase in secretions, temperature, or hypotension that may indicate a deteriorating condition. Monitor peak pressures during ventilation. Because of stiff, noncompliant lungs, the patient is at high risk for barotrauma (pneumothorax), evidenced by increased peak pressures, decreased breath sounds on one side, and restlessness.
- Monitor nutrition, maintain joint mobility, and prevent skin breakdown. Accurately record calorie intake. Give tube feedings and parenteral nutrition, as ordered. Perform passive range-of-motion exercises or help the patient perform active exercises, if possible. Provide meticulous skin care. Plan patient care to allow periods of uninterrupted sleep.
- Provide emotional support. Warn the family and the patient who's recovering from ARDS that recovery will take some time and that they will feel weak for a while.
- Watch for and immediately report all respiratory changes in the patient with injuries that may adversely affect the lungs (especially during the 2- to 3-day period after the injury, when the patient may appear to be improving).

PREVENTION *Prevent VAP through use of the Ventilator Bundle and other best practices, such as continuous removal of subglottic secretions, change of ventilator circuit no more often than every 48 hours, and performance of hand hygiene before and after contact with each patient.*

ACUTE RESPIRATORY FAILURE IN COPD

In patients with essentially normal lung tissue, ARF usually means $Paco_2$ above 50 mm Hg and Pao_2 below 50 mm Hg. These limits, however, don't apply to patients with COPD, who usually have a consistently high $Paco_2$ and low Pao_2. In patients with COPD, only acute deterioration in ABG values, with corresponding clinical deterioration, indicates ARF.

Causes and Incidence

ARF may develop in patients with COPD as a result of any condition that increases the work of breathing and decreases the respiratory drive. Such conditions include respiratory tract infection (such as bronchitis or pneumonia). The most common precipitating factor is bronchospasm, or accumulating secretions secondary to cough suppression. Other causes of ARF in COPD include the following:

- CNS depression—head trauma or injudicious use of sedatives, opioids, tranquilizers, or oxygen (O_2)
- Cardiovascular disorders—myocardial infarction, heart failure, or pulmonary emboli
- Airway irritants—smoke or fumes

- Endocrine and metabolic disorders—myxedema or metabolic alkalosis
- Thoracic abnormalities—chest trauma, pneumothorax, or thoracic or abdominal surgery

The incidence of ARF increases markedly with age and is especially high among people age 65 and older.

Pathophysiology

An acute and progressive exacerbation of COPD is triggered by the cessation of maintenance medications or some type of infection. Damage to the epithelium from ongoing exposure to noxious gases or particles impairs the mucociliary response causing the accumulation of mucus and bacteria and contributing to the obstruction of airways. The permeant enlargement of the airspaces by the terminal bronchioles leads to a decrease in the alveolar surface area for gas exchange and contributes to ineffective ventilation.

Complications

- Respiratory failure
- Pneumonia
- Hypoxemia
- Pneumothorax
- Heart failure

Signs And Symptoms

In patients who have COPD with ARF, increased ventilation–perfusion mismatch and reduced alveolar ventilation decrease Pa_{O_2} (hypoxemia) and increase Pa_{CO_2} (hypercapnia). This rise in CO_2 lowers the pH. The resulting hypoxemia and acidemia affect all body organs, especially the CNS and the respiratory and cardiovascular systems.

Specific symptoms vary with the underlying cause of ARF but may include these systems:

- Respiratory—Rate may be increased, decreased, or normal depending on the cause; respirations may be shallow, deep, or alternate between the two; and air hunger may occur. Cyanosis may or may not be present, depending on the Hb level and arterial oxygenation. Auscultation of the chest may reveal crackles, rhonchi, wheezing, or diminished breath sounds.
- CNS—When hypoxemia and hypercapnia occur, the patient may show evidence of restlessness, confusion, loss of concentration, irritability, tremulousness, diminished tendon reflexes, and papilledema; the patient may slip into a coma.
- Cardiovascular—Tachycardia, with increased cardiac output and mildly elevated blood pressure secondary to adrenal release of catecholamine, occurs early in response to low Pa_{O_2}. With myocardial hypoxia, arrhythmias may develop. Pulmonary hypertension, secondary to pulmonary capillary vasoconstriction, may cause increased pressures on the right side of the heart, jugular vein distention, an enlarged liver, and peripheral edema. Stresses on the heart may precipitate cardiac failure.

Diagnosis

Progressive deterioration in ABG levels and pH, when compared with the patient's "normal" values, strongly suggests ARF in COPD. (In patients with essentially normal lung tissue, pH below 7.35 usually indicates ARF, but patients with COPD display an even greater deviation

from this normal value, as they do with Pa_{CO_2} and Pa_{O_2}.)

Other supporting findings include:

- Bicarbonate—Increased levels indicate metabolic alkalosis or reflect metabolic compensation for chronic respiratory acidosis.
- Hematocrit (HCT) and Hb—Abnormally low levels may be due to blood loss, indicating decreased oxygen-carrying capacity. Elevated levels may occur with chronic hypoxemia.
- Serum electrolytes—Hypokalemia and hypochloremia may result from diuretic and corticosteroid therapies used to treat ARF.
- White blood cell count—Count is elevated if ARF is due to bacterial infection; Gram stain and sputum culture can identify pathogens.
- Chest X-ray—Findings identify pulmonary pathologic conditions, such as emphysema, atelectasis, lesions, pneumothorax, infiltrates, or effusions.
- Electrocardiogram—Arrhythmias commonly suggest cor pulmonale and myocardial hypoxia.

Treatment

ARF in patients with COPD is an emergency that requires cautious O_2 therapy (using nasal prongs or Venturi mask) to raise the Pa_{O_2}. In patients with chronic hypercapnia, O_2 therapy can cause hypoventilation by increasing Pa_{CO_2} and decreasing the respiratory drive, necessitating mechanical ventilation. The minimum fraction of inspired air (F_{IO_2}) required to maintain ventilation or O_2 saturation greater than 85% to 90% should be used. If significant uncompensated respiratory acidosis or unrefractory hypoxemia exists, mechanical ventilation (through an ET or a tracheostomy tube) or noninvasive ventilation (with a face or nose mask) may be necessary. Treatment routinely includes antibiotics for infection, bronchodilators, and possibly steroids.

Special Considerations

- Because most patients with ARF are treated in an intensive care unit, orient them to the environment, procedures, and routines to minimize their anxiety.
- To reverse hypoxemia, administer O_2 at appropriate concentrations to maintain Pa_{O_2} at a minimum of 50 to 60 mm Hg. Patients with COPD usually require only small amounts of supplemental O_2. Watch for a positive response—such as improvement in the patient's breathing, color, and ABG levels.
- Maintain a patent airway. If the patient is retaining CO_2, encourage them to cough and to breathe deeply. Teach them to use pursed-lip and diaphragmatic breathing to control dyspnea. If the patient is alert, have them use an incentive spirometer; if they are intubated and lethargic, turn the patient every 1 to 2 hours. Use postural drainage and chest physiotherapy to help clear secretions.
- In an intubated patient, suction the trachea as needed after hyperoxygenation. Observe for a change in quantity, consistency, and color of sputum. Provide humidification to liquefy secretions.
- Observe the patient closely for respiratory arrest. Auscultate for chest sounds. Monitor ABG levels and report any changes immediately.
- Check the cardiac monitor for arrhythmias.

If the patient requires mechanical ventilation:

- Check ventilator settings, cuff pressures, and ABG values often because the F_{IO_2} setting depends on ABG levels. Draw specimens for ABG analysis 20 to 30 minutes after every F_{IO_2} change or oximetry check.
- Prevent infection by performing hand hygiene and using sterile technique while suctioning.
- Stress ulcers are common in the intubated patient. Check gastric secretions for evidence of bleeding if the patient has a nasogastric (NG) tube or if the patient complains of epigastric tenderness, nausea, or vomiting. Monitor Hb level and HCT; check all stools for occult blood. Administer antacids, histamine-2 receptor antagonists, or sucralfate, as ordered.
- To prevent nasal necrosis, keep the nasotracheal tube midline within the patient's nostrils and provide good hygiene. Loosen the tape periodically to prevent skin breakdown. Avoid excessive movement of any tubes; make sure the ventilator tubing is adequately supported.

PREVENTION

- *To prevent VAP, implement Ventilator Bundle.*
- *Prevent tracheal erosion, which can result from artificial airway cuff overinflation. Use the minimal leak technique and a cuffed tube with high residual volume (low-pressure cuff), a foam cuff, or a pressure-regulating valve on the cuff.*
- *To prevent oral or vocal cord trauma, make sure that the ET tube is positioned midline or moved carefully from side to side every 8 hours.*

PULMONARY EDEMA

Pulmonary edema is the accumulation of fluid in the extravascular spaces of the lung. In cardiogenic pulmonary edema, fluid accumulation results from elevations in pulmonary venous and capillary hydrostatic pressures. A common complication of cardiac disorders, pulmonary edema can occur as a chronic condition or it can develop quickly to cause death. (See *How pulmonary edema develops*, page 131.)

Causes And Incidence

Pulmonary edema usually results from left-sided heart failure due to arteriosclerotic, hypertensive, cardiomyopathic, or valvular cardiac disease. In such disorders, the compromised left ventricle is unable to maintain adequate cardiac output; increased pressures are transmitted to the left atrium, pulmonary veins, and pulmonary capillary bed. This increased pulmonary capillary hydrostatic force promotes transudation of intravascular fluids into the pulmonary interstitium, decreasing lung compliance and interfering with gas exchange. Other factors that may predispose the patient to pulmonary edema include:

- excessive infusion of I.V. fluids
- decreased serum colloid osmotic pressure as a result of nephrosis, protein-losing enteropathy, extensive burns, hepatic disease, or nutritional deficiency
- impaired lung lymphatic drainage from Hodgkin lymphoma or obliterative lymphangitis after radiation
- mitral stenosis, which impairs left atrial emptying
- pulmonary veno-occlusive disease
- lung damage from a severe infection or exposure to poisonous gas
- kidney failure

Pathophysiology

A hemodynamic disturbance or alteration in the permeability of the microvasculature allowing fluid to pass through into the interstitial space. This interstitial edema progresses when the capacity of the lymphatics is exceeded and unable to drain the fluid efficiently and subsequently decreasing lung compliance and shortness of breath.

Complications

- respiratory failure
- pleural effusion
- edema to lower extremities and abdomen
- death

Signs and Symptoms

The early symptoms of pulmonary edema reflect interstitial fluid accumulation and diminished lung compliance: dyspnea on exertion, paroxysmal nocturnal dyspnea, orthopnea, and coughing. Clinical features include tachycardia, tachypnea, dependent crackles, jugular vein distention, and a diastolic (S_3) gallop. With severe pulmonary edema, the alveoli and bronchioles may fill with fluid and intensify the early symptoms. Respiration becomes labored and rapid, with more diffuse crackles and coughing that produces frothy, bloody sputum. Tachycardia increases, and arrhythmias may occur. Skin becomes cold, clammy, diaphoretic, and cyanotic. Blood pressure falls and the pulse becomes thready as cardiac output falls.

Symptoms of severe heart failure with pulmonary edema may also include signs of hypoxemia, such as anxiety, restlessness, and changes in the patient's level of consciousness.

Diagnosis

Clinical features of pulmonary edema permit a working diagnosis. ABG analysis usually shows hypoxia; the Pa_{CO_2} is variable. Profound respiratory alkalosis and acidosis may occur. Chest X-ray shows diffuse haziness of the lung fields and, commonly, cardiomegaly and pleural effusions. Ultrasound (echocardiogram) may show weak heart muscle, leaking or narrow heart valves, and fluid surrounding the heart. Pulmonary artery catheterization helps identify left-sided heart failure by showing elevated PAWPs. This helps to rule out ARDS—in which pulmonary wedge pressure is usually normal.

Treatment

Treatment measures for pulmonary edema are designed to reduce extravascular fluid, improve gas exchange and myocardial function and, if possible, correct any underlying pathologic conditions.

Administration of high concentrations of oxygen by a cannula, a face mask and, if the patient fails to maintain an acceptable Pa_{O_2} level, assisted ventilation improves oxygen delivery to the tissues and usually improves acid–base disturbances. Diuretics—furosemide and bumetanide, for example—promote diuresis, which reduces extravascular fluid.

Treatment of heart failure includes angiotensin-converting enzyme inhibitors, diuretics, inotropic drugs such as digoxin, antiarrhythmic agents, beta-adrenergic blockers, and human B-type natriuretic peptide. Vasodilator drugs, such as nitroprusside, may be used to reduce preload and afterload in acute episodes of pulmonary edema.

Morphine is used to reduce anxiety and dyspnea as well as dilate the systemic venous bed, promoting blood flow from pulmonary circulation to the periphery.

Special Considerations

- Carefully monitor the vulnerable patient for early signs of pulmonary edema, especially tachypnea, tachycardia, and abnormal breath sounds. Report any abnormalities. Assess for peripheral edema and weight gain, which may also indicate that fluid is accumulating in tissue.
- Administer oxygen as ordered.
- Monitor the patient's vital signs every 15 to 30 minutes while administering nitroprusside in dextrose 5% in water by I.V. drip. Protect the nitroprusside solution from light by wrapping the bottle or bag with aluminum foil and discard unused solution after 4 hours. Watch for arrhythmias in the patient receiving cardiac glycosides and for marked respiratory depression in the patient receiving morphine.
- Assess the patient's condition frequently, and record response to treatment. Monitor ABG levels, oral and I.V. fluid intake, urine output and, in the patient with a pulmonary artery catheter, pulmonary end-diastolic and wedge pressures. Check the cardiac monitor often. Report changes immediately.
- Carefully record the time and amount of morphine given.
- Reassure the patient, who will be anxious because of hypoxia and respiratory distress. Explain all procedures. Provide emotional support to the family as well.

COR PULMONALE

The World Health Organization defines chronic cor pulmonale as "hypertrophy of the right ventricle resulting from diseases affecting the function or the structure of the lungs, except when these pulmonary alterations are the result of diseases that primarily affect the left side of the heart or of congenital heart disease." Invariably, cor pulmonale follows some disorder of the lungs, pulmonary vessels, chest wall, or respiratory control center. For instance, COPD produces pulmonary hypertension, which leads to right ventricular hypertrophy and right-sided heart failure. Because cor pulmonale generally occurs late during the course of COPD and other irreversible diseases, the prognosis is generally poor.

Causes and Incidence

Approximately 85% of patients with cor pulmonale have COPD, and 25% of patients with COPD eventually develop cor pulmonale.

Other respiratory disorders that produce cor pulmonale include:

- obstructive lung diseases—for example, bronchiectasis and cystic fibrosis
- restrictive lung diseases—for example, pneumoconiosis, interstitial pneumonitis, scleroderma, and sarcoidosis
- loss of lung tissue after extensive lung surgery
- congenital cardiac shunts—such as a ventricular septal defect
- pulmonary vascular diseases—for example, recurrent thromboembolism, primary pulmonary hypertension, schistosomiasis, and pulmonary vasculitis
- respiratory insufficiency without pulmonary disease—for example, in chest wall disorders such as kyphoscoliosis, neuromuscular incompetence due to muscular dystrophy and

amyotrophic lateral sclerosis, polymyositis, and spinal cord lesions above C6
- obesity hypoventilation syndrome (pickwickian syndrome) and upper airway obstruction
- living at high altitudes (chronic mountain sickness)

Cor pulmonale accounts for about 25% of all types of heart failure. It's most common in areas of the world where the incidence of cigarette smoking and COPD is high; cor pulmonale affects middle-aged to elderly men more often than women, but the incidence in women is increasing. In children, cor pulmonale may be a complication of cystic fibrosis, hemosiderosis, upper airway obstruction, scleroderma, extensive bronchiectasis, neurologic diseases affecting respiratory muscles, or abnormalities of the respiratory control center.

Pathophysiology

Pulmonary capillary destruction and pulmonary vasoconstriction (usually secondary to hypoxia) reduce the area of the pulmonary vascular bed. Thus, pulmonary vascular resistance is increased, causing pulmonary hypertension. To compensate for the extra work needed to force blood through the lungs, the right ventricle dilates and hypertrophies. In response to low oxygen content, the bone marrow produces more red blood cells (RBCs), causing erythrocytosis. When the HCT exceeds 55%, blood viscosity increases, which further aggravates pulmonary hypertension and increases the hemodynamic load on the right ventricle. Right-sided heart failure is the result.

Complications

- Right- and left-sided heart failure
- Hepatomegaly
- Edema
- Ascites
- Pleural effusions
- Thromboembolism

Signs and Symptoms

As long as the heart can compensate for the increased pulmonary vascular resistance, clinical features reflect the underlying disorder and occur mostly in the respiratory system. They include chronic productive cough, exertional dyspnea, wheezing respirations, fatigue, and weakness. Progression of cor pulmonale is associated with dyspnea (even at rest) that worsens on exertion, tachypnea, orthopnea, edema, weakness, and right upper quadrant discomfort. Chest examination reveals findings characteristic of the underlying lung disease.

Signs of cor pulmonale and right-sided heart failure include dependent edema; distended jugular veins; prominent parasternal or epigastric cardiac impulse; hepatojugular reflux; an enlarged, tender liver; ascites; and tachycardia. Decreased cardiac output may cause a weak pulse and hypotension. Chest examination yields various findings, depending on the underlying cause of cor pulmonale.

In COPD, auscultation reveals wheezing, rhonchi, and diminished breath sounds. When the disease is secondary to upper airway obstruction or damage to CNS respiratory centers, chest findings may be normal, except for a right ventricular lift, gallop rhythm, and loud pulmonic component of S_2. Tricuspid insufficiency produces a pansystolic murmur heard at the lower left sternal border; its intensity increases on inspiration, distinguishing it from a murmur due to

mitral valve disease. A right ventricular early murmur that increases on inspiration can be heard at the left sternal border or over the epigastrium. A systolic pulmonic ejection click may also be heard. Alterations in the patient's level of consciousness may occur.

Diagnosis

- PAP measurements show increased right ventricular and PAPs, stemming from increased pulmonary vascular resistance. Right ventricular systolic and pulmonary artery systolic pressures will exceed 30 mm Hg. Pulmonary artery diastolic pressure will exceed 15 mm Hg.
- Echocardiography or angiography indicates right ventricular enlargement; echocardiography can estimate PAP while also ruling out structural and congenital lesions.
- Chest X-ray shows large central pulmonary arteries and suggests right ventricular enlargement by rightward enlargement of the heart's silhouette on an anterior chest film.
- ABG analysis shows decreased Pao_2 (typically less than 70 mm Hg and usually no more than 90 mm Hg on room air).
- Electrocardiogram frequently shows arrhythmias, such as premature atrial and ventricular contractions and atrial fibrillation during severe hypoxia; it may also show right bundle-branch block, right axis deviation, prominent P waves and inverted T wave in right precordial leads, and right ventricular hypertrophy.
- PFTs show results consistent with the underlying pulmonary disease.
- HCT is typically greater than 50%.

Treatment

Treatment of cor pulmonale is designed to reduce hypoxemia, increase the patient's exercise tolerance and, when possible, correct the underlying condition.

In addition to bed rest, treatment may include administration of:

- a cardiac glycoside (digoxin)
- antibiotics when respiratory infection is present; culture and sensitivity of a sputum specimen helps select an antibiotic
- potent pulmonary artery vasodilators (such as diazoxide, nitroprusside, hydralazine, angiotensin-converting enzyme inhibitors, calcium channel blockers, or prostaglandins) in primary pulmonary hypertension
- oxygen by mask or cannula in concentrations ranging from 24% to 40%, depending on Pao_2, as necessary; in acute cases, therapy may also include mechanical ventilation; patients with underlying COPD generally shouldn't receive high concentrations of oxygen because of possible subsequent respiratory depression
- a low-sodium diet, restricted fluid intake, and diuretics, such as furosemide, to reduce edema
- phlebotomy to reduce the RBC count
- anticoagulants to reduce the risk of thromboembolism

Depending on the underlying cause, some variations in treatment may be indicated. For example, a tracheotomy may be necessary if the patient has an upper airway obstruction. Steroids may be used in the patient with a vasculitis autoimmune phenomenon or acute exacerbations of COPD.

Special Considerations

- Plan diet carefully with the patient and staff dietitian. Because the patient may lack energy

and tire easily when eating, provide small, frequent feedings rather than three heavy meals.

- Prevent fluid retention by limiting the patient's fluid intake to 1 to 2 qt (1 to 2 L)/day and providing a low-sodium diet.
- Monitor serum potassium levels closely if the patient is receiving diuretics. Low serum potassium levels can increase the risk of arrhythmias associated with cardiac glycosides.
- Watch the patient for signs of digoxin toxicity, such as complaints of anorexia, nausea, vomiting, and halos around visual images and color perception shifts. Monitor for cardiac arrhythmias. Teach the patient to check their radial pulse before taking digoxin or any cardiac glycoside. They should be instructed to notify the physician if they detect changes in pulse rate.
- Reposition bedridden patients often to prevent atelectasis.
- Provide meticulous respiratory care, including oxygen therapy and, for the patient with COPD, pursed-lip breathing exercises. Periodically measure ABG levels and watch for signs of respiratory failure: changes in pulse rate, labored respirations, changes in mental status, and increased fatigue after exertion.

Before discharge, maintain the following protocol:

- Make sure that the patient understands the importance of maintaining a low-sodium diet, weighing himself daily, and watching for increased edema. Teach patient to detect edema by pressing the skin over a shin with one finger, holding it for a second or two, then checking for a finger impression. Increased weight, increased edema, or respiratory difficulty should be reported to the healthcare provider.
- Instruct the patient to plan for frequent rest periods and to do breathing exercises regularly.
- If the patient needs supplemental oxygen therapy at home, refer them to an agency that can help obtain the required equipment and, as necessary, arrange for follow-up examinations.
- If the patient has been placed on anticoagulant therapy, emphasize the need to watch for bleeding (epistaxis, hematuria, bruising) and to report signs to the physician. Also encourage patient to return for periodic laboratory tests to monitor partial thromboplastin time (PTT), fibrinogen level, platelet count, HCT, Hb level, and prothrombin time.
- Because pulmonary infection commonly exacerbates COPD and cor pulmonale, tell the patient to watch for and immediately report early signs of infection, such as increased sputum production, change in sputum color, increased coughing or wheezing, chest pain, fever, and tightness in the chest. Tell the patient to avoid crowds and persons known to have pulmonary infections, especially during the flu season. The patient should receive pneumovax and annual influenza vaccines.
- Warn the patient to avoid substances that may depress the ventilatory drive, such as sedatives and alcohol.

LEGIONNAIRES' DISEASE

Legionnaires' disease is an acute bronchopneumonia produced by a gram-negative bacillus, *Legionella pneumophila*. It derives its name and notoriety from the peculiar, highly publicized disease that struck 182 people (29 of whom died) at an American Legion convention in Philadelphia in July 1976. This disease may occur epidemically or sporadically, usually in late summer or early fall. Its severity ranges from a mild illness, with or without pneumonitis, to multilobar pneumonia, with a mortality as high as 15%. A milder, self-limiting form (Pontiac syndrome) subsides within a few days but leaves the patient fatigued for several weeks. This

form mimics Legionnaires' disease but produces few or no respiratory symptoms, no pneumonia, and no fatalities.

Causes and Incidence

Legionella pneumophila is an aerobic, gram-negative bacillus that's probably transmitted by an airborne route. In past epidemics, it has spread through cooling towers or evaporation condensers in air-conditioning systems. However, *Legionella* bacilli also flourish in soil and excavation sites. The disease doesn't spread from person to person.

Legionnaires' disease is most likely to affect:

- middle-aged and elderly people
- immunocompromised patients (particularly those receiving corticosteroids, e.g., after a transplant) or those with lymphoma or other disorders associated with delayed hypersensitivity
- patients with a chronic underlying disease, such as diabetes, chronic renal failure, or COPD
- those with alcoholism
- cigarette smokers
- those on a ventilator for extended periods

Pathophysiology

When water droplets containing a sufficient amount of the Legionella bacterium enter the atmosphere they can be inhaled into the lungs. There they invade the epithelial cells of the lungs and begin to replicate intracellularly causing a Legionnaires' infection.

Complications

- Respiratory failure
- Septic shock
- Acute kidney failure

Signs and Symptoms

The multisystem clinical features of Legionnaires' disease follow a predictable sequence, although the onset of the disease may be gradual or sudden. After a 2- to 10-day incubation period, nonspecific, prodromal signs and symptoms appear, including diarrhea, anorexia, malaise, diffuse myalgias and generalized weakness, headache, and recurrent chills. An unremitting fever develops within 12 to 48 hours with a temperature that may reach 105° F (40.6° C). A cough then develops that's nonproductive initially but eventually may produce grayish, nonpurulent, and occasionally blood-streaked sputum.

Other characteristic features include nausea, vomiting, disorientation, mental sluggishness, confusion, mild temporary amnesia, pleuritic chest pain, tachypnea, dyspnea, and fine crackles. Patients who develop pneumonia may also experience hypoxia. Other complications include hypotension, delirium, heart failure, arrhythmias, ARF, renal failure, and shock (usually fatal).

Diagnosis

The patient history focuses on possible sources of infection and predisposing conditions. Additional tests reveal the following:

- Chest X-ray shows patchy, localized infiltration, which progresses to multilobar consolidation

(usually involving the lower lobes), pleural effusion and, in fulminant disease, opacification of the entire lung.

- ◆ Auscultation reveals fine crackles, progressing to coarse crackles as the disease advances.
- ◆ Abnormal findings include leukocytosis, increased erythrocyte sedimentation rate, an increase in liver enzyme levels (alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase), hyponatremia, decreased PaO_2 and, initially, decreased $PaCO_2$. Bronchial washings and blood, pleural fluid, and sputum tests rule out other infections.

℞ **CONFIRMING DIAGNOSIS** *Definitive tests include direct immunofluorescence of respiratory tract secretions and tissue, culture of* L. pneumophila*, and indirect fluorescent antibody testing of serum comparing acute samples with convalescent samples drawn at least 3 weeks later. A convalescent serum showing a fourfold or greater rise in antibody titer for* Legionella *confirms the diagnosis.*

Treatment

Antibiotic treatment begins as soon as Legionnaires' disease is suspected and diagnostic material is collected; it shouldn't await laboratory confirmation. A quinolone (ciprofloxacin, levofloxacin, moxifloxacin, or gatifloxacin) is commonly used, although a macrolide (azithromycin, clarithromycin, or erythromycin) may be prescribed for some patients. Supportive therapy includes administration of antipyretics, fluid replacement, circulatory support with pressor drugs, if necessary, and oxygen administration by mask, cannula, or mechanical ventilation.

Special Considerations

- ◆ Closely monitor the patient's respiratory status. Evaluate chest wall expansion, depth and pattern of respirations, cough, and chest pain. Watch for restlessness as a sign of hypoxemia, which requires suctioning, repositioning, or more aggressive oxygen therapy.
- ◆ Continually monitor the patient's vital signs, oximetry or ABG values, level of consciousness, and dryness and color of lips and mucous membranes. Watch for signs of shock (decreased blood pressure, thready pulse, diaphoresis, and clammy skin).
- ◆ Keep the patient comfortable. Provide mouth care frequently. If necessary, apply soothing cream to the nostrils.
- ◆ Replace fluid and electrolytes, as needed. The patient with renal failure may require dialysis.
- ◆ Provide mechanical ventilation and other respiratory therapy, as needed. Teach the patient how to cough effectively and encourage deep-breathing exercises. Stress the need to continue these until recovery is complete.
- ◆ Give antibiotic therapy as indicated and observe carefully for adverse effects.

ATELECTASIS

Atelectasis is incomplete expansion of lobules (clusters of alveoli) or lung segments, which may result in partial or complete lung collapse. Because parts of the lung are unavailable for gas exchange, unoxygenated blood passes through these areas unchanged, resulting in hypoxemia. Atelectasis may be chronic or acute. Many patients undergoing upper abdominal or thoracic surgery experience atelectasis to some degree. The prognosis depends on prompt removal of any airway obstruction, relief of hypoxemia, and re-expansion of the collapsed lung.

Causes

Atelectasis commonly results from bronchial occlusion by mucus plugs. It's a problem in many patients with COPD, bronchiectasis, or cystic fibrosis and in those who smoke heavily. (Smoking increases mucus production and damages cilia.) Atelectasis may also result from occlusion by foreign bodies, bronchogenic carcinoma, and inflammatory lung disease.

Other causes include RDS of the neonate (hyaline membrane disease), oxygen toxicity, and pulmonary edema, in which alveolar surfactant changes increase surface tension and permit complete alveolar deflation.

External compression, which inhibits full lung expansion, or any condition that makes deep breathing painful may also cause atelectasis. Such compression or pain may result from abdominal surgical incisions, rib fractures, pleuritic chest pain, tight dressings around the chest, stab wounds, impalement accidents, car accidents in which the driver slams into the steering column, or obesity (which elevates the diaphragm and reduces tidal volume).

Prolonged immobility may also cause atelectasis by producing preferential ventilation of one area of the lung over another. Mechanical ventilation using constant small tidal volumes without intermittent deep breaths may also result in atelectasis. CNS depression (as in drug overdose) eliminates periodic sighing and is a predisposing factor of progressive atelectasis.

Pathophysiology

Atelectasis results from some type of obstruction or compression of the lungs or bronchus. Retraction of the lung occurs when the blood circulating in the alveolar capillary bed absorbs the gas from the alveolar in the unventilated lung. The alveolar spaces fill with secretions and cells, preventing the complete collapse of the lung. The surrounding tissues distend and displace, shifting the heart and mediastinum toward the ateleactactic area.

Complications

- Respiratory failure
- Pneumonia
- Hypoxemia

Signs and Symptoms

Clinical effects vary with the cause of collapse, the degree of hypoxemia, and any underlying disease but generally include some degree of dyspnea. Atelectasis of a small area of the lung may produce only minimal symptoms that subside without specific treatment. However, massive collapse can produce severe dyspnea, anxiety, cyanosis, diaphoresis, peripheral circulatory collapse, tachycardia, and substernal or intercostal retraction. Also, atelectasis may result in compensatory hyperinflation of unaffected areas of the lung, mediastinal shift to the affected side, and elevation of the ipsilateral hemidiaphragm.

Diagnosis

Diagnosis requires an accurate patient history, a physical examination, and a chest X-ray. Auscultation reveals diminished or bronchial breath sounds. When much of the lung is collapsed, percussion reveals dullness. However, extensive areas of "microatelectasis" may exist without abnormalities on the chest X-ray. In widespread atelectasis, the chest X-ray shows characteristic horizontal lines in the lower lung zones. With segmental or lobar collapse, characteristic dense shadows commonly associated with hyperinflation of neighboring lung zones are also apparent. If the cause is unknown, diagnostic procedures may include bronchoscopy to rule out an

obstructing neoplasm or a foreign body.

Treatment

Treatment includes incentive spirometry, frequent coughing, and deep-breathing exercises. If atelectasis is secondary to mucus plugging, mucolytics, chest percussion, and postural drainage may be used. If these measures fail, bronchoscopy may be helpful in removing secretions. Humidity and bronchodilators can improve mucociliary clearance and dilate airways.

   Atelectasis secondary to an obstructing neoplasm may require surgery or radiation therapy. Postoperative thoracic and abdominal surgery patients require analgesics to facilitate deep breathing, which minimizes the risk of atelectasis.

Special Considerations

- If mechanical ventilation is used, tidal volume should be maintained at appropriate levels to ensure adequate expansion of the lungs. Use the sigh mechanism on the ventilator, if appropriate, to intermittently increase tidal volume at the rate of 10 to 15 sighs/hour. Implement the Ventilator Bundle to prevent VAP.
- Use an incentive spirometer to encourage deep inspiration through positive reinforcement. Teach the patient how to use the spirometer and encourage them to use it every 1 to 2 hours.
- Humidify inspired air and encourage adequate fluid intake to mobilize secretions. To promote loosening and clearance of secretions, encourage deep-breathing and coughing exercises and use postural drainage and chest percussion.
- If the patient is intubated or uncooperative, provide suctioning, as needed. Use sedatives with discretion because they depress respirations and the cough reflex as well as suppress sighing. However, remember that the patient won't cooperate with treatment if they are in pain.
- Assess breath sounds and ventilatory status frequently; report changes at once.
- Teach the patient about respiratory care, including postural drainage, coughing, and deep breathing.
- Encourage the patient to stop smoking and lose weight, as needed. Refer them to appropriate support groups for help.
- Provide reassurance and emotional support; the patient may be anxious because of hypoxia or respiratory distress.

PREVENTION

- *In a patient who is bedridden, encourage movement and deep breathing.*
- *Administer adequate analgesics.*
- *To prevent atelectasis, encourage the postoperative or other high-risk patient to cough and deep-breathe every 1 to 2 hours. To minimize pain during coughing exercises, splint the incision; teach the patient this technique as well. Gently reposition the patient often and encourage ambulation as soon as possible.*
- *Teach patients to keep small objects out of reach of children.*

RESPIRATORY ACIDOSIS

An acid–base disturbance characterized by reduced alveolar ventilation and manifested by hypercapnia (Pa_{CO_2} greater than 45 mm Hg), respiratory acidosis can be acute (because of a

sudden failure in ventilation) or chronic (as in long-term pulmonary disease). The prognosis depends on the severity of the underlying disturbance as well as the patient's general clinical condition.

Causes and Incidence

Some predisposing factors in respiratory acidosis include:

- Drugs—Opioids, anesthetics, hypnotics, and sedatives, including some of the new designer drugs, such as Ecstasy, decrease the sensitivity of the respiratory center.
- CNS trauma—Medullary injury may impair ventilatory drive.
- Chronic metabolic alkalosis—Respiratory compensatory mechanisms attempt to normalize pH by decreasing alveolar ventilation.
- Ventilation therapy—Use of high-flow oxygen (O_2) in chronic respiratory disorders suppresses the patient's hypoxic drive to breathe.
- Neuromuscular diseases (such as myasthenia gravis, Guillain–Barré syndrome, and poliomyelitis)—Failure of the respiratory muscles to respond properly to respiratory drive decreases alveolar ventilation.
- In addition, respiratory acidosis can result from airway obstruction or parenchymal lung disease, which interferes with alveolar ventilation; COPD; asthma; severe acute respiratory distress syndrome (SARS); chronic bronchitis; large pneumothorax; extensive pneumonia; and pulmonary edema.

Hypoventilation compromises elimination of CO_2 produced through metabolism. The retained CO_2 then combines with water to form an excess of carbonic acid, decreasing the blood pH. As a result, the concentration of hydrogen ions in body fluids, which directly reflects acidity, increases.

Pathophysiology

Lung diseases or conditions that cause hypoventilation result in CO_2 being produced at a rapid rate. Lack of adequate ventilation quickly increases the partial pressure of arterial CO_2. The increase in Pa_{CO_2} also results in the decrease in bicarbonate ration and decreasing the pH to an acidotic state.

Complications

- Shock
- Cardiac arrest

Signs and Symptoms

Acute respiratory acidosis produces CNS disturbances that reflect changes in the pH of cerebrospinal fluid rather than increased CO_2 levels in cerebral circulation. Effects range from restlessness, confusion, and apprehension to somnolence, with a fine or flapping tremor (asterixis), or coma. The patient may complain of headaches as well as exhibiting dyspnea and tachypnea with papilledema and depressed reflexes. Unless the patient is receiving O_2, hypoxemia accompanies respiratory acidosis. This disorder may also cause cardiovascular abnormalities, such as tachycardia, hypertension, atrial and ventricular arrhythmias and, in severe acidosis, hypotension with vasodilation (bounding pulses and warm periphery).

Diagnosis

℞ CONFIRMING DIAGNOSIS *ABG analysis confirms the diagnosis: $Paco_2$ exceeds the normal 45 mm Hg; pH is below the normal range of 7.35 to 7.45 unless compensation has occurred; and bicarbonate is normal in the acute stage but elevated in the chronic stage.*

Chest X-ray, CT scan, and PFTs can help determine the cause.

Treatment

Effective treatment of respiratory acidosis requires correction of the underlying source of alveolar hypoventilation.

Significantly reduced alveolar ventilation may require mechanical ventilation until the underlying condition can be treated. In COPD, this includes bronchodilators, O_2, corticosteroids, and antibiotics for infectious conditions; drug therapy for conditions such as myasthenia gravis; removal of foreign bodies from the airway; antibiotics for pneumonia; dialysis or charcoal to remove toxic drugs; and correction of metabolic alkalosis.

Dangerously low blood pH (less than 7.15) can produce profound CNS and cardiovascular deterioration; careful administration of I.V. sodium bicarbonate may be required. In chronic lung disease, elevated CO_2 may persist despite optimal treatment.

Special Considerations

- Be alert for critical changes in the patient's respiratory, CNS, and cardiovascular functions. Report such changes as well as any variations in ABG values or electrolyte status immediately. Also, maintain adequate hydration.
- Maintain a patent airway and provide adequate humidification if acidosis requires mechanical ventilation. Perform tracheal suctioning regularly and vigorous chest physiotherapy if ordered. Continuously monitor ventilator settings and respiratory status.
- To prevent respiratory acidosis, closely monitor patients with COPD and chronic CO_2 retention for signs of acidosis. Also, administer O_2 at low flow rates; closely monitor all patients who receive opioids and sedatives. Instruct patients who have received general anesthesia to turn, cough, and perform deep-breathing exercises frequently to prevent the onset of respiratory acidosis.

RESPIRATORY ALKALOSIS

Respiratory alkalosis is an acid–base disturbance characterized by a decrease in the $Paco_2$ to less than 35 mm Hg, which is due to alveolar hyperventilation. Uncomplicated respiratory alkalosis leads to a decrease in hydrogen ion concentration, which results in elevated blood pH. Hypocapnia occurs when the elimination of CO_2 by the lungs exceeds the production of CO_2 at the cellular level.

Causes

Causes of respiratory alkalosis fall into two categories:

- pulmonary—severe hypoxemia, pneumonia, interstitial lung disease, pulmonary vascular disease, and acute asthma
- nonpulmonary—anxiety, fever, aspirin toxicity, metabolic acidosis, CNS disease

(inflammation or tumor), sepsis, hepatic failure, and pregnancy

Pathophysiology

An underlying condition or stimulus that causes hyperventilation, expels an increased amount of CO_2. CO_2 in the circulation is shifted causing hydrogen ions and bicarbonate to change into additional CO_2 via the enzyme carbonic anhydrase which, in turn, decreases the available hydrogen ions and increasing the pH.

Complications

- ◆ Cardiac arrhythmias
- ◆ Seizures

Signs and Symptoms

The cardinal sign of respiratory alkalosis is deep, rapid breathing, possibly exceeding 40 breaths/minute. This pattern of breathing is similar to Kussmaul's respirations that characterize diabetic acidosis. Such hyperventilation usually leads to CNS and neuromuscular disturbances, such as light-headedness or dizziness (because of below-normal CO_2 levels that decrease cerebral blood flow), agitation, circumoral and peripheral paresthesias, carpopedal spasms, twitching (possibly progressing to tetany), and muscle weakness. Severe respiratory alkalosis may cause cardiac arrhythmias (that may fail to respond to conventional treatment), seizures, or both.

Diagnosis

℞ **CONFIRMING DIAGNOSIS** *ABG analysis confirms respiratory alkalosis and rules out respiratory compensation for metabolic acidosis: $Paco_2$ less than 35 mm Hg; pH elevated in proportion to the fall in $Paco_2$ in the acute stage but falling toward normal in the chronic stage; and bicarbonate normal in the acute stage, but below normal in the chronic stage.*

Chest X-ray or PFTs may aid in diagnosing possible lung disease.

Treatment

Treatment is designed to eradicate the underlying condition—for example, removal of ingested toxins, treatment of fever or sepsis, providing oxygen for acute hypoxemia, and treatment of CNS disease. When hyperventilation is caused by severe anxiety, the patient may be instructed to breathe into a paper bag, which increases CO_2 levels and helps relieve anxiety.

Prevention of hyperventilation in patients receiving mechanical ventilation requires monitoring ABG levels and adjusting tidal volume and minute ventilation.

Special Considerations

- ◆ Watch for and report any changes in neurologic, neuromuscular, or cardiovascular functions.
- ◆ Remember that twitching and cardiac arrhythmias may be associated with alkalemia and electrolyte imbalances. Monitor ABG and serum electrolyte levels closely, reporting any variations immediately.
- ◆ Explain all diagnostic tests and procedures to reduce anxiety.

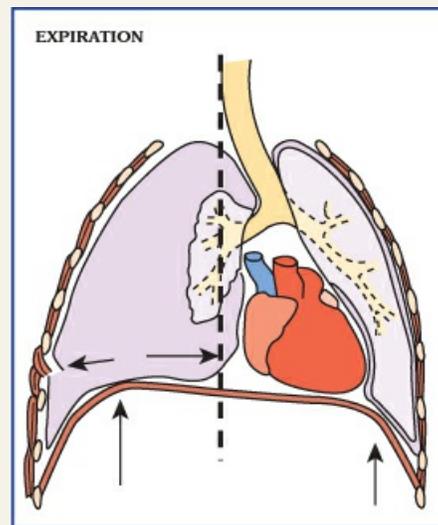
PNEUMOTHORAX

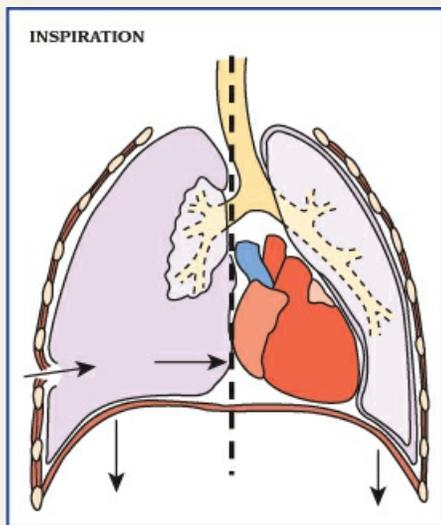
Pneumothorax is an accumulation of air or gas between the parietal and visceral pleurae. The amount of air or gas trapped in the intrapleural space determines the degree of lung collapse. In tension pneumothorax, the air in the pleural space is under higher pressure than air in adjacent lung and vascular structures. Without prompt treatment, tension or large pneumothorax results in fatal pulmonary and circulatory impairment. (See *Understanding tension pneumothorax,* page 112.)

PATHOPHYSIOLOGY
UNDERSTANDING TENSION PNEUMOTHORAX

In tension pneumothorax, air accumulates intrapleurally and can't escape. Intrapleural pressure rises, collapsing the ipsilateral lung.

On inspiration, the mediastinum shifts toward the unaffected lung, impairing ventilation.

On expiration, the mediastinal shift distorts the vena cava and reduces venous return.




Causes and Incidence

Spontaneous pneumothorax usually occurs in otherwise healthy adults 20 to 40 years old. It may be caused by air leakage from ruptured congenital blebs adjacent to the visceral pleural surface, near the apex of the lung. Secondary spontaneous pneumothorax is a complication of underlying lung disease, such as COPD, asthma, cystic fibrosis, TB, and whooping cough. Spontaneous pneumothorax may also occur in interstitial lung disease, such as eosinophilic granuloma or lymphangiomyomatosis.

Traumatic pneumothorax may result from insertion of a central venous line, thoracic surgery, or a penetrating chest injury, such as a gunshot or knife wound. It may follow a transbronchial biopsy, or it may also occur during thoracentesis or a closed pleural biopsy. When traumatic pneumothorax follows a penetrating chest injury, it frequently coexists with hemothorax (blood

in the pleural space).

In *tension pneumothorax,* positive pleural pressure develops as a result of traumatic pneumothorax. When air enters the pleural space through a tear in lung tissue and is unable to leave by the same vent, each inspiration traps air in the pleural space, resulting in positive pleural pressure. This in turn causes collapse of the ipsilateral lung and marked impairment of venous return, which can severely compromise cardiac output and may cause a mediastinal shift. Decreased filling of the great veins of the chest results in diminished cardiac output and lowered blood pressure.

Pathophysiology

Pneumothorax can be classified as open or closed. In *open pneumothorax* (usually the result of trauma), air flows between the pleural space and the outside of the body. In *closed pneumothorax,* air reaches the pleural space directly from the lung.

Complications

◆ Fatal pulmonary and circulatory impairment

Signs and Symptoms

The cardinal features of pneumothorax are sudden, sharp, pleuritic pain (exacerbated by movement of the chest, breathing, and coughing); asymmetrical chest wall movement; and shortness of breath. Additional signs of tension pneumothorax are weak and rapid pulse, pallor, jugular vein distention, and anxiety. Tracheal deviations may be present with mediastinal shift. Tension pneumothorax produces the most severe respiratory symptoms; a spontaneous pneumothorax that releases only a small amount of air into the pleural space may cause no symptoms. In a nontension pneumothorax, the severity of symptoms is usually related to the size of the pneumothorax and the degree of preexisting respiratory disease.

Diagnosis

Sudden, sharp chest pain and shortness of breath suggest pneumothorax.

CONFIRMING DIAGNOSIS *Chest X-ray showing air in the pleural space and, possibly, mediastinal shift confirms this diagnosis.*

In the absence of a definitive chest X-ray, the physical examination may reveal:

◆ on inspection—overexpansion and rigidity of the affected chest side; in tension pneumothorax, jugular vein distention with hypotension and tachycardia
◆ on palpation—crackling beneath the skin, indicating subcutaneous emphysema (air in tissue) and decreased vocal fremitus
◆ on percussion—hyperresonance on the affected side
◆ on auscultation—decreased or absent breath sounds over the collapsed lung

If the pneumothorax is significant, ABG findings include pH less than 7.35, Pa_{O_2} less than 80 mm Hg, and Pa_{CO_2} above 45 mm Hg.

Treatment

Treatment is conservative for spontaneous pneumothorax in which no signs of increased pleural

pressure (indicating tension pneumothorax) appear, lung collapse is less than 30%, and the patient shows no signs of dyspnea or other indications of physiologic compromise. Such treatment consists of bed rest, careful monitoring of blood pressure and pulse and respiratory rates, oxygen administration and, possibly, needle aspiration of air with a large-bore needle attached to a syringe. If more than 30% of the lung is collapsed, treatment to re-expand the lung includes placing a thoracostomy tube in the second or third intercostal space in the midclavicular line (or in the fifth or sixth intercostal space in the midaxillary line), connected to an underwater seal or low suction pressures.

Recurring spontaneous pneumothorax requires thoracotomy and pleurectomy; these procedures prevent recurrence by causing the lung to adhere to the parietal pleura. Traumatic and tension pneumothoraces require chest tube drainage; traumatic pneumothorax may also require surgery.

Special Considerations

ALERT *Watch for pallor, gasping respirations, and sudden chest pain. Monitor patient's vital signs at least every hour for signs of shock, increasing respiratory distress, or mediastinal shift. Listen for breath sounds over both lungs. Falling blood pressure and rising pulse and respiratory rates may indicate tension pneumothorax, which can be fatal without prompt treatment.*

- Urge the patient to control coughing and gasping during thoracotomy. However, after the chest tube is in place, encourage them to cough and breathe deeply (at least once an hour) to facilitate lung expansion.
- If the patient is undergoing chest tube drainage, watch for continuing air leakage (bubbling), indicating the lung defect has failed to close; this may require surgery. Also watch for increasing subcutaneous emphysema by checking around the neck or at the tube insertion site for crackling beneath the skin. If the patient is on a ventilator, watch for difficulty in breathing in time with the ventilator as well as pressure changes on ventilator gauges.
- Change dressings around the chest tube insertion site according to your facility's policy. Don't reposition or dislodge the tube. If it dislodges, immediately place a petroleum gauze dressing over the opening to prevent rapid lung collapse.
- Secure the chest tube drainage apparatus appropriately. Tape connections securely.
- Monitor the patient's vital signs frequently after thoracotomy. Also, for the first 24 hours, assess respiratory status by checking breath sounds hourly. Observe the chest tube site for leakage, noting the amount and color of drainage. Help the patient walk, as ordered (usually on the first postoperative day), to facilitate deep inspiration and lung expansion.
- To reassure the patient, explain what pneumothorax is, what causes it, and all diagnostic tests and procedures. Make them as comfortable as possible. (The patient with pneumothorax is usually most comfortable sitting upright.)

PNEUMONIA

Pneumonia is an acute infection of the lung parenchyma that commonly impairs gas exchange. The prognosis is generally good for people who have normal lungs and adequate host defenses before the onset of pneumonia; however, pneumonia is the sixth leading cause of death in the United States. (See *Looking at lobar pneumonia and bronchopneumonia*.)

Looking at Lobar Pneumonia and Bronchopneumonia

Pneumonia can involve the distal airways, alveoli, part of a lobe, or an entire lobe.

Causes and Incidence

Pneumonia can be classified in several ways:

◆ Microbiologic etiology—Pneumonia can be viral, bacterial, fungal, protozoan, mycobacterial, mycoplasmal, or rickettsial in origin. (See *Diagnosing and treating the types of pneumonia,* pages 114 to 116.)

Diagnosing and Treating the Types of Pneumonia

Type	Signs and symptoms	Diagnosis	Treatment
Aspiration Results from vomiting and aspiration of gastric or oropharyngeal contents into	◆ Noncardiogenic pulmonary edema that may follow damage to respiratory epithelium from contact with stomach acid	◆ *Chest X-ray:* locates areas of infiltrates, which suggest diagnosis	◆ *Antimicrobial therapy:* penicillin G or clindamycin ◆ *Supportive:* oxygen therapy, suctioning, coughing, deep breathing, and adequate hydration

trachea and lungs	◆ Crackles, dyspnea, cyanosis, hypotension, and tachycardia ◆ May be subacute pneumonia with cavity formation; lung abscess may occur if foreign body is present		
Bacterial Klebsiella	◆ Fever and recurrent chills; cough producing rusty, bloody, viscous sputum (currant jelly); cyanosis of lips and nail beds due to hypoxemia; and shallow, grunting respirations ◆ Common in patients with chronic alcoholism, pulmonary disease, diabetes, or those at risk for aspiration	◆ *Chest X-ray:* typically, but not always, consolidation in the upper lobe that causes bulging of fissures ◆ *White blood cell (WBC) count:* elevated ◆ *Sputum culture and Gram stain:* may show gram-negative *Klebsiella*	◆ *Antimicrobial therapy:* an aminoglycoside and a cephalosporin
Staphylococcus	◆ Temperature of 102° to 104° F (38.9° to 40° C), recurrent shaking chills, bloody sputum, dyspnea, tachypnea, and hypoxemia ◆ Should be suspected with viral illness, such as influenza or measles, and in patients with cystic fibrosis	◆ *Chest X-ray:* multiple abscesses and infiltrates; high incidence of empyema ◆ *WBC count:* elevated ◆ *Sputum culture and Gram stain:* may show gram-positive staphylococci	◆ *Antimicrobial therapy:* nafcillin or oxacillin for 14 days if staphylococci are penicillinase producing ◆ *Supportive:* chest tube drainage of empyema
Streptococcus (*Streptococcus pneumoniae*)	Sudden onset of severe, shaking chills and a sustained temperature of 102° to 104° F (38.9° to 40° C); commonly preceded by upper respiratory tract infection	◆ *Chest X-ray:* areas of consolidation, commonly lobar ◆ *WBC count:* elevated ◆ *Sputum culture:* may show gram-positive *S. pneumoniae*; this organism not always recovered	◆ *Antimicrobial therapy:* penicillin G (or erythromycin, if patient is allergic to penicillin) for 7 to 10 days beginning after obtaining culture specimen but without waiting for results. (Resistance to penicillin is becoming much more common and, in the patient with risk factors for resistance [extreme age, day care attendance, or immunosuppression], treatment with vancomycin, imipenem, or levofloxacin should be considered.)
Protozoan *Pneumocystis carinii (jiroveci)*	◆ Occurs in immunocompromised persons ◆ Dyspnea and nonproductive cough ◆ Anorexia, weight loss, and fatigue ◆ Low-grade fever	◆ *Fiber-optic bronchoscopy:* obtains specimens for histologic studies ◆ *Chest X-ray:* nonspecific infiltrates, nodular lesions, or spontaneous	◆ *Antimicrobial therapy:* trimethoprim and sulfamethoxazole or pentamidine by I.V. administration or inhalation. (Prophylactic pentamidine may be used for high-risk patients.) ◆ *Supportive:* oxygen, improved nutrition, and mechanical ventilation

		pneumothorax	
Viral Adenovirus (insidious onset; generally affects young adults)	Sore throat, fever, cough, chills, malaise, small amounts of mucoid sputum, retrosternal chest pain, anorexia, rhinitis, adenopathy, scattered crackles, and rhonchi	*Chest X-ray:* patchy distribution of pneumonia, more severe than indicated by physical examination *WBC count:* normal to slightly elevated	Treat symptoms only Mortality low; usually clears with no residual effects
Chicken pox (varicella) (uncommon in children, but present in 30% of adults with varicella)	Cough, dyspnea, cyanosis, tachypnea, pleuritic chest pain, hemoptysis, and rhonchi 1 to 6 days after onset of rash	*Chest X-ray:* shows more extensive pneumonia than indicated by physical examination and bilateral, patchy, diffuse, nodular infiltrates *Sputum analysis:* predominant mononuclear cells and characteristic intranuclear inclusion bodies, with characteristic skin rash, confirm diagnosis	*Supportive:* adequate hydration, and oxygen therapy in critically ill patients Therapy with I.V. acyclovir
Viral Cytomegalovirus	Difficult to distinguish from other nonbacterial pneumonias Fever, cough, shaking chills, dyspnea, cyanosis, weakness, and diffuse crackles Occurs in neonates as devastating multisystemic infection; in normal adults, resembles mononucleosis; in immunocompromised hosts, varies from clinically inapparent to devastating infection	*Chest X-ray:* in early stages, variable patchy infiltrates; later, bilateral, nodular, and more predominant in lower lobes *Percutaneous aspiration of lung tissue, transbronchial biopsy, or open lung biopsy:* microscopic examination shows typical intranuclear and cytoplasmic inclusions; the virus can be cultured from lung tissue	Generally, benign and self-limiting in mononucleosis-like form *Supportive:* adequate hydration and nutrition, oxygen therapy, and bed rest In immunosuppressed patients, disease is more severe and may be fatal; ganciclovir or foscarnet treatment is warranted
Influenza (prognosis poor even with treatment; 30% mortality)	Cough (initially nonproductive; later, purulent sputum), marked cyanosis, dyspnea, high fever, chills, substernal pain and discomfort, moist crackles, frontal headache, and	*Chest X-ray:* diffuse bilateral bronchopneumonia radiating from hilus *WBC count:* normal to slightly elevated *Sputum smears:* no specific	*Supportive:* for respiratory failure, endotracheal intubation and ventilator assistance; for fever, hypothermia blanket or antipyretics; and for influenza A, amantadine or rimantadine

	◆ myalgia ◆ Death results from cardiopulmonary collapse	organisms	
Measles (rubeola)	◆ Fever, dyspnea, cough, small amounts of sputum, coryza, rash, and cervical adenopathy	◆ *Chest X-ray:* reticular infiltrates, sometimes with hilar lymph node enlargement ◆ *Lung tissue specimen:* characteristic giant cells	◆ *Supportive:* bed rest, adequate hydration, and antimicrobials; assisted ventilation if necessary
Respiratory syncytial virus (most prevalent in infants and children)	◆ Listlessness, irritability, tachypnea with retraction of intercostal muscles, wheezing, slight sputum production, fine moist crackles, fever, severe malaise, and cough	◆ *Chest X-ray:* patchy bilateral consolidation ◆ *WBC count:* normal to slightly elevated	◆ *Supportive:* humidified air, oxygen, antimicrobials (commonly given until viral etiology confirmed), and aerosolized ribavirin ◆ Usually complete recovery

- Location—Bronchopneumonia involves distal airways and alveoli; lobular pneumonia, part of a lobe; and lobar pneumonia, an entire lobe.
- Type—Primary pneumonia results from inhalation or aspiration of a pathogen; it includes pneumococcal and viral pneumonia. Secondary pneumonia may follow initial lung damage from a noxious chemical or other insult (superinfection) or may result from hematogenous spread of bacteria from a distant focus.

Predisposing factors for bacterial and viral pneumonia include chronic illness and debilitation, cancer (particularly lung cancer), abdominal and thoracic surgery, atelectasis, common colds or other viral respiratory infections, such as acquired immunodeficiency syndrome, chronic respiratory disease (COPD, asthma, bronchiectasis, and cystic fibrosis), influenza, smoking, malnutrition, alcoholism, sickle cell disease, tracheostomy, exposure to noxious gases, aspiration, and immunosuppressive therapy.

Predisposing factors for aspiration pneumonia include old age, debilitation, artificial airway use, NG tube feedings, impaired gag reflex, poor oral hygiene, and decreased level of consciousness.

In elderly patients and patients who are debilitated, bacterial pneumonia may follow influenza or a common cold. Respiratory viruses are the most common cause of pneumonia in children 2 to 3 years old. In school-age children, mycoplasma pneumonia is more common.

Pathophysiology

A pathogen or extrinsic agent enters the respiratory tract and invades or insults the alveoli. When the host defenses are overwhelmed by the inoculum size or virulence of the pathogen, it results in an infection of the lung parenchyma.

Complications

- Septic shock

- Hypoxemia
- Respiratory failure
- Empyema
- Lung abscess
- Bacteremia
- Endocarditis
- Pericarditis
- Meningitis

Signs and Symptoms

The main symptoms of pneumonia are coughing, sputum production, pleuritic chest pain, shaking chills, shortness of breath, rapid shallow breathing, and fever. Physical signs vary widely, ranging from diffuse, fine crackles to signs of localized or extensive consolidation and pleural effusion. There may also be associated symptoms of headache, sweating, loss of appetite, excess fatigue, and confusion (in older people).

Complications include hypoxemia, respiratory failure, pleural effusion, empyema, lung abscess, and bacteremia, with spread of infection to other parts of the body, resulting in meningitis, endocarditis, and pericarditis.

Diagnosis

Clinical features, chest X-ray showing infiltrates, and sputum smear demonstrating acute inflammatory cells support the diagnosis. Gram stain and sputum culture may identify the organism. Positive blood cultures in the patient with pulmonary infiltrates strongly suggest pneumonia produced by the organisms isolated from the blood cultures. Pleural effusions, if present, should be tapped and fluid analyzed for evidence of infection in the pleural space. Occasionally, a transtracheal aspirate of tracheobronchial secretions or bronchoscopy with brushings or washings may be done to obtain material for smear and culture. The patient's response to antimicrobial therapy also provides important evidence of the presence of pneumonia.

Treatment

Antimicrobial therapy varies with the causative agent. Therapy should be reevaluated early in the course of treatment. Supportive measures include humidified oxygen therapy for hypoxemia, mechanical ventilation for respiratory failure, a high-calorie diet and adequate fluid intake, bed rest, and an analgesic to relieve pleuritic chest pain. Patients with severe pneumonia on mechanical ventilation may require PEEP to facilitate adequate oxygenation.

Special Considerations

Correct supportive care can increase patient comfort, avoid complications, and speed recovery. The following protocol should be observed throughout the illness:

- Maintain a patent airway and adequate oxygenation. Monitor pulse oximetry. Measure ABG levels, especially in hypoxemic patients. Administer supplemental oxygen if the Pa_{O_2} is less than 55 to 60 mm Hg. Patients with underlying chronic lung disease should be given oxygen cautiously.
- Teach the patient how to cough and perform deep-breathing exercises to clear secretions;

encourage them to do so often. In severe pneumonia that requires ET intubation or tracheostomy (with or without mechanical ventilation), provide thorough respiratory care. Suction often, using sterile technique, to remove secretions.

◆ Obtain sputum specimens as needed, by suction if the patient can't produce specimens independently. Collect specimens in a sterile container and deliver them promptly to the microbiology laboratory.

◆ Administer antibiotics as ordered, sedation, and pain medication as needed; record the patient's response to medications. Fever and dehydration may require I.V. fluids and electrolyte replacement.

◆ Maintain adequate nutrition to offset hypermetabolic state secondary to infection. Ask the dietary department to provide a high-calorie, high-protein diet consisting of soft, easy-to-eat foods. Encourage the patient to eat. As necessary, supplement oral feedings with NG tube feedings or parenteral nutrition. Monitor fluid intake and output. Consider limiting the use of milk products because they may increase sputum production.

◆ Provide a quiet, calm environment for the patient, with frequent rest periods.

◆ Give emotional support by explaining all procedures (especially intubation and suctioning) to the patient and family. Encourage family visits. Provide diversionary activities appropriate to the patient's age.

◆ To control the spread of infection, dispose of secretions properly. Tell the patient to sneeze and cough into a disposable tissue; tape a lined bag to the side of the bed for used tissues.

Pneumonia can be prevented as follows:

◆ Advise the patient to avoid using antibiotics indiscriminately during minor viral infections because this may result in upper airway colonization with antibiotic-resistant bacteria. If the patient then develops pneumonia, the organisms producing the pneumonia may require treatment with more toxic antibiotics.

◆ Encourage pneumococcal vaccine (pneumovax) and annual influenza vaccination for high-risk patients, such as those with COPD, chronic heart disease, or sickle cell disease.

◆ Urge all bedridden and postoperative patients to perform deep-breathing and coughing exercises frequently. Reposition such patients often to promote full aeration and drainage of secretions. Encourage early ambulation in postoperative patients.

◆ To prevent aspiration during NG tube feedings, elevate the patient's head, check the tube's position, and administer the formula slowly. Don't give large volumes at one time; this could cause vomiting. Keep the patient's head elevated for at least 30 minutes after the feeding. Check for residual formula at 4- to 6-hour intervals.

PREVENTION

◆ *Perform hand hygiene frequently to prevent infections.*
◆ *Advise patients to avoid taking antibiotics indiscriminately during viral infections.*

IDIOPATHIC BRONCHIOLITIS OBLITERANS WITH ORGANIZING PNEUMONIA

Idiopathic bronchiolitis obliterans with organizing pneumonia (BOOP), also known as *cryptogenic organizing pneumonia,* is one of several types of bronchiolitis obliterans. *Organizing pneumonia* refers to unresolved pneumonia, in which inflammatory alveolar exudate persists and eventually undergoes fibrosis. *Bronchiolitis obliterans* is a generic term used to

describe an inflammatory disease of the small airways.

Causes and Incidence

BOOP has no known cause. However, other forms of bronchiolitis obliterans and organizing pneumonia may be associated with specific diseases or situations, such as bone marrow, heart, or heart–lung transplantation; collagen vascular diseases, such as rheumatoid arthritis and systemic lupus erythematosus (LE); inflammatory diseases, such as Crohn disease, ulcerative colitis, and polyarteritis nodosa; bacterial, viral, or mycoplasmal respiratory infections; inhalation of toxic gases; and drug therapy with amiodarone, bleomycin, penicillamine, or lomustine.

Much debate still exists about the various pathologies and classifications of bronchiolitis obliterans. Most patients with BOOP are between 50 and 60 years old. Incidence is equally divided between men and women. A smoking history doesn't seem to increase the risk of developing BOOP.

Pathophysiology

BOOP is the result of an epithelial injury in the lung that progresses to the formation of fibrinoid inflammatory cell clusters and subsequently intra-alveolar fibrosis. Upon biopsy the key characteristic is fibroblastic plugs present in the alveoli, alveolar ducts, and bronchioles.

Complications

- Respiratory failure
- Interstitial lung disease
- Death

Signs and Symptoms

The presenting symptoms of BOOP are usually subacute, with a flulike syndrome of fever, persistent and nonproductive cough, dyspnea (especially with exertion), malaise, anorexia, and weight loss lasting for several weeks to several months. Physical assessment findings may reveal dry crackles as the only abnormality. Less common symptoms include a productive cough, hemoptysis, chest pain, generalized aching, and night sweats.

Diagnosis

Diagnosis begins with a thorough patient history meant to exclude any known cause of bronchiolitis obliterans or diseases with a pathophysiology that includes an organizing pneumonia pattern.

- Chest X-ray usually shows patchy, diffuse airspace opacities with a ground-glass appearance that may migrate from one location to another. High-resolution CT scans show areas of consolidation. Except for the migrating opacities, these findings are nonspecific and present in many other respiratory disorders.
- PFTs may be normal or show reduced capacities. The diffusing capacity for carbon monoxide is generally low.
- ABG analysis usually shows mild to moderate hypoxemia at rest, which worsens with exercise.
- Blood tests reveal an increased erythrocyte sedimentation rate, an increased C-reactive protein level, and an increased WBC count with a somewhat increased proportion of neutrophils and

a minor rise in eosinophils. Immunoglobulin (Ig) G and IgM levels are normal or slightly increased, and the IgE level is normal.

◆ Bronchoscopy reveals normal or slightly inflamed airways. Bronchoalveolar lavage fluid obtained during bronchoscopy shows a moderate elevation in lymphocytes and, sometimes, elevated neutrophil and eosinophil levels. Foamy-looking alveolar macrophages may also be found.

℞ **CONFIRMING DIAGNOSIS** *Lung biopsy, thoracoscopy, or bronchoscopy is required to confirm the diagnosis of BOOP. Pathologic changes in lung tissue include plugs of connective tissue in the lumen of the bronchioles, alveolar ducts, and alveolar spaces.*

These changes may occur in other types of bronchiolitis and in other diseases that cause organizing pneumonia. They also differentiate BOOP from constrictive bronchiolitis (characterized by inflammation and fibrosis that surrounds and may narrow or completely obliterate the bronchiolar airways). Although the pathologic findings in proliferative and constrictive bronchiolitis are different, the causes and presentations may overlap. Any known cause of bronchiolitis obliterans or organizing pneumonia must be ruled out before the diagnosis of BOOP is made.

Treatment

Corticosteroids are the current treatment for BOOP, although the ideal dosage and duration of treatment remain topics of discussion. Relapse is common when steroids are tapered off or stopped. This usually can be reversed when steroids are increased or resumed. Occasionally, a patient may need to continue corticosteroids indefinitely.

Immunosuppressive-cytotoxic drugs, such as cyclophosphamide, have been used in the few cases of intolerance or unresponsiveness.

Oxygen is used to correct hypoxemia. The patient may need either no oxygen or a small amount of oxygen at rest and a greater amount when they exercise.

Other treatments vary, depending on the patient's symptoms, and may include inhaled bronchodilators, cough suppressants, and bronchial hygiene therapies.

BOOP is very responsive to treatment and usually can be completely reversed with corticosteroid therapy. However, a few deaths have been reported, particularly in patients who had more widespread pathologic changes in the lung or patients who developed opportunistic infections or other complications related to steroid therapy.

Special Considerations

◆ Explain all diagnostic tests. The patient may experience anxiety and frustration because of the length of time and number of tests needed to establish the diagnosis.

◆ Explain the diagnosis to the patient and family. This uncommon diagnosis may cause confusion and anxiety.

◆ Monitor the patient for adverse effects of corticosteroid therapy: weight gain, "moon face," glucose intolerance, fluid and electrolyte imbalance, mood swings, cataracts, peptic ulcer disease, opportunistic infections, and osteoporosis leading to bone fractures. In many cases, these effects leave the patient unable to tolerate the treatment. Teach the patient and their family about these adverse effects, emphasizing which reactions should be reported to the physician.

- Teach measures that may help prevent complications related to treatment, such as infection control and improved nutrition.
- Teach breathing, relaxation, and energy conservation techniques to help the patient manage symptoms.
- Monitor oxygenation, both at rest and with exertion. The physician will probably prescribe an oxygen flow rate for use when the patient is at rest and a higher one for exertion. Teach the patient how to increase the oxygen flow rate to the appropriate level for exercise.
- If the patient needs oxygen at home, ensure continuity of care by making appropriate referrals to discharge planners, respiratory care practitioners, and home equipment vendors.

PULMONARY EMBOLISM

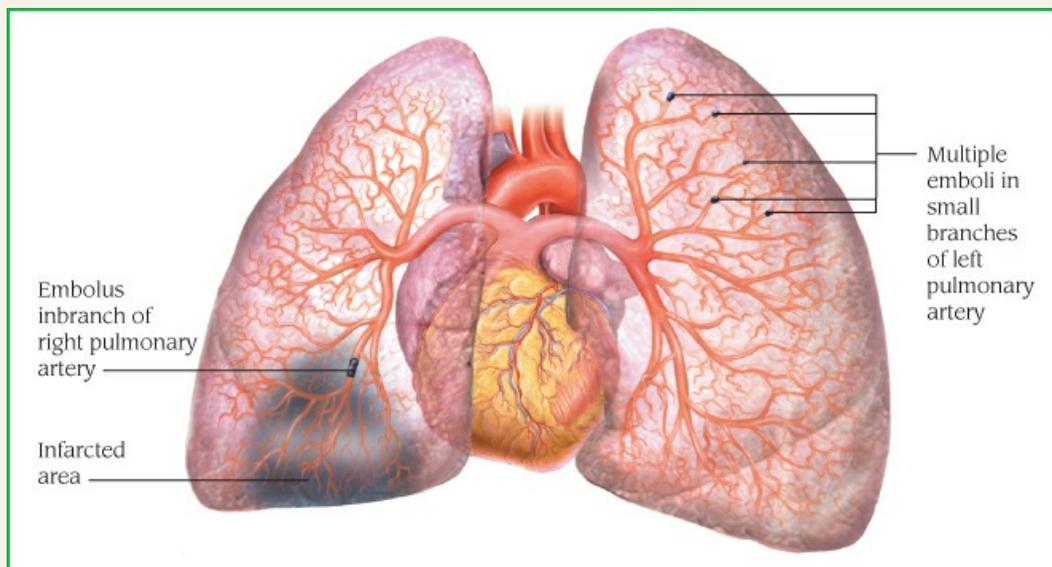
The most common pulmonary complication in hospitalized patients, pulmonary embolism is an obstruction of the pulmonary arterial bed by a dislodged thrombus, heart valve vegetation, or foreign substance. Although pulmonary infarction that results from embolism may be so mild as to be asymptomatic, massive embolism (more than 50% obstruction of pulmonary arterial circulation) and the accompanying infarction can be rapidly fatal. (See *Looking at pulmonary emboli*, page 120.)

Looking at Pulmonary Emboli

This illustration shows multiple emboli in pulmonary artery branches and a larger embolus that has resulted in an infarcted area in the lung.

Embolus inbranch of right pulmonary artery

Infarcted area

Multiple emboli in small branches of left pulmonary artery


Causes and Incidence

Pulmonary embolism generally results from dislodged thrombi originating in the leg veins. More than half of such thrombi arise in the deep veins of the legs. Other less common sources of thrombi are the pelvic veins, renal veins, hepatic vein, right side of the heart, and upper

extremities. Such thrombus formation results directly from vascular wall damage, venostasis, or hypercoagulability of the blood. Trauma, clot dissolution, sudden muscle spasm, intravascular pressure changes, or a change in peripheral blood flow can cause the thrombus to loosen or fragment. Then the thrombus—now called an *embolus*—floats to the heart's right side and enters the lung through the pulmonary artery. There, the embolus may dissolve, continue to fragment, or grow.

By occluding the pulmonary artery, the embolus prevents alveoli from producing enough surfactant to maintain alveolar integrity. As a result, alveoli collapse and atelectasis develops. If the embolus enlarges, it may clog most or all of the pulmonary vessels and cause death.

Rarely, the emboli contain air, fat, bacteria, amniotic fluid, talc (from drugs intended for oral administration, which are injected intravenously by addicts), or tumor cells.

Predisposing factors for pulmonary embolism include long-term immobility, chronic pulmonary disease, heart failure or atrial fibrillation, thrombophlebitis, polycythemia vera, thrombocytosis, autoimmune hemolytic anemia, sickle cell disease, varicose veins, recent surgery, advanced age, pregnancy, lower extremity fractures or surgery, burns, obesity, vascular injury, cancer, I.V. drug abuse, or hormonal contraceptives.

Pathophysiology

Once a thrombus dislodges, it travels through to the venous system, through the right side of the heart, and lodges in the pulmonary arteries. The thrombus can completely occlude the vessels or only partially block the flow of blood. Many physiologic factors participate in the potential outcomes including the ability of the body's thrombolytic system to break down clots, function of the right ventricle, over all condition of lungs, and number and size of emboli.

Complications

- Pulmonary infarction
- Death

Signs and Symptoms

Total occlusion of the main pulmonary artery is rapidly fatal; smaller or fragmented emboli produce symptoms that vary with the size, number, and location of the emboli. Usually, the first symptom of pulmonary embolism is dyspnea, which may be accompanied by anginal or pleuritic chest pain. Other clinical features include tachycardia, productive cough (sputum may be blood-tinged), low-grade fever, and pleural effusion. Less common signs include massive hemoptysis, chest splinting, leg edema and, with a large embolus, cyanosis, syncope, and distended jugular veins.

In addition, pulmonary embolism may cause pleural friction rub and signs of circulatory collapse (weak, rapid pulse, and hypotension) and hypoxia (restlessness and anxiety).

Diagnosis

The patient history should reveal predisposing conditions for pulmonary embolism. A triad of deep vein thrombosis (DVT) formation is stasis, endothelial injury, and hypercoagulability. Risk factors include long car or plane trips, cancer, pregnancy, hypercoagulability, prior DVT, and pulmonary emboli.

- Chest X-ray helps to rule out other pulmonary diseases; areas of atelectasis, an elevated

diaphragm and pleural effusion, a prominent pulmonary artery and, occasionally, the characteristic wedge-shaped infiltrate suggestive of pulmonary infarction, or focal oligemia of blood vessels, are apparent.

- Lung scan shows perfusion defects in areas beyond occluded vessels; however, it doesn't rule out microemboli.
- Pulmonary angiography is the most definitive test but requires a skilled angiographer and radiologic equipment; it also poses some risk to the patient. Its use depends on the uncertainty of the diagnosis and the need to avoid unnecessary anticoagulant therapy in a high-risk patient.
- Electrocardiography may show right axis deviation; right bundle-branch block; tall, peaked P waves; ST-segment depression and T-wave inversions (indicative of right-sided heart strain); and supraventricular tachyarrhythmias in extensive pulmonary embolism. A pattern sometimes observed is S_1, Q_3, and T_3 (S wave in lead I, Q wave in lead III, and inverted T wave in lead III).
- Auscultation occasionally reveals a right ventricular S_3 gallop and increased intensity of the pulmonic component of S_2. Also, crackles and a pleural rub may be heard at the embolism site.
- ABG analysis showing a decreased Pa_{O_2} and Pa_{CO_2} are characteristic but don't always occur.

If pleural effusion is present, thoracentesis may rule out empyema, which indicates pneumonia.

Treatment

Treatment is designed to maintain adequate cardiovascular and pulmonary function during resolution of the obstruction and to prevent recurrence of embolic episodes. Because most emboli resolve within 10 to 14 days, treatment consists of oxygen therapy as needed and anticoagulation with heparin to inhibit new thrombus formation, followed by oral warfarin. Heparin therapy is monitored by daily coagulation studies (PTT).

Patients with massive pulmonary embolism and shock may need fibrinolytic therapy with thrombolytic therapy (streptokinase, urokinase, or tissue plasminogen activator) to enhance fibrinolysis of the pulmonary emboli and remaining thrombi. Emboli that cause hypotension may require the use of vasopressors. Treatment of septic emboli requires antibiotics—not anticoagulants—and evaluation for the infection's source, particularly endocarditis.

Surgery is performed on patients who can't take anticoagulants, who have recurrent emboli during anticoagulant therapy, or who have been treated with thrombolytic agents or pulmonary thromboendarterectomy. This procedure (which shouldn't be performed without angiographic evidence of pulmonary embolism) consists of vena cava ligation, plication, or insertion of an inferior vena cava device to filter blood returning to the heart and lungs.

Special Considerations

- Give oxygen by nasal cannula or mask. Check ABG levels if the patient develops fresh emboli or worsening dyspnea. Be prepared to provide ET intubation with assisted ventilation if breathing is severely compromised.
- Administer heparin, as ordered, through I.V. push or continuous drip. Monitor coagulation studies daily. Effective heparin therapy raises the PTT to more than 1½ times normal. Watch closely for nosebleeds, petechiae, and other signs of abnormal bleeding; check stools for

occult blood. Patients should be protected from trauma and injury; avoid I.M. injections and maintain pressure over venipuncture sites for 5 minutes, or until bleeding stops, to reduce hematoma.

- After the patient is stable, encourage them to move about often, and assist with isometric and range-of-motion exercises. Check pedal pulses, temperature, and color of feet to detect venostasis. *Never* massage the patient's legs. Offer diversional activities to promote rest and relieve restlessness.
- Help the patient walk as soon as possible after surgery to prevent venostasis.
- Maintain adequate nutrition and fluid balance to promote healing.
- Report frequent pleuritic chest pain, so that analgesics can be prescribed. Also, incentive spirometry can assist in deep breathing. Provide tissues and a bag for easy disposal of expectorations.
- Warn the patient not to cross their legs; this promotes thrombus formation.
- To relieve anxiety, explain procedures and treatments. Encourage the patient's family to participate in their care.
- Most patients need treatment with an oral anticoagulant (warfarin) for 3 to 6 months after a pulmonary embolism. Advise these patients to watch for signs of bleeding (bloody stools, blood in urine, and large ecchymoses), to take the prescribed medication exactly as ordered, not to change dosages without consulting their physician, and to avoid taking additional medication (including aspirin and vitamins). Stress the importance of follow-up laboratory tests (international normalized ratio) to monitor anticoagulant therapy.

PREVENTION

- *Encourage early ambulation in patients predisposed to this condition. With close medical supervision, low-dose heparin may be useful prophylactically.*
- *In high-risk patients, low–molecular-weight heparin may be given.*

SARCOIDOSIS

Sarcoidosis is a multisystem, granulomatous disorder that characteristically produces lymphadenopathy, pulmonary infiltration, and skeletal, liver, eye, or skin lesions. Acute sarcoidosis usually resolves within 2 years. Chronic, progressive sarcoidosis, which is uncommon, is associated with pulmonary fibrosis and progressive pulmonary disability.

Causes and Incidence

The cause of sarcoidosis is unknown, but these factors may play a role:

- hypersensitivity response (possibly from T-cell imbalance) to such agents as atypical mycobacteria, fungi, and pine pollen
- genetic predisposition (suggested by a slightly higher incidence of sarcoidosis within the same family)
- extreme immune response to infection

Sarcoidosis occurs most commonly in adults 30 to 50 years old. In the United States, sarcoidosis occurs predominantly among blacks, affecting twice as many women as men.

Pathophysiology

In the development of sarcoidosis, T cells play an important role by initiating a significant immune reaction. In sites where there is disease activity, a concentration of CD4 cells exist along with a release of interleukin-2. This results in a disequilibrium of the CD4/CD8 ratio. The exaggerated immune response creates the characteristic noncaseating granulomas, found primarily on the lungs and intrathoracic lymph nodes.

Complications

- Pulmonary fibrosis
- Pulmonary hypertension
- Cor pulmonale

Signs and Symptoms

Initial symptoms of sarcoidosis include arthralgia (in the wrists, ankles, and elbows), fatigue, malaise, and weight loss. Other clinical features vary according to the extent and location of the fibrosis:

- Respiratory—breathlessness, cough (usually nonproductive), substernal pain; complications in advanced pulmonary disease include pulmonary hypertension and cor pulmonale
- Cutaneous—erythema nodosum, subcutaneous skin nodules with maculopapular eruptions, and extensive nasal mucosal lesions
- Ophthalmic—anterior uveitis (common), glaucoma, and blindness (rare)
- Lymphatic—bilateral hilar and right paratracheal lymphadenopathy and splenomegaly
- Musculoskeletal—muscle weakness, polyarthralgia, pain, and punched-out lesions on phalanges
- Hepatic—granulomatous hepatitis, usually asymptomatic
- Genitourinary—hypercalciuria
- Cardiovascular—arrhythmias (premature beats, bundle-branch or complete heart block) and, rarely, cardiomyopathy
- CNS—cranial or peripheral nerve palsies, basilar meningitis, seizures, and pituitary and hypothalamic lesions producing diabetes insipidus

Diagnosis

Typical clinical features with appropriate laboratory data and X-ray findings suggest sarcoidosis. A positive skin lesion biopsy supports the diagnosis.
   Other relevant findings include:

- Chest X-ray—bilateral hilar and right paratracheal adenopathy with or without diffuse interstitial infiltrates; occasionally large nodular lesions present in lung parenchyma
- Lymph node or lung biopsy—noncaseating granulomas with negative cultures for mycobacteria and fungi
- Other laboratory data—rarely, increased serum calcium, mild anemia, leukocytosis, and hyperglobulinemia
- PFTs—decreased TLC and compliance, and decreased diffusing capacity
- ABG analysis—decreased arterial oxygen tension

   Negative tuberculin skin test, fungal serologies, and sputum cultures for mycobacteria and fungi as well as negative biopsy cultures help rule out infection.

Treatment

Sarcoidosis that produces no symptoms requires no treatment. However, those severely affected with sarcoidosis require treatment with corticosteroids. Such therapy is usually continued for 1 to 2 years, but some patients may need lifelong therapy. Immunosuppressive agents, such as methotrexate, azathioprine, and cyclophosphamide, may also be used. If organ failure occurs (although this is rare), transplantation may be required. Other measures include a low-calcium diet and avoidance of direct exposure to sunlight in patients with hypercalcemia.

Special Considerations

- Watch for and report any complications. Be aware of abnormal laboratory results (e.g., anemia) that could alter patient care.
- For the patient with arthralgia, administer analgesics as ordered. Record signs of progressive muscle weakness.
- Provide a nutritious, high-calorie diet and plenty of fluids. If the patient has hypercalcemia, suggest a low-calcium diet. Weigh the patient regularly to detect weight loss.
- Monitor respiratory function. Check chest X-rays for the extent of lung involvement; note and record any bloody sputum or increase in sputum. If the patient has pulmonary hypertension or end-stage cor pulmonale, check ABG levels, observe for arrhythmias, and administer oxygen, as needed.
- Because steroids may induce or worsen diabetes mellitus, perform fingerstick glucose tests at least every 12 hours at the beginning of steroid therapy. Also, watch for other steroid adverse effects, such as fluid retention, electrolyte imbalance (especially hypokalemia), moon face, hypertension, and personality change. During or after steroid withdrawal (particularly in association with infection or other types of stress), watch for and report vomiting, orthostatic hypotension, hypoglycemia, restlessness, anorexia, malaise, and fatigue. Remember that the patient on long-term or high-dose steroid therapy is vulnerable to infection.
- When preparing the patient for discharge, stress the need for compliance with prescribed steroid therapy and regular, careful follow-up examinations and treatment. Refer the patient with failing vision to community support and resource groups and the American Foundation for the Blind, if necessary.

SEVERE ACUTE RESPIRATORY SYNDROME

SARS is a viral respiratory infection that can progress to pneumonia and, eventually, death. The disease was first recognized in 2003 with outbreaks in China, Canada, Singapore, Taiwan, and Vietnam, with other countries—including the United States—reporting smaller numbers of cases.

Causes and Incidence

SARS is caused by the SARS-associated coronavirus (SARS-CoV). Coronaviruses are a common cause of mild respiratory illnesses in humans, but researchers believe that a virus may have mutated, allowing it to cause this potentially life-threatening disease.

Close contact with a person who's infected with SARS, including contact with infectious aerosolized droplets or body secretions, is the method of transmission. Most people who contracted the disease during the 2003 outbreak contracted it during travel to endemic areas. However, the virus has been found to live on hands, tissues, and other surfaces for up to 6 hours in its droplet form. It has also been found to live in the stool of people with SARS for up to 4

days. The virus may be able to live for months or years in below-freezing temperatures.

Pathophysiology

SARS-CoV is replicated primarily in the lungs but is also found to have the same ability in the gastrointestinal (GI) tract. Once an infection has been established, the virus will cause lysis of cells in the lungs and GI tissues and initiating an immune response. Most tissue damage takes place in the pulmonary tissues and alveoli.

Complications

- Respiratory failure
- Liver failure
- Heart failure
- Myelodysplastic syndromes
- Death

Signs and Symptoms

The incubation period for SARS is typically 3 to 5 days but may last as long as 14 days. Initial signs and symptoms include fever, shortness of breath and other minor respiratory symptoms, general discomfort, headache, rigors, chills, myalgia, sore throat, and dry cough. Some individuals may develop diarrhea or a rash. Later complications include respiratory failure, liver failure, heart failure, myelodysplastic syndromes, and death.

Diagnosis

Diagnosis of severe respiratory illness is made when the patient has a fever greater than 100.4° F (38° C) or upon clinical findings of lower respiratory illness and a chest X-ray demonstrating pneumonia or ARDS. (See *Lungs and alveoli in SARS,* page 124.)

Lungs and Alveoli in SARS

Severe acute respiratory syndrome (SARS) is a viral respiratory infection that can progress from minor respiratory symptoms to pneumonia and eventually death.

Trachea

Right main bronchus

Left main bronchus

Lung (cut open)

Heart

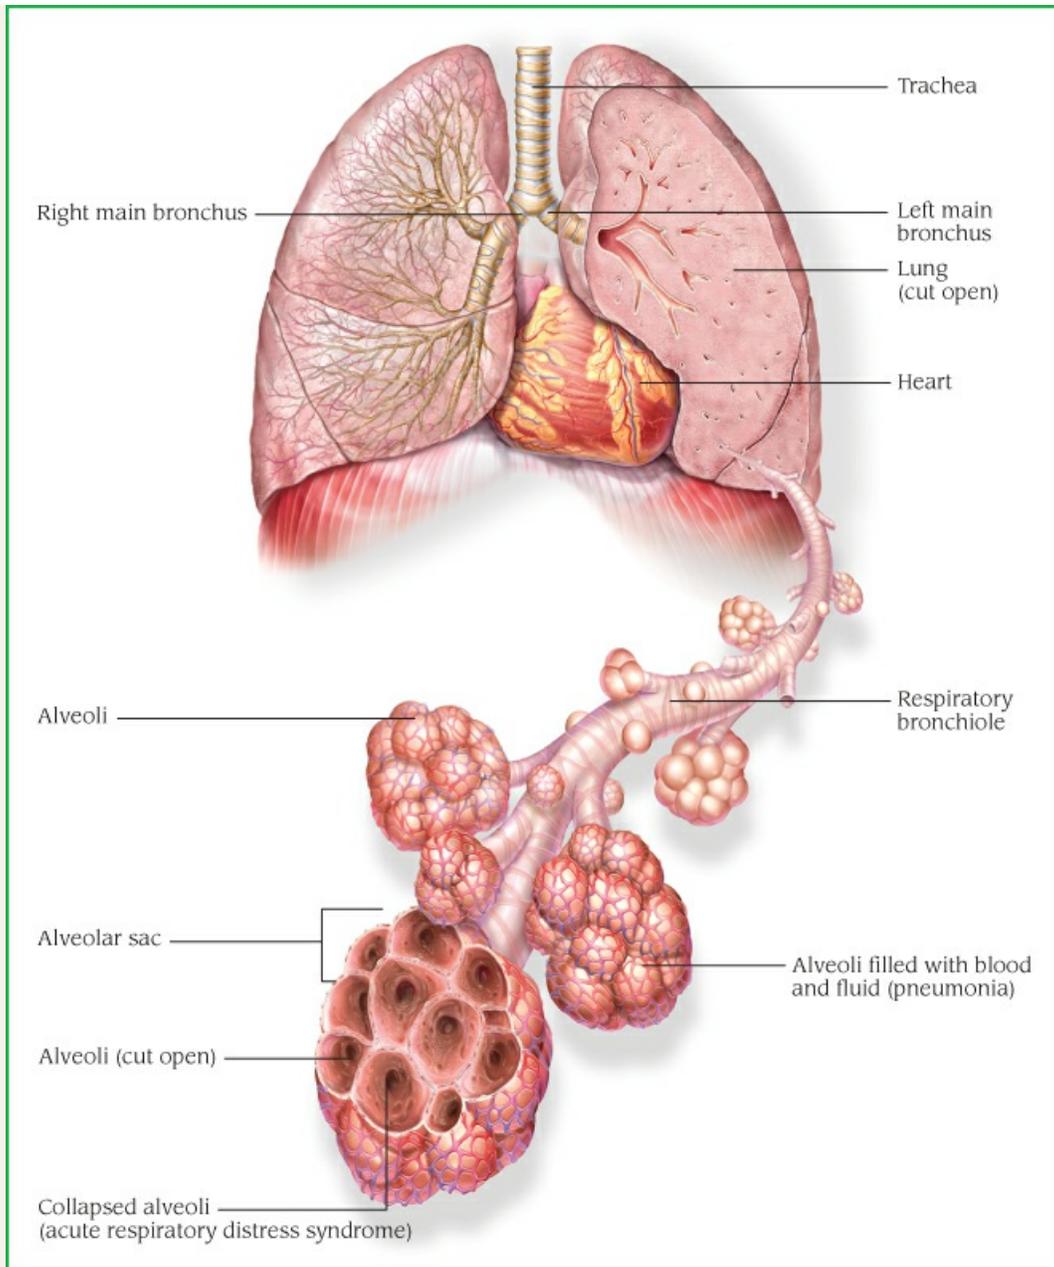
Alveoli

Respiratory bronchiole

Alveolar sac

Alveoli filled with blood and fluid (pneumonia)

Alveoli (cut open)

Collapsed alveoli (acute respiratory distress syndrome)


In pulmonary edema, diminished function of the left ventricle causes blood to pool there and in the left atrium. Eventually, blood backs up into the pulmonary veins and capillaries.

Increasing capillary hydrostatic pressure pushes fluid into the interstitial spaces and alveoli. The illustrations below show a normal alveolus and the effects of pulmonary edema.

NORMAL

Capillary

Alveolus

Interstitial space

Normal blood flow

Hydrostatic pressure pushes fluids into the interstitial space

Plasma oncotic pressure pulls fluids back into the bloodstream

CONGESTION

Capillary

Alveolus

Increased hydrostatic pressure leading to pulmonary congestion

Congested interstitium

EDEMA

Capillary

Alveolus

Greatly increased hydrostatic pressure

Large amount of fluid forced into the alveolus

Laboratory validation for the virus includes cell culture of SARS-CoV, detection of SARS-CoV ribonucleic acid by the reverse transcription polymerase chain reaction (PCR) test, or detection of serum antibodies to SARS-CoV. Detectable levels of antibodies may not be present until 21 days after the onset of illness, but some individuals develop antibodies within 14 days. A negative PCR, antibody test, or cell culture doesn't rule out the diagnosis.

Treatment

Treatment is symptomatic and supportive and includes maintenance of a patent airway and adequate nutrition. Other treatment measures include supplemental oxygen, chest physiotherapy, or mechanical ventilation. In addition to standard precautions, contact precautions requiring gowns and gloves for all patient contacts and airborne precautions utilizing a negative-pressure isolation room and properly fitted N95 respirators are recommended for patients who are hospitalized. Quarantine may be used to prevent the spread of infection.

Antibiotics may be given to treat bacterial causes of atypical pneumonia. Antiviral medications have also been used. High doses of corticosteroids have been used to reduce lung inflammation. In some serious cases, serum from individuals who have already recovered from SARS (convalescent serum) has been given. The general benefit of these treatments hasn't been determined conclusively.

Special Considerations

- Report suspected cases of SARS to local and national health organizations.
- Frequently monitor the patient's vital signs and respiratory status.
- Maintain isolation as recommended. The patient will need emotional support to deal with anxiety and fear related to the diagnosis of SARS and as a result of isolation.
- Provide patient and family teaching, including the importance of frequent handwashing, covering the mouth and nose when coughing or sneezing, and avoiding close personal contact while infected or potentially infected. Instruct the patient and family that such items as eating utensils, towels, and bedding shouldn't be shared until they have been washed with soap and hot water and that disposable gloves and household disinfectant should be used to clean any surface that may have been exposed to the patient's body fluids.
- Emphasize to the patient the importance of not going to work, school, or other public places, as recommended by the healthcare provider.

LUNG ABSCESS

Lung abscess is a lung infection accompanied by pus accumulation and tissue destruction. The abscess may be putrid (due to anaerobic bacteria) or nonputrid (due to anaerobes or aerobes) and usually has a well-defined border. The availability of effective antibiotics has made lung abscess much less common than it was in the past.

Causes and Incidence

Lung abscess is a manifestation of necrotizing pneumonia, generally the result of aspiration of oropharyngeal contents. Poor oral hygiene with dental or gingival (gum) disease is strongly associated with putrid lung abscess. Septic pulmonary emboli commonly produce cavitary lesions. Infected cystic lung lesions and cavitating bronchial carcinoma must be distinguished from lung abscesses.

Pathophysiology

The development of a lung abscess is a response to the introduction of a pathogen, likely from the mouth, into the lower airways. These anaerobes are not cleared away with the body's initial immune response and create a thick-walled cavity filled with purulent material in response to the infection. They can lead to tissue necrosis or possibly the destruction of the involved lung parenchyma.

Complications

- Rupture into pleural space, resulting in empyema
- Massive hemorrhage

Signs and Symptoms

The clinical effects of lung abscess include a cough that may produce bloody, purulent, or foul-smelling sputum, pleuritic chest pain, dyspnea, excessive sweating, chills, fever, headache, malaise, diaphoresis, and weight loss. Chronic lung abscess may cause localized bronchiectasis. Failure of an abscess to improve with antibiotic treatment suggests possible underlying neoplasm or other causes of obstruction.

Diagnosis

- Auscultation of the chest may reveal crackles and decreased breath sounds.
- Chest X-ray shows a localized infiltrate with one or more clear spaces, usually containing air–fluid levels.
- Percutaneous aspiration or bronchoscopy may be used to obtain cultures to identify the causative organism. Bronchoscopy is only used if abscess resolution is eventful and the patient's condition permits it.
- Blood cultures, Gram stain, and sputum culture are also used to detect the causative organism; leukocytosis (WBC count greater than 10,000/µL) is commonly present.

Treatment

Treatment consists of prolonged antibiotic therapy, commonly lasting for months, until radiographic resolution or definite stability occurs. Symptoms usually disappear in a few weeks. Postural drainage may facilitate discharge of necrotic material into the upper airways where expectoration is possible; oxygen therapy may relieve hypoxemia. Poor response to therapy requires resection of the lesion or removal of the diseased section of the lung. All patients need rigorous follow-up and serial chest X-rays.

Special Considerations

- Help the patient with chest physiotherapy (including coughing and deep breathing), increase fluid intake to loosen secretions, and provide a quiet, restful atmosphere.
- To prevent lung abscess in the unconscious patient and the patient with seizures, first prevent aspiration of secretions. Do this by suctioning the patient and by positioning in such a way to promote drainage of secretions.

HEMOTHORAX

In hemothorax, blood from damaged intercostal, pleural, mediastinal, and (infrequently) lung parenchymal vessels enters the pleural cavity. Depending on the amount of bleeding and the underlying cause, hemothorax may be associated with varying degrees of lung collapse and mediastinal shift. Pneumothorax—air in the pleural cavity—commonly accompanies hemothorax.

Causes and Incidence

Hemothorax usually results from blunt or penetrating chest trauma; in fact, about 25% of patients

with such trauma have hemothorax. In some cases, it results from thoracic surgery, pulmonary infarction, neoplasm, dissecting thoracic aneurysm, or as a complication of TB or anticoagulant therapy.

Pathophysiology

A hemothorax occurs when a disruption of the chest wall tissues or intrathoracic structures allows blood to enter the pleural space. Depending on the speed and volume of the circulating blood, there can be a significant hemodynamic shift including the early stages of shock.

Complications

- Mediastinal shift
- Ventilatory compromise
- Lung collapse
- Cardiopulmonary arrest

Signs and Symptoms

The patient with hemothorax may experience chest pain, tachypnea, and mild to severe dyspnea, depending on the amount of blood in the pleural cavity and associated pathologic conditions. If respiratory failure results, the patient may appear anxious, restless, possibly stuporous, and cyanotic; marked blood loss produces hypotension and shock. The affected side of the chest expands and stiffens, whereas the unaffected side rises and falls with the patient's breaths.

Diagnosis

Characteristic clinical signs and a history of trauma strongly suggest hemothorax. Percussion and auscultation reveal dullness and decreased to absent breath sounds over the affected side. Thoracentesis yields blood or serosanguineous fluid; chest X-rays show pleural fluid with or without mediastinal shift. ABG analysis may reveal respiratory failure; Hb may be decreased, depending on the amount of blood lost.

Treatment

Treatment is designed to stabilize the patient's condition, stop the bleeding, evacuate blood from the pleural space, and re-expand the underlying lung. Mild hemothorax usually clears in 10 to 14 days, requiring only observation for further bleeding. In severe hemothorax, thoracentesis not only serves as a diagnostic tool, but also removes fluid from the pleural cavity.

After the diagnosis is confirmed, a chest tube is inserted into the sixth intercostal space at the posterior axillary line. Suction may be used; a large-bore tube is used to prevent clot blockage. If the chest tube doesn't improve the patient's condition, they may need a thoracotomy to evacuate blood and clots and to control bleeding.

Special Considerations

- Give oxygen by face mask or nasal cannula.
- Give I.V. fluids and blood transfusions, as ordered, to treat shock. Monitor pulse oximetry and ABG levels often.
- Explain all procedures to the patient to allay their fears. Assist with thoracentesis. Warn the patient not to cough during this procedure.

- Carefully observe chest tube drainage and record the volume drained (at least every hour). Milk the chest tube (only if necessary and according to facility and physician protocols) to keep it open and free from clots. If the tube is warm and full of blood and the bloody fluid level in the water-seal bottle is rising rapidly, report this at once. The patient may need immediate surgery.
- Watch the patient closely for pallor and gasping respirations. Monitor vital signs diligently. Falling blood pressure, rising pulse rate, and rising respiratory rate may indicate shock or massive bleeding.

PULMONARY HYPERTENSION

Pulmonary hypertension occurs when PAP rises above normal for reasons other than aging or altitude. No definitive set of values is used to diagnose pulmonary hypertension, but the National Institutes of Health requires a mean PAP of 25 mm Hg or more. The prognosis depends on the cause of the underlying disorder, but the long-term prognosis is poor. Within 5 years of diagnosis, only 25% of patients are still alive.

Causes and Incidence

Pulmonary hypertension begins as hypertrophy of the small pulmonary arteries. The medial and intimal muscle layers of these vessels thicken, decreasing distensibility and increasing resistance. This disorder then progresses to vascular sclerosis and obliteration of small vessels.

In most cases, pulmonary hypertension occurs secondary to an underlying disease process, including:

- *alveolar hypoventilation* from COPD (most common cause in the United States), sarcoidosis, diffuse interstitial disease, pulmonary metastasis, and certain diseases such as scleroderma. (In these disorders, pulmonary vascular resistance occurs secondary to hypoxemia and destruction of the alveolocapillary bed. Other disorders that cause alveolar hypoventilation without lung tissue damage include obesity, kyphoscoliosis, and obstructive sleep apnea.)
- *vascular obstruction* from pulmonary embolism, vasculitis, and disorders that cause obstruction of small or large pulmonary veins, such as left atrial myxoma, idiopathic venoocclusive disease, fibrosing mediastinitis, and mediastinal neoplasm
- *primary cardiac disease,* which may be congenital or acquired. Congenital defects that cause left-to-right shunting of blood—such as patent ductus arteriosus or atrial or ventricular septal defect—increase blood flow into the lungs and, consequently, raise pulmonary vascular pressure. Acquired cardiac diseases, such as rheumatic valvular disease and mitral stenosis, increase pulmonary venous pressure by restricting blood flow returning to the heart

Primary (or idiopathic) pulmonary hypertension is rare, occurring most commonly—and with no known cause—in women between 20 and 40 years old. Secondary pulmonary hypertension results from existing cardiac, pulmonary, thromboembolic, or collagen vascular diseases or from the use of certain drugs.

Pathophysiology

The primary pathogenic mechanism involved in pulmonary hypertension is vascular resistance. This resistance typically results from vasoconstriction, remodeling, or a formation of a microthrombus in the pulmonary arteries or arterioles.

Complications

- Cor pulmonale
- Cardiac failure
- Cardiac arrest

Signs and Symptoms

Most patients complain of increasing dyspnea on exertion, weakness, syncope, and fatigability. Many also show signs of right-sided heart failure, including peripheral edema, ascites, jugular vein distention, and hepatomegaly. Other clinical effects vary with the underlying disorder.

Diagnosis

Characteristic diagnostic findings include:

- Auscultation reveals abnormalities associated with the underlying disorder.
- ABG analysis indicates hypoxemia (decreased Pa_{O_2}).
- Electrocardiography shows right axis deviation and tall or peaked P waves in inferior leads in the patient with right ventricular hypertrophy.
- Cardiac catheterization reveals pulmonary systolic pressure above 30 mm Hg as well as increased PAWP if the underlying cause is left atrial myxoma, mitral stenosis, or left-sided heart failure (otherwise normal).
- Pulmonary angiography detects filling defects in pulmonary vasculature such as those that develop in patients with pulmonary emboli.
- PFTs may show decreased flow rates and increased residual volume in underlying obstructive disease and decreased TLC in underlying restrictive disease.

Treatment

Treatment usually includes oxygen therapy to decrease hypoxemia and resulting pulmonary vascular resistance. It may also include vasodilator therapy (nifedipine [Procardia], diltiazem [Cardizem], or prostaglandin E). For patients with right-sided heart failure, treatment also includes fluid restriction, cardiac glycosides to increase cardiac output, and diuretics to decrease intravascular volume and extravascular fluid accumulation. Treatment also aims to correct the underlying cause.

Some patients with pulmonary hypertension may be candidates for heart–lung transplantation to improve their chances of survival.

Special Considerations

Pulmonary hypertension requires keen observation and careful monitoring as well as skilled supportive care.

- Administer oxygen therapy as ordered and observe the patient's response. Report any signs of increasing dyspnea to the physician so they can adjust treatment accordingly.
- Monitor ABG levels for acidosis and hypoxemia. Report any change in the patient's level of consciousness at once.
- When caring for a patient with right-sided heart failure, especially one receiving diuretics, record their weight daily, carefully measure intake and output, and explain all medications and diet restrictions. Check for worsening jugular vein distention, which may indicate fluid overload.

- Monitor the patient's vital signs, especially blood pressure and heart rate. Watch for hypotension and tachycardia. If they have a pulmonary artery catheter, check PAP and PAWP, as indicated. Report any changes.
- Before discharge, help the patient adjust to the limitations imposed by this disorder. Advise against overexertion and suggest frequent rest periods between activities. Refer the patient to the social services department if they will need special equipment, such as oxygen equipment, for home use. Make sure that they understand the prescribed medications and diet and the need to weigh themselves daily.

PLEURAL EFFUSION AND EMPYEMA

Pleural effusion is an excess of fluid in the pleural space. Normally, this space contains a small amount of extracellular fluid that lubricates the pleural surfaces. Increased production or inadequate removal of this fluid results in pleural effusion. Empyema is the accumulation of pus and necrotic tissue in the pleural space. Blood (hemothorax) and chyle (chylothorax) may also collect in this space.

Causes and Incidence

The balance of osmotic and hydrostatic pressures in parietal pleural capillaries normally results in fluid movement into the pleural space. Balanced pressures in visceral pleural capillaries promote reabsorption of this fluid. Effusions frequently result from heart failure, hepatic disease with ascites, peritoneal dialysis, hypoalbuminemia, and disorders resulting in overexpanded intravascular volume.

Exudative pleural effusions occur with TB, subphrenic abscess, pancreatitis, bacterial or fungal pneumonitis or empyema, malignancy, pulmonary embolism with or without infarction, collagen disease (LE and rheumatoid arthritis), myxedema, and chest trauma.

Empyema is usually associated with infection in the pleural space. Such infection may be idiopathic or may be related to pneumonitis, carcinoma, perforation, or esophageal rupture.

Pathophysiology

Pleural effusions result from excessive hydrostatic pressure or decreased osmotic pressure causing excessive amounts of fluid to pass across intact capillaries. The result is a transudative pleural effusion, an ultrafiltrate of plasma containing low concentrations of protein. Exudative pleural effusions result when capillaries exhibit increased permeability with or without changes in hydrostatic and colloid osmotic pressures, allowing protein-rich fluid to leak into the pleural space. An empyema results from an infection in the pleural space or accumulated fluid.

Complications

- Atelectasis
- Infection
- Hypoxemia

Signs and Symptoms

Patients with pleural effusion characteristically display symptoms relating to the underlying pathologic condition. Most patients with large effusions, particularly those with underlying pulmonary disease, complain of dyspnea. Those with effusions associated with pleurisy complain of pleuritic chest pain. Other clinical features depend on the cause of the effusion.

Patients with empyema also develop fever and malaise.

Diagnosis

Auscultation of the chest reveals decreased breath sounds; percussion detects dullness over the effused area, which doesn't change with breathing. Chest X-ray shows fluid in dependent regions. However, diagnosis also requires other tests to distinguish transudative from exudative effusions and to help pinpoint the underlying disorder.

The most useful test is thoracentesis, in which pleural fluid is analyzed in the laboratory to show components. Acute inflammatory WBCs and microorganisms may be evident in empyema.

In addition, if a pleural effusion results from esophageal rupture or pancreatitis, fluid amylase levels are usually higher than serum levels. Aspirated fluid may be tested for LE cells, antinuclear antibodies, and neoplastic cells. It may also be analyzed for color and consistency; acid-fast bacillus (AFB), fungal, and bacterial cultures; and triglycerides (in chylothorax). Cell analysis shows leukocytosis in empyema. A negative tuberculin skin test strongly rules against TB as the cause. In exudative pleural effusions in which thoracentesis isn't definitive, pleural biopsy may be done. This is particularly useful for confirming TB or malignancy.

Treatment

Depending on the amount of fluid present, symptomatic effusion may require thoracentesis to remove fluid or careful monitoring of the patient's own reabsorption of the fluid. Hemothorax requires drainage to prevent fibrothorax formation. Pleural effusions associated with lung cancer commonly reaccumulate quickly. If a chest tube is inserted to drain the fluid, a sclerosing agent, such as talc, may be injected through the tube to cause adhesions between the parietal and visceral pleura, thereby obliterating the potential space for fluid to recollect.

Treatment of empyema requires insertion of one or more chest tubes after thoracentesis, to allow drainage of purulent material, and possibly decortication (surgical removal of the thick coating over the lung) or rib resection to allow open drainage and lung expansion. Empyema also requires parenteral antibiotics. Associated hypoxia requires oxygen administration.

Special Considerations

- Explain thoracentesis to the patient. Before the procedure, tell the patient to expect a stinging sensation from the local anesthetic and a feeling of pressure when the needle is inserted. Instruct them to tell you immediately if they feel uncomfortable or has difficulty breathing during the procedure.
- Reassure the patient during thoracentesis. Remind them to breathe normally and avoid sudden movements, such as coughing or sighing. Monitor vital signs and watch for syncope. If fluid is removed too quickly, the patient may suffer bradycardia, hypotension, pain, pulmonary edema, or even cardiac arrest. Watch for respiratory distress or pneumothorax (sudden onset of dyspnea and cyanosis) after thoracentesis.
- Administer oxygen and, in empyema, antibiotics, as ordered.
- Encourage the patient to perform deep-breathing exercises to promote lung expansion. Use an incentive spirometer to promote deep breathing.
- Provide meticulous chest tube care, and use sterile technique for changing dressings around the tube insertion site in empyema. Ensure tube patency by watching for fluctuations of fluid or air bubbling in the underwater seal chamber. Continuous bubbling may indicate an air leak. Record the amount, color, and consistency of any tube drainage.

- If the patient has open drainage through a rib resection or intercostal tube, use hand and dressing precautions. Because weeks of such drainage are usually necessary to obliterate the space, make visiting nurse referrals for the patient who will be discharged with the tube in place.
- If pleural effusion was a complication of pneumonia or influenza, advise prompt medical attention for upper respiratory infections.

PLEURISY

Pleurisy, also known as *pleuritis*, is an inflammation of the visceral and parietal pleurae that line the inside of the thoracic cage and envelop the lungs.

Causes and Incidence

Pleurisy develops as a complication of pneumonia, TB, viruses, systemic LE, rheumatoid arthritis, uremia, Dressler syndrome, certain cancers, pulmonary infarction, and chest trauma. Pleuritic pain is caused by the inflammation or irritation of sensory nerve endings in the parietal pleura. As the lungs inflate and deflate, the visceral pleura covering the lungs moves against the fixed parietal pleura lining the pleural space, causing pain. This disorder usually begins suddenly.

In the United States, pleural effusions develop in 36% to 66% of hospitalized patients with bacterial pneumonia.

Pathophysiology

There are pain fibers located in the two layers of the pleura; the visceral pleural covers the lung and the parietal pleural line the inner chest wall. Pleurisy or pleuritis is the result of the inflammation of these pleuritic layers, usually from an infectious source.

Complications

- Pneumonia
- Pleural effusion
- Lung collapse

Signs and Symptoms

Sharp, stabbing pain that increases with deep breathing may be so severe that it limits movement on the affected side. Dyspnea also occurs. Other symptoms vary according to the underlying pathologic process.

Diagnosis

Auscultation of the chest reveals a characteristic pleural friction rub—a coarse, creaky sound heard during late inspiration and early expiration, directly over the area of pleural inflammation. Palpation over the affected area may reveal coarse vibration. Chest X-ray, ultrasound of the chest, and thoracentesis may aid in diagnosis.

Treatment

Treatment is directed at the underlying cause; bacterial infections are treated with appropriate antibiotics, TB requires special treatment, and viral infections may be permitted to run their

course. Treatment also includes measures to relieve symptoms, such as anti-inflammatory agents, analgesics, and bed rest. Severe pain may require an intercostal nerve block of two or three intercostal nerves. Pleurisy with pleural effusion calls for thoracentesis as a therapeutic and diagnostic measure.

Special Considerations

- Stress the importance of bed rest and plan your care to allow the patient as much uninterrupted rest as possible.
- Administer antitussives and pain medication, as ordered, but be careful not to overmedicate. If the pain requires an opioid analgesic, warn the patient who's about to be discharged to avoid overuse because such medication depresses coughing and respiration.
- Encourage the patient to cough. Tell them to apply firm pressure at the site of the pain during coughing exercises to minimize pain.

Chronic Disorders

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

COPD is chronic airway obstruction that results from emphysema, chronic bronchitis, asthma, or any combination of these disorders. (See *How pulmonary edema develops*, page 131. Also see *Lung changes in emphysema*, page 132.) Usually, more than one of these underlying conditions coexist; in most cases, bronchitis and emphysema occur together. It doesn't always produce symptoms and causes only minimal disability in many patients. However, COPD tends to worsen with time.

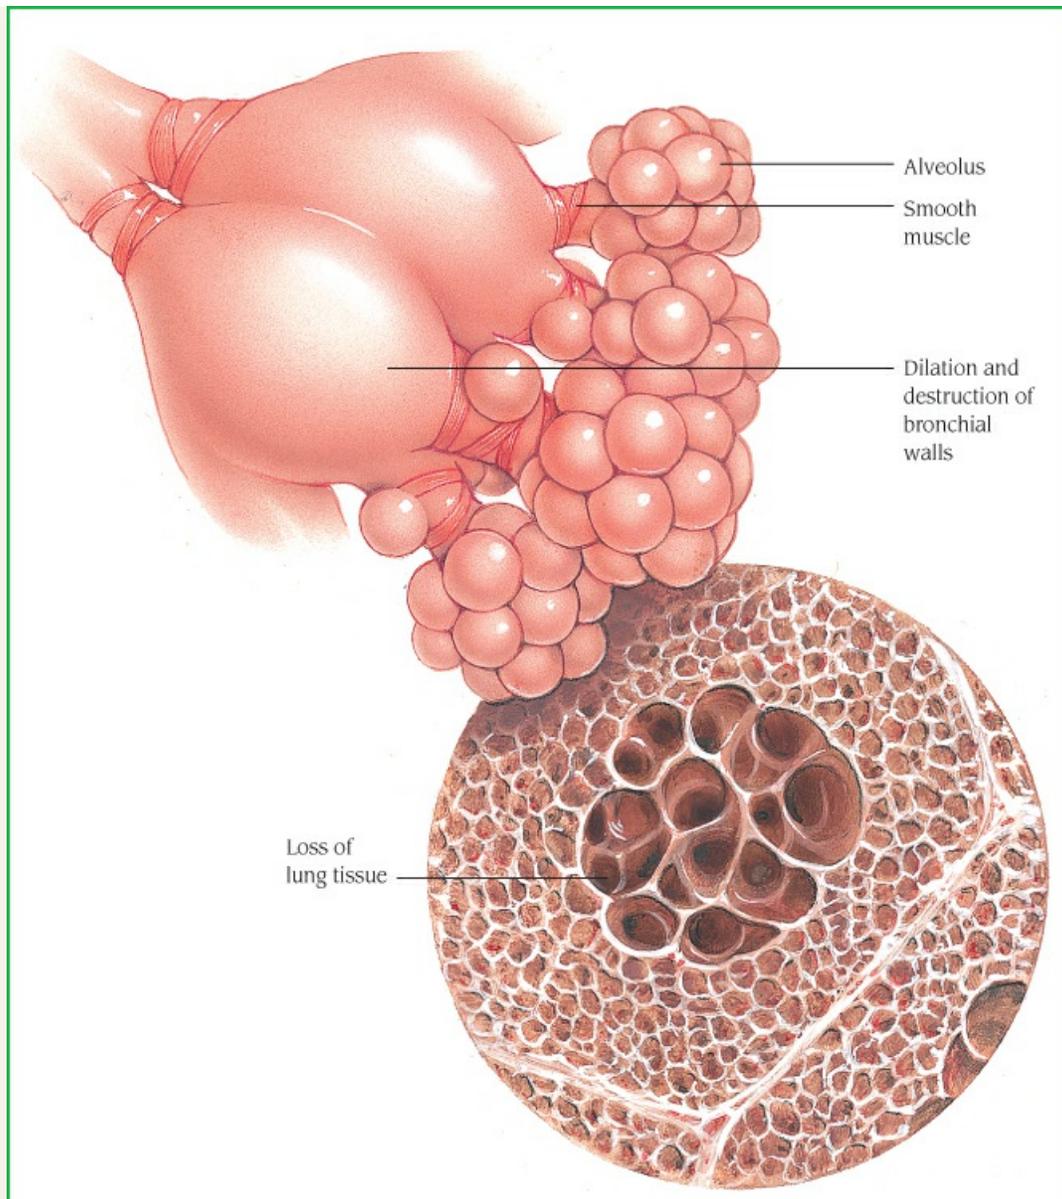
Lung Changes in Emphysema

A form of chronic obstructive pulmonary disease, emphysema is the abnormal, permanent enlargement of the acini accompanied by the destruction of the alveolar walls. Obstruction results from tissue changes, rather than mucus production, as occurs in asthma and chronic bronchitis. The distinguishing characteristic of emphysema is airflow limitation caused by a lack of elastic recoil in the lungs.

Alveolus

Smooth muscle

Dilation and destruction of bronchial walls

Loss of lung tissue


Causes and Incidence

Predisposing factors include cigarette smoking, recurrent or chronic respiratory infections, air pollution, occupational exposure to chemicals, and allergies. Early inflammatory changes may reverse if the patient stops smoking before lung destruction is extensive. Familial and hereditary factors (such as deficiency of alpha$_1$-antitrypsin) may also predispose a person to COPD.

The most common chronic lung disease, COPD (also known as *chronic obstructive lung disease*) affects an estimated 17 million Americans, and its incidence is rising. It affects more males than females, probably because until recently men were more likely to smoke heavily. COPD occurs mostly in people older than age 40.

Pathophysiology

Repeated exposure to carcinogens, such as smoking, is by far the most important causative action —it impairs ciliary action and macrophage function, inflames airways, increases mucus production, destroys alveolar septae, and causes peribronchiolar fibrosis.

Complications

- Overwhelming disability
- Cor pulmonale
- Severe respiratory failure
- Death

Signs and Symptoms

The typical patient, a long-term cigarette smoker, has no symptoms until middle age. The ability to exercise or do strenuous work gradually starts to decline, and the patient begins to develop a productive cough. These signs are subtle at first but become more pronounced as the patient gets older and the disease progresses. Eventually the patient may develop dyspnea on minimal exertion, frequent respiratory infections, intermittent or continuous hypoxemia, and grossly abnormal pulmonary function studies. Advanced COPD may cause severe dyspnea, overwhelming disability, cor pulmonale, severe respiratory failure, and death.

Diagnosis

For specific diagnostic tests used to determine COPD, see *Types of chronic obstructive pulmonary disease*.

Treatment

Treatment is designed to relieve symptoms and prevent complications. Because most patients with COPD receive outpatient treatment, they need comprehensive teaching to help them comply with therapy and understand the nature of this chronic, progressive disease. If programs in pulmonary rehabilitation are available, encourage patient to enroll.

Urge the patient to stop smoking. Provide smoking cessation counseling or refer them to a program. Avoid other respiratory irritants, such as secondhand smoke, aerosol spray products, and outdoor air pollution. An air conditioner with an air filter in the home may be helpful.

The patient is usually treated with beta-agonist bronchodilators (albuterol or salmeterol), anticholinergic bronchodilators (ipratropium), and corticosteroids (beclomethasone or triamcinolone). These are usually given by metered-dose inhaler, requiring that the patient be taught the correct administration technique.

Antibiotics are used to treat respiratory infections. Stress the need to complete the prescribed course of antibiotic therapy.

Special Considerations

- Teach the patient and family how to recognize early signs of infection; warn the patient to avoid contact with people with respiratory infections. Encourage good oral hygiene to help prevent infection. Pneumococcal vaccination and annual influenza vaccinations are important preventive measures.
- To promote ventilation and reduce air trapping, teach the patient to breathe slowly, prolong expirations to two to three times the duration of inspiration, and to exhale through pursed lips.

- To help mobilize secretions, teach the patient how to cough effectively. If the patient with copious secretions has difficulty mobilizing secretions, teach his or her family how to perform postural drainage and chest physiotherapy. If secretions are thick, urge the patient to drink 12 to 15 glasses of fluid per day. A home humidifier may be beneficial, particularly in the winter.
- Administer low concentrations of oxygen as ordered. Perform blood gas analysis to determine the patient's oxygen needs and to avoid CO_2 narcosis. If the patient is to continue oxygen therapy at home, teach them how to use the equipment correctly. The patient with COPD rarely requires more than 2 to 3 L/minute to maintain adequate oxygenation. Higher flow rates will further increase the Pa_{O_2}, but the patient whose ventilatory drive is largely based on hypoxemia commonly develops markedly increased Pa_{CO_2}. In these cases, chemoreceptors in the brain are relatively insensitive to the increase in CO_2. Teach the patient and family that excessive oxygen therapy may eliminate the hypoxic respiratory drive, causing confusion and drowsiness, signs of CO_2 narcosis.
- Emphasize the importance of a balanced diet. Because the patient may tire easily when eating, suggest that they eat frequent, small meals and consider using oxygen, administered by nasal cannula, during meals.
- Help the patient and family adjust their lifestyles to accommodate the limitations imposed by this debilitating chronic disease. Instruct the patient to allow for daily rest periods and to exercise daily as the provider directs.
- As COPD progresses, encourage the patient to discuss their fears.
- To help prevent COPD, advise all patients, especially those with a family history of COPD or those in its early stages, not to smoke.
- Assist in the early detection of COPD by urging persons to have periodic physical examinations, including spirometry and medical evaluation of a chronic cough, and to seek treatment for recurring respiratory infections promptly.
- Lung volume reduction surgery is a new procedure for carefully selected patients with primarily emphysema. Nonfunctional parts of the lung (tissue filled with disease and providing little ventilation or perfusion) are surgically removed. Removal allows more functional lung tissue to expand and the diaphragm to return to its normally elevated position.

BRONCHIECTASIS

A condition marked by chronic abnormal dilation of bronchi and destruction of bronchial walls, bronchiectasis can occur throughout the tracheobronchial tree or can be confined to one segment or lobe. However, it's usually bilateral and involves the basilar segments of the lower lobes. This disease has three forms: cylindrical (fusiform), varicose, and saccular (cystic). Bronchiectasis is irreversible once established.

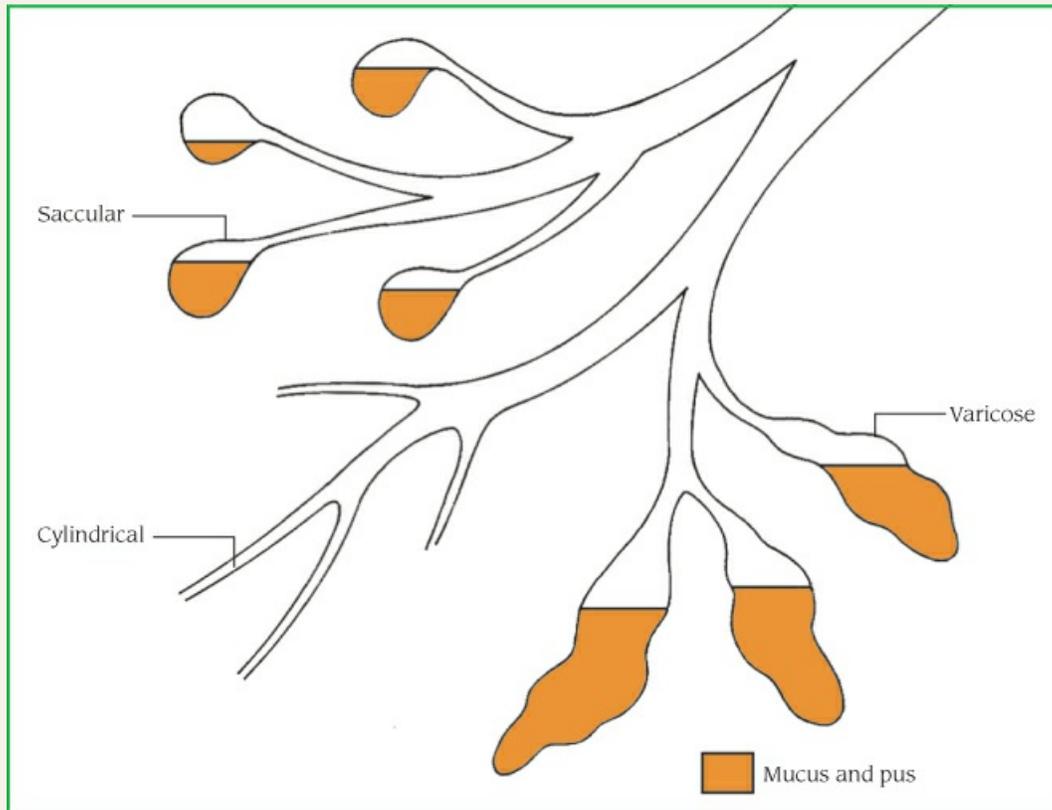
Causes and Incidence

Because of the availability of antibiotics to treat acute respiratory tract infections, the incidence of bronchiectasis has dramatically decreased in the past 20 years. Incidence is highest among Eskimos and the Maoris of New Zealand. It affects people of both sexes and all ages.

The different forms of bronchiectasis may occur separately or simultaneously. In *cylindrical bronchiectasis*, the bronchi expand unevenly, with little change in diameter, and end suddenly in a squared-off fashion. In *varicose bronchiectasis*, abnormal, irregular dilation and narrowing of the bronchi give the appearance of varicose veins. In *saccular bronchiectasis*, many large

dilations end in sacs. These sacs balloon into pus-filled cavities as they approach the periphery and are then called saccules. (See *Forms of bronchial dilatation,* page 134.)

Forms of Bronchial Dilatation

Dilatations of the air sacs occur because of bronchiectasis, as depicted below.


This disease results from conditions associated with repeated damage to bronchial walls and abnormal mucociliary clearance, which cause a breakdown of supporting tissue adjacent to airways. Such conditions include:

- cystic fibrosis
- immunologic disorders (e.g., agammaglobulinemia)
- recurrent, inadequately treated bacterial respiratory tract infections, such as TB, and complications of measles, pneumonia, pertussis, or influenza
- obstruction (by a foreign body [most common in children], tumor, or stenosis) in association with recurrent infection
- inhalation of corrosive gas or repeated aspiration of gastric juices into the lungs
- congenital anomalies (uncommon), such as bronchomalacia, congenital bronchiectasis, immotile cilia syndrome, and Kartagener syndrome, a variant of immotile cilia syndrome characterized by situs inversus, bronchiectasis, and either nasal polyps or sinusitis

Pathophysiology

In bronchiectasis, hyperplastic squamous epithelium denuded of cilia replaces ulcerated columnar epithelium. Abscess formation involving all layers of the bronchial wall produces inflammatory cells and fibrous tissue, resulting in dilation and narrowing of the airways. Mucus plugs or fibrous tissue obliterates smaller bronchioles, whereas peribronchial lymphoid tissue becomes hyperplastic. Extensive vascular proliferation of bronchial circulation occurs and produces frequent hemoptysis.

Complications

- Chronic malnutrition
- Amyloidosis
- Right ventricular failure
- Cor pulmonale

Signs and Symptoms

Initially, bronchiectasis may be asymptomatic. When symptoms do arise, they're commonly attributed to other illnesses. The patient usually complains of frequent bouts of pneumonia or hemoptysis. The classic symptom, however, is a chronic cough that produces foul-smelling, mucopurulent secretions in amounts ranging from less than 10 mL/day to more than 150 mL/day.

Cough and sputum production are observed in greater than 90% of bronchiectasis patients. Characteristic findings include coarse crackles during inspiration over involved lobes or segments, occasional wheezing, dyspnea, sinusitis, weight loss, anemia, malaise, clubbing, recurrent fever, chills, and other signs of infection.

Advanced bronchiectasis may produce chronic malnutrition as well as right-sided heart failure and cor pulmonale because of hypoxic pulmonary vasoconstriction.

Diagnosis

A history of recurrent bronchial infections, pneumonia, and hemoptysis in a patient whose chest X-rays show peribronchial thickening, areas of atelectasis, and scattered cystic changes suggest bronchiectasis.

In recent years, CT scanning has supplanted bronchography as the most useful diagnostic test for bronchiectasis. It's sometimes used with high-resolution techniques to better determine anatomic changes. Bronchoscopy doesn't establish the diagnosis of bronchiectasis, but it does help to identify the source of secretions. Bronchoscopy can also be instrumental in pinpointing the site of bleeding in hemoptysis.

Other helpful laboratory tests include:

- sputum culture and Gram stain to identify predominant organisms
- complete blood count to detect anemia and leukocytosis
- PFTs to detect decreased vital capacity, expiratory flow rate, and hypoxemia. These tests also help determine the physiologic severity of the disease and the effects of therapy and help evaluate patients for surgery

When cystic fibrosis is suspected as the underlying cause of bronchiectasis, a sweat electrolyte test is useful.

Treatment

Treatment includes antibiotics, given orally or I.V., for 7 to 10 days or until sputum production decreases. Bronchodilators, combined with postural drainage and chest percussion, help remove secretions if the patient has bronchospasm and thick, tenacious sputum. Bronchoscopy may be used to remove obstruction and secretions. Hypoxia requires oxygen therapy; severe hemoptysis commonly requires lobectomy, segmental resection, or bronchial artery embolization if pulmonary function is poor. Long-term antibiotic therapy isn't appropriate because it may predispose the patient to serious gram-negative infections and resistant organisms.

Special Considerations

- Provide supportive care and help the patient adjust to the permanent changes in lifestyle that irreversible lung damage necessitates. Thorough teaching is vital.
- Administer antibiotics as ordered and explain all diagnostic tests. Perform chest physiotherapy, including postural drainage and chest percussion designed for involved lobes, several times a day. The best times to do this are early morning and just before bedtime. Instruct the patient to maintain each position for 10 minutes, and then perform percussion and tell them to cough. Show family members how to perform postural drainage and percussion. Also teach the patient coughing and deep-breathing techniques to promote good ventilation and the removal of secretions.
- Advise the patient to stop smoking, if appropriate, to avoid stimulating secretions and irritating the airways. Refer them to a local self-help group.
- Provide a warm, quiet, comfortable environment, and urge the patient to rest as much as possible. Encourage balanced, high-protein meals to promote good health and tissue healing and plenty of fluids (2 to 3 qt [2 to 3 L])/day to hydrate and thin bronchial secretions. Give frequent mouth care to remove foul-smelling sputum. Teach the patient to dispose of all secretions properly. Instruct them to seek prompt attention for respiratory infections.
- Tell the patient to avoid air pollutants and people with upper respiratory tract infections. Instruct them to take medications (especially antibiotics) exactly as prescribed.

PREVENTION

- *Treat bacterial pneumonia vigorously.*
- *Stress the need for immunization to prevent childhood diseases.*

IDIOPATHIC PULMONARY FIBROSIS

Idiopathic pulmonary fibrosis (IPF) is a chronic and usually fatal interstitial pulmonary disease. About 50% of patients with IPF die within 5 years of diagnosis. Once thought to be a rare condition, it's now diagnosed with much greater frequency. IPF has been known by several other names over the years, including cryptogenic fibrosing alveolitis, diffuse interstitial fibrosis, idiopathic interstitial pneumonitis, and Hamman–Rich syndrome.

Causes and Incidence

IPF is the result of a cascade of events that involve inflammatory, immune, and fibrotic processes in the lung. However, despite many studies and hypotheses, the stimulus that begins the progression remains unknown. Speculation has revolved around viral and genetic causes, but no good evidence has been found to support either theory. However, it's clear that chronic inflammation plays an important role. Inflammation develops the injury and the fibrosis that

ultimately distorts and impairs the structure and function of the alveolocapillary gas exchange surface.

IPF is slightly more common in men than in women and is more common in smokers than in nonsmokers. It usually affects people 50 to 70 years old.

Pathophysiology

IPF pathophysiology is thought to be initiated when alveolar epithelial cells signal an injury and then activates the excessive formation of fibroblast migration and differentiation. Scarring to the lung structures occurs when the fibroblasts and myofibroblasts secrete large amounts of extracellular matrix proteins, such as collagens, decreasing the overall lung volume.

Complications

- Respiratory failure
- Pneumonia
- Hypoxemia
- Pneumothorax
- Pulmonary hypertension

Signs and Symptoms

The usual presenting symptoms of IPF are dyspnea and a dry, hacking, and typically paroxysmal cough. Most patients have had these symptoms for several months to 2 years before seeking medical help. Expiratory crackles, especially in the bases of the lungs, are usually heard early in the disease. Bronchial breath sounds appear later, when airway consolidation develops. Rapid, shallow breathing occurs, especially with exertion, and clubbing has been noted in more than 40% of patients. Late in the disease, cyanosis and evidence of pulmonary hypertension (augmented S_2 and S_3 gallop) commonly occur. As the disease progresses, profound hypoxemia and severe, debilitating dyspnea are the hallmark signs.

Diagnosis

Diagnosis begins with a thorough patient history to exclude a more common cause of interstitial lung disease.

CONFIRMING DIAGNOSIS *Lung biopsy is helpful in the diagnosis of IPF. In the past, an open lung biopsy was the only acceptable procedure, but now biopsies may be done through a thoracoscope or bronchoscope.*

Histologic features of the biopsy tissue vary, depending on the stage of the disease and other factors that aren't yet completely understood. The alveolar walls are swollen with chronic inflammatory cellular infiltrate composed of mononuclear cells and polymorphonuclear leukocytes. Intra-alveolar inflammatory cells may be found in early stages. As the disease progresses, excessive collagen and fibroblasts fill the interstitium. In advanced stages, alveolar walls are destroyed and are replaced by honeycombing cysts.

Chest X-rays may show one of four distinct patterns: interstitial, reticulonodular, ground-glass, or honeycomb. Although chest X-rays are helpful in identifying the presence of an abnormality, they don't correlate well with histologic findings or PFTs in determining the severity of the disease. They also don't help distinguish inflammation from fibrosis. However, serial X-rays

may help track the progression of the disease.

High-resolution CT scans provide superior views of the four patterns seen on routine X-ray film and are used routinely to help establish the diagnosis of IPF. Research is currently underway to determine whether the four patterns of abnormality seen on these scans correlate with responsiveness to treatment.

PFTs show reductions in vital capacity and TLC and impaired diffusing capacity for carbon monoxide. ABG analysis and pulse oximetry reveal hypoxemia, which may be mild when the patient is at rest early in the disease but may become severe later in the disease. Oxygenation will always deteriorate, usually to a severe level, with exertion. Serial PFTs (especially carbon monoxide diffusing capacity) and ABG values may help track the course of the disease and the patient's response to treatment.

Treatment

Although it can't change the pathophysiology of IPF, oxygen therapy can prevent the problems related to dyspnea and tissue hypoxia in the early stages of the disease process. The patient may require little or no supplemental oxygen while at rest initially, but he or she will need more as the disease progresses and during exertion.

No known cure exists. Corticosteroids and cytotoxic drugs may be given to suppress inflammation but are usually unsuccessful. Recently, interferon gamma-1b has shown some promise in treating the disease.

Lung transplantation may be successful for younger, otherwise healthy individuals.

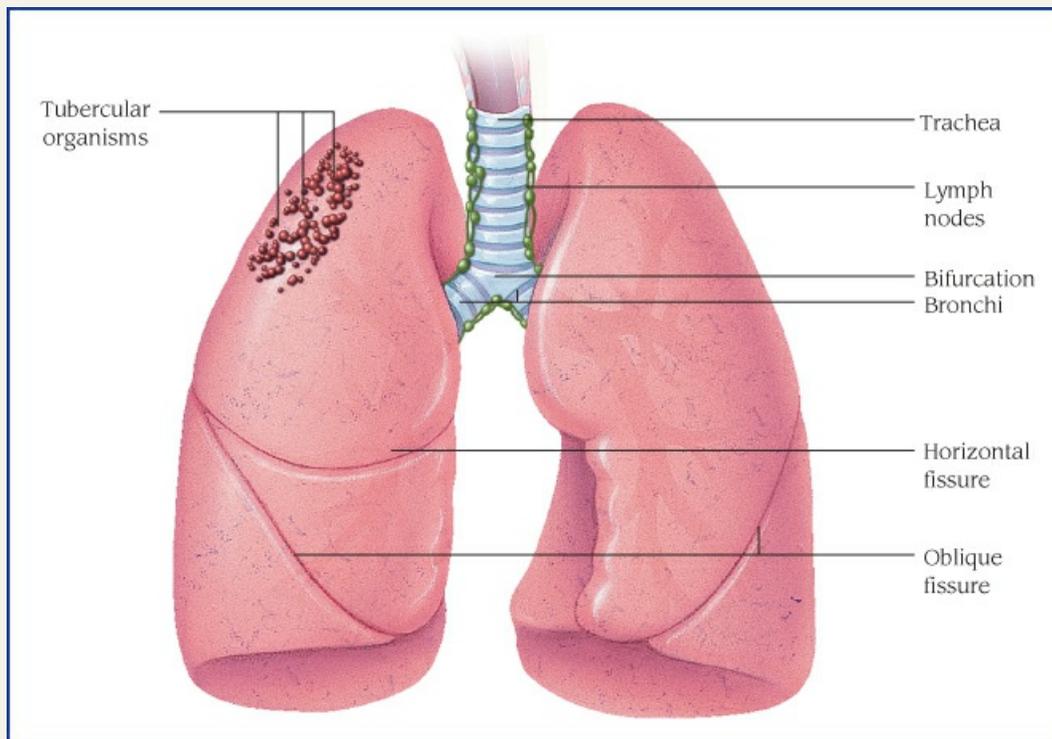
Special Considerations

- Explain all diagnostic tests to the patient, who may experience anxiety and frustration about the many tests required to establish the diagnosis.
- Monitor oxygenation at rest and with exertion. The physician may prescribe one oxygen flow rate for use when the patient is at rest and a higher one for use during exertion to maintain adequate oxygenation. Instruct the patient to increase oxygen flow rate to the appropriate level for exercise.
- As IPF progresses, the patient's oxygen requirements will increase. They may need a nonrebreathing mask to supply high oxygen percentages. Eventually, maintaining adequate oxygenation may become impossible despite maximum oxygen flow.
- Most patients will need oxygen at home. Make appropriate referrals to discharge planners, respiratory care practitioners, and home equipment vendors to ensure continuity of care.
- Teach breathing, relaxation, and energy conservation techniques to help the patient manage severe dyspnea.
- Encourage the patient to be as active as possible. Refer them to a pulmonary rehabilitation program.
- Monitor the patient for adverse reactions to drug therapy.
- Teach the patient about prescribed medications, especially adverse effects. Teach the patient and their family members infection prevention techniques.
- Encourage good nutritional habits. Small, frequent meals with high nutritional value may be necessary if dyspnea interferes with eating.
- Provide emotional support for the patient and their family as they deal with the patient's increasing disability, dyspnea, and probable death. Consult hospice as appropriate.

TUBERCULOSIS

An acute or chronic infection caused by *Mycobacterium tuberculosis,* TB is characterized by pulmonary infiltrates, formation of granulomas with caseation, fibrosis, and cavitation. (See *Understanding tuberculosis invasion*.) People who live in crowded, poorly ventilated conditions and those who are immunocompromised are most likely to become infected. In patients with strains that are sensitive to the usual antitubercular agents, the prognosis is excellent with correct treatment. However, in those with strains that are resistant to two or more of the major antitubercular agents, mortality is 50%.

PATHOPHYSIOLOGY
UNDERSTANDING TUBERCULOSIS INVASION

After infected droplets are inhaled, they enter the lungs and are deposited either in the lower part of the upper lobe or in the upper part of the lower lobe. Leukocytes surround the droplets, which leads to inflammation. As part of the inflammatory response, some mycobacteria are carried off in the lymphatic circulation by the lymph nodes.


Causes and Incidence

After exposure to *M. tuberculosis,* roughly 5% of infected people develop active TB within 1 year; in the remainder, microorganisms cause a latent infection. The host's immune system usually controls the tubercle bacillus by enclosing it in a tiny nodule (tubercle). The bacillus may lie dormant within the tubercle for years and later reactivate and spread.

Although the primary infection site is the lungs, mycobacteria commonly exist in other parts of the body. Several factors increase the risk of infection reactivation: gastrectomy, uncontrolled diabetes mellitus, Hodgkin lymphoma, leukemia, silicosis, acquired immunodeficiency syndrome, treatment with corticosteroids or immunosuppressants, and advanced age.

Cell-mediated immunity to the mycobacteria, which develops 3 to 6 weeks later, usually contains the infection and arrests the disease. If the infection reactivates, the body's response characteristically leads to caseation—the conversion of necrotic tissue to a cheese-like material. The caseum may localize, undergo fibrosis, or excavate and form cavities, the walls of which are studded with multiplying tubercle bacilli. If this happens, infected caseous debris may spread throughout the lungs by the tracheobronchial tree. Sites of extrapulmonary TB include the pleurae, meninges, joints, lymph nodes, peritoneum, genitourinary tract, and bowel.

The incidence of TB has been increasing in the United States secondary to homelessness, drug abuse, and human immunodeficiency virus infection. Globally, TB is the leading infectious cause of morbidity and mortality, generating 8 to 10 million new cases each year.

Pathophysiology

Transmission is by droplet nuclei produced when infected persons cough or sneeze. Persons with a cavitary lesion are particularly infectious because their sputum usually contains 1 to 100 million bacilli per milliliter. If an inhaled tubercle bacillus settles in an alveolus, infection occurs, with alveolocapillary dilation and endothelial cell swelling. Alveolitis results, with replication of tubercle bacilli and influx of polymorphonuclear leukocytes. These organisms spread through the lymph system to the circulatory system and then through the body.

Complications

- Respiratory failure
- Bronchopleural fistulas
- Pneumothorax
- Hemorrhage
- Pleural effusion
- Pneumonia

Signs and Symptoms

After an incubation period of 4 to 8 weeks, TB is usually asymptomatic in primary infection but may produce nonspecific symptoms, such as fatigue, weakness, anorexia, weight loss, night sweats, and low-grade fever.

ELDER TIP Fever and night sweats, the typical hallmarks of TB, may not be present in elderly patients, who instead may exhibit a change in activity or weight. Assess older patients carefully.

In reactivation, symptoms may include a cough that produces mucopurulent sputum, occasional hemoptysis, and chest pains.

Diagnosis

CONFIRMING DIAGNOSIS Diagnostic tests include chest X-rays, a tuberculin skin test, and sputum smears and cultures to identify M. tuberculosis. The diagnosis must be precise because several other diseases (such as lung cancer, lung abscess, pneumoconiosis, and

bronchiectasis) may mimic TB.

These procedures aid in diagnosis:

- Auscultation detects crepitant crackles, bronchial breath sounds, wheezing, and whispered pectoriloquy.
- Chest percussion detects dullness over the affected area, indicating consolidation or pleural fluid.
- Chest X-ray shows nodular lesions, patchy infiltrates (mainly in upper lobes), cavity formation, scar tissue, and calcium deposits; however, it may not be able to distinguish active from inactive TB.
- Tuberculin skin test detects TB infection. Intermediate-strength purified protein derivative or 5 tuberculin units (0.1 mL) are injected intracutaneously on the forearm. The test results are read in 48 to 72 hours; a positive reaction (induration of 5 to 15 mm or more, depending on risk factors) develops 2 to 10 weeks after infection in active and inactive TB. However, severely immunosuppressed patients may never develop a positive reaction.

℞ CONFIRMING DIAGNOSIS *Stains and cultures (of sputum, cerebrospinal fluid, urine, drainage from abscess, or pleural fluid) show heat-sensitive, nonmotile, aerobic, acid-fast bacilli.*

Treatment

First-line agents for the treatment of TB are isoniazid (INH), rifampin (RIF), ethambutol (EMB), and pyrazinamide. Latent TB is usually treated with daily INH for 9 months. RIF daily for 4 months may be used for people with latent TB whose contacts are INH resistant. For most adults with active TB, the recommended dosing includes the administration of all four drugs daily for 2 months, followed by 4 months of INH and RIF. Drug therapy must be selected according to patient condition and organism susceptibility. Another first-line drug used for TB is rifapentine. Second-line agents, such as cycloserine, ethionamide, *p*-aminosalicylic acid, streptomycin, and capreomycin, are reserved for special circumstances or drug-resistant strains. Interruption of drug therapy may require initiation of therapy from the beginning of the regimen or additional treatment.

Directly observed therapy (DOT) may be selected or required. In this therapy, an assigned caregiver directly observes the administration of the drug. The goal of DOT is to monitor the treatment regimen and reduce the development of resistant organisms.

Special Considerations

- Initiate AFB isolation precautions immediately for all patients suspected or confirmed to have TB. AFB isolation precautions include the use of a private room with negative pressure in relation to surrounding areas and a minimum of six air exchanges per hour (air should be exhausted directly to the outside).
- Continue AFB isolation until there's clinical evidence of reduced infectiousness (substantially decreased cough, fewer organisms on sequential sputum smears).
- Teach the infectious patient to cough and sneeze into tissues and to dispose of all secretions properly. Place a covered trash can nearby or tape a lined bag to the side of the bed to dispose of used tissues.
- Instruct the patient to wear a mask when outside his or her room.
- Visitors and staff members should wear particulate respirators that fit closely around the face

when they're in the patient's room.

◆ Remind the patient to get plenty of rest. Stress the importance of eating balanced meals to promote recovery. If the patient is anorexic, urge him or her to eat small meals frequently. Record weight weekly.

◆ Be alert for adverse effects of medications. Because INH sometimes leads to hepatitis or peripheral neuritis, monitor aspartate aminotransferase and alanine aminotransferase levels. To prevent or treat peripheral neuritis, give pyridoxine (vitamin B$_6$), as ordered. If the patient receives EMB, watch for optic neuritis; if it develops, discontinue the drug. If the patient receives RIF, watch for hepatitis and purpura. Observe the patient for other complications, such as hemoptysis.

◆ Before discharge, advise the patient to watch for adverse effects from the medication and report them immediately. Emphasize the importance of regular follow-up examinations. Instruct the patient and family concerning the signs and symptoms of recurring TB. Stress the need to follow long-term treatment faithfully.

◆ Emphasize to the patient the importance of taking the medications daily as prescribed. The patient may enroll in a supervised administration program to avoid the development of drug-resistant organisms. (See *Preventing tuberculosis,* page 139.)

PREVENTION
PREVENTING TUBERCULOSIS

The best way to prevent tuberculosis (TB) is early detection to prevent it from becoming active. Hospitalized patients with TB should be isolated from other patients using airborne precautions. Staff members should also use disposable high-efficiency particulate air filter masks, which serve as adequate respiratory protection when caring for patients who are in airborne isolation.

Other ways to prevent the spread of TB include:

◆ If a patient has a weakened immune system or has human immunodeficiency virus, it is recommended that they receive annual TB testing. Annual testing is also recommended for healthcare workers, those who work in a prison or a long-term care facility, and those with a substantially increased risk of exposure to the disease.

◆ If a patient tests positive for latent TB infection but has no evidence of active TB, he or she may be able to reduce the risk of developing active TB by taking a course of therapy with isoniazid.

To prevent the spread of disease from those with active TB or from those who are receiving treatment, the following recommendations should be followed:

◆ Stress the need to maintain the treatment regimen and to not stop or skip doses. When the treatment regimen is stopped, the TB bacteria can mutate and become drug resistant.

◆ The patient who is on a treatment regimen is still contagious until he or she has been taking the medications for 2 to 3 weeks. Encouraging the patient to stay indoors and home from school or work is recommended. If the patient must leave home, a mask is recommended during this initial treatment time to lessen the risk of transmission.

Pneumoconioses

SILICOSIS

Silicosis is a progressive disease characterized by nodular lesions that commonly progress to fibrosis. The most common form of pneumoconiosis, silicosis can be classified according to the severity of pulmonary disease and the rapidity of its onset and progression. It usually occurs as a simple asymptomatic illness.

Acute silicosis develops after 1 to 3 years in workers exposed to very high concentrations of respirable silica (sand blasters and tunnel workers). *Accelerated silicosis* appears after an average of 10 years of exposure to lower concentrations of free silica. *Chronic silicosis* develops after 20 or more years of exposure to lower concentrations of free silica. (Chronic silicosis is further subdivided into simple and complicated forms.)

The prognosis is good unless the disease progresses into the complicated fibrotic form, which causes respiratory insufficiency and cor pulmonale. It's also associated with pulmonary TB.

Causes and Incidence

Silicosis results from the inhalation and pulmonary deposition of respirable crystalline silica dust, mostly from quartz. The danger to the worker depends on the concentration of dust in the atmosphere, the percentage of respirable free silica particles in the dust, and the duration of exposure. Respirable particles are less than 10 µm in diameter, but the disease-causing particles deposited in the alveolar space are usually 1 to 3 µm in diameter.

Industrial sources of silica in its pure form include the manufacture of ceramics (flint) and building materials (sandstone). It occurs in mixed form in the production of construction materials (cement). It's found in powder form (silica flour) in paints, porcelain, scouring soaps, and wood fillers as well as in the mining of gold, coal, lead, zinc, and iron. Foundry workers, boiler scalers, and stonecutters are all exposed to silica dust and, therefore, are at high risk for developing silicosis.

The incidence of silicosis has decreased since the Occupational Safety and Health Administration instituted regulations requiring the use of protective equipment that limits the amount of silica dust inhaled.

Pathophysiology

Nodules result when alveolar macrophages ingest silica particles, which they're unable to process. As a result, the macrophages die and release proteolytic enzymes into the surrounding tissue. The subsequent inflammation attracts other macrophages and fibroblasts into the region to produce fibrous tissue and wall off the reaction. The resulting nodule has an onionskin appearance when viewed under a microscope. Nodules develop adjacent to terminal and respiratory bronchioles, concentrate in the upper lobes, and are commonly accompanied by bullous changes in both lobes. If the disease process doesn't progress, minimal physiologic disturbances and no disability occur. Occasionally, however, the fibrotic response accelerates, engulfing and destroying large areas of the lung (progressive massive fibrosis or conglomerate lesions). Fibrosis may continue even after exposure to dust has ended.

Complications

- Pulmonary fibrosis

- Cor pulmonale
- Ventricular or respiratory failure
- Pulmonary TB

Signs and Symptoms

Initially, silicosis may be asymptomatic or may produce dyspnea on exertion, usually attributed to being "out of shape" or "slowing down." If the disease progresses to the chronic and complicated stage, dyspnea on exertion worsens, and other symptoms—usually tachypnea and an insidious dry cough that's most pronounced in the morning—appear.

Progression to the advanced stage causes dyspnea on minimal exertion, worsening cough, and pulmonary hypertension, which in turn leads to right-sided heart failure and cor pulmonale. Patients with silicosis have a high incidence of active TB, which should be considered when evaluating patients with this disease. CNS changes—confusion, lethargy, and a decrease in the rate and depth of respiration as the Pa_{CO_2} increases—also occur in advanced silicosis.

Other clinical features include malaise, disturbed sleep, and hoarseness. The severity of these symptoms may not correlate with chest X-ray findings or the results of PFTs.

Diagnosis

The patient history reveals occupational exposure to silica dust. The physical examination is normal in simple silicosis; in chronic silicosis with conglomerate lesions, it may reveal decreased chest expansion, diminished intensity of breath sounds, areas of hyporesonance and hyperresonance, fine to medium crackles, and tachypnea.

In simple silicosis, chest X-rays show small, discrete, nodular lesions distributed throughout both lung fields but typically concentrated in the upper lung zones; the hilar lung nodes may be enlarged and exhibit "eggshell" calcification. In complicated silicosis, X-rays show one or more conglomerate masses of dense tissue.

PFTs show:

- FVC—reduced in complicated silicosis
- FEV_1—reduced in obstructive disease (emphysematous areas of silicosis); reduced in complicated silicosis, but ratio of FEV_1 to FVC is normal or high
- Maximal voluntary ventilation—reduced in restrictive and obstructive diseases
- CO_2 diffusing capacity—reduced when fibrosis destroys alveolar walls and obliterates pulmonary capillaries or when fibrosis thickens the alveolocapillary membrane

Treatment

The goal of treatment is to relieve respiratory symptoms, to manage hypoxemia and cor pulmonale, and to prevent respiratory tract irritation and infections. Treatment also includes careful observation for the development of TB. Respiratory symptoms may be relieved through daily use of inhaled bronchodilators and increased fluid intake (at least 3 qt [3 L] daily). Steam inhalation and chest physiotherapy techniques, such as controlled coughing and segmental bronchial drainage with chest percussion and vibration, help clear secretions. In severe cases, it may be necessary to administer oxygen by cannula or mask (1 to 2 L/minute) for the patient with chronic hypoxemia or by mechanical ventilation if arterial oxygen can't be maintained above 40 mm Hg. Respiratory infections require prompt administration of antibiotics.

Special Considerations

- Teach the patient to prevent infections by avoiding crowds and persons with respiratory infections and by receiving influenza and pneumococcal vaccines.
- Increase exercise tolerance by encouraging regular activity. Advise the patient to plan his or her daily activities to decrease the work of breathing. The patient should be instructed to pace himself or herself, rest often, and generally move slowly through his or her daily routine.

ASBESTOSIS

Asbestosis is a form of pneumoconiosis characterized by diffuse interstitial fibrosis. It can develop as long as 15 to 20 years after regular exposure to asbestos has ended. Asbestos also causes pleural plaques and mesotheliomas of pleura and the peritoneum. A potent co-carcinogen, asbestos increases the risk of lung cancer in cigarette smokers.

Causes and Incidence

Asbestosis results from the inhalation of respirable asbestos fibers (50 µm or more in length and 0.5 µm or less in diameter), which assume a longitudinal orientation in the airway and move in the direction of airflow. The fibers penetrate respiratory bronchioles and alveolar walls. Sources include the mining and milling of asbestos, the construction industry, and the fireproofing and textile industries. Asbestos was also used in the production of paints, plastics, and brake and clutch linings.

Asbestos-related diseases develop in families of asbestos workers as a result of exposure to fibrous dust shaken off workers' clothing at home. Such diseases develop in the general public as a result of exposure to fibrous dust or waste piles from nearby asbestos plants, but exposures for occupants of typical buildings are quite low and not in a range associated with asbestosis.

Inhaled fibers become encased in a brown, protein-like sheath rich in iron (ferruginous bodies or asbestos bodies), found in sputum and lung tissue. Interstitial fibrosis develops in lower lung zones, causing obliterative changes in lung parenchyma and pleurae. Raised hyaline plaques may form in parietal pleura, diaphragm, and pleura contiguous with the pericardium.

Asbestosis occurs in 4 of every 10,000 people.

Pathophysiology

Asbestos fibers penetrate the pleura tissues and are phagocytosed permanently within the lungs. This sets up cycles of cellular events and the release of cytokines. The initial irritation occurs in the alveoli and initiates a surge of asbestos-activated macrophages. These specified macrophages then produce multiple varieties of growth factors that interact to produce fibroblast proliferation.

Complications

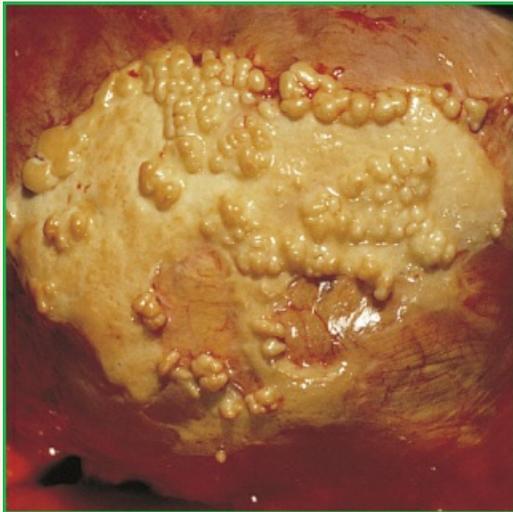
- Pulmonary fibrosis
- Respiratory failure
- Pulmonary hypertension
- Cor pulmonale

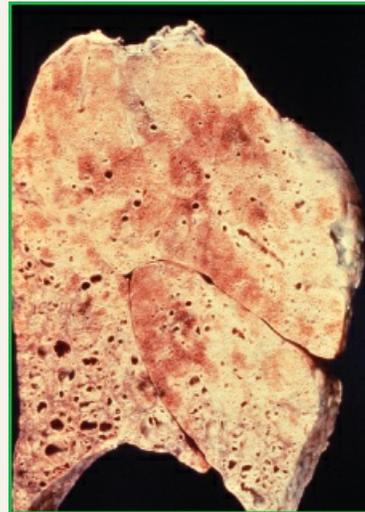
Signs and Symptoms

Clinical features may appear before chest X-ray changes. The first symptom is usually dyspnea on exertion, typically after 10 years' exposure. As fibrosis extends, dyspnea on exertion

increases until, eventually, dyspnea occurs even at rest. Advanced disease also causes a dry cough (may be productive in smokers), chest pain (commonly pleuritic), recurrent respiratory infections, and tachypnea. (See *A close look at asbestosis*.)

A Close Look at Asbestosis

After years of exposure to asbestos, healthy lung tissue progresses from simple asbestosis to massive pulmonary fibrosis, as shown below.


Simple asbestosis   **Progressive massive pulmonary fibrosis**


Cardiovascular complications include pulmonary hypertension, right ventricular hypertrophy, and cor pulmonale. Finger clubbing commonly occurs.

Diagnosis

The patient history reveals occupational, family, or neighborhood exposure to asbestos fibers. Physical examination reveals characteristic dry crackles at lung bases. Chest X-rays show fine, irregular, and linear diffuse infiltrates; extensive fibrosis results in a "honeycomb" or "ground-glass" appearance. X-rays may also show pleural thickening and calcification, with bilateral obliteration of costophrenic angles. In later stages, an enlarged heart with a classic "shaggy" heart border may be evident. CT scan of the lungs also aids in diagnosis.

PFTs show:

- Vital capacity, FVC, and TLC—decreased
- FEV_1—decreased or normal
- Carbon monoxide diffusing capacity—reduced when fibrosis destroys alveolar walls and thickens alveolocapillary membranes

ABG analysis reveals:

- Pa_{O_2}—decreased
- Pa_{CO_2}—low due to hyperventilation

Treatment

The goal of treatment is to relieve respiratory symptoms and, in advanced disease, manage hypoxemia and cor pulmonale. Respiratory symptoms may be relieved by chest physiotherapy techniques, such as controlled coughing and segmental bronchial drainage, chest percussion, and vibration. Aerosol therapy, inhaled mucolytics, and increased fluid intake (at least 3 qt [3 L] daily) may also relieve symptoms.

Diuretics, cardiac glycosides, and salt restriction may be indicated for patients with cor pulmonale. Hypoxemia requires oxygen administration by cannula or mask (1 to 2 L/minute) or by mechanical ventilation if arterial oxygen can't be maintained above 40 mm Hg. Respiratory infections require prompt administration of antibiotics.

Special Considerations

- Teach the patient to prevent infections by avoiding crowds and persons with infections and by receiving influenza and pneumococcal vaccines.
- Improve the patient's ventilatory efficiency by encouraging physical reconditioning, energy conservation in daily activities, and relaxation techniques.

COAL WORKER'S PNEUMOCONIOSIS

A progressive nodular pulmonary disease, coal worker's pneumoconiosis (CWP) occurs in two forms. Simple CWP is characterized by small lung opacities; in complicated CWP, also known as *progressive massive fibrosis,* masses of fibrous tissue occasionally develop in the patient's lungs. The risk of developing CWP (also known as *black lung disease, coal miner's disease, miner's asthma, anthracosis,* and *anthracosilicosis*) depends on the duration of exposure to coal dust (usually 15 years or longer), intensity of exposure (dust count and particle size), location of the mine, silica content of the coal (anthracite coal has the highest silica content), and the worker's susceptibility.

The prognosis varies. Simple asymptomatic disease is self-limiting, although progression to complicated CWP is more likely if CWP begins after a relatively short period of exposure. Complicated CWP may be disabling, resulting in severe ventilatory failure and cor pulmonale.

Causes and Incidence

CWP is caused by the inhalation and prolonged retention of respirable coal dust particles (less than 5 µm in diameter). Simple CWP results in the formation of macules (accumulations of macrophages laden with coal dust) around the terminal and respiratory bronchioles, surrounded by a halo of dilated alveoli. Macule formation leads to atrophy of supporting tissue, causing permanent dilation of small airways (focal emphysema).

Simple disease may progress to complicated CWP, involving one or both lungs. In this form of the disease, fibrous tissue masses enlarge and coalesce, causing gross distortion of pulmonary structures (destruction of vasculature alveoli and airways).

The incidence of CWP is highest among anthracite coal miners in the eastern United States.

Pathophysiology

When coal dust particles are inhaled into the lung bronchioles, the carbon is phagocytosed and transported by macrophages and microciliary into the mucus. An immune response is triggered as the coal-filled macrophages accumulate in the alveoli. Reticulin is secreted from the fibroblasts which then entrap the macrophages and become strangulated from the resultant interstitial fibrosis.

Complications

- Pulmonary hypertension
- Pulmonary TB
- Cor pulmonale

Signs and Symptoms

Simple CWP produces no symptoms, especially in nonsmokers. Symptoms of complicated CWP include exertional dyspnea and a cough that occasionally produces inky-black sputum (when fibrotic changes undergo avascular necrosis and their centers cavitate). Other clinical features of CWP include increasing dyspnea and a cough that produces milky, gray, clear, or coal-flecked sputum. Recurrent bronchial and pulmonary infections produce yellow, green, or thick sputum.

Complications include pulmonary hypertension, right ventricular hypertrophy, cor pulmonale, and pulmonary TB. In cigarette smokers, chronic bronchitis and emphysema may also complicate the disease.

Diagnosis

The patient history reveals exposure to coal dust. Physical examination shows barrel chest, hyperresonant lungs with areas of dullness, diminished breath sounds, crackles, rhonchi, and wheezes. In *simple CWP*, chest X-rays show small opacities (less than 10 mm in diameter). These may be present in all lung zones but are more prominent in the upper lung zones. In *complicated CWP*, one or more large opacities (1 to 5 cm in diameter), possibly exhibiting cavitation, are seen.

PFTs show:

- Vital capacity—normal in simple CWP but decreased with complicated CWP
- FEV_1—decreased in complicated disease
- Residual volume and TLC—normal in simple CWP; decreased in complicated CWP
- Carbon monoxide diffusing capacity—significantly decreased in complicated CWP as alveolar septae are destroyed and pulmonary capillaries obliterated
- Pa_{CO_2}—may be increased with concomitant COPD

Treatment

There's no specific treatment. The goal of treatment is to relieve respiratory symptoms, manage hypoxia and cor pulmonale, and avoid respiratory tract irritants and infections. Treatment also includes careful observation for the development of TB. Chest physiotherapy techniques, such as controlled coughing and segmental bronchial drainage combined with chest percussion and vibration, help remove secretions.

Other measures include increased fluid intake (at least 3 qt [3 L] daily) and respiratory therapy techniques, such as aerosol therapy, inhaled mucolytics, and intermittent positive-pressure breathing. Diuretics, cardiac glycosides, and salt restriction may be indicated in cor pulmonale.

In severe cases, it may be necessary to administer oxygen for hypoxemia by cannula or mask (1 to 2 L/minute) if the patient has chronic hypoxia; mechanical ventilation is utilized if Pa_{O_2} can't be maintained above 40 mm Hg. Respiratory infections require prompt administration of antibiotics.

Special Considerations

◆ Teach the patient to prevent infections by avoiding crowds and persons with respiratory infections and by receiving pneumococcal vaccine polyvalent and annual influenza vaccines.
◆ Encourage the patient to stay active to avoid a deterioration in his or her physical condition but to pace activities and practice relaxation techniques.

Neurologic Disorders

Introduction

The neurologic system, the body's communications network, coordinates and organizes the functions of all body systems. This intricate network has three main divisions:

- *central nervous system (CNS):* the control center, made up of the brain, the brainstem, and the spinal cord
- *peripheral nervous system:* motor and sensory nerves that connect the CNS to remote body parts and relay and receive messages from them
- *autonomic nervous system (part of the peripheral nervous system):* regulates involuntary functioning of the internal organs and vascular system.

FUNDAMENTAL UNIT

The fundamental unit of the nervous system is the neuron, a highly specialized conductor cell that receives and transmits electrochemical nerve impulses. Its structure contains delicate, threadlike nerve fibers that extend from the central cell body and transmit signals: *axons,* which carry impulses *away* from the cell body, and *dendrites,* which carry impulses *to* it. Most neurons have multiple dendrites but only one axon. *Sensory (afferent) neurons* transmit impulses from special receptors to the spinal cord or the brain, *motor (efferent) neurons* transmit impulses from the CNS to regulate activity of muscles or glands, and *interneurons (connecting or association neurons)* shuttle signals through complex pathways between sensory and motor neurons. Interneurons account for 99% of all the neurons in the nervous system and include most of the neurons in the brain. (See *Parts of a neuron,* page 147.)

Parts of a Neuron

A typical neuron, like the one shown here, has one axon and many dendrites. A myelin sheath encloses the axon.

INTRICATE CONTROL SYSTEM

This intricate network of interlocking receptors and transmitters forms, together with the brain and spinal cord, a dynamic control system—a living computer—that controls and regulates every mental and physical function. From birth to death, this astonishing system efficiently organizes the body's affairs—controlling the smallest action, thought, or feeling; monitoring communication and instinct for survival; and allowing introspection, wonder, abstract thought, and awareness of one's own intelligence. The brain, the primary center of the CNS, is the large soft mass of nervous tissue housed in the cranium and protected and supported by the meninges and skull bones.

The fragile brain, brainstem, and spinal cord are protected by bone (the skull and vertebrae), cushioning *cerebrospinal fluid (CSF)*, and three protective membranes, called *meninges:*

- ◆ The *dura mater*, or outer sheath, is made of tough white fibrous tissue.
- ◆ The *arachnoid membrane*, the middle layer, is delicate and lacelike.
- ◆ The *pia mater*, the inner meningeal layer, is made of fine blood vessels held together by connective tissue. It's thin and transparent and clings to the brain and spinal cord surfaces, carrying branches of the cerebral arteries deep into the brain's fissures and sulci.

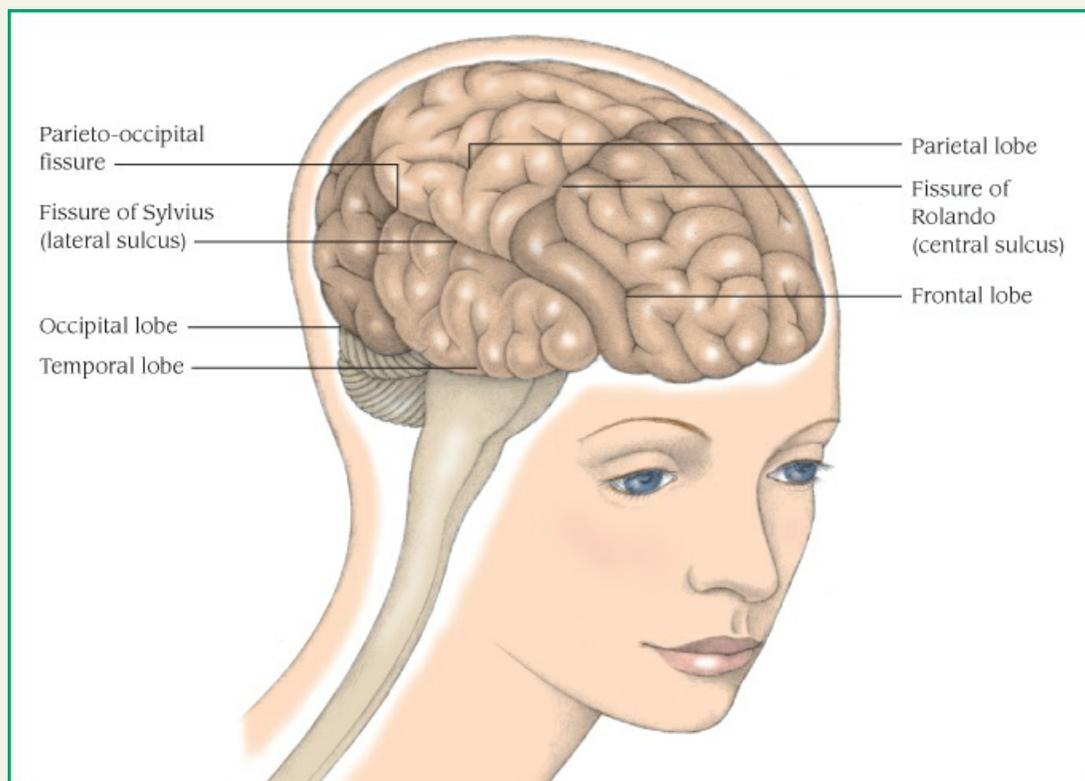
Between the dura mater and the arachnoid membrane is the *subdural space*; between the pia mater and the arachnoid membrane is the *subarachnoid space*. The subarachnoid space and the brain's four ventricles contain *CSF*, a clear liquid containing water and traces of organic materials (especially protein), glucose, and minerals.

CSF is formed from blood in capillary networks called *choroid plexus*, which are located primarily in the brain's lateral ventricles. This fluid is eventually reabsorbed into the venous

blood through the *arachnoid villi,* in dural sinuses on the brain's surface.

   The *cerebrum,* the largest portion of the brain, is the nerve center that controls sensory and motor activities and intelligence. The outer layer of the cerebrum, the *cerebral cortex*, consists of neuron cell bodies (*gray matter*); the inner layers consist of axons (*white matter*) and basal ganglia, which control motor coordination and steadiness. The cerebral surface is deeply convoluted, furrowed with elevations (*gyri*) and depressions (*sulci*). A *longitudinal fissure* divides the cerebrum into two hemispheres connected by a wide band of nerve fibers called the *corpus callosum,* through which the hemispheres share information. The hemispheres don't share equally; one always dominates, giving one side control over the other. Because motor impulses descending from the brain through the pyramidal tract cross in the medulla, the right hemisphere controls the left side of the body and the left hemisphere, the right side of the body. Several fissures divide the cerebrum into lobes, each of which is associated with specific functions. (See *A look at the lobes,* page 148.)

A Look at the Lobes

Several fissures divide the cerebrum into hemispheres and lobes; each lobe has a specific function. The *fissure of Sylvius* (lateral sulcus) separates the temporal lobe from the frontal and parietal lobes. The *fissure of Rolando* (central sulcus) separates the frontal lobes from the parietal lobe. The *parieto-occipital fissure* separates the occipital lobe from the two parietal lobes.


- The *frontal lobe* controls voluntary muscle movements and contains motor areas (including the motor area for speech, or Broca area). It's the center for personality,

behavioral, and intellectual functions, such as judgment, memory, and problem solving; for autonomic functions; and for cardiac and emotional responses.
- The *temporal lobe* is the center for taste, hearing, and smell; in the brain's dominant hemisphere, it interprets spoken language.
- The *parietal lobe* coordinates and interprets sensory information from the opposite side of the body.
- The *occipital lobe* interprets visual stimuli.

The *thalamus,* a relay center below the corpus callosum, further organizes cerebral function by transmitting impulses to and from appropriate areas of the cerebrum. In addition to its primary relay function, it's responsible for primitive emotional responses, such as fear, and for distinguishing pleasant stimuli from unpleasant ones.

The *hypothalamus,* which lies beneath the thalamus, is an autonomic center that has connections with the brain, spinal cord, autonomic nervous system, and pituitary gland. It regulates temperature control, appetite, blood pressure, breathing, sleep patterns, and peripheral nerve discharges that occur with behavioral and emotional expression. It also has partial control of pituitary gland secretion and stress reaction.

THE BASE OF THE BRAIN

Beneath the cerebrum, at the base of the brain, is the *cerebellum.* It's responsible for smooth muscle movements, coordinating sensory impulses with muscle activity, and maintaining muscle tone and equilibrium.

The brainstem houses cell bodies for most of the cranial nerves and includes the *midbrain,* the *pons,* and the *medulla oblongata.* With the thalamus and the hypothalamus, it makes up a nerve network called the *reticular formation,* which acts as an arousal mechanism and controls wakefulness. It also relays nerve impulses between the spinal cord and other parts of the brain. The midbrain is the reflex center for the third and fourth cranial nerves and mediates pupillary reflexes and eye movements. The pons helps regulate respirations; it's also the reflex center for the fifth through eighth cranial nerves and mediates chewing, taste, saliva secretion, hearing, and equilibrium. The medulla oblongata affects cardiac, respiratory, and vasomotor functions.

BLOODLINE TO THE BRAIN

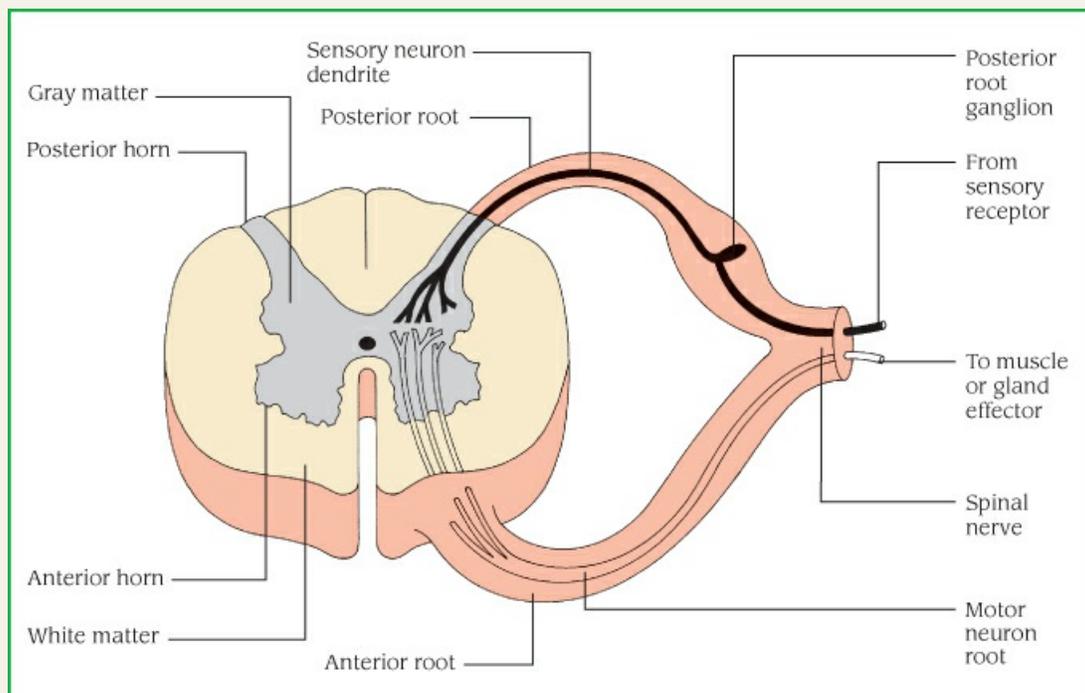
Four major arteries—two vertebral and two carotid—supply the brain with oxygenated blood. These arteries originate in or near the aortic arch. The two vertebral arteries (branches of the subclavian) converge to become the basilar artery, which supplies the posterior brain. The common carotids branch into the two internal carotids, which divide further to supply the anterior brain and the middle brain. These arteries interconnect through the *circle of Willis,* at the base of the brain. This anastomosis usually ensures continual circulation to the brain.

THE SPINAL CORD: CONDUCTOR PATHWAY

Extending downward from the brain through the vertebrae, to the level of approximately the second lumbar vertebra, is the spinal cord, a two-way conductor pathway between the brainstem and the peripheral nervous system. The spinal cord is also the reflex center for activities that don't require brain control, such as deep tendon reflexes, the jerking reaction elicited by tapping with a reflex hammer.

A cross section of the spinal cord shows an internal H-shaped mass of gray matter divided into horns, which consist primarily of neuron cell bodies. (See *Cross section of the spinal cord,* page 149.) Cell bodies in the posterior, or dorsal, horn primarily relay sensations; those in the anterior, or ventral, horn are needed for voluntary or reflex motor activity. The white matter surrounding the outer part of these horns consists of myelinated nerve fibers grouped functionally in vertical columns, called *tracts.* The sensory, or ascending, tracts carry sensory impulses up the spinal cord to the brain; the motor, or descending, tracts carry motor impulses down the spinal cord. The brain's motor impulses reach a descending tract and continue through the peripheral nervous system via upper motor neurons. These neurons originate in the brain and form two major systems:

Cross Section of the Spinal Cord

The cross section of the spinal cord below shows the anterior and posterior segments.


- The *pyramidal system* (corticospinal tract) is responsible for fine, skilled movements of skeletal muscle. An impulse in this system originates in the frontal lobe's motor cortex and travels downward to the pyramids of the medulla, where it crosses to the opposite side of the spinal cord.
- The *extrapyramidal system* (extracorticospinal tract) controls gross motor movements. An impulse traveling in this system originates in the frontal lobe's motor cortex and is mediated by basal ganglia, the thalamus, cerebellum, and reticular formation before descending to the spinal cord.

OUTLYING AREAS

Messages transmitted through the spinal cord reach outlying areas through the peripheral nervous system, which originates in 31 pairs of segmentally arranged spinal nerves attached to the spinal cord. Spinal nerves are numbered according to their point of origin in the cord:

- 8 cervical: C1 to C8
- 12 thoracic: T1 to T12
- 5 lumbar: L1 to L5
- 5 sacral: S1 to S5
- 1 coccygeal.

On the cross section of the spinal cord, you'll see that these spinal nerves are attached to the spinal cord by two roots:

- The *anterior,* or *ventral,* root consists of motor fibers that relay impulses from the cord to glands and muscles.
- The *posterior,* or *dorsal,* root consists of sensory fibers that relay sensory information from receptors to the cord. The posterior root has an enlarged area—the posterior root ganglion— which is made up of sensory neuron cell bodies.

After leaving the vertebral column, each spinal nerve separates into *rami* (branches), distributed peripherally, with extensive but organized overlapping. This overlapping reduces the chance of lost sensory or motor function from interruption of a single spinal nerve.

TWO FUNCTIONAL SYSTEMS

- The *somatic* (*voluntary*) *nervous system* is activated by will but can also function independently. It's responsible for all conscious and higher mental processes and for subconscious and reflex actions such as shivering.
- *The autonomic (involuntary) nervous system* regulates unconscious processes to control involuntary body functions, such as digestion, respiration, and cardiovascular function. It's usually divided into two competing systems: The sympathetic nervous system controls energy expenditure, especially in stressful situations, by releasing adrenergic catecholamines. The parasympathetic nervous system helps conserve energy by releasing the cholinergic neurohormone acetylcholine. These systems balance each other to support homeostasis under normal conditions.

ASSESSING NEUROLOGIC FUNCTION

A complete neurologic assessment helps confirm the diagnosis when a neurologic disorder is suspected. It establishes a clinical baseline and can offer lifesaving clues to rapid deterioration. Neurologic assessment includes:

- *Patient history:* In addition to the usual information, try to elicit the patient's and the family's perception of the disorder. Use the patient interview to make observations that help evaluate mental status and behavior.
- *Physical examination:* Pay particular attention to obvious abnormalities that may signal serious neurologic problems; for example, fluid draining from the nose or ears. Check for these significant symptoms:
  - headaches, especially if they're more severe in the morning, wake the patient, or the pain is

> unusually intense
>   - change in visual acuity, especially sudden change
>   - numbness or tingling in one or more extremities
>   - clumsiness or complete loss of function in an extremity
>   - mood swings or personality changes
>   - any new onset of seizures or change in seizure activity.

- *Neurologic examination:* Determine cerebral, cerebellar, motor, sensory, and cranial nerve function.

Obviously, there isn't always time for a complete neurologic examination during bedside assessment. It's therefore necessary to select priorities; for example, typical bedside assessment focuses on level of consciousness (LOC), pupillary response, motor function, reflexes, sensory functions, and vital signs. However, when time permits, a complete neurologic examination can provide valuable information regarding total neurologic function.

ASSESSING MENTAL STATUS, INTELLECT, AND BEHAVIOR

Mental status and behavior are good indicators of cerebral function, and they're easy to assess. Note the patient's appearance, mannerisms, posture, facial expression, grooming, and tone of voice. Check for orientation to time, place, and person and for memory of recent and past events. To test intellect, ask the patient to count backward from 100 by 7s, to read aloud, or to interpret a common proverb, and see how well they understand and follow commands. To assess executive function, ask the patient to follow a series of commands. If you make such checks frequently, vary the questions to avoid a programmed response.

ASSESSING LEVEL OF CONSCIOUSNESS

LOC is a valuable indicator of neurologic function. It can vary from alertness (response to verbal stimulus) to coma (failure to respond even to painful stimulus). Document the patient's exact response to the stimulus; for example, write, "Patient pulled away in response to nail bed pressure," rather than a simple adjective like "stuporous."

The Glasgow Coma Scale (GCS), which assesses eye opening as well as verbal and motor responses, provides a quick, standardized account of neurologic status. In this test, each response receives a numerical value. (See *Glasgow Coma Scale,* page 151.) For instance, if the patient readily responds verbally and is oriented to time, place, and person, scores a 5; if completely unable to respond verbally, scores a 1. If the patient is intubated or has a tracheostomy, assess and score accordingly, such as 5/T ("T" meaning tracheostomy). A score of 15 for all three parts is normal; 7 or less indicates coma; 3—the lowest score possible—generally (but not always) indicates brain death. Although the GCS is useful, it isn't a substitute for a complete neurologic assessment.

Glasgow Coma Scale

To quickly assess a patient's level of consciousness and to uncover baseline changes, use the Glasgow Coma Scale. This assessment tool grades consciousness in relation to eye opening and motor and verbal responses. A decreased reaction score in one or more categories warns of an impending neurologic crisis. A patient scoring 7 or less is comatose and probably has

severe neurologic damage.

Test	Patient's reaction	Score
Best eye opening response	Open spontaneously	4
	Open to verbal command	3
	Open to pain	2
	No response	1
Best motor response	Obeys verbal command	6
	Localizes painful stimuli	5
	Flexion-withdrawal	4
	Flexion-abnormal (decorticate rigidity)	3
	Extension (decerebrate rigidity)	2
	No response	1
Best verbal response	Oriented and converses	5
	Disoriented and converses	4
	Inappropriate words	3
	Incomprehensible sounds	2
	No response	1
Total		3 to 15

ASSESSING MOTOR FUNCTION

The inability to perform the following simple tests, or the presence of tics, tremors, or other abnormalities during such testing, suggests cerebellar dysfunction.

- Ask the patient to touch the nose with each index finger, alternating hands. Repeat this test with the eyes closed.
- Instruct the patient to tap the index finger and thumb of each hand together rapidly.
- Have the patient draw a figure eight in the air with one foot.
- To test tandem walk, ask the patient to walk heel to toe in a straight line.
- To test balance, perform the Romberg test: Ask the patient to stand with feet together, eyes closed, and arms outstretched without losing balance.

Motor function is a good indicator of LOC and can also point to central or peripheral nervous system damage. During all tests of motor function, watch for differences between right and left side functions.

- To check gait, ask the patient to walk while you observe posture, balance, and coordination of leg movement and arm swing.
- To check muscle tone, palpate muscles at rest and in response to passive flexion. Look for flaccidity, spasticity, and rigidity. Measure muscle size, and look for involuntary movements, such as rapid jerks, tremors, or contractions.
- To evaluate muscle strength, have the patient grip your hands and squeeze. Then ask the patient to push against your palm with a foot. Compare muscle strength on each side, using a 5-point scale (5 is normal strength, 0 is complete paralysis). Insert table of motor strength; also test the patient's ability to extend and flex the neck, elbows, wrists, fingers, toes, hips, and knees; to extend the spine; to contract and relax the abdominal muscles; and to rotate the shoulders.
- Rate reflexes on a 4-point scale (4 is clonus, 2 is normal, 0 is absent reflex). Before testing reflexes, make sure that the patient is comfortable and relaxed. To test deep reflexes, use a reflex hammer to briskly tap the biceps, the triceps, and the brachioradialis, patellar, and

Achilles tendon regions. A normal response is rapid extension and contraction. Then, to test superficial reflexes, stroke the skin of the abdominal, gluteal, plantar, and scrotal regions with a moderately sharp object that won't puncture the skin. For the superficial reflexes, abdominal gluteal and scrotal contraction should move toward the stimulus. The plantar reflex toes should curl down.

ASSESSING SENSORY FUNCTION

Impaired or absent sensation in the trunk or extremities can point to brain, spinal cord, or peripheral nerve damage. Determining the extent of sensory dysfunction is important because it helps locate neurologic damage. For instance, localized dysfunction indicates local peripheral nerve damage, dysfunction over a single dermatome (an area served by 1 of the 31 pairs of spinal nerves) indicates damage to the nerve's dorsal root, and dysfunction extending over more than one dermatome suggests brain or spinal cord damage.

In assessing sensory function, always test both sides of symmetrical areas—for instance, both arms, not just one. Reassure the patient that the test won't be painful.

◆ *Superficial pain perception:* Lightly press the point of an open safety pin against the patient's skin. Don't press hard enough to scratch the skin. Discard pin after use.
◆ *Thermal sensitivity:* The patient tells what it feels like when you place a test tube filled with hot water and one filled with cold water against the skin.
◆ *Tactile sensitivity:* Ask the patient to close the eyes and tell you what is felt when touched lightly on hands, wrists, arms, thighs, lower legs, feet, and trunk with a wisp of cotton.
◆ *Sensitivity to vibration:* Place the base of a vibrating tuning fork against the patient's wrists, elbows, knees, or other bony prominences. Hold it in place, and ask the patient to tell you when it stops vibrating.
◆ *Position sense:* Hold the lateral medial portion of the patient's fingers and toes and move them up, down, and to the side. Ask the patient to tell you the direction of movement.
◆ *Discriminatory sensation:* Ask the patient to close the eyes and identify familiar textures (velvet or burlap) or objects placed in the hand or numbers and letters traced on the palm.
◆ *Two-point discrimination:* Using calipers or other sharp objects, touch the patient in two different places simultaneously. Ask if the patient can feel one or two points. Record how many millimeters of separation are required for the patient to feel two points.

ASSESSING CRANIAL NERVE FUNCTION

By using the simple tests that follow, you can reliably localize cranial nerve dysfunction.

◆ *Olfactory nerve (I):* Have the patient close both eyes and, using each nostril separately, try to identify common nonirritating smells, such as cinnamon, coffee, or peppermint.
◆ *Optic nerve (II):* Examine the patient's eyes with an ophthalmoscope, and have them read a Snellen eye chart or a newspaper. To test peripheral vision, ask the patient to cover one eye and fix the other eye on a point directly in front of him. Then, ask if the patient can see you wiggle your finger in the four quadrants; you'd expect them to see your finger in all four.
◆ *Oculomotor nerve (III):* Compare the size and shape of the patient's pupils and the equality of pupillary response to a small light in a darkened room. Shine the light from a lateral position, not directly in front of the patient's eyes.
◆ *Trochlear nerve (IV) and abducens nerve (VI):* To assess for conjugate and lateral eye

movement, ask the patient to follow your finger with both eyes as you slowly move it from the far left to the far right.

- *Trigeminal nerve (V):* To test all three portions of this cranial nerve, test facial sensation by stroking the patient's jaws, cheeks, and forehead with a cotton swab, the point of a pin, or test tubes filled with hot or cold water. Because testing for a blink reflex is irritating to the patient, it's not commonly done. If you must test for this response (it may be decreased in patients who wear contact lenses), touch the cornea lightly with a wisp of cotton or tissue, and avoid repeating the test, if possible. To test for jaw jerk, ask the patient to hold their mouth slightly open; then tap the middle of their chin lightly with a reflex hammer. The jaw should jerk closed.
- *Facial nerve (VII):* To test upper and lower facial motor function, ask the patient to raise the eyebrows, close the eyes, wrinkle the forehead, and show the teeth. To test sense of taste, ask the patient to identify the taste of salty, sour, sweet, and bitter substances, which you have placed on their tongue.
- *Acoustic nerve (VIII):* Ask the patient to identify common sounds such as a ticking clock. With a tuning fork, test for air and bone conduction.
- *Glossopharyngeal nerve (IX):* To test gag reflex, touch a tongue blade to each side of the patient's pharynx.
- *Vagus nerve (X):* Observe ability to swallow, and watch for symmetrical movements of soft palate when the patient says, "Ah."
- *Spinal accessory nerve (XI):* To test shoulder muscle strength, palpate the patient's shoulders, and ask the patient to shrug against a resistance.
- *Hypoglossal nerve (XII):* To test tongue movement, ask the patient to stick out his or her tongue. Inspect it for tremor, atrophy, or lateral deviation. To test for strength, ask the patient to move his or her tongue from side to side while you hold a tongue blade against it.

TESTING FOR A FIRM DIAGNOSIS

A firm diagnosis of many neurologic disorders usually requires a wide range of diagnostic tests —both noninvasive and invasive. Noninvasive tests are done first and may include the following:

- Skull X-ray identifies skull malformations, fractures, erosion, or thickening. Changes in landmarks may indicate a space-occupying lesion.
- Computed tomography (CT) scan produces three-dimensional images that can identify hemorrhage, intracranial tumors, malformation, and cerebral atrophy, edema, calcification, and infarction. If a contrast medium is used, the procedure is invasive. CT angiography uses CT technology with contrast media to produce images of the intracranial vessels to identify aneurysms and arteriovenous malformations (AVMs).
- Magnetic resonance imaging (MRI) views the CNS in greater detail than a CT scan and is the procedure of choice for detecting multiple sclerosis (MS); intraluminal clots, brainstem, posterior fossa, and spinal cord lesions; early cerebral infarction; and brain tumors. A noniodinated contrast medium may be used to enhance lesions. MR angiography uses MR technique with contrast media to evaluate the cerebral vessels. MR spectroscopy provides a measure of brain chemistry. It can be used to monitor biochemical changes in tumors, epilepsy, metabolic disorders, infection, and neurodegenerative diseases.
- EEG detects abnormal electrical activity in the brain (e.g., from a seizure, metabolic disorder, or drug overdose).
- Ultrasonography detects carotid lesions or changes in carotid blood flow and velocity. High

frequency sound waves reflect back the velocity of blood flow, which is then reported as a graphic recording of a waveform.

◆ Transcranial Doppler sonography uses ultrasound high frequency sound waves to measure the rate and direction of blood flow in the intracranial vessels.

◆ Evoked potentials evaluate the visual, auditory, and somatosensory nerve pathways by measuring the brain's electrical response to stimulation of the sensory organs or peripheral nerves.

Invasive tests may include the following:

◆ In lumbar puncture, a needle is inserted into the subarachnoid space of the spinal cord, usually between L3 and L4 (or L4 and L5). This allows aspiration of CSF for analysis to detect infection or hemorrhage; to determine cell count and glucose, protein, and globulin levels; and to measure CSF pressure. Lumbar puncture is usually contraindicated in hydrocephalus and in increased intracranial pressure (ICP) because a quick pressure reduction may cause brain herniation. (See *What happens in increased ICP*, page 154.)

PATHOPHYSIOLOGY
WHAT HAPPENS IN INCREASED ICP

Intracranial pressure (ICP) is the pressure exerted within the intact skull by the intracranial volume—about 10% blood, 10% cerebrospinal fluid (CSF), and 80% brain tissue water. The rigid skull allows very little space for expansion of these substances. When ICP increases to pathologic levels, brain damage can result.

The brain compensates for increases in ICP by regulating the volumes of the three substances in the following ways:

◆ limiting blood flow to the head
◆ displacing CSF into the spinal canal
◆ increasing absorption or decreasing production of CSF—withdrawing water from brain tissue into the blood and excreting it through the kidneys. When compensatory mechanisms become overworked, small changes in volume lead to large changes in pressure.

The chart at right will help you understand the pathophysiology of increased ICP.

Brain insult
Trauma (contusion, laceration, intracranial hemorrhage)
Cerebral edema (following surgery, stroke, infection, hypoxia)
Hydrocephalus
Space-occupying lesion (tumor, abscess)

↓

Slight increase in intracranial pressure (ICP)

↓

Attempt at normal regulation of ICP by decreased blood flow to head

↓

Slight decrease in cerebral perfusion pressure (CPP)

↓

Loss of autoregulatory mechanism of constriction or dilation of cerebral blood vessels if increased ICP persists

↓

Passive dilation

↓

Increased cerebral blood flow; venous congestion

↓

Further increase in ICP

↓

Cellular hypoxia

↓   ↓

Uncal or central herniation   Further decrease in CPP

↓   ↓

Brain death

- Myelography follows a lumbar puncture and CSF removal. In this procedure, a radiologic dye is instilled and X-rays show spinal abnormalities and determine spinal cord and or nerve root compression related to back pain or extremity weakness.
- In cerebral arteriography, also known as *angiography*, a catheter is inserted into an artery—usually the femoral artery—and is threaded up to the carotid artery. Then a radiopaque dye is

injected, allowing X-ray visualization of the cerebral vasculature. Sometimes the catheter is threaded directly into the brachial or carotid artery. This test can show cerebrovascular abnormalities and spasms plus arterial changes due to a tumor, arteriosclerosis, hemorrhage, an aneurysm, or blockage. A patient undergoing this procedure is at risk for a stroke and for increased ICP.

◆ Brain scan measures gamma rays produced by a radioisotope injected I.V. Uptake and distribution of the isotope in the brain highlights intracranial masses, vascular lesions, and other problems.

◆ ICP monitoring can be a direct, invasive method of identifying trends in ICP. A subarachnoid screw or an intraventricular catheter converts CSF pressure readings into waveforms that are displayed digitally on an oscilloscope monitor. Another method uses a fiber-optic catheter inserted in the subdural space or the brain parenchyma; with this indirect method, pressure changes are reported digitally or in waveform.

◆ Electromyography detects lower motor neuron disorders, neuromuscular disorders, and nerve damage. A needle inserted into selected muscles at rest and during voluntary contraction picks up nerve impulses and measures nerve conduction time.

Congenital Anomalies

CEREBRAL PALSY

The most common cause of crippling in children, cerebral palsy (CP) is a group of neuromuscular disorders resulting from prenatal, perinatal, or postnatal CNS damage. Although nonprogressive, these disorders may become more obvious as an affected infant grows older. Three major types of CP occur—spastic, athetoid, and ataxic—sometimes in mixed forms. Motor impairment may be minimal (sometimes apparent only during physical activities such as running) or severely disabling. Associated defects, such as seizures, speech disorders, and mental retardation, are common. The prognosis varies; in cases of mild impairment, proper treatment may make a near-normal life possible.

Causes and Incidence

See *Causes of cerebral palsy* for a more detailed description of the causes of CP. Incidence is slightly higher in premature neonates (anoxia plays the greatest role in contributing to CP) and in neonates who are small for their gestational age. CP is slightly more common in males than in females. For every 1,000 births, 2 to 4 neonates are affected.

Spastic CP is the most common type of CP, affecting about 50% of CP patients. Athetoid CP affects about 20% of CP patients, ataxic CP accounts for another 10% of these patients, and the remaining 20% of patients are mixed, with a combination of symptoms.

Pathophysiology

During the early stages of brain development, a structural abnormality occurs which results in impaired motor function or a cognitive deficit. The defects are present at birth but because of relative immaturity of the CNS at birth the neurologic deficits become apparent later on.

Complications

◆ Seizure disorder

- Injuries from falls
- Speech, vision, and hearing problems
- Language and perception deficits
- Respiratory problems (poor swallowing and gag reflexes)
- Dental problems
- Mental retardation

Signs and Symptoms

Spastic CP is characterized by hyperactive deep tendon reflexes, increased stretch reflexes, rapid alternating muscle contraction and relaxation, muscle weakness, underdevelopment of affected limbs, muscle contraction in response to manipulation, and a tendency to contractures. Typically, a child with spastic CP walks on his or her toes with a scissors gait, crossing one foot in front of the other.

In athetoid CP, involuntary movements—grimacing, wormlike writhing, dystonia, and sharp jerks—impair voluntary movement. Usually, these involuntary movements affect the arms more severely than the legs; involuntary facial movements may make speech difficult. These athetoid movements become more severe during stress, decrease with relaxation, and disappear entirely during sleep.

Ataxic CP is characterized by disturbed balance, incoordination (especially of the arms), hypoactive reflexes, nystagmus, muscle weakness, tremor, lack of leg movement during infancy, and a wide-based gait as the child begins to walk. Ataxia makes sudden or fine movements almost impossible.

Causes of Cerebral Palsy

Cerebral palsy (CP) is caused by a developmental brain malformation or neurologic damage.

- Prenatal conditions that may increase risk of CP: maternal infection (especially rubella), maternal drug ingestion, radiation, anoxia, toxemia, maternal diabetes, abnormal placental attachment, malnutrition, and isoimmunization
- Perinatal and birth difficulties that increase the risk of CP: forceps delivery, breech presentation, placenta previa, abruptio placentae, metabolic or electrolyte disturbances, abnormal maternal vital signs from general or spinal anesthetic, prolapsed cord with delay in delivery of head, premature birth, prolonged or unusually rapid labor, and multiple birth (especially infants born last in a multiple birth)
- Infection or trauma during infancy: poisoning, severe kernicterus resulting from erythroblastosis fetalis, brain infection, head trauma, prolonged anoxia, brain tumor, cerebral circulatory anomalies causing blood vessel rupture, and systemic disease resulting in cerebral thrombosis or embolus

---

Some children with CP display a combination of these clinical features. In most, impaired motor function makes eating (especially swallowing) difficult and retards growth and development. Up to 40% of these children are mentally retarded, about 25% have seizure disorders, and about 80% have impaired speech. Many also have dental abnormalities, vision and hearing defects, and reading disabilities.

Diagnosis

Early diagnosis is essential for effective treatment and requires precise neurologic assessment and careful clinical observation during infancy. CT scan and MRI can reveal structural or congenital abnormalities. Suspect CP whenever an infant:

- has difficulty sucking or keeping the nipple or food in his or her mouth
- seldom moves voluntarily or has arm or leg tremors with voluntary movement
- crosses legs when lifted from behind rather than pulling them up or "bicycling" like a normal infant
- has legs that are difficult to separate, making diaper changing difficult
- persistently uses only one hand or, as they get older, uses hands well but not legs.

Infants at particular risk include those with low birth weight, low Apgar scores at 5 minutes, seizures, and metabolic disturbances. However, all infants should have a screening test for CP as a regular part of their 6-month checkup.

Treatment

CP can't be cured, but proper treatment can help affected children reach their full potential within the limitations set by this disorder. Such treatment requires a comprehensive and cooperative effort involving physicians, nurses, teachers, psychologists, the child's family, and occupational, physical, and speech therapists. Home care is usually possible. Treatment usually includes interventions that encourage optimum development:

- Braces or splints and special appliances, such as adapted eating utensils and a low toilet seat with arms, help these children perform activities independently.
- An artificial urinary sphincter may be indicated for the incontinent child who can use the hand controls.
- Range-of-motion stretches minimize contractures.
- Orthopedic surgery may be indicated to correct contractures. Botulinum toxin has been shown to reduce or delay the need for surgery.
- Phenytoin, phenobarbital, or another anticonvulsant may be used to control seizures.
- Muscle relaxants or neurosurgery may be required to decrease spasticity.

Children with milder forms of CP should attend a regular school; severely afflicted children may need special education.

Special Considerations

- A child with CP may be hospitalized for orthopedic surgery or for treatment of other complications.
- Speak slowly and distinctly. Encourage the child to ask for things he or she wants. Listen patiently and don't rush.
- Plan a high-calorie diet that's adequate to meet the child's high-energy needs.
- During meals, maintain a quiet, unhurried atmosphere with as few distractions as possible. The child should be encouraged to feed himself and may need special utensils and a chair with a solid footrest. Teach the patient to place food far back in his or her mouth to facilitate swallowing.
- Encourage the child to chew food thoroughly, drink through a straw, and suck on lollipops to develop the muscle control needed to minimize drooling.

- Allow the child to wash and dress independently, assisting only as needed. The child may need clothing modifications.
- Give all care in an unhurried manner; otherwise, muscle spasticity may increase.
- Encourage the child and their family to participate in the plan of care so they can continue it at home.
- Care for associated hearing or visual disturbances, as necessary.
- Give frequent mouth care and dental care, as necessary.
- Reduce muscle spasms that increase postoperative pain by moving and turning the child carefully after surgery; provide analgesics as needed.
- After orthopedic surgery, provide cast care. Reposition the child often, check for foul odor, and ventilate under the cast with a cool air blow-dryer. Use a flashlight to check for skin breakdown beneath the cast. Help the child relax, perhaps by giving a warm bath, before reapplying a bivalved cast.

To help the parents:

- Encourage them to set realistic individual goals.
- Assist in planning crafts and other activities.
- Stress the child's need to develop peer relationships; warn the parents against being overprotective.
- Identify and deal with family stress. The parents may feel unreasonable guilt about their child's handicap and may need psychological counseling.
- Refer the parents to supportive community organizations. For more information, tell them to contact the United Cerebral Palsy Association or their local chapter.

HYDROCEPHALUS

Hydrocephalus is an excessive accumulation of CSF within the ventricular spaces of the brain. The resulting compression can damage brain tissue. With early detection and surgical intervention, the prognosis improves but remains guarded. Even after surgery, such complications as mental retardation, impaired motor function, and vision loss can persist. Without surgery, the prognosis is poor: Mortality may result from increased ICP; infants may also die prematurely of infection and malnutrition.

Causes and Incidence

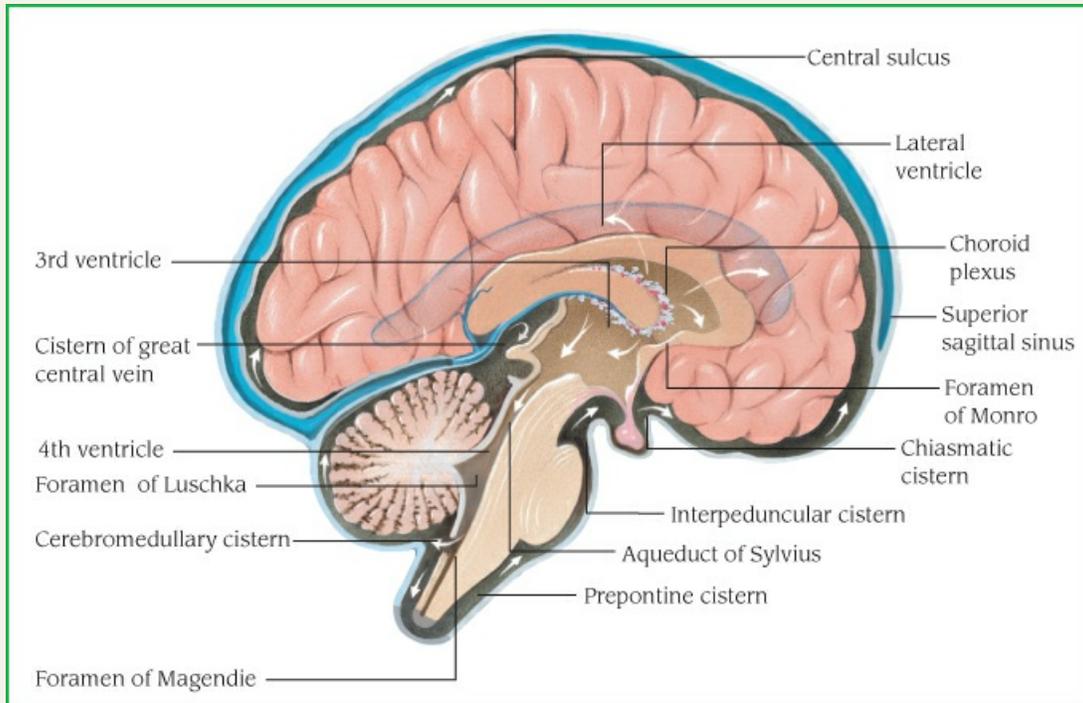
Hydrocephalus may result from an obstruction in CSF flow (noncommunicating hydrocephalus) or from faulty absorption of CSF (communicating hydrocephalus). (See *Normal circulation of CSF*.)

Normal Circulation of CSF

Cerebrospinal fluid (CSF) is produced from blood in a capillary network (choroid plexus) in the brain's lateral ventricles. From the lateral ventricles, CSF flows through the interventricular foramen (foramen of Monro) to the third ventricle. From there, it flows through the aqueduct of Sylvius to the fourth ventricle and through the foramina of Luschka and Magendie to the cisterna of the subarachnoid space.

Then, the fluid passes under the base of the brain, upward over the brain's upper surfaces,

and down around the spinal cord. Eventually, CSF reaches the arachnoid villi, where it's reabsorbed into venous blood at the venous sinuses.

Normally, the amount of fluid produced (about 500 mL/day) equals the amount absorbed. The average amount circulated at one time is 150 to 175 mL.


Hydrocephalus occurs most commonly in neonates but can also occur in adults as a result of injury or disease. It affects 1 of every 1,000 people.

Complications

- Mental retardation
- Impaired motor function
- Vision loss
- Death

Pathophysiology

In noncommunicating hydrocephalus, the obstruction occurs most frequently between the third and fourth ventricles, at the aqueduct of Sylvius, but it can also occur at the outlets of the fourth ventricle (foramina of Luschka and Magendie) or, rarely, at the foramen of Monro. This obstruction may result from faulty fetal development, infection (syphilis, granulomatous diseases, meningitis), a tumor, cerebral aneurysm, or a blood clot (after intracranial hemorrhage). In communicating hydrocephalus, faulty absorption of CSF may result from surgery to repair a myelomeningocele, adhesions between meninges at the base of the brain, or meningeal hemorrhage. Rarely, a tumor in the choroid plexus causes overproduction of CSF, producing hydrocephalus.

Complications

◆ Mental retardation
◆ Impaired motor function
◆ Vision loss
◆ Death

Signs and Symptoms

In infants, the unmistakable sign of hydrocephalus is rapidly increasing head circumference, clearly disproportionate to the infant's growth. Other characteristic changes include widening and bulging of the fontanels; distended scalp veins; thin, shiny, and fragile-looking scalp skin; and underdeveloped neck muscles. In severe hydrocephalus, the roof of the orbit is depressed, the eyes are displaced downward, and the sclerae are prominent. Sclera seen above the iris is called the *setting-sun sign*. A high-pitched, shrill cry; abnormal muscle tone of the legs; irritability; anorexia; and projectile vomiting commonly occur. In adults and older children, indicators of hydrocephalus include decreased LOC, ataxia, incontinence, loss of coordination, and impaired intellect.

Diagnosis

In infants, abnormally large head size for the patient's age strongly suggests hydrocephalus. Measurement of head circumference is a most important diagnostic technique. Skull X-rays show thinning of the skull with separation of sutures and widening of fontanels.

Other diagnostic tests for hydrocephalus, including arteriography, CT scan, and MRI, can differentiate between hydrocephalus and intracranial lesions and can also demonstrate the Arnold–Chiari deformity, which may occur in an infant with hydrocephalus. (See *Arnold–Chiari syndrome,* page 158.)

Arnold–Chiari Syndrome

Arnold–Chiari syndrome frequently accompanies hydrocephalus, especially when a myelomeningocele is also present. In this condition, an elongation or tonguelike downward projection of the cerebellum and medulla extends through the foramen magnum into the cervical portion of the spinal canal, impairing cerebrospinal fluid drainage from the fourth ventricle.

In addition to signs and symptoms of hydrocephalus, infants with Arnold–Chiari syndrome have nuchal rigidity, noisy respirations, irritability, vomiting, weak sucking reflex, and a preference for hyperextension of the neck.

Treatment requires surgery to insert a shunt like that used in hydrocephalus. Surgical decompression of the cerebellar tonsils at the foramen magnum is sometimes indicated.

Treatment

Surgical correction is the only treatment for hydrocephalus. Surgery typically consists of insertion of a ventriculoperitoneal shunt, which transports excess fluid from the lateral ventricle into the peritoneal cavity. A less common procedure is insertion of a ventriculoatrial shunt, which drains fluid from the brain's lateral ventricle into the right atrium of the heart, where the

fluid makes its way into the venous circulation.

Another procedure that can be done for noncommunicating hydrocephalus is an endoscopic third ventriculostomy. This involves inserting an endoscope into the third ventricle and fenestrating the floor of the ventricle to allow CSF to flow out.

Complications of surgery include shunt infection, septicemia (after ventriculoatrial shunt), adhesions and paralytic ileus, migration, peritonitis, and intestinal perforation (with peritoneal shunt) or failure of the third ventriculostomy and return of hydrocephalus.

Special Considerations

◆ On initial assessment, obtain a complete history from the patient or their family. Note general behavior, especially irritability, apathy, or decreased LOC. Perform a neurologic assessment. Examine the eyes: pupils should be equal and reactive to light. In adults and older children, evaluate movements and motor strength in extremities. Watch especially for ataxia, confusion, and incontinence. Ask if the patient has headaches, and watch for projectile vomiting; both are signs of increased ICP. Also watch for seizures. Note changes in vital signs.

Before surgery to insert a shunt:

◆ Encourage maternal–infant bonding when possible. When caring for the infant yourself, hold on your lap for feeding; stroke and cuddle him, and speak soothingly.
◆ Check fontanels for tension or fullness, and measure and record head circumference. On the patient's chart, draw a picture showing where to measure the head so that other staff members measure it in the same place, or mark the forehead with ink.
◆ To prevent post feeding aspiration and hypostatic pneumonia, place the infant on his or her side and reposition every 2 hours, or prop up in an infant seat.
◆ To prevent skin breakdown, make sure the infant's earlobe is flat, and place a sheepskin or rubber foam under the infant's head.
◆ When turning the infant, move the head, neck, and shoulders with the body to reduce strain on the neck.
◆ Feed the infant slowly. To lessen strain from the weight of the infant's head on your arm while holding during feeding, place head, neck, and shoulders on a pillow.

After surgery:

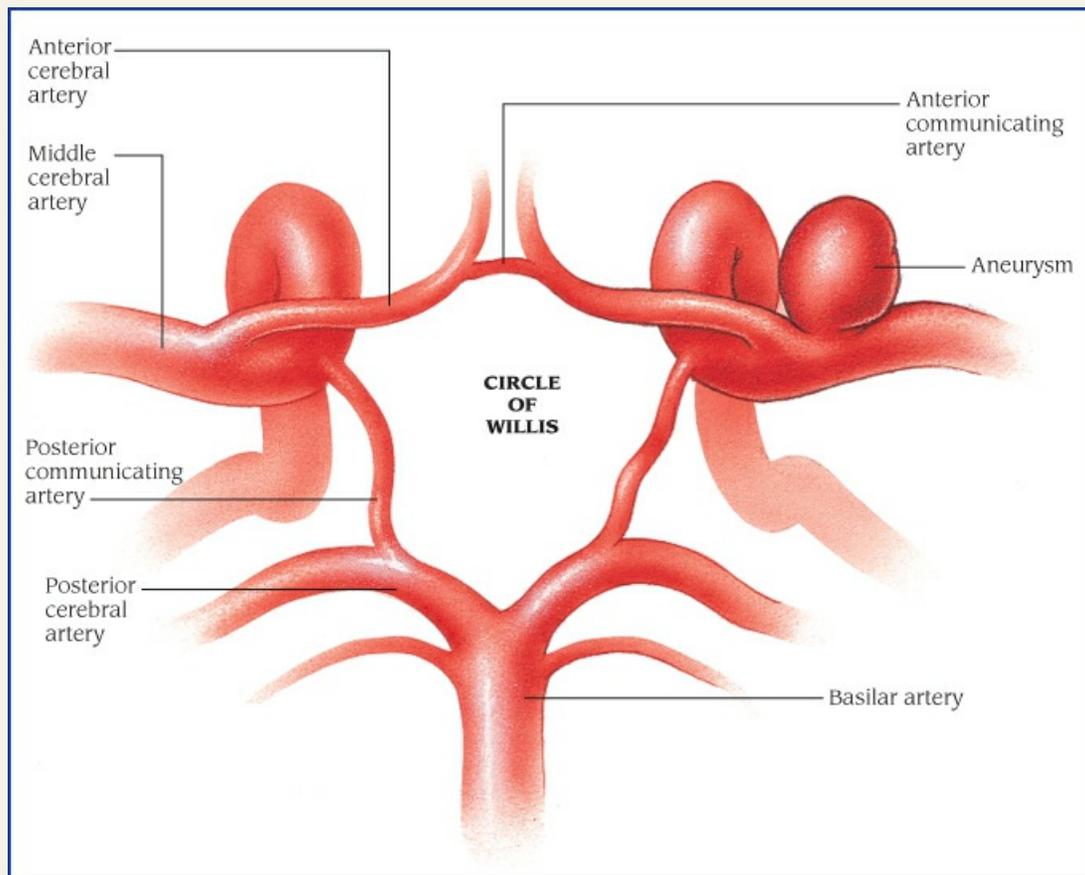
◆ Place the infant on the side opposite the operative site with the head level with the body unless the physician's orders specify otherwise.
◆ Check temperature, pulse rate, blood pressure, and LOC. Also check fontanels for fullness daily. Watch for vomiting, which may be an early sign of increased ICP and shunt malfunction.
◆ Watch for signs of infection, especially meningitis: fever, stiff neck, irritability, or tense fontanels. Also watch for redness, swelling, or other signs of local infection over the shunt tract. Check dressing often for drainage.
◆ Listen for bowel sounds after ventriculoperitoneal shunt.
◆ Check the infant's growth and development periodically, and help the parents set goals consistent with ability and potential. Help parents focus on their child's strengths, not their weaknesses. Discuss special education programs, and emphasize the infant's need for sensory stimulation appropriate for age. Teach parents to watch for signs of shunt malfunction,

infection, and paralytic ileus. Tell them that surgery for lengthening the shunt will be required periodically as the child grows older. Surgery may also be required to correct shunt malfunctioning or to treat infection. Emphasize that hydrocephalus is a lifelong problem and that the child will require regular, continuing evaluation.

CEREBRAL ANEURYSM

Cerebral aneurysm is a localized dilation of a cerebral artery that typically results from a congenital weakness in the arterial wall. Its most common form is the berry aneurysm, a saclike outpouching in a cerebral artery. Cerebral aneurysms may arise at an arterial junction in the circle of Willis, the circular anastomosis forming the major cerebral arteries at the base of the brain. Cerebral aneurysms can rupture and cause subarachnoid hemorrhage. (See *How a cerebral aneurysm forms*, page 160.)

PATHOPHYSIOLOGY
HOW A CEREBRAL ANEURYSM FORMS

In an intracranial or cerebral aneurysm, a weakness in the wall of the cerebral artery causes localized dilation. Cerebral aneurysms usually arise at an arterial junction in the circle of Willis, the circular anastomosis connecting the major cerebral arteries at the base of the brain. Many cerebral aneurysms rupture, causing a subarachnoid hemorrhage.


The prognosis is guarded. About 40% of the patients with subarachnoid hemorrhages die immediately; of those who survive untreated, 35% die from the effects of hemorrhage; another 15% die later from recurring hemorrhage. Sixty percent of patients who recover are left with neurologic deficit. Advances in imaging and interventional procedures are improving the outcome overall.

Causes and Incidence

Cerebral aneurysm may result from a congenital defect, a degenerative process, or a combination. For example, hypertension and atherosclerosis may disrupt blood flow and exert pressure against a congenitally weak arterial wall, stretching it like an overblown balloon and making it likely to rupture. After such rupture, blood spills into the space normally occupied by CSF, resulting in subarachnoid hemorrhage. Blood may also spill into the brain tissue and form a clot, which can result in potentially fatal increased ICP and brain tissue damage.

Incidence is slightly higher in women than in men, especially those in their late 40s or early to mid-50s, but cerebral aneurysm may occur at any age, in both women and men.

Pathophysiology

The pressure of arterial blood flow against a weak congenital vessel abnormality stretches the vessel walls—the walls also become thin from the pressure making rupture likely. When the aneurysm ruptures, it spills blood into the subarachnoid space, which is normally occupied by the cerebral spinal fluid. Depending on the location of the aneurysm in the cerebral circulation, blood can also be forced into the ventricular system and/or the brain parenchyma.

Complications

(Most common after a rupture)

- Subarachnoid hemorrhage
- Brain tissue infarction
- Rebleeding
- Meningeal irritation
- Hydrocephalus

Signs and Symptoms

Occasionally, rupture of a cerebral aneurysm causes premonitory symptoms that last several days, such as headache, nuchal rigidity, stiff back and legs, and intermittent nausea. Usually, however, onset is abrupt and without warning, causing a sudden severe headache, nausea, vomiting and, depending on the severity and location of bleeding, altered consciousness (including deep coma).

Bleeding causes meningeal irritation, resulting in nuchal rigidity, back and leg pain, fever, restlessness, irritability, occasional seizures, and blurred vision. Bleeding into the brain tissues causes hemiparesis, hemisensory defects, dysphagia, and visual defects. If the aneurysm is near the internal carotid artery, it compresses the oculomotor nerve and causes diplopia, ptosis, dilated pupil, and inability to rotate the eye.

The severity of symptoms varies considerably from patient to patient, depending on the site and amount of bleeding. To better describe their conditions, patients with ruptured cerebral

aneurysms are grouped as follows:

- *Grade I (minimal bleed):* Patient is alert with no neurologic deficit; he or she may have a slight headache and nuchal rigidity.
- *Grade II (mild bleed):* Patient is alert, with a mild to severe headache, nuchal rigidity and, possibly, third-nerve palsy.
- *Grade III (moderate bleed):* Patient is confused or drowsy, with nuchal rigidity and, possibly, a mild focal deficit.
- *Grade IV (severe bleed):* Patient is stuporous, with nuchal rigidity and, possibly, mild to severe hemiparesis.
- *Grade V (moribund; commonly fatal):* If nonfatal, patient is in deep coma or decerebrate.

Generally, cerebral aneurysm poses three major threats:

- *Death from increased ICP:* Increased ICP may push the brain downward, impair brainstem function, and cut off blood supply to the part of the brain that supports vital functions.
- *Rebleed:* Generally, after the initial bleeding episode, a clot forms and seals the rupture, which reinforces the wall of the aneurysm for 7 to 10 days. However, after the seventh day, fibrinolysis begins to dissolve the clot and increases the risk of rebleeding. Signs and symptoms are similar to those accompanying the initial hemorrhage. Rebleeds during the first 24 hours after initial hemorrhage aren't uncommon, and they contribute to cerebral aneurysm's high mortality.
- *Vasospasm:* Why this occurs isn't clearly understood. Usually, vasospasm occurs in blood vessels adjacent to the cerebral aneurysm, but it may extend to major vessels of the brain, causing ischemia and altered brain function.
- *Risk of vasospasm can be predicted by use of the Fisher Grading scale.*

Fisher grade	Blood on CT	Risk of vasospasm
II	Diffuse or vertical layer of subarachnoid blood < 1 mm thick	Low (range 0% to 25%)
III	Localized clot and/or vertical layer within the subarachnoid space > 1 mm thick	Low to high (range 23% to 96%)
IV	ICH or IVH with diffuse or no SAH	Low to moderate (range 0% to 35%)

ICH, intracranial hemorrhage; IVH, intraventricular hemorrhage; SAH, subarachnoid hemorrhage

Other complications of cerebral aneurysm include pulmonary embolism (a possible adverse effect of deep vein thrombosis or aneurysm treatment) and acute hydrocephalus, occurring as CSF accumulates in the cranial cavity because of blockage by blood or adhesions.

Diagnosis

Diagnosis of cerebral aneurysm is based on the patient history and a neurologic examination; CT scan, which reveals subarachnoid or ventricular blood; or MRI, which can identify a cerebral aneurysm as a flow void.

Cerebral angiography remains the procedure of choice for diagnosing cerebral aneurysm. A CT angiography is less invasive. Lumbar puncture may be used to identify blood in CSF if other studies are negative and the patient has no signs of increased ICP. Lumbar puncture should be performed if no contraindication is present and you strongly suspect a bleed, because imaging

studies may miss a bleed.

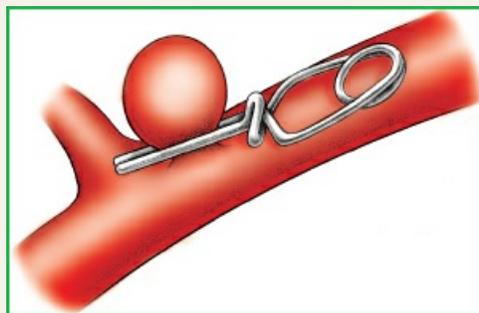
Other baseline laboratory studies include complete blood count (CBC), urinalysis, arterial blood gas (ABG) analysis, coagulation studies, serum osmolality, and electrolyte and glucose levels.

Treatment

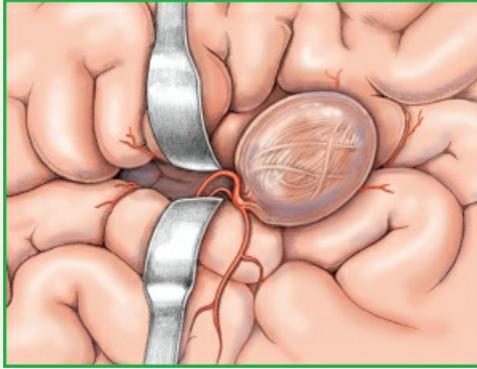
Coil embolization or clipping of the aneurysm aims to reduce the risk of bleeding, rebleeding after subarachnoid hemorrhage, and cerebral infarction. (See *Repair of cerebral aneurysm,* page 162.) Both methods have advantages and disadvantages. Reinforcing the aneurysm with wrapping when the vessel is easily accessible is an alternative in specific situations. Vasospasm, which previously had been the source of morbidity and mortality associated with successful surgical intervention, has shown therapeutic promise with transluminal balloon intraarterial nimodipine, nicardipine, verapamil, and milrinone. Newer drugs in clinical trials (fasudil hydrochloride and colforsin daropate) are still under investigation.

Repair of Cerebral Aneurysm

Clipping a Cerebral Aneurysm

The clip, which is made of materials that won't affect metal detectors and will not rust, is placed at the base of the aneurysm to stop the blood supply. The clip remains in place permanently.


Coil Embolization

In coil embolization, soft platinum coils are inserted into the aneurysm through the femoral artery. Usually five to six coils are needed to fill the aneurysm. The goal is to prevent blood flow into the aneurysm sac by filling the aneurysm with coils and thrombus.


When surgical correction is delayed or hazardous because of aneurysmal location or fitness of the patient, treatment includes:

- careful control of blood pressure (Calcium antagonists are preferred.)
- bed rest and avoidance of head-down position
- avoidance of stimulants, including caffeine and catecholamines
- avoidance of platelet inhibitors such as aspirin
- corticosteroids (sometimes used to decrease headache that results from meningeal irritation from the blood products but studies are not conclusive)
- anticonvulsants
- sedatives.

After surgical repair, the patient's condition depends on the extent of damage from the initial bleed and the success of treatment for any resulting complications. Surgery can't improve the patient's neurologic condition unless it removes a hematoma or reduces the compression effect.

Special Considerations

- An accurate neurologic assessment, good patient care, patient and family teaching, and psychological support can speed recovery and reduce complications.
- During initial treatment after hemorrhage, establish and maintain a patent airway if the patient needs supplementary oxygen. Position the patient to promote pulmonary drainage and prevent upper airway obstruction. If he or she is intubated, administering 100% oxygen before suctioning to remove secretions will prevent hypoxia and vasodilation from carbon dioxide accumulation. Suction no longer than 20 seconds to avoid increased ICP. Give frequent nose and mouth care.
- Impose aneurysm precautions to minimize the risk of rebleed and to avoid increased ICP. Such precautions include bed rest in a quiet, darkened room (keep the head of the bed flat or under 30 degrees, as ordered); limited visitors; avoiding strenuous physical activity and straining with bowel movements; and restricted fluid intake. Be sure to explain why these restrictive measures are necessary.

Preventive measures and good patient care can minimize other complications:

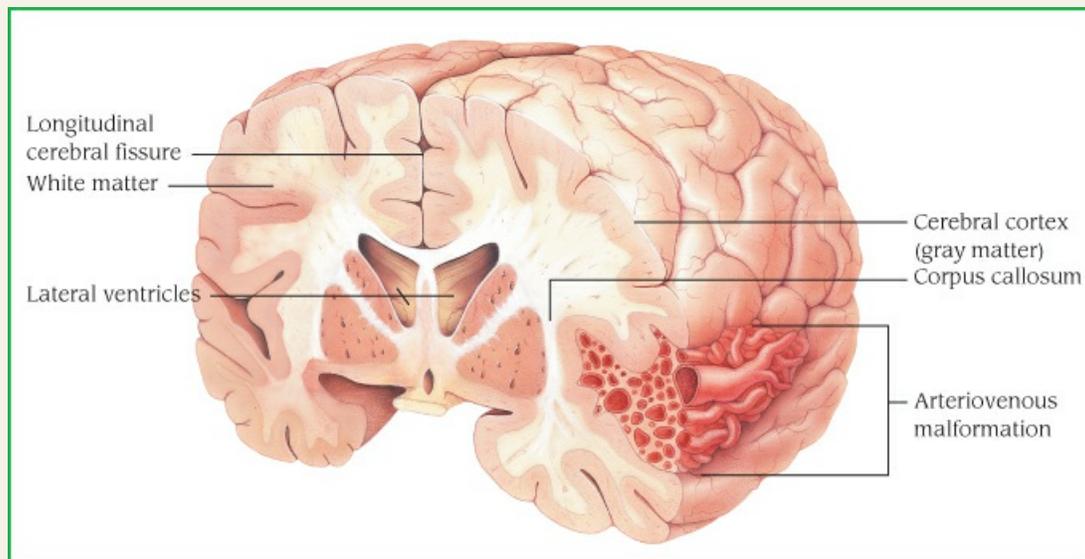
- Turn the patient often. Encourage occasional deep breathing and leg movement. Warn the patient to avoid all unnecessary physical activity. Assist with active range-of-motion exercises; if the patient is paralyzed, perform regular passive range-of-motion exercises.

- Monitor ABG levels, LOC, and vital signs often, and accurately measure intake and output. Avoid taking temperature rectally because vagus nerve stimulation may cause cardiac arrest.
- Watch for these danger signals, which may indicate an enlarging aneurysm, rebleeding, intracranial clot, vasospasm, or other complication: decreased LOC, unilateral enlarged pupil, onset or worsening of hemiparesis or motor deficit, increased blood pressure, slowed pulse, worsening of headache or sudden onset of a headache, renewed or worsened nuchal rigidity, and renewed or persistent vomiting. Intermittent signs such as restlessness, extremity weakness, and speech alterations can also indicate increasing ICP.
- Give fluids as ordered, and monitor I.V. infusions to avoid increased ICP.
- If the patient has facial weakness, assess the gag reflex and assist during meals, placing food in the unaffected side of the mouth. If the patient can't swallow, insert a nasogastric tube as ordered, and give all tube feedings slowly. Prevent skin breakdown by taping the tube so it doesn't press against the nostril. If the patient can eat, provide a high-fiber diet to prevent straining at stool, which can increase ICP. Obtain an order for a stool softener, such as dioctyl sodium sulfosuccinate, or a mild laxative, and administer as ordered. Don't force fluids. Implement a bowel program on the basis of previous habits. If the patient is receiving steroids, check the stool for blood.
- With third or facial nerve palsy, administer artificial tears or ointment to the affected eye, and tape the eye shut at night to prevent corneal damage.
- To minimize stress, encourage relaxation techniques. If possible, avoid using restraints because these can cause agitation and raise ICP.
- Administer antihypertensives as indicated. Carefully monitor blood pressure and immediately report *any* significant change, but especially a rise in systolic pressure.
- Prevent deep vein thrombosis by applying antiembolism stockings or sequential compression sleeves.
- If the patient can't speak, establish a simple means of communication, or use cards or a notepad. Try to limit conversation to topics that won't frustrate the patient. Encourage the family to speak in a normal tone, even if the patient doesn't seem to respond.
- Provide emotional support, and include the patient's family in the care as much as possible. Encourage family members to adopt a realistic attitude, but don't discourage hope.
- Before discharge, make a referral to a visiting nurse or a rehabilitation center when necessary.

ARTERIOVENOUS MALFORMATIONS

Cerebral AVM is a disorder of the blood vessels consisting of an abnormal connection between the arteries and the veins in the brain. It's a congenital disorder commonly resulting in tangled masses of thin-walled, dilated blood vessels between arteries and veins that aren't connected by capillaries. AVM primarily occurs in the posterior portion of the cerebral hemispheres. (See *Where a cerebral AVM commonly occurs,* page 164.) Adequate perfusion of brain tissue is prevented because of abnormal channels between the arterial and venous systems that allow mixing of oxygenated and unoxygenated blood. AVMs range in size from a few millimeters to large malformations that extend from the cerebral cortex to the ventricles. Patients typically present with multiple AVMs.

Where a Cerebral AVM Commonly Occurs

A cerebral arteriovenous malformation (AVM) is a disorder of blood vessels in which there is an abnormal connection between the arteries and the veins. It is a congenital disorder. Cerebral AVMs commonly occur in the posterior portion of the cerebral hemisphere.


Complications of AVM include development of aneurysm and subsequent rupture, hemorrhage (intracerebral, subarachnoid, or subdural, depending on the location of the AVM), and hydrocephalus.

Causes and Incidence

Although some AVMs occur as a result of penetrating injuries such as trauma, most are present at birth. However, symptoms typically don't occur until between ages 10 and 20. Very large AVMs may short-circuit blood flow enough to cause cardiac decompensation, in which the heart can't pump enough blood to compensate for arteriovenous shunting in the brain. This typically occurs in infants and young children.

The vessels of an AVM are very thin and one or more arteries feed into it, causing it to appear dilated and tortuous. Typically, high-pressured arterial flow moves into the venous system through the connecting channels to increase venous pressure, engorging and dilating the venous structures. If the AVM is large enough, the shunting can deprive the surrounding tissue of adequate blood flow. Thin-walled vessels may ooze small amounts of blood—they may even rupture—causing hemorrhage into the brain or subarachnoid space.

Cerebral AVMs occur in approximately 3 of 10,000 people. Although the lesion is present at birth, symptoms may occur at any time. Two thirds of cases occur before age 40. Evidence suggests that AVMs run in families. Males and females are affected equally.

Pathophysiology

AVMs lack the typical structural characteristics of blood vessels. The vessel walls are thin, can have several arteries that feed into it causing it to dilate. The arterial flow moves directly into the venous channel without the normal channel that allows for the dissipation of pressure. This

causes the venous side to dilate and it can act like a mass lesion causing pressure on the brain structures.

Complications

- Aneurysm and subsequent rupture
- Intracerebral, subarachnoid, or subdural hemorrhage
- Hydrocephalus

Signs and Symptoms

An AVM may be asymptomatic until complications occur; these may include rupture and a resulting sudden bleed in the brain, known as a hemorrhagic stroke. AVMs vary in size and location within the brain. Systolic bruit may be auscultated over the carotid artery, mastoid process, or orbit on examination.

Symptoms that occur before an AVM rupture are related to smaller and slower bleeding from the abnormal vessels, which are usually fragile because their structure is abnormal or if the AVM is larger symptoms are associated with mass effect on the surrounding brain.

In more than half of patients with AVM, hemorrhage from the malformation is the first symptom. Depending on the location and the severity of the bleed, the hemorrhage can be profoundly disabling or fatal. The risk of bleeding from an AVM is approximately 2% to 4% per year.

The first symptoms often include headache, seizure, or other sudden neurologic problems, such as vision problems, weakness, inability to move a limb or a side of the body, lack of sensation in part of the body, or abnormal sensations, such as ringing and numbness. Symptoms are the same as for stroke. The individual with an AVM may complain of chronic mild headache, a sudden and severe headache, or a localized or general headache. The headache may resemble migraine and vomiting may occur. Seizures may result from focal neurologic deficits (depending on the location of the AVM) resulting from compression and diminished perfusion. Symptoms of intracranial (intracerebral, subarachnoid, or subdural) hemorrhage result. Muscle weakness and decreased sensation can occur in any part of the body. Mental status change can occur where the individual appears sleepy, stuporous, lethargic, confused, disoriented, or irritable. Additional symptoms may include stiff neck, speech or sense of smell impairment, dysfunctional movement, fainting, facial paralysis, eyelid drooping, tinnitus, dizziness, and decreased LOC.

Intracerebral or subarachnoid hemorrhages are the most common first symptoms of cerebral AVM. In some cases, symptoms may also occur because of lack of blood flow to an area of the brain (ischemia), compression or distortion of brain tissue by large AVMs, or abnormal brain development in the area of the malformation. Progressive loss of nerve cells in the brain may occur, caused by mechanical (pressure) and ischemic (lack of blood supply) factors.

Diagnosis

Tests used to diagnose AVM include head CT scan, cranial MRI, and MR angiography. An EEG may be performed if symptoms include seizures, but this test isn't diagnostic of the specific area of the lesion.

Cerebral arteriogram confirms the presence of AVMs and evaluates blood flow. Doppler ultrasonography of cerebrovascular system indicates abnormal, turbulent blood flow.

Treatment

General support measures include aneurysm precautions to prevent possible rupture. This involves placing the patient on bed rest or with limited activity and maintaining a quiet atmosphere. Analgesics may be given for headache, and sedatives may be given to help calm the patient and prevent rupture. Stool softeners may be given to prevent straining at stool, which increases ICP.

Hemorrhage from an AVM is a medical emergency requiring immediate hospitalization. The goal of treatment is to prevent further complications by limiting bleeding, controlling seizures, and controlling ICP. Surgery for correction may include block dissection, laser, or ligation to repair the communicating channels and remove the feeding vessels. In most cases this is performed in a delayed fashion to give the patient the opportunity to recover from the hemorrhage. Embolization or radiation therapy may be done before surgery to close the communicating channels and feeder vessels, thereby reducing blood flow to the AVM or may be done as the treatment of choice in difficult to reach malformations. Open brain surgery, endovascular treatment, and radiosurgery may be used separately or in any combination, depending on the physician and the patient's individual situation. Surgery is dependent on the accessibility and size of the lesion and the patient's status. Open brain surgery involves the actual removal of the malformation in the brain through an opening made in the skull. This surgery is particularly risky because the surgery itself may cause the AVM to bleed uncontrollably.

Embolization (injecting a glue-like substance into the abnormal vessels to stop aberrant blood flow into the AVM) may be an alternative if surgery isn't feasible because of the size or location of the lesion. Stereotactic radiosurgery may also be an alternative for patients with inoperable AVMs. It's particularly useful for small, deep lesions, which are difficult to remove by surgery.

Anticonvulsant medications such as phenytoin are usually prescribed if seizures occur.

Special Considerations

- Monitor vital signs and adjust medications to control hypertension.
- Monitor neurologic status.
- Monitor for seizure activity and institute seizure precautions.
- Maintain a quiet atmosphere and provide relaxation techniques.
- Discuss the importance of reporting any signs of intracranial bleeding immediately (sudden severe headache, vision changes, decreased movement in extremities, and change in LOC).
- Refer to social service for support services if neurologic deficits have occurred from a ruptured AVM.

Paroxysmal Disorders

HEADACHE

The most common patient complaint, headache usually occurs as a symptom of an underlying disorder. Ninety percent of all headaches are vascular, muscle contraction, or a combination; 10% are due to underlying intracranial, systemic, or psychological disorders. Migraine headaches, probably the most intensively studied, are throbbing, vascular headaches that usually begin to appear in childhood or adolescence and recur throughout adulthood.

Causes and Incidence

Most chronic headaches result from tension (muscle contraction), which may be caused by

emotional stress, fatigue, menstruation, or environmental stimuli (noise, crowds, or bright lights). Other possible causes include glaucoma; inflammation of the eyes or mucosa of the nasal or paranasal sinuses; diseases of the scalp, teeth, extracranial arteries, or external or middle ear; muscle spasms of the face, neck, or shoulders; and cervical arthritis. In addition, headaches may be caused by vasodilators (nitrates, alcohol, and histamine), systemic disease, hypoxia, hypertension, head trauma and tumor, intracranial bleeding, abscess, or aneurysm.

The cause of migraine headache is unknown, but it's associated with constriction and dilation of intracranial and extracranial arteries. Certain biochemical abnormalities are thought to occur during a migraine attack. These include local leakage of a vasodilator polypeptide called *neurokinin* through the dilated arteries and a decrease in the plasma level of serotonin.

Headache pain may emanate from the pain-sensitive structures of the skin, scalp, muscles, arteries, and veins; cranial nerves V, VII, IX, and X; or cervical nerves 1, 2, and 3. Intracranial mechanisms of headaches include traction or displacement of arteries, venous sinuses, or venous tributaries and inflammation or direct pressure on the cranial nerves with afferent pain fibers.

Affecting up to 10% of Americans, headaches are more common in females and have a strong familial incidence. Drops in estrogen level may precipitate migraine headaches.

Pathophysiology

The pathophysiology of headache varies with the type of headache—migraine is thought to be the result of vascular alterations, dilation of the intracranial blood vessels which allow the leakage of neurokinin. In tension headaches, there is a central stimulus of the trigeminal nerve that involves a hypersensitivity of pain fibers. There is also a peripheral sensitization of the myofascial sensory nerves that contribute to the pain. Headaches associated with intracranial lesions such as hematomas or tumors are the result of increased ICP.

Complications

- Worsening of preexisting hypertension
- Photophobia
- Emotional lability
- Motor weakness

Signs and Symptoms

Initially, migraine headaches usually produce unilateral, pulsating pain, which later becomes more generalized. They're commonly preceded by a scintillating scotoma, hemianopsia, unilateral paresthesia, or speech disorders. The patient may experience irritability, anorexia, nausea, vomiting, and photophobia. (See *Clinical features of migraine headaches*, pages 166 and 167.)

Clinical Features of Migraine Headaches

Type	*Signs and symptoms*
Common migraine (most prevalent) Usually occurs on weekends and holidays	• Prodromal symptoms (fatigue, nausea, vomiting, and fluid imbalance) precede headache by about 1 day. • Sensitivity to light and noise (most prominent feature) • Headache pain (unilateral or bilateral, aching or throbbing)
Classic migraine	• Prodromal symptoms include visual disturbances, such as zigzag lines

Usually occurs in compulsive personalities and within families	and bright lights (most common), sensory disturbances (tingling of face, lips, and hands), or motor disturbances (staggering gait). ◆ Recurrent and periodic headaches
Hemiplegic and ophthalmoplegic migraine (rare) Usually occurs in young adults	◆ Severe, unilateral pain ◆ Extraocular muscle palsies (involving third cranial nerve) and ptosis ◆ With repeated headaches, possible permanent third cranial nerve injury ◆ In hemiplegic migraine, neurologic deficits (hemiparesis, hemiplegia) may persist after the headache subsides.
Basilar artery migraine Occurs in young women before their menstrual periods	◆ Prodromal symptoms usually include partial vision loss followed by vertigo, ataxia, dysarthria, tinnitus and, sometimes, tingling of the fingers and toes, lasting from several minutes to almost an hour. ◆ Headache pain, severe occipital throbbing, vomiting
Cluster headaches Occur in men more commonly than in women and occur at all ages, but more commonly in adolescents and middle-aged people	◆ Episodic type (more common) and involves one to three short-lived attacks of periorbital pain per day over a 4- to 8-week period followed by a pain-free interval averaging 1 year. Chronic type occurs after an episodic pattern is established. ◆ Unilateral pain occurs without warning, reaching a crescendo within 5 minutes, and is described as excruciating and deep, with attacks lasting from 30 minutes to 2 hours. ◆ Associated symptoms may include tearing, reddening of the eye, nasal stuffiness, lid ptosis, and nausea.

Both muscle contraction and traction-inflammatory vascular headaches produce a dull, persistent ache; tender spots on the head and neck; and a feeling of tightness around the head, with a characteristic "hatband" distribution. The pain is usually severe and unrelenting. If caused by intracranial bleeding, these headaches may result in mental changes and neurologic deficits, such as paresthesia and muscle weakness; narcotics may fail to relieve pain in these cases. If caused by a tumor, pain is most severe when the patient awakens.

Diagnosis

Diagnosis requires a history of recurrent headaches and physical examination of the head and neck. Such examination includes percussion, auscultation for bruits, inspection for signs of infection, and palpation for defects, crepitus, or tender spots (especially after trauma). Firm diagnosis also requires a complete neurologic examination, assessment for other systemic diseases—such as hypertension—and a psychosocial evaluation, when such factors are suspected.

Diagnostic tests include cervical spine and sinus X-rays, CT scan—performed before lumbar puncture to rule out increased ICP—or MRI. A lumbar puncture isn't done if there's evidence of increased ICP or if a brain tumor is suspected because rapidly reducing pressure by removing spinal fluid can cause brain herniation.

Treatment

Depending on the type of headache, analgesics—ranging from aspirin to codeine or ketorolac—may provide symptomatic relief. Other measures include identification and elimination of causative factors and, possibly, psychotherapy for headaches caused by emotional stress. Chronic tension headaches may also respond to muscle relaxants. A new preventive treatment for migraine has just been released. Erenumab (Aimovig) is a human monoclonal antibody that blocks a protein fragment CGRP that instigates and perpetuates migraine. It is the first drug of its kind to specifically target migraine prevention.

For migraine headaches, ergotamine alone or with caffeine may be an effective treatment. The Food and Drug Administration allows labeling of various analgesic preparations that include caffeine to state that they're for the treatment of migraine headaches. Remember that these medications can't be taken by pregnant women because they stimulate uterine contractions. These drugs and others, such as metoclopramide or nonsteroidal anti-inflammatory drugs, work best when taken early in the course of an attack. If nausea and vomiting make oral administration impossible, drugs may be given as rectal suppositories.

Drugs in the class of sumatriptan are considered by many clinicians to be the drug of choice for acute migraine attacks or cluster headaches. Drugs that can help prevent migraine headaches include antidepressants (such as nortriptyline or fluoxetine), beta-adrenergic blockers (propranolol), and calcium channel blockers (verapamil). Corticosteroids provide short-term relief for some patients with cluster headaches.

Special Considerations

- Headaches seldom require hospitalization unless caused by a serious disorder. If that's the case, direct your care to the underlying problem.
- Obtain a complete patient history: duration and location of the headache; time of day it usually begins; nature of the pain; concurrence with other symptoms such as blurred vision; precipitating factors, such as tension, menstruation, loud noises, menopause, or alcohol; medications taken such as oral contraceptives; or prolonged fasting. Exacerbating factors can also be assessed through ongoing observation of the patient's personality, habits, activities of daily living, family relationships, coping mechanisms, and relaxation activities.
- Using the history as a guide, help the patient avoid exacerbating factors. Advise the patient to lie down in a dark, quiet room during an attack and to place ice packs on the forehead or a cold cloth over the eyes.
- Instruct the patient to take the prescribed medication at the onset of migraine symptoms, to prevent dehydration by drinking plenty of fluids after nausea and vomiting subside, and to use other headache relief measures.
- The patient with a migraine headache usually needs to be hospitalized only if nausea and vomiting are severe enough to induce dehydration and possible shock.
- Avoid repeated use of narcotics—overuse of pain medication, especially narcotics, can produce rebound headache.

PREVENTION

- *get adequate sleep*
- *eat a well-balanced diet and drink plenty of water*
- *do upper-body stretching exercises*
- *quit smoking*
- *learn relaxation techniques such as yoga, medication, and deep breathing*
- *avoid known causative triggers.*

SEIZURE DISORDER

Seizure disorder, also called *epilepsy*, is a condition of the brain marked by a susceptibility to recurrent seizures—paroxysmal events associated with abnormal electrical discharges of neurons in the brain.

Causes and Incidence

In about half the cases of seizure disorder, the cause is unknown. However, some possible causes of seizure disorder include:

- birth trauma (inadequate oxygen supply to the brain, blood incompatibility, or hemorrhage)
- perinatal infection
- anoxia (after respiratory or cardiac arrest)
- infectious diseases (meningitis, encephalitis, or brain abscess)
- ingestion of toxins (mercury, lead, or carbon monoxide)
- tumors of the brain
- inherited disorders or degenerative disease, such as phenylketonuria or tuberous sclerosis
- head injury or trauma
- metabolic disorders, such as hypoglycemia or hypoparathyroidism
- stroke (hemorrhage, thrombosis, or embolism).

Alcohol withdrawal can cause nonepileptic seizures.

Seizure disorder affects 1% to 2% of the population. However, 80% of patients have good seizure control if they strictly adhere to the prescribed treatment regimen.

Pathophysiology

Seizures are the result of abnormal synaptic transmission, an imbalance in the brain neurotransmitters or the development of abnormal nerve connections after an injury. The result is a group of hypersensitive neurons that exhibit paroxysmal depolarization. In the tonic phase of a seizure, there is excitation of subcortical, thalamic, and brainstem areas, which results in loss of consciousness. The clonic phase of the seizure is the result of inhibitory neurons in the cortex, subthalamus, and basal ganglia reacting to the cortical excitation.

During the seizure oxygen is consumed at a high rate as is glucose, cerebral blood flow increases, and lactate increases in the cerebral tissues.

Complications

- Anoxia (during a seizure)
- Fall injuries

Signs and Symptoms

The hallmarks of seizure disorder are recurring seizures, which can be classified as partial or generalized (some patients may be affected by more than one type).

Partial seizures arise from a localized area of the brain, causing specific symptoms. In some patients, partial seizure activity may spread to the entire brain, causing a generalized seizure. Partial seizures include simple partial (jacksonian) and complex partial seizures (psychomotor or temporal lobe).

A simple partial motor-type seizure begins as a localized motor seizure characterized by a spread of abnormal activity to adjacent areas of the brain. It typically produces stiffening or jerking in one extremity, accompanied by a tingling sensation in the same area. For example, it may start in the thumb and spread to the entire hand and arm. The patient seldom loses consciousness, although the seizure may progress to a generalized seizure.

A simple partial sensory-type seizure involves perceptual distortion, which can include hallucinations.

The symptoms of a complex partial seizure vary but usually include purposeless behavior. The patient experiences an aura immediately before the seizure. An aura represents the beginning of abnormal electrical discharges within a focal area of the brain and may include a pungent smell, gastrointestinal (GI) distress (nausea or indigestion), a rising or sinking feeling in the stomach, a dreamy feeling, an unusual taste, or a visual disturbance. Overt signs of a complex partial seizure include a glassy stare, picking at one's clothes, aimless wandering, lip-smacking or chewing motions, and unintelligible speech; these signs may last for just a few seconds or as long as 20 minutes. Mental confusion may last several minutes after the seizure; as a result, an observer may mistakenly suspect intoxication with alcohol or drugs or psychosis.

Generalized seizures, as the term suggests, cause a generalized electrical abnormality within the brain and include several distinct types:

- Absence (*petit mal*) seizures occur most commonly in children, although they may affect adults as well. They usually begin with a brief change in LOC, indicated by blinking or rolling of the eyes, a blank stare, and slight mouth movements. There's little or no tonic–clonic movement. The patient retains posture and continues preseizure activity without difficulty. Typically, each seizure lasts from 1 to 10 seconds. If not properly treated, seizures can recur as often as 100 times/day. An absence seizure may progress to generalized tonic–clonic seizures.
- A myoclonic (*bilateral massive epileptic myoclonus*) seizure is characterized by brief, involuntary muscular jerks of the body or extremities, which may occur in a rhythmic fashion and may precede generalized tonic–clonic seizures by months or years.
- A generalized tonic–clonic (*grand mal*) seizure typically begins with a loud cry, precipitated by air rushing from the lungs through the vocal cords. The patient then falls to the ground, losing consciousness. The body stiffens (tonic phase) and then alternates between episodes of muscular spasm and relaxation (clonic phase). Tongue-biting, incontinence, labored breathing, apnea, and subsequent cyanosis may also occur. The seizure stops in 2 to 5 minutes, when abnormal electrical conduction of the neurons is completed. The patient then regains consciousness but is somewhat confused and may have difficulty talking. If the patient can talk, they may complain of drowsiness, fatigue, headache, muscle soreness, and arm or leg weakness. The patient may fall into deep sleep after the seizure. These seizures may start as facial seizures and spread to become generalized.

An akinetic seizure is characterized by a general loss of postural tone (the patient falls in a flaccid state) and a temporary loss of consciousness. It occurs in young children and is sometimes called a *drop attack* because it causes the child to fall.

Status epilepticus is a continuous seizure state that can occur in all seizure types. The most life-threatening example is generalized tonic–clonic status epilepticus, a continuous generalized tonic–clonic seizure without intervening return of consciousness. Status epilepticus is accompanied by respiratory distress. It can result from abrupt withdrawal of anticonvulsant medications, hypoxic encephalopathy, acute head trauma, metabolic encephalopathy, or septicemia secondary to encephalitis or meningitis.

Diagnosis

Clinically, the diagnosis of seizure disorder is based on the occurrence of one or more seizures and proof or the assumption that the condition that led to them is still present.

Diagnostic information is obtained from the patient's history and description of seizure

activity and from family history, physical and neurologic examinations, and CT scan or MRI. These scans offer density readings of the brain and may indicate abnormalities in internal structures. Paroxysmal abnormalities on the EEG confirm the diagnosis by providing evidence of the continuing tendency to have seizures. A negative EEG doesn't rule out seizure disorder because the paroxysmal abnormalities occur intermittently. Other tests may include serum glucose and calcium studies, skull X-rays, lumbar puncture, brain scan, and cerebral angiography.

Treatment

Generally, treatment of seizure disorder consists of anticonvulsant therapy to reduce the number of future seizures. The most commonly prescribed drugs include phenytoin, carbamazepine, phenobarbital, gabapentin, primidone, levetiracetam administered individually for generalized tonic–clonic seizures and complex partial seizures. Valproic acid, clonazepam, and ethosuximide are commonly prescribed for absence seizures. Gabapentin and felbamate are also anticonvulsant drugs.

A patient taking anticonvulsant medications requires monitoring for toxic signs: nystagmus, ataxia, lethargy, dizziness, drowsiness, slurred speech, irritability, nausea, and vomiting.

If drug therapy fails, treatment may include surgical removal of a demonstrated focal lesion to attempt to stop seizures. Emergency treatment of status epilepticus usually consists of diazepam (Valium) or lorazepam (Ativan), phenytoin or phenobarbital (Solfoton); dextrose 50% I.V. (when seizures are secondary to hypoglycemia); and thiamine I.V. (in chronic alcoholism or withdrawal).

Special Considerations

A key to support is a true understanding of the nature of seizure disorder and of the misconceptions that surround it.

- Encourage the patient and family to express their feelings about the patient's condition. Answer their questions, and help them cope by dispelling some of the myths about seizure disorder, for example, the myth that seizure disorder is contagious. Assure them that seizure disorder is controllable for most patients who follow a prescribed regimen of medication and that most patients maintain a normal lifestyle.
- Because drug therapy is the treatment of choice for most people with seizure disorder, information about medications is invaluable.
- Stress the need for compliance with the prescribed drug schedule. Reinforce dosage instructions and stress the importance of taking medication regularly, at scheduled times. Caution the patient to monitor the quantity of medication so it does not run out.
- Warn against possible adverse effects—drowsiness, lethargy, hyperactivity, confusion, and visual and sleep disturbances—all of which indicate the need for dosage adjustment. Phenytoin therapy may lead to hyperplasia of the gums, which may be relieved by conscientious oral hygiene. Instruct the patient to report adverse effects immediately.
- When administering phenytoin I.V., use a large vein and monitor vital signs frequently or administer fosphenytoin (Cerebyx), which has fewer vascular side effects. Avoid I.M. administration and mixing with dextrose solutions. Another I.V. alternative is levetiracetam.
- Emphasize the importance of having anticonvulsant blood levels checked at regular intervals, even if the seizures are under control.
- Warn the patient against drinking alcoholic beverages.

◆ Know which social agencies in your community can help epileptic patients. Refer the patient to the Epilepsy Foundation of America for general information and to the state motor vehicle department for information about a driver's license.

The primary goals of the healthcare professional and family members caring for a patient having a seizure are protection from injury, protection from aspiration, and observation of the seizure activity. Generalized tonic–clonic seizures may necessitate first aid. Show the patient's family members how to administer first aid correctly:

◆ Avoid restraining the patient during a seizure. Help the patient to a lying position, loosen any tight clothing, and place something flat and soft, such as a pillow, jacket, or hand, under head. Clear the area of hard objects. *Don't* force anything into the patient's mouth if the teeth are clenched—a tongue blade or spoon could lacerate a mouth and lips or displace teeth, precipitating respiratory distress. However, if the patient's mouth is open, protect the tongue by placing a soft object (such as a folded cloth) between the teeth. Turn the head to provide an open airway. After the seizure subsides, reassure the patient that he or she is all right, orient to time and place, and inform that he or she has had a seizure.

◆ *Don't* restrain the patient during a complex partial seizure. Clear the area of any hard objects. Protect the patient from injury by gently calling his or her name and directing away from the source of danger. After the seizure passes, reassure and tell the patient that he or she has just had a seizure.

Brain and Spinal Cord Disorders

STROKE

A stroke, also called *cerebrovascular accident* or *brain attack,* is a sudden impairment of cerebral circulation in one or more of the blood vessels supplying the brain. A stroke interrupts or diminishes oxygen supply and commonly causes serious damage or necrosis in brain tissues. The sooner circulation returns to normal after a stroke, the better chances are for complete recovery. However, about half of those who survive a stroke remain permanently disabled and experience a recurrence within weeks, months, or years.

Causes and Incidence

A stroke results from obstruction of a blood vessel, typically in extracerebral vessels, but occasionally in intracerebral vessels. Factors that increase the risk of stroke include history of transient ischemic attacks (TIAs), atherosclerosis, hypertension, kidney disease, arrhythmias (specifically atrial fibrillation), electrocardiogram changes, rheumatic heart disease, diabetes mellitus, postural hypotension, cardiac or myocardial enlargement, high serum triglyceride levels, lack of exercise, use of oral contraceptives, cigarette smoking, and a family history of stroke. (See *Transient ischemic attack*, page 171.)

Transient Ischemic Attack

A transient ischemic attack (TIA) is a transient episode of neurologic dysfunction caused by a brain ischemia without acute infarct. It's usually considered a warning sign of an

impending thrombotic stroke. In fact, TIAs have been reported in 50% to 80% of patients who have had a cerebral infarction from such thrombosis. The age of onset varies. Incidence rises dramatically after age 50 and is highest among blacks and men.

Causes

In TIA, microemboli released from a thrombus probably temporarily interrupt blood flow, especially in the small distal branches of the arterial tree in the brain. Small spasms in those arterioles may impair blood flow and also precede TIA. Predisposing factors are the same as for thrombotic strokes. The most distinctive characteristics of TIAs are the transient duration of neurologic deficits and complete return of normal function. The symptoms of TIA easily correlate with the location of the affected artery. These symptoms include double vision, speech deficits (slurring or thickness), unilateral blindness, staggering or uncoordinated gait, unilateral weakness or numbness, falling because of weakness in the legs, and dizziness.

Treatment

During an active TIA, treatment aims to prevent a completed stroke and consists of aspirin or anticoagulants to minimize the risk of thrombosis. After or between attacks, preventive treatment includes carotid endarterectomy or cerebral microvascular bypass.

The major causes of stroke are thrombosis, embolism, and hemorrhage. Thrombosis is the most common cause in middle-aged and elderly people, who have a higher incidence of atherosclerosis, diabetes, and hypertension. Thrombosis causes ischemia in brain tissue supplied by the affected vessel as well as congestion and edema; the latter may produce more clinical effects than thrombosis itself, but these symptoms subside with the edema. Thrombosis may develop while the patient sleeps or shortly after the patient awakens; it can also occur during surgery or after a myocardial infarction. The risk increases with obesity, smoking, or the use of oral contraceptives. Cocaine-induced ischemic stroke is now being seen in younger patients.

Embolism, the second most common cause of stroke, is an occlusion of a blood vessel caused by a fragmented clot, a tumor, fat, bacteria, or air. It can occur at any age, especially among patients with a history of rheumatic heart disease, endocarditis, posttraumatic valvular disease, myocardial fibrillation and other cardiac arrhythmias, or after open heart surgery. It usually develops rapidly—in 10 to 20 seconds—and without warning. When an embolus reaches the cerebral vasculature, it cuts off circulation by lodging in a narrow portion of an artery, most commonly the middle cerebral artery, causing necrosis and edema. (See *Ischemic stroke*, page 172.) If the embolus is septic and infection extends beyond the vessel wall, encephalitis or an abscess may develop.

Ischemic Stroke

The illustrations below show common sites of cardiac thrombosis and the resulting sites of embolism and infarction.

COMMON SITES OF PLAQUE FORMATION, EMBOLISM, AND INFARCTION

Anterior cerebral artery

Middle cerebral artery

Posterior cerebral artery

Anterior inferior cerebellar artery

Posterior inferior cerebellar artery

Basilar artery

Internal carotid artery

Emboli

Vertebral artery

Common carotid artery

COMMON SITES OF CARDIAC THROMBOSIS

Atrial fibrillation
Ball thrombus

Bacterial endocarditis

Mitral valve stenosis

Embolus

Myocardial infarction

Mural thrombus

Hemorrhage, the third most common cause of stroke, may, like embolism, occur suddenly, at any age, and affects more women than men. Hemorrhage results from chronic hypertension or aneurysms, which cause sudden rupture of a cerebral artery, thereby diminishing blood supply to the area served by the artery. In addition, blood accumulates deep within the brain, further compressing neural tissue and causing even greater damage.

Strokes are classified according to their course of progression. A progressive stroke, or stroke-in-evolution (thrombus-in-evolution), begins with a slight neurologic deficit and worsens in a day or two. In a completed stroke, usually embolic in nature, neurologic deficits are maximal at onset.

Stroke is the third most common cause of death in most developed countries today and the most common cause of neurologic disability. It occurs in 1 of 15 deaths in the United States each year.

Pathophysiology

Cerebral infarction occurs when an area of the brain has lost its blood supply. This results in a core of irreversible ischemia and necrosis. The central core is surrounded by a border of ischemic tissue which is still salvageable tissue. The best window of time to preserve the tissue in the

penumbra is within the first 3 hours.

Within 6 to 12 hours the affected areas pale and soften; necrosis, swelling, and mushy disintegration of the infarcted area appears within 48 to 72 hours.

Complications

- Unstable blood pressure
- Fluid imbalances
- Infection
- Sensory impairment
- Altered LOC
- Aspiration
- Pulmonary emboli

Signs and Symptoms

Clinical features of stroke vary with the artery affected (and, consequently, the portion of the brain it supplies), the severity of damage, and the extent of collateral circulation that develops to help the brain compensate for decreased blood supply. If the stroke occurs in the left hemisphere, it produces symptoms on the right side; if in the right hemisphere, symptoms are on the left side. However, a stroke that causes cranial nerve damage produces signs of cranial nerve dysfunction on the same side as the hemorrhage.

Symptoms are usually classified according to the artery affected:

- *Middle cerebral artery:* aphasia, dysphasia, visual field cuts, and hemiparesis on affected side (more severe in the face and arm than in the leg)
- *Carotid artery:* weakness, paralysis, numbness, sensory changes, and visual disturbances on affected side; altered LOC, bruits, headaches, aphasia, and ptosis
- *Vertebrobasilar artery:* weakness on affected side, numbness around lips and mouth, visual field cuts, diplopia, poor coordination, dysphagia, slurred speech, dizziness, amnesia, and ataxia
- *Anterior cerebral artery:* confusion, weakness, and numbness (especially in the leg) on affected side, incontinence, loss of coordination, impaired motor and sensory functions, and personality changes
- *Posterior cerebral arteries:* visual field cuts, sensory impairment, dyslexia, coma, and cortical blindness; typically, paralysis is absent.

Symptoms can also be classified as premonitory, generalized, and focal. Premonitory symptoms, such as drowsiness, dizziness, headache, and mental confusion, are rare. Generalized symptoms, such as headache, vomiting, mental impairment, seizures, coma, nuchal rigidity, fever, and disorientation, are typical. Focal symptoms, such as sensory and reflex changes, reflect the site of hemorrhage or infarct and may worsen.

Diagnosis

Diagnosis of stroke is based on the observation of clinical features, a history of risk factors, and the results of diagnostic tests:

- CT scan shows evidence of hemorrhagic stroke immediately but may not show evidence of thrombotic infarction for 48 to 72 hours.
- MRI may help identify ischemic or infarcted areas and cerebral swelling.

- Electrocardiogram can help diagnose underlying heart disorders.
- Carotid duplex may detect carotid artery stenosis.

Angiography outlines blood vessels and pinpoints occlusion or rupture site.

Other baseline laboratory studies may be done to exclude immune conditions or abnormal clotting that can lead to clot formation.

Treatment

Surgery performed to improve cerebral circulation for patients with thrombotic or embolic stroke includes endarterectomy (removal of atherosclerotic plaques from the inner arterial wall) and microvascular bypass (surgical anastomosis of an extracranial vessel to an intracranial vessel). Angioplasty and stenting can improve arterial circulation to the brain. Mechanical embolectomy/clot removal can be done within 8 hours of onset of symptoms.

Medications useful in stroke include the following:

- Tissue plasminogen activator has been used successfully in clot dissolution when administered within 3 hours of the onset of symptoms. In other circumstances, heparin and warfarin (Coumadin) may be used, as well as aspirin and other antiplatelet drugs.
- Clopidogrel, an antiplatelet drug, may be more effective than aspirin in preventing stroke and reducing the risk of recurrent stroke after therapy has begun.
- Anticonvulsants may be used to treat or prevent seizures.
- Stool softeners may be used to prevent straining, which increases ICP.
- Analgesics may be used to relieve the headache that typically follows hemorrhagic stroke.

Special Considerations

During the acute phase, efforts focus on survival needs and prevention of further complications. Effective care emphasizes continuing neurologic assessment, support of respiration, continuous monitoring of vital signs, careful positioning to prevent aspiration and contractures, management of GI problems, and careful monitoring of fluid, electrolyte, and nutritional status. Patient care must also include measures to prevent complications such as infection.

- Maintain a patent airway and oxygenation. Loosen constricting clothes. Watch for ballooning of the cheek with respiration. The side that balloons is the side affected by the stroke. If the patient is unconscious, it is possible that he or she could aspirate saliva, so keep the patient in a lateral position to allow secretions to drain naturally or suction secretions, as needed. Insert an artificial airway, and start mechanical ventilation or supplemental oxygen, if necessary.
- Check vital signs and neurologic status, record observations, and report any significant changes to the physician. Monitor blood pressure, LOC, pupillary changes, motor function (voluntary and involuntary movements), sensory function, speech, skin color, temperature, signs of increased ICP, and nuchal rigidity or flaccidity. Remember, if stroke is impending, blood pressure rises suddenly, pulse is rapid and bounding, and the patient may complain of a headache. Also, watch for signs of pulmonary emboli, such as chest pains, shortness of breath, dusky color, tachycardia, fever, and changed sensorium. If the patient is unresponsive, monitor the blood gases often and alert the physician to increased partial pressure of carbon dioxide or decreased partial pressure of oxygen.
- Maintain fluid and electrolyte balance. If the patient can take liquids orally, offer them as often as fluid limitations permit. Administer I.V. fluids as ordered; never give too much too fast because this can increase ICP. Offer the urinal or bedpan every 2 hours. If the patient is

incontinent, he or she may need an indwelling urinary catheter, but this should be avoided, if possible, because of the risk of infection.

- Ensure adequate nutrition. Check for gag reflex before offering small oral feedings of semisolid foods. Place the food tray within the patient's visual field because loss of peripheral vision is common. If oral feedings aren't possible, insert a nasogastric tube.
- Manage GI problems. Be alert to signs that the patient is straining at elimination because this increases ICP. Modify diet, administer stool softeners, as indicated, and give laxatives, if necessary. If the patient vomits (usually during the first few days), keep positioned on the side to prevent aspiration.
- Provide careful mouth care. Clean and irrigate the patient's mouth to remove food particles. Care for the dentures as needed.
- Provide meticulous eye care. Remove secretions with a cotton ball and sterile normal saline solution. Instill eye drops as ordered. Patch the patient's affected eye if the patient can't close the lid.
- Position the patient and align the extremities correctly. Use splints to prevent foot drop and contracture, use convoluted foam, flotation, or pulsating mattresses, or sheepskin, to prevent pressure ulcers. To prevent pneumonia, turn the patient at least every 2 hours. Elevate the affected hand to control dependent edema, and place it in a functional position. Mobilize the patient as soon as hemodynamic stability is achieved.
- Assist the patient with exercise. Perform range-of-motion exercises for both the affected and unaffected sides. Teach and encourage the patient to use the unaffected side to exercise the affected side.
- Give medications as ordered, and watch for and report adverse effects.
- Establish and maintain communication with the patient. If the patient is aphasic, set up a simple method of communicating basic needs. Then, remember to phrase your questions so the patient will be able to answer using this system. Repeat yourself quietly and calmly, and use gestures if necessary to help the patient understand. Even an unresponsive patient may be able to hear, so don't say anything in their presence you wouldn't want the patient to hear and remember.
- Provide psychological support. Set realistic short-term goals. Involve the patient's family in care when possible, and explain the deficits and strengths.
- If the patient has a visual field deficit, make sure caregivers and family members approach the patient from his visually intact side.
- For a patient who has had a stroke, start rehabilitation at admission. The amount of teaching you'll have to do depends on the extent of neurologic deficit.
- If necessary, teach the patient to comb hair, dress, and wash. With the aid of a physical therapist and an occupational therapist, obtain appliances, such as walking frames, hand bars by the toilet, and ramps, as needed. The patient may fail to recognize that they have a paralyzed side (called *unilateral neglect*) and must be taught to inspect that side of the body for injury and to protect it from harm. If speech therapy is indicated, encourage the patient to begin as soon as possible and to follow through with the speech pathologist's suggestions. To reinforce teaching, involve the patient's family in all aspects of rehabilitation. With their cooperation and support, devise a realistic discharge plan, and let them help decide when the patient can return home.
- Before discharge, warn the patient or family to report any premonitory signs of a stroke, such as severe headache, drowsiness, confusion, and dizziness. Emphasize the importance of

regular follow-up visits.

- If aspirin has been prescribed to minimize the risk of embolic stroke, tell the patient to watch for possible GI bleeding. Make sure the patient and family realize that acetaminophen isn't a substitute for aspirin.

To help prevent stroke:

- Stress the need to control diseases, such as diabetes or hypertension.
- Teach all patients (especially those at high risk) the importance of following a low-cholesterol, low-salt diet; watching their weight; increasing activity; avoiding smoking and prolonged bed rest; and minimizing stress. (See *Preventing stroke,* page 175.)

PREVENTION
PREVENTING STROKE

Lifestyle modifications can help prevent heart attack and stroke. The American Heart Association recommends the following:

Healthy Diet

Give patients the following advice:

- Eat five or more servings of fruit and vegetables daily.
- Eat six or more servings a day of grain products including whole grains.
- Eat fish at least twice a week, especially mackerel, lake trout, herring, sardines, albacore tuna, and salmon.
- Include fat-free and low-fat milk products, beans, lean meats, and skinless poultry.
- Choose fats and oils with 2 g or less of saturated fat per serving (1 tablespoon).
- Limit your intake of foods high in calories or low in protein, such as carbonated beverages, high-sugar foods, and candy.
- Eat less than 6 g of salt per day (1 teaspoon).
- Limit foods high in saturated fat, trans fat, or cholesterol, such as whole milk, fatty meats, tropical oils, and partially hydrogenated vegetable oils.

Exercise

Regular physical activity is defined by the American Heart Association as moderate to vigorous exercise 30 minutes a day on most or all days of the week. A lack of physical activity can lead to obesity and increase the risk of hypertension, heart attack, and stroke.

Smoking Cessation

Even smoking filtered and light or ultralight cigarettes can lead to atherosclerosis. Quitting or not starting is the only thing that can prevent this major risk factor for heart attack and stroke.

Blood Pressure Awareness

Individuals should know what their blood pressure is by having it checked by a practitioner. If it's high, it may be able to be lowered by following a healthy diet and including exercise in their daily routine. If diet and exercise don't lower blood pressure,

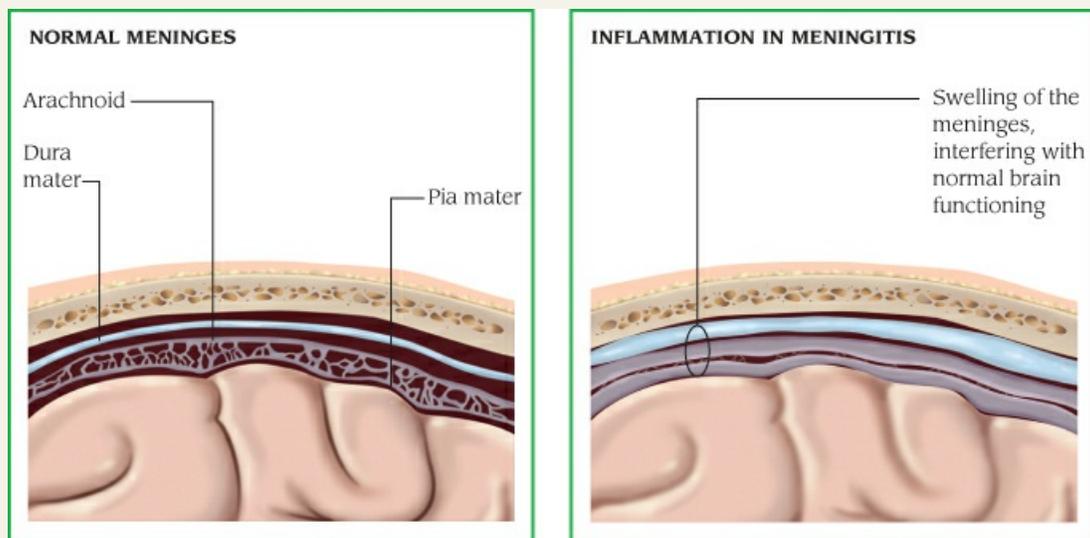
medication may be needed. Adherence to the medication regimen is foremost in reducing blood pressure and preventing stroke.

◆ Ensure that the patient understands that if symptoms develop, he or she should go to the emergency department immediately.

MENINGITIS

In meningitis, the brain and the spinal cord meninges become inflamed, usually as a result of a viral or, less commonly, a bacterial infection. Such inflammation may involve all three meningeal membranes—the dura mater, the arachnoid, and the pia mater. (See *Meningeal inflammation in meningitis*, page 175.) Viral meningitis is usually mild and often clears on its own in 10 days or less. Bacterial meningitis requires prompt treatment with I.V. antibiotics.

Meningeal Inflammation in Meningitis

The illustration below shows normal meninges and how the meninges become inflamed in meningitis.


Causes and Incidence

Bacterial meningitis is almost always a complication of another bacterial infection—bacteremia (especially from pneumonia, empyema, osteomyelitis, or endocarditis), sinusitis, otitis media, encephalitis, myelitis, or brain abscess—usually caused by *Neisseria meningitidis, Haemophilus influenzae* (in children and young adults), or *Streptococcus pneumoniae* (in adults). In some cases, a virus is suspected. (See *Lymphocytic choriomeningitis*.) Meningitis may also follow skull fracture, a penetrating head wound, lumbar puncture, or a ventricular shunting procedure. Aseptic meningitis may result from a virus or other organism. Sometimes, no causative organism can be found. Meningitis commonly begins as an inflammation of the pia-arachnoid, which may

progress to congestion of adjacent tissues and destruction of some nerve cells.

Lymphocytic Choriomeningitis

Lymphocytic choriomeningitis (LCM) is a mild, biphasic, febrile illness lasting about 2 weeks. Infection occurs through inhalation of the LCM virus or arenavirus from infectious aerosolized particles of the host (rodents such as mice or hamsters) or its excreta (urine, feces, or saliva) 1 to 3 weeks before the onset of symptoms. It can also result from contact with food contaminated with the virus or by contamination of mucous membranes, skin lesions, or cuts with infected body fluids. Handlers of infected animals or their excreta are at risk for this disease. Most cases occur in the northeast and eastern seaboard areas of the United States. LCM is more common during fall and winter.

The incubation period is 8 to 13 days after exposure. Early characteristics include fever, malaise, anorexia, weakness, muscle aches, retro-orbital headache, nausea, and vomiting. Sore throat, nonproductive cough, joint pain, chest pain, testicular pain, and parotid (salivary gland) pain may occur. Meningeal symptoms appear in 15 to 21 days, with signs and symptoms of meningitis (fever, increased headache, and stiff neck) or encephalitis (drowsiness, confusion, sensory disturbances, and motor abnormalities such as paralysis). Alopecia may also occur.

Complications include temporary or permanent neurologic damage, possible maternal transmission (pregnancy-related infection is associated with spontaneous abortion, congenital hydrocephalus, chorioretinitis, and mental retardation), myelitis, Guillain–Barré-type syndrome, orchitis or parotitis, myocarditis, psychosis, joint pain and arthritis, and prolonged convalescence with continuing dizziness, somnolence, and fatigue.

Diagnosis is made by detection of immunoglobulin M antibodies by enzyme-linked immunosorbent assay from serum or cerebrospinal fluid (CSF) (the preferred diagnostic test). Lumbar puncture CSF is typically abnormal and reveals increased opening pressure, increased protein levels, and a lymphocytic pleocytosis, usually in the range of several hundred white blood cells. Treatment is generally supportive and includes bed rest, anti-inflammatory drugs, and analgesics. Ribavirin has been shown to be effective against LCM in vitro. Acute hydrocephalus may require surgical shunting to relieve increased intracranial pressure.

Prevention involves teaching rodent control measures, basic hygiene practices, use of a personal respirator, importance of adequate ventilation, and use of a liquid disinfectant, such as a diluted household bleach solution, to clean areas with rodent droppings.

The incidence of meningitis is high among Blacks and Native Americans. Male infants have a high incidence of gram-negative neonatal meningitis.

Pathophysiology

Microorganisms invade the CNS through the nose or mouth, along a cranial or peripheral nerve, through a direct opening such as trauma or through the bloodstream. This sets off an inflammatory response in the meninges, exudate forms in the subarachnoid space causing the CSF to thicken. The exudate also irritates the cerebral cortex. This results in increased ICP.

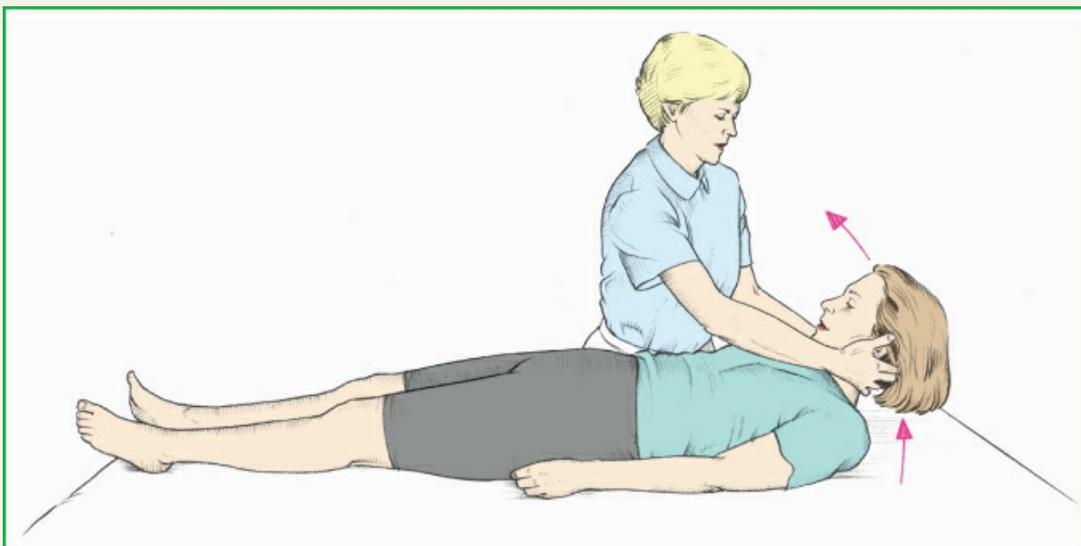
Complications

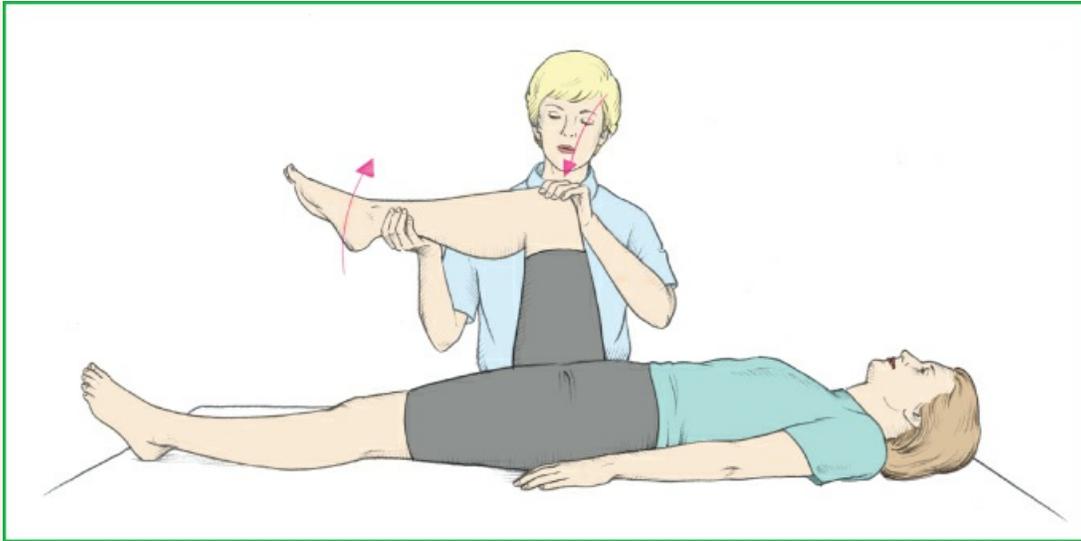
- Visual impairment
- Optic neuritis
- Cranial nerve palsies
- Personality changes
- Headache
- Paresis or paralysis
- Vasculitis
- Endocarditis

Signs and Symptoms

The cardinal signs of meningitis are infection (fever, chills, and malaise) and increased ICP (headache, vomiting, and, rarely, papilledema). Signs of meningeal irritation include nuchal rigidity, positive Brudzinski and Kernig signs, exaggerated and symmetrical deep tendon reflexes, and opisthotonos (a spasm in which the back and extremities arch backward so that the body rests on the head and heels). (See *Two signs of meningitis,* page 177.) Other manifestations of meningitis are irritability; sinus arrhythmias; photophobia, diplopia, and other visual problems; and delirium, deep stupor, and coma.

Two Signs of Meningitis

Brudzinski sign: Place the patient in a dorsal recumbent position, put your hands behind the patient's neck, and bend it forward. Pain and resistance may indicate meningeal inflammation, neck injury, or arthritis. If the patient also flexes hips and knees in response to this manipulation, chances are the patient has meningitis.


Kernig sign: Place the patient in a supine position. Flex the leg at the hip and knee and then straighten the knee. Pain or resistance points to meningitis.


An infant may not show clinical signs of infection but may be fretful and refuse to eat. Such an infant may vomit often, leading to dehydration; this prevents a bulging fontanel and thus masks this important sign of increased ICP. As the illness progresses, twitching, seizures (in 30% of infants), or coma may develop. Most older children have the same symptoms as adults. In subacute meningitis, the onset may be insidious.

Diagnosis

A lumbar puncture showing typical CSF findings, when accompanied by positive Brudzinski and Kernig signs, usually establishes a diagnosis. The following tests can uncover the primary sites of infection: cultures of blood, urine, and nose and throat secretions; chest X-ray; electrocardiogram; and a physical examination, with special attention to skin, ears, and sinuses. Lumbar puncture usually indicates elevated CSF pressure, from obstructed outflow at the arachnoid villi. The fluid may appear cloudy or milky white, depending on the number of white blood cells present. CSF protein levels tend to be high; glucose levels may be low. (In subacute meningitis, CSF findings may vary.) CSF culture and sensitivity tests usually identify the infecting organism, unless it's a virus. Leukocytosis and serum electrolyte abnormalities are also common. CT scan can rule out cerebral hematoma, hemorrhage, or tumor.

Treatment

Treatment of meningitis includes appropriate antibiotic therapy for bacterial meningitis and vigorous supportive care. Usually, I.V. antibiotics are given for at least 2 weeks, followed by oral antibiotics. Dexamethasone has been shown to be effective as adjunctive therapy in the treatment of meningitis caused by *H. influenzae* type B and in pneumococcal meningitis if given before the first dose of antibiotic. It has also been shown to reduce the incidence of deafness, a common complication of meningitis.

Other drugs include mannitol to decrease cerebral edema, an anticonvulsant (usually given I.V.) or sedative to reduce restlessness, and aspirin or acetaminophen to relieve headache and fever. Supportive measures include bed rest, fever reduction, and measures to prevent dehydration. The patient's room is kept darkened and quiet because any increase in sensory

stimulation may cause a seizure. Isolation is necessary if nasal cultures are positive. Appropriate therapy for any coexisting conditions, such as endocarditis or pneumonia, is included as well. To prevent meningitis, prophylactic antibiotics are sometimes used after ventricular shunting procedures, skull fracture, or penetrating head wounds, but this use is controversial.

For viral meningitis, treatment is supportive.

Special Considerations

Patients must be watched carefully for changes in neurologic function or other signs of worsening condition.

◆ Assess neurologic function often. Observe LOC and signs of increased ICP (plucking at the bedcovers, vomiting, seizures, and a change in motor function and vital signs). Watch for signs of cranial nerve involvement (ptosis, strabismus, and diplopia).

ALERT *Be especially alert for a temperature increase up to 102° F (38.9° C), deteriorating LOC, onset of seizures, and altered respirations, all of which may signal an impending crisis.*

◆ Monitor fluid balance. Maintain adequate fluid intake to avoid dehydration, but avoid fluid overload because of the danger of cerebral edema. Measure central venous pressure and intake and output accurately.
◆ Watch for adverse effects of I.V. antibiotics and other drugs. To avoid infiltration and phlebitis, check I.V. site often, and change the site according to hospital policy.
◆ Position the patient carefully to prevent joint stiffness and neck pain. Turn the patient often, according to a planned positioning schedule. Assist with range-of-motion exercises.
◆ Maintain adequate nutrition and elimination. It may be necessary to provide small, frequent meals or to supplement meals with nasogastric tube or parenteral feedings. To prevent constipation and minimize the risk of increased ICP resulting from straining at stool, give the patient a mild laxative or stool softener.
◆ Ensure the patient's comfort. Provide mouth care regularly. Maintain a quiet environment. Darkening the room may decrease photophobia. Relieve headache with a nonopioid analgesic, such as aspirin or acetaminophen, as ordered. (Opioids interfere with accurate neurologic assessment.)
◆ Provide reassurance and support. The patient may be frightened by the illness and frequent lumbar punctures. If the patient is delirious or confused, attempt to reorient often. Reassure the family that the delirium and behavior changes caused by meningitis usually disappear. However, if a severe neurologic deficit appears permanent, refer the patient to a rehabilitation program as soon as the acute phase of this illness has passed.
◆ To help prevent development of meningitis, teach patients with chronic sinusitis or other chronic infections the importance of proper medical treatment. Follow strict sterile technique when treating patients with head wounds or skull fractures.

PREVENTION

◆ *Give* Haemophilus influenzae *Type B and pneumococcal vaccines to children.*
◆ *Give meningococcal vaccine to college students.*
◆ *Give prophylactic antibiotics to those who have been exposed to a patient with meningitis.*

ENCEPHALITIS

Encephalitis is a severe inflammation of the brain, commonly caused by a mosquito-borne or, in some areas, a tick-borne virus. However, transmission by means other than arthropod bites may occur through ingestion of infected goat's milk and accidental injection or inhalation of the virus. Person-to-person, airborne transmission of viruses (such as measles or mumps) may also lead to encephalitis in nonimmunized populations. Eastern equine encephalitis may produce permanent neurologic damage and is commonly fatal. (See *Types of encephalitis,* pages 179 to 181.)

Types of Encephalitis

Four main viral agents cause most cases of encephalitis in the United States: eastern equine encephalitis (EEE), western equine encephalitis (WEE), St. Louis encephalitis, and La Crosse (LAC) encephalitis, all of which are transmitted by mosquitoes. Another virus, Powassan (POW) virus, is a minor cause of encephalitis in the northern United States; this virus is transmitted by ticks. Most cases of arboviral encephalitis occur from June through September, when arthropods are most active. In milder parts of the country, where arthropods are active late into the year, cases can occur into the winter months.

No vaccines are available for these U.S.-based diseases. However, a Japanese encephalitis (JE) vaccine is available for those who will be traveling to Japan, a tick-borne encephalitis vaccine is available for those who will be traveling to Europe, and an equine vaccine is available for EEE, WEE, and Venezuelan equine encephalitis (VEE). Public health measures often require spraying of insecticides to kill larvae and adult mosquitoes as well as controlling standing water that can provide mosquito breeding sites.

Eastern Equine Encephalitis
- EEE is caused by an alphavirus transmitted to humans and horses by the bite of an infected mosquito.
- Incubation is 4 to 10 days.
- Symptoms begin with a sudden onset of fever, general muscle pains, and a headache of increasing severity; can progress to seizures and coma.
- One third of those afflicted will die from the disease and of those who recover, many will suffer irreversible brain damage requiring care.
- Human cases are usually preceded by outbreaks in horses.
- The virus occurs in natural cycles involving birds in swampy areas nearly every year during the warm months. The virus doesn't escape from these areas, however, and this mosquito doesn't usually bite humans or other mammals.

Western Equine Encephalitis
- The alphavirus WEE is the causative agent. The virus is closely related to the EEE and VEE viruses.
- The enzootic cycle of WEE involves passerine birds, in which the infection is inapparent, and culicine mosquitoes, principally *Culex tarsalis,* a species associated with irrigated agriculture and stream drainages.
- Human WEE cases are usually first seen in June or July.
- Most WEE infections are asymptomatic or present as mild, nonspecific illness. Patients

with clinically apparent illness usually have a sudden onset with fever, headache, nausea, vomiting, anorexia, and malaise, followed by altered mental status, weakness, and signs of meningeal irritation.
- Children, especially those younger than age 1, are affected more severely than adults and may be left with permanent sequelae, which are seen in 5% to 30% of young patients.
- Mortality is about 3%.

St. Louis Encephalitis
- The leading cause of St. Louis encephalitis is a flavivirus. St. Louis encephalitis is the most common mosquito-transmitted human pathogen in the United States.
- Mosquitoes become infected by feeding on birds infected with the St. Louis encephalitis virus. Infected mosquitoes then transmit virus to humans and animals during the feeding process. The virus grows both in the infected mosquito and the infected bird, but doesn't make either one sick.
- Less than 1% of St. Louis encephalitis viral infections are clinically apparent; the majority are undiagnosed.
- Illness ranges in severity from a simple febrile headache to meningoencephalitis, with an overall case–fatality ratio of 30%.
- The incubation period is 5 to 15 days.
- Mild infections present with fever and headache. More severe infection is marked by headache, high fever, neck stiffness, stupor, disorientation, coma, tremors, occasional convulsions (especially in infants), and spastic (but rarely flaccid) paralysis.
- The disease is generally milder in children than in adults, but in those children who do have disease, there's a high rate of encephalitis.
- Elderly people are at highest risk for severe disease and death.
- During the summer season, St. Louis encephalitis virus is maintained in a mosquito–bird–mosquito cycle, with periodic amplification by peridomestic birds and *Culex* mosquitoes.

La Crosse encephalitis
- The LAC virus, a bunyavirus, is a zoonotic pathogen cycled between the daytime-biting tree hole mosquito, *Aedes triseriatus*, and vertebrate amplifier hosts (chipmunks, tree squirrels) in deciduous forest habitats. The virus is maintained over the winter by transmission in mosquito eggs. If the female mosquito is infected, she may lay eggs that carry the virus. The vector uses artificial containers (tires, buckets, and so forth) in addition to tree holes.
- LAC encephalitis initially presents as a nonspecific summertime illness with fever, headache, nausea, vomiting, and lethargy.
- Severe disease occurs most commonly in children younger than 16 and is characterized by seizures, coma, paralysis, and a variety of neurologic sequelae after recovery.
- Death occurs in less than 1% of clinical cases.
- Cases are often reported as aseptic meningitis or viral encephalitis of unknown etiology.
- During an average year, about 75 cases of LAC encephalitis are reported to the Centers for Disease Control and Prevention.

Powassan Encephalitis
- The POW virus is a flavivirus.

- Recently a Powassan-like virus was isolated from the deer tick, *Ixodes scapularis*. The virus has been recovered from ticks (*Ixodes marxi* and *Dermacentor andersoni*) and from the tissues of an eastern spotted skunk.
- It's a rare cause of acute viral encephalitis.
- Patients who recover may have residual neurologic problems.

Venezuelan Equine Encephalitis

- Like EEE and WEE viruses, VEE is an alphavirus that causes encephalitis in horses and humans. VEE is a significant veterinary and public health problem in Central and South America.
- Infection of humans with the VEE virus is less severe than with EEE and WEE viruses, and fatalities are rare.
- Adults usually develop only an influenza-like illness; overt encephalitis is usually confined to children.
- Effective VEE virus vaccines are available for equines.

Japanese Encephalitis

- JE virus, which is related to St. Louis encephalitis, is a flavivirus. It's widespread throughout Asia.
- Epidemics occur in late summer in temperate regions, but the infection is enzootic and occurs throughout the year in many tropical areas of Asia.
- The virus is maintained in a cycle involving culicine mosquitoes and waterbirds. It's transmitted to humans by *Culex* mosquitoes, primarily *Culex tritaeniorhynchus*, which breed in rice fields.
- Mosquitoes become infected by feeding on domestic pigs and wild birds infected with the JE virus. Infected mosquitoes then transmit the virus to humans and animals during the feeding process. The virus is amplified in domestic pigs and wild birds.
- The incubation period is 5 to 14 days.
- Mild infections occur without apparent symptoms other than fever with headache. More severe infection is marked by quick onset, headache, high fever, neck stiffness, stupor, disorientation, coma, tremors, occasional seizures (especially in infants), and spastic (but rarely flaccid) paralysis.
- The illness resolves in 5 to 7 days if there's no central nervous system involvement.
- The mortality is less than 10%, but is higher in children and can exceed 30%. Neurologic sequelae in patients who recover are reported in up to 30% of cases.
- A vaccine is currently available for human use in the United States for individuals who might be traveling to endemic countries.

Tick-Borne Encephalitis

- Tick-borne encephalitis (TBE) is caused by two closely related flaviviruses. The eastern subtype causes Russian spring-summer encephalitis (RSSE) and is transmitted by *Ixodes persulcatus*, whereas the western subtype is transmitted by *Ixodes ricinus* and causes Central European encephalitis (CEE).
- RSSE is the more severe infection, having a mortality of up to 25% in some outbreaks, whereas mortality in CEE seldom exceeds 5%.
- The incubation period is 7 to 14 days.

- Infection usually presents as a mild, influenza-type illness or as benign, aseptic meningitis, but may result in fatal meningoencephalitis.
  - Fever is often biphasic, and there may be severe headache and neck rigidity, with transient paralysis of the limbs, shoulders or, less commonly, the respiratory musculature. A few patients are left with residual paralysis.
  - Although the great majority of TBE infections follow exposure to ticks, infection has occurred through the ingestion of infected cows' or goats' milk.
  - An inactivated TBE vaccine is currently available in Europe and Russia.

West Nile Encephalitis
- West Nile virus (WNV) is a flavivirus belonging to the Japanese encephalitis serocomplex that includes the closely related St. Louis encephalitis virus, Kunjin, and Murray Valley encephalitis (MVE) viruses, as well as others.
- WNV can infect a wide range of vertebrates; in humans it usually produces either asymptomatic infection or mild febrile disease, but can cause severe and fatal infection in a small percentage of patients.
- The incubation period is thought to range from 3 to 14 days.
- Symptoms generally last 3 to 6 days.
- Like St. Louis encephalitis virus, WNV is transmitted principally by *Culex* species mosquitoes, but also can be transmitted by *Aedes, Anopheles,* and other species.
- The mild form of WNV infection has presented as a febrile illness of sudden onset often accompanied by malaise, anorexia, nausea, vomiting, eye pain, headache, myalgia, rash, and lymphadenopathy.
- A minority of patients with severe disease develop a maculopapular or morbilliform rash involving the neck, trunk, arms, or legs. Some patients experience severe muscle weakness and flaccid paralysis. Neurologic presentations include ataxia, cranial nerve abnormalities, myelitis, optic neuritis, polyradiculitis, and seizures. Although not observed in recent outbreaks, myocarditis, pancreatitis, and fulminant hepatitis have been described.

Murray Valley Encephalitis
- MVE is endemic in New Guinea and in parts of Australia.
- It's related to the St. Louis encephalitis, WNV, and JE viruses.
- Infections are common, and the small number of fatalities has mostly been in children.

In encephalitis, intense lymphocytic infiltration of brain tissues and the leptomeninges causes cerebral edema, degeneration of the brain's ganglion cells, and diffuse nerve cell destruction.

Causes and Incidence
Encephalitis typically results from infection with arboviruses specific to rural areas. However, in urban areas, it's most frequently caused by enteroviruses (coxsackievirus, poliovirus, and echovirus) and flaviviruses (WNV). Other causes include herpesvirus, mumps virus, human immunodeficiency virus, adenoviruses, rabies, and demyelinating diseases after measles, varicella, rubella, or vaccination.

Pathophysiology

Infectious organisms from a mosquito or tick causes a lymphocytic infiltration of brain tissues and the leptomeninges which causes cerebral edema, degeneration of the ganglion cells of the brain with diffuse nerve cell destruction.

Complications

- Bronchial pneumonia
- Urine retention
- Urinary tract infection
- Pressure ulcers
- Seizure disorder
- Parkinsonism
- Mental deterioration
- Coma

Signs and Symptoms

All viral forms of encephalitis have similar clinical features, although certain differences do occur. Usually, the acute illness begins with sudden onset of fever, headache, and vomiting and progresses to include signs and symptoms of meningeal irritation (stiff neck and back) and neuronal damage (drowsiness, coma, paralysis, seizures, ataxia, tremors, nausea, vomiting, and organic psychoses). After the acute phase of the illness, coma may persist for days or weeks.

The severity of arbovirus encephalitis may range from subclinical to rapidly fatal necrotizing disease. Herpes encephalitis also produces signs and symptoms that vary from subclinical to acute and commonly fatal fulminating disease. Associated effects include disturbances of taste or smell.

Diagnosis

During an encephalitis epidemic, diagnosis is readily made on clinical findings and patient history. However, sporadic cases are difficult to distinguish from other febrile illnesses, such as gastroenteritis or meningitis. Diagnosis may be assisted by serologic assays, such as immunoglobulin (Ig) M-capture ELISA (MAC-ELISA) and Ig ELISA. Early in infection, IgM antibody is more specific, whereas later, IgG is more reactive. Monoclonal antibody studies show promise in diagnosis. Polymerase chain reaction is also being investigated.

When possible, identification of the virus in CSF or blood confirms this diagnosis. The common viruses that also cause herpes, measles, and mumps are easier to identify than arboviruses. Both herpesviruses and arboviruses can be isolated by inoculating young mice with a specimen taken from the patient. In herpes encephalitis, serologic studies may show rising titers of complement-fixing antibodies.

In all forms of encephalitis, CSF pressure is elevated and despite inflammation, the fluid is usually clear. White blood cell and protein levels in CSF are slightly elevated, but the glucose level remains normal. An EEG reveals abnormalities. Occasionally, a CT scan or MRI may be ordered to rule out cerebral hematoma.

Treatment

The antiviral acyclovir must be prescribed for herpes encephalitis. Antibiotics may be prescribed if the infection is thought to be caused by bacteria. Treatment of all other forms of encephalitis is entirely supportive. Drug therapy includes phenytoin or another anticonvulsant, usually given

I.V.; steroids such as dexamethasone to reduce cerebral inflammation and edema; corticosteroids; mannitol to reduce cerebral swelling (although the evidence for benefit is weak); sedatives for restlessness; and aspirin or acetaminophen to relieve headache and reduce fever. Ribavirin and interferon alpha-2b were found to have some effect on West Nile encephalitis. Other supportive measures include adequate fluid and electrolyte intake to prevent dehydration and antibiotics for an associated infection such as pneumonia. Isolation is unnecessary. (See *Preventing mosquito-borne encephalitis*.)

PREVENTION
PREVENTING MOSQUITO-BORNE ENCEPHALITIS

Help patients prevent mosquito-borne encephalitis by urging them to follow these steps:
- Wear long-sleeved shirts and long pants if going outside between dusk and dawn.
- A mosquito repellent with a 10% to 30% concentration of *N,N*-diethyl-meta-toluamide (DEET) is recommended and should be applied to skin and clothing. Don't use DEET on the hands of young children or on infants under 2 months of age. Cover an infant's stroller or playpen with mosquito netting when outside.
- Refrain from unnecessary activity in places where mosquitoes are most prevalent.
- Repair holes in screens on doors and windows to prevent mosquitoes from entering the home.
- Eliminate areas that attract mosquitoes, such as standing water in birdbaths, wheelbarrows, flower pots, old tires, and unused containers. These items are excellent breeding areas for mosquitoes.

Special Considerations

During the acute phase of the illness:

- Assess neurologic function often. Observe LOC and signs of increased ICP (increasing restlessness, plucking at the bedcovers, vomiting, seizures, and changes in pupil size, motor function, and vital signs—such as rising blood pressure, widening pulse pressure, and slowly falling pulse). Watch for cranial nerve involvement (ptosis, strabismus, and diplopia), abnormal sleep patterns, and behavior changes.
- Maintain adequate fluid intake to prevent dehydration, but avoid fluid overload, which may increase cerebral edema. Measure and record intake and output accurately, and assess daily weights.
- Carefully position the patient to prevent joint stiffness and neck pain, and turn the patient often. Assist with range-of-motion exercises.
- Maintain adequate nutrition. It may be necessary to give the patient small, frequent meals or to supplement meals with nasogastric tube or parenteral feedings.
- To prevent constipation and minimize the risk of increased ICP resulting from straining at stool, give a mild laxative or stool softener.
- Provide mouth care.
- Maintain a quiet environment. Darkening the room may decrease photophobia and headache. If the patient naps during the day and is restless at night, plan daytime activities to minimize napping and promote sleep at night.

- Provide emotional support and reassurance because the patient is apt to be frightened by the illness and frequent diagnostic tests.
- If the patient is delirious or confused, attempt to reorient often. Providing a calendar or a clock in the patient's room may be helpful.
- Reassure the patient and family that behavior changes caused by encephalitis usually disappear. If a neurologic deficit is severe and appears permanent, refer the patient to a rehabilitation program as soon as the acute phase has passed.

BRAIN ABSCESS

Brain abscess, also known as an *intracranial abscess*, is a free or encapsulated collection of pus usually in the temporal lobe, cerebellum, or frontal lobes. It can vary in size and may occur singly or in more than one location.

Untreated brain abscess is usually fatal; even with treatment, the prognosis is only fair, and about 30% of patients develop focal seizures. Multiple metastatic abscesses secondary to systemic or other infections have the poorest prognosis.

Causes and Incidence

Brain abscess is usually secondary to some other infection, especially otitis media, sinusitis, dental abscess, and mastoiditis. Other causes include subdural empyema; bacterial endocarditis; human immunodeficiency virus infection; bacteremia; pulmonary or pleural infection; pelvic, abdominal, and skin infections; and cranial trauma, such as a penetrating head wound or compound skull fracture. Brain abscess also occurs in those with congenital heart disease and congenital blood vessel abnormalities of the lungs such as Osler–Weber–Rendu disease. These disorders carry a high risk of infection of the heart or lungs, which can then spread to the brain. Penetrating head trauma or bacteremia usually leads to staphylococcal infection; pulmonary disease, to streptococcal infection.

Brain abscess has a relatively low incidence. It has a 10% mortality rate.

Pathophysiology

Brain abscess usually begins with localized inflammatory necrosis and edema, septic thrombosis of vessels, and suppurative encephalitis. This is followed by thick encapsulation of accumulated pus and adjacent meningeal infiltration by neutrophils, lymphocytes, and plasma cells. The abscess acts like a space-occupying lesion. If the capsule of the abscess ruptures, it creates a more diffuse inflammation with more global increased ICP.

Complications

- Seizures
- Permanent weakness or paralysis
- Meningitis
- Memory difficulty
- Speech difficulty

Signs and Symptoms

Onset varies according to cause, but generally brain abscess produces clinical effects similar to those of a brain tumor. Early symptoms result from increased ICP and include constant intractable headache, worsened by straining; nausea; vomiting; and focal or generalized seizures.

Typical later symptoms include ocular disturbances, such as nystagmus, decreased vision, and unequal pupil size.

Other features differ with the site of the abscess:

- *temporal lobe abscess:* auditory-receptive dysphasia, central facial weakness, and hemiparesis
- *cerebellar abscess:* dizziness, coarse nystagmus, gaze weakness on lesion side, tremor, and ataxia
- *frontal lobe abscess:* expressive dysphasia, hemiparesis with unilateral motor seizure, drowsiness, inattention, and mental function impairment.

Signs of infection, such as fever, pallor, and bradycardia, are absent until late stages unless they result from the predisposing condition. If the abscess is encapsulated, they may never appear. Depending on abscess size and location, LOC varies from drowsiness to deep stupor.

Diagnosis

A history of infection—especially of the middle ear, mastoid, nasal sinuses, heart, or lungs—or a history of congenital heart disease, along with a physical examination showing such characteristic clinical features as increased ICP, points to brain abscess. A CT scan or MRI and, occasionally, arteriography (which highlights brain abscess by a halo) help locate the site. Blood culture will reveal any bacteria in the bloodstream. Chest X-ray may reveal lung infection.

Examination of CSF can help confirm infection, but lumbar puncture is risky because it can release the increased ICP and provoke cerebral herniation. A CT-guided stereotactic biopsy may be performed to drain and culture the abscess. Other tests include culture and sensitivity of drainage to identify the causative organism, skull X-rays, and a radioisotope scan.

Treatment

Management of patients with brain abscess has become increasingly challenging because of the proliferation of unusual bacterial, fungal, and parasitic infections, particularly in immunocompromised patients. Therapy consists of antibiotics to combat the underlying infection and surgical aspiration or drainage of the abscess. Surgical drainage or excision may be performed (CT scan or MRI can help determine the need for these procedures). Antimicrobials may be injected directly into the mass. Administration of antibiotics for at least 2 weeks before surgery can reduce the risk of spreading infection.

Other treatments during the acute phase are palliative and supportive and include mechanical ventilation, administration of I.V. fluids with diuretics (urea, mannitol, or hypertonic saline), to combat increased ICP and cerebral edema. Anticonvulsants, such as phenytoin, levetiracetam, or phenobarbital, help prevent seizures.

Special Considerations

The patient with an acute brain abscess requires intensive monitoring.

- Frequently assess neurologic status, especially LOC, speech, and sensorimotor and cranial nerve functions. Watch for signs of increased ICP (decreased LOC, vomiting, abnormal pupil response, and depressed respirations), which may lead to cerebral herniation with such signs as fixed and dilated pupils, widened pulse pressure, bradycardia or tachycardia, and absent respirations.
- Assess and record vital signs at least every hour.
- Monitor fluid intake and output carefully because fluid overload can contribute to cerebral

edema.

If surgery is necessary, explain the procedure to the patient and answer any questions. After surgery:

- Continue frequent neurologic assessment. Monitor vital signs and intake and output.
- Watch for signs of meningitis (nuchal rigidity, headaches, chills, and sweats), an ever present threat.
- Be sure to change a damp dressing often, using sterile technique and noting the amount of drainage. Never allow bandages to remain damp. To promote drainage and prevent reaccumulation of purulent material in the abscess, position the patient on the operative side.
- If the patient remains stuporous or comatose for an extended period, give meticulous skin care to prevent pressure ulcers, and position to preserve function and prevent contractures.
- Encourage the patient to ambulate as soon as possible to prevent immobility and encourage independence.

PREVENTION

- *Stress the need for treatment of otitis media, mastoiditis, dental abscess, and other infections.*
- *Give prophylactic antibiotics after compound skull fracture or penetrating head wound.*

HUNTINGTON DISEASE

Also called *Huntington chorea*, hereditary chorea, chronic progressive chorea, or adult chorea, Huntington disease is a hereditary disease in which degeneration in the cerebral cortex and basal ganglia causes chronic progressive chorea and mental deterioration, ending in dementia.

Causes and Incidence

Huntington disease is inherited as a single faulty gene on chromosome 4 whereby part of the gene is repeated in multiple copies. It's transmitted as an autosomal dominant trait; either sex can transmit and inherit it. Each child of a parent with this disease has a 50% chance of inheriting it.

The disease usually strikes people between ages 35 and 55; however, 2% of cases occur in children, and 5% of cases occur as late as age 60. Death usually results 10 to 15 years after onset, from suicide, heart failure, or pneumonia. Genetic testing is available for persons with a family history of the disease.

Pathophysiology

Huntington disease involves a disturbance in neurotransmitters—primarily gamma-aminobutyric acid (GABA) and dopamine. GABA neurons in the basal ganglia, frontal cortex, and cerebellum are destroyed and replaced by glial cells which create a deficiency of GABA and an excess of dopamine. This imbalance alters neural transmission along the affected pathway.

Complications

- Aspiration
- Pneumonia
- Heart failure
- Infections
- Suicidal ideation

Signs and Symptoms

Onset is insidious. The patient eventually becomes totally dependent—emotionally and physically—through loss of musculoskeletal control, and develops progressively severe choreic movements. Such movements are rapid, usually violent, and purposeless. Initially, they're unilateral and more prominent in the face and arms than in the legs, progressing from mild fidgeting to grimacing, tongue smacking, dysarthria (indistinct speech), athetoid movements (especially of the hands) related to emotional state, and torticollis.

Ultimately, the patient with Huntington disease develops progressive dementia, although the dementia doesn't always progress at the same rate as the chorea. Dementia can be mild at first, but eventually causes severe disruption of the personality. Personality changes include obstinacy, carelessness, untidiness, moodiness, apathy, inappropriate behavior, loss of memory and concentration and, occasionally, paranoia.

Diagnosis

Huntington disease can be detected by positron emission tomography and deoxyribonucleic acid analysis. Diagnosis is based on a characteristic clinical history: progressive chorea and dementia, onset in early middle age (35 to 40 years old), and confirmation of a genetic link. CT scan and MRI demonstrate brain atrophy. Molecular genetics may detect the gene for Huntington disease in people at risk while they're still asymptomatic.

Treatment

Because Huntington disease has no known cure, treatment is supportive, protective, and symptomatic. Dopamine blockers, such as phenothiazine or haloperidol, help control choreic movements and reduce abnormal behaviors. Reserpine and other drugs have been used with varying success to control choreic movements and reduce abnormal behavior. Drugs such as tetrabenazine and amantadine are used to control extra movements. Some evidence suggests that co-enzyme Q10 may minimally decrease progression of the disease. Institutionalization may be necessary because of mental deterioration, which can't be halted or managed by drugs.

Special Considerations

Patient comfort and support are the primary considerations.

- Provide physical support by attending to the patient's basic needs, such as hygiene, skin care, bowel and bladder care, and nutrition. Increase this support as mental and physical deterioration make the patient increasingly immobile.
- Offer emotional support to the patient and family. Teach them about the disease, and listen to their concerns and special problems. Keep in mind the patient's dysarthria, and allow extra time to express himself, thereby decreasing frustration. Teach the family to participate in the patient's care.
- Stay alert for possible suicide attempts. Control the patient's environment to protect from suicide or other self-inflicted injury. Pad the side rails of the bed, but avoid restraints, which may cause the patient to injure himself with violent, uncontrolled movements.
- If the patient has difficulty walking, provide a walker to help maintain balance.
- Make sure affected families receive genetic counseling. All affected family members should realize that each of their offspring has a 50% chance of inheriting this disease.
- Refer people at risk who desire genetic testing to centers specializing in Huntington's care,

where psychosocial support is available.
- Refer the patient and family to the appropriate community organizations.
- For more information about this degenerative disease, refer the patient and family to the Huntington's Disease Society of America.

PARKINSON DISEASE

Named for James Parkinson, the English physician who wrote the first accurate description of the disease in 1817, Parkinson disease characteristically produces progressive muscle rigidity, akinesia, involuntary tremor, and dementia. Death may result from aspiration pneumonia or an infection.

Causes and Incidence

Although the cause of Parkinson disease is unknown, study of the extrapyramidal brain nuclei (corpus striatum, globus pallidus, and substantia nigra) has established that a dopamine deficiency prevents affected brain cells from performing their normal inhibitory function within the CNS. Parkinson disease occurs in families in some cases.

Parkinson disease, also called *parkinsonism*, paralysis agitans, and shaking palsy, is one of the most common crippling diseases in the United States. Parkinson disease strikes 2 in every 1,000 people, most often developing in those older than 50; however, it also occurs in children and young adults. Because of increased longevity, this amounts to roughly 60,000 new cases diagnosed annually in the United States alone. Incidence increases in persons with repeated brain injury, including professional athletes, and persons using psychoactive substances, whether prescribed or illicit.

Pathophysiology

Parkinson is a degenerative process involving the dopaminergic neurons in the substantia nigra. Stimulation of the basal ganglia usually results in refined motor response because acetylcholine (excitatory) and dopamine (inhibitory) are balanced. The degeneration of the dopaminergic neurons results in an imbalance leading to excess acetylcholine at the synapse. The result is rigidity, tremors, and bradykinesia.

Complications

- Injury from falls
- Aspiration
- Urinary tract infections
- Skin breakdown

Signs and Symptoms

The cardinal symptoms of Parkinson disease are muscle rigidity and akinesia and an insidious resting tremor that begins in the fingers (unilateral pill-roll tremor), increases during stress or anxiety, and decreases with purposeful movement and sleep. Muscle rigidity results in resistance to passive muscle stretching, which may be uniform (lead-pipe rigidity) or jerky (cogwheel rigidity). Akinesia causes the patient to walk with difficulty (gait lacks normal parallel motion and may be retropulsive or propulsive) and produces a high-pitched, monotone voice; drooling; a masklike facial expression; loss of posture control (the patient walks with body bent forward); and dysarthria, dysphagia, or both. Occasionally, akinesia may also cause oculogyric crises (eyes

are fixed upward, with involuntary tonic movements) or blepharospasm (eyelids are completely closed). Parkinson disease itself doesn't impair the intellect, but a coexisting disorder, such as arteriosclerosis, may do so.

Diagnosis

Generally, laboratory data are of little value in identifying Parkinson disease; consequently, diagnosis is based on the patient's age, history, and characteristic clinical picture.

Conclusive diagnosis is possible only after ruling out other causes of tremor, involutional depression, cerebral arteriosclerosis and, in patients younger than 30, intracranial tumors, Wilson disease, or phenothiazine or other drug toxicity.

Treatment

Because Parkinson disease has no cure, the primary aim of treatment is to relieve symptoms and keep the patient functional as long as possible. Treatment consists of drugs, physical therapy and, in severe disease states unresponsive to drugs, stereotactic neurosurgery or the controversial treatment called fetal cell transplantation. In this treatment, fetal brain tissue is injected into the patient's brain. If the injected cells grow within the recipient's brain, they will allow the brain to process dopamine, thereby either halting or reversing disease progression. Neurotransplantation techniques, including the use of nerve cells from other parts of the patient's body, have been attempted with varying results.

Drug therapy usually includes levodopa, a dopamine replacement that's most effective during early stages. It's given in increasing doses until symptoms are relieved or adverse effects appear. Because adverse effects can be serious, levodopa is usually given in combination with carbidopa to halt peripheral dopamine synthesis. Occasionally, levodopa proves ineffective, producing dangerous adverse effects that include postural hypotension, hallucinations, and increased libido leading to inappropriate sexual behavior. In that case, alternative drug therapy includes anticholinergics such as trihexyphenidyl, antihistamines such as diphenhydramine, and amantadine, an antiviral agent.

Research into the oxidative stress theory has caused a controversy in drug therapy for Parkinson disease. Traditionally, levodopa–carbidopa has been a first-line drug in management; however, it has also been associated with an acceleration of disease process. Inclusion of entacapone potentiates the effects of levodopa–carbidopa treatment so that less frequent doses are required.

Selegiline, an enzyme-inhibiting agent, allows conservation of dopamine and enhances the therapeutic effect of levodopa. Selegiline used with tocopherols delays the time when the patient with Parkinson disease becomes disabled.

ELDER TIP Elderly patients may need smaller doses of antiparkinsonian drugs because of reduced tolerance. Be alert for and report orthostatic hypotension, irregular pulse, blepharospasm, and anxiety or confusion.

When drug therapy fails, stereotactic neurosurgery, such as subthalamotomy and pallidotomy, may be an alternative. In these procedures, electrical coagulation, freezing, radioactivity, or ultrasound destroys the ventrolateral nucleus of the thalamus to prevent involuntary movement. This is most effective in young, otherwise healthy people with unilateral tremor or muscle rigidity. Neurosurgery can only relieve symptoms. Brain stimulator implantation alters the activity of the area where Parkinson disease symptoms originate. A pacemaker is implanted into

the chest wall, and the electrode is threaded (using MRI for guidance) to the thalamus, pallidum, or subthalamic nucleus. A successful procedure reduces the need for medication, thus reducing the medication-related adverse effects experienced by the patient.

Individually planned physical therapy complements drug treatment and neurosurgery to maintain normal muscle tone and function. Appropriate physical therapy includes both active and passive range-of-motion exercises, routine daily activities, walking, and baths and massage to help relax muscles.

Special Considerations

Effectively caring for the patient with Parkinson disease requires careful monitoring of drug treatment, emphasis on teaching self-reliance, and generous psychological support.

- Monitor drug treatment and adjust dosage, if necessary, to minimize adverse effects.
- If the patient has surgery, watch for signs of hemorrhage and increased ICP by frequently checking LOC and vital signs.
- Encourage independence. The patient with excessive tremor may achieve partial control of his or her body by sitting on a chair and using its arms to steady themselves. Advise the patient to change position slowly and dangle the legs before getting out of bed. Remember that fatigue may cause the patient to depend more on others.
- Help the patient overcome problems related to eating and elimination. For example, if the patient has difficulty eating, offer supplementary or small, frequent meals to increase caloric intake. Help establish a regular bowel routine by encouraging the patient to drink at least 2 qt (about 2 L) of liquids daily and eat high-fiber foods. The patient may need an elevated toilet seat to assist from a standing to a sitting position.
- Give the patient and family emotional support. Teach them about the disease, its progressive stages, and drug adverse effects. Show the family how to prevent pressure ulcers and contractures by proper positioning. Inform them of the dietary restrictions levodopa imposes, and explain household safety measures to prevent accidents. Help the patient and family express their feelings and frustrations about the progressively debilitating effects of the disease. Establish long- and short-term treatment goals, and be aware of the patient's need for intellectual stimulation and diversion. Refer the patient and family to the National Parkinson Foundation or the United Parkinson Foundation for more information.

MYELITIS AND ACUTE TRANSVERSE MYELITIS

Myelitis, or inflammation of the spinal cord, can result from several diseases. Poliomyelitis affects the cord's gray matter and produces motor dysfunction; leukomyelitis affects only the white matter and produces sensory dysfunction. These types of myelitis can attack any level of the spinal cord, causing partial destruction or scattered lesions. Acute transverse myelitis, which affects the entire thickness of the spinal cord, produces both motor and sensory dysfunctions. It has a rapid onset and is the most devastating form of myelitis.

The prognosis depends on the severity of cord damage and prevention of complications. If spinal cord necrosis occurs, prognosis for complete recovery is poor. Even without necrosis, residual neurologic deficits usually persist after recovery. Patients who develop spastic reflexes early in the course of the illness are more likely to recover than those who don't.

Causes and Incidence

Acute transverse myelitis has a variety of causes. It commonly follows acute infectious diseases,

such as measles or pneumonia (the inflammation occurs after the infection has subsided), and primary infections of the spinal cord itself, such as syphilis or acute disseminated encephalomyelitis. Acute transverse myelitis can accompany demyelinating diseases, such as an acute exacerbation of MS, and inflammatory and necrotizing disorders of the spinal cord such as hematomyelia.

Certain toxic agents (carbon monoxide, lead, and arsenic) can cause a type of myelitis in which acute inflammation (followed by hemorrhage and possible necrosis) destroys the entire circumference (myelin, axis cylinders, and neurons) of the spinal cord. Other forms of myelitis may result from poliovirus, herpes zoster, herpesvirus B, or rabies virus; disorders that cause meningeal inflammation, such as syphilis, abscesses and other suppurative conditions, and tuberculosis; smallpox or polio vaccination; parasitic and fungal infections; and chronic adhesive arachnoiditis.

Peak incidence occurs between 10 and 19 years old, then again between 30 and 39. Approximately 1,400 new cases are diagnosed each year in the United States. About 33,000 Americans have some type of disability from this disorder.

Pathophysiology

Caused by an acute infection, myelitis is an inflammation of the spinal cord. It can affect only the gray matter—which leads to motor dysfunction, or it can affect the white matter which leads to sensory dysfunction. In acute transvers myelitis the entire cord is affected leading to both motor and sensory deficits.

Complications

- Hypertension
- Urinary tract infection
- Urolithiasis
- Pneumonia
- Skeletal and smooth muscle deformities
- Myocarditis
- Paralytic ileus

Signs and Symptoms

In acute transverse myelitis, onset is rapid, with motor and sensory dysfunctions below the level of spinal cord damage appearing in 1 to 2 days.

Patients with acute transverse myelitis develop flaccid paralysis of the legs (sometimes beginning in just one leg) with loss of sensory and sphincter functions. Such sensory loss may follow pain in the legs or trunk. Reflexes disappear in the early stages but may reappear later. The extent of damage depends on the level of the spinal cord affected; transverse myelitis seldom involves the arms. If spinal cord damage is severe, it may cause shock (hypotension and hypothermia).

Diagnosis

Paraplegia of rapid onset usually points to acute transverse myelitis. In such patients, neurologic examination confirms paraplegia or neurologic deficit below the level of the spinal cord lesion and absent (or, in later stages) hyperactive reflexes. CSF may be normal or show increased lymphocytes or elevated protein levels. Diagnostic evaluation must rule out spinal cord tumor

and identify the cause of any underlying infection.

Treatment

No effective treatment exists for acute transverse myelitis. However, this condition requires appropriate treatment of any underlying infection. Some patients with postinfectious or MS-induced myelitis have received steroid therapy, but its benefits aren't clear.

Special Considerations

Managing symptoms and treating the underlying infection are the primary considerations.

- Frequently assess vital signs. Watch carefully for signs of spinal shock (hypotension and excessive sweating).
- Prevent contractures with range-of-motion exercises and proper alignment.
- Watch for signs of urinary tract infections from indwelling urinary catheters.
- Prevent skin infections and pressure ulcers with meticulous skin care. Check pressure points often and keep skin clean and dry; use a low-pressure specialty or rotational bed or other pressure-relieving device.
- Initiate rehabilitation immediately. Assist the patient with physical therapy, bowel and bladder training, and the lifestyle changes the condition requires.

ALZHEIMER DISEASE

Alzheimer disease, also called *primary degenerative dementia*, accounts for more than half of all dementias. It results in memory loss, confusion, impaired judgment, personality changes, disorientation, and loss of language skills. Because this is a primary progressive dementia, the prognosis for a patient with this disease is poor.

Causes and Incidence

The cause of Alzheimer disease is unknown; however, several factors are thought to be implicated in this disease. These include *neurochemical factors,* such as deficiencies in the neurotransmitter acetylcholine, somatostatin, substance P, and norepinephrine; *environmental factors*; and *genetic immunologic factors.* Genetic studies show that an autosomal dominant form of Alzheimer disease is associated with early onset and early death, accounting for about 100,000 deaths a year. A family history of Alzheimer disease and the presence of Down syndrome are two established risk factors. Alzheimer disease isn't exclusive to the elder population; its onset begins in middle age in 1% to 10% of cases.

   The brain tissue of patients with Alzheimer disease has three hallmark features: neurofibrillary tangles, neuritic plaques, and granulovascular degeneration. Examination of the brain after death also finds that it's atrophic, commonly weighing less than 1,000 g, compared with a normal brain weight of about 1,380 g. (See *Tissue changes in Alzheimer disease,* page 189.)

Tissue Changes in Alzheimer Disease

About 360,000 new cases of Alzheimer disease are diagnosed each year.

Pathophysiology

Structural changes in the brain that occur in Alzheimer disease are neurofibrillary tangle (which are fibrous proteins), neuritic plaques (which are degenerative axons and dendrites), and granulovascular changes. There is significant brain tissue loss and loss of cholinergic pathways in the frontal lobe and hippocampus which are responsible for memory and cognitive function.

Complications

- Injury
- Pneumonia
- Infection
- Malnutrition
- Dehydration

Signs and Symptoms

Onset is insidious. Initially, the patient undergoes almost imperceptible changes, such as forgetfulness, recent memory loss, difficulty learning and remembering new information, deterioration in personal hygiene and appearance, and an inability to concentrate. Gradually, tasks that require abstract thinking and activities that require judgment become more difficult. Progressive difficulty in communication and severe deterioration in memory, language, and motor function result in a loss of coordination and an inability to write or speak. Personality changes (restlessness, irritability) and nocturnal awakenings are common.

Patients also exhibit loss of eye contact, a fearful look, wringing of the hands, and other signs of anxiety. When someone with Alzheimer disease is overwhelmed with anxiety, he or she becomes dysfunctional, acutely confused, agitated, compulsive, or fearful.

Eventually, the patient becomes disoriented, and emotional lability and physical and intellectual disability progress. The patient becomes susceptible to infection and accidents. Usually, death results from infection.

Diagnosis

Early diagnosis of Alzheimer disease is difficult because the patient's signs and symptoms are subtle. (See *Organic brain syndrome.*) Diagnosis relies on an accurate history from a reliable family member, mental status and neurologic examinations, and psychometric testing. A positron emission tomography scan measures the metabolic activity of the cerebral cortex and may help in early diagnosis. An EEG and a CT scan may help in later diagnosis. Currently, the disease is diagnosed by exclusion; that is, tests are performed to rule out other disorders. The presence of Alzheimer disease can't be confirmed until death, when pathologic findings are revealed at autopsy.

Organic Brain Syndrome

Although many behavioral disturbances are clearly linked to organic brain dysfunction, the clinical syndromes associated with this type of impairment are sometimes hard to detect because they aren't always determined by the affected area of the brain or even by the extent of tissue damage. Instead, the way the patient's personality interacts with the brain injury determines the specific clinical effects. General symptoms often include impairment of orientation, memory, and intellectual and emotional function. These primary cognitive deficits help to distinguish organic brain syndromes from neurosis and depression.

Diagnosis

Diagnosis of an organic brain syndrome depends on a detailed history of the onset of cognitive and behavioral disturbances; a complete neurologic assessment; and such tests as EEG, computed tomography scans, brain X-rays, cerebrospinal fluid analysis, and psychological studies. Organic brain syndromes are classified by etiology and specific clinical effects. Causes include infection, brain trauma, nutritional deficiency, cerebrovascular disease, degenerative disease, tumor, toxins, and metabolic or endocrine disorders.

Treatment

Effective treatment requires correction of the underlying cause. Special considerations may

include reality orientation, emotional support for the patient and the family, a safe environment, mat therapy for an agitated or aggressive patient, and referral for psychological counseling.

Treatment

Therapy consists of attempts to slow disease progression, manage behavioral problems, modify the home environment, and elicit family support. Some medications have proven helpful. Tacrine, a centrally acting anticholinesterase agent, is given to treat memory deficits. It has slowed progression of the disease and improved cognitive function in some patients. Other agents include donepezil and rivastigmine. Memantine hydrochloride reduces chemical actions in the brain that contribute to the symptoms of Alzheimer disease. Underlying disorders that contribute to the patient's confusion, such as hypoxia, are also identified and treated.

Special Considerations

Overall care is focused on supporting the patient's remaining abilities and compensating for those lost.

- Establish an effective communication system with the patient and family to help them adjust to the patient's altered cognitive abilities.
- Offer emotional support to the patient and family members. Behavior problems may be worsened by excess stimulation or change in established routine. Teach them about the disease, and refer them to social service and community resources for legal and financial advice and support.
- Anxiety may cause the patient to become agitated or fearful. Intervene by helping the patient focus on another activity.
- Provide the patient with a safe environment. Encourage the patient to exercise, as ordered, to help maintain mobility.

CREUTZFELDT–JAKOB DISEASE

Creutzfeldt–Jakob disease (CJD) is a rare, rapidly progressive viral disease that attacks the CNS, causing dementia and neurologic signs and symptoms, such as myoclonic jerking, ataxia, aphasia, visual disturbances, and paralysis. CJD is always fatal. A new variant of CJD (vCJD) emerged in Europe in 1996. (See *Understanding vCJD*, page 191.)

Understanding vCJD

Like conventional Creutzfeldt–Jakob disease (CJD), the variant of the disease (vCJD) is a rare, fatal neurodegenerative disease. Most cases have been reported in the United Kingdom. vCJD is most likely caused by exposure to bovine spongiform encephalopathy (BSE)—a fatal brain disease in cattle also known as *mad cow disease*—via ingestion of beef products from cattle with BSE.

vCJD affects patients at a much younger age (younger than 55) than CJD, and the duration of the illness is much longer (14 months).

Regulations have been established in Europe to control outbreaks of BSE in cattle and to prevent contaminated meat from entering the food supply.

Causes and Incidence

The causative organism is difficult to identify because no foreign ribonucleic acid or deoxyribonucleic acid has been linked to the disease. CJD is believed to be caused by a specific protein called a *prion,* which lacks nucleic acids, resists proteolytic digestion, and spontaneously aggregates in the brain. Most cases are sporadic; 5% to 15% are familial, with an autosomal dominant pattern of inheritance. Although CJD isn't transmitted by normal casual contact, human-to-human transmission can occur as a result of certain medical procedures, such as corneal and cadaveric dura mater grafts. Isolated cases have resulted from childhood treatment with harvested human growth hormone and from improperly decontaminated neurosurgical instruments and brain electrodes.

CJD typically affects adults 40 to 65 years old and occurs in more than 50 countries. Males and females are affected equally. In people younger than 30, the incidence is 5 in 1 billion; in all other age groups, the incidence is 1 in 1 million.

Pathophysiology

Caused by prions which are deviant forms of harmless proteins found in the brains of mammals and birds. As the prions replicate, they convert normal forms of the protein into their abnormal shape. As the prions accumulate into the nerve cell, they cause neurodegeneration.

Complications

- Impaired gait
- Incontinence
- Akinetic mute state
- Bronchopneumonia
- Death

Signs and Symptoms

Early signs and symptoms of mental impairment may include slowness in thinking, difficulty concentrating, impaired judgment, and memory loss. Dementia is progressive and occurs early. Involuntary movements, such as muscle twitching, trembling, and peculiar body movements, and visual disturbances appear with disease progression and advancing mental deterioration. Hallucinations are also common. The duration of the typical illness is 4 months.

Diagnosis

CJD must be considered for anyone with signs of progressive dementia. Neurologic examination is the most effective tool in diagnosing CJD. Difficulty with rapid alternating movements and point-to-point movements are typically evident early in the disease.

An EEG may be performed to assess the patient for typical changes in brain wave activity. CT scan, MRI of the brain, and lumbar puncture may be useful in ruling out other disorders that cause dementia. Though not diagnostic, the presence of the 14-3-3 protein in the spinal fluid is highly suggestive of the disease when it's accompanied by other characteristic symptoms. Definitive diagnosis usually isn't obtained until an autopsy is done and brain tissue is examined.

Treatment

There's no cure for CJD, and its progress can't be slowed. Palliative care is provided to make the patient comfortable and to ease symptoms. Medications may be needed to control aggressive behaviors. These include sedatives and antipsychotics.

The need to provide a safe environment, control aggressive or agitated behavior, and meet physiologic needs may require monitoring and assistance in the home or in an institutionalized setting. Family counseling may help in coping with the changes required for home care.

Behavior modification may be helpful, in some cases, for controlling unacceptable or dangerous behaviors. Reality orientation, with repeated reinforcement of environmental and other cues, may help reduce disorientation.

Legal advice may be appropriate early in the course of the disorder regarding advance directives, power of attorney, and other legal actions that may make it easier to make ethical decisions regarding the care of an individual with CJD.

Special Considerations

◆ Offer emotional support to the patient and family. Teach them about the disease, and assist them through the grieving process. Refer the patient and family to CJD support groups, and encourage participation.
◆ Contact social services and hospice, as appropriate, to assist the family with their needs.
◆ Encourage the patient and family to discuss and complete advance directives.
◆ To prevent disease transmission, use caution when handling body fluids and other materials from patients suspected of having CJD.

REYE SYNDROME

Reye syndrome is an acute illness affecting children and, less commonly, adults. It causes fatty infiltration of the liver with concurrent hyperammonemia, encephalopathy, and increased ICP. In addition, fatty infiltration of the kidneys, brain, and myocardium may occur.

Prognosis depends on the severity of CNS depression. Until recently, mortality was as high as 90%. Today, ICP monitoring and, consequently, early treatment of increased ICP, along with other treatment measures, have cut mortality to about 20%. Death is usually a result of cerebral edema or respiratory arrest. Comatose patients who survive may have residual brain damage.

Causes and Incidence

Reye syndrome typically begins within 1 to 3 days of an acute viral infection, such as an upper respiratory tract infection, type B influenza, or varicella (chickenpox). Incidence commonly rises during influenza outbreaks and may be linked to salicylate use. For this reason, use of aspirin for children younger than 15 isn't recommended. The Reye's Syndrome Foundation warns against the use of salicylates, even in topical preparations, when a viral illness is suspected.

In Reye syndrome, damaged hepatic mitochondria disrupt the urea cycle, which normally changes ammonia to urea for its excretion from the body. This results in hyperammonemia, hypoglycemia, and an increase in serum short-chain fatty acids, leading to encephalopathy. Simultaneously, fatty infiltration occurs in renal tubular cells, neuronal tissue, and muscle tissue, including the heart.

Reye syndrome affects children from infancy to adolescence and occurs equally in boys and girls. Peak incidence is at 6 years old.

Pathophysiology

Reye syndrome is the result of damaged hepatic mitochondria which disrupts the urea cycle. The result is hyperammonemia, hypoglycemia, and an increase in serum short-chain fatty acids which leads to encephalopathy.

Complication

- Increased ICP

Signs and Symptoms

The severity of the child's signs and symptoms varies with the degree of encephalopathy and cerebral edema. In any case, Reye syndrome develops in five stages. After the initial viral infection, a brief recovery period follows when the child doesn't seem seriously ill. A few days later, the patient develops intractable vomiting; lethargy; rapidly changing mental status (mild to severe agitation, confusion, irritability, and delirium); rising blood pressure, respiratory rate, and pulse rate; and hyperactive reflexes.

Reye syndrome commonly progresses to coma. As coma deepens, seizures develop, followed by decreased tendon reflexes and, usually, respiratory failure.

Increased ICP, a serious complication, is now considered the result of an increased cerebral blood volume causing intracranial hypertension. Such swelling may develop as a result of acidosis, increased cerebral metabolic rate, and an impaired autoregulatory mechanism.

Diagnosis

A history of a recent viral disorder with typical clinical features strongly suggests Reye syndrome. An increased serum ammonia level, abnormal clotting studies, and hepatic dysfunction confirm it. Testing serum salicylate level rules out aspirin use. Absence of jaundice despite increased liver aminotransferase levels rules out acute hepatic failure and hepatic encephalopathy.

Abnormal test results may include:

- Liver function studies—aspartate aminotransferase and alanine aminotransferase elevated to twice normal levels; bilirubin level usually normal.
- Liver biopsy—fatty droplets uniformly distributed throughout cells.
- CSF analysis—white blood cell count less than 10/µL; with coma, increased CSF pressure.
- Coagulation studies—prothrombin time and partial thromboplastin time prolonged.
- Blood values—serum ammonia levels elevated; serum glucose levels normal or, in 15% of cases, low; serum fatty acid and lactate levels increased.

Treatment

For treatment guidelines, see *Stages of treatment for Reye syndrome*.

Stages of Treatment for Reye Syndrome

Signs and symptoms	Baseline treatment	Baseline intervention
Stage I: vomiting, lethargy, hepatic dysfunction	To decrease intracranial pressure (ICP) and brain edema, give I.V. fluids at ⅔ maintenance. Also give an osmotic diuretic or furosemide.	Monitor the patient's vital signs and check the level of consciousness for increasing lethargy. Take vital signs more often as the patient's condition deteriorates.

Stage		
	To treat hypoprothrombinemia, give vitamin K; if vitamin K is unsuccessful, give fresh frozen plasma. ◆ Monitor serum ammonia and blood glucose levels and plasma osmolality every 4 to 8 hours to check progress.	Monitor fluid intake and output to prevent fluid overload. Maintain urine output at 1.0 mL/kg/hour; plasma osmolality, 290 mOsm; and blood glucose, 150 mg/mL. (*Goal:* Keep glucose level high, osmolality normal to high, and ammonia level low.) Also, restrict protein.
Stage II: hyperventilation, delirium, hepatic dysfunction, hyperactive reflexes	◆ Continue baseline treatment.	◆ Maintain seizure precautions. ◆ Immediately report any signs of coma that require invasive, supportive therapy, such as intubation. ◆ Keep the head of the bed at a 30-degree angle.
Stage III: coma, hyperventilation, decorticate rigidity, hepatic dysfunction	◆ Continue baseline and seizure treatment. ◆ Monitor ICP with a subarachnoid screw or other invasive device. ◆ Provide endotracheal intubation and mechanical ventilation to control the partial pressure of arterial carbon dioxide (Pa_{CO_2}) levels. A paralyzing agent, such as atracurium or pancuronium I.V., may help maintain ventilation. ◆ Give mannitol I.V. or glycerol by nasogastric tube.	◆ Monitor ICP (should be less than 20 mm Hg before suctioning) or give a barbiturate I.V., as ordered; hyperventilate the patient as necessary. ◆ When ventilating the patient, maintain Pa_{CO_2} between 25 and 30 mm Hg and the partial pressure of arterial oxygen between 80 and 100 mm Hg. ◆ Closely monitor cardiovascular status with a pulmonary artery catheter or central venous pressure line. ◆ Give skin and mouth care and perform range-of-motion exercises.
Stage IV: deepening coma; decerebrate rigidity; large, fixed pupils; minimal hepatic dysfunction	◆ Continue baseline and supportive care. ◆ If all previous measures fail, some pediatric centers use barbiturate coma, decompressive craniotomy, hypothermia, or exchange transfusion.	◆ Check the patient for loss of reflexes and signs of flaccidity. ◆ Give the patient's family the extra support they need, considering their child's poor prognosis.
Stage V: seizures, loss of deep tendon reflexes, flaccidity, respiratory arrest, ammonia level above 300 mg/dL	◆ Continue baseline and supportive care.	◆ Help the patient's family to face impending death.

PREVENTION *Advise parents to give nonsalicylate analgesics and antipyretics such as acetaminophen. For more information, refer parents to the National Reye's Syndrome Foundation.*

GUILLAIN–BARRÉ SYNDROME

Guillain–Barré syndrome is an acute, rapidly progressive, and potentially fatal form of polyneuritis that causes muscle weakness and mild distal sensory loss. Recovery is spontaneous and complete in about 95% of patients, although mild motor or reflex deficits in the feet and legs may persist. The prognosis is best when symptoms clear between 15 and 20 days after onset.

Causes and Incidence

Precisely what causes Guillain–Barré syndrome is unknown, but it may be a cell-mediated immunologic attack on peripheral nerves in response to a virus. The major pathologic effect is segmental demyelination of the peripheral nerves. Because this syndrome causes inflammation and degenerative changes in both the posterior (sensory) and anterior (motor) nerve roots, signs

of sensory and motor losses occur simultaneously.

This syndrome (also called infectious polyneuritis, Landry–Guillain–Barré syndrome, and acute idiopathic polyneuritis) can occur at any age but is most common between 30 and 50 years old; it affects both sexes equally. In the United States, it has an incidence of 0.6 to 2.4 cases per 100,000 people.

Pathophysiology

Guillain–Barré is the result of segmental demyelination of the peripheral nerves resulting in inflammation and swelling. The result is impairment of impulse transmission along the dorsal and anterior nerve roots—motor and sensory loss occurs simultaneously.

Complications

- Thrombophlebitis
- Pressure ulcers
- Contractures
- Muscle wasting
- Aspiration
- Respiratory tract infections
- Respiratory and cardiac compromise

Signs and Symptoms

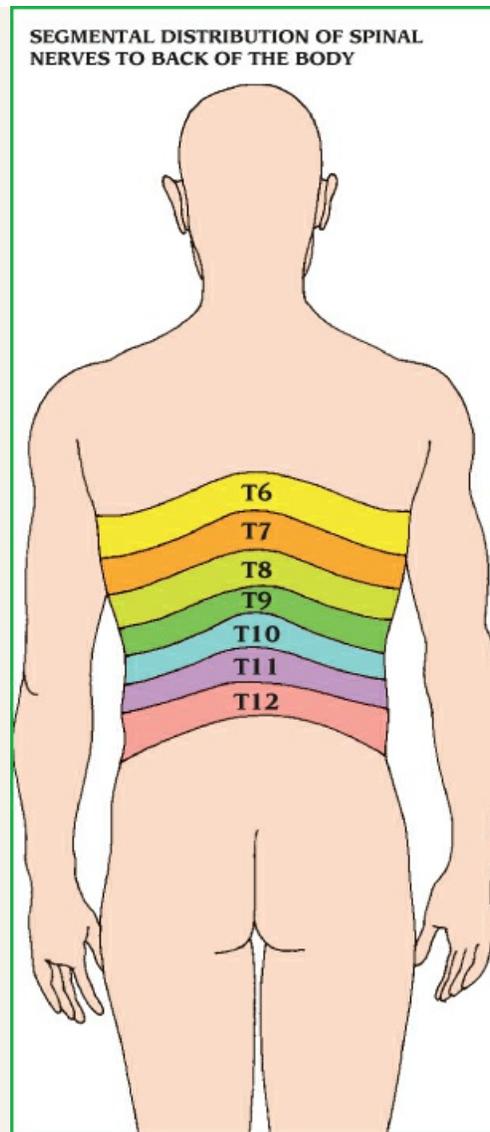
About 50% of patients with Guillain–Barré syndrome have a history of minor febrile illness (10 to 14 days before onset), usually an upper respiratory tract infection or, less commonly, gastroenteritis with *Campylobacter jejuni*. When infection precedes onset of Guillain–Barré syndrome, signs of infection subside before neurologic features appear. Other possible precipitating factors include surgery; rabies or swine influenza vaccination, viral illness such as Epstein–Barr virus, cytomegalovirus, hepatitis, and HIV; Hodgkin or other malignant disease; and lupus erythematosus.

Symmetrical muscle weakness, the major neurologic sign, usually appears in the legs first (ascending type) and then extends to the arms and facial nerves in 24 to 72 hours. Sometimes, muscle weakness develops in the arms first (descending type) or in the arms and legs simultaneously. (See *Testing for thoracic sensation,* page 195.) In milder forms of this disease, muscle weakness may affect only the cranial nerves or may not occur at all.

Testing for Thoracic Sensation

When Guillain–Barré syndrome progresses rapidly, test for ascending sensory loss by touching the patient or pressing the skin lightly with a pin every hour. Move systematically from the iliac crest (T12) to the scapula, occasionally substituting the blunt end of the pin to test the patient's ability to discriminate between sharp and dull.

Mark the level of diminished sensation to measure any change. If diminished sensation ascends to T8 or higher, the patient's intercostal muscle function (and consequently respiratory function) will probably be impaired. As Guillain–Barré syndrome subsides, sensory and motor weakness descends to the lower thoracic segments, heralding a return of intercostal and extremity muscle function.

SEGMENTAL DISTRIBUTION OF SPINAL
NERVES TO BACK OF THE BODY


Key: T, thoracic segments.

Another common neurologic sign is paresthesia, which sometimes precedes muscle weakness but tends to vanish quickly. However, some patients with this disorder never develop this symptom. Other clinical features may include facial diplegia (possibly with ophthalmoplegia), dysphagia or dysarthria and, less commonly, weakness of the muscles supplied by cranial nerve XI. Muscle weakness develops so quickly that muscle atrophy doesn't occur, but hypotonia and areflexia do. Stiffness and pain in the form of a severe "charley horse" commonly occur.

The clinical course of Guillain–Barré syndrome is divided into three phases. The initial phase begins when the first definitive symptom appears and ends 1 to 3 weeks later, when no further deterioration manifests. The plateau phase lasts several days to 2 weeks and is followed by the recovery phase, which is believed to coincide with remyelination and axonal process regrowth. The recovery phase extends over a period of 4 to 6 months; patients with severe disease may take up to 2 years to recover, and recovery may not be complete.

Diagnosis

A history of febrile illness (usually a respiratory tract infection) and typical clinical features suggest Guillain–Barré syndrome.

Several days after onset of signs and symptoms, CSF protein levels begin to rise, peaking in 4 to 6 weeks, probably as a result of widespread inflammatory disease of the nerve roots. CSF white blood cell count remains normal, but in severe disease, CSF pressure may rise above normal. Probably because of predisposing infection, CBC shows leukocytosis and a shift to immature forms early in the illness, but blood studies soon return to normal. Electromyography may show repeated firing of the same motor unit instead of widespread sectional stimulation. Nerve conduction velocities are slowed soon after paralysis develops and show demyelination. Diagnosis must rule out similar diseases such as acute poliomyelitis.

Treatment

Treatment is primarily supportive, including such measures as endotracheal (ET) intubation or tracheotomy if the patient has difficulty clearing secretions. Preventing complications is another goal of treatment.

Plasmapheresis is useful in decreasing severity of symptoms, thereby facilitating a more rapid recovery. I.V. immune globulin is equally effective in reducing the severity and duration of symptoms.

Special Considerations

Monitoring the patient for escalation of symptoms is of special concern.

- Watch for ascending sensory loss, which precedes motor loss. Also, monitor vital signs and LOC.
- Assess and treat respiratory dysfunction. If respiratory muscles are weak, take serial vital capacity recordings. Use a respirometer with a mouthpiece or a face mask for bedside testing.
- Obtain ABG measurements. Because neuromuscular disease results in primary hypoventilation with hypoxemia and hypercapnia, watch for respiratory failure. Be alert to signs of rising partial pressure of carbon dioxide (such as confusion and tachypnea).
- Auscultate breath sounds, turn and position the patient, and encourage coughing and deep breathing. Begin respiratory support at the first sign of dyspnea or with decreasing partial pressure of arterial oxygen.
- If respiratory failure becomes imminent, establish an emergency airway with an ET tube.
- Give meticulous skin care to prevent skin breakdown and contractures. Establish a strict turning schedule; inspect the skin (especially sacrum, heels, and ankles) for breakdown, and reposition the patient every 2 hours. After each position change, stimulate circulation by carefully massaging pressure points. Also, use foam, gel, or alternating pressure pads at points of contact.
- Perform passive range-of-motion exercises within the patient's pain limits. When the patient's condition stabilizes, change to gentle stretching and active assistance exercises.
- To prevent aspiration, test the gag reflex, and elevate the head of the bed before giving the patient anything to eat. If the gag reflex is absent, give nasogastric feedings until this reflex returns. If the patient has severe paralysis and is expected to have a long recovery period, a gastrostomy tube may be necessary to provide adequate nourishment.
- As the patient regains strength and can tolerate a vertical position, be alert to postural hypotension. Monitor blood pressure and pulse during tilting periods and, if necessary, apply

- toe-to-groin elastic bandages to prevent postural hypotension.
- Inspect the patient's legs regularly for signs of thrombophlebitis (localized pain, tenderness, erythema, edema, and positive Homans sign), a common complication of Guillain–Barré syndrome. To prevent thrombophlebitis, apply antiembolism stockings and give prophylactic anticoagulants, as ordered.
- If the patient has facial paralysis, give eye and mouth care every 4 hours.
- Watch for urine retention. Measure and record intake and output every 8 hours, and offer the bedpan every 3 to 4 hours. Encourage adequate fluid intake of 2 qt (about 2 L) per day, unless contraindicated. If urine retention develops, begin intermittent catheterization as ordered. Because the abdominal muscles are weak, the patient may need manual pressure on the bladder (Credé method) before they can urinate.
- To prevent or relieve constipation, offer the patient plenty of water, prune juice, and a high-bulk diet. If necessary, give daily or alternate-day suppositories (glycerin or bisacodyl) or enemas, as ordered.
- Before discharge, prepare a home care plan. Teach the patient how to transfer from bed to wheelchair, from wheelchair to toilet or tub, and how to walk short distances with a walker or a cane. Teach the family how to help the patient eat, compensating for facial weakness, and how to help avoid skin breakdown. Stress the need for a regular bowel and bladder routine. Refer the patient for physical therapy as needed.
- Refer the patient's family to the Guillain–Barré Syndrome Foundation International.

Neuromuscular Disorders

MYASTHENIA GRAVIS

Myasthenia gravis produces sporadic but progressive weakness and abnormal fatigability of striated (skeletal) muscles, exacerbated by exercise and repeated movement, but improved by anticholinesterase drugs. Usually, this disorder affects muscles innervated by the cranial nerves (face, lips, tongue, neck, and throat), but it can affect any muscle group. Myasthenia gravis follows an unpredictable course of recurring exacerbations and periodic remissions. There's no known cure. Drug treatment has improved prognosis and allows patients to lead relatively normal lives except during exacerbations. When the disease involves the respiratory system, it may be life threatening.

Causes and Incidence

Myasthenia gravis causes a failure in transmission of nerve impulses at the neuromuscular junction. Theoretically, such impairment may result from an autoimmune response, ineffective acetylcholine release, or inadequate muscle fiber response to acetylcholine. (See *What happens in myasthenia gravis,* page 197.)

What Happens in Myasthenia Gravis

During normal neuromuscular transmission, a motor nerve impulse travels to a motor nerve terminal, stimulating the release of a chemical neurotransmitter called *acetylcholine*. When acetylcholine diffuses across the synapse, receptor sites in the motor end plate react and

depolarize the muscle fiber. The depolarization spreads through the muscle fiber, causing muscle contraction.

In myasthenia gravis, antibodies attach to the acetylcholine receptor sites. They block, destroy, and weaken these sites, leaving them insensitive to acetylcholine, thereby blocking neuromuscular transmission.

Myasthenia gravis affects 3 of every 10,000 people at any age, but it's more common in young women and older men. About 20% of neonates born to mothers with myasthenia gravis have transient (or occasionally persistent) myasthenia. This disease may coexist with immunologic and thyroid disorders; about 15% of patients with myasthenia gravis have thymomas. Remissions occur in about 25% of patients.

Pathophysiology

Myasthenia gravis is a breakdown of transmission across the neuromuscular junction. The site of action is the postsynaptic membrane. It is thought that receptor antibodies weaken or reduce the number of acetylcholine receptors at the neuromuscular junction reducing muscle depolarization.

Complications

◆ Respiratory distress
◆ Pneumonia

- ◆ Chewing and swallowing difficulties
- ◆ Aspiration

Signs and Symptoms

The dominant symptoms of myasthenia gravis are skeletal muscle weakness and fatigability. In the early stages, easy fatigability of certain muscles may appear with no other findings. Later, it may be severe enough to cause paralysis. Typically, myasthenic muscles are strongest in the morning but weaken throughout the day, especially after exercise. Short rest periods temporarily restore muscle function. Muscle weakness is progressive; more and more muscles become weak, and eventually some muscles may lose function entirely. Resulting symptoms depend on the muscle group affected; they become more intense during menses and after emotional stress, prolonged exposure to sunlight or cold, or infections.

Onset may be sudden or insidious. In many patients, weak eye closure, ptosis, and diplopia are the first signs that something is wrong. Patients with myasthenia gravis usually have blank, expressionless faces and nasal vocal tones. They experience frequent nasal regurgitation of fluids and have difficulty chewing and swallowing. Because of this, they usually worry about choking. Their eyelids droop (ptosis), and they may have to tilt their heads back to see. Their neck muscles may become too weak to support their heads without bobbing.

In patients with weakened respiratory muscles, decreased tidal volume and vital capacity make breathing difficult and predispose to pneumonia and other respiratory tract infections. Respiratory muscle weakness (myasthenic crisis) may be severe enough to require an emergency airway and mechanical ventilation.

Diagnosis

Repeated muscle use over a very short time that fatigues and then improves with rest suggests a diagnosis of myasthenia gravis. Tests for this neurologic condition record the effect of exercise and subsequent rest on muscle weakness. Electromyography, with repeated neural stimulation, may help confirm this diagnosis. Acetylcholine receptor antibodies may be present in the blood.

CONFIRMING DIAGNOSIS *The classic proof of myasthenia gravis is improved muscle function after an I.V. injection of edrophonium or neostigmine (anticholinesterase drugs).*

In patients with myasthenia gravis, muscle function improves within 30 to 60 seconds and lasts up to 30 minutes. Long-standing ocular muscle dysfunction may fail to respond to such testing. This test can differentiate a myasthenic crisis from a cholinergic crisis (caused by acetylcholine overactivity at the neuromuscular junction). The acetylcholine receptor antibody titer may be elevated in generalized myasthenia. Evaluation should rule out thyroid disease and thymoma.

Treatment

Treatment is symptomatic. Anticholinesterase drugs, such as neostigmine and pyridostigmine, counteract fatigue and muscle weakness and allow about 80% of normal muscle function. However, these drugs become less effective as the disease worsens. Corticosteroids may relieve symptoms. Immunosuppressants are also used. Plasmapheresis is used in severe myasthenic exacerbation.

Patients with thymomas require thymectomy, which may cause remission in some cases of

adult-onset myasthenia. Acute exacerbations that cause severe respiratory distress necessitate emergency treatment. Tracheotomy, positive-pressure ventilation, and vigorous suctioning to remove secretions usually produce improvement in a few days. Because anticholinesterase drugs aren't effective in myasthenic crisis, they're stopped until respiratory function improves. Myasthenic crisis requires immediate hospitalization and vigorous respiratory support.

Special Considerations

Careful baseline assessment, early recognition and treatment of potential crises, supportive measures, and thorough patient teaching can minimize exacerbations and complications. Continuity of care is essential.

- Establish an accurate neurologic and respiratory baseline. Thereafter, monitor tidal volume and vital capacity regularly. The patient may need a ventilator and frequent suctioning to remove accumulating secretions.
- Be alert to signs of an impending crisis (increased muscle weakness, respiratory distress, and difficulty in talking or chewing).
- To prevent relapses, adhere closely to the ordered drug administration schedule. Be prepared to give atropine for anticholinesterase overdose or toxicity.
- Plan exercise, meals, patient care, and activities to make the most of energy peaks. For example, give medication 20 to 30 minutes before meals to facilitate chewing or swallowing. Allow the patient to participate in care.
- When swallowing is difficult, give soft, solid foods instead of liquids to lessen the risk of choking.
- Patient teaching is essential because myasthenia gravis is usually a lifelong condition. Help the patient plan daily activities to coincide with energy peaks. Stress the need for frequent rest periods throughout the day. Emphasize that periodic remissions, exacerbations, and day-to-day fluctuations are common.
- Teach the patient how to recognize adverse effects and signs of toxicity of anticholinesterase drugs (headaches, weakness, sweating, abdominal cramps, nausea, vomiting, diarrhea, excessive salivation, and bronchospasm) and corticosteroids (euphoria, insomnia, edema, and increased appetite).
- Warn the patient to avoid strenuous exercise, stress, infection, and needless exposure to the sun or cold. All of these things may worsen signs and symptoms.
- For more information and an opportunity to meet other myasthenia gravis patients who lead full, productive lives, refer the patient to the Myasthenia Gravis Foundation.

AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS), also called *Lou Gehrig disease*, is the most common of the motor neuron diseases that cause muscle atrophy. (See *Motor neuron disease,* page 199.) Other motor neuron diseases include progressive muscular atrophy and progressive bulbar palsy. A chronic, progressively debilitating disease, ALS may be fatal in less than 1 year or may continue for 10 years or more, depending on the muscles it affects.

Motor Neuron Disease

In its final stages, motor neuron disease affects both upper and lower motor neuron cells.

However, the site of initial cell damage varies according to the specific disease:

- *progressive bulbar palsy:* degeneration of upper motor neurons in the medulla oblongata
- *progressive muscular atrophy:* degeneration of lower motor neurons in the spinal cord
- *amyotrophic lateral sclerosis:* degeneration of upper motor neurons in the medulla oblongata and lower motor neurons in the spinal cord.

Causes and Incidence

ALS affects about 1 of 100,000 people. The exact cause of ALS is unknown, but about 10% of cases have a genetic component. In these patients, it's an autosomal dominant trait and affects men and women equally.

Other than a family member affected with the hereditary form, there are no known risk factors.

Pathophysiology

The principle feature in ALS is the loss of both upper and lower motor neurons. Loss of the motor neurons results in axonal degeneration and secondary demyelination with glial proliferation and sclerosis.

Complications

- Pneumonia
- Aspiration
- Pressure ulcers
- Contractures

Signs and Symptoms

Progressive loss of muscle strength and coordination eventually interfere with everyday activities. Patients with ALS develop fasciculations, accompanied by atrophy and weakness, especially in the muscles of the feet and the hands. Other signs include impaired speech; difficulty chewing, swallowing, and breathing; and, occasionally, choking and excessive drooling. Mental deterioration doesn't occur, but patients may become depressed as a reaction to the disease.

Diagnosis

Characteristic clinical features indicate a combination of upper and lower motor neuron involvement without sensory impairment. Electromyography and muscle biopsy indicate that the motor nerves aren't functioning, yet sensory nerves are normal. CT scan and MRI may help rule out other conditions, such as MS, spinal cord neoplasm, CNS syphilis, polyarteritis, syringomyelia, myasthenia gravis, progressive muscular dystrophy, and progressive strokes.

Treatment

Management aims to control symptoms and provide emotional, psychological, and physical support. Riluzole may increase quality of life and survival but doesn't reverse or stop disease progression.

Baclofen or diazepam helps control spasticity that interferes with activities of daily living. Trihexyphenidyl or amitriptyline may be used for impaired ability to swallow saliva. Gastrostomy may be needed early to prevent choking; referral to an otolaryngologist is advised.

Physical therapy, rehabilitation, and use of appliances or orthopedic intervention may be required to maximize function. Devices to assist in breathing at night or mechanical ventilation should be discussed, but the patient's wishes should be respected.

Special Considerations

Because mental status remains intact while progressive physical degeneration takes place, the patient acutely perceives every change. This threatens the patient's relationships, career, income, muscle coordination, sexuality, and energy.

- Implement a rehabilitation program designed to maintain independence for as long as possible.
- Help the patient obtain assistive equipment, such as a walker and a wheelchair. Arrange for a visiting nurse to oversee the patient's status, to provide support, and to teach the family about the illness.
- Depending on the patient's muscular capacity, assist with bathing, personal hygiene, and transfers from wheelchair to bed. Help establish a regular bowel and bladder routine.
- To help the patient handle increased accumulation of secretions and dysphagia, teach them how to perform self-suction. He should have a suction machine handy at home to reduce the fear of choking.
- To prevent skin breakdown, provide good skin care when the patient is bedridden. Turn the patient often, keep skin clean and dry, and use pressure-reducing devices such as alternating air mattress.
- If the patient has trouble swallowing, give soft, solid foods and position upright during meals. Gastrostomy and nasogastric tube feedings may be necessary if the patient can no longer swallow. Teach the patient (if still able to feed self) or family how to administer gastrostomy feedings.
- Provide emotional support. A discussion of directives regarding healthcare decisions should be instituted before the patient becomes unable to communicate his or her wishes. Prepare the patient and family members for eventual death, and encourage the start of the grieving process. Patients with ALS may benefit from a hospice program or the local ALS support group chapter.

MULTIPLE SCLEROSIS

MS is a progressive disease caused by demyelination of the white matter of the brain and spinal cord. (See *Understanding myelin breakdown*, page 201.) In this disease, sporadic patches of demyelination throughout the CNS induce widely disseminated and varied neurologic dysfunction. Characterized by exacerbations and remissions, MS is a major cause of chronic disability in young adults.

Understanding Myelin Breakdown

Myelin plays a key role in speeding electrical impulses to the brain for interpretation. The myelin sheath is a lipoprotein complex formed of glial cells. It protects the neuron's long nerve fiber (axon) much like the insulation on an electrical wire. Because of its high electrical resistance and weak ability to store an electrical charge, the myelin sheath permits conduction of nerve impulses from one node of Ranvier to the next.

Effects of Injury

Myelin can be injured by hypoxemia, toxic chemicals, vascular insufficiency, or autoimmune responses. When this occurs, the myelin sheath becomes inflamed and the membrane layers break down into smaller components. These components become well-circumscribed plaques filled with microglial elements, macroglia, and lymphocytes. This process is called *demyelination*.

The damaged myelin sheath impairs normal conduction, causing partial loss or dispersion of the action potential and consequent neurologic dysfunction.

Dendrites

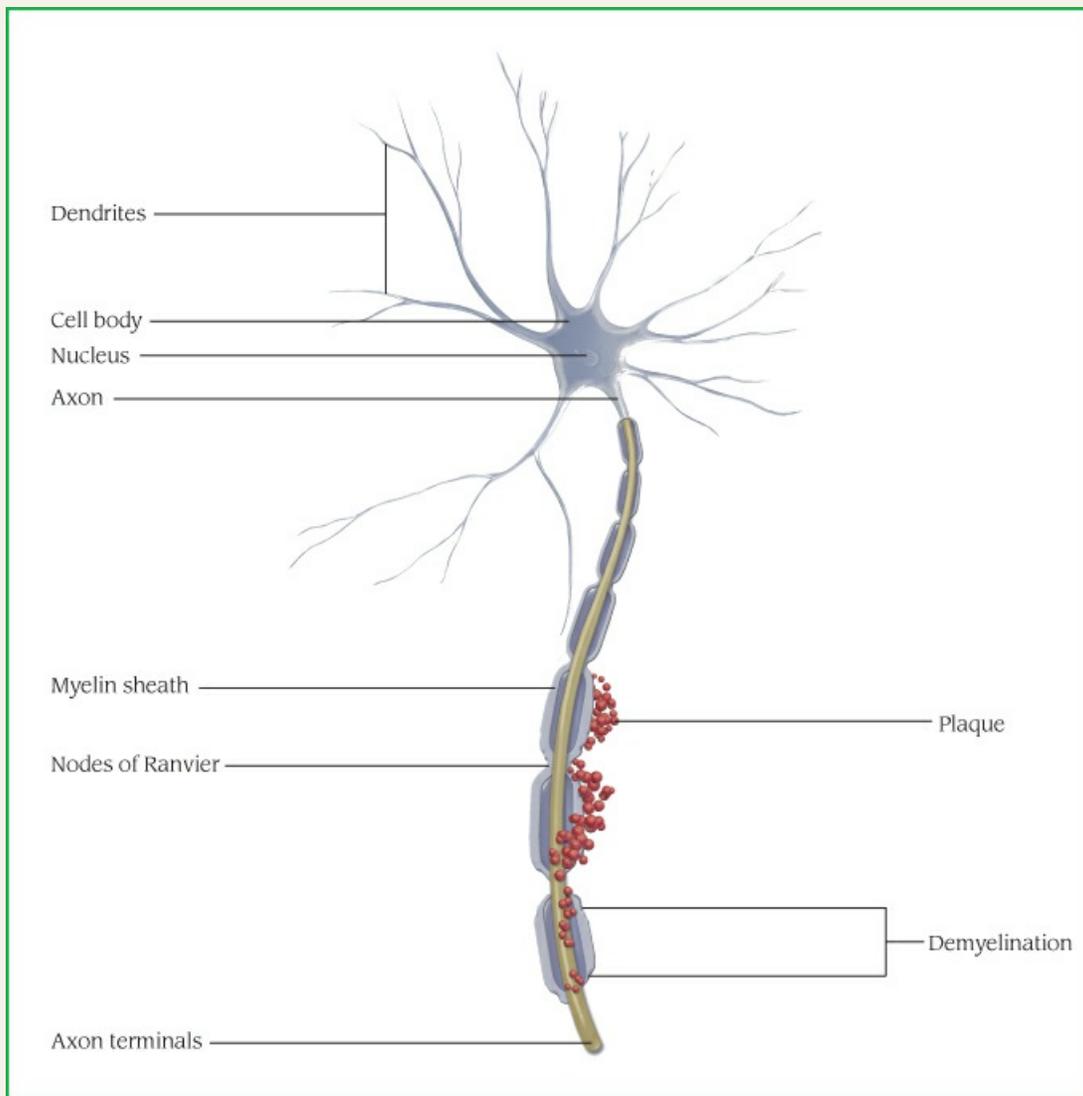
Cell body
Nucleus
Axon

Myelin sheath

Plaque

Nodes of Ranvier

Demyelination

Axon terminals


The prognosis varies; MS may progress rapidly, disabling some patients by early adulthood or causing death within months of onset. However, 70% of patients lead active, productive lives with prolonged remissions.

Causes and Incidence

The exact cause of MS is unknown, but current theories suggest a slow-acting or latent viral infection and an autoimmune response. Other theories suggest that environmental and genetic factors may also be linked to MS. Emotional stress, overwork, fatigue, pregnancy, and acute respiratory tract infections have been known to precede the onset of this illness.

MS usually begins between 20 and 40 years old. It affects more women than men. A family history of MS and living in a geographical area with a higher incidence of MS (northern Europe, northern United States, southern Australia, and New Zealand) increase the risk.

Pathophysiology

There is sporadic patchy axon demyelination and nerve fiber loss throughout the CNS. Loss of the myelin sheath disrupts nerve conduction with subsequent neuronal death and atrophy.

Complications

- Injuries from falls
- Urinary tract infections
- Constipation
- Joint contractures
- Pressure ulcers
- Rectal distention
- Pneumonia

Signs and Symptoms

Clinical findings in MS depend on the extent and site of myelin destruction, the extent of remyelination, and the adequacy of subsequent restored synaptic transmission.

Signs and symptoms in MS may be transient, or they may last for hours or weeks. They may wax and wane with no predictable pattern, vary from day to day, and be bizarre and difficult for the patient to describe.

In most patients, visual problems and sensory impairment, such as numbness and tingling sensations (paresthesia), are the first signs that something may be wrong.

Other characteristic changes include:

- *ocular disturbances*—optic neuritis, diplopia, ophthalmoplegia, blurred vision, and nystagmus
- *muscle dysfunction*—weakness, paralysis ranging from monoplegia to quadriplegia, spasticity, hyperreflexia, intention tremor, and gait ataxia
- *urinary disturbances*—incontinence, frequency, urgency, and frequent infections
- *emotional lability*—characteristic mood swings, irritability, euphoria, and depression.

Associated signs and symptoms include poorly articulated or scanning speech and dysphagia. Clinical effects may be so mild that the patient is unaware of them or so bizarre that they appear hysterical.

Diagnosis

A misdiagnosis of psychiatric problems is common. Because early symptoms may be mild, years may elapse between onset of the first signs and the diagnosis, which typically requires evidence of multiple neurologic attacks and characteristic remissions and exacerbations. MRI may detect MS lesions; however, diagnosis still remains difficult. Periodic testing and close observation of the patient are necessary, perhaps for years, depending on the course of the disease.

Abnormal EEG findings occur in one third of patients. Lumbar puncture shows elevated gamma globulin fraction of immunoglobulin G but normal total CSF protein levels. Elevated CSF gamma globulin is significant only when serum gamma globulin levels are normal because it reflects hyperactivity of the immune system due to chronic demyelination. Oligoclonal bands of immunoglobulin can be detected when gamma globulin in CSF is examined by electrophoresis, and these bands are present in most patients, even when the percentage of gamma globulin in CSF is normal. In addition, the white blood cell count in CSF may rise. Differential diagnosis must rule out spinal cord compression, foramen magnum tumor (may mimic the exacerbations and remissions of MS), multiple small strokes, syphilis or other infection, and psychological disturbances.

Treatment

The aim of treatment is to shorten exacerbations and relieve neurologic deficits so that the patient can resume a normal lifestyle. Those with relapsing–remitting courses are placed on immune modulating therapy, with interferon or glatiramer acetate. Steroids are used to reduce the associated edema of the myelin sheath during exacerbations.

Other drugs include baclofen, tizanidine, or diazepam to relieve spasticity; cholinergic agents to relieve urine retention and minimize frequency and urgency; amantadine to relieve fatigue; and antidepressants to help with mood or behavioral symptoms. During acute exacerbations, supportive measures include bed rest, comfort measures such as massages, prevention of fatigue, prevention of pressure ulcers, bowel and bladder training (if necessary), administration of antibiotics for bladder infections, physical therapy, and counseling. Physical therapy, speech therapy, occupational therapy, and support groups are also useful. Planned exercise programs help with maintaining muscle tone.

Special Considerations

Management considerations focus on educating the patient and family.

- Assist with physical therapy. Increase patient comfort with massages and relaxing baths. Assist with active, resistive, and stretching exercises to maintain muscle tone and joint mobility, decrease spasticity, improve coordination, and boost morale.
- Educate the patient and family concerning the chronic course of MS. Emphasize the need to avoid temperature extremes, stress, fatigue, and infections and other illnesses, all of which can trigger an MS attack. Advise the patient to maintain independence by developing new ways of performing daily activities.
- Stress the importance of eating a nutritious, well-balanced diet that contains sufficient roughage and adequate fluids to prevent constipation.
- Evaluate the need for bowel and bladder training during hospitalization. Encourage adequate fluid intake and regular urination. Eventually, the patient may require urinary drainage by self-catheterization or, in men, condom drainage. Teach the correct use of suppositories to help establish a regular bowel schedule.
- Promote emotional stability. Help the patient establish a daily routine to maintain optimal functioning. Activity level is regulated by tolerance level. Encourage regular rest periods to prevent fatigue and daily physical exercise.
- Inform the patient that exacerbations are unpredictable, necessitating physical and emotional adjustments in lifestyle.
- For more information, refer the patient to the National Multiple Sclerosis Society.

Cranial Nerve Disorders

TRIGEMINAL NEURALGIA

Trigeminal neuralgia, also called *tic douloureux*, is a painful disorder of one or more branches of the fifth cranial (trigeminal) nerve that produces paroxysmal attacks of excruciating facial pain precipitated by stimulation of a trigger zone. It can subside spontaneously, and remissions may last from several months to years.

Causes and Incidence

Although the cause remains undetermined, trigeminal neuralgia may reflect an afferent reflex in the brainstem or in the sensory root of the trigeminal nerve. Such neuralgia may also be related to compression of the nerve root by posterior fossa tumors, middle fossa tumors, or vascular lesions (subclinical aneurysm), although such lesions usually produce simultaneous loss of sensation. Occasionally, trigeminal neuralgia is a manifestation of MS or herpes zoster. Regardless of the cause, the pain of trigeminal neuralgia is probably produced by an interaction or short-circuiting of touch and pain fibers.

Trigeminal neuralgia occurs mostly in people older than 40, in women more commonly than in men, and on the right side of the face more commonly than on the left. The incidence is 4 to 5 cases per 100,000 people.

Pathophysiology

The exact pathophysiology of trigeminal neuralgia is controversial. It can be either centrally mediated or peripherally mediated. The trigeminal nerve itself can cause the pain as its major function is sensory. There is also a belief that the pain is mediated by vascular compression of the nerve but in 85% of people there is no structural lesion. Microanatomic small and large fiber demyelination is often seen at the root entry zone. There is a lack of inhibitory inputs and a re-entry mechanism causes an amplification of sensory inputs.

Complications

- Double vision
- Jaw weakness
- Loss of corneal reflex
- Malnutrition
- Numbness of face

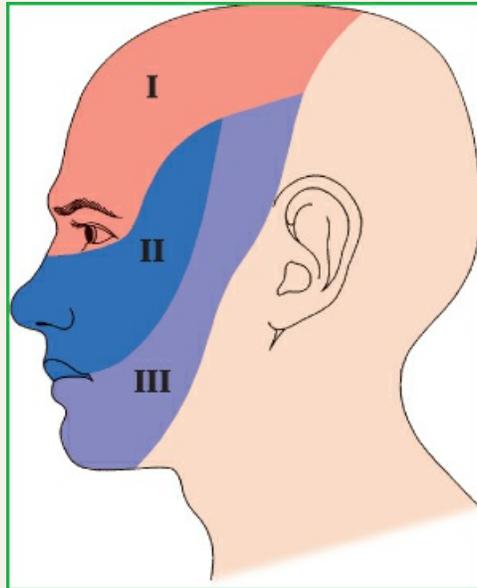
Signs and Symptoms

Typically, the patient reports a searing or burning pain that occurs in lightning like jabs and lasts from 1 to 15 minutes (usually 1 to 2 minutes) in an area innervated by one of the divisions of the trigeminal nerve, primarily the superior mandibular or maxillary division. The pain rarely affects more than one division and seldom the first division (ophthalmic) or both sides of the face. It affects the second (maxillary) and third (mandibular) divisions of the trigeminal nerve equally. (See *Trigeminal nerve function and distribution*.)

Trigeminal Nerve Function and Distribution

- Motor: chewing movements
- Sensory: sensations of face, scalp, and teeth (mouth and nasal chamber)

Distribution

1. Ophthalmic
2. Maxillary
3. Mandibular


These attacks characteristically follow stimulation of a trigger zone, usually by a light touch to a hypersensitive area, such as the tip of the nose, the cheeks, or the gums. Although attacks can occur at any time, they may follow a draft of air, exposure to heat or cold, eating, smiling, talking, or drinking hot or cold beverages. The frequency of attacks varies greatly, from many times a day to several times a month or year. Between attacks, most patients are free from pain, although some have a constant, dull ache. No patient is ever free from the fear of the next attack.

Diagnosis

The patient's pain history is the basis for diagnosis because trigeminal neuralgia produces no objective clinical or pathologic changes. Physical examination shows no impairment of sensory or motor function; indeed, sensory impairment implies a space-occupying lesion as the cause of pain.

Observation during the examination shows the patient favoring (splinting) the affected area. To ward off a painful attack, the patient commonly holds the face immobile when talking. The patient may also leave the affected side of the face unwashed and unshaven or protect it with a coat or shawl. When asked where the pain occurs, the patient points to—but never touches—the affected area. Witnessing a typical attack helps to confirm diagnosis. Rarely, a tumor in the posterior fossa can produce pain that's clinically indistinguishable from trigeminal neuralgia.

Skull X-rays, CT scan, and MRI rule out sinus or tooth infections and tumors. If the patient has trigeminal neuralgia, these test results are normal.

Treatment

Oral administration of carbamazepine (Tegretol), gabapentin (Neurontin), or phenytoin may temporarily relieve or prevent pain. Opioids are of little help during the pain episode. Caution should be used when treating a chronic problem with opioids.

When these medical measures fail or attacks become increasingly frequent or severe, neurosurgical procedures may provide permanent relief. The preferred procedure is percutaneous electrocoagulation of nerve rootlets under a local anesthetic. Other treatments include a percutaneous radio frequency procedure, which causes partial root destruction and relieves pain, and microsurgery for vascular decompression of the trigeminal nerve. Gamma knife radiosurgery, the least invasive procedure, can be done for patients refractory to medications or patients who have multiple medical comorbidities.

Special Considerations

The focus here is management of pain.

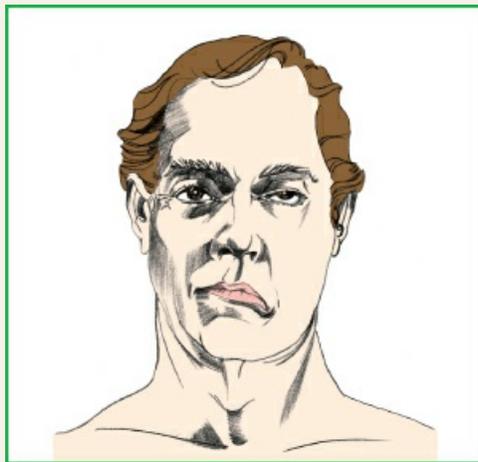
- Observe and record the characteristics of each attack, including the patient's protective mechanisms.
- Provide adequate nutrition in small, frequent meals served at room temperature.
- Avoid jarring the bed and causing increased discomfort.
- If the patient is receiving neuroleptics, watch for cutaneous and hematologic reactions (erythematous and pruritic rashes, urticaria, photosensitivity, exfoliative dermatitis, leukopenia, agranulocytosis, eosinophilia, aplastic anemia, and thrombocytopenia) and, possibly, urine retention and transient drowsiness. For the first 3 months of therapy, monitor CBC and liver function weekly, then monthly thereafter. Warn the patient to immediately report fever, sore throat, mouth ulcers, easy bruising, or petechial or purpuric hemorrhage because these may signal thrombocytopenia or aplastic anemia and may require discontinuation of drug therapy.
- If the patient is receiving phenytoin, also watch for adverse effects, including ataxia, skin eruptions, gingival hyperplasia, and nystagmus.
- After resection of the first branch of the trigeminal nerve, tell the patient to avoid rubbing their eyes and using aerosol spray. Advise the patient to wear glasses or goggles outdoors and to blink often.
- After surgery to sever the second or third branch, tell the patient to avoid hot foods and drinks, which could burn the mouth, and to chew carefully to avoid biting the mouth. The patient may need to eat pureed food, possibly through a straw. Advise the patient to place food in the unaffected side of the mouth when chewing, to brush teeth and rinse the mouth often, and to see the dentist twice a year to detect cavities because they won't experience pain from cavities in the area of the severed nerve.
- After surgical decompression of the root or partial nerve dissection, check neurologic and vital signs often.
- Provide emotional support, and encourage the patient to express their feelings. Promote independence through self-care and maximum physical activity. Reinforce natural avoidance of stimulation (air, heat, and cold) of trigger zones (lips, cheeks, and gums).

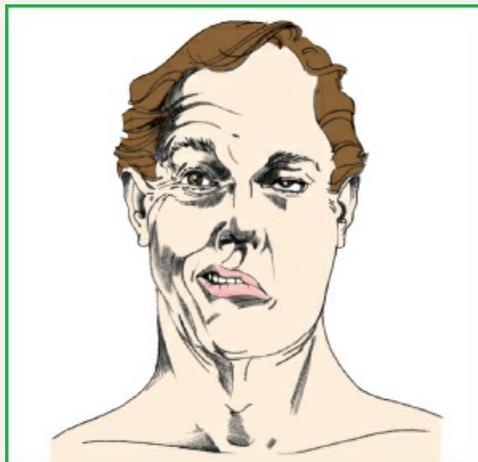
BELL PALSY

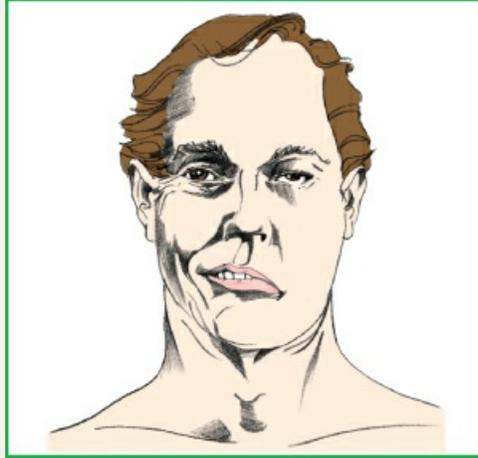
Bell palsy is a disease of the seventh cranial nerve (facial) that produces unilateral or bilateral facial weakness or paralysis. (See *Recognizing unilateral Bell palsy*.) Onset is rapid. In 80% to 90% of patients, Bell palsy subsides spontaneously, with complete recovery in 1 to 8 weeks; however, recovery may be delayed in the elderly. If recovery is partial, contractures may develop on the paralyzed side of the face. Bell palsy may recur on the same or opposite side of the face.

Recognizing Unilateral Bell Palsy

Bell palsy usually causes a unilateral facial paralysis. This produces a distorted appearance with an inability to wrinkle the forehead, close the eyelid, smile, show the teeth, or puff out the cheek.

Distorted appearance


Wrinkling the forehead


Smiling


Causes and incidence

Bell palsy blocks the seventh cranial nerve, which is responsible for motor innervation of the muscles of the face. The conduction block is from an inflammatory reaction around the nerve (usually at the internal auditory meatus), which may result from infection, hemorrhage, tumor, meningitis, local trauma, hypertension, sarcoidosis, Lyme disease, or infarction of the nerve.

Bell palsy affects all age groups and males and females nearly equally, although females are slightly more likely to develop it during their late teens and early 20s. In the United States, the incidence is 23 cases per 100,000 people.

Pathophysiology

Bell palsy is thought to occur related to inflammation of the seventh cranial nerve; pressure is produced where the nerve exits the skull through a bony foramen blocking the transmission of the nerve impulse.

Complications

- Corneal ulcers
- Blindness
- Impaired nutrition

Signs and symptoms

Bell palsy usually produces unilateral facial weakness, occasionally with aching pain around the angle of the jaw or behind the ear. On the weak side, the mouth droops (causing the patient to drool saliva from the corner of the mouth), and taste perception is distorted over the affected anterior portion of the tongue. The forehead appears smooth, and the patient's ability to close his eye on the weak side is markedly impaired. When the patient tries to close this eye, it rolls upward (Bell phenomenon) and shows excessive tearing. Although Bell phenomenon occurs in normal people, it isn't apparent because the eyelids close completely and cover this eye motion. In Bell palsy, incomplete eye closure makes this upward motion obvious. Other symptoms may include loss of taste and ringing in the ear.

Diagnosis

Diagnosis is based on clinical presentation: distorted facial appearance and the inability to raise the eyebrow, close the eyelid, smile, show the teeth, or puff out the cheek. Electromyography helps determine the severity of nerve damage. Blood tests may be done to rule out acute causes (sarcoidosis or Lyme disease). If no improvement is evident within several weeks of onset, MRI will rule out other causes of dysfunction.

Treatment

Treatment consists of corticosteroids to reduce facial nerve edema and improve nerve conduction and blood flow. They must be given early—within 24 hours of onset of paralysis—to be most effective. Lubricants or an eye ointment may be needed to protect the eye, as well as patching during sleep.

Special considerations

Patient care includes observation for adverse drug effects, pain relief, and emotional support.

- During treatment with corticosteroids, watch for adverse effects, such as GI distress and fluid retention. If GI distress is troublesome, a concomitant antacid usually provides relief. If the patient has diabetes, frequent monitoring of serum glucose levels is necessary.
- To reduce pain, apply moist heat to the affected side of the face, taking care not to burn the skin.
- To help maintain muscle tone, massage the patient's face with a gentle upward motion two to three times daily for 5 to 10 minutes, or have the patient massage the face himself. When the patient is ready for active exercises, teach how to exercise by grimacing in front of a mirror.
- Advise the patient to protect the eye by covering it with an eye patch, especially when outdoors. Tell the patient to keep warm and avoid exposure to dust and wind. When exposure is unavoidable, instruct the patient to cover the face.
- Instruct the patient to chew on the unaffected side of the mouth. Provide a soft, nutritionally balanced diet, eliminating hot foods and fluids. Give the patient frequent mouth care, being particularly careful to remove residual food that collects between the cheeks and gums.
- Offer psychological support.

PERIPHERAL NEURITIS

Peripheral neuritis (also called *multiple neuritis*, *peripheral neuropathy*, and *polyneuritis*) is the degeneration of peripheral nerves supplying mainly the distal muscles of the extremities. It results in muscle weakness with sensory loss and atrophy and decreased or absent deep tendon reflexes. This syndrome is associated with a noninflammatory degeneration of the axon and myelin sheaths, chiefly affecting the distal muscles of the extremities. Because onset is usually insidious, patients may compensate by overusing unaffected muscles. If the cause can be identified and eliminated, the prognosis is good.

Causes and incidence

Causes of peripheral neuritis include:

- hereditary disorders (Charcot–Marie–Tooth disease or Friedreich ataxia)
- exposure to toxic compounds (sniffing glue or toxic compounds, nitrous oxide, industrial agents—especially solvents, and heavy metals, such as lead, arsenic, or mercury)
- infectious or inflammatory diseases (acquired immunodeficiency syndrome, botulism,

Colorado tick fever, hepatitis, human immunodeficiency virus infection, leprosy, rheumatoid arthritis, sarcoidosis, systemic lupus erythematosus, diphtheria, syphilis, and Guillain–Barré syndrome)
- systemic or metabolic disorders (diabetes mellitus, dietary deficiencies [especially B_{12}], excessive use of alcohol, uremia, and cancer)
- neuropathy secondary to drugs
- miscellaneous causes (ischemia and prolonged exposure to cold temperature).

Peripheral neuropathy is common. Risk factors include diabetes, heavy alcohol use, and exposure to certain drugs and chemicals. Prolonged pressure on a nerve (such as with a cast, splint, or other device) is also a risk factor for developing nerve injury. Although it can occur at any age, incidence is highest in men between 30 and 50 years old.

Pathophysiology

The pathophysiology of peripheral neuritis is unclear. However, evidence suggests that the manifestation is related to an increased number of sodium channels or an abnormal sodium channel subtype in the injured nerve—creating abnormal nerve activity.

Complications

- Impotence
- Difficulty breathing
- Dysphagia

Signs and symptoms

The clinical effects of peripheral neuritis develop slowly, and the disease usually affects the motor and sensory nerve fibers. Symptoms vary according to which type of nerve is affected (sensory, motor, or autonomic). Neuropathy can affect any one or be a combination of all three types.

- *Sensory changes:* Damage to sensory fibers results in changes in sensation, ranging from abnormal sensations, such as burning, nerve pain, or tingling, to numbness or an inability to determine joint position in the area. Sensation changes often begin in the feet and progress toward the center of the body with involvement of other areas as the condition worsens.
- *Motor changes:* Damage to the motor fibers interferes with muscle control and can cause weakness, loss of muscle bulk, and loss of dexterity. Muscle cramping may be a sign of motor nerve involvement. Other muscle-related symptoms include lack of muscle control, difficulty or inability to move a part of the body (paralysis), muscle atrophy, muscle twitching (fasciculation) or cramping, difficulty breathing or swallowing, falling (from legs buckling or tripping over toes), or lack of dexterity (such as the inability to button a shirt).
- *Autonomic changes:* The autonomic nerves control involuntary or semi-voluntary functions, such as control of internal organs and blood pressure. Damage to autonomic nerves can cause blurred vision, decreased ability to sweat (anhidrosis), dizziness that occurs when standing up or fainting associated with a fall in blood pressure, heat intolerance with exertion (decreased ability to regulate body temperature), nausea or vomiting after meals, abdominal bloating (swelling), feeling full after eating a small amount (early satiety), diarrhea, constipation, unintentional weight loss (more than 5% of body weight), urinary incontinence, feeling of incomplete bladder emptying, difficulty beginning to urinate (urinary hesitancy), and male

impotence.

Diagnosis

Patient history and physical examination delineate characteristic distribution of motor and sensory deficits. Electromyography may show a delayed action potential if this condition impairs motor nerve function. Nerve biopsy and nerve conduction tests can facilitate diagnosis.

Treatment

Effective treatment of peripheral neuritis consists of supportive measures to relieve pain, adequate bed rest, and physical therapy, vocational therapy, occupational therapy, and orthopedic interventions to promote independence, as needed. Most importantly, however, the underlying cause must be identified and corrected. For instance, it's essential to identify and remove the toxic agent, correct nutritional and vitamin deficiencies (the patient needs a high-calorie diet rich in vitamins, especially B-complex), and counsel the patient to avoid alcohol.

Over-the-counter analgesics or prescription pain medications may be needed to control nerve pain. Anticonvulsants (phenytoin, carbamazepine, and gabapentin) or tricyclic antidepressants may be used to reduce the stabbing pains that some patients experience. Whenever possible, medication use should be minimized to avoid adverse effects.

Fludrocortisone or similar medications may be beneficial in reducing postural hypotension for some patients. Medications that increase gastric motility, such as metoclopramide, are helpful for patients with reduced gastric motility.

For patients with bladder dysfunction, manual expression of urine (pressing over the bladder with the hands), intermittent catheterization, or medications such as bethanechol may be necessary.

Special considerations

Patient care includes promoting maximal independence and control of symptoms.

- Exercises and retraining may be used to increase muscle strength and control. Appliances, such as wheelchairs, braces, and splints, may improve mobility or the ability to use an affected extremity.
- The patient with decreased sensation should be taught to check feet or other affected areas frequently for bruises, open skin areas, or other injuries. A podiatrist can usually determine whether special orthotic devices are needed.
- Discuss safety measures in the home. Safety measures for the patient experiencing difficulty with movement may include railings, specialized appliances, removal of obstacles (such as loose rugs that may slip on the floor), and other measures, as appropriate. Safety measures for the patient with diminished sensation include adequate lighting (including lights left on at night), testing water temperature before bathing or immersing the body in water, and the use of protective shoes (no open toes and no high heels). Shoes should be checked often for grit or rough spots that may cause injury to the feet.
- The patient with neuropathy (especially the patient with polyneuropathy or mononeuropathy multiplex) is prone to new nerve injury at pressure points, such as the knees and elbows. Caution the patient to avoid prolonged pressure on these areas from leaning on the elbows, crossing the knees, or similar positions.
- Advise the patient with orthostatic hypotension to use elastic stockings and sleep with the head elevated.

- Instruct the patient with reduced gastric motility to eat small, frequent meals and sleep with the head elevated.
- Assist the patient with bladder dysfunction with manual expression of urine and intermittent catheterization, as necessary.
- To prevent pressure ulcers, assist in turning and repositioning every 2 hours and apply a food cradle. To prevent contractures, provide range-of-motion exercises as well as arrange for the patient to obtain splints, boards, braces, or other orthopedic appliances.
- Suggest that the patient's family contact the Neuropathy Association for additional information.

Pain disorders

COMPLEX REGIONAL PAIN SYNDROME

Complex regional pain syndrome (CRPS), also known as *reflex sympathetic dystrophy* (CRPS1) or *causalgia* (CRPS2), is a chronic pain disorder that results from abnormal healing after an injury—either minor or major—to a bone, muscle, or nerve. The development of symptoms is commonly disproportionate to the severity of the injury and seems to result from abnormal functioning of the sympathetic nervous system, the part of the nervous system that controls the diameter of blood vessels. One or more limbs and other parts of the body may be affected.

Causes and incidence

The exact cause of CRPS is unknown. Impaired communication between the damaged nerves of the sympathetic nervous system and the brain may cause interference with normal signals for sensations, temperature, and blood flow. This leads to problems in the nerves, blood vessels, skin, bones, and muscles. Infection or injury to an arm or leg may initiate CRPS. It can also occur after heart attacks and strokes. However, the condition can sometimes appear without obvious injury to the affected limb. This condition is more common in people between 40 and 60 years old but has been seen in younger people too. CRPS may also be seen in postoperative patients and in patients with diseases that can cause chronic pain, such as cancer and arthritis. The annual incidence is unknown because CRPS is often misdiagnosed. However, it has been reported in 1% to 2% of patients with various fractures and in 2% to 5% of patients with peripheral nerve injury.

Pathophysiology

The exact mechanism of CRPS is not well understood. Research suggests that it is multifactorial involving both sympathetic and central fibers, resulting in peripheral and central sensitization, inflammation and altered sympathetic and catecholinergic function and psychophysiologic functions.

Complications

- Depression
- Drug dependence

Signs and symptoms

Patients usually report severe and constant pain; severe pain is common with CRPS2 in particular. The affected area may have altered blood flow, feeling either warm or cool to the touch, with discoloration, sweating, or swelling. In time, skin, hair, and nail changes may occur along with impaired mobility and muscle wasting, especially if adequate treatment is delayed.

Diagnosis

There's no laboratory test for CRPS, so the diagnosis is based on the patient's history and clinical findings. A history of injury to an extremity may point to CRPS. Bone X-rays may aid in ruling out other conditions, such as osteomyelitis and stress fractures, which cause similar signs and symptoms. Additional tests may include bone scans, nerve conduction studies, and thermography (a test to show temperature changes and lack of blood supply in the painful area of the affected limb). With early diagnosis, prognosis improves.

Treatment

Treatment typically includes a combination of therapies such as drug therapy, with an anti-inflammatory, antidepressant, vasodilator, and analgesic used singly or in varying combinations, depending on the patient and the severity of symptoms. Steroids may be given in some patients; others may be given bone loss medications such as Actonel. Physical therapy to the injured area, application of heat and cold, the use of a transcutaneous electrical nerve stimulator unit, biofeedback, and psychological support are helpful for some patients.

Treatment may also include techniques for interrupting the hyperactivity of the sympathetic nervous system, such as nerve or regional blocks. Surgical sympathectomy—radical surgery that involves cutting the nerves to destroy the pain—may be done in severe cases; however, this method is rarely used because other sensation may be destroyed in the process.

Special considerations

- Offer emotional support to the patient and the family. Teach them about the disease.
- Monitor effects of prescribed medications.
- In addition to attending physical therapy sessions, the patient may need a home therapy regimen that includes stretching, active and passive exercises, strengthening exercises, compressive stockings or gloves to control edema, and heat or cold pack applications.
- Consult a pain care specialist to provide additional options for the patient, and help manage discomfort.
- Because chronic pain can be an emotional burden to the patient and the family, provide information on resources, such as counseling, support groups, stress reduction methods, meditation, relaxation training, and hypnosis.

Gastrointestinal Disorders

Introduction

The gastrointestinal (GI) tract, also known as the *alimentary canal*, is a long, hollow, musculomembranous tube consisting of glands and accessory organs (salivary glands, liver, gallbladder, and pancreas). (See *Reviewing GI anatomy and physiology*, page 210. See also *Histology of the GI tract*, page 211.) The GI tract breaks down food—carbohydrates, fats, and proteins—into molecules small enough to permeate cell membranes, thus providing cells with the necessary energy to function properly; it prepares food for cellular absorption by altering its physical and chemical composition. (See *Primary source of digestive hormones*, page 211.) Consequently, a malfunction along the GI tract can produce far-reaching metabolic effects, eventually threatening life itself. The GI tract is an unsterile system filled with bacteria and other flora; these organisms can cause superinfection from antibiotic therapy or they can infect other systems when a GI organ ruptures. A common indication of GI problems is referred pain, which makes diagnosis especially difficult.

Reviewing GI Anatomy and Physiology

The GI tract includes the mouth, pharynx, esophagus, stomach (fundus, body, and antrum), small intestine (duodenum, jejunum, and ileum), and large intestine (cecum, colon, rectum, and anal canal).

Digestion begins in the mouth through chewing and through the action of an enzyme secreted in saliva—ptyalin (amylase)—which breaks down starch. Digestion continues in the stomach, where the lining secretes gastric juice that contains hydrochloric acid and the enzymes pepsin (begins protein digestion), lipase (speeds hydrolysis of emulsified fats) and, in infants, rennin (curdles milk).

Through a churning motion, the stomach breaks food into tiny particles, mixes them with gastric juice, and pushes the mass toward the pylorus. The liquid portion (chyme) enters the duodenum in small amounts; any solid material remains in the stomach until it liquefies (usually from 1 to 6 hours). The stomach also produces an intrinsic factor necessary for the absorption of vitamin B_{12}. Although limited amounts of water, alcohol, and some drugs are absorbed in the stomach, chyme passes unabsorbed into the duodenum.

Small Intestine'S Role

Most digestion and absorption occur in the small intestine, where the surface area is increased by millions of villi in the mucous membrane lining. For digestion, the small intestine relies on a vast array of enzymes produced by the pancreas or by the intestinal lining itself. Pancreatic enzymes include trypsin, which digests protein to amino acids; lipase, which digests fat to fatty acids and glycerol; and amylase, which digests starches to sugars. Intestinal enzymes include erepsin, which digests protein to amino acids; lactase, maltase, and sucrase, which digest complex sugars such as glucose, fructose, and galactose; and enterokinase, which activates trypsin.

In addition, bile, secreted by the liver and stored in the gallbladder, helps neutralize stomach acid and aids the small intestine to emulsify and absorb fats and fat-soluble vitamins.

Final Stages

By the time the ingested material reaches the ileocecal valve (where the small intestine joins the large intestine), all nutritional value has been absorbed through the villi of the small intestine into the bloodstream.

The large intestine, so named because it's larger in diameter than the small intestine, absorbs water from the digestive material before passing it on for elimination. Rectal distention by feces stimulates the defecation reflex, which, when assisted by voluntary sphincter relaxation, permits defecation.

Throughout the GI tract, peristalsis (a coordinated, rhythmic contraction of smooth muscle) propels ingested material along; sphincters prevent its reflux.

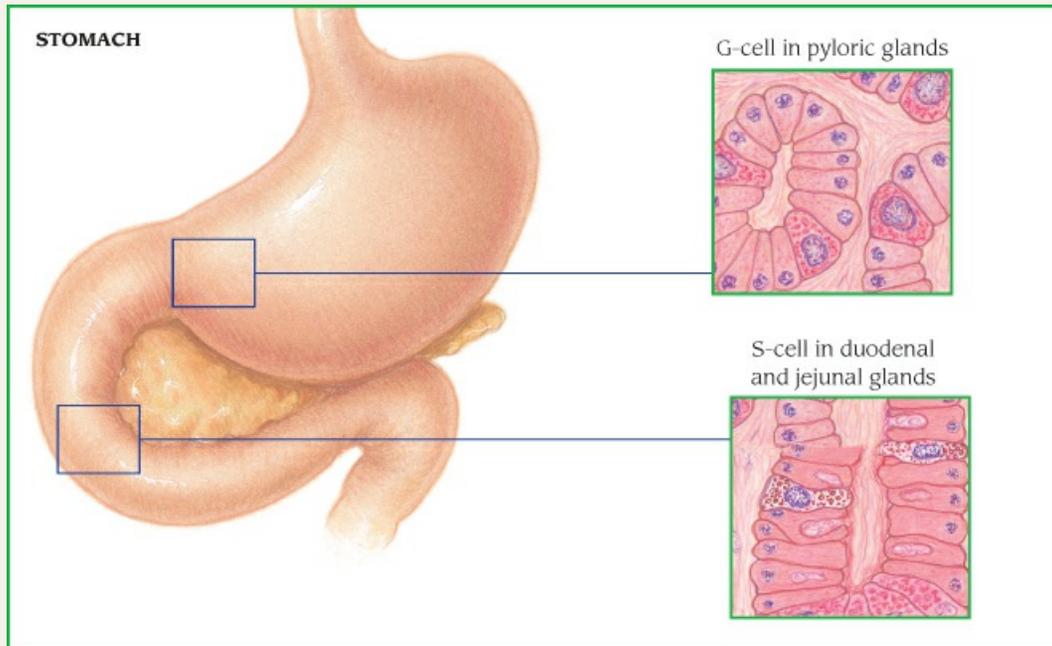
Histology of the GI Tract

The GI tract consists of four tissue layers, the structure of which varies in different organs:

- *Mucous membrane*—innermost layer; secretes gastric juice, protects the tract, and absorbs nutrients
- *Submucosa*—connective tissue that contains the major blood vessels and nerves
- *External muscle coat* (*muscularis externa*)—double layer of smooth muscle fibers; inner circular and outer longitudinal layers propel gastric contents downward by peristalsis
- *Fibroserous coat* (*serosa*)—outermost protective layer of connective tissue; forms the peritoneum, which is the largest serous membrane of the body. The peritoneum's parietal layer covers the walls of the abdominal cavity. An extension of the parietal peritoneum, called the *mesentery*, anchors the small intestine to the abdominal wall. The visceral layer drapes most of the abdominal organs, covering the upper surface of the pelvic organs.

Primary Source of Digestive Hormones

This cross section of the stomach shows the G-cells (which secrete gastrin) in the pyloric glands. The cross sections of the duodenum and jejunum show the S-cells (which secrete

secretin) in the duodenal and jejunal glands.


ACCURATE ASSESSMENT VITAL

Your assessment of the patient with suspected GI disease must begin with a careful history that includes occupation, family history, and recent travel. The medical history should include previous hospital admissions; surgical procedures (including recent tooth extraction); family history of ulcers, colitis, liver disease, or cancer; and current medications, whether prescribed, over-the-counter, or herbal remedies, with particular attention to aspirin, steroids, and anticoagulants. In addition, assess for food or drug allergies.

Have the patient describe the chief concern in subjective words. Does he or she have abdominal pain, indigestion, heartburn, or rectal bleeding? How long has this been present? What relieves these symptoms or makes them worse? Has the patient experienced nosebleeds or difficulty in swallowing recently? Has there been recent unintentional weight loss or gain? Is the patient on a special diet? Does the patient drink alcoholic beverages or smoke? If yes to either, how much and how often? Ask about bowel habits. Is there regular use of laxatives or enemas? If the patient experiences nausea and vomiting, what does the vomitus look like? Does changing position relieve nausea?

Next, try to define and locate any pain. Ask the patient to describe the pain. Is it dull, sharp, burning, aching, spasmodic, or intermittent? Where is it located? Does it radiate? How long does it last? When does it occur? What triggers it? What relieves it?

VISUAL ASSESSMENT

Observe how the patient looks, and note appropriateness of behavior. Changes in fluid and electrolyte balance, severe infection, drug toxicity, and hepatic disease may cause abnormal behavior. Your visual examination should check:

- *Skin*—loss of turgor, jaundice, cyanosis, pallor, diaphoresis, petechiae, bruises, edema, and texture (dry or oily)
- *Head*—color of sclerae, sunken eyes, dentures, caries, lesions, tongue (color, swelling, dryness), and breath odor
- *Chest*—shape (asymmetrical, barrel, or sunken)
- *Lungs*—rate, rhythm, and quality of respirations
- *Abdomen*—size and shape (distention, contour, visible masses, and protrusions), abdominal scars or fistulae, excessive skin folds (may indicate wasting), and abnormal respiratory movements (inflammation of diaphragm)

AUSCULTATION, PALPATION, AND PERCUSSION

Auscultation provides helpful clues to GI abnormalities and should always be performed before palpation and percussion to avoid altering the assessment. For example, the absence of bowel sounds over the area to the lower right of the umbilicus may indicate peritonitis. High-pitched sounds that coincide with colicky pain may indicate small bowel obstruction. Less intense, low-pitched rumbling noises may accompany minor irritation.

Palpating the abdomen after auscultation helps detect tenderness, muscle guarding, and abdominal masses. Watch for muscle tone (boardlike rigidity points to peritonitis or hemorrhage; transient rigidity suggests severe pain) and tenderness (rebound tenderness may indicate peritoneal inflammation).

Percussion helps detect air, fluid, and solid matter in the abdominal region.

DIAGNOSTIC TESTS

After physical assessment, several tests can identify GI malfunction.

- A barium or Gastrografin swallow is used primarily to examine the esophagus. Gastrografin may be used instead of barium. Like barium, Gastrografin facilitates X-ray imaging. However, if Gastrografin escapes from the GI tract, it's absorbed by the surrounding tissue, whereas escaped barium isn't absorbed and can cause complications.
- In an upper GI series, swallowed barium sulfate travels through the esophagus, stomach, and duodenum to reveal abnormalities. The barium outlines stomach walls and delineates ulcer craters and defects.
- A small bowel series, an extension of the upper GI series, visualizes barium flowing through the small intestine to the ileocecal valve.
- A barium enema (lower GI series) allows X-ray visualization of the colon.
- A stool specimen is useful to detect suspected GI bleeding, infection, or malabsorption as well as the presence of parasites. Guaiac test for occult blood, microscopic stool examination for ova and parasites, and tests for fat require several specimens.
- In esophagogastroduodenoscopy, insertion of a fiberoptic scope allows direct visual inspection of the esophagus, stomach, and duodenum. These structures are examined for varices, tumors, inflammation, hernias, polyps, ulcers, and obstruction.
- Proctosigmoidoscopy permits inspection of the rectum and distal sigmoid colon; colonoscopy is used for inspection of the descending, transverse, and ascending colon. These tests help visualize tumors, polyps, hemorrhoids, or ulcers.
- Gastric analysis examines gastric secretions for the presence of high levels of gastrin and the amount of acid produced.
- Endoscopic retrograde cholangiopancreatography (ERCP) directly visualizes the esophagus,

stomach, proximal duodenum, and fluoroscopically visualizes the pancreatic, hepatic, and biliary ducts. This test can help visualize duct obstruction, benign structures, cysts, anatomic variations, and malignant tumors. ERCP can be used to relieve or remove obstructions of the biliary tree.

INTUBATION

Certain GI disorders require nasogastric (NG) intubation to empty the stomach and intestine, to aid diagnosis and treatment, to decompress obstructed areas, to detect and treat GI bleeding, and to administer medications or feedings. Tubes generally inserted through the nose are the short NG tubes (the Levin, the Salem Sump, and the specialized Sengstaken–Blakemore) and the long intestinal tubes (Cantor and Miller–Abbott). The larger Ewald tube is usually inserted orally.

When caring for the patient with a tube:

- Explain the procedure before intubation.
- Maintain accurate intake and output records. Measure gastric drainage every 8 hours; record the amount, color, odor, and consistency. When irrigating the tube, note the amount of saline solution instilled and aspirated. Check for fluid and electrolyte imbalances.
- Provide good oral and nasal care. Brush the patient's teeth frequently and provide mouthwash. Make sure that the tube is secure, but isn't causing pressure on the nostrils. Change the tape to the nose every 24 hours. Gently wash the area around the tube, and apply a water-soluble lubricant to soften crusts. These measures help prevent sore throat and nose, dry lips, nasal excoriation, and parotitis.
- Ensure maximum patient comfort. After insertion of a long intestinal tube, instruct the patient to turn from side to side to facilitate its passage through the GI tract. Note the tube's progress. Never attach an intestinal tube to a patient's gown, bed linens, side rails of the bed, and so forth.
- With both types of tubes, tell the patient to expect a feeling of dryness or a lump in the throat; if allowed, suggest that the patient chew gum or eat hard candy to relieve discomfort.
- Always keep scissors taped to the wall near the bed when the patient has a Sengstaken–Blakemore tube in place. If the tube should dislodge and obstruct the bronchus, cut the lumen to the balloons immediately. Sometimes the tube is taped to the face piece of a football helmet worn by the patient to prevent the tube from dislodging and to put traction on the tube.
- After removing the tube from a patient with GI bleeding, watch for signs and symptoms of recurrent bleeding, such as hematemesis, decreased hemoglobin level, pallor, chills, diaphoresis, hypotension, and rapid pulse.
- Provide emotional support because the patient may panic at the sight of a tube. A calm, reassuring manner can help minimize fear.

Mouth and Esophagus

STOMATITIS AND OTHER ORAL INFECTIONS

Stomatitis is an inflammation of the oral mucosa that may extend to the buccal mucosa, lips, and palate. It's a common infection that may occur alone or as part of a systemic disease. There are two main types: acute herpetic stomatitis and aphthous stomatitis. Acute herpetic stomatitis is usually self-limiting; however, it may be severe and, in neonates, may be generalized and potentially fatal. Aphthous stomatitis, also known as *canker sores,* usually heals spontaneously,

without a scar, in 10 to 14 days. It may be an extraintestinal symptom of irritable bowel disease. Other oral infections include gingivitis, candidiasis, glossitis, periodontitis, and Vincent's angina. (See *Types of oral infections*, page 213.)

Types of Oral Infections

Disease and causes	Signs and symptoms	Treatment
Candidiasis (*infection of the oropharyngeal mucosa*)		
• Fungal infection caused by *Candida albicans* or related species • High-risk patients include premature neonates, older adults, the immunosuppressed, and those taking antibiotics or long-term steroids	• Cream-colored or bluish white patches of exudate on the tongue, mouth, or pharynx • Painful fissures at the corners of the mouth	• Antifungals for infection • May benefit from eating active-culture yogurt or other live lactobacillus • Topical anesthetic to relieve discomfort • Nonirritating mouthwash to loosen tenacious secretions
Gingivitis (*inflammation of the gingiva*)		
• Early sign of hypovitaminosis, diabetes, blood dyscrasias • Occasionally related to use of hormonal contraceptives	• Inflammation with painless swelling, redness, change in normal contours, bleeding, and periodontal pocket (gum detachment from teeth)	• Removal of irritating factors (calculus, faulty dentures) • Good oral hygiene, regular dental checkups, vigorous chewing • Oral or topical corticosteroids
Glossitis (*inflammation of the tongue*)		
• Streptococcal infection • Irritation or injury; jagged teeth; ill-fitting dentures; biting during seizures; alcohol; spicy foods; smoking; sensitivity to toothpaste or mouthwash • Vitamin B deficiency; anemia • Skin conditions: lichen planus, erythema multiforme, pemphigus vulgaris	• Reddened, ulcerated, or swollen tongue (may obstruct airway) • Painful chewing and swallowing • Speech difficulty • Painful tongue without inflammation	• Treatment of underlying cause • Topical anesthetic mouthwash or systemic analgesics (acetaminophen) for painful lesions • Good oral hygiene, regular dental checkups, vigorous chewing • Avoidance of hot, cold, or spicy foods and alcohol
Periodontitis (*gingival infection and recession, loosening of teeth*)		
• Early sign of hypovitaminosis, diabetes, blood dyscrasias • Occasionally related to use of hormonal contraceptives • Dental factors: calculus, poor oral hygiene, malocclusion; major cause of tooth loss after middle age	• Acute onset of bright red gum inflammation, painless swelling of interdental papillae, easy bleeding • Loosening of teeth, typically without inflammatory symptoms, progressing to loss of teeth and alveolar bone • Acute systemic infection (fever, chills)	• Scaling, root planing, and curettage for infection control • Periodontal surgery to prevent recurrence • Good oral hygiene, regular dental checkups, vigorous chewing
Vincent's angina (*"trench mouth," necrotizing ulcerative gingivitis*)		
• Fusiform bacillus or spirochete infection • Predisposing factors: stress, poor oral hygiene, insufficient rest, nutritional deficiency, smoking	• Sudden onset: painful, superficial bleeding; gingival ulcers (rarely, on buccal mucosa) covered with a gray-white membrane • Ulcers become punched-out lesions after slight pressure or irritation • Malaise, mild fever, excessive salivation, bad breath, pain on	• Removal of devitalized tissue with ultrasonic cavitron • Antibiotics for infection • Analgesics, as needed • Hourly mouth rinses (with equal amounts of hydrogen peroxide and

| | | swallowing or talking, enlarged submaxillary lymph nodes | ◆ warm water)
 ◆ Soft, nonirritating diet; rest; no smoking
 ◆ With treatment, improvement common within 24 hours |

Causes and Incidence

Acute herpetic stomatitis results from the herpes simplex virus. It's common in children 6 months to 5 years old. The cause of aphthous stomatitis is unknown, but predisposing factors include stress, fatigue, anxiety, febrile states, trauma, and solar overexposure. This type is common in young and teenage girls.

Pathophysiology

Tissue destruction takes place as a result of herpes simplex virus type 1 (HSV-1) viral replication and cell lysis. When the virus enters into the sensory and autonomic nerve endings, it is transported to the cell nuclei and can remain latent until reactivation.

Complications

- ◆ Nutritional deficiencies
- ◆ Esophagitis
- ◆ Sepsis

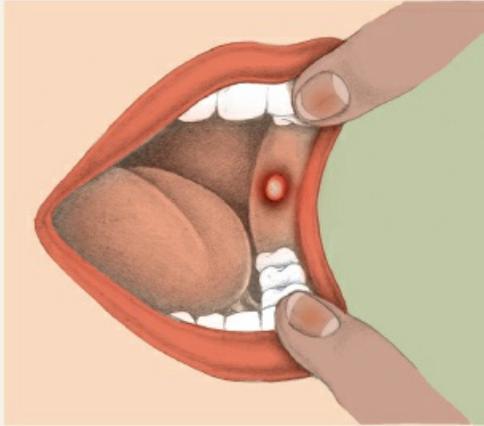
Signs and Symptoms

Acute herpetic stomatitis begins suddenly with mouth pain, malaise, lethargy, anorexia, irritability, and fever, which may persist for 1 to 2 weeks. Gums are swollen and bleed easily, and the mucous membrane is extremely tender.

Papulovesicular ulcers appear in the mouth and throat and eventually become punched-out lesions with reddened areolae. Submaxillary lymphadenitis is common. Pain usually disappears 2 to 4 days before healing of ulcers is complete. If the child with stomatitis sucks his or her thumb, these lesions spread to the hand.

A patient with aphthous stomatitis typically reports burning, tingling, and slight swelling of the mucous membrane. Single or multiple shallow ulcers with whitish centers and red borders appear and heal at one site and then reappear at another. (See *Looking at aphthous stomatitis*.)

Looking at Aphthous Stomatitis

In aphthous stomatitis, numerous small, round vesicles appear. They soon break and leave shallow ulcers with red areolae.


Diagnosis

Diagnosis is based on the physical examination; in Vincent's angina, a smear of ulcer exudate allows for identification of the causative organism.

Treatment

For acute herpetic stomatitis, treatment is conservative. For local symptoms, supportive measures include warm saltwater mouth rinses (antiseptic mouthwashes are contraindicated because they are irritating) and a topical anesthetic to relieve mouth ulcer pain. Topical antihistamines, antacids, or corticosteroids may also be recommended. Supplementary treatment includes a bland or liquid diet and, in severe cases, I.V. fluids and bed rest.

For aphthous stomatitis, primary treatment is application of a topical anesthetic. Effective long-term treatment requires alleviation or prevention of precipitating factors.

GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux disease (GERD) is a disease process that results from continued backflow of gastric or duodenal contents, or both, into the esophagus and past the lower esophageal sphincter (LES) without associated belching or vomiting. Reflux may cause symptoms or pathologic changes. Persistent reflux may cause reflux esophagitis (inflammation of the esophageal mucosa). Prognosis varies with the underlying cause.

Causes and Incidence

The function of the LES—a high-pressure area in the lower esophagus, just above the stomach—is to prevent gastric contents from backing up into the esophagus. Normally, the LES creates pressure, closing the lower end of the esophagus, but relaxes after each swallow to allow food into the stomach. Reflux occurs when LES pressure is deficient or when pressure within the stomach exceeds LES pressure. (See *Influences on LES pressure,* page 215.)

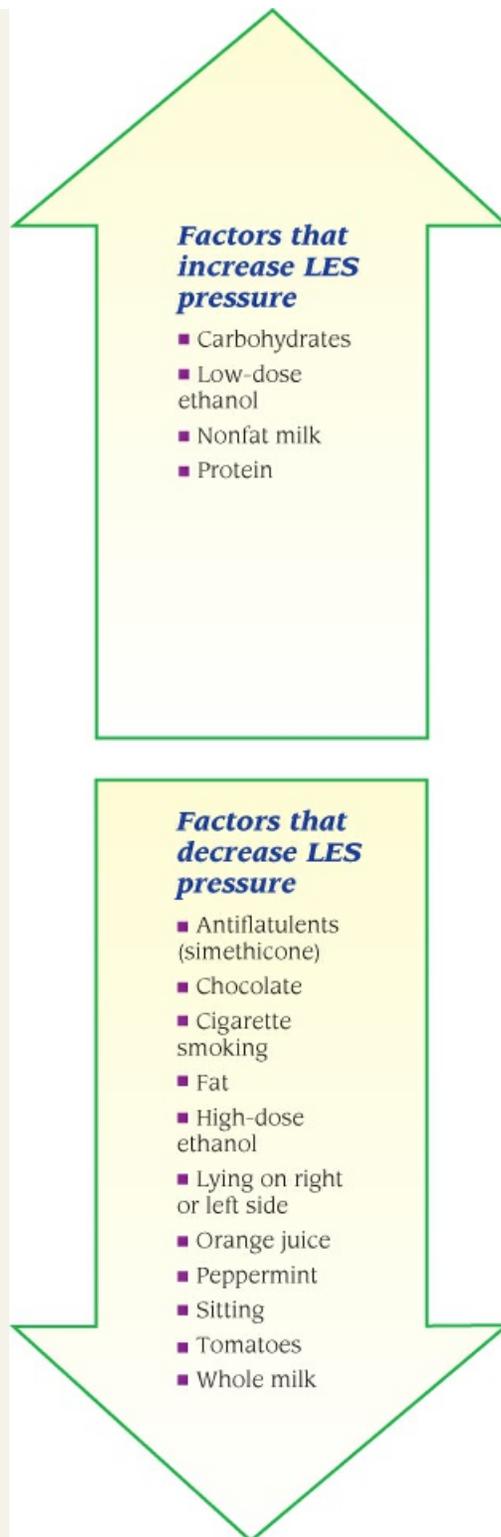
Influences on Lower Esophageal Sphincter (LES) Pressure

Several factors can influence LES pressure, thereby affecting reflux, as noted here.

Factors that increase LES pressure

- Carbohydrates
- Low-dose ethanol
- Nonfat milk
- Protein

Factors that decrease LES pressure

- Antiflatulents (simethicone)
- Chocolate
- Cigarette smoking
- Fat
- High-dose ethanol
- Lying on right or left side
- Orange juice
- Peppermint
- Sitting
- Tomatoes
- Whole milk


In 2015, there were 7 million diagnoses of gastroesophageal reflux. True figures may be even higher because many people with GERD take over-the-counter remedies without reporting their

symptoms. Studies show that GERD is common and may be overlooked in infants and children. It can cause repeated vomiting, coughing, and other respiratory problems. An immature digestive system is usually responsible, and most infants grow out of GERD by the time they are age 1.

Patients with symptom-producing reflux can't swallow often enough to create sufficient peristaltic amplitude to clear gastric acid from the lower esophagus. This results in prolonged periods of acidity in the esophagus when reflux occurs.

Predisposing factors include:

◆ pyloric surgery (alteration or removal of the pylorus), which allows reflux of bile or pancreatic juice
◆ long-term NG intubation (>4 days)
◆ any agent that lowers LES pressure, such as food, alcohol, cigarettes, anticholinergics (atropine, belladonna, and propantheline), or other drugs (morphine, diazepam, calcium channel blockers, and meperidine)
◆ hiatal hernia with an incompetent sphincter
◆ any condition or position that increases intra-abdominal pressure, such as straining, bending, coughing, pregnancy, obesity, and recurrent or persistent vomiting

Pathophysiology

Most commonly, the excessive relaxation of the LES is the cause of GERD; this allows reflux contents into the esophagus, and the esophageal mucosa is then exposed to acidic contents.

Signs and Symptoms

GERD doesn't always cause symptoms, and in patients showing clinical effects, it isn't always possible to confirm physiologic reflux. The most common feature of GERD is heartburn, which may become more severe with vigorous exercise, bending, or lying down, and may be relieved by antacids or sitting upright. The pain of esophageal spasm resulting from reflux esophagitis tends to be chronic and may mimic angina pectoris, radiating to the neck, jaws, and arms.

Other symptoms include odynophagia, which may be followed by a dull substernal ache from severe, long-term reflux; dysphagia from esophageal spasm, stricture, or esophagitis; and bleeding (bright red or dark brown). Nocturnal regurgitation can awaken the patient with coughing, choking, and a mouthful of saliva. Reflux may be associated with hiatal hernia. Direct hiatal hernia becomes clinically significant only when reflux is confirmed.

Pulmonary symptoms result from reflux of gastric contents into the throat and subsequent aspiration; they include chronic pulmonary disease or nocturnal wheezing, bronchitis, asthma, morning hoarseness, and cough. In children, other signs consist of failure to thrive and forceful vomiting from esophageal irritation. Such vomiting sometimes causes aspiration pneumonia.

Complications

◆ Esophageal ulcer
◆ Esophageal stricture
◆ Barrett's esophagus
◆ Hoarseness
◆ Reflux esophagitis

Diagnosis

CONFIRMING DIAGNOSIS *After a careful history and physical examination, tests to confirm GERD include barium swallow fluoroscopy, esophageal pH probe, esophageal manometry, and esophagoscopy. In children, barium esophagography under fluoroscopic control can show reflux.*

Recurrent reflux after age 6 weeks is abnormal. An acid perfusion (Bernstein) test can show that reflux is the cause of symptoms. Finally, endoscopy and biopsy allow visualization and confirmation of any pathologic changes in the mucosa.

Treatment

Promotility agents help increase LES sphincter tone and stimulate upper GI motility. Proton pump inhibitors and histamine-2 (H_2) receptor antagonists help reduce gastric acidity. If possible, NG intubation shouldn't be continued for more than 5 days because the tube interferes with sphincter integrity and allows reflux, especially when the patient lies flat.

PEDIATRIC TIP *Positional therapy is especially useful in infants and children who experience GERD without complications. Strategies, such as burping the infant several times during feeding, keeping the infant in an upright position for 30 minutes after feeding, and avoiding feeding 2 to 3 hours before bedtime, may help.*

Surgery may be necessary to control severe and refractory symptoms, such as pulmonary aspiration, hemorrhage, obstruction, severe pain, perforation, an incompetent LES, or associated hiatal hernia. Surgical procedures that create an artificial closure at the gastroesophageal junction may be needed in some patients. These include a procedure that invaginates the esophagus into the stomach and procedures that create a gastric wraparound with or without fixation. The fundoplication procedure can be performed endoscopically.

Special Considerations

Teach the patient what causes reflux, how to avoid reflux with an antireflux regimen (medication, diet, and positional therapy), and what symptoms to watch for and report.

◆ Instruct the patient to avoid circumstances that increase intra-abdominal pressure (such as bending, coughing, vigorous exercise, tight clothing, constipation, and obesity) as well as substances that reduce sphincter control (cigarettes, alcohol, fatty foods, and caffeine).
◆ Advise the patient to sit upright, particularly after meals, and to eat small, frequent meals. Tell him to avoid highly seasoned food, acidic juices, alcoholic drinks, bedtime snacks, and foods high in fat or carbohydrates, which reduce LES pressure. Meals should be eaten at least 2 to 3 hours before lying down.
◆ Tell the patient to take antacids, as ordered (usually 1 hour before or 3 hours after meals and at bedtime).
◆ Teach the patient correct preparation for diagnostic testing, and not to eat 6 to 8 hours before a barium swallow or endoscopy.
◆ After surgery using a thoracic approach, carefully watch and record chest tube drainage and the patient's respiratory status. If needed, give chest physiotherapy and oxygen. Position the patient with an NG tube in semi-Fowler's position to help prevent reflux. Offer reassurance and emotional support. (See *Preventing GI reflux,* page 217.)

Changing lifestyle will help the patient to prevent GI reflux.

Diet and Eating Habits

Foods, such as caffeine, chocolate, spicy food, carbonated beverages, orange juice, liquor, wine, and tomato sauce, stimulate the production of acid. Large meals expand the stomach and put pressure on the lower esophageal sphincter (LES). Gravity helps keep the stomach juices from backing up into the esophagus: Don't allow the patient to lie down for 2 hours after eating. If nighttime heartburn is a concern, raise the head of the bed 6″ to 8″ because a flat position places pressure on the LES.

Weight

Being overweight increases abdominal pressure, which can then push stomach contents up into the esophagus.

Smoking

Nicotine relaxes the esophageal sphincter and stimulates the production of stomach acid. Smoking also may injure the esophagus by causing irritation making it more susceptible to damage from acid reflux. Smoking can decrease gastric motility and reduce the effectiveness of digestion because the stomach takes longer to empty.

Stress

Although stress itself doesn't cause heartburn, the anxiety that comes along with stress can lead to behaviors that increase the risk of heartburn, such as overeating, drinking, and smoking.

Alcohol

Alcohol can increase the production of stomach acid and can also lower the esophageal sphincter, which allows stomach acids to move up into the esophagus. Alcohol also makes the esophagus more sensitive to stomach acid.

TRACHEOESOPHAGEAL FISTULA AND ESOPHAGEAL ATRESIA

Tracheoesophageal fistula is a developmental anomaly characterized by an abnormal connection between the trachea and the esophagus. It usually accompanies esophageal atresia, in which the esophagus is closed off at some point. Although these malformations have numerous anatomic variations, the most common, by far, is esophageal atresia with fistula to the distal segment. (See *Types of tracheoesophageal anomalies,* page 218.)

Types of Tracheoesophageal Anomalies

Congenital malformations of the esophagus occur in about 1 in 3,500 live births. Anatomic

variations of tracheoesophageal anomalies are classified as follows.

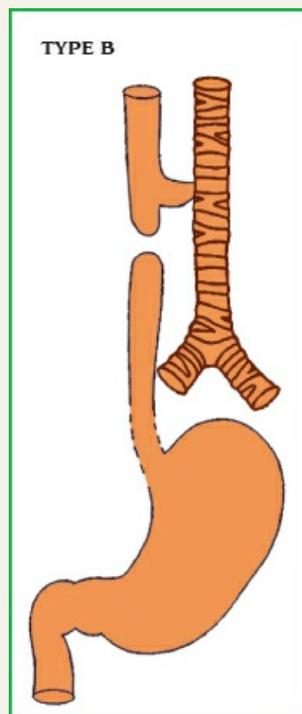
- Type A: esophageal atresia without fistula
- Type B: esophageal atresia with tracheoesophageal fistula to the proximal segment
- Type C (the most common): esophageal atresia with fistula to the distal segment
- Type D: esophageal atresia with fistula to both segments
- Type E (or H-Type): tracheoesophageal fistula without atresia

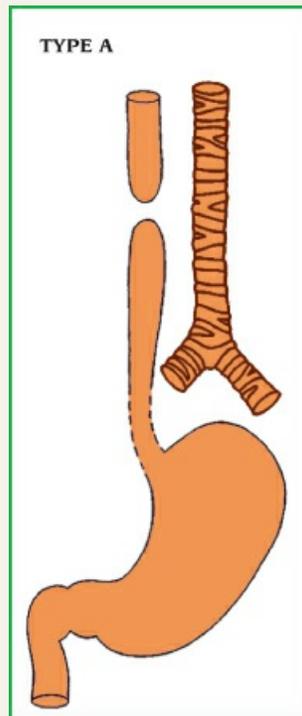
TYPE A

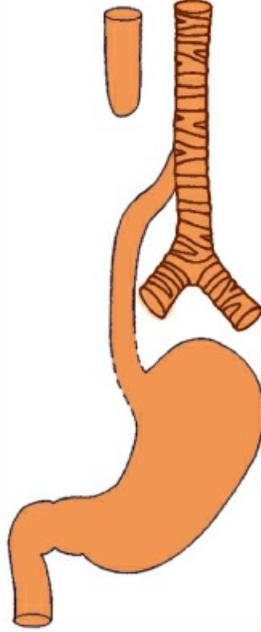
TYPE B

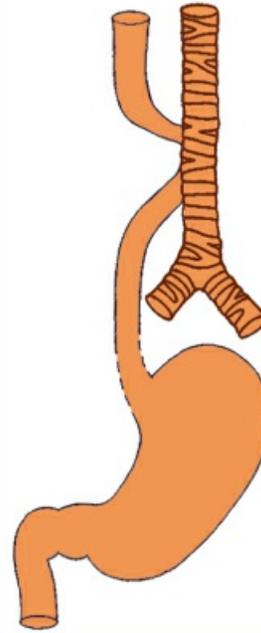
TYPE C

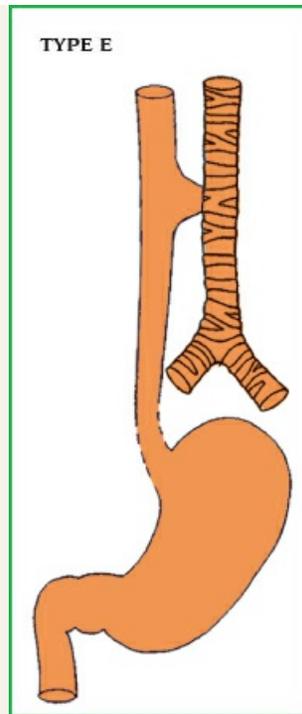
TYPE D

TYPE E










These disorders, two of the most serious surgical emergencies in neonates, require immediate diagnosis and correction. They may coexist with other serious anomalies, such as congenital heart disease, imperforate anus, genitourinary abnormalities, and intestinal atresia.

Causes and Incidence

Tracheoesophageal fistula and esophageal atresia result from failure of the embryonic esophagus and trachea to develop and separate correctly. Respiratory system development begins at about day 26 of gestation. Abnormal development of the septum during this time can lead to tracheoesophageal fistula. The most common abnormality is type C tracheoesophageal fistula with esophageal atresia, in which the upper section of the esophagus terminates in a blind pouch, and the lower section ascends from the stomach and connects with the trachea by a short fistulous tract. Esophageal atresia occurs in about 1 of every 2,500 to 4,000 live births.

Pathophysiology

In type A atresia, both esophageal segments are blind pouches, and neither is connected to the airway. In type E (or H-type), tracheoesophageal fistula without atresia, the fistula may occur anywhere between the level of the cricoid cartilage and the midesophagus, but is usually higher in the trachea than in the esophagus. Such a fistula may be as small as a pinpoint. In types B and D, the upper portion of the esophagus opens into the trachea; neonates with this anomaly may experience life-threatening aspiration of saliva or food.

Complications

- Recurrent fistulas
- Abnormal esophageal motility

- Pneumothorax
- Esophageal stricture

Signs and Symptoms

A neonate with type C tracheoesophageal fistula with esophageal atresia appears to swallow normally but soon after swallowing coughs, struggles, becomes cyanotic, and stops breathing as he aspirates fluids returning from the blind pouch of the esophagus through his nose and mouth. Stomach distention may cause respiratory distress; air and gastric contents (bile and gastric secretions) may reflux through the fistula into the trachea, resulting in chemical pneumonitis.

An infant with type A esophageal atresia appears normal at birth. The infant swallows normally, but as secretions fill the esophageal sac and overflow into the oropharynx, they develop mucus in the oropharynx and drools excessively. When the infant is fed, regurgitation and respiratory distress follow aspiration. Suctioning the mucus and secretions temporarily relieves these symptoms. Excessive secretions and drooling in the neonate strongly suggest esophageal atresia.

Repeated episodes of pneumonitis, pulmonary infection, and abdominal distention may signal type E (or H-type) tracheoesophageal fistula. When a child with this disorder drinks, he or she coughs, chokes, and becomes cyanotic. Excessive mucus builds up in the oropharynx. Crying forces air from the trachea into the esophagus, producing abdominal distention. Because such a child may appear normal at birth, this type of tracheoesophageal fistula may be overlooked, and diagnosis may be delayed as long as 1 year.

Type B (proximal fistula) and type D (fistula to both segments) cause immediate aspiration of saliva into the airway and bacterial pneumonitis.

Diagnosis

Respiratory distress and drooling in a neonate suggest tracheoesophageal fistula and esophageal atresia. The following procedures confirm the diagnosis:

- A size 10 or 12 French catheter passed through the nose meets an obstruction (esophageal atresia) approximately 4″ to 5″ (10 to 12.5 cm) distal from the nostrils. Aspirate of gastric contents is less acidic than normal.
- Chest X-ray demonstrates the position of the catheter and can also show a dilated, air-filled upper esophageal pouch, pneumonia in the right upper lobe, or bilateral pneumonitis. Both pneumonia and pneumonitis suggest aspiration.
- Abdominal X-ray shows gas in the bowel in a distal fistula (type C) but none in a proximal fistula (type B) or in atresia without fistula (type A).
- Cinefluorography allows visualization on a fluoroscopic screen. After a size 10 or 12 French catheter is passed through the patient's nostril into the esophagus, a small amount of contrast medium is instilled to define the tip of the upper pouch and to differentiate between overflow aspiration from a blind end (atresia) and aspiration due to passage of liquid through a tracheoesophageal fistula.

Treatment

Tracheoesophageal fistula and esophageal atresia require surgical correction and are usually surgical emergencies. The type and timing of surgical procedure depend on the nature of the anomaly, the patient's general condition, and the presence of coexisting congenital defects. In premature neonates who are poor surgical risks, correction of combined tracheoesophageal

fistula and esophageal atresia is done in two stages: first, gastrostomy (for gastric decompression, prevention of reflux, and feeding) and closure of the fistula; then, 1 to 2 months later, anastomosis of the esophagus.

Before and after surgery, positioning varies with the physician's philosophy and the infant's anatomy: the infant may be placed supine, with the head positioned low to facilitate drainage, or with the head elevated to prevent aspiration.

The infant should receive I.V. fluids, as necessary, and appropriate antibiotics for superimposed infection.

Postoperative complications after correction of tracheoesophageal fistula include recurrent fistulas, esophageal motility dysfunction, esophageal stricture, recurrent bronchitis, pneumothorax, and failure to thrive. Esophageal motility dysfunction or hiatal hernia may develop after surgery to correct esophageal atresia.

Correction of esophageal atresia alone requires anastomosis of the proximal and distal esophageal segments in one or two stages. End-to-end anastomosis commonly produces postoperative stricture; end-to-side anastomosis is less likely to do so. If the esophageal ends are widely separated, treatment may include a colonic interposition (grafting a piece of the colon) or elongation of the proximal segment of the esophagus by bougienage. About 10 days after surgery, and again 1 and 3 months later, X-rays are required to evaluate the effectiveness of surgical repair.

Postoperative treatment includes placement of a suction catheter in the upper esophageal pouch to control secretions and prevent aspiration, maintaining the infant in an upright position to avoid reflux of gastric juices into the trachea, I.V. fluids (nothing by mouth), gastrostomy to prevent reflux and allow feeding, and appropriate antibiotics for pneumonia.

Postoperative complications may include impaired esophageal motility (in one third of patients), hiatal hernia, and reflux esophagitis.

Special Considerations

Postoperative care should include the following:

- Monitor the infant's respiratory status. Administer oxygen and perform pulmonary physiotherapy and suctioning, as needed. Provide a humid environment.
- Administer antibiotics and parenteral fluids, as ordered. Keep accurate intake and output records.
- If the infant has chest tubes postoperatively, check them frequently for patency. Maintain proper suction; measure and mark drainage periodically.
- Observe carefully for signs of complications.
- Maintain gastrostomy tube feedings, as ordered. Such feedings initially consist of dextrose and water (not >5% solution); later, add a proprietary formula (first diluted and then full strength). If the infant develops gastric atony, use an iso-osmolar formula. Oral feedings can usually resume 8 to 10 days postoperatively. If gastrostomy feedings and oral feedings are impossible because of intolerance to them or decreased intestinal motility, the infant requires total parenteral nutrition (TPN).
- If the infant can safely handle secretions, give a pacifier to satisfy sucking needs; however, this is done *only* when the child can safely handle secretions because sucking stimulates saliva secretion.
- Offer the parents support and guidance in dealing with their infant's acute illness. Encourage them to participate in the infant's care and to hold and touch as much as possible to facilitate

bonding.

CORROSIVE ESOPHAGITIS AND STRICTURE

Corrosive esophagitis is inflammation and damage to the esophagus after ingestion of a caustic chemical. Severe injury can quickly lead to esophageal perforation, mediastinitis, and death from infection, shock, and massive hemorrhage (due to aortic perforation).

Causes and Incidence

The most common chemical injury to the esophagus follows the ingestion of lye or other strong alkali; ingestion of strong acids is less common. The type and amount of chemical ingested determine the severity and location of the damage. In children, household chemical ingestion is accidental; in adults, it's usually a suicide attempt or gesture.

Esophageal tissue damage occurs in three phases: the acute phase, consisting of edema and inflammation; the latent phase, with ulceration, exudation, and tissue sloughing; and the chronic phase, in which there is diffuse scarring.

Corrosive strictures account for less than 5% of all stricture cases.

Pathophysiology

In corrosive esophagitis, the chemical may damage only the mucosa or submucosa or it may damage all layers of the esophagus. Similar to a burn, this injury may be temporary or may lead to permanent stricture (narrowing or stenosis) of the esophagus that's correctable only through surgery.

Complications

- Esophageal perforation
- Mediastinitis
- Infection, massive hemorrhage, shock

Signs and Symptoms

Effects vary from none at all to intense pain and edema in the mouth, anterior chest pain, marked salivation, inability to swallow, and tachypnea. Bloody vomitus containing pieces of esophageal tissue signals severe damage. Signs of esophageal perforation and mediastinitis, especially crepitation, indicate destruction of the entire esophagus. Inability to speak implies laryngeal damage.

The acute phase subsides in 3 to 4 days, enabling the patient to eat again. Fever suggests secondary infection. Symptoms of dysphagia return if stricture develops, usually within weeks; rarely, stricture is delayed and develops several years after the injury.

Diagnosis

℞ CONFIRMING DIAGNOSIS *A history of chemical ingestion and physical examination revealing oropharyngeal burns (including white membranes and edema of the soft palate and uvula) usually confirm the diagnosis.*

The type and amount of the chemical ingested must be identified; this may be done by examining the container of the ingested material or by calling the poison control center.

Two procedures are helpful in evaluating the severity of the injury:

- Endoscopy (in the first 24 hours after ingestion) delineates the extent and location of the esophageal injury and assesses the depth of the burn. This procedure may also be performed a week after ingestion to assess stricture development.
- Barium swallow (1 week after ingestion and every 3 weeks thereafter) may identify segmental spasm or fistula, but doesn't always show mucosal injury.

Treatment

Conservative treatment of corrosive esophagitis and stricture includes monitoring the patient's condition; early endoscopy; administering corticosteroids, such as prednisone and hydrocortisone, to control inflammation and inhibit fibrosis; and using a broad-spectrum antibiotic, such as ampicillin, to protect the corticosteroid-immunosuppressed patient against infection by his own mouth flora.

Treatment may also include bougienage, a procedure in which a slender, flexible, cylindrical instrument called a *bougie* is passed into the esophagus to dilate it and minimize stricture. Some physicians begin bougienage immediately and continue it regularly to maintain a patent lumen and prevent stricture; others delay it for a week to avoid the risk of esophageal perforation.

Surgery is needed immediately for esophageal perforation or later to correct stricture untreatable with bougienage. Corrective surgery may involve transplanting a piece of the colon to the damaged esophagus. However, even after surgery, stricture may recur at the site of the anastomosis.

Supportive treatment includes I.V. therapy to replace fluids or TPN while the patient can't swallow, gradually progressing to clear liquids and a soft diet.

Special Considerations

If you're the first healthcare professional to see the patient who has ingested a corrosive chemical, the quality of your emergency care will be critical. Carefully follow these important guidelines:

- *Don't* induce vomiting or lavage because this will expose the esophagus and oropharynx to additional injury.
- *Don't* perform gastric lavage because the corrosive chemical may cause further damage to the mucous membrane of the GI lining.
- Provide vigorous support of vital functions, as needed, such as oxygen, mechanical ventilation, administration of I.V. fluids, and treatment for shock, depending on the severity of the injury.
- Carefully observe and record intake and output.
- Before X-rays and endoscopy, explain the procedure to the patient to lessen anxiety during the tests and to obtain cooperation.
- Because the adult who has ingested a corrosive agent may have done so with suicidal intent, assist the patient and family in seeking psychological counseling. Monitor the patient according to facility protocol if the attempt was a suicide.
- Provide emotional support for parents whose child has ingested a chemical. They'll be distraught and may feel guilty about the accident. Also be alert in case there is any suspicion of child abuse that may have accompanied the ingestion. Report according to facility and demographic protocol.

- Encourage long-term follow-up because of the increased risk of squamous cell carcinoma.

PREVENTION *Tell parents to lock accessible cabinets and keep all corrosive agents out of a child's reach.*

MALLORY–WEISS SYNDROME

Mallory–Weiss syndrome is mild to massive, usually painless bleeding due to a tear in the mucosa or submucosa of the cardia or lower esophagus. Such a tear, usually singular and longitudinal, results from prolonged or forceful vomiting.

Causes and Incidence

Forceful or prolonged vomiting can cause esophageal tearing when the upper esophageal sphincter fails to relax during vomiting; this lack of sphincter coordination seems more common after excessive alcohol intake. Other factors that can increase intra-abdominal pressure and predispose a person to this type of tear include coughing, straining during bowel movements, traumatic injury, seizures, childbirth, hiatal hernia, esophagitis, gastritis, and atrophic gastric mucosa. The incidence of Mallory–Weiss syndrome among patients with upper GI bleeding ranges from 8% to 15%. The condition most commonly occurs in patients under 40.

Pathophysiology

The pathophysiology of Mallory–Weiss syndrome is not completely understood, but it is thought that mucosal lacerations develop after a sudden increase in intra-abdominal pressure.

Complications

- Hypovolemia (if bleeding is excessive)
- Fatal shock

Signs and Symptoms

Mallory–Weiss syndrome typically begins with vomiting of blood or passing large amounts of blood rectally a few hours to several days after forceful vomiting. The bleeding, which may be accompanied by epigastric or back pain, may range from mild to massive, but is usually more profuse than in esophageal rupture. In Mallory–Weiss syndrome, the blood vessels are only partially severed, preventing retraction and closure of the lumen.

ALERT *Massive bleeding—most likely when the tear is on the gastric side, near the cardia— may quickly lead to fatal shock.*

Diagnosis

CONFIRMING DIAGNOSIS *Fiberoptic endoscopy (esophagogastroduodenoscopy) confirms Mallory–Weiss syndrome by identifying esophageal tears. Recent tears appear as erythematous longitudinal cracks in the mucosa; older tears appear as raised white streaks surrounded by erythema.*

Treatment

Treatment varies with the severity of bleeding. GI bleeding usually stops spontaneously, thereafter requiring supportive measures and careful observation but no definitive treatment. However, if bleeding continues, treatment may include:

- proton pump inhibitors or H_2 receptor antagonists to help decrease acidity
- blood transfusions if blood loss is great
- endoscopy with electrocoagulation or heater probe for hemostasis
- transcatheter embolization or thrombus formation with an autologous blood clot or other hemostatic material (such as a shredded adsorbent gelatin sponge)
- surgery to suture each esophageal laceration

Special Considerations

Observation is necessary to determine whether bleeding is transitory or ongoing.

- Evaluate the patient's respiratory status, monitor arterial blood gas values, and administer oxygen as necessary.
- Assess the amount of blood lost and record the color, amount, consistency, and frequency of hematemesis and melena.
- Draw blood for coagulation studies (prothrombin time, partial thromboplastin time, and platelet count), and type and crossmatch.
- Keep 3 units of blood available at all times. Insert a 14G to 18G I.V. line, and start an infusion of I.V. solution, as ordered. (If the I.V. infusion is for blood transfusion, use normal saline solution; if the infusion is for fluid replacement, use lactated Ringer's solution or another appropriate solution, depending on the results of laboratory tests.)
- Monitor the patient's vital signs, central venous pressure, urine output, neurologic status, and overall clinical status.
- Explain diagnostic tests to the patient.
- Keep the patient warm and maintain a safe environment.
- Obtain a detailed history of recent medications taken, dietary habits, and alcohol ingestion.
- Administer antiemetics, as ordered, to prevent postoperative retching and vomiting.
- Advise the patient to avoid aspirin, alcohol, and other irritating substances.

ESOPHAGEAL DIVERTICULA

Esophageal diverticula are hollow outpouchings of one or more layers of the esophageal wall. They occur in three main areas: immediately above the upper esophageal sphincter (Zenker's, or pulsion, diverticulum, the most common type); near the midpoint of the esophagus (traction diverticulum); and immediately above the LES (epiphrenic diverticulum). Generally, esophageal diverticula occur later in life—although they can affect infants and children—and are three times more common in men than in women. Epiphrenic diverticula usually occur in middle-aged men, whereas Zenker's diverticula typically affect men older than 60 (and often older than 75).

Causes and Incidence

Some esophageal diverticula arise from primary muscular abnormalities. Most diverticula occur in middle-aged and elderly patients. Zenker's diverticula occur most commonly in patients older than 50 and are especially prevalent in patients in their 70s and 80s.

Pathophysiology

Zenker's diverticulum occurs when the pouch results from increased intraesophageal pressure; traction diverticulum occurs when the pouch is pulled out by adjacent inflamed tissue or lymph nodes. Zenker's diverticulum results from developmental muscular weakness of the posterior pharynx above the border of the cricopharyngeal muscle. The pressure of swallowing aggravates this weakness, as does contraction of the pharynx before relaxation of the sphincter.

Esophageal diverticula are due to primary muscular abnormalities that may be congenital or to inflammatory processes adjacent to the esophagus. Some authorities classify all diverticula as traction diverticula. A midesophageal (traction) diverticulum is a response to scarring and pulling on esophageal walls by an external inflammatory process such as tuberculosis. An epiphrenic diverticulum (rare) is generally right-sided and usually accompanies an esophageal motor disturbance, such as esophageal spasm or achalasia. It's thought to be caused by traction and pulsation.

Complications

- Malnutrition
- Dehydration

Signs and Symptoms

Midesophageal and epiphrenic diverticula with an associated motor disturbance (achalasia or spasm) seldom produce symptoms, although the patient may experience dysphagia and heartburn. Zenker's diverticulum, however, produces distinctly staged symptoms, beginning with initial throat irritation followed by dysphagia and near-complete obstruction. In early stages, regurgitation occurs soon after eating; in later stages, regurgitation after eating is delayed and may even occur during sleep, leading to food aspiration and pulmonary infection.

ELDER TIP Hoarseness, asthma, and pneumonitis may be the only signs of esophageal diverticula in older adults.

Other signs and symptoms include noise when liquids are swallowed, chronic cough, hoarseness, a bad taste in the mouth or foul breath and, rarely, bleeding.

Diagnosis

CONFIRMING DIAGNOSIS *X-rays taken following a barium swallow usually confirm the diagnosis by showing characteristic outpouching.*

Esophagoscopy can rule out another lesion; however, the procedure risks rupturing the diverticulum by passing the scope into it rather than into the lumen of the esophagus, a special danger with Zenker's diverticulum.

Treatment

Treatment of Zenker's diverticulum is usually palliative and includes a bland diet, thorough chewing, and drinking water after eating to flush out the sac. However, severe symptoms or a large diverticulum necessitates surgery to remove the sac or facilitate drainage. An esophagomyotomy may be necessary to prevent recurrence. Endoscopic stapling or laser surgery using CO_2 microscopy is commonly performed in patients who can't tolerate traditional surgeries.

A midesophageal diverticulum seldom requires therapy except when esophagitis aggravates

the risk of rupture, in which case treatment includes antacids and an antireflux regimen: keeping the head elevated, maintaining an upright position for 2 hours after eating, eating small meals, controlling chronic coughing, and avoiding constrictive clothing.

Epiphrenic diverticulum requires treatment of accompanying motor disorders. Achalasia is treated by repeated dilations of the esophagus; acute spasm is controlled by anticholinergic administration and diverticulum excision; and dysphagia or severe pain is relieved by surgical excision or suspending the diverticulum to promote drainage. Treatment may also include parenteral feeding to improve the patient's nutritional status.

Special Considerations

Care includes documenting the patient's symptoms and nutritional status and providing education about the disorder.

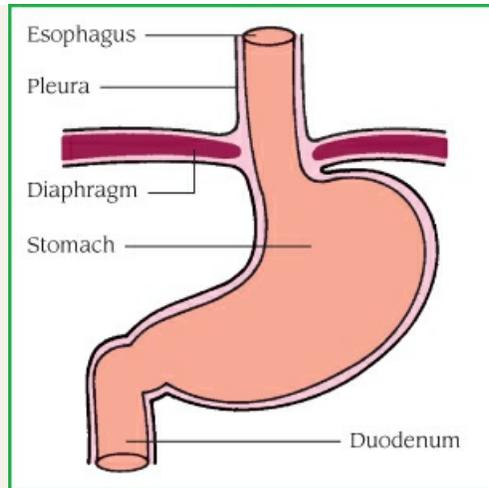
- Regularly assess the patient's nutritional status (weight, calorie intake, and appearance).
- If the patient regurgitates food and mucus, protect against aspiration by careful positioning (head elevated or turned to one side). To prevent aspiration, tell the patient to empty any visible outpouching in the neck by massage or postural drainage before retiring.
- If the patient has dysphagia, record well-tolerated foods and what circumstances ease swallowing. Provide a pureed diet, with vitamin or protein supplements, and encourage thorough chewing.
- Teach the patient about this disorder. Explain treatment instructions and diagnostic procedures.

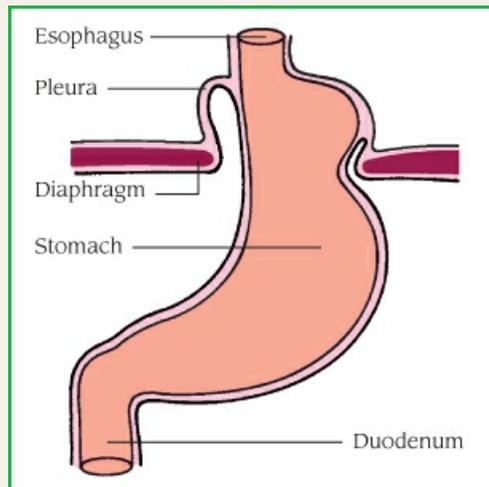
HIATAL HERNIA

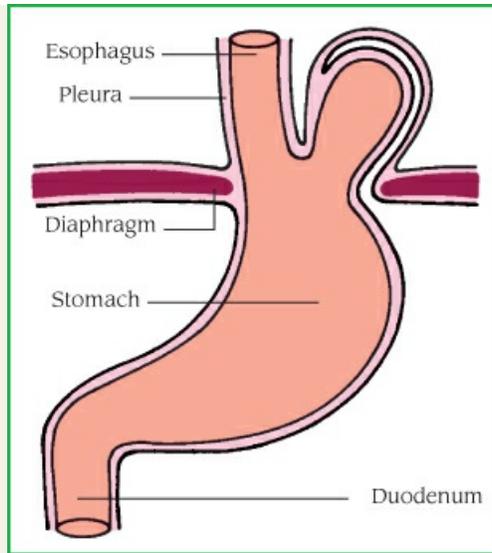
Hiatal hernia, also called *hiatus hernia,* is a defect in the diaphragm that permits a portion of the stomach to pass through the diaphragmatic opening into the chest. Hiatal hernia is the most common problem of the diaphragm affecting the alimentary canal. Four types of hiatal hernia can occur: sliding hiatal hernia (Type I), paraesophageal hiatal hernia (Type II), mixed hiatal hernia (Type III), or a Type IV, which is an aggravated form of Type II that includes other abdominal visceral herniation. (See *Types of hiatal hernia,* page 224.)

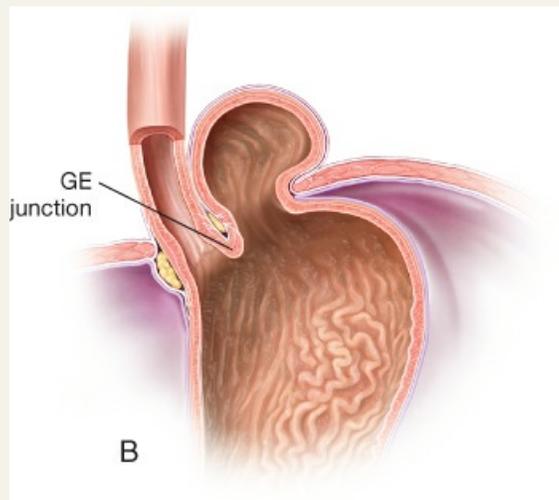
Types of Hiatal Hernia

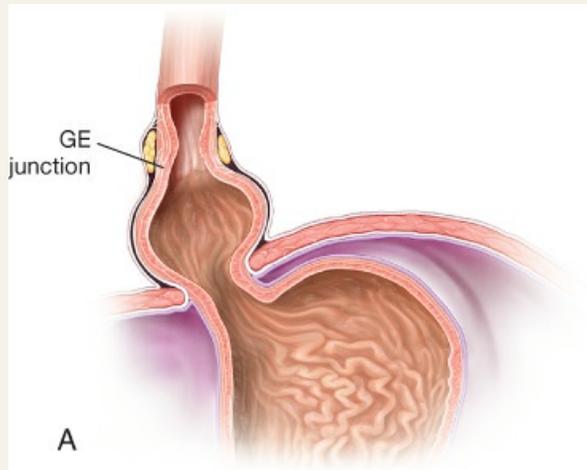
A hiatal hernia is a displacement of the normal anatomy, as shown in the illustrations below.

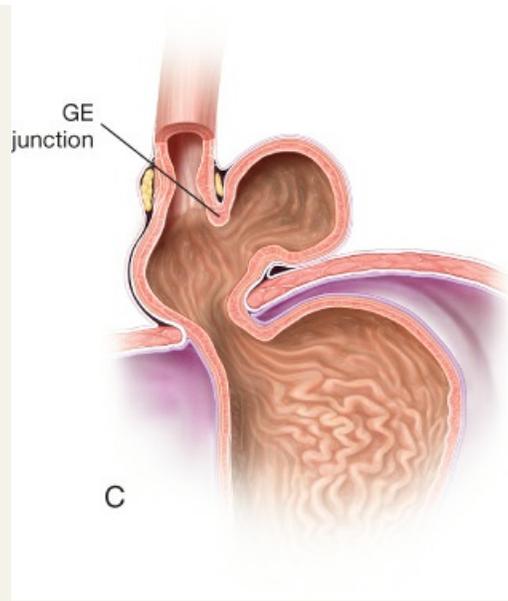
Normal Stomach


Sliding Hiatal Hernia


Paraesophageal Hernia


Mixed Hiatal Hernia






Causes and Incidence

Hiatal hernia typically results from muscle weakening that's common with aging and may be secondary to esophageal carcinoma, kyphoscoliosis, trauma, or certain surgical procedures. It may also result from certain diaphragmatic malformations that may cause congenital weakness. Obesity and smoking are common risk factors.

In hiatal hernia, the muscular collar around the esophageal and diaphragmatic junction loosens, permitting the lower portion of the esophagus and the stomach to rise into the chest when intra-abdominal pressure increases (possibly causing gastroesophageal reflux). Such increased intra-abdominal pressure may result from ascites, pregnancy, obesity, constrictive clothing, bending, straining, coughing, Valsalva's maneuver, or extreme physical exertion.

Sliding hernias are more common than paraesophageal hernias. The incidence of hiatal hernia increases with age (most occur in people older than 40), and prevalence is higher in women than in men (especially the paraesophageal type). Contributing factors include obesity and trauma.

Pathophysiology

In a sliding hiatal hernia, the stomach and the gastroesophageal junction slip up into the chest, so the gastroesophageal junction is above the diaphragmatic hiatus. In paraesophageal hiatal hernia, a part of the greater curvature of the stomach rolls through the diaphragmatic defect. A mixed hiatal hernia is a combination of Type I and Type II hernias, and often occurs with other diseases such as GERD, peptic ulcer disease (PUD), cholecystitis, cholelithiasis, chronic pancreatitis, and diverticulosis. In Type IV hiatal hernias, the entire stomach and other abdominal organs slide into the thorax.

Complications

- Dysphagia
- Gastroesophageal reflux
- Barrett's esophagus

- Esophageal adenocarcinoma

Signs and Symptoms

Typically, a paraesophageal hernia produces no symptoms; it's usually an incidental finding during a barium swallow or when testing for occult blood. Because this type of hernia leaves the closing mechanism of the cardiac sphincter unchanged, it rarely causes acid reflux or reflux esophagitis. Symptoms result from displacement or stretching of the stomach and may include a feeling of fullness in the chest or pain resembling angina pectoris. Even if it produces no symptoms, this type of hernia needs surgical treatment because of the high risk of strangulation that can occur when a large portion of the stomach becomes caught above the diaphragm.

A sliding hernia without an incompetent sphincter produces no reflux or symptoms and, consequently, doesn't require treatment. When a sliding hernia causes symptoms, they are typical of gastric reflux, resulting from the incompetent LES, and may include the following:

- Pyrosis (heartburn) occurs 1 to 4 hours after eating (especially overeating) and is aggravated by reclining, belching, and increased intra-abdominal pressure. It may be accompanied by regurgitation or vomiting.
- Retrosternal or substernal chest pain results from reflux of gastric contents, stomach distention, and spasm or altered motor activity. Chest pain usually occurs after meals or at bedtime and is aggravated by reclining, belching, and increased intra-abdominal pressure.

Other common symptoms reflect possible complications:

- Dysphagia occurs when the hernia produces esophagitis, esophageal ulceration, or stricture, especially with ingestion of very hot or cold foods, alcoholic beverages, or a large amount of food.
- Bleeding may be mild or massive, frank or occult; the source may be esophagitis or erosions of the gastric pouch.
- Severe pain and shock result from incarceration, in which a large portion of the stomach is caught above the diaphragm (usually occurs with paraesophageal hernia). Incarceration may lead to perforation of the gastric ulcer and strangulation and gangrene of the herniated portion of the stomach. It requires immediate surgery.

Diagnosis

Diagnosis of hiatal hernia is based on typical clinical features and on the results of these laboratory studies and procedures:

- In barium study, hernia may appear as an outpouching containing barium at the lower end of the esophagus. Small hernias, however, are difficult to recognize. This study also shows diaphragmatic abnormalities.
- Endoscopy (esophagogastroduodenoscopy) and biopsy differentiate among hiatal hernia, varices, and other small gastroesophageal lesions; identify the mucosal junction and the edge of the diaphragm indenting the esophagus; and can rule out malignancy that otherwise may be difficult to detect.
- Esophageal motility studies assess the presence of esophageal motor abnormalities before surgical repair of the hernia.
- pH studies assess for reflux of gastric contents.

Treatment

The primary goals of treatment are to relieve symptoms by minimizing or correcting the incompetent cardia and to manage and prevent complications. Medical intervention is used first because symptoms usually respond to it and because hiatal hernia tends to recur after surgery. Such treatment attempts to modify or reduce reflux by changing the quantity or quality of refluxed gastric contents, by strengthening the LES muscle pharmacologically, or by decreasing the amount of reflux through gravity. These measures include restricting any activity that raises intra-abdominal pressure (coughing, straining, or bending), giving antiemetics, avoiding constrictive clothing, modifying diet, giving stool softeners or laxatives to prevent straining at stool, and discouraging smoking because it stimulates gastric acid production.

Modifying the diet means eating small, frequent, bland meals at least 2 hours before lying down, avoidance of bedtime snacking, eating slowly, and avoiding spicy foods, fruit juices, alcoholic beverages, and coffee. Antacids also modify the fluid refluxed into the esophagus and are effective treatment for intermittent reflux.

To reduce the amount of reflux, the patient who is overweight should lose weight to decrease intra-abdominal pressure. Elevating the head of the bed 6″ (15 cm) reduces gastric reflux by gravity.

Drug therapy includes antacids to neutralize stomach acid, medications to reduce acid production, and medications to block acid production and to heal the esophagus.

Surgical repair is necessary when symptoms can't be controlled medically or with the onset of complications, such as stricture, bleeding, pulmonary aspiration, strangulation, or incarceration. Surgery typically involves creating an artificial closing mechanism at the gastroesophageal junction to strengthen the LES's barrier function. The surgeon may use an abdominal or a thoracic approach, or may repair the hernia by laparoscopic surgery, which allows for less dependence on an NG tube and a shorter hospital stay.

Special Considerations

To enhance compliance with treatment, teach the patient about this disorder. Explain treatments, diagnostic tests, and significant symptoms.

- Prepare the patient for diagnostic tests as needed. After endoscopy, watch for signs of perforation (falling blood pressure, rapid pulse, shock, and sudden pain).
- If surgery is scheduled, review preoperative and postoperative considerations with the patient.
- After surgery, carefully record intake and output, including NG tube and wound drainage.
- While the NG tube is in place, provide meticulous mouth and nose care, but don't manipulate the tube. Give ice chips, if permitted, to moisten oral mucous membranes.
- If the surgeon used a thoracic approach, the patient may have chest tubes in place. Carefully observe chest tube drainage and the patient's respiratory status, and perform pulmonary physiotherapy.
- Before discharge, tell the patient what foods he or she can eat, and recommend small, frequent meals. Teach about avoidance of activities that cause increased intra-abdominal pressure, and recommend a slow return to normal functions (within 6 to 8 weeks).

Stomach, Intestine, and Pancreas

GASTRITIS

Gastritis, an inflammation of the gastric mucosa, may be acute or chronic. Acute gastritis

produces mucosal reddening, edema, hemorrhage, and erosion. Chronic gastritis is common among elderly people and people with pernicious anemia. It typically occurs as chronic atrophic gastritis, in which all stomach mucosal layers are inflamed, with reduced numbers of chief and parietal cells. Acute or chronic gastritis can occur at any age.

Causes and Incidence

Acute gastritis has numerous causes, including:

- chronic ingestion of (or an allergic reaction to) irritating foods or beverages, such as hot peppers or alcohol
- drugs, such as aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs; in large doses), cytotoxic agents, corticosteroids, antimetabolites, phenylbutazone, and indomethacin
- ingestion of poisons, especially DDT, ammonia, mercury, carbon tetrachloride, and corrosive substances
- endotoxins released from infecting bacteria, such as staphylococci, *Escherichia coli*, or salmonella

Acute gastritis leading to stress ulcers also may develop in acute illnesses, especially when the patient has had major traumatic injuries; burns; severe infection; hepatic, renal, or respiratory failure; or major surgery.

Chronic gastritis can occur at any age, and may be associated with PUD or gastrostomy, both of which cause chronic reflux of pancreatic secretions, bile, and bile acids from the duodenum into the stomach. Recurring exposure to irritating substances, such as drugs, alcohol, cigarette smoke, or environmental agents, may also lead to chronic gastritis. Chronic gastritis may occur with pernicious anemia, renal disease, or diabetes mellitus. Pernicious anemia is commonly associated with atrophic gastritis, a chronic inflammation of the stomach resulting from degeneration of the gastric mucosa. In pernicious anemia, the stomach can no longer secrete intrinsic factor, which is needed for vitamin B_{12} absorption.

Bacterial infection with *Helicobacter pylori* is a common cause of nonerosive chronic gastritis. About 50% of adults are infected with *H. pylori*, with a higher prevalence in developing nations.

Pathophysiology

Acute gastritis is caused by injury of the protective mucosal barrier; mechanisms of injury include drugs, chemicals, or *H. pylori* infection. NSAIDs inhibit the action of cyclooxygenase-1 (COX-1) and cause gastritis because of the inhibited prostaglandin synthesis which normally stimulates mucus secretion and suppresses inflammation.

Chronic gastritis is classified as type A (immune, or fundal), type B (nonimmune, or antral) associated with *H. pylori,* type AB (when types A and B occur at the same time), or type C (which is associated with bile reflux and pancreatic secretions into the stomach).

Complications

- Hemorrhage
- Shock
- Obstruction
- Perforation
- Peritonitis

◆ Gastric cancer

Signs and Symptoms

After exposure to the offending substance, the patient with acute gastritis typically reports a rapid onset of symptoms, such as epigastric discomfort, indigestion, cramping, anorexia, nausea, vomiting, and hematemesis. The symptoms last from a few hours to a few days.

The patient with chronic gastritis may describe similar symptoms or may have only mild epigastric discomfort. Concerns may be vague, such as intolerance for spicy or fatty foods or slight pain relieved by eating.

Diagnosis

℞ CONFIRMING DIAGNOSIS *Esophagogastroduodenoscopy or gastroscopy (with biopsy) confirms gastritis when done before lesions heal (usually within 24 hours). This test is contraindicated after ingestion of a corrosive agent.*

Laboratory analyses can detect occult blood in vomitus or stool (or both) if the patient has gastric bleeding. Hemoglobin level and hematocrit are decreased if the patient has developed anemia from bleeding.

Treatment

Treatment for gastritis focuses on eliminating the cause; for example, bacterial gastritis is treated with antibiotics, whereas gastritis caused by ingested poison is treated by neutralizing the poison with the appropriate antidote. Proton pump inhibitors or H_2 receptor antagonists may reduce gastric acid production. Many over-the-counter preparations are available. Antacids may be used as buffers.

For critically ill patients, antacids administered hourly, with or without H_2-receptor antagonists, may reduce the frequency of gastritis attacks. Some patients also require analgesics. Until healing occurs, patients' oxygen needs, blood volume, and fluid and electrolyte balance must be monitored.

When gastritis causes massive bleeding, treatment includes blood replacement; iced saline lavage, possibly with norepinephrine; angiography with vasopressin infused in normal saline solution; and, sometimes, surgery.

Vagotomy and pyloroplasty achieve limited success when conservative treatments fail. Rarely, partial or total gastrectomy may be required.

Simply avoiding aspirin and spicy foods may prevent exacerbations of chronic gastritis. If symptoms develop or persist, antacids may be taken. If pernicious anemia is the cause, vitamin B_{12} may be administered parenterally. A combination of two antibiotics, such as clarithromycin and amoxicillin, is typically given for 14 days to treat *H. pylori*. Acid-reducing medications may help to enhance the effectiveness of the antibiotics.

Special Considerations

Patient care includes education and attention to various aspects of nutritional status to control symptoms and prevent their recurrence.

◆ For vomiting, give antiemetics and I.V. fluids, as ordered. Monitor fluid intake and output and electrolyte levels.

- Monitor the patient for recurrent symptoms as food is reintroduced; provide a bland diet.
- Offer smaller, more frequent meals to reduce irritating gastric secretions. Eliminate foods that cause gastric upset.
- Administer proton pump inhibitors, H_2-receptor antagonists, and antacids, as ordered.
- If pain or nausea interferes with the patient's appetite, give analgesics or antiemetics 1 hour before meals.
- Teach the patient to avoid alcohol, caffeine, and irritating foods such as spicy or highly seasoned foods.
- If the patient smokes, provide referral to a smoking-cessation program.
- Urge the patient to seek immediate attention for recurring symptoms, such as hematemesis, nausea, or vomiting.
- To prevent exacerbation, urge the patient to take prophylactic medications, as ordered.

PREVENTION *Advise the patient to take steroids with milk, food, or antacids. Instruct to take antacids between meals and at bedtime and to avoid aspirin-containing compounds.*

GASTROENTERITIS

A self-limiting disorder, gastroenteritis is characterized by diarrhea, nausea, vomiting, and acute or chronic abdominal cramping. Also called *intestinal flu, traveler's diarrhea, viral enteritis*, or *food poisoning*, it occurs in persons of all ages and is a major cause of morbidity and mortality in underdeveloped nations. It also can be life-threatening in elderly or debilitated people.

Causes and Incidence

Gastroenteritis has many possible causes, including:

- bacteria (responsible for acute food poisoning), such as *Staphylococcus aureus, Salmonella, Shigella, Clostridium botulinum, C. perfringens*, and *E. coli*
- amebae, especially *Entamoeba histolytica*
- parasites, such as *Ascaris, Enterobius*, and *Trichinella spiralis*
- viruses (may be responsible for traveler's diarrhea) such as adenoviruses, echoviruses, or coxsackieviruses
- ingestion of toxins, including plants or toadstools
- drug reactions; for example, to antibiotics
- enzyme deficiencies
- food allergens

The bowel reacts to any of these enterotoxins with hypermotility, producing severe diarrhea and secondary depletion of intracellular fluid. Chronic gastroenteritis is usually the result of another GI disorder such as ulcerative colitis. The incidence of gastroenteritis is relevant to the causative agent. The prevalence of norovirus is approximately 18%, and higher in low-mortality developing and developed countries versus high-mortality developing and developed countries.

Pathophysiology

Pathophysiology of gastroenteritis is related to the causative agent.

Complications

- Severe dehydration
- Electrolyte loss
- Shock
- Vascular collapse
- Renal failure

Signs and Symptoms

Signs and symptoms vary depending on the pathologic organism and on the level of the GI tract involved. However, gastroenteritis in adults is usually an acute, self-limiting, nonfatal disease producing diarrhea, abdominal discomfort (ranging from cramping to pain), nausea, and vomiting. Other possible signs and symptoms include fever, malaise, and borborygmi. In children, older adults, and the immunocompromised, gastroenteritis produces the same symptoms, but these patients' intolerance to electrolyte and fluid losses leads to a higher mortality.

Diagnosis

Patient history can aid in the diagnosis of gastroenteritis. Stool culture (by direct rectal swab) or blood culture identifies the causative bacteria or parasites.

Treatment

Treatment is usually supportive and consists of rest, nutritional support, and increased fluid intake. When gastroenteritis is severe or affects a young child or an elderly or debilitated person, treatment may necessitate hospitalization, specific antimicrobials, I.V. fluid and electrolyte replacement and, possibly, antiemetics (given orally, I.M., or by rectal suppository).

Special Considerations

Patient care includes education, administering medications, and assessing symptoms for signs of improvement or worsening.

- Administer medications as ordered; correlate dosages, routes, and times appropriately with the patient's meals and activities (e.g., give antiemetics 30 to 60 minutes before meals).
- If the patient can eat and is not dehydrated, replace lost fluids and electrolytes with foods and diluted fruit juice, sports drinks. No specific diet is required, yet a bland diet may be better tolerated. Saltine crackers, broths, soups, broiled starches or cereals, bananas, and vegetables can help to meet fluid and sodium needs. Vary the diet to make it more enjoyable, and allow some choice of foods. Teach the patient to avoid milk and milk products, which may provoke recurrence.
- Record intake and output carefully and obtain serial weight measurements. Watch for signs of dehydration, such as dry skin and mucous membranes, fever, and sunken eyes.
- Wash hands thoroughly after giving care to avoid spreading infection.
- To ease anal irritation, provide warm sitz baths or apply witch hazel compresses.
- If food poisoning is the likely cause of gastroenteritis, contact public health authorities so they can interview patients and food handlers, and take samples of the suspected contaminated food.

PREVENTION *Teach good hygiene to prevent recurrence. Instruct patients to cook foods—*

especially pork—thoroughly; to refrigerate perishable foods, such as milk, mayonnaise, potato salad, and cream-filled pastries; to always wash hands thoroughly with warm water and soap before handling food, and especially after using the bathroom; to clean utensils thoroughly; to avoid drinking water or eating raw fruit or vegetables when visiting a foreign country; and to eliminate flies and roaches in the home.

PEPTIC ULCERS

Peptic ulcers—circumscribed lesions in the mucosal membrane—can develop in the lower esophagus, stomach, pylorus, duodenum, or jejunum. Most peptic ulcers are duodenal ulcers, which affect the proximal part of the small intestine.

Gastric ulcers, which affect the stomach mucosa, are commonly seen in chronic users of NSAIDs, alcohol, or tobacco. Duodenal ulcers usually follow a chronic course, with remissions and exacerbations; a small percentage of patients develop complications that necessitate surgery.

Causes and Incidence

Researchers recognize two primary major causes of PUD: infection with *H. pylori* (formerly known as *Campylobacter pylori*), and use of NSAIDs, and pathologic hypersecretory disorders such as Zollinger–Ellison syndrome.

Pathophysiology

In the United States, about 1.6 million people develop peptic ulcers yearly. Men and women are affected equally, and incidence increases with age. A higher percentage of *H. pylori* infection occurs in people older than age 50. See box *how peptic ulcers develop* for pathophysiology.

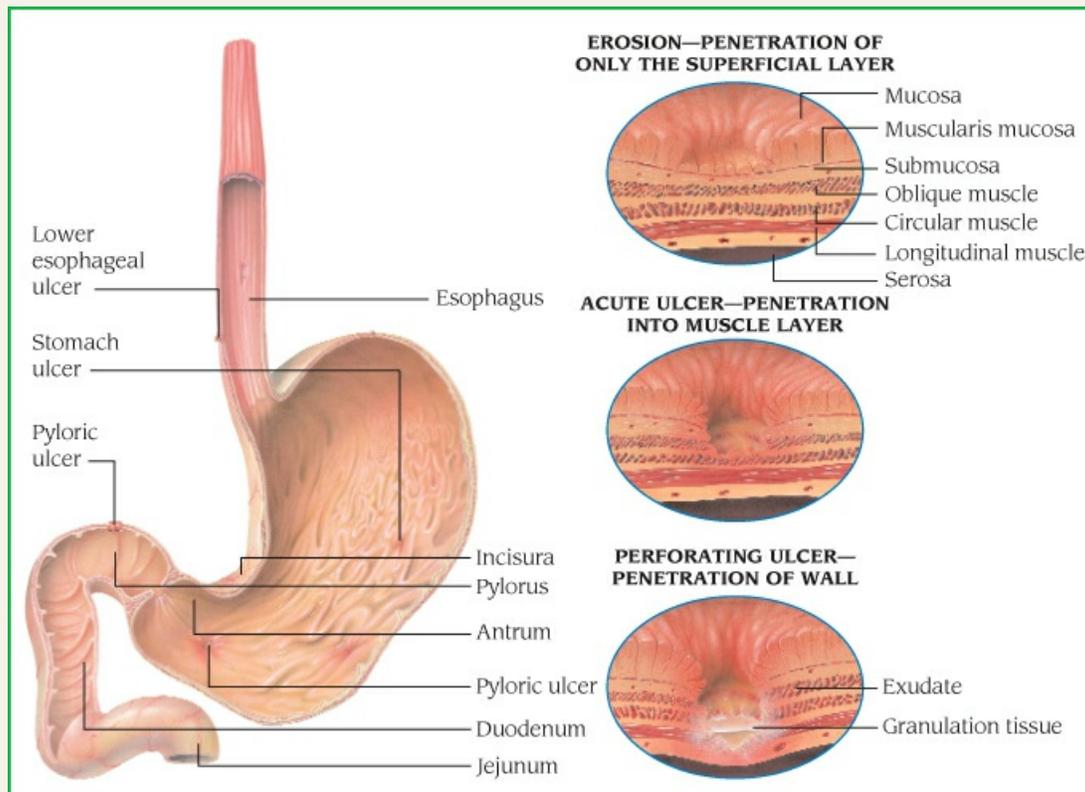
PATHOPHYSIOLOGY
HOW PEPTIC ULCERS DEVELOP

Peptic ulcers can result from factors that increase gastric acid production or from factors that impair mucosal barrier protection.

Increased number of parietal and chief cells	→		
Increased sensitivity to food and other stimuli such as caffeine	→	Increased gastric acid production	
Excess vagal stimulation	→		
Decreased inhibition of gastric secretions	→		PEPTIC ULCER FORMATION
Inadequate mucosal blood supply	→		
Impaired mucus production	→	Impaired mucosal barrier protection	
Bile or pancreatic enzyme reflux from duodenum	→		
Aspirin, nonsteroidal anti-inflammatory drugs, or alcohol ingestion	→		
Colonization by *Helicobacter pylori*	→		

Helicobacter pylori produces an ulcer by damaging the mucous coating that protects the stomach and duodenum.

Salicylates and other NSAIDs encourage ulcer formation by inhibiting the secretion of prostaglandins (the substances that suppress ulceration). Certain illnesses, such as pancreatitis, hepatic disease, Crohn disease, preexisting gastritis, and Zollinger–Ellison syndrome, are also known causes.

Besides peptic ulcer's main causes, several predisposing factors are acknowledged. They include blood type (gastric ulcers tend to strike people with type A blood; duodenal ulcers tend to afflict people with type O blood) and other genetic factors. Exposure to irritants, such as alcohol, coffee, and tobacco, may contribute by accelerating gastric acid emptying and promoting mucosal breakdown. Ulceration occurs when the acid secretion exceeds the buffering factors. Physical trauma, emotional stress, and normal aging are additional predisposing conditions. (See *Common ulcer types and sites*.)


Complications

- GI hemorrhage
- Hypovolemic shock
- Perforation
- Obstruction
- Extension of ulcer into adjacent structures
- Dumping syndrome
- Vitamin deficiency

Signs and Symptoms

Heartburn and indigestion usually signal the beginning of a gastric ulcer attack. Eating stretches the gastric wall and may cause or, in some cases, relieve pain and feelings of fullness and distention. Other typical effects include weight loss and repeated episodes of massive GI bleeding.

Duodenal ulcers produce heartburn, well-localized midepigastric pain (relieved by food),

weight gain (because the patient eats to relieve discomfort), and a peculiar sensation of hot water bubbling in the back of the throat. Attacks usually occur about 2 hours after meals, whenever the stomach is empty, or after consumption of orange juice, coffee, aspirin, or alcohol. Exacerbations tend to recur several times per year and then fade into remission. Vomiting and other digestive disturbances are rare.

Ulcers may penetrate the pancreas and cause severe back pain. Other complications of peptic ulcers include perforation, hemorrhage, and pyloric obstruction. Ulcers may, on occasion, produce no symptoms.

Diagnosis

℞ CONFIRMING DIAGNOSIS *Esophagogastroduodenoscopy confirms the presence of an ulcer and permits cytologic studies and biopsy to rule out* H. pylori *or cancer*.

Diagnosis may be confirmed by the following tests:

- Barium swallow or upper GI and small bowel series may reveal the presence of the ulcer. This is the initial test performed on a patient whose symptoms aren't severe.
- Laboratory analysis may detect occult blood in stools.
- Serologic testing may disclose clinical signs of infection such as an elevated white blood cell count.
- Carbon 13 (^{13}C) urea breath test results reflect activity of *H. pylori*.

Treatment

Experts recommend treating the patient with two antibiotics and a proton pump inhibitor or H_2 receptor antagonists to eradicate *H. pylori*. The patient taking NSAIDs may take a prostaglandin analog (misoprostol) to suppress ulceration (or the patient may take the analog with NSAIDs to prevent ulceration). H_2 receptor antagonists or proton pump inhibitors may reduce acid secretion. A coating agent or bismuth may be administered to the patient with a duodenal ulcer to protect the lining.

If GI bleeding occurs, emergency treatment begins with passage of an NG tube to allow for iced saline lavage, possibly containing norepinephrine. Gastroscopy allows visualization of the bleeding site and coagulation by laser or cautery to control bleeding. This type of therapy allows postponement of surgery until the patient's condition stabilizes. Surgery is indicated for perforation, unresponsiveness to conservative treatment, and suspected malignancy. Surgery for peptic ulcers may include:

- Vagotomy and pyloroplasty—severing one or more branches of the vagus nerve to reduce hydrochloric acid secretion and refashioning the pylorus to create a larger lumen and facilitate gastric emptying
- Distal subtotal gastrectomy (with or without vagotomy)—excising the antrum of the stomach, thereby removing the hormonal stimulus of the parietal cells, followed by anastomosis of the rest of the stomach to the duodenum or the jejunum
- Pyloroplasty—surgical enlargement of the pylorus to provide drainage of gastric secretions.

Special Considerations

Management of peptic ulcers requires careful administration of medications, thorough patient

teaching, and skillful postoperative care.

- Watch for adverse reactions to H_2-receptor antagonists and proton pump inhibitors (dizziness, fatigue, rash, and mild diarrhea).
- Advise any patient who uses antacids, who has a history of cardiac disease, or who follows a sodium-restricted diet to take only those antacids that contain low amounts of sodium.
- Warn the patient to avoid NSAIDs because they irritate the gastric mucosa. For the same reason, advise the patient to stop smoking and to avoid stressful situations, excessive intake of coffee, and drinking alcoholic beverages during exacerbations of PUD.

After gastric surgery:

- Keep the NG tube patent. If the tube isn't functioning, don't reposition it; you might damage the suture line or anastomosis. Notify the surgeon promptly.
- Monitor intake and output, including NG tube drainage. Check for bowel sounds, and allow the patient nothing by mouth until peristalsis resumes and the NG tube is removed or clamped.
- Replace fluids and electrolytes. Assess the patient for signs of dehydration, sodium deficiency, and metabolic alkalosis, which may occur secondary to gastric suction.
- Monitor the patient for possible dumping syndrome (a rapid gastric emptying, causing distention of the duodenum or jejunum produced by a bolus of food). Signs and symptoms of dumping syndrome include diaphoresis, weakness, nausea, flatulence, explosive diarrhea, distention, and palpitations within 30 minutes after a meal.
- To avoid dumping syndrome, advise the patient to lie down after meals, to drink fluids *between* meals rather than with meals, to avoid eating large amounts of carbohydrates, and to eat four to six small, high-protein, low-carbohydrate meals during the day.

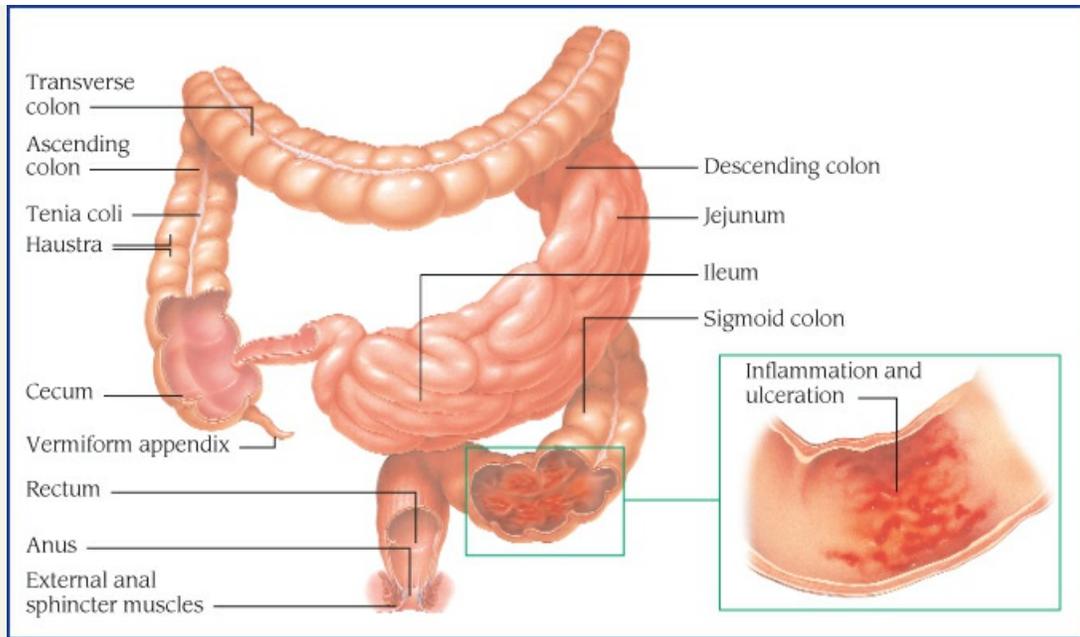
ULCERATIVE COLITIS

Ulcerative colitis is an inflammatory, usually chronic disease that affects the mucosa of the colon. It invariably begins in the rectum and sigmoid colon and commonly extends upward into the entire colon; it rarely affects the small intestine, except for the terminal ileum. Ulcerative colitis produces edema (leading to mucosal friability) and ulcerations. Severity is categorized as mild, moderate, or severe. (See *Mucosal changes in ulcerative colitis*.)

PATHOPHYSIOLOGY
MUCOSAL CHANGES IN ULCERATIVE COLITIS

In ulcerative colitis, the colon goes through inflammation and ulceration.

Transverse colon
Ascending colon
Tenia coli
Haustra
Cecum
Vermiform appendix
Rectum
Anus
External anal sphincter muscles

Descending colon
Jejunum
Ileum
Sigmoid colon
Inflammation and ulceration


Causes and Incidence

Although the etiology of ulcerative colitis is unknown, it's thought to be related to abnormal immune response in the GI tract, possibly associated with food or bacteria such as *E. coli*. Stress was once thought to be a cause of ulcerative colitis, but studies show that it isn't a cause, although it does increase the severity of the attack.

Ulcerative colitis occurs primarily in young adults. It's also more prevalent among those of Jewish ancestry, indicating a possible familial tendency. In North America, the incidence of the disease has risen in the past decade, with approximately 286 of every 100,000 persons affected. The onset of symptoms is generally noted between 15 and 40 years old, with a second peak between 50 and 80.

Pathophysiology

Complications

- Nutritional deficiency
- Perineal sepsis
- Anal fissure or fistula
- Perirectal abscess
- Hemorrhage
- Toxic megacolon
- Coagulation deficit

Signs and Symptoms

The hallmark of ulcerative colitis is recurrent attacks of bloody diarrhea, in many cases containing pus and mucus, interspersed with asymptomatic remissions. The intensity of these attacks varies with the extent of inflammation. It isn't uncommon for a patient with ulcerative

colitis to have as many as 15 to 20 liquid, bloody stools daily. Other symptoms include spastic rectum and anus, abdominal pain, irritability, weight loss, weakness, anorexia, nausea, and vomiting.

Ulcerative colitis may lead to complications, such as hemorrhage, stricture, or perforation of the colon. Other complications include joint inflammation, ankylosing spondylitis, eye lesions, mouth ulcers, liver disease, and pyoderma gangrenosum. Researchers anticipate that these complications occur when the immune system triggers inflammation in other parts of the body. These disorders are usually mild and disappear when the colitis is treated.

Patients with ulcerative colitis have an increased risk of developing colorectal cancer; children with ulcerative colitis may experience impaired growth and sexual development.

Diagnosis

CONFIRMING DIAGNOSIS *Sigmoidoscopy showing increased mucosal friability, decreased mucosal detail, pinpoint hemorrhages, and thick inflammatory exudate suggests this diagnosis. Biopsy can help confirm it.*

Colonoscopy may be required to determine the extent of the disease and to evaluate stricture areas and pseudopolyps for which a biopsy would then be done during the colonoscopy. Barium enema can assess the extent of the disease and detect complications, such as strictures and carcinoma.

A stool sample should be cultured and analyzed for leukocytes, ova, and parasites. Other supportive laboratory values include decreased serum levels of potassium, magnesium, hemoglobin, and albumin as well as leukocytosis and increased prothrombin time. An elevated erythrocyte sedimentation rate correlates with the severity of the attack.

Treatment

The goals of treatment are to control inflammation, replace nutritional losses and blood volume, and prevent complications. Supportive treatment includes bed rest, I.V. fluid replacement, and a clear-liquid diet. For patients awaiting surgery or showing signs of dehydration and debilitation from excessive diarrhea, TPN rests the intestinal tract, decreases stool volume, and restores positive nitrogen balance. Blood transfusions or iron supplements may be needed to correct anemia.

Sulfasalazine and mesalamine are used for their anti-inflammatory action. Immune system suppressors may be used to decrease the frequency of attacks. Drug therapy to control inflammation may include steroids. Antispasmodics and antidiarrheals are used only in patients whose ulcerative colitis is under control but who have frequent, loose stools.

ALERT *Antispasmodics and antidiarrheals may lead to massive dilation of the colon (toxic megacolon) and are generally contraindicated.*

Surgery is the last resort if the patient has toxic megacolon, fails to respond to drugs and supportive measures, or finds symptoms unbearable. A common surgical technique is proctocolectomy with ileostomy. Another procedure, the ileoanal pull-through, is being performed in more cases. This procedure entails performing a total proctocolectomy and mucosal stripping, creating a pouch from the terminal ileum, and anastomosing the pouch to the anal canal. A temporary ileostomy is created to divert stool and allow the rectal anastomosis to heal.

The ileostomy is closed in 2 to 3 months, and the patient can then evacuate stool rectally. This procedure removes all the potentially malignant epithelia of the rectum and colon. Total colectomy and ileorectal anastomosis isn't as common because of its mortality rate. This procedure removes the entire colon and anastomoses the terminal ileum to the rectum; it requires observation of the remaining rectal stump for any signs of cancer or colitis.

Pouch ileostomy (Kock pouch or continent ileostomy), in which the surgeon creates a pouch from a small loop of the terminal ileum and a nipple valve from the distal ileum, may be an option. The resulting stoma opens just above the pubic hairline, and the pouch is emptied periodically through a catheter inserted in the stoma. In ulcerative colitis, a colectomy may have to be performed after colonic perforation (although this is rare) or after years of active disease because of the increased incidence of colon cancer in these cases. Performing a partial colectomy to prevent colon cancer is controversial.

Special Considerations

Patient care includes close monitoring for changes in status.

- Accurately record intake and output, particularly the frequency and volume of stools. Watch for signs of dehydration and electrolyte imbalances, especially signs and symptoms of hypokalemia (muscle weakness and paresthesia) and hypernatremia (tachycardia, flushed skin, fever, and dry tongue). Monitor hemoglobin level and hematocrit, and give blood transfusions as ordered. Provide good mouth care for the patient who's allowed nothing by mouth.
- After each bowel movement, thoroughly clean the skin around the rectum. Provide an air mattress or sheepskin to help prevent skin shear and breakdown.
- Administer medications, as ordered. Monitor for adverse effects of prolonged corticosteroid therapy (moon face, hirsutism, edema, and gastric irritation). Be aware that corticosteroid therapy may mask infection.
- If the patient needs TPN, change dressings as ordered, assess for inflammation at the insertion site, and check capillary blood glucose levels every 4 to 6 hours.
- Take precautionary measures if the patient is prone to bleeding. Watch closely for signs of complications, such as a perforated colon and peritonitis (fever, severe abdominal pain, abdominal rigidity and tenderness, and cool, clammy skin) and toxic megacolon (abdominal distention and decreased bowel sounds).

For the patient requiring surgery:

- Carefully prepare the patient for surgery, and teach about ileostomy.
- Perform bowel preparation, as ordered.
- After surgery, provide meticulous supportive care and continue teaching correct stoma care.
- Keep the NG tube patent. After removal of the tube, provide a clear-liquid diet and gradually advance to a low-residue diet, as tolerated.
- After a proctocolectomy and ileostomy, teach good stoma care. Wash the skin around the stoma with soapy water and dry it thoroughly. Apply karaya gum around the stoma's base to avoid irritation, and make a watertight seal. Attach the pouch over the karaya ring. Cut an opening in the ring to fit over the stoma, and secure the pouch to the skin. Empty the pouch when it's one third full. Encourage the patient to report stoma color changes or purulent drainage to the healthcare provider.
- After a pouch ileostomy, uncork the catheter every hour to allow contents to drain. After 10 to

14 days, gradually increase the length of time the catheter is left corked until it can be opened every 3 hours. Then remove the catheter and reinsert it every 3 to 4 hours for drainage. Teach the patient how to insert the catheter and how to take care of the stoma.
- ◆ Encourage the patient to have regular physical examinations.

NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis (NEC) is characterized by diffuse or patchy intestinal necrosis, accompanied by fatal sepsis in about one third of cases. Sepsis usually involves *E. coli, Clostridia, Salmonella, Pseudomonas,* or *Klebsiella*. Initially, necrosis is localized, occurring anywhere along the intestine, but usually in the ileum, ascending colon, or rectosigmoid. If diffuse bleeding occurs, NEC usually results in disseminated intravascular coagulation (DIC).

Causes and Incidence

The exact cause of NEC is not fully understood, although it is thought to be related to mucosal injury by cytotoxic drugs, profound neutropenia, and/or impaired host defense when invaded by microorganisms.

NEC usually occurs in premature infants (<32 weeks of gestation) and those of very low birth weight (<1,500 g). NEC is more common in some geographic areas, thought to be due to the higher incidence of premature neonates and neonates who have low birth weights in these areas. In the United States, it is estimated that this condition occurs in 1 to 3 per 1,000 live births.

Pathophysiology

The etiology of NEC is not fully known, although it is thought to be related to mucosal injury as noted above. Other predisposing factors are thought to include birth asphyxia, postnatal hypotension, respiratory distress, hypothermia, umbilical vessel catheterization, exchange transfusion, or patent ductus arteriosus. NEC may also be a response to significant prenatal stress, such as premature rupture of membranes, placenta previa, maternal sepsis, toxemia of pregnancy, or breech or cesarean birth.

NEC may develop when the infant suffers perinatal hypoxemia due to shunting of blood from the gut to more vital organs. Subsequent mucosal ischemia provides an ideal medium for bacterial growth. Accumulation of gas in the intestine can cause pressure that impedes blood flow; vasoconstriction may play a role in contribution to this condition. Hypertonic formula may increase bacterial activity because—unlike maternal breast milk—it doesn't provide protective immunologic activity and it contributes to the production of hydrogen gas. As the bowel swells and breaks down, gas-forming bacteria invade damaged areas, producing free air in the intestinal wall. This may result in fatal perforation and peritonitis.

Complications

- ◆ Perforation
- ◆ Mechanical and functional abnormalities of the intestine

Signs and Symptoms

Neonates who have suffered from perinatal hypoxemia have the potential for developing NEC. A distended (especially tense or rigid) abdomen with gastric retention is the earliest and most common sign of oncoming NEC, which usually appears 1 to 10 days after birth. Other clinical features are increasing residual gastric contents (which may contain bile), bile-stained vomitus,

and occult blood in the stool. A portion of patients may have bloody diarrhea. A red or shiny, taut abdomen may indicate peritonitis.

Nonspecific signs and symptoms include thermal instability, lethargy, metabolic acidosis, jaundice, and DIC. The major complication is perforation, which requires surgery. Recurrence of NEC and mechanical and functional abnormalities of the intestine, especially stricture, are the usual cause of residual intestinal malfunction in any infant who survives acute NEC; this complication may develop as late as several months postoperatively.

Diagnosis

Successful treatment of NEC is reliant upon early recognition.

℞ **CONFIRMING DIAGNOSIS** *Abdominal X-rays confirm the diagnosis, showing nonspecific intestinal dilation and, in later stages of NEC, pneumatosis cystoides intestinalis (gas or air in the intestinal wall).*

Blood studies show several abnormalities. Platelet count may fall below 50,000/µL. Serum sodium levels are decreased, and arterial blood gas levels indicate metabolic acidosis (a result of sepsis). Infection-induced red blood cell breakdown elevates bilirubin levels. Blood and stool cultures identify the infecting organism, clotting studies and the hemoglobin level reveal associated DIC, and the guaiac test detects occult blood in the stool.

Treatment

The first signs of NEC necessitate removal of the umbilical catheter (arterial or venous) and discontinuation of oral intake for 7 to 10 days to rest the injured bowel. I.V. fluids, including TPN, maintain fluid and electrolyte balance and nutrition during this time; passage of an NG tube aids bowel decompression. If coagulation studies indicate a need for transfusion, the infant usually receives dextran to promote hemodilution, increase mesenteric blood flow, and reduce platelet aggregation. Antibiotic therapy consists of parenteral agents—administered through an NG tube, if necessary—to suppress bacterial flora and prevent bowel perforation. Anteroposterior and lateral X-rays are repeated to monitor disease progression.

Surgery is indicated if the patient shows any of these signs or symptoms: signs of perforation (free intraperitoneal air on X-ray or symptoms of peritonitis), respiratory insufficiency (caused by severe abdominal distention), progressive and intractable acidosis, or DIC. Surgery removes all necrotic and acutely inflamed bowel and creates a temporary colostomy or ileostomy. At least 12″ (30.5 cm) of bowel must remain or the infant may suffer from malabsorption or chronic vitamin B_{12} deficiency.

Special Considerations

⚠ **ALERT** *Be alert for signs or symptoms of gastric distention and perforation: apnea, cardiovascular shock, sudden drop in temperature, bradycardia, sudden listlessness, rag-doll limpness, increasing abdominal tenderness, edema, erythema, or involuntary abdominal rigidity.*

- ◆ To avoid perforating the bowel, *don't* take rectal temperatures.
- ◆ Prevent cross-contamination by disposing of soiled diapers properly and washing hands immediately after diaper changes.

- After surgery, the infant needs mechanical ventilation. Gently suction secretions, and assess breathing often.
- Replace fluids lost through NG tube and stoma drainage. Include drainage losses in output records. Weigh the infant daily. A daily weight gain of 10 to 20 g indicates a favorable response to therapy.
- An infant with a temporary colostomy or ileostomy needs special care. Explain to the parents what a colostomy or ileostomy is and why it's necessary. Encourage them to participate in their infant's physical care after the condition is no longer critical.
- Because of the infant's small abdomen, the suture line is near the stoma; as a result, keeping the suture line clean can be a problem. Good skin care is essential because the immature infant's skin is fragile and vulnerable to excoriation and the active enzymes in bowel secretions are corrosive. Improvise premature-sized colostomy bags from urine collection bags, medicine cups, or condoms. Karaya gum is helpful in making a seal. Watch for wound disruption, infection, and excoriation—potential dangers because of severe catabolism.
- Watch for intestinal malfunction from stricture or short-gut syndrome. Such complications usually develop a month after the infant resumes normal feedings.

PREVENTION *Encourage mothers to breast-feed because breast milk contains live macrophages that fight infection and has a low pH that inhibits the growth of many organisms. Also, colostrum—fluid secreted from the breast before the milk—contains high concentrations of immunoglobulin A, which directly protects the gut from infection and which the neonate lacks for several days postpartum. Tell mothers that they may refrigerate their milk for 48 hours but shouldn't freeze or heat it because this destroys antibodies.*

CROHN DISEASE

Crohn disease, also known as *regional enteritis* and *granulomatous colitis*, is an idiopathic inflammation of any part of the GI tract from mouth to anus (usually the ileum or proximal portion of the colon).

Causes and Incidence

In Crohn disease, lacteal blockage in the intestinal wall leads to edema and, eventually, inflammation, ulceration, and stenosis. Abscesses and fistulas may also occur.

Although the exact cause of Crohn disease is unknown, risk factors include family history, smoking cigarettes, Jewish ethnicity, urban residency, age of less than 40, and an altered gut microbiome. It is most prevalent in adults 15 to 30 years old. It's two to three times more common in those of Jewish ancestry.

The incidence of Crohn disease has risen steadily over the past 50 years; it now affects 20.2 of every 100,000 people.

Pathophysiology

Crohn disease involves "skip lesions" (granulomas surrounded by normal mucosa) with mixed areas of transmural inflammation (versus areas that are noninflamed) noncaseating granulomas, fistulas, and deep ulcers. The surface of the inflamed GI tract usually has a cobblestone appearance, which is different from alternating areas of inflammation and fissure crevices. The progression of Crohn disease involves neutrophil infiltration of the crypts, which leads to the formation of abscesses and crypt destruction.

Complications

- Anal fistula
- Perineal abscess
- Intestinal obstruction
- Nutritional deficiency
- Peritonitis (rare)

Signs and Symptoms

Clinical effects may be mild and nonspecific initially; they vary according to the location and extent of the lesion. Acute inflammatory signs and symptoms mimic appendicitis and include steady, colicky pain in the right lower quadrant, cramping, tenderness, flatulence, nausea, fever, and diarrhea. Bleeding may occur and, although usually mild, may be massive. Bloody stools may also occur.

Chronic symptoms, which are more typical of the disease, are more persistent and less severe; they include diarrhea (four to six stools per day) with pain in the right lower abdominal quadrant, steatorrhea (excess fat in feces), marked weight loss and, rarely, clubbing of fingers. The patient may complain of weakness and fatigue. Complications include intestinal obstruction, fistula formation between the small bowel and the bladder, perianal and perirectal abscesses and fistulas, intra-abdominal abscesses, and perforation.

Diagnosis

℞ **CONFIRMING DIAGNOSIS** *Barium enema showing the string sign (segments of stricture separated by normal bowel) supports a diagnosis of Crohn disease.* (See *The "String Sign."*)

The "String Sign"

The characteristic "string sign" (marked narrowing of the bowel), resulting from inflammatory disease and scarring, strengthens the diagnosis of Crohn disease.

Sigmoidoscopy and colonoscopy may show patchy areas of inflammation, thus helping to rule out ulcerative colitis. However, biopsy is required for a definitive diagnosis.

Laboratory findings commonly indicate increased white blood cell count and erythrocyte sedimentation rate, hypokalemia, hypocalcemia, hypomagnesemia, and a decreased hemoglobin level.

Treatment

To control the inflammatory process, medications, such as mesalamine and sulfasalazine, may be prescribed. Corticosteroids and immune system suppressors, such as azathioprine (Imuran) and mercaptopurine (Purinethol), may be prescribed if mesalamine isn't effective or in patients with severe Crohn disease. In debilitated patients, therapy includes TPN to maintain nutritional status while resting the bowel. If abscesses or fistulas occur, antibiotics may be prescribed. Infliximab (Remicade), an antibody to tumor necrosis factor-alpha (an immune chemical that promotes inflammation), may also be prescribed. Other medications prescribed for refractory Crohn disease include certolizumab (Cimzia), adalimumab (Humira), and natalizumab (Tysabri). Some clinicians start with these medications in patients with severe Crohn disease, where others step up to these medications when the patient fails traditional treatment.

Effective treatment requires important changes in lifestyle: physical rest, restricted diet (specific foods vary from person to person), vitamin B_{12} injections and supplements, and elimination of dairy products for lactose intolerance.

Surgery may be necessary to correct bowel perforation, massive hemorrhage, fistulas, or acute intestinal obstruction. Colectomy with ileostomy is necessary in many patients with extensive disease of the large intestine and rectum.

Special Considerations

Although treatment is based largely on symptoms, monitor the patient's status carefully for signs of worsening.

- Record fluid intake and output (including the amount of stool), and weigh the patient daily. Watch for dehydration, and maintain fluid and electrolyte balance. Be alert for signs of intestinal bleeding (bloody stools); check stools daily for occult blood.
- Check hemoglobin level and hematocrit regularly. Give iron supplements and blood transfusions, as ordered.
- Provide hygiene and mouth care if the patient is restricted to having nothing by mouth. After each bowel movement, provide thorough skin care. Always keep a clean, covered bedpan within the patient's reach. Ventilate the room to eliminate odors.
- Observe the patient for fever and pain or pneumaturia, which may signal bladder fistula. Abdominal pain and distention and fever may indicate intestinal obstruction. Watch for stools from the vagina and an enterovaginal fistula.
- Before ileostomy, arrange for a visit by an enterostomal therapist.
- After surgery, frequently check the patient's I.V. line and NG tube for proper functioning. Monitor vital signs and fluid intake and output. Watch for wound infection. Provide meticulous stoma care and teach proper care to the patient and family. Realize that ileostomy changes the patient's body image; provide reassurance and emotional support.
- Stress the need for a severely restricted diet and bed rest, which may be challenging,

particularly for a young patient. Encourage reduction in tension. If stress is clearly an aggravating factor, refer the patient for counseling.
- Refer the patient to a support group such as the Crohn's and Colitis Foundation of America.

PSEUDOMEMBRANOUS ENTEROCOLITIS

Pseudomembranous enterocolitis is an acute inflammation and necrosis of the small and large intestines, which usually affects the mucosa but may extend into the submucosa and, rarely, other layers. Marked by severe diarrhea, this rare condition is generally fatal in 1 to 7 days due to severe dehydration and toxicity, peritonitis, or perforation.

Causes and Incidence

The exact cause of pseudomembranous enterocolitis is unknown. The incidence of antibiotic-related diarrhea varies from 5% to 39%, depending on the antibiotic. Pseudomembranous enterocolitis complicates 10% of these cases.

PEDIATRIC TIP *Ampicillin is the most common antibiotic associated with pseudomembranous enterocolitis in children.*

Pathophysiology

Although the pathophysiology of pseudomembranous enterocolitis is not fully understood, *Clostridium difficile* is thought to produce a toxin that may play a role in its development. Pseudomembranous enterocolitis has occurred postoperatively in debilitated patients who undergo abdominal surgery and in patients treated with broad-spectrum antibiotics. Irrespective of the cause, necrotic mucosa is replaced by a pseudomembrane filled with staphylococci, leukocytes, mucus, fibrin, and inflammatory cells.

Complications

- Severe dehydration
- Electrolyte imbalance
- Hypotension
- Shock
- Colonic perforation
- Peritonitis

Signs and Symptoms

Pseudomembranous enterocolitis begins suddenly with copious watery or bloody diarrhea that may contain pus or mucus, abdominal pain, and fever. Serious complications, including severe dehydration, electrolyte imbalance, hypotension, shock, and colonic perforation, may occur in this disorder.

Diagnosis

Diagnosis is difficult in many cases because of the abrupt onset of enterocolitis and the emergency situation it creates, so consideration of patient history is essential. A rectal biopsy through sigmoidoscopy confirms pseudomembranous enterocolitis. Stool cultures can identify *C. difficile*.

Treatment

A patient receiving broad-spectrum antibiotic therapy must discontinue antibiotics at once. Effective treatment usually includes metronidazole. Oral vancomycin is superior to metronidazole for all cases. A patient with mild pseudomembranous enterocolitis may receive anion exchange resins, such as cholestyramine, to bind the toxin produced by *C. difficile*. Supportive treatment must maintain fluid and electrolyte balance, and combat hypotension and shock with a pressor, such as dopamine.

Special Considerations

Careful observation for signs of worsening is essential.

- Monitor the patient's vital signs, skin color, and level of consciousness. Immediately report signs of shock.
- Record fluid intake and output, including fluid lost in stools. Watch for symptoms that indicate dehydration (poor skin turgor, sunken eyes, and decreased urine output).
- Check serum electrolyte levels daily, and watch for clinical signs of hypokalemia, especially malaise, and a weak, rapid, irregular pulse.

PREVENTION *Antibiotics should be used only as prescribed by healthcare providers. Research indicates that the use of probiotics along with antibiotics may help address a variety of GI problems.*

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is a condition marked by abdominal pain and altered bowel habits. Some patients experience chronic or periodic diarrhea, alternating with constipation, while others experience only one or the other (IBS-D, for diarrhea, or IBS-C, for constipation). Supportive treatment or avoidance of a known irritant often relieves symptoms.

Causes and Incidence

This brain-gut disorder has been associated with psychological stress, yet it is important to recognize that continuing research shows that it is a multisystem interaction that causes the symptoms. Physical factors such as diverticular disease, hormonal changes during the menstrual cycle, ingestion of irritants (coffee, raw fruits, or vegetables), lactose intolerance, laxative abuse, food poisoning, or colon cancer may contribute to symptoms. Some patients may experience a disturbance in the movement of the intestine or a lower tolerance for stretching and movement of the intestine.

IBS affects approximately 12% of North American individuals, is more common in women than in men, and has a higher prevalence in youth and middle-aged people.

Pathophysiology

The pathophysiology of IBS is not fully understood. A multisystem interaction is anticipated, including visceral hypersensitivity; abnormal GI permeability, motility, secretion, and sensitivity; alteration in gut microbes; food allergy or intolerance; and psychological factors.

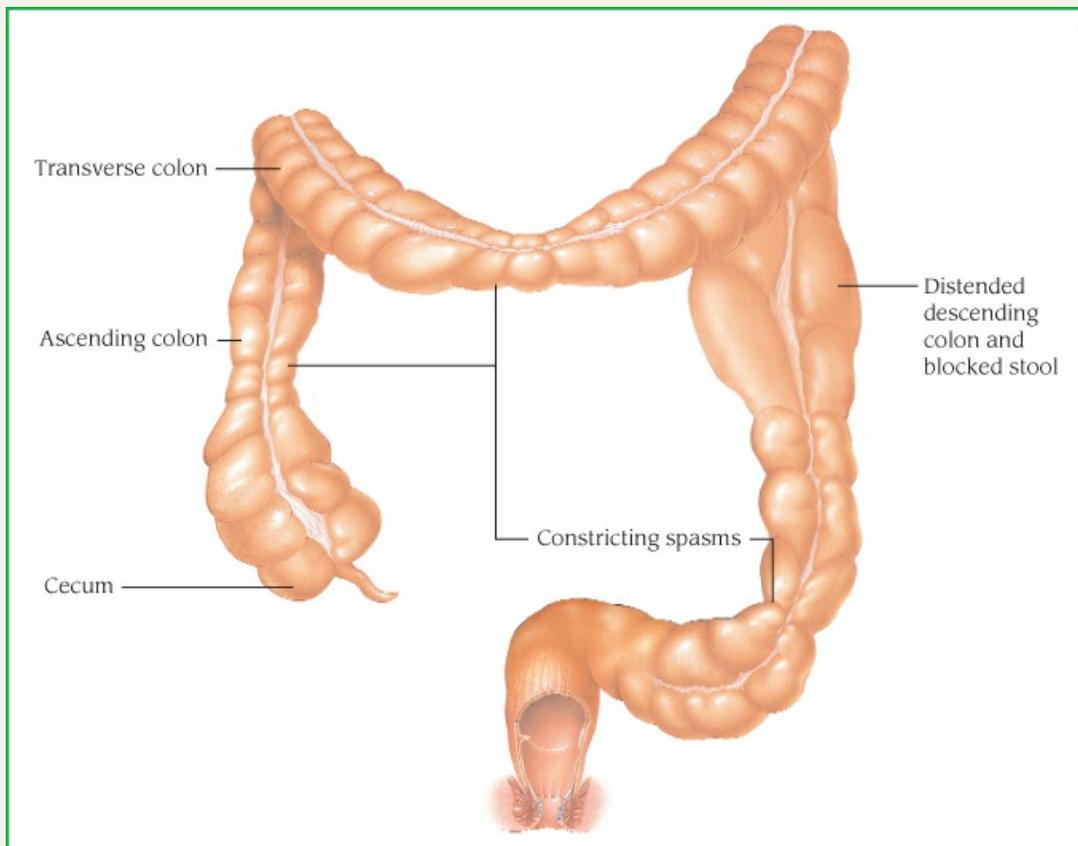
Complications

- ◆ Hemorrhoid aggravation
- ◆ Malnourishment

Signs and Symptoms

IBS characteristically produces lower abdominal pain (usually relieved by defecation or passage of gas) and diarrhea or constipation that typically occurs during the day. Stools are commonly small and contain visible mucus. Dyspepsia and abdominal distention may occur. (See *Effects of irritable bowel syndrome*, page 239.)

Effects of Irritable Bowel Syndrome

The illustration below shows partial obstructing in the bowel caused by irritable bowel syndrome.


Symptoms of IBS are two to three times more common in women than in men, and are often noted in patients who have anxiety, depression, or reduced quality of life.

Diagnosis

The diagnosis of IBS requires a careful history to determine contributing factors. Psychological factors should be assessed in addition to physiological contributors. Diagnosis must also rule out

other disorders, such as amebiasis, diverticulitis, colon cancer, and lactose intolerance. Appropriate diagnostic procedures include sigmoidoscopy, colonoscopy, barium enema, rectal biopsy, and stool examination for blood, parasites, and bacteria.

Treatment

Therapy aims to relieve symptoms. Strict dietary restrictions aren't beneficial, but food irritants should be investigated, and the patient should be instructed to avoid them. Rest and heat applied to the abdomen may be helpful, as is extremely judicious use of sedatives and antispasmodics. However, with chronic use, the patient may become dependent on these drugs. If the cause of IBS involves chronic laxative abuse, bowel training may help correct the condition. If psychological factors appear to contribute to the syndrome, counseling to help the patient understand the relationship between stress and illness can be helpful. Current strategies of treating patients with IBS may include antidepressants such as amitriptyline to decrease sensitivity to pain and probiotics to correct the underlying problematic bowel pattern. Lubiprostone (Amitiza) and rifaximin (Xifaxan) are helpful treatments for patients with IBS.

Special Considerations

Because the patient with IBS usually isn't hospitalized, focus care on patient teaching.

- Tell the patient to avoid irritating foods, and encourage development of regular bowel habits.
- Help the patient identify concerns associated with stress.
- Teach about dependence on sedatives or antispasmodics.
- Encourage regular checkups because IBS is associated with a higher-than-normal incidence of diverticulitis and colon cancer. For patients older than 40, emphasize the need for consideration of an annual sigmoidoscopy and rectal examination.

CELIAC DISEASE

Celiac disease (also known as *celiac sprue* and *gluten-sensitive enteropathy*) is characterized by poor food absorption and intolerance of gluten, a protein in wheat and wheat products. Malabsorption in the small bowel results from atrophy of the villi and a decrease in the activity and amount of enzymes in the surface epithelium. The prognosis is good with treatment (eliminating gluten from the patient's diet), but residual bowel changes may persist in adults.

Causes and Incidence

In celiac disease, an intramucosal enzyme defect produces an inability to digest gluten. Resulting tissue toxicity produces rapid cell turnover, increases epithelial lymphocytes, and damages surface epithelium of the small bowel. Celiac disease has a prevalence of approximately 1%; however, evidence indicates that only a fraction of those affected have actually been diagnosed and treated.

Celiac disease is present with greater frequency in individuals (especially children) who have:

- Type I diabetes
- Autoimmune thyroid or liver disease
- Down, Turner, or Williams syndrome
- Selective IgA deficiency
- Addison disease

Pathophysiology

The pathophysiology of celiac disease is complicated, involving genetic, and cellular and humoral immunologic factors, as well as environmental factors. The major characteristic is an HLA-DQ2- or HLA-DQ8-induced CD4$^+$ T-cell-mediated autoimmune injury to the small intestinal epithelial cells of individuals who are genetically susceptible.

Complications

- Anemia from malabsorption
- Syncope, heart failure, and angina from anemia
- Bleeding disorders from vitamin K deficiency
- Intestinal lymphoma (higher incidence)

Signs and Symptoms

Celiac disease produces clinical effects on many body systems:

- GI symptoms include recurrent attacks of diarrhea, steatorrhea, abdominal distention due to flatulence, stomach cramps, weakness, anorexia and, occasionally, increased appetite without weight gain. Atrophy of intestinal villi leads to malabsorption of fat, carbohydrates, and protein as well as loss of calories, fat-soluble vitamins (A, D, and K), calcium, and essential minerals and electrolytes. In adults, celiac disease produces multiple nonspecific ulcers in the small bowel, which may perforate or bleed.
- Hematologic effects include normochromic, hypochromic, or macrocytic anemia due to poor absorption of folate, iron, and vitamin B$_{12}$ and to hypoprothrombinemia from jejunal loss of vitamin K.
- Osteomalacia, osteoporosis, tetany, and bone pain (especially in the lower back, rib cage, and pelvis) are some of the musculoskeletal symptoms of celiac disease. These signs and symptoms are due to calcium loss and vitamin D deficiency, which weakens the skeleton, causing rickets in children and compression fractures in adults.
- Neurologic effects may include peripheral neuropathy, seizures, or paresthesia.
- Dry skin, eczema, psoriasis, dermatitis herpetiformis, and acne rosacea are some of the dermatologic effects of celiac disease. Deficiency of sulfur-containing amino acids may cause generalized fine, sparse, prematurely gray hair; brittle nails; and localized hyperpigmentation on the face, lips, or mucosa.
- Endocrine symptoms include amenorrhea, hypometabolism and, possibly, with severe malabsorption, adrenocortical insufficiency.
- Psychosocial effects include mood changes and irritability.

Symptoms may develop as early as the first year of life, when gluten is introduced into the child's diet; in half of affected children, onset occurs by 18 months old. The severity of symptoms varies greatly between affected individuals.

Diagnosis

CONFIRMING DIAGNOSIS *Histologic changes seen on small bowel biopsy specimens obtained with an esophagogastroduodenoscopy confirm the diagnosis: a mosaic pattern of alternating flat and bumpy areas on the bowel surface due to an almost total absence of villi and an irregular, blunt, and disorganized network of blood vessels. These changes appear most*

prominently in the jejunum.

An elevated alkaline phosphatase level may indicate bone loss, which is commonly experienced before diagnosis. Low cholesterol and albumin levels may reflect malabsorption and malnutrition. Mildly elevated liver enzymes and abnormal blood clotting may also be noted as well as anemia.

Antibody blood tests useful in screening for celiac disease include IgA antiendomysial antibody, anti-tissue transglutaminase, antigliadin (IgA and IgG), and total serum IgA. Combined, these antibodies provide a sensitive and specific indicator for the presence of celiac disease.

Treatment

Treatment requires elimination of gluten from the patient's diet for life—educate the patient to follow this gluten-free diet (GFD). Even with this exclusion, a full return to normal absorption and bowel histology may not occur for months or may never occur.

Supportive treatment may include supplemental iron, vitamin B_{12}, and folic acid; reversal of electrolyte imbalance (by I.V. infusion, if necessary); I.V. fluid replacement for dehydration; corticosteroids to treat accompanying adrenal insufficiency; and vitamin K for hypoprothrombinemia.

Special Considerations

Explain the necessity of the GFD to the patient (and to the parents or caregivers, if the patient is a child). Advise eliminating wheat, barley, rye, and oats as well as foods made from these grains, such as breads and baked goods; suggest substituting corn or rice. Consult a dietitian for nutritional instruction on the GFD. Depending on individual tolerance, the diet initially consists of proteins and gradually expands to include other foods. Assess the patient's acceptance and understanding of the disease, and encourage regular reevaluation.

ALERT *Because many foods contain hidden sources of gluten, teach the patient to read food labels carefully and thoroughly.*

- Observe the patient's nutritional status and progress by daily calorie counts and weight checks. Evaluate tolerance to new foods. In the early stages, offer small, frequent meals to counteract anorexia.
- Assess the patient's fluid status: record intake, urine output, and number of stools (which may exceed 10 per day). Watch for signs of dehydration, such as dry skin and mucous membranes, and poor skin turgor.
- Check serum electrolyte levels. Watch for signs of hypokalemia (weakness, lethargy, rapid pulse, nausea, and diarrhea) and low calcium levels (impaired blood clotting, muscle twitching, and tetany).
- Monitor prothrombin time, hemoglobin level, and hematocrit. Protect the patient from bleeding and bruising. The patient may need iron replenishment. If the patient can tolerate oral iron, give it between meals, when absorption is best. Dilute oral iron preparations, and give them through a straw to prevent staining teeth.
- Protect the patient with osteomalacia from injury by keeping the bed side rails up and assisting with ambulation, as necessary.

- Advise the patient to contact the Gluten Intolerance Group of North America or the Celiac Disease Foundation for information and support.

DIVERTICULAR DISEASE

In diverticular disease, bulging pouches (diverticula) in the GI wall push the mucosal lining through the surrounding muscle. The most common site for diverticula is in the sigmoid colon, but they may develop anywhere, from the proximal end of the pharynx to the anus. Other typical sites are the duodenum, near the pancreatic border or the ampulla of Vater, and the jejunum. Diverticular disease of the stomach is rare and is usually a precursor of peptic or neoplastic disease. Diverticular disease of the ileum (Meckel's diverticulum) is the most common congenital anomaly of the GI tract. (See *Meckel's diverticulum*.)

Meckel's Diverticulum

In Meckel's diverticulum, a congenital abnormality—a blind tube, like the appendix—opens into the distal ileum near the ileocecal valve. This disorder results from failure of the intra-abdominal portion of the yolk sac to close completely during fetal development. It occurs in approximately 1.2% to 2% of the population, mostly in males.

Uncomplicated Meckel's diverticulum produces no symptoms, but complications cause abdominal pain, especially around the umbilicus, and dark red melena or hematochezia. The lining of the diverticulum is gastric mucosa. This disorder may lead to peptic ulceration, perforation, and peritonitis and may resemble acute appendicitis.

Meckel's diverticulum also may cause bowel obstruction when a fibrous band that connects the diverticulum to the abdominal wall, the mesentery, or other structures snares a loop of the intestine. This may cause intussusception into the diverticulum or volvulus near the diverticular attachment to the back of the umbilicus or another intra-abdominal structure. Meckel's diverticulum should be considered in cases of GI obstruction or hemorrhage, especially when routine GI X-rays are negative.

Treatment consists of surgical resection of the inflamed bowel and antibiotic therapy if infection is present.

Diverticular disease has two clinical forms. In *diverticulosis,* asymptomatic diverticula are present. In *diverticulitis,* diverticula are inflamed and may cause potentially fatal obstruction, infection, or hemorrhage.

Causes and Incidence

Diet may be a contributing factor to diverticular disease because insufficient fiber reduces fecal residue, narrows the bowel lumen, and leads to higher intra-abdominal pressure during defecation. Diverticulosis is age-dependent; less than 20% of patients develop this before age 40, yet 60% have been diagnosed by age 60; between 4% and 15% of those with diverticulosis develop diverticulitis, with a mean age at admission of 63. Left-sided diverticulitis is more common in North America; right-sided diverticulitis is most commonly seen in Asian countries.

ELDER TIP Many older adults develop diverticulosis. In older adults, a rare complication of diverticulosis (without diverticulitis) is hemorrhage from colonic diverticula. Such hemorrhage is usually mild to moderate and easily controlled, yet may occasionally be massive

and life-threatening.

Pathophysiology

In diverticulitis, retained undigested food mixed with bacteria accumulates in the diverticular sac, forming a hard mass (fecalith). This substance cuts off the blood supply to the thin walls of the sac, making them more susceptible to attack by colonic bacteria. Inflammation follows, possibly leading to perforation, abscess, peritonitis, obstruction, or hemorrhage. Occasionally, the inflamed colon segment may produce a fistula by adhering to the bladder or other organs.

Diverticula probably result from high intraluminal pressure on areas of weakness in the GI wall, where blood vessels enter.

Complications

- Rectal hemorrhage
- Portal pyemia
- Fistula

Signs and Symptoms

Diverticulosis usually produces no symptoms but may cause recurrent left lower quadrant pain, which is commonly accompanied by alternating constipation and diarrhea and is relieved by defecation or the passage of flatus. Symptoms resemble IBS and suggest that the disorders may coexist.

Mild diverticulitis produces moderate left lower abdominal pain, mild nausea, gas, irregular bowel habits, low-grade fever, and leukocytosis. In severe diverticulitis, the diverticula can rupture and produce abscesses or peritonitis, which occurs in approximately one in five of patients. Symptoms of rupture include abdominal rigidity and left lower quadrant pain. Peritonitis follows release of fecal material from the rupture site and causes signs of sepsis and shock (high fever, chills, and hypotension). Rupture of the diverticulum near a vessel may cause microscopic or massive hemorrhage, depending on the vessel's size.

Chronic diverticulitis may cause fibrosis and adhesions that narrow the bowel's lumen and lead to bowel obstruction. Symptoms of incomplete obstruction are constipation, ribbonlike stools, intermittent diarrhea, and abdominal distention. Increasing obstruction causes abdominal rigidity and pain, diminishing or absent bowel sounds, nausea, and vomiting.

Diagnosis

In many cases, diverticular disease produces no symptoms and is found during an upper GI series performed as part of a differential diagnosis.

Tests showing diverticular disease include computed tomography (CT; reveals areas of inflammation), colonoscopy, sigmoidoscopy, and barium enema.

CONFIRMING DIAGNOSIS *A barium study confirms the diagnosis. An upper GI series confirms or rules out diverticulosis of the esophagus and upper bowel; a barium enema confirms or rules out diverticulosis of the lower bowel.*

Barium-filled diverticula can be single, multiple, or clustered and may have a wide or narrow mouth. Barium outlines—but doesn't fill—diverticula blocked by impacted feces. In patients with acute diverticulitis, a barium enema may rupture the bowel, so this procedure requires

caution. If IBS accompanies diverticular disease, X-rays may reveal colonic spasm.

Biopsy rules out cancer; however, a colonoscopic biopsy isn't recommended during acute diverticular disease because of the strenuous bowel preparation it requires. Blood studies may show an elevated erythrocyte sedimentation rate in diverticulitis, especially if the diverticula are infected.

Treatment

Asymptomatic diverticulosis doesn't necessitate treatment. Intestinal diverticulosis with pain, mild GI distress, constipation, or difficult defecation may respond to a liquid or bland diet, stool softeners, and occasional doses of mineral oil. These measures relieve symptoms, minimize irritation, and lessen the risk of progression to diverticulitis. After pain subsides, patients also benefit from a high-residue diet and bulk medication such as psyllium.

Treatment of mild diverticulitis without signs of perforation must prevent constipation and combat infection. It may include bed rest, a liquid diet, stool softeners, and a broad-spectrum antibiotic.

If diverticulitis is refractory to medical treatment, a colon resection is necessary to remove the involved segment. Perforation, peritonitis, obstruction, or fistula that accompanies diverticulitis may require a temporary colostomy to drain abscesses and rest the colon, followed by later reanastomosis 6 weeks to 3 months after initial surgery.

Special Considerations

Management of uncomplicated diverticulosis chiefly involves thorough patient education about fiber and dietary habits.

- Make sure that the patient understands the importance of dietary fiber and the harmful effects of constipation and straining during defecation. Encourage increased intake of foods high in indigestible fiber, including fresh fruits and vegetables, whole grain bread, and wheat or bran cereals. Warn that a high-fiber diet may temporarily cause flatulence and discomfort. Teach the patient to relieve constipation with stool softeners or bulk-forming cathartics. However, caution the patient against taking bulk-forming cathartics without plenty of water; if swallowed dry, they may absorb enough moisture in the mouth and throat to swell and obstruct the esophagus or trachea.
- If the patient with diverticular disease is hospitalized, observe stools carefully for frequency, color, and consistency, and keep accurate pulse and temperature charts because changes may signal developing inflammation or complications.

After surgery to resect the colon:

- Monitor for signs of infection.
- Provide meticulous wound care because perforation may already have infected the area.
- Check drain sites frequently for signs of infection (purulent drainage or foul odor) or fecal drainage.
- Change dressings as necessary.
- Encourage coughing and deep breathing to prevent atelectasis.
- Watch for signs of postoperative bleeding (hypotension and decreased hemoglobin level and hematocrit).
- Record intake and output accurately.
- Keep the NG tube patent.

- Teach ostomy care as needed.
- Arrange for a visit by an enterostomal therapist.

APPENDICITIS

Appendicitis is inflammation of the vermiform appendix.

Causes and Incidence

Appendicitis, the most common surgical emergency of the abdomen, is thought to result from an obstruction of the appendiceal lumen caused by a fecal mass, stricture, barium ingestion, or viral infection. This obstruction sets off an inflammatory process that can lead to infection, thrombosis, necrosis, and perforation. If the appendix ruptures or perforates, the infected contents spill into the abdominal cavity, causing peritonitis, the most common and most perilous complication of appendicitis.

Appendicitis occurs more commonly in men than in women, in the second or third decades of life.

Pathophysiology

Although the pathophysiology of appendicitis is not fully understood, causes are postulated to be obstruction of the lumen with stool, tumors, or foreign bodies which cause increased intraluminal pressure, ischemia, bacterial infection, and inflammation.

Complications

- Perforation
- Peritonitis
- Appendiceal abscess
- Pyelophlebitis

Signs and Symptoms

Typically, appendicitis begins with generalized or localized abdominal pain in the right upper abdomen, followed by anorexia, nausea, and vomiting (rarely profuse). Pain eventually localizes in the right lower abdomen (McBurney's point) with abdominal "boardlike" rigidity, retractive respirations, increasing tenderness, increasingly severe abdominal spasms and, almost invariably, rebound tenderness. (Rebound tenderness on the opposite side of the abdomen suggests peritoneal inflammation.)

Later signs and symptoms include constipation or diarrhea, slight fever, and tachycardia. The patient may walk bent over or lie with his right knee flexed to reduce pain.

ALERT *Sudden cessation of abdominal pain indicates perforation or infarction of the appendix; this is considered an emergent condition.*

Diagnosis

Diagnosis of appendicitis is based on physical findings and characteristic clinical symptoms. Supportive findings include a low-grade temperature up to approximately 101° F (38.33° C) and a moderately elevated white blood cell count (>10,000/μL), with increased immature neutrophil cells.

Diagnosis must rule out illnesses with similar symptoms: gastritis, gastroenteritis, ileitis,

colitis, diverticulitis, pancreatitis, renal colic, bladder infection, ovarian cyst, and uterine disease. It may be strongly suspected based on abdominal sonography or CT scan. Appendicitis can be confirmed by exploratory laparoscopy.

Treatment

Appendectomy is the only effective treatment. Laparoscopic appendectomies decrease the recovery time and thus the hospital stay. If peritonitis develops, treatment involves GI intubation, parenteral replacement of fluids and electrolytes, and administration of antibiotics.

Special Considerations

If appendicitis is suspected, or during preparation for appendectomy:

- Administer I.V. fluids to prevent dehydration. *Never* administer cathartics or enemas, which may rupture the appendix. Give the patient nothing by mouth, and administer analgesics judiciously because they may mask symptoms.
- To lessen pain, place the patient in Fowler's position.

ALERT *Never apply heat to the right lower abdomen; this may cause the appendix to rupture.*

An ice bag may be used for pain relief.
After appendectomy:

- Monitor the patient's vital signs and intake and output. Give analgesics, as ordered.
- Encourage the patient to cough, breathe deeply, and turn frequently to prevent pulmonary complications.
- Document bowel sounds, passing of flatus, and bowel movements. In a patient whose nausea and abdominal rigidity have subsided, these signs indicate readiness to resume oral fluids.
- Watch closely for possible surgical complications. Continuing pain and fever may signal an abscess. The complaint that "something gave way" or "popped" may indicate wound dehiscence. If an abscess or peritonitis develops, incision and drainage may be necessary. Frequently assess the dressing for wound drainage.
- Help the patient ambulate as soon as possible after surgery.
- In appendicitis complicated by peritonitis, an NG tube may be needed to decompress the stomach and reduce nausea and vomiting. If so, record drainage and provide mouth and nose care.

PERITONITIS

Peritonitis is an acute or chronic inflammation of the peritoneum, the membrane that lines the abdominal cavity and covers the visceral organs. Inflammation may extend throughout the peritoneum or may be localized as an abscess. Peritonitis commonly decreases intestinal motility and causes intestinal distention with gas. Death can occur as a result of bowel obstruction.

Causes and Incidence

Although the GI tract normally contains bacteria, the peritoneum is sterile. When bacteria invade the peritoneum due to inflammation and perforation of the GI tract, peritonitis results. Because there are varying conditions that contribute to peritonitis, incidence is difficult to determine.

Pathophysiology

Bacterial invasion of the peritoneum typically results from appendicitis, diverticulitis, peptic ulcer, ulcerative colitis, volvulus, strangulated obstruction, abdominal neoplasm, or a stab wound. Peritonitis may also occur following chemical inflammation, as in the rupture of a fallopian or ovarian tube or the bladder, perforation of a gastric ulcer, or released pancreatic enzymes. It may also be associated with peritoneal dialysis.

In chemical and bacterial inflammation, accumulated fluids containing protein and electrolytes make the transparent peritoneum opaque, red, inflamed, and edematous. Because the peritoneal cavity is so resistant to contamination, infection is commonly localized as an abscess instead of disseminated as a generalized infection.

Complications

- Abscess
- Septicemia
- Respiratory compromise
- Bowel obstruction
- Shock

Signs and Symptoms

The key symptom of peritonitis is sudden, severe, and diffuse abdominal pain that tends to intensify and localize in the area of the underlying disorder. For instance, if appendicitis causes the rupture, pain eventually localizes in the right lower quadrant. Many patients display weakness, pallor, excessive sweating, and cold skin as a result of excessive loss of fluid, electrolytes, and protein into the abdominal cavity. Decreased intestinal motility and paralytic ileus result from the effect of bacterial toxins on the intestinal muscles. Intestinal obstruction causes nausea, vomiting, and abdominal rigidity.

Other clinical characteristics include hypotension, tachycardia, signs and symptoms of dehydration (oliguria, thirst, dry swollen tongue, and pinched skin), an acutely tender abdomen associated with rebound tenderness, temperature of 103° F (39.4° C) or higher, and hypokalemia. Inflammation of the diaphragmatic peritoneum may cause shoulder pain and hiccups. Abdominal distention and resulting upward displacement of the diaphragm may decrease respiratory capacity. Typically, the patient with peritonitis tends to breathe shallowly and move as little as possible to minimize pain. The patient may prefer to lie on his or her back, with knees flexed, to relax abdominal muscles.

Diagnosis

Severe abdominal pain in a person with direct or rebound tenderness suggests peritonitis. Abdominal X-rays or CT scan showing edematous and gaseous distention of the small and large bowel support the diagnosis. In the case of perforation of a visceral organ, the X-ray shows air lying under the diaphragm in the abdominal cavity. Other appropriate tests include the following:

- Chest X-ray may show elevation of the diaphragm.
- Blood studies show leukocytosis (>20,000/μL).
- Paracentesis reveals bacteria, exudate, blood, pus, or urine.
- Laparotomy may be necessary to identify the underlying cause.

Treatment

Early treatment of GI inflammatory conditions and preoperative and postoperative antibiotic therapy help prevent peritonitis. After peritonitis develops, emergency treatment must combat infection, restore intestinal motility, and replace fluids and electrolytes.

Antibiotic therapy depends on the infecting organisms. If peritonitis is associated with peritoneal dialysis, antibiotics may be infused through the dialysis catheter; however, if the infection is severe, the catheter must be removed. To decrease peristalsis and prevent perforation, the patient should receive nothing by mouth; supportive fluids and electrolytes should be given parenterally.

Other supplementary treatment measures include preoperative and postoperative administration of an analgesic, NG intubation to decompress the bowel and, possibly, using a rectal tube to facilitate passage of flatus. When peritonitis results from perforation, surgery is necessary as soon as possible. Surgery aims to eliminate the source of infection by evacuating the spilled contents and inserting drains.

Special Considerations

Patient care includes monitoring and measures to prevent complications and the spread of infection.

- Monitor the patient's vital signs, fluid intake and output, and amount of NG drainage or vomitus.
- Place the patient in semi-Fowler's position to facilitate deep breathing with less pain; this helps to prevent pulmonary complications and localize purulent exudate in the lower abdomen or pelvis.

After surgery to evacuate the peritoneum:

- Maintain parenteral fluid and electrolyte administration, as ordered. Accurately record fluid intake and output, including NG tube and any drain output.
- Place in semi-Fowler's position to promote drainage (through drainage tube) by gravity. Move the patient carefully because the slightest movement will intensify the pain.
- Implement other safety measures if fever and pain disorient the patient.
- Encourage and assist ambulation, as ordered, usually on the first postoperative day.
- Watch for signs of dehiscence (the patient may complain that "something gave way" or "popped") and abscess formation (continued abdominal tenderness and fever).
- Frequently assess for peristaltic activity by listening for bowel sounds and checking for gas, bowel movements, and a soft abdomen.
- Gradually decrease parenteral fluids and increase oral fluids.

INTESTINAL OBSTRUCTION

Intestinal obstruction is the partial or complete blockage of the lumen in the small or large bowel. Small bowel obstruction, far more common, is usually more serious. Complete obstruction in any part of the bowel, if untreated, can cause death within hours from shock and vascular collapse. Intestinal obstruction usually occurs after abdominal surgery or in persons with congenital bowel deformities.

Causes and Incidence

Adhesions and strangulated hernias usually cause small bowel obstruction; large-bowel obstruction is typically due to carcinomas. Mechanical intestinal obstruction results from foreign bodies (fruit pits, gallstones, or worms) or compression of the bowel wall due to stenosis, intussusception, volvulus of the sigmoid or cecum, tumors, or atresia. Nonmechanical obstruction results from physiologic disturbances, such as paralytic ileus, electrolyte imbalances, toxicity (uremia or generalized infection), neurogenic abnormalities (spinal cord lesions), and thrombosis or embolism of mesenteric vessels. (See *Paralytic ileus*.)

Paralytic Ileus

Paralytic ileus is a physiologic form of intestinal obstruction that usually develops in the small bowel after abdominal surgery. It causes decreased or absent intestinal motility that usually recovers spontaneously after 2 to 3 days. The clinical effects of paralytic ileus include severe abdominal distention, extreme distress, and, possibly, vomiting. The patient may be severely constipated or may pass flatus and small, liquid stools.

Causes
This condition can develop as a response to trauma, toxemia, or peritonitis or as a result of electrolyte deficiencies (especially hypokalemia) and the use of certain drugs, such as ganglionic blocking agents and anticholinergics. It can also result from vascular causes, such as thrombosis or embolism. Excessive air swallowing may contribute to it, but paralytic ileus brought on by this factor alone seldom lasts more than 24 hours.

Treatment
Paralytic ileus lasting longer than 48 hours requires intubation for decompression and nasogastric suctioning. Because of the absence of peristaltic activity, a long, weighted intestinal tube—called a *Miller–Abbott tube*—may be necessary in the patient with extraordinary abdominal distention. However, such procedures must be used with extreme caution because additional trauma to the bowel can aggravate ileus. When paralytic ileus results from surgical manipulation of the bowel, treatment may also include cholinergic agents, such as neostigmine (Bloxiverz) or bethanechol (Urecholine).

When caring for patients with paralytic ileus, warn those receiving cholinergic agents to expect certain paradoxical adverse effects, such as intestinal cramps and diarrhea. Remember that neostigmine produces cardiovascular adverse effects, usually bradycardia and hypotension. Check frequently for returning bowel sounds.

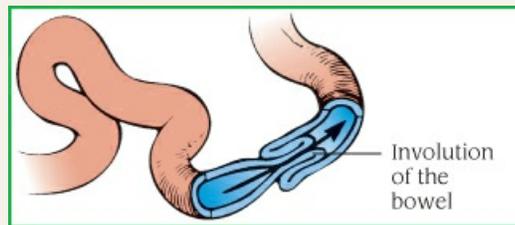
Intestinal obstruction develops in three forms:

- *Simple:* Blockage prevents intestinal contents from passing, with no other complications or with a change in blood flow.
- *Strangulated:* The blood supply to part or all of the obstructed section is cut off, in addition to blockage of the lumen.
- *Close-looped:* Both ends of a bowel section are occluded, isolating it from the rest of the intestine. (See *Causes of intestinal obstruction,* page 247.)

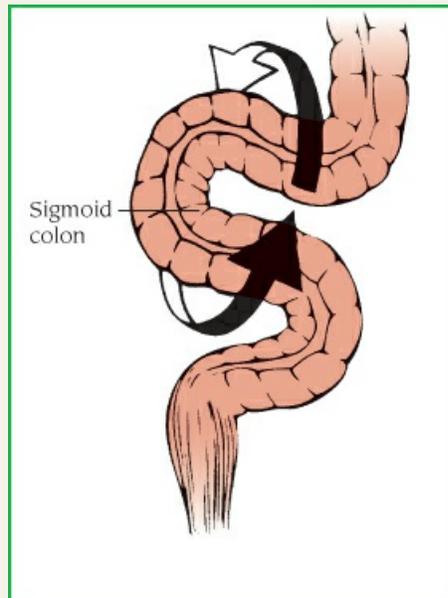
Causes of Intestinal Obstruction

Intestinal obstruction is a partial or complete blockage of the lumen in the small or large bowel. Adhesions and strangulated hernias usually cause small bowel obstruction; large-bowel obstruction is typically due to carcinomas. Other causes include intussusception, volvulus, and inguinal hernia.

Intussusception With Invagination

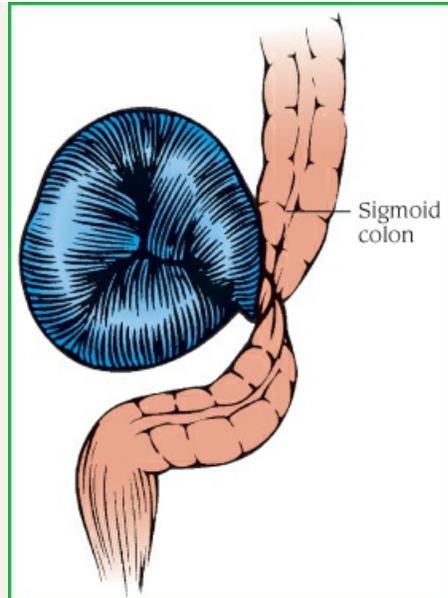
The bowel is shortened by the involution of one segment of the bowel into another.


Volvulus

In most cases, the bowel twists counterclockwise.


Inguinal Hernia

Intestine, omentum, and the other abdominal contents pass through the hernia opening.

Sigmoid
colon


Pathophysiology

See box for *pathophysiology of intestinal obstruction*.

The physiologic effects are similar in all three forms of obstruction: When intestinal obstruction occurs, fluid, air, and gas collect near the site. Peristalsis increases temporarily as the bowel tries to force its contents through the obstruction, injuring intestinal mucosa and causing distention at and above the site of the obstruction. Distention blocks the flow of venous blood and halts normal absorptive processes; as a result, the bowel begins to secrete water, sodium, and potassium into the fluid pooled in the lumen.

Obstruction in the small intestine results in metabolic alkalosis from dehydration and loss of gastric hydrochloric acid; lower bowel obstruction causes slower dehydration and loss of intestinal alkaline fluids, resulting in metabolic acidosis. Ultimately, intestinal obstruction may lead to ischemia, necrosis, and death. (See *Symptom progression in intestinal obstruction,* page 248.)

PATHOPHYSIOLOGY
SYMPTOM PROGRESSION IN INTESTINAL OBSTRUCTION

A partial or complete blockage of the small or large intestine creates an obstruction with resultant symptoms.

Obstruction → Fluid, gas, and air collect behind obstruction. → Peristalsis temporarily increases in an attempt to force contents past obstruction. → Distention increases at and above obstruction site. → Dehydration results because fluids aren't absorbed into bloodstream. → Gas-forming bacteria collect above obstruction, increasing distention. → Bowel wall swells as water, sodium, and potassium are secreted into intestine and not absorbed from it. → Distention impedes blood supply to bowel, halting absorption. → With no treatment, severe hypovolemia occurs and leads to: → Shock → Sepsis → Death

ELDER TIP *Watch for air-fluid lock syndrome in older adults who remain recumbent for extended periods. In this syndrome, fluid first collects in the dependent bowel loops. Then peristalsis is too weak to push fluid "uphill." The resulting obstruction primarily occurs in the large bowel.*

Complications

- Perforation
- Peritonitis
- Septicemia
- Secondary infection
- Metabolic acidosis or alkalosis
- Hypovolemic or septic shock

Signs and Symptoms

Colicky pain, nausea, vomiting, constipation, and abdominal distention characterize small bowel obstruction. It may also cause drowsiness, intense thirst, malaise, and aching and may dry up oral mucous membranes and the tongue. Auscultation reveals bowel sounds, borborygmi, and rushes; occasionally, these are loud enough to be heard without a stethoscope. Palpation elicits abdominal tenderness, with moderate distention; rebound tenderness occurs when obstruction

has caused strangulation with ischemia. In late stages, signs of hypovolemic shock result from progressive dehydration and plasma loss.

In complete small bowel obstruction, vigorous peristaltic waves propel bowel contents toward the mouth instead of the rectum. Spasms may occur every 3 to 5 minutes and last about 1 minute each, with persistent epigastric or periumbilical pain. Passage of small amounts of mucus and blood may occur. The higher the obstruction, the earlier and more severe the vomiting. Vomitus initially contains gastric juice, then bile, and finally contents of the ileum.

Symptoms of large-bowel obstruction develop more slowly because the colon can absorb fluid from its contents and distend well beyond its normal size. Constipation may be the only clinical effect for days. Colicky abdominal pain may then appear suddenly, producing spasms that last less than 1 minute each and recur every few minutes. Continuous hypogastric pain and nausea may develop, but vomiting is usually absent at first. Large-bowel obstruction can cause dramatic abdominal distention; loops of the large bowel may become visible on the abdomen. Eventually, complete large-bowel obstruction may cause fecal vomiting, continuous pain, or localized peritonitis.

Patients with partial obstruction may display any of the previously discussed signs and symptoms in a milder form. However, leakage of liquid stool around the obstruction is common in partial obstruction.

Diagnosis

Progressive, colicky, abdominal pain and distention, with or without nausea and vomiting, suggest bowel obstruction.

Ⓡ **CONFIRMING DIAGNOSIS** *Tests that show obstruction include barium enema, abdominal CT, upper GI and small bowel series, and abdominal films. Abdominal films show the presence and location of intestinal gas or fluid. In small bowel obstruction, a typical "stepladder" pattern emerges, with alternating fluid and gas levels apparent in 3 to 4 hours. In large-bowel obstruction, barium enema reveals a distended, air-filled colon or a closed loop of sigmoid with extreme distention (in sigmoid volvulus).*

Laboratory results supporting this diagnosis include:

◆ decreased sodium, chloride, and potassium levels (due to vomiting)
◆ a slightly elevated white blood cell count (with necrosis, peritonitis, or strangulation)
◆ an increased serum amylase level (possibly from irritation of the pancreas by bowel loop).

Treatment

Preoperative therapy consists of correction of fluid and electrolyte imbalances, decompression of the bowel to relieve vomiting and distention, and treatment of shock and peritonitis. Strangulated obstruction usually necessitates blood replacement as well as I.V. fluid administration. Decompression of the intestine may be accomplished with the use of an NG tube inserted into the stomach or intestine to relieve distention and vomiting.

Close monitoring of the patient's condition determines the duration of treatment; if the patient fails to improve or if the condition deteriorates, surgery is necessary. In large-bowel obstruction, surgical resection with anastomosis, colostomy, or ileostomy commonly follows decompression with an NG tube.

TPN may be appropriate if the patient suffers a protein deficit from chronic obstruction,

postoperative or paralytic ileus, or infection. Drug therapy includes analgesics, sedatives, and antibiotics for peritonitis due to bowel strangulation or infarction.

Special Considerations

Effective management of intestinal obstruction, a life-threatening condition that commonly causes overwhelming pain and distress, requires skillful supportive care and close observation.

ALERT *Monitor the patient's vital signs frequently. A drop in blood pressure may indicate reduced circulating blood volume due to blood loss from a strangulated hernia. Observe the patient closely for signs of shock (pallor, rapid pulse, and hypotension).*

- Stay alert for signs and symptoms of metabolic alkalosis (changes in sensorium; slow, shallow respirations; hypertonic muscles; and tetany) or acidosis (shortness of breath on exertion, disorientation and, later, deep, rapid breathing, weakness, and malaise).
- Watch for signs and symptoms of secondary infection, such as fever and chills.
- Monitor the patient's urine output carefully to assess renal function, circulating blood volume, and possible urine retention caused by bladder compression by the distended intestine. If bladder compression is suspected, catheterize the patient for residual urine immediately after voiding. Also, measure abdominal girth frequently to detect progressive distention.
- Provide mouth and nose care if the patient has vomited or undergone decompression by intubation. Assess for signs of dehydration (thick, swollen tongue; dry, cracked lips; and dry oral mucous membranes).
- Record the amount and color of drainage from the decompression tube. Irrigate the tube with normal saline solution to maintain patency. If a weighted tube has been inserted, check periodically to make sure it's advancing. Help the patient turn from side to side (or walk around, if able) to facilitate passage of the tube.
- Keep the patient in Fowler's position as much as possible to promote pulmonary ventilation and ease respiratory distress from abdominal distention. Listen for bowel sounds, and watch for signs of returning peristalsis (passage of flatus and mucus through the rectum).
- Explain all diagnostic and therapeutic procedures to the patient, and answer any questions. Make sure the patient understands that these procedures are necessary to relieve the obstruction and reduce pain. Teach to lie on the left side for about a half hour before X-rays are taken.
- Prepare the patient and family for the possibility of surgery, and provide emotional support and positive reinforcement afterward. Arrange for an enterostomal therapist to visit the patient who has had an ostomy.

INGUINAL HERNIA

A hernia occurs when part of an internal organ protrudes through an abnormal opening in the containing wall of its cavity. Hernias typically occur in the abdominal cavity. Although many kinds of abdominal hernias are possible, inguinal hernias are most common. (See *Common sites of hernia*, page 250.) In an inguinal hernia, the large or small intestine, omentum, or bladder protrudes into the inguinal canal. Hernias can be reduced (if the hernia can be manipulated back into place with relative ease), incarcerated (if the hernia can't be reduced because adhesions have formed, obstructing the intestinal flow), or strangulated (part of the herniated intestine becomes twisted or edematous, seriously interfering with normal blood flow and peristalsis, and possibly

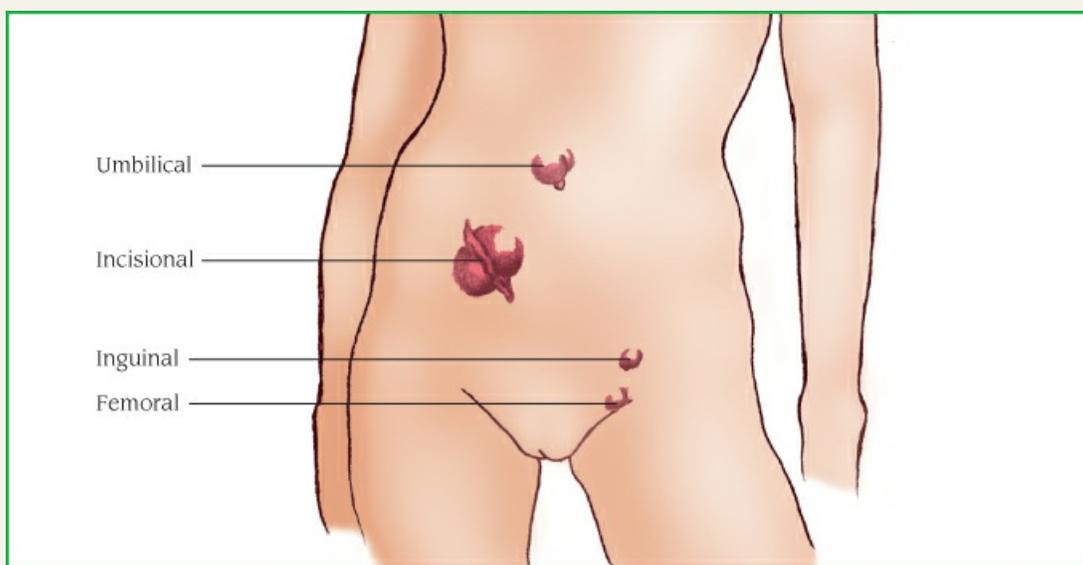
leading to intestinal obstruction and necrosis).

Common sites of hernia

Femoral hernia occurs where the femoral artery passes into the femoral canal. Typically, a fatty deposit within the femoral canal enlarges and eventually creates a hole big enough to accommodate part of the peritoneum and bladder. A femoral hernia appears as a swelling or bulge at the pulse point of the large femoral artery. It's usually a soft, pliable, reducible, nontender mass, but commonly becomes incarcerated or strangulated.

Umbilical hernia results from abnormal muscular structures around the umbilical cord. This hernia is quite common in neonates, but also occurs in women who are obese or who have had several pregnancies. Because most umbilical hernias in infants close spontaneously, surgery is warranted only if the hernia persists for more than 4 or 5 years. Taping or binding the affected area or supporting it with a truss may relieve symptoms until the hernia closes. Severe congenital umbilical hernia allows the abdominal viscera to protrude outside the body. This condition necessitates immediate repair.

Incisional (ventral) hernia develops at the site of previous surgery, usually along vertical incisions. This hernia may result from a weakness in the abdominal wall, perhaps as a result of an infection or impaired wound healing. Inadequate nutrition, extreme abdominal distention, or obesity also predispose the patient to incisional hernia. Palpation of an incisional hernia may reveal several defects in the surgical scar. Effective repair requires pulling the layers of the abdominal wall together without creating tension. If this isn't possible, surgical reconstruction uses Teflon, Marlex mesh, or tantalum mesh to close the opening.

Inguinal hernia can be direct or indirect. Indirect inguinal hernia causes the abdominal viscera to protrude through the inguinal ring and follow the spermatic cord (in males) or round ligament (in females). Direct inguinal hernia results from a weakness in the fascial floor of the inguinal canal.


Causes and Incidence

An inguinal hernia may be indirect or direct. An indirect inguinal hernia may develop at any age, is more common in males, occurs more often in those of Caucasian ethnicity, and can occur in infants younger than 1. The lifetime risk of developing a groin hernia is approximately 25% in men, and less than 5% in women.

Pathophysiology

An indirect inguinal hernia, the more common form, results from weakness in the fascial margin of the internal inguinal ring. In an indirect hernia, abdominal viscera leave the abdomen through the inguinal ring and follow the spermatic cord (in males) or round ligament (in females); they emerge at the external ring and extend down the inguinal canal, commonly into the scrotum or labia. A direct inguinal hernia results from a weakness in the fascial floor of the inguinal canal. Instead of entering the canal through the internal ring, the hernia passes through the posterior inguinal wall, protrudes directly through the transverse fascia of the canal (in an area known as *Hesselbach's triangle*), and comes out at the external ring.

In males, during the seventh month of gestation, the testicle normally descends into the scrotum, preceded by the peritoneal sac. If the sac closes improperly, it leaves an opening through which the intestine can slip. In either sex, a hernia can result from weak abdominal muscles (caused by congenital malformation, trauma, or aging) or increased intra-abdominal pressure (due to heavy lifting, pregnancy, obesity, or straining).

Complications

- Incarceration or strangulation of the bowel
- Intestinal obstruction
- Intestinal necrosis

Signs and Symptoms

Inguinal hernia usually causes a lump to appear over the herniated area when the patient stands or strains. The lump disappears when the patient is supine. Tension on the herniated contents may cause a sharp, steady pain in the groin, which fades when the hernia is reduced. Strangulation produces severe pain and may lead to partial or complete bowel obstruction and even intestinal necrosis. Partial bowel obstruction may cause anorexia, vomiting, pain and tenderness in the groin, an irreducible mass, and diminished bowel sounds. Complete obstruction may cause shock, high fever, absent bowel sounds, and bloody stools.

PEDIATRIC TIP *In an infant, an inguinal hernia commonly coexists with an undescended testicle or a hydrocele.*

Diagnosis

In a patient with a large hernia, physical examination reveals an obvious swelling or lump in the inguinal area. In the patient with a small hernia, the affected area may simply appear full. Palpation of the inguinal area while the patient is performing Valsalva's maneuver confirms the diagnosis. To detect a hernia in a male patient, the patient is asked to stand with his ipsilateral leg slightly flexed and his weight resting on the other leg. The examiner inserts an index finger into the lower part of the scrotum and invaginates the scrotal skin so the finger advances through the

external inguinal ring to the internal ring (about 1½″ to 2″ [4 to 5 cm] through the inguinal canal). The patient is then told to cough. If the examiner feels pressure against the fingertip, an indirect hernia exists; if pressure is felt against the side of the finger, a direct hernia exists.

A patient history of sharp or "catching" pain when lifting or straining may help confirm the diagnosis. Suspected bowel obstruction requires X-rays and a white blood cell count (may be elevated).

Treatment

If the hernia is reducible, the pain may be temporarily relieved by pushing the hernia back into place. A truss may keep the abdominal contents from protruding into the hernial sac; however, this won't cure the hernia. This device is especially beneficial for an older adult or debilitated patient for whom surgery might be hazardous.

For infants, adults, and otherwise healthy older adult patients, herniorrhaphy is the treatment of choice. Herniorrhaphy replaces the contents of the hernial sac into the abdominal cavity and closes the opening. In many cases, this procedure is performed under local anesthesia in a short-term unit or as a single-day admission. Another effective surgical procedure for repairing hernia is hernioplasty, which reinforces the weakened area with steel mesh, fascia, or wire.

A strangulated or necrotic hernia necessitates bowel resection. Rarely, an extensive resection may require temporary colostomy. In either case, bowel resection lengthens postoperative recovery and requires antibiotics, parenteral fluids, and electrolyte replacement.

Special Considerations

Care includes managing symptoms to increase patient comfort and prevent worsening.

- Apply a truss only after a hernia has been reduced. For best results, apply it in the morning, before the patient gets out of bed.
- To prevent skin irritation, tell the patient to bathe daily and apply cornstarch. Teach against applying the truss over clothing because this reduces the effectiveness of the device and may make it slip.

⚠️ **ALERT** *If incarceration and strangulation occur, don't try to reduce the hernia because this may perforate the bowel. If severe intestinal obstruction develops because of hernial strangulation, inform the healthcare provider immediately. An NG tube may be inserted promptly to empty the stomach and relieve pressure on the hernial sac.*

- Before surgery for an incarcerated hernia, closely monitor the patient's vital signs. Administer I.V. fluids and analgesics, as ordered. Place the patient in Trendelenburg's position to reduce pressure on the hernia site.
- Give special reassurance and emotional support to a child and parents or caregivers when hernia repair is scheduled. Encourage questions, and answer them as thoroughly as possible.
- After outpatient surgery, make sure that the patient voids before leaving the hospital. Teach the patient to check the incision and dressing for drainage, inflammation, or swelling and to watch for fever. If any of these occur, notify the healthcare provider.
- To reduce scrotal swelling, have the patient support the scrotum with a rolled towel and apply an ice bag.
- Instruct the patient to drink plenty of fluids to maintain hydration and prevent constipation.
- Before discharge, teach the patient to avoid lifting heavy objects or straining during bowel

movements. Additionally, instruct to watch for signs and symptoms of infection (oozing, tenderness, warmth, and redness) at the incision site and to keep the incision clean and covered until the sutures are removed.

◆ Advise the patient not to resume normal activity or return to work without the surgeon's permission.

INTUSSUSCEPTION

Intussusception is a telescoping (invagination) of a proximal segment into a distal segment of the intestine, which causes an obstruction. Intussusception may be fatal, especially if treatment is delayed for more than 24 hours.

Causes and Incidence

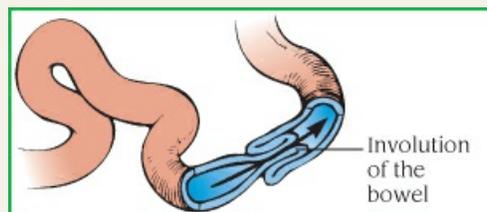
The cause of intussusception is idiopathic; however, it has been associated with lead points (polyps or tumors, Meckel's diverticulum, intestinal adhesions), cystic fibrosis, and as occurring immediately after abdominal surgery. Although it can affect adults, intussusception is most common in infants between 5 and 7 months of age. It occurs more often in males than in females, with 4 to 5.5 per 10,000 children hospitalized in the United States annually for this condition.

Seasonal peaks—between fall and winter—coinciding with the peak incidence of respiratory tract infections—have been noted in the incidence of intussusception, suggesting a connection to viral infections. Other potential causes include a mass, such as a lymph node, polyp, or tumor that telescopes the gut and leads to intussusception.

Pathophysiology

When a bowel segment (the intussusceptum) invaginates, peristalsis propels it along the bowel, pulling more bowel along with it; the receiving segment is the intussuscipiens. This invagination produces edema, hemorrhage from venous engorgement, incarceration, and obstruction. If treatment is delayed for longer than 24 hours, strangulation of the intestine usually occurs, with gangrene, shock, and perforation. (See *Understanding intussusception.*)

Understanding Intussusception

In intussusception, a bowel section invaginates and is propelled along by peristalsis, pulling in more bowel. Intussusception typically produces edema, hemorrhage from venous engorgement, incarceration, and obstruction.


Complications

- Strangulation of intestine
- Gangrene
- Shock
- Perforation
- Peritonitis

Signs and Symptoms

PEDIATRIC TIP *In an infant or child, intussusception produces four cardinal clinical effects:*

- *Intermittent attacks of colicky pain cause the child to scream, draw the legs up to the abdomen, turn pale and diaphoretic and, possibly, display grunting respirations.*
- *Vomiting of stomach contents may occur initially, followed by further vomiting of bile-stained or fecal material.*
- *"Currant-jelly" stools, containing a mixture of blood and mucus, may be observed.*
- *The patient will have a tender, distended abdomen, with a palpable, sausage-shaped abdominal mass; the viscera are usually absent from the right lower quadrant.*

In adults, intussusception produces nonspecific, chronic, and intermittent symptoms, including colicky abdominal pain and tenderness, vomiting, diarrhea (occasionally constipation), bloody stools, and weight loss. Abdominal pain usually localizes in the right lower quadrant, radiates to the back, and increases with eating. Adults with severe intussusception may develop strangulation with excruciating pain, abdominal distention, and tachycardia.

Diagnosis

CONFIRMING DIAGNOSIS *Abdominal ultrasound and radiographic imaging studies can confirm the presence of intussusception.*

Upright abdominal X-rays may show a soft-tissue mass and signs of complete or partial obstruction, with dilated loops of bowel. Signs of dehydration or shock support the diagnosis, as does the presence of a palpable mass in the abdomen.

Treatment

In children, spontaneous reduction may occur; in the absence of spontaneous reduction, therapy may include hydrostatic reduction or surgery. Surgery is indicated for children with recurrent intussusception, for those who show signs of shock or peritonitis, and for those in whom symptoms have been present longer than 24 hours. In adults, surgery is always the treatment of choice.

During hydrostatic reduction, the radiologist drips a barium solution into the rectum from a height of no more than 3′ (1 m); fluoroscopy traces the progress of the barium. If the procedure is successful, the barium backwashes into the ileum, and the mass disappears. If not, the procedure is stopped, and the patient is prepared for surgery.

During surgery, manual reduction is attempted first. After compressing the bowel above the intussusception, the physician attempts to milk the intussusception back through the bowel. However, if manual reduction fails or if the bowel is gangrenous or strangulated, the physician will perform a resection of the affected bowel segment.

Special Considerations

Care focuses on changes in the patient's condition that might indicate worsening of the condition.

ALERT *Monitor the patient's vital signs before and after surgery. A change in temperature may indicate sepsis; infants may become hypothermic at the onset of infection. Rising pulse rate and falling blood pressure may be signs of peritonitis.*

- Check the patient's intake and output. Watch for signs of dehydration and bleeding.
- An NG tube is inserted to decompress the intestine and minimize vomiting. Monitor tube drainage and replace volume lost, as ordered.
- Monitor the patient who has undergone hydrostatic reduction for passage of stools and barium, a sign that the reduction was successful. Keep in mind that the patient may have a recurrence of intussusception, usually within the first 24 to 36 hours after the reduction.
- After surgery, administer antibiotics, as ordered. Closely check the incision for inflammation, drainage, or suture separation.
- Encourage deep breathing and productive coughing. Teach the patient to splint the incision when coughing.
- The NG tube may be removed when bowel sounds and peristalsis resume. The patient's diet can be advanced as tolerated.
- Check for abdominal distention after the patient resumes a normal diet, and monitor general condition.
- Offer special reassurance and emotional support to the child and parents or caregivers. This condition is considered a pediatric emergency, and parents or caregivers are generally unprepared for their child's hospitalization and possible surgery. They may feel guilty for not seeking medical aid sooner. Similarly, the child is unprepared for a separation from parents and home.

To minimize the stress of hospitalization, encourage parents or caregivers to participate in their child's care as much as possible.

VOLVULUS (TORSION)

Volvulus (torsion) is a twisting of the intestine at least 180 degrees on its mesenteric pedicle, which results in blood vessel compression and ischemia.

Causes and Incidence

Twisting in volvulus may result from an anomaly of rotation, an ingested foreign body, or an adhesion; in some cases, however, the cause is unknown. Volvulus usually occurs in a bowel segment with a mesentery long enough to twist. The most common area, particularly in adults, is the sigmoid; the small bowel is a common site in children. Other common sites include the stomach and cecum. Volvulus secondary to meconium ileus may occur in patients with cystic fibrosis.

- Acute gastric volvulus has a high-mortality rate. There's no racial predilection, and it affects males and females equally. Peak incidence occurs in people over the age of 50.

Pathophysiology

Volvulus is a twisting of the intestine on its mesenteric pedicle, with blood supply occlusion; it is often associated with fibrous adhesions in the small intestine, although it occurs more frequently in the large intestine in older adults.

Complications

- Strangulation of the twisted intestinal loop
- Ischemia
- Infarction
- Perforation
- Fatal peritonitis

Signs and Symptoms

Vomiting and rapid, marked abdominal distention follow sudden onset of severe abdominal pain. Nausea, vomiting, bloody stools, constipation, and shock may occur. Without immediate treatment, volvulus can lead to strangulation of the twisted bowel loop, ischemia, infarction, perforation, and fatal peritonitis.

Diagnosis

The sudden onset of severe abdominal pain and physical examination that may reveal a palpable mass suggest volvulus. Appropriate tests include the following:

- X-rays—Abdominal X-rays may show obstruction and abnormal air-fluid levels in the sigmoid and cecum; in midgut volvulus, abdominal X-rays may be normal.
- CT scan—may show evidence of intestinal obstruction.
- Barium enema—In cecal volvulus, barium fills the colon distal to the section of cecum; in sigmoid volvulus in children, barium may twist to a point and, in adults, it may take on an "ace of spades" configuration.
- Upper GI series (with small bowel follow-through)—In midgut volvulus, obstruction and possibly a twisted contour show in a narrow area near the duodenojejunal junction, where barium won't pass.
- White blood cell count—In strangulation, the count is greater than 15,000/μL; in bowel infarction, greater than 20,000/μL.

Treatment

Treatment varies according to the severity and location of the volvulus. For children with midgut volvulus, treatment is surgical. For adults with sigmoid volvulus, a proctoscopic examination is performed to check for infarction, and nonsurgical treatment includes reduction by careful insertion of a sigmoidoscope or a long rectal tube to deflate the bowel.

The success of nonsurgical reduction is indicated by expulsion of gas and immediate relief from abdominal pain. If the bowel is distended but viable, surgery consists of detorsion (untwisting); if the bowel is necrotic, surgery includes resection and anastomosis.

Special Considerations

After surgical correction of volvulus:

- Monitor the patient's vital signs, watching for temperature changes (a sign of sepsis) and a rapid pulse rate and falling blood pressure (signs of shock and peritonitis). Carefully monitor

fluid intake and output (including stools), electrolyte values, and complete blood count. Be sure to measure and record drainage from the NG tube and drains.

◆ Encourage frequent coughing and deep breathing with splinting of the incision.

◆ Reposition the patient often and perform suction as needed.

◆ Record excessive or unusual drainage.

◆ Check for incisional inflammation and separation of sutures.

◆ When bowel sounds and peristalsis return, remove the NG tube and begin oral feedings with clear liquids, as ordered. When solid food can be tolerated, gradually expand the diet. Reassure the patient and family or caregivers appropriately, and explain all diagnostic procedures. If the patient is a child, encourage parents or caregivers to participate in their child's care to minimize the stress of hospitalization.

PANCREATITIS

Pancreatitis, inflammation of the pancreas, occurs in acute and chronic forms and may be due to edema, necrosis, or hemorrhage. Alcohol use is associated with approximately 30% of cases of acute pancreatitis in the United States. The prognosis is better when pancreatitis follows biliary tract disease, but poor when it follows alcoholism. Mortality rises are high when pancreatitis is associated with necrosis and hemorrhage. (See *Chronic pancreatitis*.)

Chronic Pancreatitis

Chronic pancreatitis is associated with alcoholism in more than 45% of patients, but it also may follow hyperparathyroidism (causing hypercalcemia), hyperlipidemia or, infrequently, gallstones, trauma, or peptic ulcer. Inflammation and fibrosis cause progressive pancreatic insufficiency and eventually destroy the pancreas.

Symptoms of chronic pancreatitis include constant dull pain with occasional exacerbations, malabsorption, severe weight loss, and hyperglycemia (leading to diabetic symptoms). Diagnosis is based on the patient history, X-rays showing pancreatic calcification, an elevated erythrocyte sedimentation rate, and examination of stool for steatorrhea.

In many cases, the severe pain of chronic pancreatitis requires large doses of analgesics or opioids, making addiction a serious problem. Treatment also includes a low-fat diet and oral administration of pancreatic enzymes, such as pancreatin or pancrelipase, to control steatorrhea; insulin or oral hypoglycemics to curb hyperglycemia; and, occasionally, surgical repair of biliary or pancreatic ducts or the sphincter of Oddi to reduce pressure and promote the flow of pancreatic juice. The prognosis is favorable if the patient can avoid alcohol, but poor if not avoided.

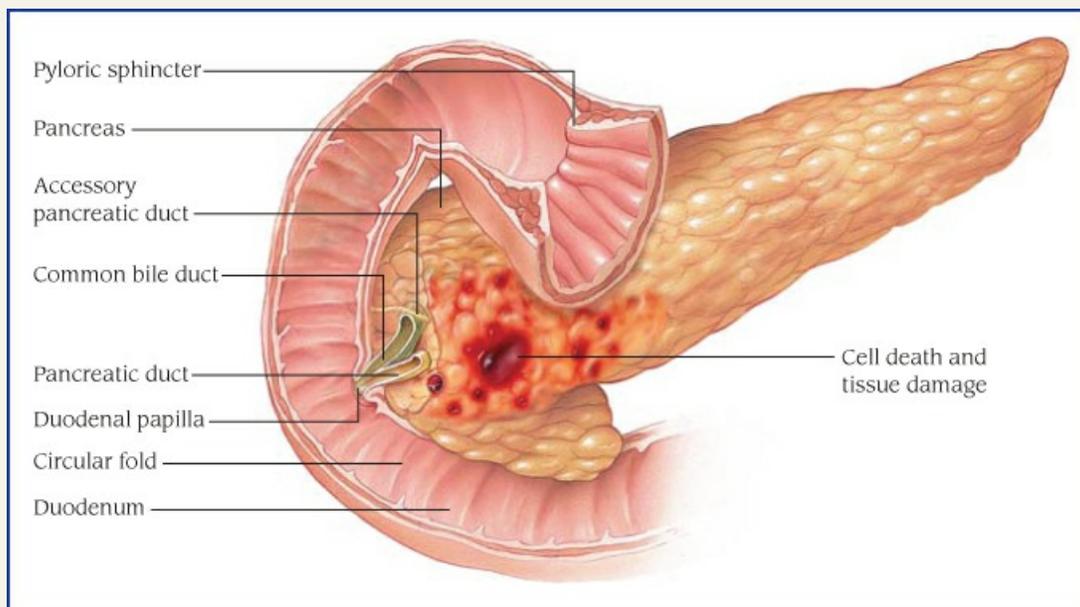
Causes and Incidence

The most common causes of pancreatitis are biliary tract disease and alcoholism, but it can also result from pancreatic cancer, trauma, or use of certain drugs, such as glucocorticoids, sulfonamides, chlorothiazide, and azathioprine. This disease also may develop as a complication of peptic ulcer, mumps, or hypothermia. Rarer causes are stenosis or obstruction of the sphincter of Oddi, hyperlipidemia, metabolic endocrine disorders (hyperparathyroidism and hemochromatosis), vasculitis or vascular disease, viral infections, mycoplasmal pneumonia, and

pregnancy.

Diabetes, pancreatic insufficiency, and calcification occur in young people, probably from malnutrition and alcoholism, and lead to pancreatic atrophy. (See *Necrotizing pancreatitis*.)

PATHOPHYSIOLOGY
NECROTIZING PANCREATITIS

Acute pancreatitis can occur as necrotizing pancreatitis when there is cell death and tissue damage.


The incidence of acute pancreatitis varies; its incidence ranges from 4.9 to 35 per 100,000 affected. Alcohol is estimated to account for 45% of cases of chronic pancreatitis in the United States.

Pathophysiology

Regardless of the cause, pancreatitis involves autodigestion: The enzymes normally excreted by the pancreas digest pancreatic tissue. Autodigestion causes vascular damage, coagulative and fat necrosis, and pseudocyst formation.

Complications

- Diabetes mellitus (if islets of Langerhans are damaged)
- Massive hemorrhage
- Destruction of pancreas
- Diabetes acidosis
- Shock
- Coma

- Adult respiratory distress syndrome
- Atelectasis
- Pulmonary effusion
- Pneumonia
- GI bleeding
- Pancreatic abscess

Signs and Symptoms

In many patients, the first and only symptom of mild pancreatitis is steady epigastric pain centered close to the umbilicus, radiating between the tenth thoracic and sixth lumbar vertebrae, and unrelieved by vomiting. However, a severe attack causes extreme pain, persistent vomiting, abdominal rigidity, diminished bowel activity (suggesting peritonitis), crackles at lung bases, and left pleural effusion. Progression produces extreme malaise and restlessness, with mottled skin, tachycardia, low-grade fever (100° to 102° F [37.7° to 38.8° C]), and cold, sweaty extremities. The proximity of the inflamed pancreas to the bowel may cause ileus.

If pancreatitis damages the islets of Langerhans, complications may include diabetes mellitus. Fulminant pancreatitis causes massive hemorrhage and total destruction of the pancreas, resulting in diabetic acidosis, shock, or coma.

Diagnosis

A thorough patient history (especially for alcoholism) and physical examination are the first steps in diagnosis, but the retroperitoneal position of the pancreas makes physical assessment difficult.

℞ CONFIRMING DIAGNOSIS *Dramatically elevated serum amylase levels—in many cases over 500 U/L—confirm pancreatitis and rule out perforated peptic ulcer, acute cholecystitis, appendicitis, and bowel infarction or obstruction. Similarly, dramatic elevations of amylase also occur in urine, ascites, or pleural fluid. Characteristically, amylase levels return to normal 48 hours after the onset of pancreatitis, despite continuing symptoms.*

Supportive laboratory values include:

- increased serum lipase levels, which rise more slowly than serum amylase
- low serum calcium levels (hypocalcemia) from fat necrosis and formation of calcium soaps
- white blood cell counts ranging from 8,000 to 20,000/μL, with increased polymorphonuclear leukocytes
- elevated glucose levels—as high as 500 to 900 mg/dL, indicating hyperglycemia

Tests used to diagnose pancreatitis may include the following:

- Abdominal X-rays or CT scans show dilation of the small or large bowel or calcification of the pancreas.
- Ultrasound or CT scan reveals an increased pancreatic diameter and helps distinguish acute cholecystitis from acute pancreatitis.

Treatment

The goal of therapy is to maintain circulation and fluid volume. Treatment measures must also relieve pain and decrease pancreatic secretions.

Emergency treatment of shock (which is the most common cause of death in early-stage pancreatitis) consists of vigorous I.V. replacement of electrolytes and proteins. Metabolic acidosis that develops secondary to hypovolemia and impaired cellular perfusion requires vigorous fluid volume replacement.

Drug treatment may include meperidine for pain, diazepam for restlessness and agitation, and antibiotics for bacterial infections. Morphine and codeine are usually avoided as pain medications because of their effect on the sphincter of Oddi. If the patient has hypocalcemia, they may need an infusion of 10% calcium gluconate. Elevated serum glucose levels may require insulin therapy.

After the emergency phase, continuing I.V. therapy should provide adequate electrolytes and protein solutions that don't stimulate the pancreas for 5 to 7 days. If the patient isn't ready to resume oral feedings by then, TPN may be necessary. Nonstimulating elemental gavage feedings may be safer because of the decreased risk of infection and overinfusion. In extreme cases, laparotomy to debride the pancreatic bed, partial pancreatectomy, or a combination of both and feeding jejunostomy may be necessary.

Special Considerations

Acute pancreatitis is a life-threatening emergency, requiring meticulous supportive care and continuous monitoring of vital systems.

- Monitor the patient's vital signs and pulmonary artery pressure or central venous pressure closely. Give plasma or albumin, if ordered, to maintain blood pressure. Record fluid intake and output, check urine output hourly, and monitor electrolyte levels. Assess for crackles, rhonchi, or decreased breath sounds.
- For bowel decompression, maintain constant or intermittent NG suctioning, and give nothing by mouth. Perform good mouth and nose care.
- Watch for signs and symptoms of calcium deficiency—tetany, cramps, carpopedal spasm, and seizures. If hypocalcemia is suspected, keep airway and suction apparatus handy and pad side rails.
- Administer analgesics as needed to relieve the patient's pain and anxiety. Remember that anticholinergics reduce salivary and sweat gland secretions. Teach the patient that dry mouth and facial flushing may be experienced. *Caution:* Narrow-angle glaucoma contraindicates the use of atropine or its derivatives.
- Monitor glucose levels.
- Watch for complications due to TPN, such as sepsis, hypokalemia, overhydration, and metabolic acidosis. Watch for fever, cardiac irregularities, changes in arterial blood gas measurements, and deep respirations. Use strict aseptic technique when caring for the catheter insertion site.

Anorectum

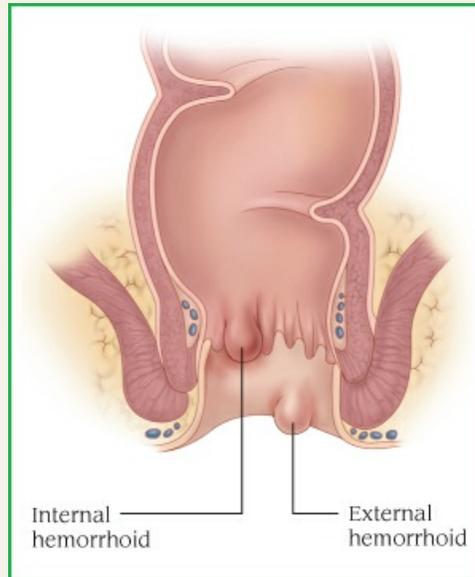
HEMORRHOIDS

Hemorrhoids are varicosities in the superior or inferior hemorrhoidal venous plexus. Dilation and enlargement of the superior plexus produce internal hemorrhoids; dilation and enlargement of the inferior plexus produce external hemorrhoids that may protrude from the rectum. (See *Types of hemorrhoids*.) Hemorrhoids occur in both sexes; incidence is self-reported to be at the highest

between 45 and 65 years old.

Types of Hemorrhoids

Covered by mucosa, *internal hemorrhoids* bulge into the rectal lumen and may prolapse during defecation. Covered by skin, *external hemorrhoids* protrude from the rectum and are more likely to thrombose than internal hemorrhoids.

Internal hemorrhoid — External hemorrhoid


Causes and Incidence

Predisposing factors include occupations that require prolonged standing or sitting; straining due to constipation, diarrhea, coughing, sneezing, or vomiting; heart failure; hepatic disease, such as cirrhosis, amebic abscesses, or hepatitis; alcoholism; anorectal infections; loss of muscle tone due to old age, rectal surgery, or episiotomy; anal intercourse; and pregnancy.

Pathophysiology

Hemorrhoids are thought to result from increased venous pressure in the hemorrhoidal plexus.

Complications

- Local infection
- Thrombosis

Signs and Symptoms

Although hemorrhoids may be asymptomatic, they characteristically cause painless, intermittent bleeding, which occurs on defecation. Bright red blood appears streaked on stool or on toilet paper due to injury of the fragile mucosa covering the hemorrhoid. These first-degree hemorrhoids may itch because of poor anal hygiene. When second-degree hemorrhoids prolapse, they're usually painless and spontaneously return to the anal canal following defecation. Third-

degree hemorrhoids cause constant discomfort and prolapse in response to any increase in intra-abdominal pressure. They must be manually reduced. Thrombosis of external hemorrhoids produces sudden rectal pain and a subcutaneous, large, firm lump that the patient can feel. If hemorrhoids cause severe or recurrent bleeding, they may lead to secondary anemia with significant pallor, fatigue, and weakness; however, such systemic complications are rare.

Diagnosis

Physical examination confirms external hemorrhoids. Proctoscopy confirms internal hemorrhoids and rules out rectal polyps.

Treatment

Treatment depends on the type and severity of the hemorrhoid and on the patient's overall condition. Generally, treatment includes measures to ease pain, combat swelling, and regulate bowel habits. The patient can relieve constipation by increasing the amount of raw vegetables, fruit, and whole grains consumed in the diet or by occasionally using stool softeners. Venous congestion can be prevented by avoiding prolonged sitting; local swelling and pain can be decreased with local anesthetic agents (lotions, creams, or suppositories), astringents, or cold compresses, followed by warm sitz baths or thermal packs. Rarely, the patient with chronic, profuse bleeding may require a blood transfusion. Other nonsurgical treatments include injection of a sclerosing solution to produce scar tissue that decreases prolapse, manual reduction, and hemorrhoid band ligation or laser ablation.

Hemorrhoidectomy, the most effective treatment, is necessary for patients with severe bleeding, intolerable pain and pruritus, and large prolapse. This procedure is contraindicated in patients with blood dyscrasias (acute leukemia, aplastic anemia, or hemophilia) or GI carcinoma and during the first trimester of pregnancy.

Special Considerations

Patient care includes preoperative and postoperative support.

- To prepare the patient for hemorrhoidectomy, administer an enema as appropriate (usually 2 to 4 hours before surgery), and record results. Prepare the area as ordered.
- Postoperatively, check for signs of prolonged rectal bleeding, administer adequate analgesics, and provide sitz baths as ordered.
- As soon as the patient can resume oral intake, administer a bulk medication, such as psyllium, about 1 hour after the evening meal, to ensure a daily stool. Teach to refrain from using stool-softening medications soon after hemorrhoidectomy because a firm stool acts as a natural dilator to prevent anal stricture from the scar tissue. (The patient may need repeated digital dilation to prevent such narrowing.)
- Keep the wound site clean to prevent infection and irritation.
- Before discharge, stress the importance of regular bowel habits and good anal hygiene. Discourage too vigorous wiping with washcloths and using harsh soaps. Encourage the use of medicated astringent pads and white toilet paper (the fixative in colored paper can irritate the skin).

ANORECTAL ABSCESS AND FISTULA

Anorectal abscess is a localized collection of pus due to inflammation of the soft tissue near the

rectum or anus. Inflammation may produce an anal fistula—an abnormal opening in the anal skin—that may communicate with the rectum.

Causes and Incidence

Causes of anorectal abscess and fistula are many (see *Pathophysiology* below). The peak incidence of anorectal abscess occurs in people in their 30s and 40s, but there's also a high occurrence in infants. Men are affected two to three times more often than women. About 30% of patients have a previous history of abscess.

Pathophysiology

The inflammatory process that leads to abscess may begin with an abrasion or tear in the lining of the anal canal, rectum, or perianal skin and subsequent infection by *E. coli*, staphylococci, or streptococci. Trauma may result from injections for treatment of internal hemorrhoids, enema-tip abrasions, puncture wounds from ingested eggshells or fish bones, or insertion of foreign objects. Other preexisting lesions include infected anal fissure, infections from the anal crypt through the anal gland, ruptured anal hematoma, prolapsed thrombosed internal hemorrhoids, and septic lesions in the pelvis, such as acute appendicitis, acute salpingitis, and diverticulitis. Systemic illnesses that may cause abscesses include ulcerative colitis and Crohn disease. However, many abscesses develop without preexisting lesions.

As the abscess (particularly from an infected anal crypt gland) produces more pus, a fistula may form in the soft tissue beneath the muscle fibers of the sphincters (especially the external sphincter), usually extending into the perianal skin. The internal (primary) opening of the abscess or fistula is usually near the anal glands and crypts; the external (secondary) opening, in the perianal skin.

Complications

- Anorectal fistula
- Perineal cellulitis
- Scar tissue formation
- Anal stricture

Signs and Symptoms

Characteristics are throbbing pain and tenderness at the site of the abscess. A hard, painful lump develops on one side, preventing comfortable sitting. Discharge of pus may occur from the rectum, and there may be constipation or pain associated with bowel movements.

Diagnosis

Anorectal abscess is detectable on physical examination. If the abscess drains by forming a fistula, the pain usually subsides and the major signs become pruritic drainage and subsequent perianal irritation. The external opening of a fistula generally appears as a pink or red, elevated, discharging sinus or ulcer on the skin near the anus. Depending on the severity of the infection, the patient may have chills, fever, nausea, vomiting, and malaise. Digital examination may reveal a palpable indurated tract and a drop or two of pus on palpation. The internal opening may be palpated as a depression or ulcer in the midline anteriorly or at the dentate line posteriorly. Examination with a probe may require an anesthetic. A proctosigmoidoscopy may be performed to exclude associated diseases.

Treatment

Anorectal abscesses require surgical incision under caudal anesthesia to promote drainage. Fistulas require a fistulotomy—removal of the fistula and associated granulation tissue—under caudal anesthesia. If the fistula tract is epithelialized, treatment requires fistulectomy—removal of the fistulous tract—followed by insertion of drains, which remain in place for 48 hours. Warm sitz baths are useful to relieve inflammation; however, pain medication and antibiotics may be needed.

Special Considerations

After incision to drain anorectal abscess, follow these guidelines:

- Provide adequate medication for pain relief, as ordered.
- Examine the wound frequently to assess proper healing, which should progress from the inside out. Healing should be complete in 4 to 5 weeks for perianal fistulas; in 12 to 16 weeks for deeper wounds.
- Inform the patient that complete recovery takes time, and offer encouragement.
- Stress the importance of perianal cleanliness.
- Be alert for the first postoperative bowel movement. The patient may suppress the urge to defecate because of anticipated pain; the resulting constipation increases pressure at the wound site. Such a patient may benefit from a stool-softening laxative.

RECTAL POLYPS

Rectal polyps are masses of tissue that rise above the mucosal membrane and protrude into the GI tract. Types of polyps include common polypoid adenomas, villous adenomas, hereditary polyposis, focal polypoid hyperplasia, and juvenile polyps (hamartomas). Most rectal polyps are benign; however, villous and hereditary polyps show a marked inclination to become malignant. Indeed, a striking feature of familial polyposis is that it's commonly associated with rectosigmoid adenocarcinoma.

Causes and Incidence

Polyps form as a result of unrestrained cell growth in the upper epithelium. Predisposing factors include heredity, age, infection, and diet.

Villous adenomas are most prevalent in men over 50 years old, and are more common in African American men than those of other ethnicity. Incidence in both sexes rises after 70 years old.

Pathophysiology

Polyps are masses or finger-like projections that arise from the intestinal mucosal epithelium. Adenomatous polyps form in an area where there is hyperproliferation of epithelial cells and crypt dysplasia; after traversing the muscularis mucosae, the polyp can become invasive and malignant.

Complications

- Anemia from slow bleeding
- Bowel obstruction
- Colorectal cancer

Signs and Symptoms

Because rectal polyps don't generally cause symptoms, they're usually discovered incidentally during a digital examination or rectosigmoidoscopy. Rectal bleeding is a common sign; high rectal polyps leave a streak of blood on the stool, whereas low rectal polyps bleed freely.

Rectal polyps vary in appearance. Common polypoid adenomas are small, multiple lesions that are redder than normal mucosa. They're commonly pedunculated (attached to rectal mucosa by a long, thin stalk) and granular, with a red, lobular, or eroded surface.

Villous adenomas are usually sessile (attached to the mucosa by a wide base) and vary in size from 0.5 to 12 cm. They are soft, friable, and finely lobulated. They may grow large and cause painful defecation; however, because adenomas are soft, they rarely cause bowel obstruction. Sometimes adenomas prolapse outside the anus, expelling parts of the adenoma with feces. These polyps may cause diarrhea, bloody stools, and subsequent fluid and electrolyte depletion, with hypotension and oliguria.

In hereditary polyposis, rectal polyps resemble benign adenomas but occur as hundreds of small (0.5 cm) lesions carpeting the entire mucosal surface. Associated signs include diarrhea, bloody stools, and secondary anemia. In patients with hereditary polyposis, changes in bowel habits with abdominal pain usually signal rectosigmoid cancer.

Juvenile polyps are large, inflammatory lesions, commonly without an epithelial covering. Mucus-filled cysts cover their usually smooth surface.

Focal polypoid hyperplasia produces small (<3 mm), granular, sessile lesions, similar to the colon in color, or gray or translucent. They usually occur at the rectosigmoid junction.

Diagnosis

Rx CONFIRMING DIAGNOSIS *Firm diagnosis of rectal polyps requires identification of the polyps through proctosigmoidoscopy or colonoscopy and rectal biopsy.*

Barium enema can help identify polyps that are located high in the colon. Supportive laboratory findings include occult blood in the stools, low hemoglobin level and hematocrit (with anemia) and, possibly, serum electrolyte imbalances in patients with villous adenomas.

Treatment

Treatment varies according to the type and size of the polyps and their location in the colon. Common polypoid adenomas less than 1 cm require polypectomy, usually by fulguration (destruction by high-frequency electricity) during endoscopy. For common polypoid adenomas larger than 4 cm and all invasive villous adenomas, treatment usually consists of abdominoperineal resection or low anterior resection.

Focal polypoid hyperplasia can be obliterated by biopsy. Depending on GI involvement, hereditary polyps necessitate total abdominoperineal resection with a permanent ileostomy, subtotal colectomy with ileoproctostomy, or ileoanal anastomosis. Juvenile polyps are prone to autoamputation; if this doesn't occur, snare removal during colonoscopy is the treatment of choice.

Special Considerations

During diagnostic evaluation:

- Check sodium, potassium, and chloride levels daily in the patient with fluid imbalances;

adjust fluid and electrolytes, as necessary. Administer normal saline solution with potassium I.V., as ordered. Weigh the patient daily, and record the amount of diarrhea. Watch for signs of dehydration (decreased urine output and increased blood urea nitrogen levels).

◆ Tell the patient to watch for and report evidence of rectal bleeding.

After biopsy and fulguration:

◆ Check for signs of perforation and hemorrhage, such as sudden hypotension, a decrease in hemoglobin level or hematocrit, shock, abdominal pain, and passage of red blood through the rectum.
◆ Have the patient walk as soon as possible after the procedure.
◆ Watch for and record the first bowel movement, which may not occur for 2 to 3 days.
◆ Provide sitz baths for 3 days.
◆ If the patient has benign polyps, stress the need for routine follow-up studies to check the polypoid growth rate.
◆ Prepare the patient with precancerous or familial lesions for abdominoperineal resection. Provide emotional support and preoperative instruction.

After ileostomy or subtotal colectomy with ileoproctostomy:

◆ Properly care for abdominal dressings, I.V. lines, and indwelling urinary catheters. Record intake and output, and check the patient's vital signs for hypotension and surgical complications. Administer pain medication, as ordered.
◆ To prevent embolism, have the patient walk as soon as possible, and apply antiembolism stockings; encourage range-of-motion exercises.
◆ Provide enterostomal therapy and teach the patient proper stoma care.

PILONIDAL DISEASE

In pilonidal disease, a coccygeal cyst forms in the intergluteal cleft on the posterior surface of the lower sacrum. It usually contains hair and becomes infected, producing an abscess, a draining sinus, or a fistula. Incidence is highest among hirsute white men around age 19.

Causes and Incidence

Pilonidal disease may develop congenitally from a tendency to hirsutism, or it may be acquired from stretching or irritation of the sacrococcygeal area (intergluteal fold) from prolonged rough exercise (such as horseback riding), heat, excessive perspiration, or constrictive clothing.

The incidence rate of pilonidal disease is 0.7%. It affects men two to four times more often than women, but the onset is earlier in females, possibly because they begin puberty at an earlier age.

Pathophysiology

The pathophysiology of pilonidal disease is not fully understood; however, hair and inflammation present in the natal cleft are recognized as contributing factors. As the patient sits or bends, the natal cleft stretches, hair follicles are damaged or broken, and a pore is opened. This pore collects debris and serves as a receptacle for shed hairs from others parts of the body to become embedded. Negative pressure is created in the subcutaneous space as the skin becomes taut over the natal cleft; this draws the hairs deeper into the pore, and friction then causes the hairs to form a sinus.

Complications

- Impaired social interaction due to pain and discomfort
- Difficulty performing work-related activities

Signs and Symptoms

Generally, a pilonidal cyst produces no symptoms until it becomes infected, causing local pain, tenderness, swelling, or heat. Other clinical features include continuous or intermittent purulent drainage, followed by development of an abscess, chills, fever, headache, and malaise.

Diagnosis

℞ **CONFIRMING DIAGNOSIS** *Physical examination confirms the diagnosis and may reveal a series of openings along the midline, with thin, brown, foul-smelling drainage or a protruding tuft of hair.*

Pressure on the sinus tract may produce purulent drainage. Passing a probe back through the sinus tract toward the sacrum shouldn't reveal a perforation between the anterior sinus and the anal canal. Cultures of discharge from the infected sinus may show staphylococci or skin bacteria, but don't usually contain bowel bacteria.

Treatment

Conservative treatment of pilonidal disease consists of incision and drainage of abscesses, regular extraction of protruding hairs, and sitz baths (four to six times daily). However, persistent infections may necessitate surgical excision of the entire affected area.

After excision of a pilonidal abscess, the patient requires regular follow-up care to monitor wound healing. The surgeon may periodically palpate the wound during healing with a cotton-tipped applicator, curette excess granulation tissue, and extract loose hairs to promote wound healing from the inside out and to prevent dead cells from collecting in the wound. Complete healing may take several months.

Special Considerations

Care includes preoperative and postoperative support and patient education.

- Before incision and drainage of a pilonidal abscess, assure the patient adequate pain medication will first be administered.
- After surgery, check the compression dressing for signs of excessive bleeding, and change the dressing as directed.
- Encourage the patient to walk as soon as possible after the procedure.
- Tell the patient to place a gauze pad over the wound site after the dressing is removed to allow ventilation and prevent friction from clothing. Teach the patient to take sitz baths and to let the area air-dry instead of rubbing or patting it dry with a towel.
- After healing, the patient should briskly wash the area daily with a washcloth to remove loose hairs. Encourage the patient with obesity to establish a weight loss plan.

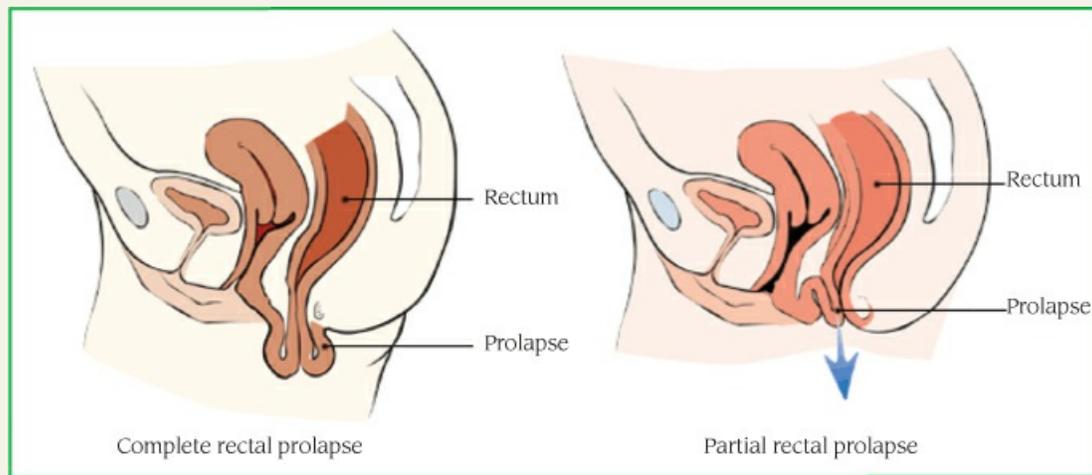
RECTAL PROLAPSE

Rectal prolapse is the circumferential protrusion of one or more layers of the mucous membrane

through the anus. Prolapse may be complete (with displacement of the anal sphincter or bowel herniation) or partial (mucosal layer). (See *Types of rectal prolapse,* page 262.)

Types of Rectal Prolapse

Partial rectal prolapse involves only the rectal mucosa and a small mass of radial mucosal folds. However, in complete rectal prolapse (also known as procidentia), the full rectal wall, sphincter muscle, and a large mass of concentric mucosal folds protrude. Ulceration is possible after complete prolapse.

Complete rectal prolapse   Partial rectal prolapse


Causes and Incidence

Rectal prolapse usually occurs in older multiparous females who have given birth vaginally. It's commonly associated with other conditions, such as prior pelvic surgery, history of chronic straining, chronic constipation or diarrhea, cystic fibrosis, dementia, stroke, pelvic floor dysfunction, and pelvic floor anatomic defects.

True incidence figures are unavailable because many cases go unreported.

Pathophysiology

See *Types of rectal prolapse* box for pathophysiology.

Complications

- Rectal ulceration
- Bleeding
- Incontinence

Signs and Symptoms

In rectal prolapse, protrusion of tissue from the rectum may occur during defecation or walking. Other symptoms include a persistent sensation of rectal fullness, bloody diarrhea, pain in the lower abdomen due to ulceration, a feeling of incomplete evacuation, and rectal incontinence.

Hemorrhoids or rectal polyps may coexist with a prolapse.

Diagnosis

Typical clinical features and visual examination confirm the diagnosis. In complete prolapse, examination reveals the full thickness of the bowel wall and, possibly, the sphincter muscle protruding and mucosa falling into bulky, concentric folds. In partial prolapse, examination reveals only partially protruding mucosa and a smaller mass of radial mucosal folds. Straining during examination may disclose the full extent of prolapse.

Treatment

In some cases, eliminating the underlying cause is the only treatment necessary. The rectal mucosa can be returned to the rectum manually. While the patient is in a knee-chest position, a soft, warm, wet cloth may be used to apply gentle pressure to the mass to push it back through the anal opening, thereby allowing gravity to help return the prolapse into place. In an older adult, injection of a sclerosing agent to cause a fibrotic reaction fixes the rectum in place. Severe or chronic prolapse requires surgical repair by strengthening or tightening the sphincters with wire or by anterior or rectal resection of prolapsed tissue.

Special Considerations

Provide the patient with education regarding underlying causes and preoperative and postoperative support.

PREVENTION *Help the patient prevent constipation by teaching the correct diet and stool-softening regimen.*

- Advise the patient with severe prolapse and incontinence to wear a perineal pad.
- Before surgery, explain possible complications, including permanent rectal incontinence.
- After surgery, monitor for immediate complications (hemorrhage) and later ones (pelvic abscess, fever, pus drainage, pain, rectal stenosis, constipation, or pain on defecation). Teach perineal strengthening exercises: Have the patient lie down, with the back flat on the mattress; then ask the patient to pull in the abdomen and squeeze while taking a deep breath. Also have the patient repeatedly squeeze and relax the buttocks while sitting on a chair.

ANAL FISSURE

Anal fissure is a laceration or crack in the lining of the anus that extends to the circular muscle. Most fissures heal on their own and don't require treatment, aside from good diaper hygiene. However, some fissures may require medical treatment. The prognosis is very good, especially with fissurectomy and good anal hygiene.

Causes and Incidence

Anal fissure results from passage of large, hard stools that stretch the lining beyond its limits. It may also be due to prolonged diarrhea, strain on the perineum during childbirth and, rarely, from scar stenosis. Occasionally, anal fissure is secondary to proctitis, anal tuberculosis, cancer, or Crohn disease.

Anal fissures are common in young infants and most often affect those who are middle-aged.

Actual incidence is unknown since many cases are attributed to hemorrhoids.

Pathophysiology

A tear to the anoderm within the distal half of the anal canal usually begins an anal fissure; a cycle of anal pain and bleeding may result. Spasms may result from the exposed internal sphincter muscle, which can also restrict blood flow to the area, preventing healing.

Complications

- Abscess, fistula, and septicemia (rare)
- Scar tissue
- Hampered bowel elimination

Signs and Symptoms

The onset of an acute anal fissure is characterized by tearing, cutting, or burning pain during or immediately after a bowel movement. A few drops of blood may streak toilet paper or underclothes. Painful anal sphincter spasms result from ulceration of a "sentinel pile" (swelling at the lower end of the fissure). A fissure may heal spontaneously and completely, or it may partially heal and break open again. Chronic fissure produces scar tissue that hampers normal bowel evacuation.

Diagnosis

Anoscopy showing a longitudinal tear and typical clinical features help establish the diagnosis. Digital examination that elicits pain and bleeding supports the diagnosis. Gentle traction on perianal skin can create sufficient eversion to visualize the fistula directly.

Treatment

Treatment varies according to the severity of the tear. Conservative treatment measures include stool softeners, dietary adjustment (addition of bulk to absorb water while in the intestinal tract), use of petroleum jelly and sitz baths, and cleaning more gently. Anesthetic ointment may be useful if pain interferes with normal bowel movements. Topical muscle relaxants may also be soothing. These measures generally heal most anal fissures. For fissures that don't heal with these treatments, a minor surgical procedure to relax the sphincter may be necessary.

For superficial fissures without hemorrhoids, forcible digital dilatation of the anal sphincter under local anesthesia stretches the lower portion of the sphincter. For complicated fissures, treatment includes surgical excision of tissue, adjacent skin, and mucosal tags and division of hypertrophied internal sphincter muscle to release tension.

Special Considerations

Care consists of patient education and support.

- Prepare the patient for rectal examination; explain the necessity for the procedure.
- Provide warm sitz baths, warm soaks, and local anesthetic ointment to relieve pain. A low-residue diet, adequate fluid intake, and stool softeners prevent straining during defecation.
- Give diphenoxylate (Lomotil) or other antidiarrheals to control diarrhea.

ANAL PRURITUS

Anal pruritus is perianal itching, irritation, or superficial burning.

Causes and Incidence

Factors that contribute to pruritus ani include overcleaning of the perianal area (harsh soap, vigorous rubbing with a washcloth or toilet paper); minor trauma caused by straining to defecate; poor hygiene; sensitivity to spicy foods, coffee, alcohol, food preservatives, perfumed or colored toilet paper, detergents, or certain fabrics; specific medications (antibiotics, antihypertensives, or antacids that cause diarrhea); excessive sweating (in occupations associated with physical labor or high stress levels); anal skin tags; systemic disease, especially diabetes; skin disorders, such as psoriasis or eczema; certain skin lesions, such as those associated with squamous cell carcinoma, basal cell carcinoma, Bowen disease, Paget disease, melanoma, syphilis, and tuberculosis; fungal or parasitic infection; and local anorectal disease (fissure, hemorrhoids, and fistula). This disorder is more common in males than in females, and often occurs between 40 and 60 years old.

Pathophysiology

Pathophysiology is associated with the root cause of the pruritus. Idiopathic anal pruritus is thought to be associated with perianal fecal contamination, and subsequent traumatic wiping or scratching.

Signs and Symptoms

The key symptom of anal pruritus is perianal itching or burning after a bowel movement, during stress, or at night. In acute anal pruritus, scratching produces reddened skin, with weeping excoriations; in chronic anal pruritus, skin becomes thick and leathery, with excessive pigmentation.

Diagnosis

A detailed patient history is essential. Rectal examination rules out fissures and fistulas; biopsy rules out cancer. Allergy testing may also be helpful.

Treatment

After elimination of the underlying cause, treatment is symptomatic, such as advising the patient to avoid scratching or rubbing the itchy areas. Lukewarm baths and a skin-soothing oatmeal or cornstarch bath may be comforting. Temporary relief may be obtained with cold compresses. Topical over-the-counter ointments or creams containing hydrocortisone or zinc oxide are also useful.

Special Considerations

- Make sure that the patient understands the condition and its causes.
- Recommend keeping fingernails short to avoid skin damage from inadvertent scratching. Suggest using cool, light, loose bedclothes and avoiding wearing rough clothing, particularly wool, over the irritated area.
- Advise the patient to avoid prolonged exposure to excessive heat and humidity.
- Advise the patient to avoid self-prescribed creams or powders, perfumed soaps, colored toilet paper, and moistened wipes because they may be irritating.
- Teach the patient to keep the perianal area clean and dry. Suggest witch hazel pads for wiping

and cotton balls tucked between the buttocks to absorb moisture.

PROCTITIS

Proctitis is an acute or chronic inflammation of the rectal mucosa. It can result in discomfort, bleeding, and possibly a discharge of mucus or pus.

Causes and Incidence

Proctitis caused by sexually transmitted disease (STD) occurs with high frequency among individuals who engage in anal intercourse. STDs that can cause proctitis include gonorrhea, herpes, chlamydia, and lymphogranuloma venereum.

In children, beta-hemolytic streptococcus may cause proctitis. Autoimmune proctitis is associated with such diseases as ulcerative colitis or Crohn disease. Proctitis may also be caused by medications, radiation, or noxious agents such as chemicals inserted into the rectum.

Other contributing factors include chronic constipation, habitual laxative use, emotional upset, radiation (especially for cancer of the cervix or uterus), endocrine dysfunction, rectal injury, rectal medications, bacterial infections, allergies (especially to milk), vasomotor disturbance that interferes with normal muscle control, and food poisoning.

Pathophysiology

Pathophysiology is associated with the root cause mechanism.

Complications

Complications are congruent with root cause mechanism.

Signs and Symptoms

Key symptoms include tenesmus, constipation, a feeling of rectal fullness, and abdominal cramps on the left side. The patient feels an intense urge to defecate, which produces a small amount of stool that may contain blood and mucus.

Diagnosis

A detailed patient history is essential. In acute proctitis, sigmoidoscopy or proctoscopy reveals edematous, bright red or pink rectal mucosa that's thick, shiny, friable and, possibly, ulcerated. In chronic proctitis, sigmoidoscopy shows thickened mucosa, loss of vascular pattern, and stricture of the rectal lumen. Other supportive tests include biopsy to rule out cancer as well as rectal culture and examination of a stool sample.

Treatment

Primary treatment eliminates the underlying cause (fecal impaction, laxatives, or other medications). Proctitis caused by infection is treated with antibiotics specific for the causative organism. Corticosteroids or mesalamine suppositories may relieve symptoms in Crohn disease or ulcerative colitis. Soothing enemas or steroid (hydrocortisone) suppositories or enemas may be helpful if proctitis is due to radiation.

Special Considerations

◆ Tell the patient to watch for and report bleeding and other persistent symptoms.

- ◆ Fully explain proctitis and its treatment to the patient to foster understanding of the disorder and prevent its recurrence.
- ◆ Offer explanations, emotional support, and reassurance during rectal examinations and treatment.

Hepatobiliary Disorders

Introduction

The liver is the largest internal organ in the body, weighing slightly more than 3 lb (1,200 to 1,600 g) in the average adult. It is also one of the busiest, performing well over 100 separate functions. The most important of these are the formation and secretion of bile; detoxification of harmful substances; storage of vitamins; metabolism of carbohydrates, fats, and proteins; and production of plasma proteins. This remarkably resilient organ serves as the body's warehouse and is essential to life.

LOBULAR STRUCTURE

Located above the right kidney, stomach, pancreas, and intestines and immediately below the diaphragm, the liver divides into a left and a right lobe separated by the falciform ligament. The right lobe is six times larger than the left. Glisson's capsule, a network of connective tissue, covers the entire organ and extends into the parenchyma along blood vessels and bile ducts. Within the parenchyma, cylindrical lobules comprise the basic functional units of the liver, consisting of cellular plates that radiate from a central vein, somewhat like spokes in a wheel. Small bile canaliculi fit between the cells in the plates and empty into terminal bile ducts, which join two larger ones that merge into a single hepatic duct upon leaving the liver. The hepatic duct then joins the cystic duct to form the common bile duct.

The liver receives blood from two major sources: the hepatic artery and the portal vein. The two vessels carry approximately 1,500 mL of blood to the liver per minute, nearly 75% of which is supplied by the portal vein. Sinusoids—offshoots of the hepatic artery and portal vein—run between each row of the hepatic cells. Phagocytic Kupffer's cells, part of the reticuloendothelial system, line the sinusoids, destroying old or defective red blood cells and detoxifying harmful substances. The liver has a large lymphatic supply; consequently, cancer frequently metastasizes there.

LIVER FUNCTION

One of the liver's most important functions is the conversion of bilirubin, a breakdown product of hemoglobin, into bile. Liberated by the spleen into plasma and bound loosely to albumin, bilirubin reaches the liver in an unconjugated (water-insoluble) state. The liver then conjugates

or dissociates it, converting it to a water-soluble derivative before excreting it as bile. All hepatic cells continually form bile.

The liver also detoxifies many substances through inactivation or through conjugation. Inactivation involves reduction, oxidation, and hydroxylation. An important liver function is the inactivation of many drugs that are metabolized primarily in the liver. Such drugs must be used with caution in hepatic disease because their effects may be markedly prolonged.

ELDER TIP In elderly people, the blood supply to the liver decreases, and certain liver enzymes become less active. As a result, the liver loses some of its ability to metabolize drugs, and higher levels of drugs remain in the circulation, causing more intense drug effects. This increases the risk of drug toxicity.

As still another example of its amazing versatility, the liver forms vitamin A from certain vegetables and stores vitamins K, D, and B_{12}. It also stores iron in the form of ferritin.

METABOLIC FUNCTIONS

The liver figures indispensably in the metabolism of the three major food groups: carbohydrates, fats, and proteins. In carbohydrate metabolism, the liver plays one of its most vital roles by extracting excess glucose from the blood and reserving it for times when blood glucose levels fall below normal, when it releases glucose into the circulation, and then replenishes the supply by a process called *glyconeogenesis*. To prevent dangerously low blood glucose levels, the liver can also convert galactose or amino acids into glucose (gluconeogenesis). The liver also forms many critical chemical compounds from the intermediate products of carbohydrate metabolism.

The liver performs more than half the body's preliminary breakdown of fats because liver cells metabolize fats more quickly and efficiently than do other body cells. Liver cells break fats down into glycerol and fatty acids and convert the fatty acids into small molecules that can be oxidized. The liver also produces substantial quantities of cholesterol and phospholipids, manufactures lipoproteins, and synthesizes fat from carbohydrates and proteins to be transported in lipoproteins for eventual storage in adipose tissue.

Like so many of its functions, the liver's role in protein metabolism is essential to life. The liver deaminates amino acids so they can be used for energy or converted into fats or carbohydrates. It forms urea to remove ammonia from body fluids and forms all plasma proteins (as much as 50 to 100 g/day) except gamma globulin. The liver is such an effective synthesizer of protein that it can replenish as much as half its plasma proteins in 4 to 7 days. The liver also synthesizes nonessential amino acids and forms other important chemical compounds from amino acids.

PRODUCTION OF PLASMA PROTEINS

The liver synthesizes most of the body's large molecules of plasma proteins, including all of the albumin, which binds many substances in plasma and maintains colloid osmotic pressure.

Normally, plasma proteins and amino acid levels maintain equilibrium in the blood. When amino acid levels decrease, plasma proteins split into amino acids to restore this equilibrium. Reacting to decreased levels of amino acids, the liver steps up the production of plasma proteins. The liver may synthesize approximately 400 g of protein daily; for this reason, significant liver damage leads to hyperproteinemia, which in turn disrupts the colloid osmotic pressure and amino acid levels.

The liver also produces most of the plasma proteins necessary for blood coagulation, including

prothrombin and fibrinogen, which are the most abundant. The liver forms prothrombin in a process dependent on vitamin K and the production of bile. Fibrinogen, a large-molecule protein formed entirely by the liver, is an essential factor in the coagulation cascade.

Together, the plasma proteins maintain colloid osmotic pressure throughout the capillaries. Because the plasma protein molecules are too large to cross the capillary membrane, they concentrate at the capillary line and produce an osmotic pressure of pull. This constant colloid osmotic pressure at the arteriolar and venular sections of the capillary provides the major osmotic force regulating the return of fluid to the intravascular compartment.

Because of their large molecular size, plasma proteins don't easily cross into the interstitial spaces. Their only route for return to the bloodstream is through lymphatic drainage. The lymphatic vessels drain into the lymphatic and thoracic ducts, which drain directly into the superior vena cava.

ASSESSING FOR LIVER DISEASE

In many cases, a careful physical examination and patient history can detect hepatic disease. Watch especially for its cardinal signs: jaundice (a result of increased serum bilirubin levels), ascites (commonly with hemoconcentration, edema, and oliguria), and hepatomegaly. Other signs and symptoms may include right upper quadrant abdominal pain, lassitude, anorexia, nausea, and vomiting. The presence of a palpable left lobe is always pathologic and usually suggestive of chronic liver disease. Another primary sign is portal hypertension (portal vein pressure >6 cm H_2O) revealed by the presence of caput medusae (dilated veins seen on the abdomen). Surgical insertion of a catheter into the portal vein allows measurement of portal vein pressure.

⚠️ **ALERT** *Carefully assess the patient's neurologic status because neurologic symptoms, such as those associated with hepatic encephalopathy (confusion, muscle tremors, and asterixis), may signal the onset of life-threatening hepatic failure.*

Other common signs of hepatic disease include pallor (commonly linked to cirrhosis or carcinoma), parotid gland enlargement (in alcohol-induced liver damage), Dupuytren's contracture, gynecomastia, testicular atrophy, decreased axillary or pubic hair, bleeding disorders (ecchymosis and purpura), spider angiomas, and palmar erythema.

Careful abdominal palpation and auscultation can also detect hepatocellular carcinoma or metastasis, which turns the liver rock-hard and causes abdominal bruits. In hepatitis, the liver is usually enlarged; palpation may elicit tenderness at the liver's edge. In cirrhosis, the atrophic liver is difficult to palpate. In neoplastic disease or hepatic abscess, auscultation may detect a pleural friction rub.

COMPREHENSIVE HISTORY ESSENTIAL

Ask if the patient has ever had jaundice, anemia, or a splenectomy. Ask about occupational or other exposure to toxins (carbon tetrachloride, beryllium, or vinyl chloride), which may predispose the patient to hepatic disease. Consider recent travel or contact with persons who have traveled to areas where hepatic disease is endemic.

Make sure to ask about alcohol consumption, a significant factor in suspected hepatic disease. Remember, an alcoholic may deliberately underestimate their alcohol intake, so interview the patient's family as well. Ask about recent contact with a jaundiced person and about any recent

blood or plasma transfusions, blood tests, body piercings, tattoos, or dental work. Find out if the patient takes any drugs that may cause liver damage, such as sedatives, tranquilizers, analgesics, and diuretics that cause potassium loss. Ask if the onset of symptoms was abrupt or insidious or if it followed abdominal injury that could have damaged the liver. Ask if the patient bruises or bleeds easily. Check for light or clay-colored stools and dark urine, and ask about any change in bowel habits. Also ask if the patient's weight has fluctuated recently.

LIVER FUNCTION STUDIES

Numerous tests are available to detect hepatic disease. Perhaps the most useful tests are liver function studies, which measure serum enzymes and other substances. Typical findings in hepatic disease include the following:

- Increased bilirubin levels
- Increased alkaline phosphatase and 5'-nucleotidase levels
- Elevated levels of aspartate aminotransferase (AST) and alanine aminotransferase (ALT): possible hepatocellular damage, viral hepatitis, or acute hepatic necrosis
- Elevated gamma-glutamyltransferase levels: sensitive for alcoholic liver disease
- Hypoalbuminemia: subacute or massive hepatic necrosis or cirrhosis
- Hyperglobulinemia: chronic inflammatory disorders
- Prolonged prothrombin time or partial thromboplastin time: hepatitis or cirrhosis
- Elevated serum ammonia levels: hepatic encephalopathy
- Decreased serum total cholesterol levels: liver disease
- Positive antinuclear antibodies (ANA) test (in chronic active hepatitis and the presence of hepatitis B antigen)

Liver function studies are less reliable after liver trauma. For instance, tests done long after the injury might miss an initial rise in serum AST and ALT levels. Several less specific blood tests for detecting hepatic disease are urine urobilinogen, lactate dehydrogenase, and ornithine carbamoyltransferase.

Other useful diagnostic tests include the following:

- Plain abdominal X-rays may indicate gross hepatomegaly and hepatic masses by elevation or distortion of the diaphragm and may show calcification in the gallbladder, biliary tree, pancreas, and liver.
- Abdominal ultrasounds show fatty infiltration, hepatomegaly, gallbladder inflammation or obstruction, ascites, and cirrhosis. Doppler ultrasound demonstrates blood flow.
- Magnetic resonance imaging shows masses, fatty infiltration, and cirrhosis and its complications.
- Percutaneous transhepatic cholangiography distinguishes mechanical biliary obstruction from intrahepatic cholestasis.
- Angiography demonstrates hepatic arterial circulation (altered in cirrhosis) and helps diagnose primary or secondary hepatic tumor masses.
- Radioisotope liver scans (scintiscans) may show an area of decreased uptake (a "hole") using a colloidal or bengal scan or an area of increased uptake (a "hot spot") using a gallium scan in hepatoma or hepatic abscess.
- Computed tomography (CT) scan produces in-depth, three-dimensional images of the biliary tract (the liver as well as the pancreas) that help distinguish between obstructive and nonobstructive jaundice and also helps identify space-occupying hepatic lesions.

- Portal and hepatic vein manometry localizes obstructions in the extrahepatic portion of the portal vein and portal inflow system or increased pressure in the presinusoidal vessels.
- Percutaneous or transvenous liver biopsy can determine the cause of unexplained hepatomegaly, hepatosplenomegaly, cholestasis, or persistently abnormal liver function tests; it's also useful when systemic infiltrative disease (such as sarcoidosis) or primary or metastatic hepatic tumors are suspected.
- Laparoscopy visualizes the serosal lining, liver, gallbladder, spleen, and other organs and is useful in unexplained hepatomegaly, ascites, or an abdominal mass.

GALLBLADDER ANATOMY

The gallbladder is a pear-shaped organ that lies in the fossa on the underside of the liver and is capable of holding 50 mL of bile. Attached to the large organ above by connective tissue, the peritoneum, and blood vessels, the gallbladder is divided into four parts: the fundus, or broad inferior end; the body, which is funnel-shaped and bound to the duodenum; the neck, which empties into the cystic duct; and the infundibulum, which lies between the body and the neck and sags to form Hartmann's pouch. The hepatic artery supplies the cystic and hepatic ducts with blood, which drains out of the gallbladder through the cystic vein. Rich lymph vessels in the submucosal layer also drain the gallbladder as well as the head of the pancreas.

The biliary duct system provides a passage for bile from the liver to the intestine and regulates bile flow. The gallbladder itself collects, concentrates, and stores bile. The normally functioning gallbladder also removes water and electrolytes from hepatic bile, increases the concentration of the larger solutes, and reduces its pH to less than 7. In gallbladder disease, bile becomes more alkaline, altering bile salts and cholesterol and predisposing the organ to stone formation.

MECHANISMS OF CONTRACTION

The gallbladder responds to sympathetic and parasympathetic innervation. Sympathetic stimulation inhibits muscle contraction, mild vagal stimulation causes the gallbladder to contract and the sphincter of Oddi to relax, and stronger stimulation causes the sphincter to contract. The gallbladder also responds to substances released by the intestine. For instance, after chyme (semiliquid, partially digested food) enters the duodenum from the stomach, the duodenum releases cholecystokinin (CCK) and pancreozymin (PCZ) into the bloodstream and stimulates the gallbladder to contract. The gallbladder also produces secretin, which stimulates the liver to secrete bile and CCK-PCZ. The gallbladder may also respond to some type of hormonal control, a theory based in part on the fact that the gallbladder empties more slowly during pregnancy.

ASSESSING FOR GALLBLADDER DISEASE

During your physical examination of a patient with suspected gallbladder disease, look for its telltale signs and symptoms: pain, jaundice (a result of blockage of the common bile duct), fever, chills, indigestion, nausea, and intolerance of fatty foods. Pain may range from vague discomfort (as when pressure within the common bile duct gradually increases) to deep visceral pain (as when the gallbladder suddenly distends). Abrupt onset of pain with epigastric distress indicates gallbladder inflammation or obstruction of bile outflow by a stone or spasm.

The onset of jaundice also varies. If the gallbladder is healthy, jaundice may be delayed several days after bile duct blockage; if the gallbladder is absent or diseased, jaundice may appear within 24 hours after the blockage. Other effects of obstruction—pruritus, steatorrhea, and bleeding tendencies—may accompany jaundice. Gallbladder disorders rarely cause internal

bleeding, but when they do—as in cholecystitis or obstructive clots in the biliary tree from gastrointestinal (GI) bleeding—they can be fatal.

DIAGNOSTIC TESTS

After taking a thorough patient history and carefully assessing the clinical features, the next step in accurate diagnosis of gallbladder disease is to perform diagnostic testing.

Diagnostic tests for gallbladder disease include the following:

◆ Magnetic resonance cholangiopancreatography (MRCP), CT, or ultrasound are used to diagnose gallbladder disease. An MRCP uses magnetic resonance imaging that creates images of the bile and pancreatic ducts. The CT identifies gallstones and pancreatic cancer and is the preferred method for assessing pancreatitis. The ultrasound visualizes the bile ducts, liver, and pancreas. It is less effective in obese patients.

◆ Percutaneous transhepatic cholangiography differentiates extrahepatic from intrahepatic obstructive jaundice and helps detect biliary masses and calculi. Needle insertion in a bile duct permits withdrawal of bile and injection of dye. Fluoroscopic tests evaluate the filling of the hepatic and biliary trees. The test also permits palliative internal or external placement of biliary catheters for free flow of bile.

◆ Endoscopic ultrasound is used to diagnose and stage gallbladder cancer. An endoscope with an ultrasound transducer on the end is passed down into the intestines, where it can visualize the bile ducts, gallbladder, and pancreatic ducts.

◆ In endoscopic retrograde cholangiopancreatography (ERCP), duodenal endoscopy with dye injection and fluoroscopy are used to cannulate and visualize bile ducts and pancreatic ducts. This test is useful in locating obstruction, calculi, carcinoma, or stricture and for obtaining bile or pancreatic juice for analysis. Internal stents can be inserted to allow free flow of bile or pancreatic juice.

◆ A hepatobiliary iminodiacetic acid scan (HIDA) creates pictures of liver, gallbladder, bile duct, and small intestine. It is a nuclear scan, which requires that the patient take nothing by mouth after midnight, the night before the test. A radioactive tracer is administered intravenously and then filmed by the HIDA camera. The test takes approximately 2 hours.

◆ In gallbladder ultrasound, sound waves are used to visualize the gallbladder and locate obstruction, stones, and tumors. This test is 95% accurate in detecting stones.

Other appropriate tests for biliary disease are the same as those for hepatic disease.

Liver Disorders

VIRAL HEPATITIS

Viral hepatitis is a fairly common systemic disease, marked by hepatic cell destruction, necrosis, and autolysis, leading to anorexia, jaundice, and hepatomegaly. In most patients, hepatic cells eventually regenerate with little or no residual damage. However, old age and serious underlying disorders make complications more likely. The prognosis is poor if edema and hepatic encephalopathy develop.

Pathophysiology

Hepatitis occurs in these forms:

- Type A (infectious or short-incubation hepatitis—15 to 45 days) is an acute-onset infection and most often affects children and young adults. Hepatitis A does not persist and, thus, does not lead to chronic hepatitis.
- Type B (serum or long-incubation hepatitis—40 to 150 days) is an insidious-onset infection and affects all age groups. It may be directly cytopathic to hepatocytes. The immune system–mediated cytotoxicity plays a predominant role in causing liver damage. This is driven by human leukocyte antigen class I–restricted CD8 cytotoxic T lymphocytes that recognize hepatitis B core antigen (HBcAg) and hepatitis B e antigen (HBeAg) on the cell membranes of infected hepatocytes. Routine screening of donor blood for the hepatitis B surface antigen (HBsAg) has decreased the incidence of posttransfusion cases, but transmission by needles shared by drug abusers and sexual transmission remain major problems.
- Type C accounts for about 20% of all viral hepatitis cases. Incubation period is generally around 8 weeks. It tends to follow a mild course. With aminotransferase levels rarely higher than 1,000 U/L, approximately 15% to 45% of patients acutely infected with hepatitis C virus lose virologic markers. As much as 55% to 85% of patients remain viremic and could develop chronic liver disease. Most cases are related to injectable drug use.
- Type D (delta hepatitis) is responsible for about 50% of all cases of fulminant hepatitis, which has a high mortality. Developing in 1% of patients, fulminant hepatitis causes unremitting liver failure with encephalopathy. It progresses to coma and commonly leads to death within 2 weeks. Type D is uncommon in the United States.
- Type E (formerly grouped with type C under the name non-A, non-B hepatitis) has an incubation period of 2 to 10 weeks. This is characterized by fluctuating aminotransferase levels. It occurs primarily among patients who have recently returned from an endemic area (such as India, Africa, Asia, or Central America); it is more common in young adults and more severe in pregnant women.

Causes and Incidence

The major forms of viral hepatitis result from infection with the causative viruses: A, B, C, D, or E. (See *Viral hepatitis from A to E,* page 271.)

Viral Hepatitis from A to E

The following chart compares the features of each type of viral hepatitis.

Feature	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Incubation	15 to 45 days	30 to 180 days	15 to 160 days	14 to 64 days	14 to 60 days
Onset	Acute	Insidious	Insidious	Acute	Acute
Age group most affected	Children, young adults	Any age	More common in adults	Any age	Ages 20 to 40
Transmission	Fecal-oral, sexual (especially oral-anal contact), nonpercutaneous (sexual, maternal-neonatal), percutaneous	Blood-borne; parenteral route, sexual, maternal-neonatal; virus is shed in all body fluids	Blood-borne; parenteral route	Parenteral route; most people infected with hepatitis D are also infected with hepatitis B	Primarily fecal-oral

	(rare)				
Severity	Mild	Usually severe	Moderate	Can be severe and lead to fulminant hepatitis	Highly virulent with common progression to fulminant hepatitis and hepatic failure, especially in pregnant patients
Prognosis	Generally good	Worsens with age and debility	Moderate	Fair; worsens in chronic cases; can lead to chronic hepatitis D and chronic liver disease	Good unless pregnant
Progression to chronicity	None	Occasional	10% to 50% of cases	Occasional	None

Type A hepatitis is highly contagious and is usually transmitted by the fecal-oral route. However, it may also be transmitted parenterally, sexually (especially with oral or anal contact), and perinatally. Hepatitis A usually results from ingestion of contaminated food, milk, or water. Many outbreaks of this type are traced to ingestion of seafood from polluted water. In 2008, there were more than 25,000 acute cases of hepatitis A infection reported in the United States.

Type B hepatitis, once thought to be transmitted only by the direct exchange of contaminated blood, is now known to be transmitted also by contact with bodily fluids. As a result, nurses, physicians, laboratory technicians, and dentists are frequently exposed to type B hepatitis, in many cases as a result of wearing defective gloves. Transmission also occurs during intimate sexual contact as well as through perinatal transmission. Hepatitis B may also be transmitted by the parenteral route through equipment that has been contaminated. An estimated 38,000 new cases of hepatitis B virus (HBV) and 3,000 deaths from HBV occurred in the United States in 2008.

Historically, hepatitis C is transmitted through transfused blood from asymptomatic donors. Hepatitis C may be transmitted parenterally through the use of contaminated equipment. Hepatitis C accounted for 18,000 new infections and 12,000 deaths in the United States in 2008. Most exposures (60%) occur through the use of illicit I.V. drugs. However, sexual transmission is responsible for a small number of cases. Approximately, 3.2 million people in the United States have chronic hepatitis C infection.

Type D hepatitis is found only in patients with an acute or chronic episode of hepatitis B and requires the presence of HBsAg. The type D virus depends on the double-shelled type B virus to replicate. For this reason, type D infection can't outlast a type B infection. About 15 million people are infected with hepatitis D worldwide. It's more common in adults than in children. People with a history of illicit I.V. drug use and people who live in the Mediterranean basin have a higher incidence.

Type E hepatitis is transmitted enterically, much like type A. Because this virus is inconsistently shed in feces, detection is difficult. In the United States, the prevalence of hepatitis E is less than 2%. It is typically found in developing countries that lie near the Equator. Incidence is highest among people in the age group of 15 to 40 years.

Other proposed causative factors, such as non-ABCDE viral hepatitis and type F, are under investigation.

Complications

- Chronic active hepatitis (with late hepatitis B or C)
- Primary liver cancer (hepatitis B or C)
- Pancreatitis
- Cirrhosis
- Lymphoma
- Aplastic anemia
- Peripheral neuropathy

Signs and Symptoms

Assessment findings are similar for the different types of hepatitis. Typically, signs and symptoms progress in several stages.

In the prodromal (preicteric) stage, the patient typically complains of easy fatigue and anorexia (possibly with mild weight loss), generalized malaise, depression, headache, weakness, arthralgia, myalgia, photophobia, and nausea with vomiting. The patient also may describe changes in senses of taste and smell.

Assessment of the patient's vital signs may reveal a fever of 100° to 102° F (37.8° to 38.9° C). As the prodromal stage ends, usually 1 to 5 days before the onset of the clinical jaundice stage, inspection of urine and stool specimens may reveal dark-colored urine and clay-colored stools.

If the patient has progressed to the clinical jaundice stage, they may report pruritus, abdominal pain or tenderness, and indigestion. Early in this stage, the patient may complain of anorexia; later, the appetite may return. Inspection of the sclerae, mucous membranes, and skin may reveal jaundice, which can last for 1 to 2 weeks. Jaundice indicates that the damaged liver is unable to remove bilirubin from the blood; however, its presence doesn't indicate the severity of the disease. Occasionally, hepatitis occurs without jaundice (anicteric hepatitis).

During the clinical jaundice stage, inspection of the skin may detect rashes, erythematous patches, or urticaria, especially if the patient has hepatitis B or C. Palpation may disclose abdominal tenderness in the right upper quadrant, an enlarged and tender liver, and, in some cases, splenomegaly and cervical adenopathy.

During the recovery (posticteric) stage, most of the patient's symptoms decrease or subside. On palpation, a decrease in liver enlargement may be noted. The recovery phase commonly lasts from 2 to 12 weeks, although sometimes this phase lasts longer in the patient with hepatitis B, C, or E.

Diagnosis

A hepatitis profile, which identifies antibodies specific to the causative virus and establishes the type of hepatitis, is routine in suspected viral hepatitis.

- Type A: Detection of an antibody to hepatitis A confirms the diagnosis.
- Type B: The presence of HBsAg or hepatitis B IgM antibodies confirms the diagnosis.
- Type C: Hepatitis C antibody positively confirms exposure (usually 4 to 10 weeks after exposure). Hepatitis C serum RNA is detectable 2 to 3 weeks after exposure.
- Type D: Detection of intrahepatic delta antigens or immunoglobulin antidelta antigens in acute disease (or IgM and IgG in chronic disease) establishes the diagnosis.
- Type E: Detection of hepatitis E antigens confirms the diagnosis.

Additional findings from liver function studies support the diagnosis:

- Serum aspartate aminotransferase and serum alanine aminotransferase levels are increased in the prodromal stage of acute viral hepatitis.
- Serum alkaline phosphatase levels are slightly increased.
- Serum bilirubin levels are elevated. Levels may continue to be high late in the disease, especially in severe cases.
- Prothrombin time can be prolonged (>3 seconds longer than normal indicates severe liver damage).
- White blood cell (WBC) counts commonly reveal transient neutropenia and lymphopenia followed by lymphocytosis.
- Liver biopsy is performed if chronic hepatitis is suspected; however, it is performed for acute hepatitis only if the diagnosis is questionable.

Treatment

No specific drug therapy has been developed for hepatitis, with the exception of hepatitis B and hepatitis C. Chronic hepatitis B can be treated with interferon alfa, pegylated interferon, lamivudine, adefovir dipivoxil, telbivudine, and tenofovir. Hepatitis C is treated with pegylated interferon, ribavirin, Victrelis (boceprevir), Olysio (simeprevir), Sovaldi (sofosbuvir), Harvoni (ledipasvir/sofosbuvir), Zepatier (elbasvir/grazoprevir), and Epclusa (sofosbuvir/velpatasvir). Patients are advised to rest in the early stages of the illness and to combat anorexia by eating small, high-calorie, high-protein meals. (Protein intake should be reduced if signs or symptoms of precoma—lethargy, confusion, and mental changes—develop.) Large meals are usually better tolerated in the morning because many patients experience nausea late in the day.

In acute viral hepatitis, hospitalization usually is required only for the patient with severe symptoms or complications. Parenteral nutrition may be required if the patient experiences persistent vomiting and is unable to maintain oral intake.

Antiemetics may be given 30 minutes before meals to relieve nausea and prevent vomiting; phenothiazines have a cholestatic effect and should be avoided. For severe pruritus, the resin cholestyramine may be given.

Special Considerations

Use enteric precautions when caring for patients with type A or E hepatitis. Practice standard precautions for all patients.

- Inform visitors about isolation precautions.
- Provide rest periods throughout the day. Schedule treatments and tests so that the patient can rest between bouts of activity.
- Because inactivity may make the patient anxious, include diversionary activities as part of the daily care regimen. Gradually add activities to the patient's schedule as the patient begins to recover.
- Encourage the patient to eat. Don't overload the meal tray or overmedicate the patient because this will diminish the patient's appetite.
- Encourage fluids (at least 4 qt [4 L]/day). Encourage the anorectic patient to drink fruit juice. Also offer chipped ice and effervescent soft drinks to maintain hydration without inducing vomiting.
- Administer supplemental vitamins and commercial feedings, as ordered. If symptoms are severe and the patient can't tolerate oral intake, provide I.V. therapy and parenteral nutrition, as ordered by the physician.

- Record the patient's weight daily, and keep intake and output records. Observe stools for color, consistency, and amount and record the frequency of bowel movements.
- Watch for signs of fluid shift, such as weight gain and orthostasis.
- Watch for signs of hepatic coma, dehydration, pneumonia, vascular problems, and pressure ulcers.
- In fulminant hepatitis, maintain electrolyte balance and a patent airway, prevent infections, and control bleeding. Correct hypoglycemia and other complications while awaiting liver regeneration and repair.
- Before discharge, emphasize the importance of having regular medical checkups for at least 1 year. The patient will have an increased risk of developing hepatoma. Warn the patient against using alcohol or over-the-counter drugs during this period. Teach the patient to recognize the signs of a recurrence.
- Inform the patient about the availability of support groups for people with all types of hepatitis and provide contact information if he's interested.

PREVENTION *Review the following with your patient to prevent the spread of hepatitis:*

- *Stress the importance of thorough and frequent hand washing.*
- *Tell the patient not to share food, eating utensils, or toothbrushes.*
- *If the patient has hepatitis A or E, warn them not to contaminate food or water with fecal matter, because the disease is transmitted by the fecal-oral route.*
- *If the patient has hepatitis B, C, or D explain that transmission occurs through exchange of blood or body fluids that contain blood. While infected, the patient shouldn't donate blood or have sexual contact.*
- *Advise the patient to take extra care to avoid cutting himself.*

NONVIRAL HEPATITIS

Nonviral inflammation of the liver is a form of hepatitis that is classified as toxic, drug-induced (idiosyncratic), or autoimmune. Most patients recover from drug-induced hepatitis, although a few develop fulminating hepatitis or cirrhosis.

Causes, Incidence, and Pathophysiology

Various hepatotoxins—carbon tetrachloride, acetaminophen, trichloroethylene, poisonous mushrooms, and vinyl chloride—can cause the toxic form of this disease. Liver damage usually occurs within 24 to 48 hours after exposure to these agents, depending on the size of the dose or degree of exposure. Alcohol, anoxia, and preexisting liver disease exacerbate the toxic effects of some of these agents.

Drug-induced (idiosyncratic) hepatitis may stem from a hypersensitivity reaction unique to the affected individual, unlike toxic hepatitis, which appears to affect all people indiscriminately. Among the drugs that may cause this type of hepatitis are niacin, halothane, sulfonamides, isoniazid, methyldopa, and phenothiazines (cholestasis-induced hepatitis). Other drugs that have been associated with this form of hepatitis include amoxicillin and clavulanic acid, stains, methotrexate, amiodarone, nonsteroidal anti-inflammatory drugs, and vitamin A. In hypersensitive people, symptoms of hepatic dysfunction may appear at any time during or after exposure to these drugs but usually emerge after 2 to 5 weeks of therapy. Not all adverse drug reactions are toxic. Hormonal contraceptives, for example, may impair liver function and

produce jaundice without causing necrosis, fatty infiltration of liver cells, or hypersensitivity.

Autoimmune hepatitis, also known as *lupoid hepatitis,* is a disease in which the body's immune system attacks liver cells, causing them to become inflamed. Researchers think a genetic factor may predispose some people to autoimmune diseases. An environmental agent may trigger the autoimmune response against liver antigens, causing inflammatory liver damage. About 70% of those with autoimmune hepatitis are women, most in the age range of 15 to 40 years. It is usually chronic and can lead to cirrhosis.

Complications

- Cirrhosis
- Chronic hepatitis
- Liver failure

Signs and Symptoms

Clinical features of toxic and drug-induced hepatitis vary with the severity of the liver damage and the causative agent. In most patients, signs and symptoms resemble those of viral hepatitis: anorexia, nausea, vomiting, jaundice, dark urine, hepatomegaly, possible abdominal pain (with acute onset and massive necrosis), and clay-colored stools or pruritus with the cholestatic form of hepatitis. Carbon tetrachloride poisoning also produces headache, dizziness, drowsiness, and vasomotor collapse; halothane-related hepatitis produces fever, moderate leukocytosis, and eosinophilia; chlorpromazine toxicity produces abrupt fever, rash, arthralgia, lymphadenopathy, and epigastric or right upper quadrant pain.

Diagnosis

Diagnostic findings include elevations in serum aspartate aminotransferase and alanine aminotransferase, total and direct bilirubin (with cholestasis), alkaline phosphatase, WBC count, and eosinophil count (possible in drug-induced type). To diagnose autoimmune hepatitis, antibodies, including antinuclear antibodies (ANA), anti-smooth muscle antibodies (ASMA/anti-liver-kidney), or liver and kidney microsome antibodies (anti-LKM), will be elevated. Liver biopsy may help identify the underlying pathology, especially infiltration with WBCs and eosinophils. Liver function tests have limited value in distinguishing between nonviral and viral hepatitis.

Treatment

Effective treatment must remove the causative agent by lavage, catharsis, or hyperventilation, depending on the route of exposure. Acetylcysteine (Acetadote) serves as an antidote for toxic hepatitis caused by acetaminophen poisoning but doesn't prevent drug-induced hepatitis caused by other substances. Corticosteroids may be ordered for patients with drug-induced and autoimmune hepatitis. Azathioprine (Imuran), an immunosuppressant, may also be used in conjunction with corticosteroids to treat autoimmune hepatitis.

Special Considerations

- Monitor laboratory studies and note trends.
- Monitor the patient's vital signs and provide support to maintain vital functioning, depending on the severity of symptoms.

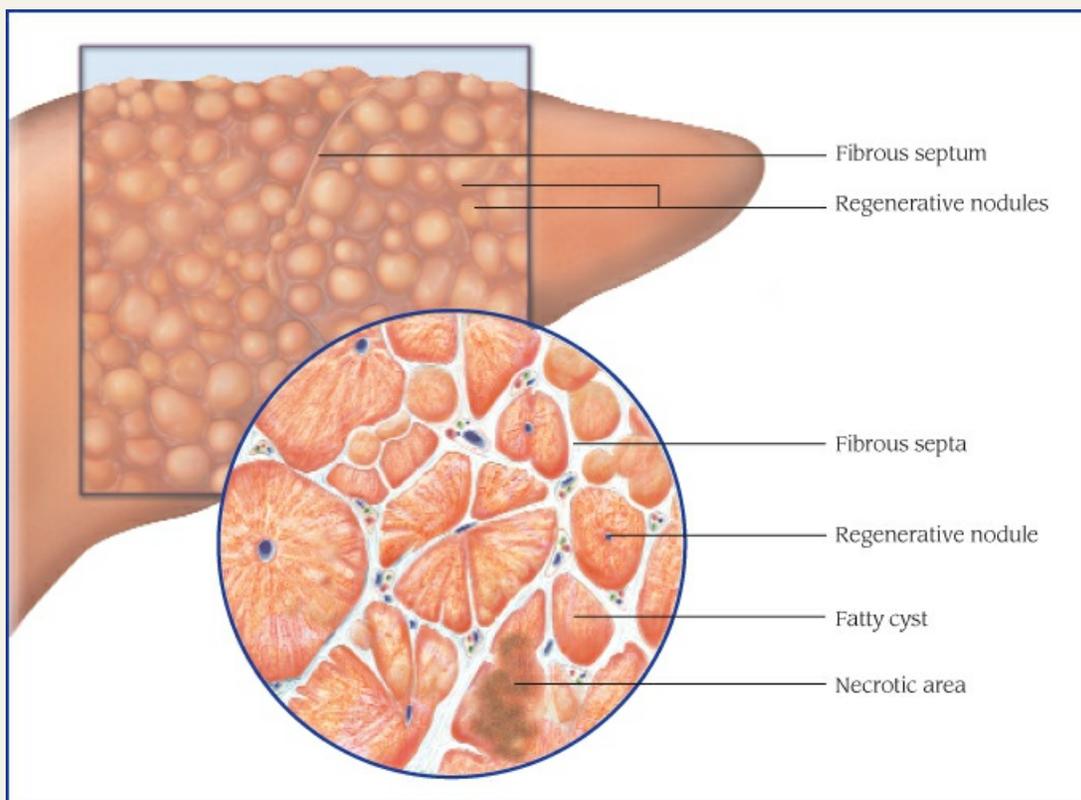
- Preventive measures should include instructing the patient about the proper use of drugs and the proper handling of cleaning agents and solvents.

CIRRHOSIS AND FIBROSIS

Cirrhosis is a chronic hepatic disease characterized by diffuse destruction and fibrotic regeneration of hepatic cells. As necrotic tissue yields to fibrosis, this disease alters liver structure and normal vasculature, impairs blood and lymph flow, and ultimately causes hepatic insufficiency. The prognosis is better in noncirrhotic forms of hepatic fibrosis, which cause minimal hepatic dysfunction and don't destroy liver cells. (See *Cirrhotic changes in the liver*, page 275.)

PATHOPHYSIOLOGY
CIRRHOTIC CHANGES IN THE LIVER

The following illustration shows the nodular changes that occur in cirrhosis.

- Fibrous septum
- Regenerative nodules
- Fibrous septa
- Regenerative nodule
- Fatty cyst
- Necrotic area


Causes and Incidence

These clinical types of cirrhosis reflect its diverse etiology:

- Portal, nutritional, or alcoholic (Laennec) cirrhosis, the most common type, occurs in 30% to 50% of cirrhotic patients, up to 90% of whom have a history of alcoholism. Liver damage has

been associated with malnutrition, especially of dietary protein, and chronic alcohol ingestion. Fibrous tissue forms in portal areas and around central veins.

- Biliary cirrhosis (15% to 20% of patients) results from injury or prolonged obstruction.
- Postnecrotic (posthepatic) cirrhosis (10% to 30% of patients) stems from various types of hepatitis.
- Pigment cirrhosis (5% to 10% of patients) may result from disorders such as hemochromatosis.
- Cardiac cirrhosis (rare) refers to cirrhosis caused by right-sided heart failure.
- Idiopathic cirrhosis (about 10% of patients) has no known cause.

Noncirrhotic fibrosis may result from schistosomiasis or congenital hepatic fibrosis or may be idiopathic.

Pathophysiology

Growth regulators induce hepatocellular hyperplasia (producing regenerating nodules) and arterial growth (angiogenesis). Among the growth regulators are cytokines and hepatic growth factors (e.g., epithelial growth factor, hepatocyte growth factor, transforming growth factor-alpha, tumor necrosis factor). Insulin, glucagon, and patterns of intrahepatic blood flow determine how and where nodules develop.

Angiogenesis produces new vessels within the fibrous sheath that surrounds nodules. These vessels connect the hepatic artery and portal vein to hepatic venules, restoring the intrahepatic circulatory pathways. Such interconnecting vessels provide relatively low-volume, high-pressure venous drainage that cannot accommodate as much blood volume as normal. As a result, portal vein pressure increases. Such distortions in blood flow contribute to portal hypertension, which increases because the regenerating nodules compress hepatic venules.

Complications

- Portal hypertension
- Esophageal varices
- Hepatic encephalopathy
- Hepatorenal syndrome
- Ascites
- Liver cancer

Signs and Symptoms

Clinical manifestations of cirrhosis and fibrosis are similar for all types, regardless of the cause. Early indications are vague, but usually include GI signs and symptoms (anorexia, indigestion, nausea, vomiting, cachexia, constipation, or diarrhea) and a dull abdominal ache. Major and late signs and symptoms develop as a result of hepatic insufficiency and portal hypertension:

- Respiratory—pleural effusion and limited thoracic expansion due to abdominal ascites, interfering with efficient gas exchange and leading to hypoxia
- Central nervous system—progressive signs or symptoms of hepatic encephalopathy— lethargy, mental changes, slurred speech, asterixis (flapping tremor), peripheral neuritis, paranoia, hallucinations, extreme obtundation, and coma
- Hematologic—bleeding tendencies (nosebleeds, easy bruising, and bleeding gums) and anemia

- Endocrine—testicular atrophy, menstrual irregularities, gynecomastia, and loss of chest and axillary hair
- Skin—severe pruritus, extreme dryness, poor tissue turgor, abnormal pigmentation, spider angiomas, palmar erythema, and possibly jaundice
- Hepatic—jaundice, hepatomegaly, ascites, edema of the legs, hepatic encephalopathy, and hepatorenal syndrome comprise the other major effects of full-fledged cirrhosis
- Miscellaneous—musty breath, enlarged superficial abdominal veins, muscle atrophy, pain in the right upper abdominal quadrant that worsens when the patient sits up or leans forward, palpable liver or spleen, and temperature of 101° to 103° F (38.3° to 39.4° C). Bleeding from esophageal varices results from portal hypertension.

Diagnosis

CONFIRMING DIAGNOSIS *Liver biopsy, the definitive test for cirrhosis, detects destruction and fibrosis of hepatic tissue.*

Liver imaging, including CT scan, ultrasound, and magnetic resonance imaging, may confirm the diagnosis of cirrhosis through visualization of masses, abnormal growths, metastases, and venous malformations. Liver scan shows abnormal thickening and a liver mass. Cholecystography and cholangiography visualize the gallbladder and the biliary duct system, respectively; splenoportal venography visualizes the portal venous system. Percutaneous transhepatic cholangiography differentiates extrahepatic from intrahepatic obstructive jaundice and discloses hepatic pathology and the presence of gallstones.

Laboratory findings that are characteristic of cirrhosis include the following:

- Decreased WBC count, hemoglobin level and hematocrit, albumin, or platelets
- Elevated levels of globulin, serum ammonia, total bilirubin, alkaline phosphatase, serum aspartate aminotransferase, and serum alanine aminotransferase
- Prolonged prothrombin and partial thromboplastin times
- Deficiencies of folic acid, iron, and vitamins A, B_{12}, C, and K are common.

Treatment

Treatment is designed to remove or alleviate the underlying cause of cirrhosis or fibrosis, prevent further liver damage, and prevent or treat complications. The patient may benefit from a high-calorie and moderate- to high-protein diet. Developing hepatic encephalopathy mandates restricted protein intake. In addition, sodium is usually restricted 2 g/day and fluids to 1 to 1½ qt (about 1 to 1.5 L)/day.

If the patient's condition deteriorates, the patient may need tube feedings or total parenteral nutrition. the patient also may need supplemental vitamins—A, B complex, D, and K—to compensate for the liver's inability to store them and vitamin B_{12}, folic acid, and thiamine for deficiency anemia. Rest, moderate exercise, and avoidance of infections and toxic agents are essential.

Drug therapy requires special caution because the cirrhotic liver can't detoxify harmful substances efficiently. If required, octreotide may be prescribed for esophageal varices, and diuretics may be given for edema. However, diuretics require careful monitoring because fluid and electrolyte imbalance may precipitate hepatic encephalopathy. Encephalopathy is treated with lactulose. Antibiotics are used to decrease intestinal bacteria and reduce ammonia

production, which is one of the causes of encephalopathy. Coagulopathy may be treated with blood products or vitamin K.

Paracentesis and infusions of salt-poor albumin, in addition to fluid and salt restriction, may alleviate ascites. Surgical procedures include treatment of varices by upper endoscopy with banding or the TIPS (transjugular intrahepatic portosystemic shunt) procedure to relieve portal hypertension. (See *Understanding portal hypertension and esophageal varices,* page 277, and *Circulation in portal hypertension,* page 278.)

Understanding Portal Hypertension and Esophageal Varices

Portal hypertension—elevated pressure in the portal vein—occurs when blood flow meets increased resistance. The disorder is a common result of cirrhosis, but may also stem from mechanical obstruction and occlusion of the hepatic veins (Budd–Chiari syndrome) or portal vein. As portal pressure rises, blood backs up into the spleen and flows through collateral channels to the venous system, bypassing the liver. Consequently, portal hypertension produces splenomegaly with thrombocytopenia, dilated collateral veins (esophageal varices, hemorrhoids, or prominent abdominal veins), and ascites. In many patients, the first sign of portal hypertension is bleeding from esophageal varices—dilated tortuous veins in the submucosa of the lower esophagus. Bleeding esophageal varices commonly cause massive hematemesis, requiring emergency treatment to control hemorrhage and prevent hypovolemic shock.

Diagnosis and Treatment

These procedures help diagnose and correct esophageal varices.

- Endoscopy identifies the ruptured varix as the bleeding site, excludes other potential sources in the upper gastrointestinal (GI) tract, and allows for banding ligation of actively bleeding varices.
- Angiography may aid diagnosis, but is less precise than endoscopy.
- Vasopressin infused into the superior mesenteric artery may temporarily stop bleeding. When angiography is unavailable, vasopressin may be infused by I.V. drip or diluted with 5% dextrose in water (except in patients with coronary vascular disease), but this route is usually less effective.
- Octreotide is administered intravenously to slow the blood flow into the portal vein and decreases portal hypertension. It is used in combination with endoscopic therapy to treat bleeding esophageal varices. Octreotide is currently used more frequently than vasopressin.
- A Sengstaken–Blakemore or Minnesota tube may also help control hemorrhage by applying pressure on the bleeding site. Iced saline lavage through the tube may help control bleeding.

The use of vasopressin or octreotide or a Minnesota or Sengstaken–Blakemore tube is a temporary measure, especially in the patient with a severely deteriorated liver. Fresh blood and fresh frozen plasma, if available, are preferred for blood transfusions to replace clotting factors. Treatment with lactulose promotes elimination of old blood from the GI tract, which combats excessive ammonia production and accumulation.

An appropriate bypass procedure is the transjugular intrahepatic portosystemic shunt

(TIPS), which creates an artificial path for the blood traveling from the intestines, through the liver, and back to the heart. The procedure is done in the interventional radiology department. A tube is placed between the portal vein and the hepatic vein, causing the blood to bypass a portion of the liver and to be shunted to the heart. This reduces portal vein pressure and the hypertension complications of recurrent variceal bleeding and ascites. TIPS is an effective therapeutic measure to reduce portal hypertension. The TIPS procedure provides a salvage therapy for those patients who have failed medical treatment and may be used as a bridge for patients awaiting transplant. A complication of the TIPS procedure is encephalopathy, which may occur as a result of the shunted blood bypassing the liver and being sent into the systemic circulation without being detoxified by the liver.

Patient Care

Care for the patient who has portal hypertension with esophageal varices focuses on careful monitoring for signs and symptoms of hemorrhage and subsequent hypotension, compromised oxygen supply, and altered level of consciousness (LOC).

- Monitor the patient's vital signs, urine output, and central venous pressure to determine fluid volume status.
- Assess the patient's LOC often.
- Provide emotional support and reassurance after massive GI bleeding, which is always frightening.
- Keep the patient as quiet and comfortable as possible, but remember that tolerance of sedatives and tranquilizers may be decreased because of liver damage.
- Clean the patient's mouth, which may be dry and flecked with dried blood.
- Carefully monitor the patient with a Minnesota or Sengstaken–Blakemore tube in place for persistent bleeding in gastric drainage, signs of asphyxiation from tube displacement, proper inflation of balloons, and correct traction to maintain tube placement.

PATHOPHYSIOLOGY
CIRCULATION IN PORTAL HYPERTENSION

As portal vein pressure rises, blood backs up into the spleen and flows through collateral channels to the venous system, bypassing the liver and resulting in esophageal varices.

Low-protein diets are controversial. They aid in managing acute hepatic encephalopathy but are rarely necessary in chronic conditions because of the underlying protein-calorie malnutrition.

⚠ **ALERT** *If cirrhosis progresses and becomes life-threatening, a liver transplant should be considered.*

Special Considerations

The patient with cirrhosis needs close observation, first-rate supportive care, and sound nutritional counseling.

◆ Check the patient's skin, gums, stools, and vomitus regularly for bleeding. Apply pressure to injection sites to prevent bleeding. Warn the patient against taking nonsteroidal anti-inflammatory drugs, straining at stool, and blowing the nose or sneezing too vigorously. Suggest using an electric razor and soft toothbrush.

⚠ **ALERT** *Observe the patient closely for changes in behavior or personality. Report increasing stupor, lethargy, hallucinations, or neuromuscular dysfunction. Awaken the patient periodically to determine their level of consciousness. Watch for asterixis, a sign of developing hepatic encephalopathy.*

- To assess fluid retention, weigh the patient and measure abdominal girth at least daily, inspect ankles and sacrum for dependent edema, and accurately record intake and output. Carefully evaluate the patient before, during, and after paracentesis.
- To prevent skin breakdown associated with edema and pruritus, avoid using soap when you bathe the patient; instead, use lubricating lotion or moisturizing agents. Handle the patient gently, and turn and reposition often to keep skin intact.
- Tell the patient that rest and good nutrition will conserve energy and decrease metabolic demands on the liver. Urge the patient to eat frequent, small meals. Stress the need to avoid infections and abstain from alcohol. Refer the patient to Alcoholics Anonymous, if necessary.

LIVER ABSCESS

A liver abscess occurs when bacteria or protozoa destroy hepatic tissue, producing a cavity, which fills with infectious organisms, liquefied liver cells, and leukocytes. Necrotic tissue then walls off the cavity from the rest of the liver.

Although liver abscess is relatively uncommon, it carries a mortality of 10% to 30%. Complications include rupture into the peritoneum, pleura, or pericardium, as well as sepsis and multi-organ failure, significantly increasing mortality.

Causes and Incidence

In pyogenic liver abscesses, the common infecting organisms are *Escherichia coli, Klebsiella, Staphylococcus, Streptococcus, Bacteroides*, and enterococcus.

An amebic abscess results from infection with a protozoa.

There are 8 to 16 cases of liver abscess for every 100,000 people hospitalized, and the mortality rate is 5% to 30%. Most cases occur in people in their 60s and 70s.

Pathophysiology

In pyogenic liver abscess, the infecting organisms may invade the liver directly after a liver wound, or they may spread from the lungs, skin, or other organs by the hepatic artery, portal vein, or biliary tract. Biliary tract disease is the most common form. Obstruction of bile allows for bacterial growth. Pyogenic abscesses are generally multiple and can follow cholecystitis, peritonitis, pneumonia, appendicitis, and bacterial endocarditis.

An amebic abscess results from infection with the protozoa *Entamoeba histolytica*, the organism that causes amebic dysentery. Amebic liver abscesses usually occur singly, in the right lobe.

Complication

- Abscess rupture into pleura, peritoneum, or pericardium

Signs and Symptoms

The clinical manifestations of a liver abscess depend on the degree of involvement. Some patients are acutely ill; in others, the abscess is recognized only at autopsy, after death from another illness. The onset of symptoms of a pyogenic abscess is usually sudden; in an amebic abscess, the onset is more insidious. Common signs and symptoms include right abdominal and shoulder pain, weight loss, fever, chills, diaphoresis, nausea, vomiting, and anemia. Signs of right pleural effusion, such as dyspnea and pleural pain, develop if the abscess extends through the diaphragm. Liver damage may cause jaundice.

Diagnosis

CONFIRMING DIAGNOSIS *Ultrasound and computed tomography (CT) scan with contrast medium can accurately define intrahepatic lesions and assess intra-abdominal pathology. Percutaneous needle aspiration and drainage of the abscess can be performed using ultrasound or CT guidance to identify the causative organism.*

Relevant laboratory values include elevated serum aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, and bilirubin levels; increased WBC count; and decreased serum albumin levels. A blood culture can identify the bacterial agent; in amebic abscess, a stool culture and serologic and hemagglutination tests can assist in diagnosis.

Treatment

If the organism causing the liver abscess is unknown, long-term antibiotic therapy begins immediately. When culture results are obtained, antibiotics are prescribed specific to treat the organism. I.V. antibiotic therapy usually continues for 14 days and then is replaced with an oral preparation to complete a 6-week course. Surgery is usually avoided, but it may be done for a single pyogenic abscess or for an amebic abscess that fails to respond to antibiotics. Placement of drains (using CT or ultrasound guidance), particularly in large abscesses, reduces the need for abdominal surgery. In acutely toxic patients, percutaneous needle aspiration and decompression may be needed to remove the abscess.

Special Considerations

- Provide supportive care, monitor the patient's vital signs (especially temperature), and maintain fluid and nutritional intake.
- Administer anti-infectives and antibiotics as ordered, and watch for possible adverse effects. Stress the importance of compliance with therapy.
- Explain diagnostic and surgical procedures.
- Watch carefully for complications of abdominal surgery, such as hemorrhage or sepsis.

FATTY LIVER

Fatty liver, also known as *steatosis* or *nonalcoholic steatohepatitis (NAFLD)*, is a common clinical finding consisting of accumulated triglycerides and other fats in liver cells. In severe fatty liver, fat comprises as much as 40% of the liver's weight (as opposed to 5% in a normal liver), and the weight of the liver may increase from 3.31 lb (1.5 kg) to as much as 11 lb (4.9 kg). Minimal fatty changes are temporary and asymptomatic; severe or persistent changes may cause liver dysfunction. Fatty liver is reversible by simply eliminating the cause.

Causes and Incidence

Chronic alcoholism is the most common cause of fatty liver in the United States and in Europe, with the severity of hepatic disease directly related to the amount of alcohol consumed. (Fatty liver can occur in people who consume as little as 10 oz of alcohol per week.)

Other causes of nonalcoholic steatohepatitis include malnutrition (especially protein deficiency), obesity, diabetes mellitus, jejunoileal bypass surgery, Cushing syndrome, Reye syndrome, pregnancy, large doses of hepatotoxins such as I.V. tetracycline, carbon tetrachloride intoxication, prolonged parenteral nutrition, and DDT poisoning. Whatever the cause, fatty

infiltration of the liver probably results from mobilization of fatty acids from adipose tissues or altered fat metabolism.

Pathophysiology

Steatosis, the earliest response of the liver to alcohol abuse, is characterized by the accumulation of fat (mainly triglycerides, phospholipids, and cholesterol esters) in hepatocytes. Early studies indicated that alcohol consumption increases the ratio of reduced nicotinamide adenine dinucleotide/oxidized nicotinamide adenine dinucleotide in hepatocytes, which disrupts mitochondrial beta-oxidation of fatty acids and results in steatosis. Alcohol intake has also been shown to augment the supply of lipids to the liver from the small intestine, increasing mobilization of fatty acids from adipose tissue and uptake of fatty acids by the liver.

  Nonalcoholic steatohepatitis mechanism is complex and incompletely understood; a two-hit hypothesis has been proposed, in which the first hit involves an imbalance of fatty acid metabolism that leads to hepatic triglyceride accumulation (steatosis). The second hit may be oxidative or metabolic stress and dysregulated cytokine production resulting from efforts to compensate for altered lipid homeostasis, leading to subsequent inflammation and fibrosis. Data show that hepatic mitochondrial dysfunction is crucial to the pathogenesis of NAFLD.

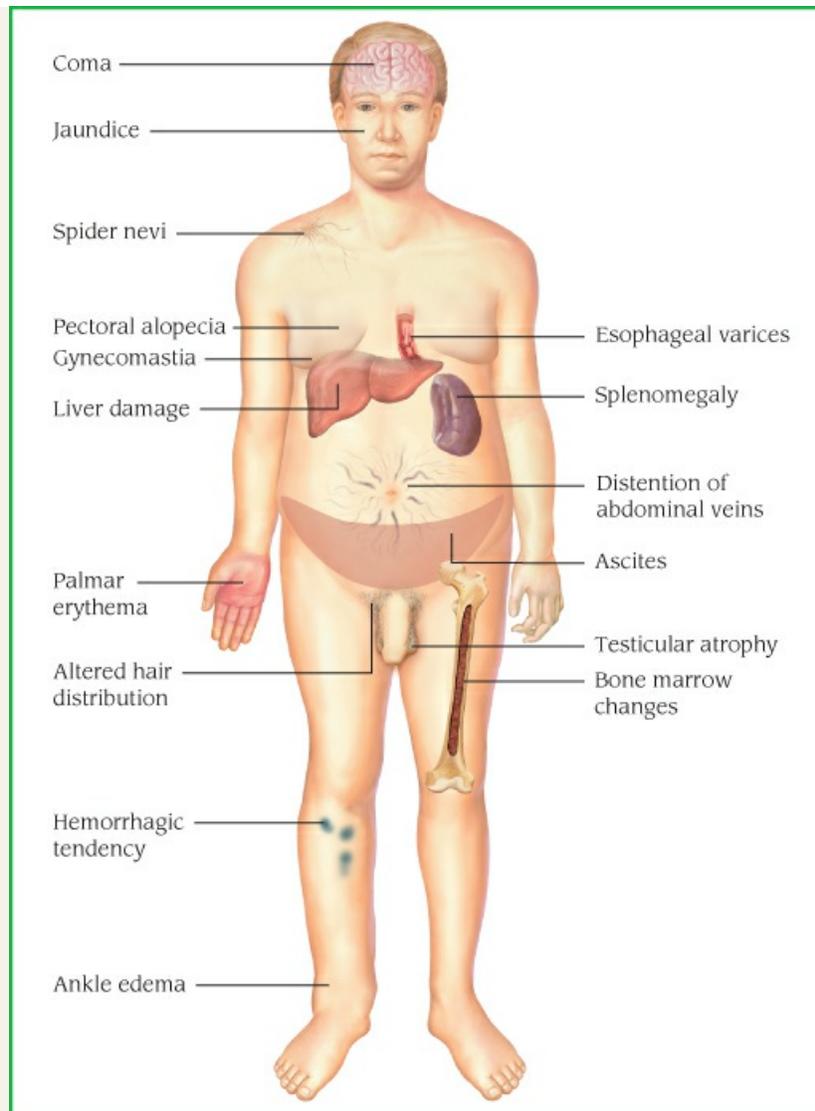
Complications

- Cirrhosis
- Portal hypertension
- Metabolic disturbances and insulin assistance
- Renal failure
- Coma

Signs and Symptoms

Clinical features of fatty liver vary with the degree of lipid infiltration, and many patients are asymptomatic. The most typical sign is a large, tender liver (hepatomegaly). Common signs and symptoms include right upper quadrant pain (with massive or rapid infiltration), ascites, edema, jaundice, and fever (all with hepatic necrosis or biliary stasis). (See *Signs of liver failure*, page 281.) Nausea, vomiting, and anorexia are less common. Splenomegaly frequently accompanies cirrhosis. Rarer changes are spider angiomas, varices, transient gynecomastia, and menstrual disorders.

Signs of Liver Failure

Liver failure may be a complication of hepatitis, cirrhosis, and fatty liver. The signs of liver failure may be visible in many areas of the body.


Coma
Jaundice
Spider nevi
Pectoral alopecia
Gynecomastia
Liver damage
Palmar erythema
Altered hair distribution
Hemorrhagic tendency
Ankle edema
Esophageal varices
Splenomegaly
Distention of abdominal veins
Ascites
Testicular atrophy
Bone marrow changes

Diagnosis

Typical clinical features—especially in patients with chronic alcoholism, malnutrition, poorly controlled diabetes mellitus, or obesity—suggest fatty liver.

℞ **CONFIRMING DIAGNOSIS** *A liver biopsy confirms excessive fat in the liver. These liver function tests support this diagnosis:*

- *Albumin—somewhat low*
- *Globulin—usually elevated*
- *Cholesterol—usually elevated*
- *Total bilirubin—elevated*
- *Alkaline phosphatase—elevated*
- *Transaminase—elevated*

◆ *Prothrombin time—possibly prolonged.*

Other findings may include anemia, leukocytosis, elevated WBC count, albuminuria, hyperglycemia or hypoglycemia, and iron, folic acid, and vitamin B_{12} deficiencies.

Treatment

Treatment of fatty liver is essentially supportive and consists of correcting the underlying condition or eliminating its cause. For instance, when fatty liver results from parenteral nutrition, decreasing the rate of carbohydrate infusion may correct the disease. In alcoholic fatty liver, abstinence from alcohol and a proper diet can begin to correct liver changes within 4 to 8 weeks. In nonalcoholic fatty liver disease, gradual weight loss is the standard treatment.

Special Considerations

Providing support to the patient and family is an important element in the care of the patient with steatosis.

◆ Suggest counseling for the alcoholic patient and provide emotional support for the family.
◆ Teach the patient with diabetes—and family—about proper care, such as the purpose of insulin injections, diet, and exercise. Refer the patient to home health nurses or to group classes, as necessary, to promote compliance with treatment. Emphasize the need for long-term medical supervision and urge the patient to report any changes in health immediately.
◆ Instruct an obese patient and their family about proper diet. Warn against fad diets, which are usually nutritionally inadequate. Recommend medical supervision for a patient who's more than 20% overweight. Encourage attendance at group diet and exercise programs and, if necessary, suggest behavior modification programs to correct eating habits. Be sure to follow up on the patient's progress and provide positive reinforcement for any weight loss.

◆ Assess for malnutrition, especially protein deficiency, in the patient with chronic illness. Suggest dietary changes and refer the patient to a dietitian.
◆ Advise patients receiving hepatotoxins and those at risk for occupational exposure to watch for and immediately report signs of toxicity.
◆ Inform the patient that fatty liver is reversible *only* if they strictly follow the therapeutic program; otherwise, the patient risks permanent liver damage.

HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy, also known as *portosystemic encephalopathy* or *hepatic coma,* is a neurologic syndrome that develops as a complication of chronic liver disease. It may be acute and self-limiting or chronic and progressive. Treatment requires correction of the precipitating cause and reduction of blood ammonia levels. In advanced stages, the prognosis is extremely poor despite vigorous treatment.

Causes and Incidence

Hepatic encephalopathy follows rising blood ammonia levels.

Other factors that predispose to rising ammonia levels include excessive protein intake, sepsis, excessive accumulation of nitrogenous body wastes (from constipation or GI hemorrhage), and bacterial action on protein and urea to form ammonia. Certain other factors heighten the brain's sensitivity to ammonia intoxication: hypoxia, azotemia, impaired glucose metabolism, infection,

and administration of sedatives, narcotics, and general anesthetics. Depletion of the intravascular volume, from bleeding or diuresis, reduces hepatic and renal perfusion and leads to contraction alkalosis. In turn, hypokalemia and alkalosis increase ammonia production and impair its excretion.

Complication

- Irreversible coma
- Death

Pathophysiology

Most common in patients with cirrhosis, this syndrome is due primarily to ammonia intoxication of the brain. Normally, the ammonia produced by protein breakdown in the bowel is metabolized to urea in the liver. When portal blood shunts past the liver, ammonia directly enters the systemic circulation and is carried to the brain. Such shunting may result from the collateral venous circulation that develops in portal hypertension or from surgically created portosystemic shunts (such as a TIPS). Cirrhosis further compounds this problem because impaired hepatocellular function prevents conversion of ammonia that reaches the liver.

Signs and Symptoms

Clinical manifestations of hepatic encephalopathy vary (depending on the severity of neurologic involvement) and develop in four stages:

- In stage I (minimal hepatic encephalopathy), early signs and symptoms are commonly overlooked because they're so subtle: slight personality changes (disorientation, forgetfulness, and slurred speech) and a slight tremor.
- During the stage II, tremor progresses into asterixis (liver flap and flapping tremor), the hallmark of hepatic encephalopathy. Asterixis is characterized by quick, irregular extensions and flexions of the wrists and fingers, when the wrists are held out straight and the hands flexed upward. Lethargy, aberrant behavior, and apraxia also occur.
- At the stage III, hyperventilation occurs; the patient is typically stuporous, but becomes noisy and abusive when aroused.
- In stage IV, the patient has hyperactive reflexes, a positive Babinski sign, fetor hepaticus (musty, sweet odor to the breath), and coma.

Diagnosis

CONFIRMING DIAGNOSIS *Clinical features, a history of liver disease, and elevated serum ammonia levels in venous and arterial samples confirm hepatic encephalopathy.*

Treatment

Effective treatment stops progression of encephalopathy by reducing blood ammonia levels. Treatment includes eliminating ammonia-producing substances from the GI tract by administering rifaximin to suppress bacterial flora (preventing the conversion of amino acids into ammonia), performing sorbitol-induced catharsis to produce osmotic diarrhea and continuous aspiration of blood from the stomach, and reducing dietary protein intake.

Lactulose, which traps ammonia in the bowel and promotes its excretion, is administered to reduce blood ammonia levels. Bacterial enzymes change lactulose to lactic acid, thereby

rendering the colon too acidic for bacterial growth. At the same time, the resulting increase in free hydrogen ions prevents diffusion of ammonia through the mucosa; lactulose promotes conversion of systemically absorbable ammonia to ammonium, which is poorly absorbed and can be excreted. It is usually given orally. However, if the patient is in a coma, it may be administered by retention enema.

Treatment may also include potassium supplements to correct alkalosis due to increased ammonia levels, especially if the patient is taking diuretics. Hemodialysis may sometimes be used to clear toxic blood temporarily. Salt-poor albumin may be used to maintain fluid and electrolyte balance, replace depleted albumin levels, and restore plasma. Sedatives, tranquilizers, and other medications metabolized or excreted by the liver should be avoided if possible. Medications containing ammonium (including certain antacids) should also be avoided.

Special Considerations

Patient care includes monitoring symptoms and support.

- Assess and record the patient's level of consciousness frequently. Continually orient the patient to place and time. Keep a daily record of the patient's handwriting to monitor the progression of neurologic involvement.
- Monitor the patient's intake, output, and fluid and electrolyte balance. Check daily weight and measure abdominal girth. Watch for, and immediately report, signs of anemia (decreased hemoglobin level), infection, alkalosis (increased serum bicarbonate), and GI bleeding (melena and hematemesis).
- If the encephalopathy is acute, ask the dietary department to provide the specified low-protein diet, with carbohydrates supplying most of the calories.
- Promote rest, comfort, and a quiet atmosphere. Prevent falls.
- Use restraints, if necessary, but avoid sedatives. Protect the comatose patient's eyes from corneal injury by using artificial tears or eye patches.
- Provide emotional support for the patient's family in the terminal stage of encephalopathy.

Gallbladder and Duct Disorders

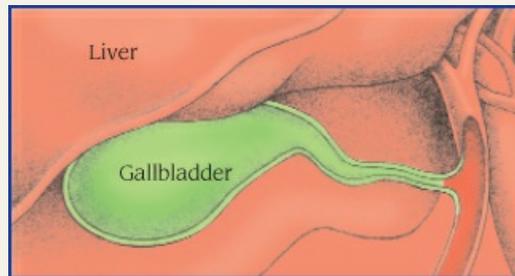
CHOLELITHIASIS AND RELATED DISORDERS

Diseases of the gallbladder and biliary tract are common and, in many cases, painful conditions that frequently require surgery and may be life-threatening. They are generally associated with deposition of calculi and inflammation. (See *Understanding gallstone formation,* page 284.)

PATHOPHYSIOLOGY
UNDERSTANDING GALLSTONE FORMATION

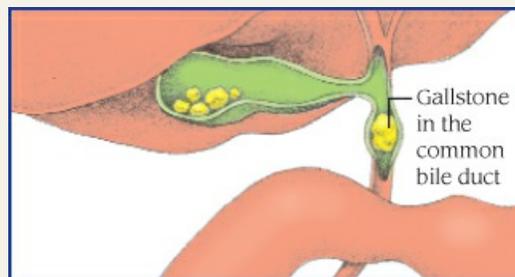
Abnormal metabolism of cholesterol and bile salts plays an important role in gallstone formation. Bile is made continuously by the liver and is concentrated and stored in the gallbladder until the duodenum needs it to help digest fat. Changes in the composition of bile may allow gallstones to form. Changes to the absorptive ability of the gallbladder lining may also contribute to gallstone formation.

Too Much Cholesterol

Certain conditions, such as age, obesity, and estrogen imbalance, cause the liver to secrete bile that's abnormally high in cholesterol or lacking the proper concentration of bile salts.


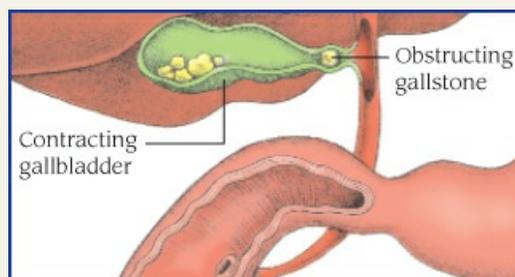
Jaundice, Irritation, Inflammation

If a stone lodges in the common bile duct, the bile flow into the duodenum becomes obstructed. Bilirubin is absorbed into the blood, causing jaundice.

Biliary narrowing and swelling of the tissue around the stone can also cause irritation and inflammation of the common bile duct.


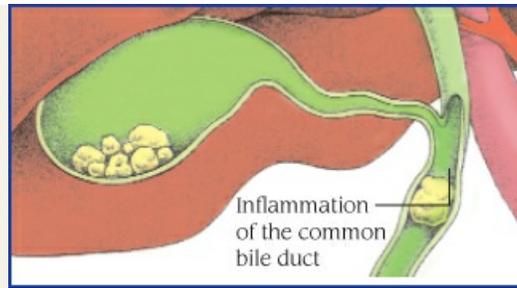
Inside the Gallbladder

When the gallbladder concentrates this bile, inflammation may occur. Excessive water and bile salts are reabsorbed, making the bile less soluble. Cholesterol, calcium, and bilirubin precipitate into gallstones.

Fat entering the duodenum causes the intestinal mucosa to secrete the hormone cholecystokinin, which stimulates the gallbladder to contract and empty. If a stone lodges in the cystic duct, the gallbladder contracts but can't empty.


Up The Biliary Tree

Inflammation can progress up the biliary tree and cause infection of any of the bile ducts. This causes scar tissue, fluid accumulation, cirrhosis, portal hypertension, and bleeding.

Inflammation of the common bile duct


Causes and Incidence

Cholelithiasis, stones or calculi (gallstones) in the gallbladder, results from changes in bile components. Gallstones are made of cholesterol, calcium bilirubinate, or a mixture of cholesterol and bilirubin pigment. They arise during periods of sluggishness in the gallbladder due to pregnancy, hormonal contraceptives, diabetes mellitus, celiac disease, cirrhosis of the liver, and pancreatitis. Cholelithiasis is a common health problem, affecting about 50% of white women and 30% of white men. The prognosis is usually good with treatment unless infection occurs, in which case the prognosis depends on its severity and response to antibiotics.

One out of every 10 patients with gallstones develops *choledocholithiasis*, or gallstones in the common bile duct (sometimes called *common duct stones*). This occurs when stones passed out of the gallbladder lodge in the hepatic and common bile ducts and obstruct the flow of bile into the duodenum. Prognosis is good unless infection occurs.

Cholangitis, infection of the bile duct, is commonly associated with choledocholithiasis and may follow percutaneous transhepatic cholangiography or occlusion of endoscopic stents. Predisposing factors may include bacterial or metabolic alteration of bile acids. Widespread inflammation may cause fibrosis and stenosis of the common bile duct. The prognosis for this condition is poor without stenting or surgery.

Cholecystitis, acute or chronic inflammation of the gallbladder, is usually associated with a gallstone impacted in the cystic duct, causing painful distention of the gallbladder. Cholecystitis accounts for most patients requiring gallbladder surgery. The acute form is most common during middle age; the chronic form usually occurs among elderly patients. The prognosis is good with treatment.

Biliary cirrhosis is a disorder whose primary cause is unknown. This condition usually leads to obstructive jaundice and involves the portal and periportal spaces of the liver. It is nine times more common among women 40 to 60 years old than among men. The prognosis is poor without liver transplantation.

Gallstone ileus results from a gallstone lodging at the terminal ileum; it's more common in the elderly. The prognosis is good with surgery.

Postcholecystectomy syndrome is the presence of GI symptoms after cholecystectomy. It occurs in 10% to 15% of all patients whose gallbladders have been surgically removed and may produce right upper quadrant abdominal pain, biliary colic, fatty food intolerance, dyspepsia, and indigestion. The prognosis is good with selected radiologic procedures, endoscopic procedures, or surgery.

Acalculous cholecystitis is more common in critically ill patients, accounting for about 5% of cholecystitis cases. It may result from primary infection with such organisms as *Salmonella typhi, E. coli,* or *Clostridium* or from obstruction of the cystic duct due to lymphadenopathy or a

tumor. It appears that ischemia, usually related to a low cardiac output, also has a role in the pathophysiology of this disease. Signs and symptoms of acalculous cholecystitis include unexplained sepsis, right upper quadrant pain, fever, leukocytosis, and a palpable gallbladder.

Each of these disorders produces its own set of complications. Cholelithiasis may lead to any of the disorders associated with gallstone formation: cholangitis, cholecystitis, choledocholithiasis, and gallstone ileus. Cholecystitis can progress to gallbladder complications, such as empyema, hydrops or mucocele, or gangrene. Gangrene may lead to perforation, resulting in peritonitis, fistula formation, pancreatitis, limy bile, and porcelain gallbladder. Other complications include chronic cholecystitis and cholangitis.

Choledocholithiasis may lead to cholangitis, obstructive jaundice, pancreatitis, and secondary biliary cirrhosis. Cholangitis, especially in the suppurative form, may progress to septic shock and death. Gallstone ileus may cause bowel obstruction, which can lead to intestinal perforation, peritonitis, septicemia, secondary infection, and septic shock.

In most cases, gallbladder and bile duct diseases occur in people who are older than 40 years; they are more prevalent in women and Native Americans.

Complications

Each of these disorders produces a set of complications.

- Cholelithiasis may lead to any of the disorders associated with gallstone formation: cholangitis, cholecystitis, choledocholithiasis, and gallstone ileus.
- Cholecystitis can progress to gallbladder complications, such as empyema, hydrops or mucocele, and gangrene. Gangrene may lead to perforation, resulting in peritonitis, fistula formation, pancreatitis, limy bile syndrome, and porcelain gallbladder. Other complications include chronic cholecystitis and cholangitis.
- Cholecholithiasis may lead to cholangitis, obstructive jaundice, pancreatitis, and secondary biliary cirrhosis.
- Cholangitis may progress to septic shock and death, especially in the suppurative form.
- Gallstone ileus may cause bowel obstruction, which can lead to intestinal perforation, peritonitis, septicemia, secondary infection, and septic shock.

Signs and Symptoms

Although gallbladder disease may produce no symptoms, acute cholelithiasis, acute cholecystitis, and choledocholithiasis produce the symptoms of a classic gallbladder attack. Attacks usually follow meals rich in fats or may occur at night, suddenly awakening the patient. They begin with acute abdominal pain in the right upper quadrant that may radiate to the back, between the shoulders, or to the front of the chest; the pain may be so severe that the patient seeks emergency department care. Other features may include recurring fat intolerance, biliary colic, belching, flatulence, indigestion, diaphoresis, nausea, vomiting, chills, low-grade fever, jaundice (if a stone obstructs the common bile duct), and clay-colored stools (with choledocholithiasis).

Clinical features of cholangitis include a rise in neutrophils, jaundice, right upper quadrant abdominal pain, high fever, and chills; biliary cirrhosis may produce jaundice, related itching, weakness, fatigue, slight weight loss, and abdominal pain. Gallstone ileus produces signs and symptoms of small-bowel obstruction—nausea, vomiting, abdominal distention, and absent bowel sounds if the bowel is completely obstructed. Its most telling symptom is intermittent recurrence of colicky pain over several days.

Diagnosis

Ultrasonography detects gallstones. Other tests may include the following:

- Abdominal CT scan may detect stones in the gallbladder.
- Percutaneous transhepatic cholangiography, done under fluoroscopic control, distinguishes between gallbladder or bile duct disease and cancer of the pancreatic head in patients with jaundice.
- ERCP visualizes the biliary tree after insertion of an endoscope down the esophagus into the duodenum, cannulation of the common bile and pancreatic ducts, and injection of contrast medium.
- HIDA scan detects obstruction of the cystic duct.
- Magnetic resonance cholangiopancreatography can detect gallstones, choledocholithiasis, masses, biliary strictures, and dilation.

Elevated total bilirubin, urine bilirubin, and alkaline phosphatase levels support the diagnosis. The WBC count is slightly elevated during a cholecystitis attack. Differential diagnosis is essential because gallbladder disease can mimic other diseases (myocardial infarction, angina, pancreatitis, pancreatic head cancer, pneumonia, peptic ulcer, hiatal hernia, esophagitis, and gastritis). Serum amylase levels distinguish gallbladder disease from pancreatitis. With suspected heart disease, serial cardiac enzyme tests and electrocardiography should precede gallbladder and upper GI diagnostic tests.

Treatment

Surgery, usually elective, is the treatment of choice for gallbladder and bile duct diseases. Laparoscopic cholecystectomy and cholecystectomy with operative cholangiography are the most frequently performed surgeries. Open cholecystectomy is reserved from complicated cases. Other treatments include a low-fat diet to prevent attacks and vitamin K for itching, jaundice, and bleeding tendencies due to vitamin K deficiency. Treatment during an acute attack may include insertion of a nasogastric tube and an I.V. line and, possibly, antibiotic administration.

ERCP with sphincterotomy is the treatment of choice for choledocholithiasis with obstruction or cholangitis due to obstruction.

Ursodeoxycholic acid, which dissolves radiolucent stones, provides an alternative for patients who are poor surgical risks or who refuse surgery.

Special Considerations

Patient care for gallbladder and bile duct diseases focuses on supportive care and close postoperative observation.

- Before surgery, teach the patient to deep-breathe, cough, expectorate, and perform leg exercises that are necessary after surgery. Also teach splinting, repositioning, and ambulation techniques. Explain the procedures that will be performed before, during, and after surgery to help ease the patient's anxiety and to help ensure cooperation.
- After surgery, monitor the patient's vital signs for signs of bleeding, infection, or atelectasis.
- Evaluate the incision site for bleeding. Serosanguineous drainage is common during the first 24 to 48 hours if the patient has a wound drain. If, after a choledochostomy, a T-tube drain is placed in the duct and attached to a drainage bag, make sure that the drainage tube has no kinks. Also check that the connecting tubing from the T-tube is well secured to the patient to prevent dislodgment.

- Measure and record T-tube drainage daily (200 to 300 mL is normal).
- Teach patients who will be discharged with a T-tube how to perform dressing changes and routine skin care.
- Monitor the patient's intake and output. Allow the patient nothing by mouth for 24 to 48 hours or until bowel sounds return and nausea and vomiting cease (postoperative nausea may indicate a full bladder).
- If the patient doesn't void within 8 hours (or if the amount voided is inadequate based on I.V. fluid intake), percuss over the symphysis pubis for bladder distention (especially in the patient receiving anticholinergics). The patient who has had a laparoscopic cholecystectomy may be discharged the same day or within 24 hours after surgery. The patient should have minimal pain, be able to tolerate a regular diet within 24 hours after surgery, and be able to return to normal activity within a few days to a week.
- Encourage deep-breathing and leg exercises every hour. The patient should ambulate after surgery. Provide elastic stockings to support the leg muscles and promote venous blood flow, thus preventing stasis and clot formation.
- Evaluate the location, duration, and character of any pain. Administer adequate medication to relieve pain, especially before such activities as deep breathing and ambulation, which increase pain.
- At discharge, advise the patient against heavy lifting or straining for 6 weeks. Urge the patient to walk daily. Tell them that food restrictions are unnecessary unless they have intolerance to a specific food or some underlying condition (such as diabetes, atherosclerosis, celiac disease or allergy, or obesity) that requires such restriction.
- Instruct the patient to notify the surgeon if they have pain for more than 24 hours or notices any jaundice, anorexia, nausea or vomiting, fever, or tenderness in the abdominal area because these may indicate a biliary tract injury from cholecystectomy, requiring immediate attention.

Musculoskeletal Disorders

Introduction

A complex system of bones, muscles, ligaments, tendons, and other connective tissue, the musculoskeletal system gives the body its form and shape. It also protects vital organs, makes movement possible, stores calcium and other minerals, and provides sites for hematopoiesis. A fibrous layer called the *periosteum* covers all bones, except at joints, where they're covered by articular cartilage.

The human skeleton contains 206 bones, which are composed of inorganic salts, such as calcium and phosphate, embedded in a framework of collagen fibers. Bones are classified by shape as long, short, flat, or irregular.

LONG BONES

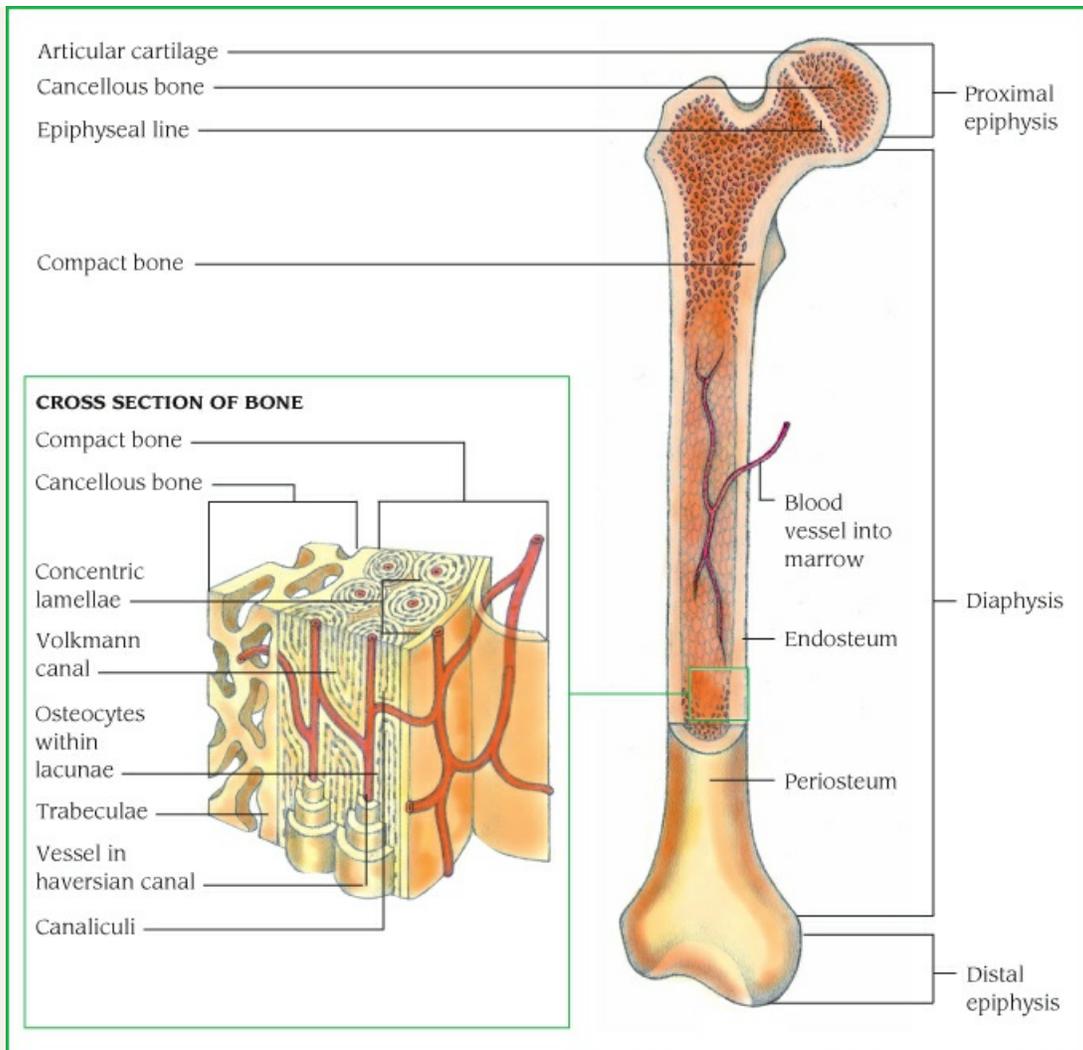
Long bones, which are found in the limbs, include the humerus, radius, and ulna of the arm; the femur, tibia, and fibula of the leg; and the phalanges, metacarpals, and metatarsals in the hands and feet. These bones have a long shaft, or *diaphysis,* and widened, bulbous ends, called *epiphyses*. A long bone is made up mainly of compact bone, which surrounds the medullary cavity (also called the *yellow marrow*), a storage site for fat. The lining of the medullary cavity (the *endosteum*) is a thin layer of connective tissue. The outer layer is the periosteum. (See *Long-bone structure*, page 288.)

Long-bone Structure

Long-bone composition is depicted below, with an illustrated cross section.

Articular cartilage
Cancellous bone
Epiphyseal line
Compact bone
Proximal epiphysis

CROSS SECTION OF BONE
Compact bone
Cancellous bone
Concentric lamellae
Volkmann canal
Osteocytes within lacunae
Trabeculae
Vessel in haversian canal
Canaliculi

Blood vessel into marrow
Endosteum
Periosteum
Diaphysis
Distal epiphysis


In children and young adults, lengthwise growth occurs at the epiphyseal cartilage between the diaphysis and epiphysis. In adults, in whom bone growth is complete, this cartilage is ossified and forms the epiphyseal line. The epiphysis also has a surface layer made up of compact bone, but its center is made of spongy or cancellous bone. Cancellous bone contains open spaces between thin threads of bone, called *trabeculae,* which are arranged in various directions to correspond with the lines of maximum stress or pressure. This configuration gives the bone added structural strength.

Unlike cancellous bone, adult compact bone consists of numerous orderly networks of interconnecting canals that run parallel to the bone's long axis. Each of these networks, called a *haversian system,* consists of a central haversian canal surrounded by layers (*lamellae*) of bone. Between adjacent lamellae are small openings (*lacunae*), which contain bone cells (*osteocytes*). All lacunae are joined by an interconnecting network of tiny canals (*canaliculi*), each of which contains one or more capillaries and provides a route for movement of tissue fluids. The haversian system carries blood to the bone through blood vessels that enter the system through channels called *Volkmann's canals.*

SHORT, FLAT, OR IRREGULAR BONES

Short bones include the tarsal and carpal bones; flat bones, the frontal and parietal bones of the cranium, ribs, sternum, scapulae, ilium, and pubis; and irregular bones, the bones of the spine (vertebrae, sacrum, and coccyx) and certain bones of the skull (sphenoid, ethmoid, and mandible).

Short, flat, and irregular bones have an outer layer of compact bone and an inner portion of spongy bone. In the sternum and certain areas in the flat bones of the skull, the spongy bone contains red marrow.

JOINTS

The tissues connecting two bones make up a joint, which permits motion between the bones and provides stability. Joints, like bones, have varying forms.

- Fibrous joints (*synarthroses*) have only minute motion and provide stability when tight union is necessary, as in the seams, called *sutures*, that join the cranial bones.
- Cartilaginous joints (*amphiarthroses*) have limited motion, as between vertebrae and symphysis pubis.
- Synovial joints (*diarthroses*) are the most common and have the greatest degree of movement. Such joints include the elbows, shoulders, and knees. Synovial joints have special characteristics: the articulating surfaces of each bone have a smooth hyaline covering (articular cartilage), which is resilient to pressure; their opposing surfaces are congruous and glide smoothly on each other without touching each other; a fibrous (articular) capsule holds them together. Beneath the capsule and lining the joint cavity, the synovial membrane secretes the clear, viscous synovial fluid. This fluid lubricates the two opposing surfaces during motion and also nourishes the articular cartilage. Surrounding a synovial joint are ligaments, muscles, and tendons, which strengthen and stabilize the joint but allow free movement.

In some synovial joints, the synovial membrane forms two additional structures—bursae and tendon sheaths—which reduce friction that normally accompanies movement. Bursae are small, cushionlike sacs lined with synovial membranes and filled with synovial fluid; most are located between tendons and bones. Tendon sheaths wrap around the tendon and cushion it as it crosses the joint.

The synovial joints permit angular and circular movements. Angular movements include *flexion* (decrease in joint angle), *extension* (increase in joint angle), and *hyperextension* (increase in the angle of extension beyond the usual arc). Joints of the knees, elbows, and phalanges permit such movement. Other angular movements are *abduction* (movement away from the body's midline) and *adduction* (movement toward the body's midline).

Circular movements include *rotation* (motion around a central axis), as in the ball-and-socket joints of the hips and shoulders; *pronation* (wrist motion to place palmar surface of the hand down, with the thumb toward the body); *supination* (begging position, with palm up). Other kinds of movement are *inversion* (movement facing inward), *eversion* (movement facing outward), *protraction* (as in forward motion of the mandible), and *retraction* (returning protracted part into place).

MUSCLES

Muscle tissues' most specialized feature—*contractility*—makes movement of bones and joints possible. Muscles also pump blood through the body, move food through the intestines, and

make breathing possible. Muscular activity produces heat, so it's an important component in temperature regulation. Muscles maintain body positions, such as sitting and standing. Muscle mass accounts for about 40% of the body weight of a person of average size.

Muscles are classified in many ways. *Skeletal* muscles are attached to bone, *visceral* muscles permit function of internal organs, and *cardiac* muscles make up the heart wall. Also, muscles may be striated or nonstriated (smooth), depending on their cellular configuration.

Muscles classified according to activity are called *voluntary* or *involuntary*. Voluntary muscles can be controlled at will and are under the influence of the somatic nervous system; these are the skeletal muscles. Involuntary muscles, controlled by the autonomic nervous system, include the cardiac and visceral muscles.

Each skeletal muscle consists of many elongated muscle cells, called *muscle fibers,* through which run slender threads of protein, called *myofibrils*. Muscle fibers are held together in bundles by sheaths of fibrous tissue, called *fascia*. Blood vessels and nerves pass through the fascia to reach the individual muscle fibers.

Skeletal muscles are attached to bone directly or indirectly by fibrous cords called *tendons*. The least movable end of the muscle attachment is called *the point of origin*; the most movable end is *the point of insertion.*

MECHANISM OF CONTRACTION

To stimulate muscle contraction and movement, the brain sends motor impulses through the peripheral motor nerves to motor nerve fibers in the voluntary muscle. These nerve fibers reach membranes of skeletal muscle cells at neuromuscular (*myoneural*) junctions. When an impulse reaches the myoneural junction, it triggers the following sequence: release of the neurochemical acetylcholine, transient release of calcium from the sarcoplasmic reticulum (a membranous network in the muscle fiber), and muscle contraction. The arriving impulse at the myoneural junction also triggers release of adenosine triphosphate, the energy source for muscle contraction. Muscle relaxation is believed to take place by reversal of the above mechanisms.

MUSCULOSKELETAL ASSESSMENT

Most patients with musculoskeletal disorders are elderly, have concurrent medical conditions, or have experienced trauma. Younger patients tend to experience more benign, self-limited conditions. Generally, they face prolonged immobilization. These factors make thorough assessment essential. Your assessment should include a complete history and a careful physical examination to determine a possible cause of the symptoms.

Interview the patient carefully to obtain a complete medical, social, and personal history. Ask about general activity, for example jogging daily or sedentary life which may be significantly altered by musculoskeletal disease or trauma. Does the patient have any systemic symptoms, such as fever, chills, weight loss, or skin rashes? Obtain information about occupation, diet, sexual activity, and elimination habits, drugs taken, and use of safety devices, and try to assess how the problem will affect body image. Also, ask how the patient functions at home. Is the patient independent with activities of daily living, are there stairs to the bedroom or bathroom, any prosthetic devices, any family members who help with personal care?

Get an accurate account of the musculoskeletal problem. Ask if it has caused any changes to everyday routines. When did symptoms begin and how did they progress? Has the patient received treatment for this problem? Has there been any trauma? If so, find out the details.

Assess the level of pain. Is the patient in pain now? Ask what makes the discomfort worse or

better (movement, position, and so forth). Evaluate past and present responses to treatment. For instance, if the patient has arthritis and uses corticosteroids, ask about their effectiveness. Is more of less medication needed than before? Are there any issues with adherence to the prescribed treatment?

Physical examination helps to determine the diagnosis and reveals any existing disabilities. (These baseline data will help when the effects of treatment are evaluated.) Observe the patient's appearance. Look for localized edema, pigmentation, redness and tenderness at pressure points, and other deformities such as atrophy. Note mobility, strength, and gait. To check range of motion (ROM), ask the patient to abduct, adduct, or flex the muscles in question. Obtain height, weight, and vital signs. Check neurovascular status, including motion sensation and circulation. Measure and record discrepancies in muscle circumference or leg length. Compare one side or limb to the other. If a neck injury is suspected, don't force ROM.

DIAGNOSTIC TOOLS

- X-rays are a useful diagnostic tool to evaluate musculoskeletal diseases. They can help to identify joint disruption, bone deformities, calcifications, and bone destruction and fractures. X-rays also measure bone density.
- Myelography is an invasive procedure used to evaluate abnormalities of the spinal canal and cord. It entails injection of a radiopaque contrast medium into the subarachnoid space of the spine. Serial X-rays visualize the progress of the contrast medium as it passes through the subarachnoid space. Displacement of the medium indicates a space-occupying lesion, such as a herniated disk or a tumor.
- Magnetic resonance imaging (MRI) is useful in evaluating soft-tissue injuries or ligament tears, such as rotator cuff tears or meniscal tears.
- Computed tomography (CT) scan can be used to identify injuries to bones, soft tissue, ligaments, tendons, and muscles.
- Arthroscopy is the visual examination of the interior of a joint with a fiberoptic endoscope.

Other useful tests include bone and muscle biopsies, electromyography, microscopic examination of synovial fluid, and multiple laboratory studies of urine and blood to identify systemic abnormalities.

PATIENT CARE

Each patient with musculoskeletal disease needs an individual care plan formulated early in the hospital stay by the entire clinical team, including the physician, physical therapist, and occupational therapist. Develop this plan with short- and long-term goals, during and after hospitalization.

Caring for the patient with a musculoskeletal disease usually includes at least one of the following: traction, casts, braces, splints, crutches, intermittent ROM devices, prolonged immobilization, physical therapy, occupational therapy, and self-care measures; adequate vitamin D intake, weight loss, dietary modifications, and drugs.

Traction is the manual or mechanical application of a steady pulling force to reduce a fracture, minimize muscle spasms, or immobilize or align a joint.

- Skin traction is the indirect application of traction to the skeletal system through skin and soft tissues.
- Skeletal traction is the direct application of traction to bones by means of a pin (Steinmann

pin) or wire (Kirschner wire) through the affected bone or by calipers or a tonglike device (Gardner-Wells tongs) that grips the bone.

◆ Manual traction, for emergency use, is the direct application of traction to a body part by hand.

During the use of all types of traction:

◆ Explain to the patient how traction works and advise the patient about permissible amounts of activity and elevation of the head of the bed. Inform the patient of the anticipated duration of traction and whether the traction is removable. Teach active ROM exercises.

◆ Check neurovascular status to prevent nerve damage. Also, make sure the mattress is firm, that the traction ropes aren't frayed, that they're on the center track of the pulley, and that traction weights are hanging free. Thoroughly investigate any complaint the patient makes.

◆ Check for signs of infection (odor, local inflammation and drainage, or fever) at pin sites if the patient is in skeletal traction. Also, check with the physician's or the facility's procedure regarding pin-site care, such as use of peroxide or povidone–iodine.

Ideally, a cast immobilizes without adding too much weight. It's snug-fitting but doesn't constrict and has a smooth inner surface and smooth edges to prevent pressure or skin irritation. Casts require comprehensive patient education.

◆ A plaster cast takes 24 to 48 hours to dry. To prevent indentations, tell the patient not to squeeze the cast, not to cover or walk on the cast until it has dried, and not to bump a damp cast on hard surfaces because dents can cause pressure areas. Warn the patient that while the cast is drying, there may be a temporary sensation of heat under the cast.

◆ If fiberglass is used, the cast may feel dry and the patient may be able to bear weight immediately. Advise the patient, however, not to get the cast wet. Although the fiberglass won't disintegrate as plaster would, the padding will become wet and potentially cause maceration of the skin.

◆ Emphasize the need to keep the cast above heart level for *24 hours* after its application to reduce swelling in the limb.

◆ While the cast is drying and after drying is complete, the patient should watch for and immediately report persistent pain in the limb inside or distal to the cast as well as edema, changes in skin color, coldness, or tingling or numbness in this area. If any of these signs occur, tell the patient to position the casted body part above heart level and notify the physician.

◆ The patient should also report drainage through the cast or an odor that may indicate infection. Warn against inserting foreign objects under the cast, getting it wet, pulling out its padding, or scratching inside it. Tell the patient to seek immediate attention for a broken cast.

◆ Instruct the patient to exercise the joints above and below the cast to prevent stiffness and contracture.

Braces, splints, and slings also provide alignment, immobilization, and pain relief for musculoskeletal diseases. Slings and splints are usually used for short-term immobilization. Explain to the patient and the family why these appliances are necessary and show them the proper way to apply the sling, splint, or brace for optimal benefit. Tell the patient how long the appliance will have to be worn and advise the patient of any activity limitations that must be observed. If the patient has a brace, check with the orthotist (orthopedic appliance specialist) about proper care. Encourage the patient to refer additional questions to the physician. Teach

proper crutch walking.

COPING WITH IMMOBILITY

Immobilized patients require meticulous care to prevent complications. Without constant care, the bedridden patient becomes susceptible to pressure ulcers, caused by the increased pressure on tissue over bony prominences, and is especially vulnerable to cardiopulmonary complications.

- To prevent pressure ulcers, turn the patient every 2 hours and, if possible, reposition in a 30-degree side-lying position for short periods. In addition, place a flotation pad or sheepskin pad under bony prominences, or use an alternating-air-current, convoluted foam, or foam mattress. Show the patient how to use a Balkan frame with a trapeze to move about in bed.
- Keep the patient's skin dry and clean.
- Keep the sheets wrinkle-free.
- Increase fluid intake to minimize risk of renal calculi.
- Provide adequate nutrition; a high-protein diet is preferred, if tolerated.
- Perform passive ROM exercises on the affected side, as ordered, to prevent contractures, and instruct the patient in active ROM exercises on the unaffected side. Apply footboards or high-topped sneakers to prevent footdrop. Keep the patient's heels off the bed to prevent heel breakdown. Also, watch for reddened elbows.
- Because most bedridden patients involuntarily perform a Valsalva's maneuver when using the upper arms and trunk to move, instruct the patient to exhale (instead of holding their breath) while turning. This will prevent possible cardiac complications that result from increased intrathoracic pressure.
- Emphasize the importance of coughing and deep breathing and teach the patient how to use the incentive spirometer if ordered.
- Because constipation is a common problem in bedridden patients, establish a bowel program (fluids, fiber, laxatives, stool softeners), as needed.

REHABILITATION

Restoring the patient to a former state of health isn't always possible. When it isn't, help the patient adjust to a modified lifestyle. During hospitalization, promote independence by letting patients finish difficult tasks independently. If necessary, refer the patient to a community facility for continued rehabilitation.

Congenital Disorders

CLUBFOOT

Clubfoot, or *talipes*, is the most common congenital disorder of the lower limbs. It's marked primarily by a deformed talus and shortened Achilles tendon, which give the foot a characteristic clublike appearance. In talipes equinovarus, the foot points downward (equinus) and turns inward (varus), whereas the front of the foot curls toward the heel (forefoot adduction).

Causes and Incidence

It is no longer believed that clubfoot is caused by fetal position in utero. Heredity is a definite factor in some cases, although the mechanism of transmission is undetermined. In children

without a family history of clubfoot, this anomaly seems linked to arrested development during the 9th and 10th weeks of embryonic life, when the feet are formed. Researchers also suspect muscle abnormalities, leading to variations in length and tendon insertions, as possible causes of clubfoot. Environmental factors play a role. Studies strongly link clubfoot to cigarette smoking during pregnancy, especially if there is a family history of clubfoot.

Clubfoot, which has an incidence of about 1 per 1,000 live births, usually occurs bilaterally and is twice as common in boys. It may be associated with other birth defects, such as myelomeningocele, spina bifida, and arthrogryposis. However, most cases are sporadic occurrences.

Pathophysiology

Abnormal development of the foot during fetal growth leads to abnormal muscles and joints and contracture of soft tissue. Clubfoot can also occur because of paralysis, poliomyelitis, or cerebral palsy. The condition called *apparent clubfoot* results when a fetus maintains a position in utero that gives feet a clubfoot appearance at birth; it can usually be corrected manually. Another form of apparent clubfoot is inversion of the feet, resulting from the denervation type of progressive muscular atrophy and progressive muscular dystrophy.

Complication

- Retention deformity

Signs and Symptoms

Talipes equinovarus varies greatly in severity. Deformity may be so extreme that the toes touch the inside of the ankle, or it may be only vaguely apparent. In every case, the talus is deformed, the Achilles tendon shortened, and the calcaneus somewhat shortened and flattened. Depending on the degree of the varus deformity, the calf muscles are shortened and underdeveloped, and soft-tissue contractures form at the site of the deformity. The foot is tight in its deformed position and resists manual efforts to push it into normal position. Clubfoot is painless, except in elderly, arthritic patients. In older children, clubfoot may be secondary to paralysis, poliomyelitis, or cerebral palsy, in which case treatment must include management of the underlying disease.

Diagnosis

Early diagnosis of clubfoot is usually possible because the deformity is obvious. In subtle deformity, however, true clubfoot must be distinguished from apparent clubfoot (metatarsus varus or pigeon toe). Apparent clubfoot is inversion of the feet, resulting from the peroneal type of progressive muscular atrophy and progressive muscular dystrophy. In true clubfoot, X-rays show superimposition of the talus and the calcaneus and a ladderlike appearance of the metatarsals. (See *Recognizing clubfoot.*)

Recognizing Clubfoot

Congenital skeletal anomalies frequently involve the foot and the ankle and are referred to as "clubfoot."

Treatment

Clubfoot is correctable with prompt treatment, which is performed in three stages: correcting the deformity, maintaining the correction until the foot regains normal muscle balance, and observing the foot closely for several years to prevent the deformity from recurring. In neonates with true clubfoot, corrective treatment should begin at once. An infant's foot contains large amounts of cartilage; the muscles, ligaments, and tendons are supple. The ideal time to begin treatment is during the first few days and weeks of life, when the foot is most malleable.

Clubfoot deformities are usually corrected in sequential order. Several therapeutic methods have been found effective in correcting clubfoot. In all patients, the first procedure should be simple manipulation and casting, whereby the foot is gently manipulated into a partially corrected position and held in place by a cast for several days or weeks. (The skin should be painted with a nonirritating adhesive liquid beforehand to prevent the cast from slipping.) After the cast is removed, the foot is manipulated into an even better position and casted again. This procedure is repeated as many times as necessary. In some cases, the shape of the cast can be transformed through a series of wedging maneuvers instead of changing the cast each time.

After correction of clubfoot, proper foot alignment should be maintained through exercise, night splints, and orthopedic shoes. With manipulating and casting, correction usually takes about 3 months. The Denis Browne splint, a device that consists of two padded, metal footplates connected by a flat, horizontal bar, is sometimes used as a follow-up measure to help promote bilateral correction and strengthen the foot muscles.

Resistant clubfoot may require surgery. Older children, for example, with recurrent or neglected clubfoot usually need surgery. Tenotomy, tendon transfer, stripping of the plantar fascia, and capsulotomy are some of the surgical procedures that may be used. In severe cases, bone surgery (wedge resections, osteotomy, or astragalectomy) may be appropriate. After surgery, a cast is applied to preserve the correction. Clubfoot severe enough to require surgery is rarely totally correctable; however, surgery can usually ameliorate the deformity.

Special Considerations

The primary concern is recognition of clubfoot as early as possible, preferably in neonates.

- Look for any exaggerated attitudes in an infant's feet. Make sure you recognize the difference between true clubfoot and apparent clubfoot. Don't use excessive force in trying to manipulate a clubfoot. The foot with apparent clubfoot moves easily.
- Stress to parents the importance of prompt treatment. Make sure they understand that clubfoot demands immediate therapy and orthopedic supervision until growth is completed.

- After casting, elevate the child's feet with pillows. Check the toes every 1 to 2 hours for temperature, color, sensation, motion, and capillary refill time; watch for edema. Before a child in a clubfoot cast is discharged, teach parents to recognize circulatory impairment.
- Insert plastic petals over the top edges of a new cast while it's still wet to keep urine from soaking and softening the cast. This is done as follows: Cut a plastic sheet into strips long enough to cover the outside of the cast and tuck them about a finger length beneath the cast edges. Using overlapping strips of tape, tack the corner of each petal to the outside of the cast. When the cast is dry, petal the edges with adhesive tape to keep out plaster crumbs and prevent skin irritation. Perform good skin care under the cast edges every 4 hours, washing and carefully drying the skin. (Don't rub the skin with alcohol, and don't use oils or powders, which tend to macerate the skin.)
- If the child is old enough to walk, caution parents not to let the foot part of the cast get soft and thin from wear. If it does, much of the correction may be lost.
- When the wedging method of shaping the cast is being used, check circulatory status frequently; it may be impaired by increased pressure on tissues and blood vessels. The equinus (posterior release) correction especially places considerable strain on ligaments, blood vessels, and tendons.
- After surgery, elevate the child's feet with pillows to decrease swelling and pain. Report signs of discomfort or pain right away. Try to locate the source of pain; it may result from cast pressure rather than from the incision. If bleeding occurs under the cast, circle the location and mark the time on the cast. If bleeding spreads, report it.
- Explain to the older child and the parents that surgery can improve clubfoot with good function but can't totally correct it; the affected calf muscle will remain slightly underdeveloped.
- Emphasize the need for long-term orthopedic care to maintain correction. Teach parents the prescribed exercises that the child can do at home. Urge them to make the child wear the corrective shoes ordered and the splints during naps and at night. Make sure they understand that treatment for clubfoot continues during the entire growth period. Correcting this defect permanently takes time and patience.

DEVELOPMENTAL DYSPLASIA OF THE HIP

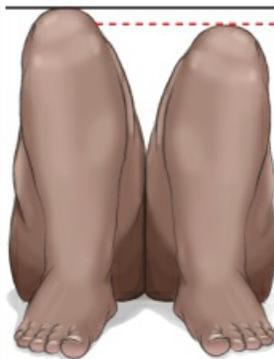
Developmental dysplasia of the hip (DDH), an abnormality of the hip joint present from birth, is the most common disorder affecting hip joints of children younger than 3 years old. DDH can be unilateral or bilateral. (See *Characteristics of developmental hip dysplasia*, page 294.) This abnormality occurs in three forms of varying severity: *unstable hip dysplasia,* in which the hip is positioned normally but can be dislocated by manipulation; *subluxation or incomplete dislocation,* in which the femoral head rides on the edge of the acetabulum; and *complete or true congenital dislocation,* in which the femoral head is totally outside the acetabulum.

Characteristics of Developmental Hip Dysplasia

The classic characteristics of developmental hip dysplasia are illustrated below.

ASYMMETRIC SKIN FOLDS ON THE THIGHS OR BUTTOCKS

LIMITED ABDUCTION OF THE HIP

LEG-LENGTH DISCREPANCY


Developmental hip subluxation or dislocation can cause abnormal acetabular development and permanent disability.

Causes and Incidence

Experts are uncertain about the causes of DDH. Dislocation is 10 times more common after breech delivery (malpositioning in utero) than after cephalic delivery, and it's also more common among large neonates and twins. It's a lot more common in firstborn children. Girls are affected more often than boys and white children more than black children. Genetic factors may also play a role.

Although DDH is found throughout the world, incidence is particularly high among Native Americans.

Pathophysiology

The precise cause of congenital dislocation is unknown. Excessive or abnormal movement of the joint during a traumatic birth may cause dislocation. Displacement of bones within the joint may damage joint structures, including articulating surfaces, blood vessels, tendons, ligaments, and nerves. This may lead to ischemic necrosis because of the disruption of blood flow to the joint.

Complications

- Degenerative hip changes (if treatment is delayed)
- Lordosis
- Joint malformation
- Crippling osteoarthritis

Signs and Symptoms

Clinical effects of hip dysplasia vary with age. In neonates, dysplasia doesn't cause gross deformity or pain. However, in complete dysplasia, the hip rides above the acetabulum, causing the level of the knees to be uneven. As the child grows older and begins to walk, the abduction on the dislocated side is limited. Uncorrected bilateral dysplasia may cause the child to sway from side to side, a condition known as "duck waddle"; unilateral dysplasia may produce a limp. If corrective treatment isn't begun until after age 2, DDH may cause degenerative hip changes, lordosis, joint malformation, and soft-tissue damage.

Diagnosis

Several observations during physical examination of the relaxed child strongly suggest DDH. First, place the child on the back, and inspect the folds of skin over the thighs. Usually, a child in this position has an equal number of thigh folds on each side, but a child with subluxation or dislocation may have an extra fold on the affected side (this extra fold is also apparent when the child lies prone). Next, with the child lying prone, check for alignment of the buttock fold. In a child with dysplasia, the buttock fold on the affected side is higher. In addition, abduction of the affected hip is restricted.

CONFIRMING DIAGNOSIS *A positive Ortolani or Trendelenburg sign confirms DDH. To elicit Ortolani sign, place the infant on back, with hip flexed and abducted. Adducting the hip while pressing the femur downward will dislocate the hip. Then, abducting the hip while moving the femur upward will move the femoral head over the acetabular rim. If you hear a click or feel a jerk as the femoral head moves, the test is positive. This sign indicates subluxation in a neonate younger than 1 month and subluxation or complete dislocation in an older infant.*

To elicit Trendelenburg sign, have the child put weight on the side of the dislocation and lift the other knee. The pelvis drops on the normal side because of weak abductor muscles in the affected hip. However, when the child stands with weight on the normal side and lifts the other knee, the pelvis remains horizontal.

Ultrasound of the hip reveals hip deformity. X-rays show the location of the femur head and a shallow acetabulum. X-rays may also show acetabular dysplasia or a teratologica dislocation. MRI may also be used to assess reduction.

Treatment

The earlier the infant receives treatment, the better the chances are for normal development. Treatment varies with the patient's age and is tailored to the specific pathological condition. In infants younger than 6 months, treatment includes *gentle* manipulation to reduce the dislocation, followed by holding the hips in a flexed and abducted position with a splint-brace or harness to maintain the reduction. The infant must wear this apparatus continuously for 2 to 3 months and then use a night splint for another month, so the joint capsule can tighten and stabilize in correct alignment.

If treatment doesn't begin until after age 3 months, it may include bilateral skin traction (in infants) or skeletal traction (in children who have started walking) to reduce the dislocation by gradually abducting the hips. In Bryant's traction, or divarication traction, both legs are placed in traction, even if only one is affected, to help maintain immobilization. This type of traction is used in children who are younger than 3 years and weigh less than 35 lb (16 kg). The length of treatment is 2 to 3 weeks.

If traction fails, gentle closed reduction under general anesthetic can further abduct the hips; the child is then placed in a spica cast for 4 to 6 months. If closed treatment fails, open reduction, followed by immobilization in a spica cast for an average of 6 months, or osteotomy may be considered.

In the child 2 to 5 years old, treatment is difficult and includes skeletal traction and subcutaneous adductor tenotomy. Treatment begun after age 5 rarely restores satisfactory hip function.

Special Considerations

The child who must wear a splint, brace, or body cast needs special personal care that requires parent education.

- Teach parents how to correctly splint or brace the hips, as ordered. Stress the need for frequent checkups.
- Listen sympathetically to the parents' expressions of anxiety and fear. Explain possible causes of DDH, and give reassurance that early, prompt treatment will probably result in complete correction.
- During the child's first few days in a cast or splint-brace, expect some irritability due to the unaccustomed restricted movement. Encourage the parents to stay with the child as much as possible and to calm to provide reassurance.
- Assure parents that the child will adjust to this restriction and return to normal sleeping, eating, and playing behavior in a few days.
- Instruct parents to remove braces and splints while bathing the infant but to replace them immediately afterward. Stress good hygiene; parents should bathe and change the child frequently and wash perineum with warm water and soap at each diaper change.

If treatment requires a spica cast:

◆ When transferring the child immediately after casting, use your palms to avoid making dents in the cast. Such dents predispose the patient to pressure sores. Remember that the plaster cast needs 24 to 48 hours to dry naturally. Don't use heat to make it dry faster because heat also makes it more fragile.
◆ Immediately after the cast is applied, use a plastic sheet to protect it from moisture around the perineum and buttocks. Cut the sheet into strips long enough to cover the outside of the cast and tuck them about a finger length beneath the cast edges. Using overlapping strips of tape, tack the corner of each petal to the outside of the cast. Remove the plastic under the cast every 4 hours; then wash, dry, and retuck it. Disposable diapers folded lengthwise over the perineum may also be used.
◆ Position the child either on a Bradford frame elevated on blocks, with a bedpan under the frame, or on pillows to support the child's legs. Be sure to keep the cast dry and change the child's diapers often.
◆ Turn the child every 2 hours during the day and every 4 hours at night. Check color, sensation, and motion of the infant's legs and feet. Be sure to examine all toes. Notify the physician of dusky, cool, or numb toes.
◆ Check the cast daily for odors, which may herald infection.
◆ If the child complains of itching, he may benefit from diphenhydramine, or you may aim a hair dryer set on cool at the cast edges to relieve itching. Don't scratch or probe under the cast. Investigate any persistent itching.
◆ Provide adequate nutrition and maintain adequate fluid intake to avoid renal calculi and constipation, both complications of inactivity.
◆ Provide adequate stimuli to promote growth and development.
◆ Tell parents to watch for signs that the child is outgrowing the cast (cyanosis, cool limbs, or pain).
◆ Tell parents that treatment may be prolonged and requires patience.
◆ The patient in Bryant's traction may be cared for at home if the parents are taught traction application and maintenance.
◆ Encourage the parents to cuddle and hold the child and encourage interactions with siblings and friends.
◆ Maintain skin integrity and check circulation at least every 2 hours.
◆ Feed the child carefully to avoid aspiration and choking.
◆ Refer the child and parents to a child life specialist to ensure continued developmental progress.

MUSCULAR DYSTROPHY

Muscular dystrophy is a group of congenital disorders characterized by progressive symmetrical wasting of skeletal muscles without neural or sensory defects. Paradoxically, these wasted muscles tend to enlarge because of connective tissue and fat deposits, giving an erroneous impression of muscle strength. The main types of muscular dystrophy are Duchenne (pseudohypertrophic), Becker (benign pseudohypertrophic), facioscapulohumeral (Landouzy–Dejerine), limb-girdle dystrophy, Emery–Dreifuss muscular dystrophy, and myotonia congenita.

The prognosis varies. Duchenne muscular dystrophy generally strikes during early childhood and usually results in death in the 20s or early 30s. Patients with Becker muscular dystrophy typically live into their 40s. Facioscapulohumeral and limb-girdle dystrophies usually don't

shorten life.

Causes and Incidence

Muscular dystrophy is caused by various genetic mechanisms. Duchenne and Becker muscular dystrophies are X-linked recessive disorders. Both result from defects in the gene coding for the muscle protein dystrophin; the gene has been mapped to the Xp21 locus.

The incidence of muscular dystrophy is about 1 in 651,450 persons in the United States. Duchenne and Becker muscular dystrophies affect males almost exclusively.

Facioscapulohumeral dystrophy is an autosomal dominant disorder. Limb-girdle dystrophy is usually autosomal recessive. These two types affect both sexes about equally.

Pathophysiology

Abnormally permeable cell membranes allow leakage of various muscle enzymes, particularly creatine kinase. This metabolic defect that causes the muscle cells to die is present from fetal life onward. The absence of progressive muscle wasting at birth suggests that other factors compound the effect of dystrophin deficiency. The specific trigger is unknown, but phagocytosis of the muscle cells by inflammatory cells causes scarring and loss of muscle function.

As the disease progresses, skeletal muscle becomes almost totally replaced by fat and connective tissue. The skeleton eventually becomes deformed, causing progressive immobility. Cardiac and smooth muscle of the gastrointestinal (GI) tract typically become fibrotic. No consistent structural abnormalities are seen in the brain.

Complications

- Inhibited pulmonary function due to deformities
- Greater risk for pneumonia
- Respiratory problems lead to arrhythmias and hypertrophy

Signs and Symptoms

Although all four types of muscular dystrophy cause progressive muscular deterioration, the degree of severity and age of onset vary.

Duchenne muscular dystrophy begins insidiously, between ages 2 and 3. Initially, it affects leg and pelvic muscles but eventually spreads to the involuntary muscles. Muscle weakness produces a waddling gait, toe walking, and lordosis. Children with this disorder have difficulty climbing stairs, fall often, can't run properly, and their scapulae flare out (or "wing") when they raise their arms. Calf muscles especially become enlarged and firm. Muscle deterioration progresses rapidly, and contractures develop. Some have abrupt intermittent oscillations of the irises in response to light (Gower sign). Usually, these children are confined to wheelchairs by ages 9 to 12. Late in the disease, progressive weakening of cardiac muscle causes tachycardia, electrocardiogram abnormalities, and pulmonary complications. Death commonly results from sudden heart failure, respiratory failure, or infection.

Signs and symptoms of Becker muscular dystrophy resemble those of Duchenne muscular dystrophy, but they progress more slowly. It generally affects older boys and young men. Children affected usually walk through their teens and into adulthood—sometimes into their 40s. Cardiac involvement is much less frequent.

Facioscapulohumeral dystrophy is a slowly progressive and relatively benign form of muscular dystrophy that commonly occurs before age 10 but may develop during early

adolescence. The earlier the disease occurs, the more rapid and progressive it is. Initially, it weakens the muscles of the face, shoulders, and upper arms but eventually spreads to all voluntary muscles, producing a pendulous lower lip and absence of the nasolabial fold. Early symptoms include the inability to pucker the mouth or whistle, abnormal facial movements, and the absence of facial movements when laughing or crying. Other signs consist of diffuse facial flattening that leads to a masklike expression, winging of the scapulae, the inability to raise the arms above the head and, in infants, the inability to suckle.

Limb-girdle dystrophy follows a similarly slow course and commonly causes only slight disability. Usually, it begins between ages 6 and 10; less commonly, in early adulthood. The later the onset, the more rapid the progression. Muscle weakness first appears in the upper arm and pelvic muscles. Other symptoms include winging of the scapulae, lordosis with abdominal protrusion, waddling gait, poor balance, and the inability to raise the arms.

Diagnosis

Diagnosis depends on typical clinical findings, family history, and diagnostic test findings. If another family member has muscular dystrophy, its clinical characteristics can indicate the type of dystrophy the patient has and how he may be affected.

Electromyography typically demonstrates short, weak bursts of electrical activity or high-frequency, repetitive waxing and waning discharges in affected muscles. Muscle biopsy shows variations in the size of muscle fibers and, in later stages, shows fat and connective tissue deposits; dystrophin is absent in Duchenne dystrophy and diminished in Becker dystrophy. Serum creatine kinase level is markedly elevated in Duchenne, but only moderately elevated in Becker and facioscapulohumeral dystrophies.

Immunologic and molecular biologic assays available in specialized medical centers facilitate accurate prenatal and postnatal diagnosis of Duchenne and Becker muscular dystrophies and are replacing muscle biopsy and elevated serum creatine kinase levels in diagnosing these dystrophies. These assays can also help to identify carriers.

Treatment

No treatment stops the progressive muscle impairment of muscular dystrophy. However, orthopedic appliances, exercise, physical therapy, and surgery to correct contractures can help preserve the patient's mobility and independence. Prednisone improves muscle strength in patients with Duchenne.

Special Considerations

Comprehensive long-term care and follow-up, patient and family teaching, and psychological support can help the patient and the family deal with this disorder.

◆ When respiratory involvement occurs in Duchenne muscular dystrophy, encourage coughing, deep-breathing exercises, and diaphragmatic breathing. Teach parents how to recognize early signs of respiratory complications.
◆ Encourage and assist with active and passive ROM exercises to preserve joint mobility and prevent muscle atrophy.
◆ Advise the patient to avoid long periods of bed rest and inactivity; if necessary, limit TV viewing and other sedentary activities.
◆ Refer the patient for physical therapy. Splints, braces, trapeze bars, overhead slings, and a wheelchair can help preserve mobility. A footboard or high-topped sneakers and a foot cradle

increase comfort and prevent footdrop.
- Refer the patient to surgery to correct contractures.
- Because inactivity may cause constipation, encourage adequate fluid intake, increase dietary bulk, and obtain an order for a stool softener. The patient is prone to obesity due to reduced physical activity; assist with planning a low-calorie, high-protein, high-fiber diet if needed.
- Always allow the patient plenty of time to perform even simple physical tasks because if feeling slow and awkward.
- Encourage communication between the patient's family members to help them deal with the emotional strain this disorder produces. Provide emotional support to help the patient cope with continual changes in body image.

PEDIATRIC TIP *Help the child with Duchenne muscular dystrophy to maintain peer relationships and to realize the intellectual potential by encouraging the parents to keep the child in a regular school if possible.*

- If necessary, refer adult patients for counseling. Refer those who must acquire new job skills for vocational rehabilitation. (Contact the Department of Labor and Industry in your state for more information.) For information on social services and financial assistance, refer these patients and their families to the Muscular Dystrophy Association.
- Refer the patient's family members for genetic counseling.

Joints

SEPTIC ARTHRITIS

Septic, or infectious, arthritis is a medical emergency that occurs when bacterial invasion of a joint causes inflammation of the synovial lining, effusion and pyogenesis, and destruction of bone and cartilage. Septic arthritis can lead to ankylosis and even fatal septicemia. However, prompt antibiotic therapy and joint aspiration or drainage cures most patients.

Causes and Incidence

In most cases of septic arthritis, bacteria spread from a primary site of infection—usually in adjacent bone or soft tissue—through the bloodstream to the joint. Common infecting organisms in children are group B *Streptococcus* and *Haemophilus influenzae*. Adults are usually infected by *Staphylococcus, Streptococcus, Neisseria gonorrhoeae* (pneumonia), and group B *Streptococcus*, whereas chronic septic arthritis is caused by *Mycobacterium tuberculosis* and *Candida albicans*.

Various factors can predispose a person to septic arthritis. Any concurrent bacterial infection (of the genitourinary or the upper respiratory tract, for example) or serious chronic illness (such as malignancy, renal failure, rheumatoid arthritis, systemic lupus erythematosus, diabetes, or cirrhosis) heightens susceptibility. Consequently, elderly people and those who abuse I.V. drugs run a higher risk of developing septic arthritis. Of course, diseases that depress the immune system and immunosuppressant therapy increase susceptibility. Other predisposing factors include recent articular trauma, joint arthroscopy or other surgery, intra-articular injections, local joint abnormalities, animal or human bites, and nail puncture wounds.

Septic arthritis may be seen at any age in children, but it occurs most often in children younger than 3 years old. It's uncommon from age 3 until adolescence, at which time the incidence increases again.

Pathophysiology

Previously damaged joints, especially those damaged by rheumatoid arthritis, are the most susceptible to infection. The synovial membranes of these joints exhibit neovascularization and increased adhesion factors; both conditions increase the chance of bacteremia, resulting in a joint infection. Some microorganisms have properties that promote their tropism to the synovium. *Staphylococcus aureus* readily binds to articular sialoprotein, fibronectin collage, elastin, hyaluronic acid, and prosthetic material via specific tissue adhesion factors (microbial surface components recognizing adhesive matrix molecules). In adults, the arteriolar anastomosis between the epiphysis and the synovium permits the spread of osteomyelitis into the joint space.

Complications

- Joint degeneration
- Osteomyelitis

Signs and Symptoms

Acute septic arthritis begins abruptly, causing intense pain, inflammation, and swelling of the affected joint and low-grade fever. It usually affects a single joint. It most commonly develops in the large joints but can strike any joint, including the spine and small peripheral joints. The hip is a frequent site in infants. Systemic signs of inflammation may not appear in some patients. Migratory polyarthritis sometimes precedes localization of the infection. If the bacteria invade the hip, pain may occur in the groin, upper thigh, or buttock or may be referred to the knee.

Diagnosis

℞ **CONFIRMING DIAGNOSIS** *Identifying the causative organism in a Gram stain or culture of synovial fluid or a biopsy of synovial membrane confirms septic arthritis. When synovial fluid culture is negative, positive blood culture may confirm the diagnosis. Ultrasound of the hip is the modality of choice to detect fluid collections in the hip joint and can serve as a guide during aspiration procedures.*

Joint fluid analysis shows gross pus or watery, cloudy fluid of decreased viscosity, usually with 50,000/µL or more white cells, primarily neutrophils. Synovial fluid glucose concentration is usually greater than 40 mg/dL. (See *Other types of arthritis,* page 299.)

Other Types of Arthritis

Hemophilic Arthrosis

Hemophilic arthrosis produces transient or permanent joint changes. Often precipitated by trauma, hemophilic arthrosis usually arises between ages 1 and 5 and tends to recur until about age 10. It usually affects only one joint at a time—most commonly the knee, elbow, or ankle—and tends to recur in the same joint. Initially, the patient may feel only mild

discomfort; later, he may experience warmth, swelling, tenderness, and severe pain with adjacent muscle spasm that leads to flexion of the extremity.

Mild hemophilic arthrosis may cause only limited stiffness that subsides within a few days. In prolonged bleeding, however, symptoms may subside after weeks or months or not at all. Severe hemophilic arthrosis may be accompanied by fever and leukocytosis; severe, prolonged, or repeated bleeding may lead to chronic hemophilic joint disease.

Effective treatment includes I.V. infusion of the deficient clotting factor, bed rest with the affected extremity elevated, application of ice packs, analgesics, and joint aspiration. Physical therapy includes progressive range-of-motion and muscle-strengthening exercises to restore motion and to prevent contractures and muscle atrophy.

Intermittent Hydrarthrosis

Intermittent hydrarthrosis is a rare, benign condition characterized by regular, recurrent joint effusions. It most commonly affects the knee. The patient may have difficulty moving the affected joint but have no other arthritic symptoms. The cause of intermittent hydrarthrosis is unknown; onset is usually at or soon after puberty and may be linked to familial tendencies, allergies, or menstruation. No effective treatment exists.

Henoch–Schönlein Purpura

Henoch–Schönlein purpura—a vasculitic syndrome—is marked by palpable purpura, abdominal pain, and arthralgia that most commonly affects the knees and ankles, producing swollen, warm, and tender joints without joint erosion or deformity. Renal involvement is also common. Most patients have microscopic hematuria and proteinuria 4 to 8 weeks after onset. Incidence is highest in children and young adults, occurring most often in the spring after a respiratory infection. Treatment may include corticosteroids.

Traumatic Arthritis

Traumatic arthritis results from blunt, penetrating, or repeated trauma or from forced inappropriate motion of a joint or ligament. Clinical effects may include swelling, pain, tenderness, joint instability, and internal bleeding. Treatment includes analgesics, nonsteroidal anti-inflammatory drugs, application of cold followed by heat and, if needed, compression dressings, splinting, joint aspiration, casting, or possibly surgery.

Other diagnostic measures include the following:

- X-rays can show typical changes as early as 1 week after initial infection—distention of joint capsules, for example, followed by narrowing of joint space (indicating cartilage damage) and erosions of bone (joint destruction).
- White blood cell (WBC) count may be elevated, with many polymorphonuclear cells; erythrocyte sedimentation rate is increased.
- Triple-phase bone scan is often used in children. A whole body scan is preferred in very young children.
- CT and MRI can provide useful images to delineate the extent of the infection.

Treatment

Antibiotic therapy should begin as soon as a Gram stain has been done; it may be modified when

drug sensitivity of the infecting organism is known. Bioassays or bactericidal assays of synovial fluid and bioassays of blood may confirm clearing of the infection.

Rest, immobilization, elevation, and warm compresses help with pain relief. Analgesics are given for pain, if needed. The affected joint can be immobilized with a splint or put into traction until the patient can tolerate movement.

In severe cases, needle aspiration (arthrocentesis) or surgery may be done under sterile conditions to remove grossly purulent or infected joint fluid. Late reconstructive surgery is warranted only for severe joint damage and only after all signs of active infection have disappeared, which usually takes several months. Recommended procedures include arthroplasty and joint fusion. Prosthetic replacement remains controversial because it may exacerbate the infection, but it has helped patients with damaged femoral heads or acetabula.

Special Considerations

Management of septic arthritis demands meticulous supportive care, close observation, and control of infection.

- Practice strict sterile technique for all procedures. Wash hands carefully before and after giving care. Dispose of soiled linens and dressings properly. Prevent contact between immunosuppressed patients and infected patients.
- Watch for signs of joint inflammation: heat, redness, swelling, pain, or drainage. Monitor vital signs and fever pattern. Remember that corticosteroids mask signs of infection.
- Check splints or traction regularly. Keep the joint in proper alignment but avoid prolonged immobilization. Start passive ROM exercises immediately, and progress to active exercises as soon as the patient can move the affected joint and put weight on it.
- Monitor pain levels and medicate accordingly, especially before exercise, remembering that the pain of septic arthritis is easy to underestimate. Administer analgesics and opioids for acute pain and heat or ice packs for moderate pain.
- Warn the patient before the first aspiration that it will be *extremely* painful. Carefully evaluate the patient's condition after joint aspiration.

ELDER TIP Monitor older adults who are on long-term opioid therapy because these drugs can impair mental status and may contribute to falls and other accidents.

GOUT

Gout, also called *gouty arthritis*, is a metabolic disease marked by urate deposits, which cause painfully arthritic joints. (See *Gouty deposits*.) It can strike any joint but favors those in the feet and legs. Gout follows an intermittent course and typically leaves patients totally free from symptoms for years between attacks. It can cause chronic disability or incapacitation and, rarely, severe hypertension and progressive renal disease. The prognosis is good with treatment.

Gouty Deposits

The final stage of gout is marked by painful polyarthritis, with large, subcutaneous, tophaceous deposits in cartilage, synovial membranes, tendons, and soft tissue. The skin over the tophus is shiny, thin, and taut.

Causes and Incidence

Although the exact cause of primary gout remains unknown, it appears to be linked to a genetic defect in purine metabolism, which causes elevated blood levels of uric acid (hyperuricemia) due to overproduction of uric acid, retention of uric acid, or both. In secondary gout, which develops during the course of another disease (such as obesity, diabetes mellitus, hypertension, sickle cell anemia, and renal disease), hyperuricemia results from the breakdown of nucleic acids. Myeloproliferative and lymphoproliferative diseases, psoriasis, and hemolytic anemia are the most common causes. Primary gout usually occurs in men and in postmenopausal women; secondary gout occurs in elderly people.

Secondary gout can also follow drug therapy that interferes with uric acid excretion. Increased concentration of uric acid leads to urate deposits (*tophi*) in joints or tissues and consequent local necrosis or fibrosis. The risk is greater in men, postmenopausal women, and those who use alcohol.

Pathophysiology

When uric acid becomes supersaturated in blood and other body fluids, it crystallizes and forms a precipitate of urate salts that accumulate in connective tissue throughout the body; these deposits are called *tophi*. The presence of the crystals triggers an acute inflammatory response when neutrophils begin to ingest the crystals. Tissue damage begins when the neutrophils release their lysosomes (see Chapter 8). The lysosomes not only damage the tissues but also perpetuate the inflammation.

In asymptomatic gout, the serum urate level increases, but the urate doesn't crystallize or produce symptoms. As the disease progresses, it may cause hypertension or urate kidney stones may form.

Complications

- Renal calculi
- Atherosclerotic disease
- Cardiovascular disease
- Stroke
- Coronary thrombosis
- Hypertension

◆ Infection when tophi rupture

Signs and Symptoms

Gout develops in four stages: asymptomatic, acute, intercritical, and chronic. In asymptomatic gout, serum urate levels rise but produce no symptoms. As the disease progresses, it may cause hypertension or nephrolithiasis, with severe back pain. The first acute attack strikes suddenly and peaks quickly. Although it generally involves only one or a few joints, this initial attack is extremely painful. Affected joints are hot, tender, inflamed, and appear dusky-red or cyanotic. The metatarsophalangeal joint of the great toe usually becomes inflamed first (*podagra*), followed by the instep, ankle, heel, knee, or wrist joints. Sometimes a low-grade fever is present. Mild acute attacks usually subside quickly but tend to recur at irregular intervals. Severe attacks may persist for days or weeks.

Intercritical periods are the symptom-free intervals between gout attacks. Most patients have a second attack within 6 months to 2 years, but in some the second attack doesn't occur for 5 to 10 years. Delayed attacks are more common in untreated patients and tend to be longer and more severe than initial attacks. Such attacks are also polyarticular, invariably affecting joints in the feet and legs, and are sometimes accompanied by fever. A migratory attack sequentially strikes various joints and the Achilles tendon and is associated with either subdeltoid or olecranon bursitis.

Eventually, chronic polyarticular gout sets in. This final, unremitting stage of the disease is marked by persistent painful polyarthritis, with large, subcutaneous tophi in cartilage, synovial membranes, tendons, and soft tissue. Tophi form in fingers, hands, knees, feet, ulnar sides of the forearms, helix of the ear, Achilles tendons and, rarely, internal organs, such as the kidneys and myocardium. The skin over the tophus may ulcerate and release a chalky, white exudate or pus. Chronic inflammation and tophaceous deposits precipitate secondary joint degeneration, with eventual erosions, deformity, and disability. Kidney involvement, with associated tubular damage, leads to chronic renal dysfunction. Hypertension and albuminuria occur in some patients; urolithiasis is common.

Diagnosis

R **CONFIRMING DIAGNOSIS** *The presence of monosodium urate monohydrate crystals in synovial fluid taken from an inflamed joint or tophus establishes the diagnosis.*

Aspiration of synovial fluid (arthrocentesis) or of tophaceous material reveals needlelike intracellular crystals of sodium urate. Although hyperuricemia isn't specifically diagnostic of gout, serum uric acid is above normal. Urinary uric acid is usually higher in secondary gout than in primary gout. In acute attacks, erythrocyte sedimentation rate and WBC count may be elevated, and WBC count shifts to the left.

Initially, X-rays are normal. However, in chronic gout, X-rays show "punched out" erosions, sometimes with periosteal overgrowth. Outward displacement of the overhanging margin from the bone contour characterizes gout. X-rays rarely show tophi. (See *Understanding pseudogout*.)

Understanding Pseudogout

Also known as *calcium pyrophosphate disease,* pseudogout results when calcium

pyrophosphate crystals collect in periarticular joint structures.

Signs and Symptoms

Like true gout, pseudogout causes sudden joint pain and swelling, most commonly of the knee, wrist, and ankle or other peripheral joints.

Pseudogout attacks are self-limiting and triggered by stress, trauma, surgery, severe dieting, thiazide therapy, or alcohol abuse. Associated symptoms resemble those of rheumatoid arthritis and osteoarthritis. Many patients may be asymptomatic.

Establishing a Diagnosis

Diagnosis of pseudogout hinges on joint aspiration and synovial biopsy to detect calcium pyrophosphate crystals. X-rays show calcium deposits in the fibrocartilage and linear markings along the bone ends. Blood tests may detect an underlying endocrine or metabolic disorder.

Relief for Pressure and Inflammation

Management of pseudogout may include aspirating the joint to relieve pressure; instilling corticosteroids and administering analgesics, salicylates, phenylbutazone, or other nonsteroidal anti-inflammatory drugs to treat inflammation and, if appropriate, treating the underlying disorder. Without treatment, pseudogout leads to permanent joint damage in about half of those it affects, most of whom are older adults.

Treatment

Correct management seeks to terminate an acute attack, reduce hyperuricemia, and prevent recurrence, complications, and the formation of renal calculi. (See *Preventing gout*.) Colchicine is effective in reducing pain, swelling, and inflammation; pain often subsides within 12 hours of treatment and is completely relieved in 48 hours. Treatment for the patient with acute gout consists of bed rest; immobilization and protection of the inflamed, painful joints; and local application of heat or cold, whichever works for the patient. Maximal doses of nonsteroidal anti-inflammatory drugs (NSAIDs) usually provide excellent relief for patients who can tolerate them; doses should be gradually reduced after several days.

PREVENTION
PREVENTING GOUT

Because the cause of gout is unknown, the disease can't be prevented. However, it's important to teach your patients how to prevent acute gout attacks to reduce the risk of joint damage. Acute gout attacks can be prevented by dietary changes, weight reduction, adequate fluid intake, and drugs.

Dietary Restrictions

Dietary changes include avoidance of foods high in purine, such as alcohol (especially beer and wine), organ meats, sardines, sweetbreads, peas, and lentils.

Weight Reduction

Obese patients need to lose weight at a slow rate. Losing weight rapidly may temporarily increase uric acid levels.

Fluid Intake

It's also important to drink adequate amounts of fluids to dilute the amount of uric acid in the blood. This will help decrease the risk of kidney stone formation. Taking the prescribed drug slows the production of uric acid and speeds its elimination from the body.

ELDER TIP Older patients are at risk for GI bleeding associated with NSAID use. Encourage the elderly patient to take these drugs with meals and monitor the patient's stools for occult blood.

Resistant inflammation may require oral corticosteroids or intra-articular corticosteroid injection to relieve pain. Treatment for chronic gout aims to decrease serum uric acid level. Continuing maintenance dosage of allopurinol may be given to suppress uric acid formation or control uric acid levels, preventing further attacks. However, this powerful drug should be used cautiously in patients with renal failure. Uricosuric agents promote uric acid excretion and inhibit accumulation of uric acid, but their value is limited in patients with renal impairment. These medications shouldn't be given to patients with renal calculi.

Adjunctive therapy emphasizes a few dietary restrictions, primarily the avoidance of alcohol and purine-rich foods (organ meats, beer, wine, and certain types of fish are high in purines). Obese patients should try to lose weight because obesity puts additional stress on painful joints.

In some cases, surgery may be necessary to improve joint function or correct deformities. Tophi must be excised and drained if they become infected or ulcerated. They can also be excised to prevent ulceration, improve the patient's appearance, or make it easier for the patient to wear shoes or gloves.

Special Considerations

Patient care for gout includes these interventions:

- ◆ Encourage bed rest but use a bed cradle to keep bedcovers off extremely sensitive, inflamed joints.
- ◆ Give pain medication, as needed, especially during acute attacks. Apply hot or cold packs to inflamed joints according to what the patient finds effective. Administer anti-inflammatory medication and other drugs, as ordered. Watch for adverse effects. Be alert for GI disturbances with colchicine.
- ◆ Watch for acute gout attacks 24 to 96 hours after surgery. Even minor surgery can precipitate an attack. Before and after surgery, administer colchicine as ordered, to help prevent gout attacks.
- ◆ Tell the patient to avoid high-purine foods, such as anchovies, liver, sardines, kidneys, sweetbreads, lentils, and alcoholic beverages—especially beer and wine—which raise the urate level. Explain the principles of a gradual weight-reduction diet to obese patients.
- ◆ Advise the patient to report any adverse effects of allopurinol, such as drowsiness, dizziness, nausea, vomiting, urinary frequency, or dermatitis.

NEUROGENIC ARTHROPATHY

Neurogenic arthropathy, also called *Charcot arthropathy*, is a progressively degenerative disease of peripheral and axial joints, resulting from impaired sensory innervation. The loss of sensation in the joints causes progressive deterioration, resulting from trauma or primary disease, which leads to laxity of supporting ligaments and eventual disintegration of the affected joints.

Causes and Incidence

Neurogenic arthropathy is most common in men older than 40 years. In adults, the most common cause of neurogenic arthropathy is diabetes mellitus. Other causes include tabes dorsalis (especially among patients 40 to 60 years old), syringomyelia (progresses to neurogenic arthropathy in about 25% of patients), myelopathy of pernicious anemia, spinal cord trauma, paraplegia, hereditary sensory neuropathy, and Charcot–Marie–Tooth disease. Amyloidosis, peripheral nerve injury, myelomeningocele (in children), leprosy, and alcoholism may cause neurogenic arthropathy, but only in rare occurrences.

Frequent intra-articular injection of corticosteroids has also been linked to neurogenic arthropathy. The analgesic effect of the corticosteroids may mask symptoms and allow continuous stress to accelerate joint destruction.

Pathophysiology

Many conditions predispose to neurogenic arthropathy. Impaired deep pain sensation or proprioception affects the joint's normal protective reflexes, often allowing trauma (especially repeated minor episodes) and small periarticular fractures to go unrecognized. Increased blood flow to bone from reflex vasodilation, resulting in active bone resorption, contributes to bone and joint damage.

Each new injury sustained by the joint causes more distortion as it heals. Hemorrhagic joint effusions and multiple small fractures can occur, accelerating disease progression. Ligamentous laxity, muscular hypotonia, and rapid destruction of joint cartilage are common, predisposing to joint dislocations, which also accelerate disease progression. Advanced neurogenic arthropathy can cause hypertrophic changes, destructive changes, or both.

Complications

- Joint subluxation or dislocation
- Pathologic fractures
- Infection
- Pseudogout
- Neurovascular compression

Signs and Symptoms

Neurogenic arthropathy begins insidiously with swelling, warmth, decreased mobility, and instability in a single joint or in many joints. It can progress to deformity. The first clue to vertebral neuroarthropathy, which progresses to gross spinal deformity, may be nothing more than a mild, persistent backache. Characteristically, pain is minimal despite obvious deformity.

The specific joint affected varies according to the underlying cause. Diabetes usually attacks the joints and bones of the feet; tabes dorsalis attacks the large weight-bearing joints, such as the knee, hip, ankle, or lumbar and dorsal vertebrae (Charcot spine); syringomyelia causes occurrence in the shoulder, elbow, or cervical intervertebral joint. Neurogenic arthropathy caused by intra-articular injection of corticosteroids usually develops in the hip or knee joint.

Diagnosis

Patient history of painless joint deformity and underlying primary disease suggests neurogenic arthropathy. Physical examination may reveal bone fragmentation in advanced disease. X-rays confirm diagnosis and assess severity of joint damage. In the early stage of the disease, soft-tissue swelling or effusion may be the only overt effect; in the advanced stage, articular fracture, subluxation, erosion of articular cartilage, periosteal new bone formation, and excessive growth of marginal loose bodies (osteophytosis) or resorption may be seen. CT scan helps define the extent of disease.

Other diagnostic measures include:

- vertebral examination: narrowing of disk spaces, deterioration of vertebrae, and osteophyte formation, leading to ankylosis and deforming kyphoscoliosis
- synovial biopsy: bony fragments and bits of calcified cartilage.

Treatment

Effective management relieves pain with analgesics and immobilization using crutches, splints, braces, and restriction of weight bearing to the affected joint.

In severe disease, surgery may include arthrodesis or, in severe diabetic neuropathy, amputation. However, surgery risks further damage through nonunion and infection.

Special Considerations

Assess the pattern of pain and give analgesics, as needed. Check sensory perception, ROM, alignment, joint swelling, and the status of underlying disease.

- Teach the patient to use joint protection techniques, to avoid physically stressful actions that may cause pathologic fractures, and to take safety precautions, such as removing throw rugs and other objects over which the patient may trip.
- Advise the patient to report severe joint pain, swelling, or instability. Warm compresses may be applied to relieve local pain and tenderness.
- Instruct the patient in the proper technique for crutches or other orthopedic devices. Stress the importance of proper fitting and regular professional readjustment of such devices. Warn the patient that impaired sensation might allow damage from these aids to occur and progress without discomfort.
- Emphasize the need to continue regular treatment of the underlying disease.

OSTEOARTHRITIS

Osteoarthritis, the most common form of arthritis, is a chronic disease that causes deterioration of the joint cartilage and formation of reactive new bone at the margins and subchondral areas of the joints. This degeneration results from a breakdown of chondrocytes, most commonly in the distal interphalangeal and proximal interphalangeal joints, but also in the hip and knee joints.

Osteoarthritis is widespread, occurring equally in both sexes. Its earliest symptoms typically begin after age 40 and may progress with advancing age.

Disability depends on the site and severity of involvement and can range from minor limitation of the dexterity of the fingers to severe disability in persons with hip or knee involvement. The rate of progression varies, and joints may remain stable for years in an early stage of deterioration.

Causes and Incidence

Studies indicate that osteoarthritis is acquired and probably results from a combination of metabolic, genetic, chemical, and mechanical factors. Secondary osteoarthritis usually follows an identifiable predisposing event—most commonly trauma, metabolic conditions, congenital deformity, or obesity—and leads to degenerative changes.

Osteoarthritis may first appear between ages 30 and 40 and is present in almost everyone by age 70. Before age 55, it affects men and women equally, but after age 55 the incidence is higher in women.

ELDER TIP Primary osteoarthritis is strongly associated with aging, and indeed aging may predispose to the cartilage degeneration common in persons with osteoarthritis.

Pathophysiology

The major defect in primary and secondary osteoarthritis is loss of articular cartilage. Articular cartilage is probably lost through enzymatic breakdown of the cartilage matrix—the proteoglycans, glycosaminoglycans, and collagen. Other studies indicate that interleukin-1 may play a part in cartilage destruction.

Osteoarthritis occurs in synovial joints. The joint cartilage deteriorates, and reactive new bone forms at the margins and subchondral areas of the joints. The degeneration results from damage to the chondrocytes. Cartilage softens with age, narrowing the joint space. Mechanical injury erodes articular cartilage, leaving the underlying bone unprotected. This causes sclerosis or thickening and hardening of the bone underneath the cartilage.

Articular cartilage particles within the joint irritate the synovial lining, which becomes fibrotic and limits joint movement. Synovial fluid may be forced into defects in the bone, causing cysts. New bone, called *osteophyte* (bone spur), forms at joint margins as the articular cartilage erodes, causing gross alteration of the bony contours and enlargement of the joint. The spurlike bony projections enlarge until small pieces called joint mice break off into the synovial cavity.

Complications

- Flexion contractures
- Subluxation and deformity
- Ankylosis
- Bony cysts
- Gross bone overgrowth
- Central cord syndrome
- Nerve root compression
- Cauda equina syndrome

Signs and Symptoms

The most common symptom of osteoarthritis is a deep, aching joint pain, particularly after exercise or weight bearing, usually relieved by rest. Other symptoms include stiffness in the morning and after inactivity (improves with activity), aching during changes in weather, "grating" of the joint during motion, altered gait contractures, joint instability, and limited movement. These symptoms increase with poor posture, obesity, and stress to the affected joint.

Osteoarthritis of the interphalangeal joints produces irreversible joint changes and node formation. The nodes eventually become red, swollen, and tender, causing numbness and loss of dexterity. (See *What happens in osteoarthritis*.)

PATHOPHYSIOLOGY
WHAT HAPPENS IN OSTEOARTHRITIS

The characteristic breakdown of articular cartilage is a gradual response to aging or to predisposing factors, such as joint abnormalities or traumatic injury.

Chondrocytes break down.

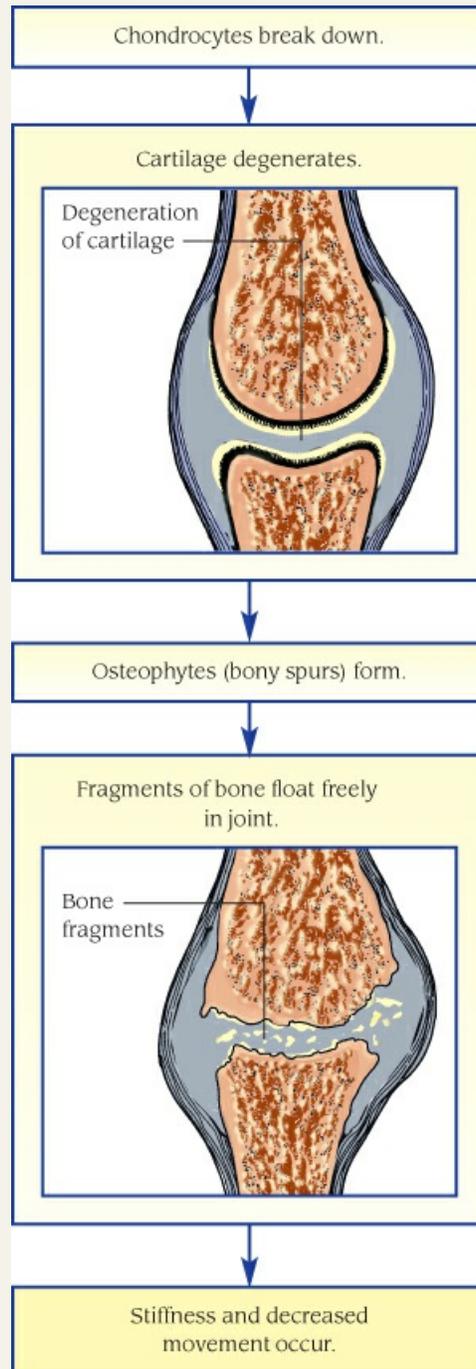
Cartilage degenerates.

Degeneration of cartilage

Osteophytes (bony spurs) form.

Fragments of bone float freely in joint.

Bone fragments

Stiffness and decreased movement occur.


Diagnosis

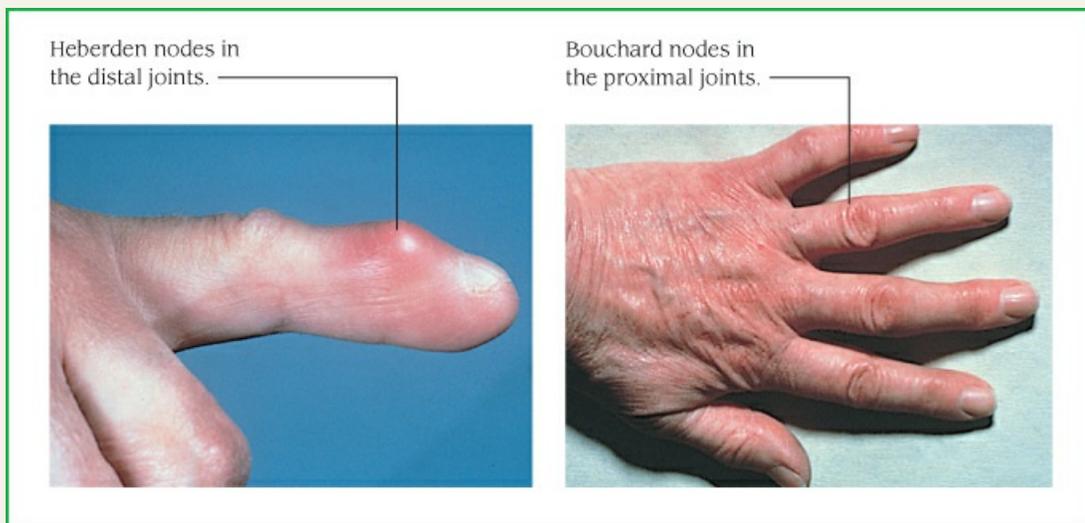
A thorough physical examination confirms typical symptoms, and absence of systemic symptoms rules out an inflammatory joint disorder. X-rays of the affected joint help confirm diagnosis of osteoarthritis but may be normal in the early stages. X-rays may require many views and typically show:

- narrowing of joint space or margin
- cystlike bony deposits in joint space and margins and sclerosis of the subchondral space
- joint deformity due to degeneration or articular damage
- bony growths at weight-bearing areas
- fusion of joints. (See *A close look at the effects of osteoarthritis*, page 306.)

A Close Look at the Effects of Osteoarthritis

Involvement of the interphalangeal (finger bone) joints produces irreversible changes in the distal joints (Heberden nodes) and the proximal joints (Bouchard nodes), as shown below. These nodes can be painless initially, with gradual progression to or sudden flare-ups of redness, swelling, tenderness, and impaired sensation and dexterity.

Heberden nodes in the distal joints.

Bouchard nodes in the proximal joints.


MRI and CT scans may be used to show cartilage breakdown and bone abnormalities. Importantly, MRI can detect signs of inflammation of the bone or the synovial membrane.

Treatment

Treatment is aimed at relieving pain, maintaining or improving mobility, and minimizing disability. Medications include NSAIDs, cyclo-oxygenase-2 inhibitors and, in some cases, intra-articular injections of corticosteroids. Studies indicate that glucosamine and chondroitin may be useful in controlling symptoms and reducing functional impairment. Injecting artificial joint fluid into the knee can provide relief of pain for up to 6 months.

Effective treatment also reduces stress by weight loss and supporting or stabilizing the joint

with crutches, braces, cane, walker, cervical collar, or traction. Exercise, such as through physical therapy, is integral to maintaining or improving joint mobility. Other supportive measures include massage, moist heat, paraffin dips for hands, protective techniques to prevent undue stress on the joints, and adequate rest (particularly after activity).

Surgical treatment, such as one of the following, is reserved for patients who have severe disability or uncontrollable pain:

- Arthroplasty (partial or total): replacement of deteriorated part of joint with prosthetic appliance
- Arthrodesis: surgical fusion of bones, used primarily in spinal surgery (laminectomy)
- Osteoplasty: scraping and lavage of deteriorated bone from joint
- Osteotomy: change in alignment of bone to relieve stress by excision of wedge of bone or cutting of bone

Special Considerations

Patient care for osteoarthritis includes the following:

- Promote adequate rest, particularly after activity. Plan rest periods during the day and provide for adequate sleep at night. Moderation is the key—teach the patient to pace daily activities.
- Assist with physical therapy, and encourage the patient to perform gentle, isometric ROM exercises.
- Provide emotional support and reassurance to help the patient cope with limited mobility. Explain that osteoarthritis *isn't* a systemic disease.

Specific patient care depends on the affected joint:

- *Hand:* Apply hot soaks and paraffin dips to relieve pain, as ordered.
- *Spine (lumbar and sacral):* Recommend a firm mattress (or bed board) to decrease morning pain.
- *Spine (cervical):* Check cervical collar for constriction; watch for redness with prolonged use.
- *Hip:* Use moist heat pads to relieve pain and administer antispasmodic drugs, as ordered. Assist with ROM and strengthening exercises, always making sure the patient gets the proper rest afterward. Check crutches, cane, braces, and walker for proper fit, and teach the patient to use them correctly. For example, the patient with unilateral joint involvement should use an orthopedic appliance such as a walker or a cane. Recommend the use of cushions when sitting as well as the use of an elevated toilet seat.
- *Knee:* Twice daily, assist with prescribed ROM exercises, exercises to maintain muscle tone, and progressive resistance exercises to increase muscle strength. Provide elastic supports or braces if needed.

To minimize the long-term effects of osteoarthritis:

- Teach the patient to take medication exactly as prescribed and to report adverse effects immediately.
- Advise the patient to avoid overexertion, taking care to stand and walk correctly, to minimize high-impact activities, and to be especially careful when stooping or picking up objects.
- Instruct the patient to wear proper-fitting, supportive shoes and not to allow the heels to become worn down.
- Advise the patient to install safety devices at home such as guard rails in the bathroom.
- Instruct the patient to maintain proper body weight to lessen strain on joints.

Bones

OSTEOMYELITIS

Osteomyelitis is a pyogenic bone infection that may be chronic or acute. It commonly results from a combination of local trauma, which is usually quite trivial but results in hematoma formation, and an acute infection originating elsewhere in the body. Although osteomyelitis usually remains localized, it can spread through the bone to the marrow, cortex, and periosteum. Acute osteomyelitis is usually a blood-borne disease, which most commonly affects rapidly growing children. Chronic osteomyelitis, which is rare, is characterized by multiple draining sinus tracts and metastatic lesions. (See *Stages of osteomyelitis*.)

PATHOPHYSIOLOGY
STAGES OF OSTEOMYELITIS

The illustrations show the progression of osteomyelitis.

INITIAL INFECTION

Initial site of infection
Periosteum
Fibula
Tibia

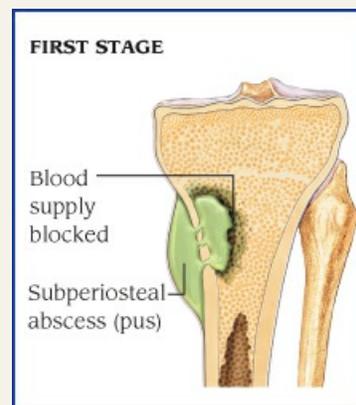
FIRST STAGE

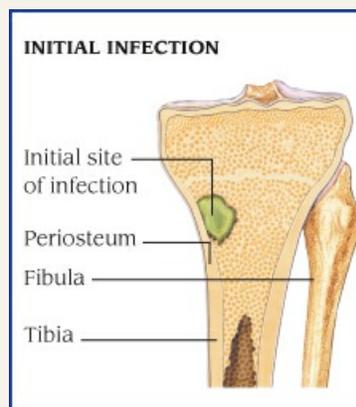
Blood supply blocked
Subperiosteal abscess (pus)

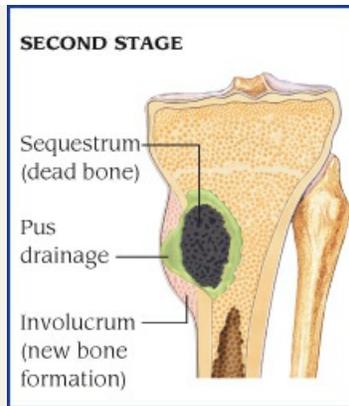
SECOND STAGE

Sequestrum (dead bone)

Pus drainage

Involucrum (new bone formation)






Causes and Incidence

Virtually any pathogenic bacteria can cause osteomyelitis under the right circumstances. Typically, these organisms find a culture site in a hematoma from recent trauma or in a weakened area, such as the site of surgery or local infection (for example, furunculosis), and spread directly to bone. As the organisms grow and form pus within the bone, tension builds within the rigid medullary cavity, forcing pus through the haversian canals. This forms a subperiosteal abscess that deprives the bone of its blood supply and may eventually cause necrosis. In turn, necrosis stimulates the periosteum to create new bone (*involucrum*); the old bone (*sequestrum*) detaches and works its way out through an abscess or the sinuses. By the time sequestrum forms, osteomyelitis is chronic.

Osteomyelitis occurs more commonly in children (especially boys) than in adults—usually as a complication of an acute localized infection. The most common sites in children are the lower end of the femur and the upper end of the tibia, humerus, and radius. The most common sites in adults are the pelvis and vertebrae, generally because of contamination associated with surgery or trauma. Other common sites are sternoclavicular, sacroiliac, and symphysis pubis. The incidence of both chronic and acute osteomyelitis is declining, except in drug abusers. With prompt treatment, the prognosis for acute osteomyelitis is very good; for chronic osteomyelitis, which is more prevalent in adults, the prognosis is still poor.

Pathophysiology

Typically, bacteria find a culture site in a hematoma from recent trauma or in a weakened area, such as the site of local infection (e.g., furunculosis), and travel through the bloodstream to the metaphysis, the section of a long bone that's continuous with the epiphysis plates, where the blood flows into sinusoids. Predisposing factors include diabetes mellitus, sickle cell disease, and being immunocompromised.

Complications

- Chronic osteomyelitis
- Poor joint function
- Amputation of limb

Signs and Symptoms

The onset of acute osteomyelitis is usually rapid, with sudden pain accompanied by tenderness, heat, swelling, and restricted movement of the affected area. Associated systemic symptoms may include tachycardia, sudden fever, nausea, and malaise. Generally, the clinical features of both chronic and acute osteomyelitis are the same, except that chronic infection can persist intermittently for years, flaring up spontaneously after minor trauma. Sometimes, however, the only symptom of chronic infection is the persistent drainage of pus from an old pocket in a sinus tract.

Diagnosis

Patient history, physical examination, and blood tests help to confirm osteomyelitis:

- WBC count shows leukocytosis.
- Erythrocyte sedimentation rate or C-reactive protein is usually elevated but nonspecific in acute cases.
- Cultures of the lesion indicate the source of the organism. Blood cultures help identify causative organism.
- MRI is best for detecting spinal infection.
- CT is best for visualizing islands of dead bone.

X-rays may not show bone involvement until the disease has been active for some time, usually 2 to 3 weeks. Bone scans can detect early infection. Diagnosis must rule out poliomyelitis, rheumatic fever, myositis, and bone fractures.

CONFIRMING DIAGNOSIS *The gold standard for diagnosing osteomyelitis is histopathologic and microscopic examination of bone.*

Treatment

Treatment for acute osteomyelitis should begin before definitive diagnosis. Treatment includes administration of antibiotics after blood cultures are taken; early surgical drainage to relieve pressure buildup and sequestrum formation; immobilization of the affected bone by a cast, traction, or bed rest; and supportive measures, such as analgesics and I.V. fluids.

If an abscess forms, treatment includes incision and drainage, followed by a culture of the drained fluid. Intracavitary instillation of antibiotics may be done through closed-system continuous irrigation with low intermittent suction; limited irrigation with blood drainage system with suction; or local application of packed, wet, antibiotic-soaked dressings.

In addition to these therapies, chronic osteomyelitis usually requires surgery to remove dead bone (*sequestrectomy*) and to promote drainage (*saucerization*). The area may be filled with bone graft or packing material to promote new bone tissue. An infected prosthesis is removed and a new one is implanted the same day or after resolution of the infection.

Some centers use hyperbaric oxygen to increase the activity of naturally occurring leukocytes. Free-tissue transfers and local muscle flaps are also used to fill in dead space and increase blood supply.

Special Considerations

Your major concerns are to control infection, protect the bone from injury, and offer meticulous supportive care.

- Use strict sterile technique when changing dressings and irrigating wounds. If the patient is in

skeletal traction for compound fractures, cover insertion points of pin tracks with small, dry dressings, and instruct not to touch the skin around the pins and wires.

◆ Administer I.V. fluids to maintain adequate hydration as necessary. Provide a diet high in protein and vitamin C.

◆ Assess vital signs, wound appearance, and new pain, which may indicate secondary infection, daily.

◆ Carefully monitor suctioning equipment and the amount of solution it instills and suctions.

◆ Support the affected limb with firm pillows. Keep the limb level with the body; *don't* let it sag. Turn the patient gently every 2 hours and watch for signs of developing pressure ulcers. Report any signs of pressure ulcer formation immediately.

◆ Support the cast with firm pillows and smooth rough cast edges by petaling with pieces of adhesive tape or moleskin. Check circulation and drainage; if a wet spot appears on the cast, circle it with a marking pen, and note the time of appearance (on the cast). Be aware of how much drainage is expected. Check the circled spot at least every 4 hours and report any enlargement immediately.

◆ Protect the patient from mishaps, such as jerky movements and falls, which may threaten bone integrity. Report sudden pain, crepitus, or deformity immediately. Watch for any sudden malposition of the limb, which may indicate fracture.

◆ Provide emotional support and appropriate diversions. Before discharge, teach the patient how to protect and clean the wound and, most importantly, how to recognize signs of recurring infection (increased temperature, redness, localized heat, and swelling). Stress the need for follow-up examinations. Instruct the patient to seek prompt treatment for possible sources of recurrence—blisters, boils, styes, and impetigo.

OSTEOPOROSIS

Osteoporosis is a metabolic bone disorder in which the rate of bone resorption accelerates while the rate of bone formation slows down, causing a loss of bone mass. Bones affected by this disease lose calcium and phosphate salts and thus become porous, brittle, and abnormally vulnerable to fractures. Osteoporosis may be primary or secondary to an underlying disease. Primary osteoporosis is commonly called *postmenopausal osteoporosis* because it typically develops in postmenopausal women. (See *What is osteoporosis,* page 309.)

PATHOPHYSIOLOGY
WHAT IS OSTEOPOROSIS?

Osteoporosis is a metabolic disease of the skeleton that reduces the amount of bone tissue. Bones weaken as local cells resorb, or take up, bone tissue. Trabecular bone at the core becomes less dense, and cortical bone on the perimeter losses thickness.

Trabecular bone

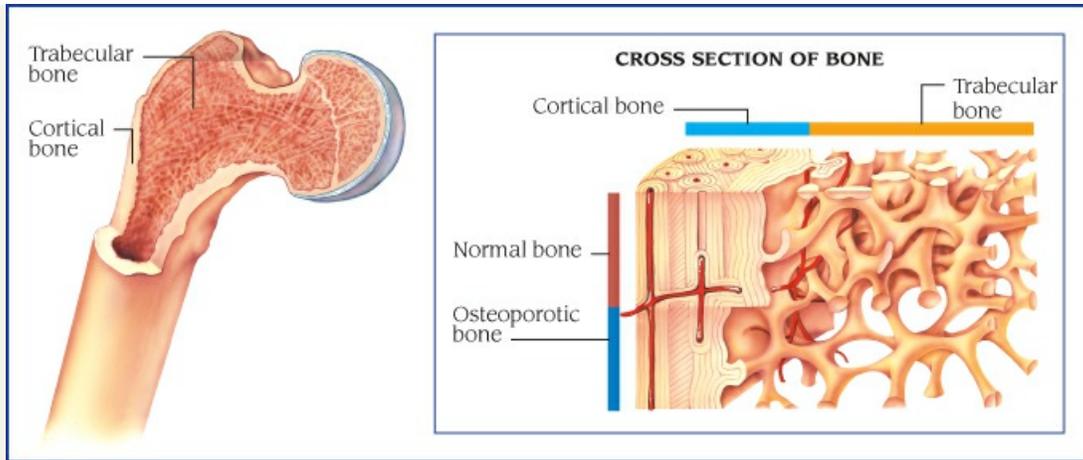
Cortical bone

CROSS SECTION OF BONE

Cortical bone

Trabecular bone

Normal bone

Osteoporotic bone


Causes and Incidence

The cause of primary osteoporosis is unknown; however, a mild but prolonged negative calcium balance, resulting from an inadequate dietary intake of calcium, may be an important contributing factor—as may declining gonadal or adrenal function, faulty protein metabolism due to estrogen deficiency, and sedentary lifestyle. (See *Preventing osteoporosis*, page 310.) Causes of secondary osteoporosis are many: prolonged therapy with steroids or heparin, cigarette smoking, total immobilization or disuse of a bone (as with hemiplegia, for example), alcoholism, malnutrition, malabsorption, celiac disease, scurvy, lactose intolerance, osteogenesis imperfecta, Sudeck atrophy (localized to hands and feet, with recurring attacks), and endocrine disorders (hypopituitarism, acromegaly, thyrotoxicosis, long-standing diabetes mellitus, hyperthyroidism).

PREVENTION
PREVENTING OSTEOPOROSIS

To help prevent osteoporosis, tell the patient to follow these guidelines.

Maintain Adequate Calcium and Vitamin D Intake

Postmenopausal women and all men and women older than 65 years should consume 1,500 mg of calcium and at least 800 international units of vitamin D daily. Getting enough vitamin D is as important as getting enough calcium because vitamin D aids in absorption of calcium and improves muscle strength.

Most people get adequate amounts of vitamin D from sunlight; however, this may not be a good source for those who live in high latitudes, are housebound, or regularly use sunscreen or avoid the sun entirely because of the risk of skin cancer. Calcium supplements with added vitamin D are a good alternative.

Exercise

Exercise can help build strong bones and slow bone loss. Strength-training exercises should be combined with weight-bearing exercises. Strength training helps strengthen muscles and bones in the arms and upper spine, and weight-bearing exercises mainly affect the bones in

the legs, hips, and lower spine.

Limit Alcohol Intake

Consuming more than two alcoholic drinks a day may decrease bone formation and reduce the body's ability to absorb calcium.

Limit Caffeine

Limit the amount of caffeinated beverages to about two to three cups of coffee a day. If the diet contains adequate calcium, moderate caffeine consumption won't harm you. Don't forget to count caffeine-containing beverages such as colas and teas.

The incidence of osteoporosis is high, with an estimated 10 million U.S. residents suffering from osteoporosis and another 18 million suffering from low bone mass, or osteopenia. Incidence is higher in women than in men, with women older than 50 years accounting for 20% of cases. Another 30% of women have osteopenia, which can deteriorate into osteoporosis.

Pathophysiology

In normal bone, the rates of bone formation and resorption are constant; replacement follows resorption immediately, and the amount of bone replaced equals the amount of bone resorbed. Osteoporosis develops when the remodeling cycle is interrupted, and new bone formation falls behind resorption.

When bone is resorbed faster than it forms, the bone becomes less dense. Men have about 30% greater bone mass than women, which may explain why osteoporosis develops later in men.

Complication

- ◆ Bone fractures, especially in vertebrae, femoral neck, and distal radius

Signs and Symptoms

Osteoporosis is usually discovered incidentally on X-ray; the patient may have been asymptomatic for years. Vertebral collapse, causing a backache with pain that radiates around the trunk, is the most common presenting feature. Any movement or jarring aggravates the backache.

In another common pattern, osteoporosis can develop insidiously, with increasing deformity, kyphosis, and loss of height. Sometimes a dowager hump is present. As bones weaken, spontaneous wedge fractures, pathologic fractures of the neck or femur, Colles fractures after a minor fall, and hip fractures become increasingly common.

ELDER TIP Osteoporosis usually affects older people and is a major risk factor in vertebral compression fractures and hip fractures.

Osteoporosis primarily affects the weight-bearing vertebrae. Only when the condition is advanced or severe, as in Cushing syndrome or hyperthyroidism, do comparable changes occur in the skull, ribs, and long bones.

Diagnosis

Differential diagnosis must exclude other causes of rarefying bone disease, especially those

affecting the spine, such as metastatic cancer and advanced multiple myeloma. The differential diagnosis should also exclude osteomalacia, osteogenesis imperfecta tarda, skeletal hyperparathyroidism, and hyperthyroidism. Initial evaluation attempts to identify the specific cause of osteoporosis through the patient history.

- Bone mineral density testing is performed in dual-energy X-ray absorptiometry (DEXA) and measures the mineralization of bones. It's the gold standard for evaluating osteoporosis.
- A spine CT scan shows demineralization. Quantitative CT can evaluate bone density but is less available and more expensive than DEXA.
- X-rays show fracture or vertebral collapse in severe cases.
- Urine calcium can provide evidence of bone turnover but is limited in value. Newer tests include urinary N-telopeptide to help diagnose osteoporosis.

Treatment

Treatment aims to slow down or prevent bone loss, prevent additional fractures, and control pain. A physical therapy program that emphasizes gentle exercise and activity is an important part of the treatment. Medications may include bisphosphonates, such as alendronate and risedronate, to prevent bone loss and reduce the risk of fractures. The physician may also recommend adequate calcium and vitamin D intake. Raloxifene and calcitonin have also been prescribed. Weakened vertebrae should be supported, usually with a back brace. Surgery can correct pathologic fractures of the femur by open reduction and internal fixation. Colles fracture requires reduction with casting immobilization for 4 to 10 weeks.

The incidence of primary osteoporosis may be reduced through adequate intake of dietary calcium and regular exercise. Fluoride treatments may also offer some preventive benefit. Hormone replacement therapy (HRT) with estrogen and progesterone may retard bone loss and prevent the occurrence of fractures; however, this therapy remains controversial. HRT decreases bone reabsorption and increases bone mass. Secondary osteoporosis can be prevented through effective treatment of the underlying disease as well as corticosteroid therapy, early mobilization after surgery or trauma, careful observation for signs of malabsorption, and prompt treatment of hyperthyroidism. Men with osteoporosis, hypogonadism, and low libido may benefit from testosterone replacement therapy. Decreased alcohol consumption and caffeine use, as well as smoking cessation, are also helpful preventive measures.

Special Considerations

Your care plan should focus on the patient's fragility, stressing careful positioning, ambulation, and prescribed exercises.

- Check the patient's skin daily for redness, warmth, and new sites of pain, which may indicate new fractures. Encourage activity; help the patient walk several times daily. As appropriate, perform passive ROM exercises or encourage the patient to perform active exercises. Make sure the patient regularly attends scheduled physical therapy sessions.
- Impose safety precautions. Keep the side rails of the patient's bed in raised position. Move the patient gently and carefully always. Explain to the patient's family and ancillary health care personnel how easily an osteoporotic patient's bones can fracture.
- Provide a balanced diet, high in nutrients that support skeletal metabolism: vitamin D, calcium, and protein. Administer analgesics and heat to relieve pain.
- Make sure the patient and the family clearly understand the prescribed drug regimen. Tell

them how to recognize significant adverse effects and to report them immediately. The patient should also report any new pain sites immediately, especially after trauma, no matter how slight. Advise the patient to sleep on a firm mattress and avoid excessive bed rest. Ensure the patient knows how to wear the back brace.

◆ Thoroughly explain osteoporosis to the patient and the family. If the patient/family don't understand the nature of this disease, they may feel the fractures could have been prevented if they had been more careful.

◆ Teach the patient to use good body mechanics—to stoop before lifting anything and to avoid twisting movements and prolonged bending.

LEGG–CALVÉ–PERTHES DISEASE

Legg–Calvé–Perthes disease (also called *coxa plana*) is ischemic necrosis that leads to eventual flattening of the head of the femur caused by vascular interruption. The disease occurs in five stages.

◆ Growth arrest: Avascular phase; may last 6 to 12 months. Early changes include inflammation and synovitis of the hip and ischemic changes in the ossific nucleus of the femoral head.

◆ Subchondral fracture: Radiographic visualization of the fracture varies with the age of the child at clinical onset and the extent of epiphyseal involvement; may last 3 to 8½ months.

◆ Reabsorption, also called *fragmentation* or *necrosis:* The necrotic bone beneath the subchondral fracture is gradually and irregularly reabsorbed; lasts 6 to 12 months.

◆ Reossification, or healing stage: Ossification of the primary bone begins irregularly in the subchondral area and progresses centrally; takes 6 to 24 months.

◆ Healed stage, also called *residual stage:* Complete ossification of the epiphysis of the femoral head, with or without residual deformity.

Although this disease usually runs its course in 3 to 4 years, it may lead to premature osteoarthritis later in life from misalignment of the acetabulum and flattening of the femoral head.

Causes and Incidence

The exact vascular obstructive changes that initiate Legg–Calvé–Perthes disease are unknown. Current etiologic theories include venous obstruction with secondary intraepiphyseal thrombosis, trauma to retinacular vessels, vascular irregularities (congenital or developmental), vascular occlusion secondary to increased intracapsular pressure from acute transient synovitis, and increased blood viscosity resulting in stasis and decreased blood flow.

Legg–Calvé–Perthes disease occurs most frequently in boys 4 to 10 years old and tends to occur in families. Although typically unilateral, it occurs bilaterally in 20% of patients.

Pathophysiology

The disease occurs in four stages. The first stage, synovitis, is characterized by synovial inflammation and increased joint fluid, and typically lasts 1 to 3 weeks. In the second (avascular) stage, vascular interruption causes necrosis of the ossification center of the femoral head (usually in several months to 1 year). In the third stage (which ordinarily lasts 2 to 4 years), revascularization, a new blood supply causes bone resorption and deposition of immature bone cells. New bone replaces necrotic bone and the femoral head gradually reforms. The final, or residual, stage involves healing and regeneration. Immature bone cells are replaced by normal

bone cells, thereby fixing the joint's shape. There may or may not be residual deformity, based on the degree of necrosis that occurred in stage two.

Complications

- Permanent disability
- Premature osteoarthritis

Signs and Symptoms

The first indication of Legg–Calvé–Perthes disease is usually a persistent thigh pain or limp that becomes progressively severe. This symptom appears during the second stage, when bone resorption and deformity begin. Other effects may include mild pain in the hip, thigh, or knee that's aggravated by activity and relieved by rest; muscle spasm; atrophy of muscles in the upper thigh; slight shortening of the leg; and severely restricted abduction and internal rotation of the hip.

Diagnosis

℞ CONFIRMING DIAGNOSIS *A thorough physical examination and clinical history suggest Legg–Calvé–Perthes disease. Hip X-rays confirm the diagnosis, with findings that vary according to the stage of the disease. Anterior–posterior X-ray and MRI enhance early diagnosis of necrosis and visualization of articular surface.*

Diagnostic evaluation must also differentiate between Legg–Calvé–Perthes disease (restriction of only the abduction and rotation of the hip) and infection or arthritis (restriction of all motion). Aspiration and culture of synovial fluid rule out joint sepsis.

Treatment

The aim of treatment is to protect the femoral head from further stress and damage by containing it within the acetabulum. After 1 to 2 weeks of bed rest, therapy may include reduced weight bearing by means of bed rest in bilateral split counterpoised traction, then application of hip abduction splint or cast, or weight bearing while a splint, cast, or brace holds the leg in abduction. Braces may remain in place for 6 to 18 months. Analgesics help relieve pain. Physical therapy with passive and active ROM exercises after cast removal helps restore motion.

For a young child in the early stages of the disease, osteotomy and subtrochanteric derotation provide maximum confinement of the epiphysis within the acetabulum to allow return of the femoral head to normal shape and full ROM. Proper placement of the epiphysis thus allows remolding with ambulation. Postoperatively, the patient requires a spica cast for about 2 months.

Special Considerations

When caring for the hospitalized child, do the following.

- Monitor the patient's fluid intake and output. Maintain sufficient fluid balance. Provide a diet sufficient for growth without causing excessive weight gain, which might necessitate cast change and loss of the corrective position.
- Provide cast care. Turn the child every 2 to 3 hours to expose the cast to air. When the cast is still wet, turn the child with your palms because depressions in the plaster may lead to pressure ulcers. After the cast dries, petal it with pieces of adhesive tape or moleskin,

changing them as they become soiled. Protect the cast with a plastic covering during each bowel movement.

- Watch for circulatory or neurologic changes in the leg. Check toes for color, temperature, swelling, sensation, and motion; report dusky, cool, numb toes immediately. Check the skin under the cast with a flashlight every 4 hours while the patient is awake. Follow a consistent plan of skin care to prevent skin breakdown. *Never* use oils or powders under the cast because they increase skin breakdown and soften the cast. Check under the cast daily for odors, particularly after surgery, to detect skin breakdown or wound problems. Report persistent soreness.
- Relieve itching by using a hair dryer (set on cool) at the cast edges; this also decreases dampness from perspiration. If itching becomes excessive, get an order for an antipruritic. *Never* insert an object under the cast to scratch.
- Provide continuous emotional support. Explain all procedures and the need for bed rest, cast, or braces to the child; encourage the child to verbalize fears and anxiety. Encourage parents to participate in their child's care. Teach them proper cast care and how to recognize signs of skin breakdown. Offer tips for making home management of the bedridden child easier. Tell them what special supplies are needed: pajamas and trousers a size larger (open the side seam, and attach Velcro fasteners to close it), bedpan, adhesive tape, moleskin and, possibly, a hospital bed.
- When the cast is removed, debride dry, scaly skin *gradually* by applying lotion after bathing.
- Stress the need for follow-up care to monitor rehabilitation. Also stress home tutoring and socialization to promote normal mental and emotional growth and development.

OSGOOD–SCHLATTER DISEASE

Osgood–Schlatter disease, also called *osteochondrosis*, is a painful, incomplete separation of the epiphysis of the tibial tubercle from the tibial shaft. This is the common cause of knee pain in an adolescent. Severe disease may cause permanent tubercle enlargement.

Causes and Incidence

Osgood–Schlatter disease probably results from trauma before the complete fusion of the epiphysis to the main bone has occurred (between ages 10 and 15). Other causes include locally deficient blood supply and genetic factors. It's most common in active adolescent boys, generally affecting one or both knees. It may occur in girls, typically between ages 10 and 11.

Pathophysiology

The proximal tibia has two ossification centers, the proximal tibial epiphysis and the tibial tuberosity, which are separated by a cartilage bridge. Before ossification, the tibial tuberosity is composed of fibrocartilage that has good tensile strength. However, during ossification, columnated cartilaginous cells with poor tensile strength replace the fibrocartilage, and it is within this small window between fibrocartilage and ossified matrix that the tibial tuberosity is at risk of avulsion fractures.

Complications

- Irregular growth
- Partial avascular necrosis of proximal tibial epiphysis

Signs and Symptoms

The patient complains of constant aching and pain and tenderness over the tibial tubercle, which worsens during any activity that causes forceful contraction of the patellar tendon on the tubercle, such as ascending or descending stairs, running, squatting, jumping, or forced flexion. The pain may be associated with some obvious soft-tissue swelling and localized heat and tenderness.

Diagnosis

Physical examination supports the diagnosis: the examiner forces the tibia into internal rotation while slowly extending the patient's knee from 90 degrees of flexion; at about 30 degrees, flexion produces pain that subsides immediately with external rotation of the tibia. Visible soft-tissue edema may be present over proximal tibial tuberosity with tenderness to palpation. Some patients' quadriceps may atrophy.

X-rays may be normal or show epiphyseal separation and soft-tissue swelling for up to 6 months after onset; eventually, they may show bone fragmentation. Bone scan may show increased uptake in the tibial tuberosity—even greater than the typical increased uptake in the normal epiphysis of the unaffected side.

Treatment

Osteochondrosis is usually self-limiting, and conservative treatment designed to reduce pain and decrease stress to the affected knee is usually adequate. Avoid strenuous exercises that involve the knee; use frequent ice applications after exercise for pain. Rest and quadriceps strengthening, hip extension, adductor strengthening, and hamstring and quadriceps-stretching exercises are recommended. Knee immobilization in extension for 6 to 8 weeks may be necessary. Analgesics and NSAIDs may be given for pain relief and reduction of local swelling.

Rarely, conservative measures fail, and surgery may be necessary. Such surgery includes removal or fixation of the epiphysis or drilling holes through the tubercle to the main bone to form channels for rapid revascularization.

Special Considerations

The following special considerations should be observed for patients with Osgood–Schlatter disease:

- Monitor the patient's circulation, sensation, and pain, and watch for excessive bleeding after surgery.
- Assess daily for limitation of motion. Administer analgesics as needed.
- Make sure knee support or splint isn't too tight. Keep the cast dry and clean, and petal it around the top and bottom margins to avoid skin irritation. Teach proper use of crutches. Tell the patient to protect the injured knee with padding and to avoid trauma and repeated flexion (running, contact sports).
- Monitor for muscle atrophy.
- Give reassurance and emotional support because disruption of normal activities is difficult for an active teenager. Emphasize that restrictions are temporary.

PAGET DISEASE

Paget disease, also called *osteitis deformans*, is a slowly progressive metabolic bone disease

characterized by an initial phase of excessive bone resorption (osteoclastic phase), followed by a reactive phase of excessive abnormal bone formation (osteoblastic phase). The new bone structure, which is chaotic, fragile, and weak, causes painful deformities of both external contour and internal structure. Paget disease usually localizes in one or more areas of the skeleton, but occasionally skeletal deformity is widely distributed. The bones most frequently affected are pelvis, leg, spine, arm, collar, and skull. It can be fatal, particularly when it's associated with heart failure (widespread disease creates a continuous need for high cardiac output), bone sarcoma, or giant-cell tumors.

Causes and Incidence

The disease occurs worldwide, but is more common in Europe, Australia, and New Zealand, where it's seen in up to 5% of the elderly population. The incidence is higher in men than in women and usually occurs in patients older than 40 years. Although its exact cause is unknown, one theory holds that early viral infection causes a dormant skeletal infection that erupts many years later as Paget disease. Genetic factors are also suspected.

Pathophysiology

Repeated episodes of accelerated osteoclastic resorption of spongy bone occur. The trabeculae diminish, and vascular fibrous tissue replaces marrow. This is followed by short periods of rapid, abnormal bone formation. The collagen fibers in this new bone are disorganized, and glycoprotein levels in the matrix decrease. The partially resorbed trabeculae thicken and enlarge because of excessive bone formation, and the bone becomes soft and weak.

Eventually, Paget disease progresses to an inactive phase in which abnormal remodeling is minimal or absent.

Complications

- Fractures
- Vertebral collapse
- Paraplegia
- Blindness and hearing loss (impingement on cranial nerves)
- Osteoarthritis
- Sarcoma
- Hypertension
- Renal calculi
- Hypercalcemia
- Gout

Signs and Symptoms

Clinical effects of Paget disease vary. Early stages may be asymptomatic, but when pain does develop, it's usually severe and persistent and may coexist with impaired movement resulting from impingement of abnormal bone on the spinal cord or sensory nerve root. Such pain intensifies with weight bearing.

The patient with skull involvement shows characteristic cranial enlargement over frontal and occipital areas (hat size may increase) and may complain of headaches. Other deformities include kyphosis (spinal curvature due to compression fractures of pagetic vertebrae), accompanied by a barrel-shaped chest and asymmetrical bowing of the tibia and femur, which

commonly reduces height. Pagetic sites are warm and tender and are susceptible to pathologic fractures after minor trauma. Pagetic fractures heal slowly and usually incompletely.

Bony impingement on the cranial nerves may cause blindness and hearing loss with tinnitus and vertigo. Other complications include hypertension, renal calculi, hypercalcemia, gout, heart failure, a waddling gait (from softening of pelvic bones), and hearing loss.

Diagnosis

X-rays taken before overt symptoms develop show increased bone expansion and density. A bone scan, which is more sensitive than X-rays, clearly shows early pagetic lesions (radioisotope collects around areas of active disease). CT scan or MRI shows extra bony extension if sarcomatous degeneration occurs. Bone biopsy reveals characteristic mosaic pattern.

Other laboratory findings include:

- elevated serum alkaline phosphatase levels (an index of osteoblastic activity and bone formation)
- elevated serum calcium

Increasing use of routine chemistry screens (including serum alkaline phosphatase) is making early diagnosis more common. Serum osteocalcin and N-telopeptide are usually increased.

Treatment

Primary treatment consists of drug therapy and includes one of the following:

- Calcitonin (subcutaneously or intranasally) is used to retard bone resorption (which relieves bone lesions) and reduce levels of serum alkaline phosphate and urinary hydroxyproline secretion. Although calcitonin therapy requires long-term maintenance, improvement is noticeable after the first few weeks of treatment.
- Bisphosphonates, such as alendronate, ibandronate, pamidronate, risedronate, and zoledronic acid, produce rapid reduction in bone turnover and relieve pain. They also reduce serum alkaline phosphate and urinary hydroxyproline secretion. Therapy produces noticeable improvement after 1 to 3 months.
- Plicamycin, a cytotoxic antibiotic, is used to decrease calcium, urinary hydroxyproline, and serum alkaline phosphatase. It produces remission of symptoms within 2 weeks and biochemical improvement in 1 to 2 months. Plicamycin is used to control the disease and is reserved for severe cases with neurologic compromise and for those resistant to other therapies. However, it may destroy platelets or compromise renal function.

Orthopedic surgery is used to correct specific deformities in severe cases, reduce or prevent pathologic fractures, correct secondary deformities, or relieve neurologic impairment. Joint replacement is difficult because bonding material (methyl methacrylate) doesn't set properly on pagetic bone.

Other treatment varies according to symptoms. Analgesics or NSAIDs may be given to control pain.

Special Considerations

Patients with Paget disease require the following special considerations:

- To evaluate the effectiveness of analgesics, assess level of pain daily. Watch for new areas of pain or restricted movements, which may indicate new fracture sites, and sensory or motor

disturbances, such as difficulty in hearing, seeing, or walking.

◆ Monitor serum calcium and alkaline phosphatase levels.

◆ If the patient is confined to prolonged bed rest, prevent pressure ulcers by providing good skin care. Reposition the patient frequently and use a flotation mattress. Provide high-topped sneakers to prevent footdrop.

◆ Monitor intake and output. Encourage adequate fluid intake to minimize renal calculi formation.

◆ Demonstrate how to inject calcitonin and rotate injection sites properly or how to perform nasal inhalation of the drug if that's the form prescribed. Warn the patient that adverse effects may occur (nausea, vomiting, local inflammatory reaction at injection site, facial flushing, itching of hands, and fever). Give reassurance that these adverse effects are usually mild and infrequent.

◆ To help the patient adjust to the changes in lifestyle imposed by this disease, teach how to pace activities and, if necessary, how to use assistive devices. Encourage the patient to follow a recommended exercise program, avoiding both immobilization and excessive activity. Suggest a firm mattress or a bed board to minimize spinal deformities. Warn against imprudent use of analgesics because diminished sensitivity to pain resulting from analgesic use may make the patient unaware of new fractures. To prevent falls at home, advise removal of throw rugs and other obstacles.

◆ Help the patient and family make use of community support resources, such as a visiting nurse or home health agency. For more information, refer them to the Paget's Disease Foundation.

HALLUX VALGUS

Hallux valgus is a lateral deviation of the great toe at the metatarsophalangeal joint. It occurs with medial enlargement of the first metatarsal head and bunion formation (bursa and callus formation at the bony prominence).

Causes and Incidence

Hallux valgus may be acquired or congenital. Acquired hallux valgus results from degenerative arthritis or prolonged pressure on the foot, especially from narrow-toed or high-heeled shoes that compress the forefoot. Bony alignment is normal at the outset of the disorder. This form typically occurs more frequently in women.

In congenital hallux valgus, abnormal bony alignment—increased space between first and second metatarsal (metatarsus primus varus)—causes bunion formation. This form is usually first observed in childhood.

Pathophysiology

During the gait cycle, the hallux and digits generally remain parallel to the long axis of the foot, regardless of the degree of forefoot abduction (or pronation) occurring. This is because of the pull of the conjoined adductor tendon, extensor hallucis longus, and flexor hallucis longus tendons. The tendons gain greater mechanical advantage the further the joint is displaced, with tension created in the medial aspect of the joint and compression laterally.

Line of pull of extensor hallucis longus causing metatarsal to deviate medially and hallux to deviate laterally.

Medial tension causes the medial collateral ligaments to pull on the dorsomedial aspect of the

first metatarsal head, causing bone proliferation. Lateral tension causes the sesamoid apparatus to fixate in a laterally dislocated position. Remodeling also occurs laterally in addition to medially, as evidenced by the increase in the proximal articular set angle or structural remodeling of the cartilage. Therefore, without correction of the biomechanical factors, excessive pronation continues, with propagation of the deformity.

Complications

- Foot deformity
- Difficulty walking

Signs and Symptoms

Hallux valgus characteristically begins as a tender bunion covered by deformed, hard, erythematous skin and palpable bursa, typically distended with fluid. The first indication of hallux valgus may be pain over the bunion from shoe pressure. Pain can also stem from traumatic arthritis, bursitis, or abnormal stresses on the foot because hallux valgus changes the body's weight-bearing pattern. In an advanced stage, a flat, splayed forefoot may occur, with severely curled toes (*hammer toes*) and formation of a small bunion on the fifth metatarsal. (See *Hammer toe*.)

Hammer Toe

In hammer toe, the toe assumes a clawlike appearance from hyperextension of the metatarsophalangeal joint, flexion of the proximal interphalangeal joint, and hyperextension of the distal interphalangeal joint, usually under pressure from hallux valgus displacement. A painful corn forms on the back of the interphalangeal joint and on the bone end, and a callus forms on the sole of the foot, both of which make walking painful. Hammer toe may be mild or severe and can affect one toe or all five, as in clawfoot (which also causes a very high arch).

Hammer toe can be congenital (and familial) or acquired from constantly wearing short, narrow shoes, which put pressure on the end of the long toe. Acquired hammer toe is commonly bilateral and often develops in children who rapidly outgrow shoes and socks.

In young children, or adults with early deformity, repeated foot manipulation and splinting of the affected toe relieve discomfort and may correct the deformity. Other treatment includes protection of protruding joints with felt pads, corrective footwear (open-toed shoes and sandals or special shoes that conform to the shape of the foot), the use of a metatarsal arch support, and exercises, such as passive manual stretching of the proximal interphalangeal joint. Severe deformity requires surgical fusion of the proximal interphalangeal joint in a straight position.

Diagnosis

℞ **CONFIRMING DIAGNOSIS** *A red, tender bunion makes hallux valgus obvious. X-rays confirm the diagnosis by showing medial deviation of the first metatarsal and lateral deviation of the great toe.*

Treatment

In the very early stages of acquired hallux valgus, good foot care and wide-toed shoes may eliminate the need for further treatment. Other useful measures for early management include felt pads to protect the bunion, foam pads or other devices to separate the first and second toes at night, and a supportive pad and exercises to strengthen the metatarsal arch. Early treatment is vital in patients predisposed to foot problems, such as those with rheumatoid arthritis or diabetes mellitus. If the disease progresses to severe deformity with disabling pain, bunionectomy is necessary.

After surgery, the toe is immobilized in its corrected position in one of two ways: with a soft compression dressing that may cover the entire foot or just the great toe and the second toe, thereby serving as a splint, or with a short cast such as a light slipper spica cast.

The patient may need crutches or controlled weight bearing. Depending on the extent of the surgery, some patients walk on their heels a few days after surgery; others must wait 4 to 6 weeks to bear weight on the affected foot. Supportive treatment may include physical therapy, such as warm compresses, soaks, and exercises, and analgesics to relieve pain and stiffness.

Special Considerations

Before surgery, obtain a patient history and assess the neurovascular status of the foot (temperature, color, sensation, and blanching sign). If necessary, teach the patient how to walk with crutches.

After bunionectomy:

- Apply ice to reduce swelling. Support the patient's foot with pillows, elevate the foot of the bed, or put the bed in Trendelenburg position.
- Record the neurovascular status of the toes, including the patient's ability to move the toes (dressing may inhibit movement), every hour for the first 24 hours and then every 4 hours. Report any change in neurovascular status to the surgeon immediately.
- Prepare the patient for walking by instructing to dangle the affected foot over the side of the bed for a short time before standing, allowing a gradual increase in venous pressure. If crutches are needed, supervise the patient in using them, and make sure this skill is mastered before discharge. The patient should have a proper cast shoe or boot to protect the cast or dressing.
- Before discharge, instruct the patient to limit activities, to rest frequently with feet elevated, to elevate feet whenever pain or swelling is experienced, and to wear wide-toed shoes and sandals after the dressings are removed. Urge female patients not to resume wearing high-heeled, pointy-toed shoes.

- Teach proper foot care, such as cleanliness, massages, and cutting toenails straight across to prevent ingrown nails and infection.
- Suggest exercises to do at home to strengthen foot muscles, such as standing at the edge of a step on the heel and then raising and inverting the top of the foot.
- Stress the importance of follow-up care and prompt medical attention for painful bunions, corns, and calluses.

KYPHOSIS

Kyphosis, also called *roundback* or *hunchback*, is an anteroposterior curving of the spine that causes a bowing of the back, commonly at the thoracic, but sometimes at the thoracolumbar or

sacral, level. The normal spine displays some convexity, but excessive thoracic kyphosis is pathologic.

Causes and Incidence

Kyphosis occurs in children and adults. Although congenital kyphosis is rare, it's usually severe, with resultant cosmetic deformity and reduced pulmonary function.

Adolescent kyphosis (also called *Scheuermann disease*, *juvenile kyphosis*, and *vertebral epiphysitis*), the most common form of this disorder, may result from growth retardation or a vascular disturbance in the vertebral epiphysis (usually at the thoracic level) during periods of rapid growth or from congenital deficiency in the thickness of the vertebral plates. Other causes include infection, inflammation, aseptic necrosis, and disk degeneration. The subsequent stress of weight bearing on the compromised vertebrae may result in the thoracic hump commonly seen in adolescents with kyphosis. Symptomatic adolescent kyphosis is more prevalent in girls than in boys and occurs most commonly between ages 12 and 16.

Adult kyphosis (adult roundback) may result from aging and associated degeneration of intervertebral disks, atrophy, and osteoporotic collapse of the vertebrae; from endocrine disorders, such as hyperparathyroidism and Cushing disease; and from prolonged steroid therapy. Adult kyphosis may also result from conditions such as arthritis, Paget disease, polio, compression fracture of the thoracic vertebrae, metastatic tumor, plasma cell myeloma, or tuberculosis (TB). In both children and adults, kyphosis may also result from poor posture.

Disk lesions called *Schmorl nodes* may develop in anteroposterior curving of the spine and are localized protrusions of nuclear material through the cartilage plates and into the spongy bone of the vertebral bodies. If the anterior portions of the cartilage are destroyed, bridges of new bone may transverse the intervertebral space, causing ankylosis.

Pathophysiology

The pathophysiology of kyphosis depends on the etiologic factor. The exact cause of Scheuermann disease is still imprecisely defined. Scheuermann postulated that the condition resulted from avascular necrosis of the apophyseal ring. Other theories include histologic abnormalities at the endplate, osteoporosis, and mechanical factors that affect spinal growth. A Danish study demonstrated an important genetic component to the entity.

Postural kyphosis is present when accentuated kyphosis is observed without the characteristic 5 degrees of wedging over three consecutive vertebral segments that defines Scheuermann kyphosis. This is felt to be due to muscular imbalance leading to the roundback appearance of these individuals.

When focal kyphosis occurs after a fracture, more height is lost in the anterior aspect than in the posterior aspect; this is the typical fracture pattern. The angulation can increase as the fracture heals, placing pressure on the spinal cord. Patients with fractures have historically been treated with laminectomy alone, especially in the thoracic spine, and they often had progressive kyphosis at the fracture site.

Postinfectious kyphosis occurs in a manner similar to that just described. The mechanical integrity of the anterior column is lost as a consequence of the infectious process. Bending forces then accentuate the normal sagittal contour.

Complications

- Debilitating back pain

- Leg weakness or paralysis
- Decreased lung capacity

Signs and Symptoms

Development of adolescent kyphosis is usually insidious and may be asymptomatic except for the obvious curving of the back (sometimes more than 90 degrees). In some adolescents, kyphosis may produce mild pain at the apex of the curve (about 50% of patients), fatigue, tenderness or stiffness in the involved area or along the entire spine, and prominent vertebral spinous processes at the lower dorsal and upper lumbar levels, with compensatory increased lumbar lordosis, and hamstring tightness. Rarely, kyphosis may cause neurologic damage: spastic paraparesis secondary to spinal cord compression or herniated nucleus pulposus. In both adolescent and adult forms of kyphosis that aren't due to poor posture alone, the spine won't straighten when the patient assumes a recumbent position.

Adult kyphosis produces a characteristic roundback appearance, possibly associated with pain, weakness of the back, and generalized fatigue. Unlike the adolescent form, adult kyphosis rarely produces local tenderness, except in osteoporosis with a recent compression fracture.

Diagnosis

Physical examination reveals curvature of the thoracic spine in varying degrees of severity. X-rays may show vertebral wedging, Schmorl nodes, irregular end plates, and possibly mild scoliosis of 10 to 20 degrees. MRI should be used to distinguish adolescent kyphosis from TB and other inflammatory or neoplastic diseases that cause vertebral collapse; the severe pain, bone destruction, or systemic symptoms associated with these diseases help rule out a diagnosis of kyphosis. Other sites of bone disease, primary sites of malignancy, and infection must also be evaluated, possibly through vertebral biopsy.

Treatment

For kyphosis caused by poor posture alone, treatment may consist of therapeutic exercises, bed rest on a firm mattress (with or without traction), and a brace to straighten the kyphotic curve until spinal growth is complete. Corrective exercises include pelvic tilt to decrease lumbar lordosis, hamstring stretch to overcome muscle contractures, and thoracic hyperextension to flatten the kyphotic curve. These exercises may be performed in or out of the brace. Lateral X-rays taken every 4 months evaluate correction. Gradual weaning from the brace can begin after maximum correction of the kyphotic curve and after vertebral wedging has decreased and the spine has reached full skeletal maturity. Loss of correction indicates that weaning from the brace has been too rapid, and time out of the brace is decreased accordingly.

Treatment for both adolescent and adult kyphosis also includes appropriate measures for the underlying cause and, possibly, spinal arthrodesis for relief of symptoms. Although rarely necessary, surgery may be recommended when kyphosis causes neurologic damage, a spinal curve greater than 60 degrees, or intractable and disabling back pain in a patient with full skeletal maturity. Preoperative measures may include halo-femoral traction. Corrective surgery includes a posterior spinal fusion with spinal instrumentation, iliac bone grafting, and plaster immobilization. Anterior spinal fusion followed by immobilization in plaster may be necessary when kyphosis produces a spinal curve greater than 70 degrees.

Special Considerations

Effective management of kyphosis necessitates first-rate supportive care for patients in traction or a brace, skillful patient teaching, and sensitive emotional support.

- Teach the patient with adolescent kyphosis caused by poor posture alone the prescribed therapeutic exercises and the fundamentals of good posture. Suggest bed rest when pain is severe. Encourage use of a firm mattress, preferably with a bed board. If the patient needs a brace, explain its purpose, how and when to wear it.
- Teach good skin care. Tell the patient not to use lotions, ointments, or powders where the brace contacts the skin. Provide instructions that only the physician or orthotist should adjust the brace.
- If corrective surgery is needed, explain all preoperative tests thoroughly as well as the need for postoperative traction or casting, if applicable. After surgery, check neurovascular status every 2 to 4 hours for the first 48 hours, and report any changes immediately. Turn the patient often by logrolling and teach the patient how to logroll independently. Provide meticulous skin care. Check the skin at the cast edges several times a day; use heel and elbow protectors to prevent skin breakdown. Remove antiembolism stockings, if ordered, at least three times a day for at least 30 minutes. Change dressings as ordered.
- Provide emotional support. The adolescent patient is likely to exhibit mood changes and periods of depression. Maintain communication and offer frequent encouragement and reassurance.
- Assist during removal of sutures and application of a new cast (usually about 10 days after surgery). Encourage gradual ambulation (usually with the use of a tilt table in the physical therapy department).
- At discharge, provide detailed, written cast care instructions. Tell the patient to immediately report pain, burning, skin breakdown, loss of feeling, tingling, numbness, or cast odor. Advise the patient to drink plenty of liquids to avoid constipation and to report any illness immediately. Arrange for home visits by a social worker and a home care nurse, as needed.

HERNIATED DISK

Herniated disk, also called *ruptured* or *slipped disk* and *herniated nucleus pulposus*, occurs when all or part of the nucleus pulposus—the soft, gelatinous, central portion of an intervertebral disk —is forced through the disk's weakened or torn outer ring (anulus fibrosus). When this happens, the extruded disk may impinge on spinal nerve roots as they exit from the spinal canal or on the spinal cord itself, resulting in back pain and other signs of nerve root irritation.

Causes and Incidence

Herniated disks may result from severe trauma or strain or may be related to intervertebral joint degeneration. Although herniated disks usually occur in adults (mostly men) younger than 45 years old, elderly people are also at risk because minor trauma may cause herniation in disks that have begun to deteriorate due to age. Ninety percent of herniation occurs in the lumbar and lumbosacral regions of the spine; 8% in the cervical region; and 1% to 2% in the thoracic region. Patients with a congenitally small lumbar spinal canal or with osteophyte formation on the vertebrae may be more susceptible to nerve root compression by a herniated disk and more likely to have neurologic symptoms.

Pathophysiology

An intervertebral disk has two parts: the soft center called the *nucleus pulposus* and the tough,

fibrous surrounding ring called the *anulus fibrosus*. The nucleus pulposus acts as a shock absorber, distributing the mechanical stress applied to the spine when the body moves.

Physical stress, usually a twisting motion, can tear or rupture the anulus fibrosus so that the nucleus pulposus herniates into the spinal canal. When this happens, the extruded disk may impinge on spinal nerve roots as they exit from the spinal canal or on the spinal cord itself, resulting in back pain and other signs of nerve root irritation. The vertebrae move closer together and in turn exert pressure on the nerve roots as they exit between the vertebrae. Pain and possibly sensory and motor loss follow. A herniated disk can also follow intervertebral joint degeneration; minor trauma may cause herniation.

Herniation occurs in three steps:

- *protrusion*—nucleus pulposus presses against the anulus fibrosus
- *extrusion*—nucleus pulposus bulges forcibly through the anulus fibrosus, pushing against the nerve root
- *sequestration*—anulus fibrosis gives way as the disk's core bursts and presses against the nerve root.

Complications

- Long-term back pain
- Rarely, spinal cord injuries, resulting in loss of movement or sensation in legs and feet or loss of bowel and bladder function

Signs and Symptoms

The overriding symptom of lumbar herniated disk is severe low back pain that radiates to the buttocks, legs, and feet, usually unilaterally. When herniation follows trauma, the pain may begin suddenly, subside in a few days, and then recur at shorter intervals and with progressive intensity. Sciatic pain follows, beginning as a dull pain in the buttocks. Valsalva's maneuver, coughing, sneezing, or bending intensifies the pain, which is commonly accompanied by muscle spasms. Herniated disk may also cause paresthesias or hyperesthesias, as well as sensory and motor loss in the area innervated by the compressed spinal nerve root and, in later stages, weakness and atrophy of leg muscles.

Diagnosis

Obtaining a careful patient history is vital because the events that intensify disk pain are diagnostically significant. The straight-leg–raising test and its variants are perhaps the best tests for herniated disk but may still be negative.

For the straight-leg–raising test, the patient lies in a supine position while the examiner places one hand on the patient's ilium, to stabilize the pelvis, and the other hand under the ankle, then slowly raises the patient's leg. The test is positive only if the patient complains of posterior leg (sciatic) pain, not back pain. In Lasègue's test, the patient lies flat while the thigh and knee are flexed to a 90-degree angle. Resistance and pain as well as loss of ankle or knee-jerk reflex indicate spinal root compression.

X-rays of the spine are essential to rule out other abnormalities but may not diagnose herniated disk because marked disk prolapse can be present despite a normal X-ray. A thorough check of the patient's peripheral vascular status—including posterior tibial and dorsalis pedis pulses and skin temperature of limbs—helps rule out ischemic disease, another cause of leg pain or

numbness. After physical examination and X-rays, myelography, CT scans, and MRI provide the most specific diagnostic information, showing spinal canal compression by herniated disk material. MRI is the method of choice to confirm the diagnosis and determine the exact level of herniation. A myelogram can define the size and location of disk herniation. An electromyogram can determine the exact nerve root involved. A nerve conduction velocity test may also be performed.

Treatment

Unless neurologic impairment progresses rapidly, treatment is initially conservative and consists of several weeks of bed rest (possibly with pelvic traction), administration of NSAIDs, heat applications, and an exercise program. Epidural corticosteroids, short-term oral corticosteroids, nerve root blocks, or physical therapy may be used to decrease pain. Muscle relaxants, such as diazepam, methocarbamol, or cyclobenzaprine, may relieve associated muscle spasms.

A herniated disk that fails to respond to conservative treatment may necessitate surgery. The most common procedure, laminectomy, involves excision of a portion of the lamina and removal of the protruding disk. If laminectomy doesn't alleviate pain and disability, a spinal fusion may be necessary to overcome segmental instability. Laminectomy and spinal fusion are sometimes performed concurrently to stabilize the spine. Microdiskectomy can also be used to remove fragments of nucleus pulposus.

Injection of the enzyme chymopapain into the herniated disk produces a loss of water and proteoglycans from the disk, thereby reducing both the disk's size and the pressure in the nerve root.

Special Considerations

Herniated disk requires supportive care, careful patient teaching, and strong emotional support to help the patient cope with the discomfort and frustration of chronic low back pain.

- If the patient requires myelography, question carefully about allergies to iodides, iodine-containing substances, or seafood because such allergies may indicate sensitivity to the test's radiopaque dye. Reinforce previous explanations of the need for this test and tell the patient to expect some pain. Provide assurance that a sedative will be provided before the test, if needed, to promote comfort and lessen anxiety. After the test, urge the patient to remain in bed with the head elevated (especially if metrizamide was used) and to drink plenty of fluids. Monitor intake and output. Watch for seizures and allergic reaction.
- During conservative treatment, watch for any deterioration in neurologic status (especially during the first 24 hours after admission), which may indicate an urgent need for surgery. Use antiembolism stockings as prescribed, and encourage the patient to move the legs, as allowed. Provide high-topped sneakers to prevent footdrop. Work closely with the physical therapy department to ensure a consistent regimen of leg- and back-strengthening exercises. Give plenty of fluids to prevent renal stasis, and remind the patient to cough, deep breathe, and use blow bottles or an incentive spirometer to preclude pulmonary complications. Provide good skin care. Assess for bowel and bladder functions. Use a fracture bedpan for the patient on complete bed rest.
- After laminectomy, microdiskectomy, or spinal fusion, enforce bed rest, as indicated. If a blood drainage system (Hemovac or Jackson–Pratt drain) is in use, check the tubing frequently for kinks and a secure vacuum. Empty the Hemovac at the end of each shift and record the amount and color of drainage. Report colorless moisture on dressings (possible

cerebrospinal fluid leakage) or excessive drainage immediately. Observe neurovascular status of the legs (color, motion, temperature, and sensation).

◆ Monitor vital signs and check for bowel sounds and abdominal distention. Use logrolling technique to turn the patient. Administer analgesics as ordered, especially 30 minutes before initial attempts at sitting or walking. Give the patient assistance during the first attempt to walk. Provide a straight-backed chair for limited sitting.

◆ Teach the patient who has undergone spinal fusion how to wear a brace. Assist with straight-leg–raising and toe-pointing exercises, as indicated. Before discharge, teach proper body mechanics—bending at the knees and hips (never at the waist), standing straight, and carrying objects close to the body. Advise the patient to lie down when tired and to sleep on either side (never on abdomen) on an extra-firm mattress or a bed board. Urge maintenance of proper weight to prevent lordosis caused by obesity.

◆ After chemonucleolysis, enforce bed rest as ordered. Administer analgesics and apply heat, as needed. Urge the patient to cough and deep breathe. Assist with physical therapy as necessary and advise the patient to continue these exercises after discharge.

◆ Tell the patient who must receive a muscle relaxant of possible adverse effects, especially drowsiness. Provide instruction to avoid activities that require alertness until the effects to the medication are known, and a tolerance has been built up.

◆ Provide emotional support. Try to cheer the patient up during periods of frustration and depression. Provide reassurance of progress, and offer encouragement. (See *Preventing a herniated disk*, page 321.)

PREVENTION
PREVENTING A HERNIATED DISK

To prevent a herniated disk, tell your patient to follow these guidelines.

Exercise

Getting regular exercise can slow the degeneration of the disks related to aging. Muscle strength gained through exercising can strengthen and stabilize the spine. If the patient has previously had a herniated disk, he should remember to avoid high-impact activities such as jogging, tennis, and high-impact aerobics for the first few months after a herniated disk.

Maintain Good Posture

Good posture reduces the pressure on the spine and disks. Keeping the back straight and aligned is essential, particularly when sitting for longer periods. Also, heavy objects should be lifted properly by letting the legs—not the back—do most of the work.

Maintain a Healthy Weight

Excess weight puts more pressure on the spine and disks, making them more susceptible to a herniation.

SCOLIOSIS

Scoliosis is a lateral curvature of the spine that may occur in the thoracic, lumbar, or

thoracolumbar spinal segment. The curve may be convex to the right (more common in thoracic curves) or to the left (more common in lumbar curves). Rotation of the vertebral column around its axis occurs and may cause rib cage deformity. Scoliosis is commonly associated with kyphosis (*roundback*) and lordosis (*swayback*).

Causes and Incidence

Scoliosis may be functional, structural, or idiopathic. Functional (postural) scoliosis usually results from a discrepancy in leg lengths rather than from a fixed deformity of the spinal column; it corrects when the patient bends toward the convex side. Structural scoliosis results from a deformity of the vertebral bodies, and it doesn't correct when the patient bends to the side. Structural scoliosis may be:

- *congenital:* usually related to a congenital defect, such as wedge vertebrae, fused ribs or vertebrae, or hemivertebrae; may result from trauma to zygote or embryo
- *paralytic or musculoskeletal:* develops several months after asymmetrical paralysis of the trunk muscles due to polio, cerebral palsy, or muscular dystrophy
- *idiopathic* (*the most common form*)*:* may be transmitted as an autosomal dominant or multifactorial trait. This form appears in a previously straight spine during the growing years. Brainstem dysfunction, possibly due to a lesion of the posterior columns or the inner ear, may be the cause

PEDIATRIC TIP *Idiopathic scoliosis can be classified as infantile, which affects mostly male infants between birth and age 3 and causes left thoracic and right lumbar curves; juvenile, which affects both sexes between ages 4 and 10 and causes varying types of curvature; or adolescent, which generally affects girls between age 10 and achievement of skeletal maturity and causes varying types of curvature.*

Pathophysiology

Differential stress on vertebral bone causes an imbalance of osteoblastic activity; thus, the curve progresses rapidly during adolescent growth spurt. Without treatment, the imbalance continues into adulthood.

Complications

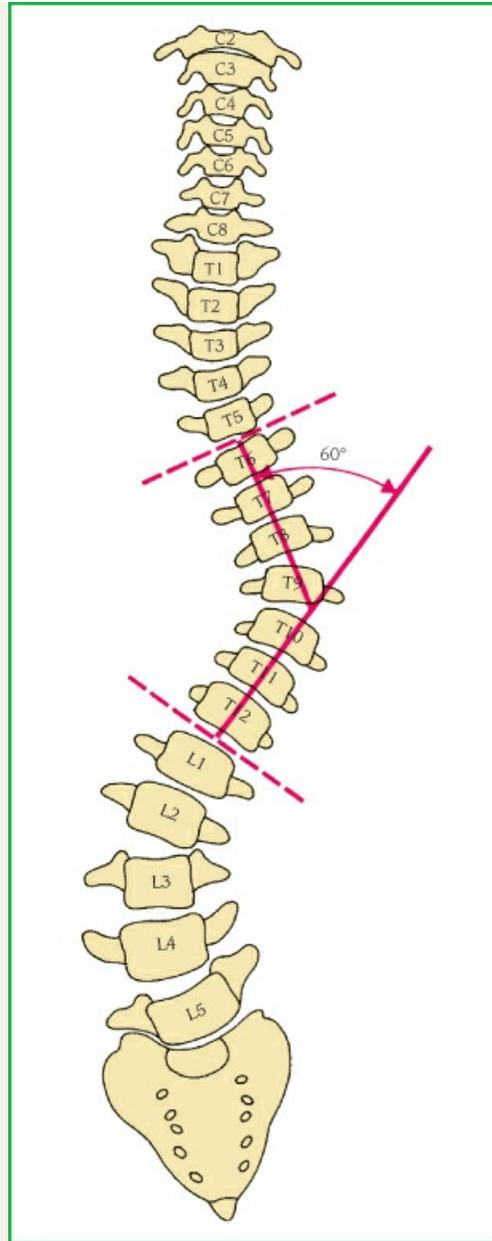
- Debilitating back pain
- Reduced pulmonary function
- Cor pulmonale

Signs and Symptoms

The most common curve in functional or structural scoliosis arises in the thoracic segment, with convexity to the right, and compensatory curves (S curves) in the cervical segment above and the lumbar segment below, both with convexity to the left. (See *Cobb method for measuring angle of curvature,* page 322.) As the spine curves laterally, compensatory curves develop to maintain body balance and mark the deformity. Scoliosis rarely produces subjective symptoms until it's well established; when symptoms do occur, they include backache, fatigue, and dyspnea. Because many teenagers are shy about their bodies, their parents suspect that something is wrong only after they notice uneven hemlines, pant legs that appear unequal in length, or subtle

physical signs like one hip appearing higher than the other. Untreated scoliosis may result in pulmonary insufficiency (curvature may decrease lung capacity), back pain, degenerative arthritis of the spine, disk disease, and sciatica.

Cobb Method for Measuring Angle of Curvature

The Cobb method measures the angle of curvature in scoliosis. The top vertebra in the curve (T6 in the illustration) is the uppermost vertebra whose upper face tilts toward the curve's concave side. The bottom vertebra in the curve (T12) is the lowest vertebra whose lower face tilts toward the curve's concave side. The angle at which perpendicular lines drawn from the upper face of the top vertebra and the lower face of the bottom vertebra intersect is the angle of the curve.


Diagnosis

℞ CONFIRMING DIAGNOSIS *Anterior, posterior, and lateral spinal X-rays, taken with the patient standing upright and bending, confirm scoliosis and determine the degree of curvature (Cobb method) and flexibility of the spine.*

A scoliometer can also be used to measure the angle of trunk rotation. Physical examination reveals unequal shoulder heights, elbow levels, and heights of the iliac crests. Muscles on the convex side of the curve may be rounded and those on the concave side flattened, producing asymmetry of paraspinal muscles.

Treatment

Only two treatments effectively treat scoliosis: spinal bracing and surgery. If monitored closely, a properly constructed and fitted brace can successfully halt progression of a curve in approximately 70% of cooperative patients. Most braces should be worn over a long T-shirt or similar article of clothing for 23 hours a day. However, mild curvatures may require wearing the brace for fewer hours a day. Exercises must be done daily both in and out of the brace to maintain muscle strength. Patients should be seen for follow-up and brace adjustment every 3 months. Radiographs should be repeated at 6-month intervals. As the skeleton matures, as seen radiographically, brace wear should be gradually decreased until it's worn only at night.

The primary indications for surgery are relentless curve progression (usually curves over 40 degrees) or significant curve progression despite bracing. Surgery corrects lateral curvature by posterior spinal fusion and internal stabilization with metal rods. A distraction rod on the concave side of the curve "jacks" the spine into a straight position and provides an internal splint. An alternative procedure, anterior spinal fusion, corrects curvature with vertebral staples and an anterior stabilizing cable. Some spinal fusions may require postoperative immobilization in a brace. Postoperatively, periodic checkups are required for several months to monitor stability of the correction.

Special Considerations

It's important to provide emotional support in addition to meticulous skin care and patient teaching.

If the patient needs a brace:

- Enlist the help of a physical therapist, a social worker, and an orthotist. Before the patient goes home, explain what the brace does and how to care for it (how to check the screws for tightness and pad the uprights to prevent excessive wear on clothing). Suggest that loose-fitting, oversized clothes be worn for greater comfort.
- Tell the patient to wear the brace 23 hours/day and to remove it only for bathing and exercise. While still adjusting to the brace, instruct to lie down and rest several times per day.
- Suggest a soft mattress if a firm one is uncomfortable.
- To prevent skin breakdown, advise the patient not to use lotions, ointments, or powders on areas where the brace contacts the skin. Instruct keeping the skin dry and clean and to wear a snug T-shirt under the brace.
- Advise the patient to increase activities gradually and avoid vigorous sports. Emphasize the importance of conscientiously performing prescribed exercises.
- Instruct the patient to turn the whole body, instead of just the head, when looking to the side. To make reading easier, instruct to hold the book so it will be straight ahead at it instead of down. Prism glasses may be beneficial if this is difficult.

If the patient needs traction or a cast before surgery:

- Explain these procedures to the patient and the family. Remember that application of a body cast can be traumatic because it's done on a special frame and the patient's head and face are covered throughout the procedure.
- Check the skin around the cast edge daily. Keep the cast clean and dry and the edges of the cast petaled. Warn the patient not to insert or let anything get under the cast and to immediately report cracks in the cast, pain, burning, skin breakdown, numbness, or odor.

After corrective surgery:

ALERT *Check sensation, movement, color, and blood supply in all limbs every 2 to 4 hours for the first 48 hours and then several times a day, for signs of neurovascular deficit, a serious complication following spinal surgery. Logroll the patient often.*

- Measure intake, output, and urine specific gravity to monitor effects of blood loss, which is usually substantial.
- Monitor abdominal distention and bowel sounds.
- Encourage deep-breathing exercises to avoid pulmonary complications.
- Medicate for pain, especially before any activity.
- Promote active ROM arm exercises to help maintain muscle strength. Remember that any exercise, even brushing the hair or teeth, is helpful. Encourage the patient to perform quadriceps-setting, calf-pumping, and active ROM exercises of the ankles and feet.
- Watch for skin breakdown and signs of cast syndrome. Teach the patient how to recognize these signs. (See *Cast syndrome*.)

Cast Syndrome

Cast syndrome is a serious complication that sometimes follows spinal surgery and application of a body cast. Characterized by nausea, abdominal pressure, and vague abdominal pain, cast syndrome probably results from hyperextension of the spine. This hyperextension accentuates lumbar lordosis, compressing the third portion of the duodenum between the superior mesenteric artery anteriorly and the aorta and vertebral column posteriorly. High intestinal obstruction produces nausea, vomiting, and ischemic infarction of the mesentery.

After removal of the cast, treatment includes gastric decompression and I.V. fluids, with nothing by mouth. Antiemetics should be given sparingly because they may mask symptoms of cast syndrome, which, if untreated, may be fatal.

Teach patients who are discharged in body jackets, localizer casts, or high hip-spica casts how to recognize cast syndrome, which may manifest several weeks or months after application of the cast.

- Offer emotional support to help prevent depression that may result from altered body image and immobility. Encourage the patient to wear his or her own clothes, wash hair, and use makeup.
- If the patient is being discharged with a rod and cast and must have bed rest, arrange for a social worker and a visiting nurse to provide home care. Before discharge, check with the surgeon about activity limitations, and make sure the patient understands them.
- If you work in a school, screen children routinely for scoliosis during physical examinations.

Muscle and Connective Tissue

TENDINITIS AND BURSITIS

Tendinitis is a painful inflammation of tendons and of tendon-muscle attachments to bone, usually in the shoulder rotator cuff, hip, Achilles tendon, or hamstring. *Bursitis* is a painful inflammation of one or more of the bursae—closed sacs lubricated with small amounts of synovial fluid that facilitate the motion of muscles and tendons over bony prominences. Bursitis usually occurs in the subdeltoid, olecranon, trochanteric, calcaneal, or prepatellar bursae.

Causes and Incidence

Tendinitis commonly results from overuse or injury (such as strain during sports activity), another musculoskeletal disorder (such as rheumatic diseases or congenital defects), or aging.

Bursitis can occur at any age but usually occurs in older individuals due to an inflammatory joint disease (such as rheumatoid arthritis or gout) or recurring trauma that stresses or pressures a joint. Chronic bursitis follows attacks of acute bursitis or repeated trauma and infection. Septic bursitis may result from wound infection or from bacterial invasion of skin over the bursa.

Pathophysiology

In tendinitis, fluid from inflammation accumulates, causing swelling of the tendon and its enclosing sheath. Inflammatory changes cause thickening of the sheath, which limits movements and causes pain. Microtears cause bleeding, edema, and pain in the involved tendon or tendons. At times, after repeated inflammations, calcium may be deposited in the tendon origin area, causing a calcific tendinitis.

The usual bursitis is an inflammation that is reactive to overuse or excessive pressure. The inflamed bursal sac becomes engorged, and the inflammation can spread to adjacent tissues. The inflammation may decrease with rest, heat, and aspiration of the fluid.

Complications

- Contractures of the tendon
- Scarring
- Muscle wasting
- Disability

Signs and Symptoms

The patient with tendinitis of the shoulder complains of restricted shoulder movement, especially abduction, and localized pain, which is most severe at night and usually interferes with sleep. The pain extends from the acromion (the shoulder's highest point) to the deltoid muscle insertion, predominantly in the so-called painful arc—that is, when the patient abducts the arm between 50 and 130 degrees. Fluid accumulation causes swelling. In calcific tendinitis, calcium deposits in the tendon cause proximal weakness and, if calcium erodes into adjacent bursae, acute calcific bursitis.

In bursitis, fluid accumulation in the bursae causes irritation, inflammation, sudden or gradual pain, and limited movement. Other symptoms vary according to the affected site. Subdeltoid bursitis impairs arm abduction, prepatellar bursitis (housemaid's knee) produces pain when the patient climbs stairs, and hip bursitis makes crossing the legs painful.

Diagnosis

In tendinitis, X-rays may be normal at first but later show bony fragments, osteophyte sclerosis, or calcium deposits. Arthrography is usually normal, with occasional small irregularities on the

undersurface of the tendon. CT scan and MRI have replaced X-ray and even arthrography of the shoulder as diagnostic tools. An MRI will usually identify tears, partial tears, inflammation, or tumor but cannot reveal irregularities of the tendon sheath itself. Diagnosis of tendinitis must rule out other causes of shoulder pain, such as myocardial infarction, cervical spondylosis, degenerative changes, and tendon tear or rupture. Significantly, in tendinitis, heat aggravates shoulder pain; in other painful joint disorders, heat usually provides relief.

Localized pain and inflammation and a history of unusual strain or injury 2 to 3 days before onset of pain are the bases for diagnosing bursitis. During early stages, X-rays are usually normal, except in calcific bursitis, where X-rays may show calcium deposits.

Treatment

Treatment to relieve pain includes resting the joint (by immobilization with a sling, splint, or cast, or via activity modification), NSAIDs, analgesics, application of cold or heat, ultrasound, or local injection of an anesthetic and corticosteroids to reduce inflammation. A mixture of a corticosteroid and an anesthetic such as lidocaine generally provides immediate pain relief. Extended-release injections of a corticosteroid, such as triamcinolone or prednisolone, offer long-term pain relief. Until the patient is free of pain and able to perform ROM exercises easily, treatment also includes oral NSAIDs, such as ibuprofen, naproxen, indomethacin, or oxaprozin. Short-term analgesics include propoxyphene, codeine, acetaminophen with codeine and, occasionally, oxycodone.

Supplementary treatment includes fluid removal by aspiration and heat therapy; for calcific tendinitis, ice packs, physical therapy, ultrasonography, or hydrotherapy generally helps maintain or regain ROM. It may be necessary to delay treatment until the acute attack is over to ensure maximum patient compliance. Rarely, calcific tendinitis requires surgical removal of calcium deposits. Long-term control of chronic bursitis and tendinitis may require changes in lifestyle to prevent recurring joint irritation.

Special Considerations

When treating patients with tendinitis or bursitis, remember to consider the following:

- Assess the severity of pain and the ROM to determine the effectiveness of the treatment.
- Before injecting corticosteroids or local anesthetics, ask the patient about drug allergies.
- Assist with intra-articular injection. Scrub the patient's skin thoroughly with povidone–iodine or a comparable solution. After the injection, massage the area to ensure penetration through the tissue and joint space. Apply ice intermittently for about 4 hours to minimize pain. Avoid applying heat to the area for 2 days.
- Tell the patient to take anti-inflammatory agents with milk to minimize GI distress and to report any signs of distress immediately.
- Advise the patient to perform strengthening exercises and avoid activities that aggravate the joint.
- Remind the patient to wear a splint or sling during the first few days of an attack of subdeltoid bursitis or tendinitis to support the arm and protect the shoulder, particularly at night. Demonstrate how to wear the sling so it won't put too much weight on the shoulder.
- Advise the patient to maintain joint mobility and prevent muscle atrophy by performing exercises or physical therapy when free of pain.

EPICONDYLITIS

Lateral epicondylitis of the elbow (tennis elbow) is inflammation of the extensor tendons of the forearm. Medial epicondylitis (golfer's elbow) is inflammation at the origin of the flexor muscles of the wrist.

Causes and Incidence

Epicondylitis probably begins as a partial tear and is common among tennis players or persons whose activities require a forceful grasp, wrist extension against resistance, or frequent rotation of the forearm, such as using a screwdriver. Untreated epicondylitis may become disabling as adherent fibers form between the tendons and the elbow capsule.

Pathophysiology

Epicondylitis is the result of irritation and inflammation where the tendon attaches to a bone. Overuse and excessive pressure are factors.

Complications

- Recurrence of injury
- Tendon rupture

Signs and Symptoms

The patient's initial symptom is elbow pain that gradually worsens and commonly radiates to the forearm and back of the hand whenever an object is grasped, or the elbow is twisted. Other associated signs and symptoms include tenderness over the involved lateral or medial epicondyle or over the head of the radius and a weak grasp. In rare instances, epicondylitis may cause local heat, swelling, or restricted ROM.

Diagnosis

Because X-rays are almost always negative, diagnosis typically depends on clinical signs and symptoms and a patient history of playing tennis or engaging in similar activities. The pain can be reproduced by wrist extension and supination with lateral epicondyle involvement or by flexion and pronation with medial epicondyle involvement.

Treatment

Treatment aims to relieve pain, usually by NSAIDs or local injection of corticosteroids and an anesthetic. Supportive treatment includes an immobilizing splint from the distal forearm to the elbow or wrist splint, which generally relieves pain in 2 to 3 weeks; heat therapy, such as warm compresses, short-wave diathermy, and ultrasound (alone or in combination with diathermy); and physical therapy, such as manipulation and massage to detach the tendon from the chronically inflamed periosteum. A "tennis elbow strap" or counterface brace has helped many patients. This strap, which is wrapped snugly around the forearm approximately 1 (2.5 cm)

below the epicondyle, helps relieve the strain on affected forearm muscles and tendons. If these measures prove ineffective, surgical release of the tendon at the epicondyle may be necessary.

Special Considerations

The following special considerations accompany diagnosis and treatment of epicondylitis:

- Assess the patient's level of pain, ROM, and sensory function. Monitor heat therapy to prevent burns.
- Advise the patient to take anti-inflammatory drugs with food to avoid GI irritation.
- Instruct the patient to rest the elbow, wrist, or both until inflammation subsides.
- Remove the support daily, and gently move the arm to prevent stiffness and contracture.
- Instruct the patient to follow the prescribed exercise program. For example, the arm may be stretched and the wrist flexed to the maximum then press the back of the hand against a wall until a pull can be felt in the forearm and hold this position for 1 minute.
- Advise the patient to warm up for 15 to 20 minutes before beginning any sports activity.
- Urge the patient to wear an elastic support or splint during any activity that stresses the forearm or elbow.
- Tell the patient to check the equipment. For example, a tennis racquet may not be the right size or weight. Also, changing surfaces may help to reduce stress.

ACHILLES TENDON CONTRACTURE

Achilles tendon contracture is a shortening of the Achilles tendon (*tendo calcaneus* or *heel cord*) that causes foot pain and strain and limits ankle dorsiflexion.

Causes and Incidence

Achilles tendon contracture may reflect a congenital structural anomaly or a muscular reaction to chronic poor posture, especially in women who wear high-heeled shoes or joggers who land on the balls of their feet instead of their heels. Other causes include paralytic conditions of the legs, such as poliomyelitis or cerebral palsy.

Pathophysiology

The Achilles tendon spans two joints and connects the calcaneus to the gastrocnemius and soleus muscles, comprising the largest and strongest muscle complex in the calf. The tendon is vulnerable to injury because of its limited blood supply, especially when subjected to strong forces.

The blood supply to the tendon is provided by longitudinal arteries that run the length of the muscle complex. The area of the tendon with the poorest blood supply is approximately 2 to 6 cm above the insertion into the calcaneus. The blood supply diminishes with age, predisposing this area of the tendon to chronic inflammation and possible rupture.

Complication

- Permanent weakness

Signs and Symptoms

Sharp, spasmodic pain during dorsiflexion of the foot characterizes the reflex type of Achilles tendon contracture. In footdrop (fixed equinus), contracture of the flexor foot muscle prevents

placing the heel on the ground.

Diagnosis

Physical examination and patient history suggest Achilles tendon contracture.

℞ CONFIRMING DIAGNOSIS *A simple test confirms Achilles tendon contracture: While the patient keeps the knee flexed, the examiner places the foot in dorsiflexion; gradual knee extension forces the foot into plantar flexion.*

Treatment

Conservative treatment aims to correct Achilles tendon contracture by raising the inside heel of the shoe in the reflex type; by gradually lowering the heels of shoes (sudden lowering can aggravate the problem) and stretching exercises if the cause is high heels; or by using support braces or casting to prevent footdrop in a paralyzed patient. Alternative therapy includes using wedged plaster casts or stretching the tendon by manipulation. Analgesics may be given to relieve pain.

With fixed footdrop, treatment may include surgery. Although this procedure may weaken the tendon, it allows further stretching by cutting the tendon. After surgery, a short leg cast maintains the foot in 90-degree dorsiflexion for 6 weeks. Some surgeons allow partial weight bearing on a walking cast after 2 weeks.

Special Considerations

After surgery to lengthen the Achilles tendon:

- Elevate the casted foot to decrease venous pressure and edema by raising the foot of the bed or supporting the foot with pillows.
- Record the neurovascular status of the toes (temperature, color, sensation, capillary refill time, and toe mobility) every hour for the first 24 hours and then every 4 hours. If any changes are detected, increase the elevation of the patient's legs and notify the surgeon immediately.
- Prepare the patient for ambulation by dangling the foot over the side of the bed for short periods (5 to 15 minutes) before getting out of bed, allowing for a gradual increase in venous pressure. Assist the patient in walking, as ordered (usually within 24 hours of surgery), using crutches and a nonweight-bearing or touch-down gait.
- Protect the patient's skin with moleskin or by petaling the edges of the cast. Before discharge, teach the patient how to care for the cast, and advise to elevate the foot regularly when sitting or whenever the foot throbs or becomes edematous. Also, make sure the patient understands how much exercise and walking are recommended after discharge.
- To prevent Achilles tendon contracture in paralyzed patients, apply support braces, universal splints, casts, or high-topped sneakers. Make sure the weight of the sheets doesn't keep paralyzed feet in plantar flexion. For other patients, teach good foot care and urge them to seek immediate medical care for foot problems. Warn women against wearing high heels constantly and suggest regular foot (dorsiflexion) exercises.

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome, a form of repetitive stress injury, is the most common of the nerve entrapment syndromes. It results from compression of the median nerve at the wrist, within the carpal tunnel. This compression neuropathy causes sensory and motor changes in the median

distribution of the hand.

Causes and Incidence

The carpal tunnel is formed by the carpal bones and the transverse carpal ligament. (See *The carpal tunnel*.) Inflammation or fibrosis of the tendon sheaths that pass through the carpal tunnel commonly causes edema and compression of the median nerve. Many conditions can cause the contents or structure of the carpal tunnel to swell and press the median nerve against the transverse carpal ligament, including rheumatoid arthritis, flexor tenosynovitis (commonly associated with rheumatic disease), nerve compression, pregnancy, renal failure, menopause, diabetes mellitus, acromegaly, edema following Colles fracture, hypothyroidism, amyloidosis, myxedema, benign tumors, TB, and other granulomatous diseases. Another source of damage to the median nerve is dislocation or acute sprain of the wrist.

The Carpal Tunnel

The carpal tunnel is clearly visible in this palmar view and cross section of a right hand. Note the median nerve, flexor tendons of fingers, and blood vessels passing through the tunnel on their way from the forearm to the hand.

Radial nerve

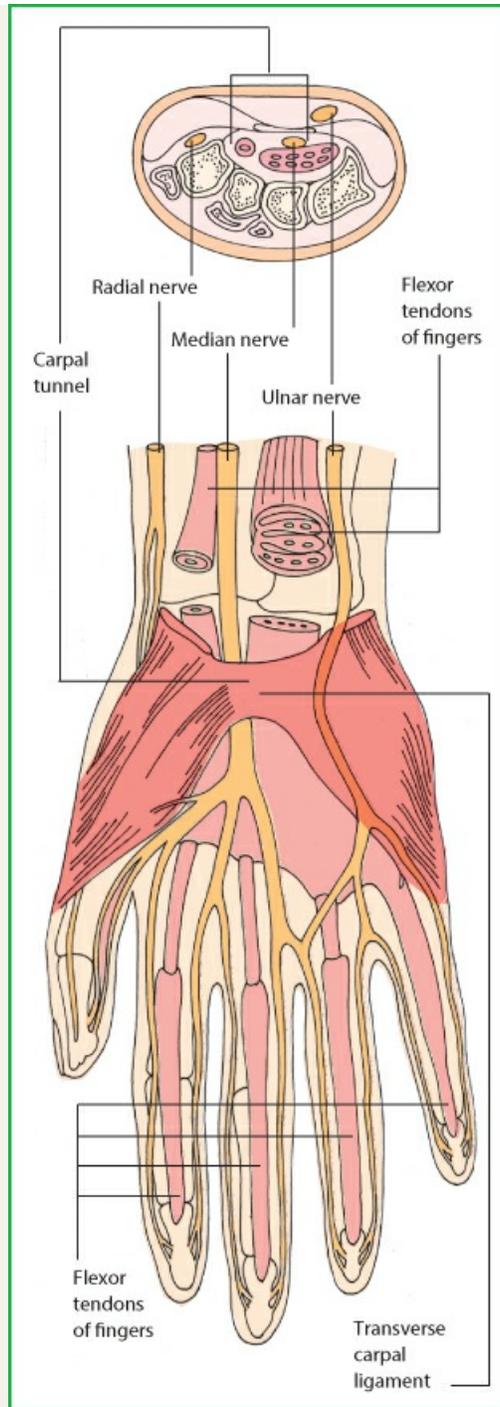
Carpal tunnel

Median nerve

Flexor tendons of fingers

Ulnar nerve

Flexor tendons of fingers

Transverse carpal ligament


Carpal tunnel injury is five times more common in women than in men. It usually occurs in women between ages 30 and 60 and poses a serious occupational health problem. Assembly-line workers and packers and people who repeatedly use poorly designed tools are most likely to develop this disorder. Any strenuous use of the hands—sustained grasping, twisting, or flexing—aggravates this condition. (See *Preventing carpal tunnel syndrome*.)

Pathophysiology

The carpal bones and the transverse carpal ligament form the carpal tunnel. Inflammation or fibrosis of the tendon sheaths that pass through the carpal tunnel usually causes edema and compression of the median nerve. (See *Cross section of the wrist with carpal tunnel syndrome*, page 327.) This compression neuropathy causes sensory and motor changes in the median distribution of the hands, initially impairing sensory transmission to the thumb, index finger, second finger, and inner aspect of the third finger.

Complications

- Decreased wrist function
- Permanent nerve damage
- Loss of movement and sensation

Signs and Symptoms

The patient with carpal tunnel syndrome usually complains of weakness, pain, burning, numbness, or tingling in one or both hands. This paresthesia affects the thumb, forefinger, middle finger, and half of the fourth finger. The patient is unable to clench the hand into a fist; the nails may be atrophic, the skin dry and shiny.

Because of vasodilatation and venous stasis, symptoms are typically worse at night and in the

morning. The pain may spread to the forearm and, in severe cases, as far as the shoulder or neck. The patient can usually relieve such pain by shaking or rubbing hands vigorously or dangling his arms.

Diagnosis

Physical examination reveals decreased sensation to light touch or pinpricks in the affected fingers. Thenar muscle atrophy occurs in about half of all cases of carpal tunnel syndrome, but it's usually a late sign. The patient exhibits a positive Tinel's sign (tingling over the median nerve on light percussion) and responds positively to Phalen's wrist-flexion test (holding the forearms vertically and allowing both hands to drop into complete flexion at the wrists for 1 minute reproduces symptoms of carpal tunnel syndrome). A compression test supports this diagnosis: A blood pressure cuff inflated above systolic pressure on the forearm for 1 to 2 minutes provokes pain and paresthesia along the distribution of the median nerve.

Electromyography and nerve conduction velocity detect a median nerve motor conduction delay of more than 5 ms. Other laboratory tests may identify the underlying disease.

Treatment

Conservative treatment should be tried first, including resting the hands by splinting the wrist in neutral extension for 1 to 2 weeks. NSAIDs usually provide symptomatic relief. Injection of the carpal tunnel with hydrocortisone and lidocaine may provide significant but temporary relief. If a definite link has been established between the patient's occupation and the development of repetitive stress injury, seeking another type of work may be recommended. Effective treatment may also require correction of an underlying disorder. When conservative treatment fails, the only alternative is surgical decompression of the nerve by resecting the entire transverse carpal tunnel ligament or by using endoscopic surgical techniques. Neurolysis (freeing of the nerve fibers) may also be necessary.

Special Considerations

Patient care for carpal tunnel syndrome includes the following:

- Administer mild analgesics as needed. Encourage the patient to use the hands as much as possible. If the dominant hand has been impaired, you may have to help with eating and bathing.
- Teach the patient how to apply a splint. Instruct to not to make it too tight. Demonstrate how to remove the splint to perform gentle ROM exercises, which should be done daily. Make sure the patient knows how to do these exercises before discharge.
- After surgery, monitor vital signs, and regularly check the color, sensation, and motion of the affected hand.
- Advise the patient who's about to be discharged to occasionally exercise the hands in warm water. If the arm is in a sling, instruct to remove the sling several times a day to do exercises for the elbow and shoulder.
- Suggest occupational counseling for the patient who must change jobs because of repetitive stress injury.

TORTICOLLIS

Torticollis, sometimes called *wryneck*, is a neck deformity in which the sternocleidomastoid

(SCM) neck muscles are spastic or shortened, causing bending of the head to the affected side and rotation of the chin to the opposite side.

Causes and Incidence

Torticollis may be congenital or acquired. The three types of acquired torticollis—acute, spasmodic, and hysterical—have differing causes. The acute form results from muscular damage caused by inflammatory diseases, such as myositis, lymphadenitis, or TB; from cervical spinal injuries that produce scar tissue contracture; and, less commonly, from tumor or medication. The spasmodic form results from rhythmic muscle spasms caused by an organic central nervous system disorder (probably due to irritation of the nerve root by arthritis or osteomyelitis). Hysterical torticollis is due to a psychogenic inability to control neck muscles.

Acquired torticollis usually develops during the first 10 years of life or between ages 30 and 60. The incidence of congenital (muscular) torticollis is highest in infants after difficult delivery (breech presentation), in firstborn infants, and in girls. Possible causes of congenital torticollis include malposition of the head in utero, prenatal injury, fibroma, interruption of blood supply, or fibrotic rupture of the SCM muscle, with hematoma and scar formation.

Pathophysiology

Congenital Torticollis

Congenital muscular torticollis is rare (<2%) and is believed to be caused by local trauma to the soft tissues of the neck just before or during delivery. The most common explanation involves birth trauma to the SCM muscle, resulting in fibrosis or that intrauterine malpositioning leads to unilateral shortening of the SCM. There may be resultant hematoma formation followed by muscular contracture. These children often have undergone breech or difficult forceps delivery.

The fibrosis in the muscle may be due to venous occlusion and pressure on the neck in the birth canal because of cervical and skull position. Another hypothesis includes malposition in utero resulting in intrauterine or perinatal compartment syndrome. Other causes of congenital torticollis include postural torticollis, pterygium colli (webbed neck), SCM cysts, vertebral anomalies, odontoid hyperplasia, spina bifida, hypertrophy or absence of cervical musculature, and Arnold–Chiari syndrome. It can also be seen with clavicular fractures, especially in neonates secondary to birth trauma. Up to 20% of children with congenital muscular torticollis have congenital dysplasia of the hip as well.

Acquired Torticollis

The pathophysiology of acquired torticollis depends on the underlying disease process. Cervical muscle spasm causing torticollis can result from any injury or inflammation of the cervical muscles or cranial nerves from different disease processes.

Acute torticollis can be the result of blunt trauma to head and neck, or from simply sleeping in an awkward position. Acute torticollis may be self-limited in days to weeks or the result of idiosyncrasy to certain medications (e.g., traditional dopamine receptor blockers, metoclopramide, phenytoin, or carbamazepine). After stopping medication, it quickly resolves without further action. After the resolution of acute traumatic torticollis, a chronic or persistent form may reappear after days or weeks of a quiescent interval. This situation often has legal implications regarding liability associated with the acute traumatic incident.

Complication

◆ Permanent contracture

Signs and Symptoms

PEDIATRIC TIP *The first sign of congenital torticollis is commonly a firm, nontender, palpable enlargement of the SCM muscle that's visible at birth and for several weeks afterward. It slowly regresses during a period of 6 months, although incomplete regression can cause permanent contracture. If the deformity is severe, the infant's face and head flatten from sleeping on the affected side; this asymmetry gradually worsens. The infant's chin turns away from the side of the shortened muscle, and the head tilts to the shortened side. The shoulder may elevate on the affected side, restricting neck movement.*

The first sign of acquired torticollis is usually recurring unilateral stiffness of neck muscles followed by a drawing sensation and a momentary twitching or contraction that pulls the head to the affected side. This type of torticollis commonly produces severe neuralgic pain throughout the head and neck.

Diagnosis

A history of painless neck deformity from birth suggests congenital torticollis; gradual onset of painful neck deformity suggests acquired torticollis. Diagnosis must rule out TB of the cervical spine, pharyngeal or tonsillar inflammations, spinal accessory nerve damage, ruptured transverse ligaments, subdural hematoma, tumors of soft tissue or bone, dislocations and fractures, scoliosis, congenital abnormalities of the cervical spine and base of the skull, rheumatoid arthritis, and osteomyelitis. In acquired torticollis, cervical spine X-rays are negative for bone or joint disease but may reveal an associated disorder (such as TB, scar tissue formation, tumor, deformities, or arthritis). CT scan or MRI may help rule out pathogenic causes.

Treatment

Treatment of congenital torticollis aims to stretch the shortened muscle. Nonsurgical treatment includes passive neck stretching and proper positioning during sleep for an infant and active stretching exercises for an older child—for example, touching the ear opposite the affected side to the shoulder and touching the chin to the same shoulder.

Surgical correction involves sectioning the SCM muscle; this should be done during preschool years and only if other therapies fail.

Treatment of acquired torticollis aims to control pain and correct the underlying cause of the disease. In the acute form, application of heat, cervical traction, and gentle massage may help relieve pain; analgesics may also be helpful. Stretching exercises and a neck brace may relieve symptoms of the spasmodic and hysterical forms. Drug treatment includes anticholinergic drugs such as baclofen. Botulinum toxin injections are effective in temporarily relieving torticollis, but injections must be repeated every 3 months.

Special Considerations

Patient care for torticollis includes the following:

◆ To aid early diagnosis of congenital torticollis, observe the infant for limited neck movement,

and thoroughly assess the degree of discomfort.

- Teach the parents of an affected child how to perform stretching exercises with the infant. Suggest placing toys or mobiles on the side of the crib opposite the affected side of the child's neck to encourage the child to move the head and stretch the neck.
- If surgery is necessary, prepare the patient by shaving the neck to the hairline on the affected side.

After corrective surgery:

- Monitor the patient closely for nausea or signs of respiratory complications, especially if in cervical traction. Keep suction equipment available to prevent aspiration.
- The patient may be in a cast or in traction day and night or at night only. Monitor the skin around the chin, ears, and back of the head if the patient is in cervical traction. Monitor for problems related to clenching of teeth. If the patient is in a cast, give meticulous cast care, including the monitoring of circulation, sensation, and color around the cast. Protect the cast around the patient's chin and mouth with waterproof material. Check for skin irritation, pressure areas, or softening of cast pad.
- Provide emotional support for the patient and the family to relieve their anxiety due to fear, pain, limitations from the brace or traction, and an altered body image.
- Begin stretching exercises as soon as the patient can tolerate them.
- Before discharge, explain to the patient or the parents the importance of continuing daily heat applications, massages, and stretching exercises, as prescribed, and of keeping the cast clean and dry. Emphasize that physical therapy is essential for a successful rehabilitation after the cast is removed.

RHABDOMYOLYSIS

Rhabdomyolysis is the breakdown of muscle fibers that results in the release of muscle fiber content into the circulation. It results from the toxicity of destroyed muscle cells, causing kidney damage or failure. Predisposing factors include trauma, ischemia, polymyositis, and drug overdose. Toxins and environmental, infectious, and metabolic factors may induce it. Rhabdomyolysis accounts for 8% to 15% of cases of acute renal failure; about 5% of cases result in death.

Causes and Incidence

Rhabdomyolysis follows direct injury to the skeletal muscle fibers, specifically the sarcolemma, which then release myoglobin into the bloodstream. Myoglobin is an oxygen-binding protein pigment found in skeletal muscle. When this muscle is damaged, myoglobin is released into the bloodstream. It's then filtered by the kidneys.

Myoglobin may occlude the structures of the kidney causing damage, such as acute tubular necrosis or kidney failure. Myoglobin can also cause kidney failure because it breaks down into potentially toxic compounds. Necrotic skeletal muscle may cause massive fluid shifts from the bloodstream into the muscle, reducing the relative fluid volume of the body and leading to shock and reduced blood flow to the kidneys.

The disorder may be caused by any condition that results in damage to skeletal muscle. Rhabdomyolysis may result from blunt trauma; extensive burn injury; viral, bacterial, or fungal infection (such as Legionnaires' disease or, especially, influenza type A or B); prolonged immobilization; near electrocution or near drowning; metabolic or genetic factors; drug therapy;

or toxins. Heavy exercise may result in rhabdomyolysis. Other causes include shaken baby syndrome, exposure to extreme cold, heatstroke, and snakebite.

In the United States, rhabdomyolysis affects about 8% to 15% of people with acute renal failure and has a slightly higher incidence in men than in women. The overall mortality rate is 5%. It can occur in infants, toddlers, and adolescents who inherited enzyme deficiencies of carbohydrate and lipid metabolism or those with inherited myopathies, such as Duchenne muscular dystrophy, and malignant hyperthermia.

Pathophysiology

Muscle trauma that compresses tissue causes ischemia and necrosis. The ensuing local edema further increases compartment pressure and tamponade; pressure from severe swelling causes blood vessels to collapse, leading to tissue hypoxia, muscle infarction, neural damage in the area of the fracture, and release of myoglobin from the necrotic muscle fibers into the circulation. Myoglobin may occlude the structures of the kidney, causing such damage as acute tubular necrosis or kidney failure. Myoglobin can also cause kidney failure because it breaks down into potentially toxic compounds.

Complications

- Acute tubular necrosis
- Kidney failure

Signs and Symptoms

Signs and symptoms of rhabdomyolysis include myalgias or muscle pain (especially in the thighs, calves, or lower back), weakness, tenderness, malaise, fever, dark urine, nausea, and vomiting. The patient may also experience weight gain, seizures, joint pain, and fatigue. Symptoms may be subtle initially. Rhabdomyolysis can result in acute renal failure.

Diagnosis

A serum or urine myoglobin test is positive. Creatine kinase levels 100 times above normal or higher suggest rhabdomyolysis. A urinalysis may reveal casts and may be positive for hemoglobin without evidence of red blood cells on microscopic examination. Serum potassium may be very high (potassium is released from cells into the bloodstream when cell breakdown occurs).

Treatment

Early, aggressive hydration may prevent complications from rhabdomyolysis by rapidly eliminating the myoglobin from the kidneys. I.V. hydration and diuretics promote diuresis. Diuretic medications, such as mannitol or furosemide, may aid in flushing the pigment out of the kidneys. If urine output is sufficient, bicarbonate may be given to maintain an alkaline urine state, thereby helping to prevent the dissociation of myoglobin into toxic compounds. Hyperkalemia should be treated if present. Kidney failure should be treated as appropriate. Dialysis may be necessary and, in severe cases, kidney transplantation.

Special Considerations

- Monitor the patient's intake and output, vital signs, electrolyte levels, daily weight, and

laboratory results.

⚠️ **ALERT** *Watch for signs of renal failure (such as decreasing urine output and increasing urine specific gravity), fluid overload (such as dyspnea and tachycardia), pulmonary edema, and electrolyte imbalances (such as serum potassium).*

- Provide reassurance and emotional support for the patient and the family.
- To help prevent rhabdomyolysis from occurring, ensure adequate hydration, monitor the patient for adverse reactions to any prescribed medications, and monitor blood transfusion administration carefully.

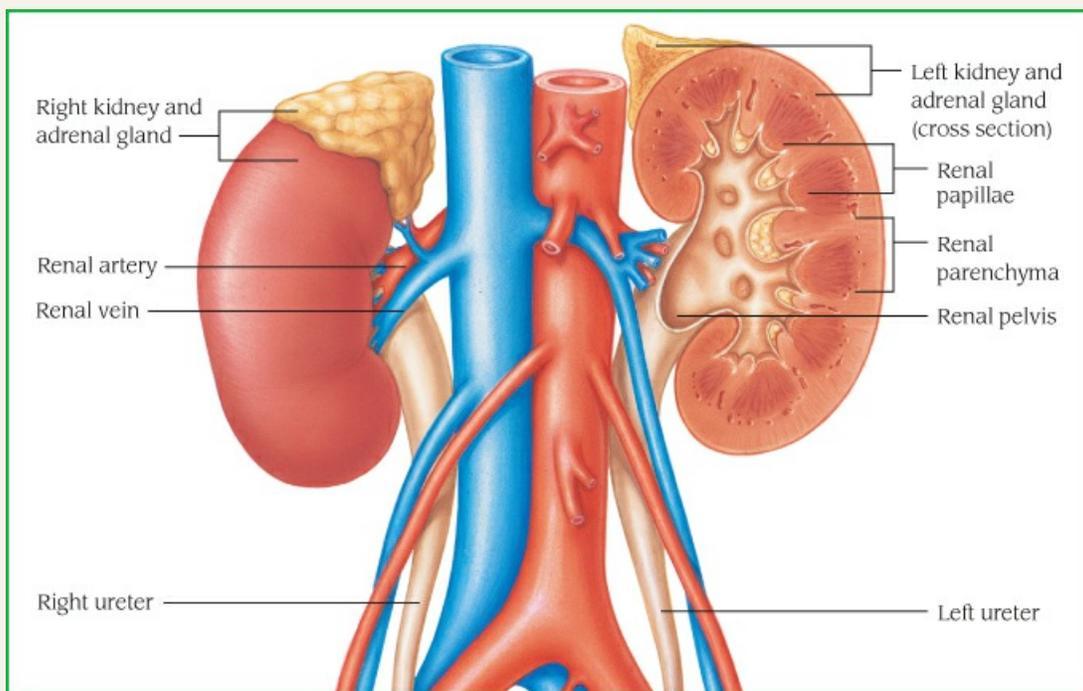
Renal and Urologic Disorders

Introduction

The kidneys are located retroperitoneally in the lumbar area, with the right kidney a little lower than the left because of the liver above it. The left kidney is slightly longer than the right and closer to the midline. The kidneys move as body position changes. They're covered by the fibrous capsule, perirenal fat, renal fascia, and pararenal fat. (See *Structure of the kidneys,* page 334.)

Structure of the Kidneys

The major components of the kidneys are depicted below.


Renal arteries branch into five segmental arteries that supply different areas of the kidneys. The segmental arteries then branch into several divisions from which the afferent arterioles and vasa recta arise. Renal veins follow a similar branching pattern, characterized by stellate vessels and segmental branches, and empty into the inferior vena cava. The tubular system receives its blood supply from a peritubular capillary network of vessels.

The gross structure of each kidney includes the lateral and medial margins, the hilus, the renal sinus, and renal parenchyma. The hilus, located at the medial margin, is the indentation where the blood and lymph vessels enter the kidney and the ureter emerges. The hilus leads to the renal sinus, which is a spacious cavity filled with adipose tissue, branches of the renal vessels, calyces, the renal pelvis, and the ureter. The renal sinus is surrounded by parenchyma, which consists of a cortex and a medulla.

The cortex (outermost layer of the kidney) contains glomeruli (parts of the nephron), cortical arches (areas that separate the medullary pyramids from the renal surface), columns of Bertin (areas that separate the pyramids from one another), and medullary rays of Ferrein (long, delicate processes from the bases of the pyramids that mix with the cortex). The medulla contains pyramids (cone-shaped structures of parenchymal tissue), papillae (apical ends of the pyramids through which urine oozes into the minor calyces), and papillary ducts of Bellini (collecting ducts in the pyramids that empty into the papillae).

URETERS

The ureters are a pair of retroperitoneally located, mucosa-lined, fibromuscular tubes that transport urine from the renal pelvis to the urinary bladder. Although the ureters have no sphincters, their oblique entrance into the bladder creates a mucosal fold that may produce a sphincterlike action.

The adult urinary bladder is a spherical, hollow muscular sac, with a normal capacity of 300 to 600 mL. It is located anterior and inferior to the peritoneal cavity, and posterior to the pubic bones. The gross structure of the bladder includes the fundus (large central, posterosuperior portion of the bladder), the apex (anterosuperior region), the body (posteroinferior region containing the ureteral orifices), and the urethral orifice, or neck (most inferior portion of the bladder). The three orifices comprise a triangular area called the *trigone*.

NEPHRONS

The functional units of each kidney are its 1 to 3 million nephrons. Each nephron is composed of the renal corpuscle and the tubular system. The renal corpuscle includes the glomerulus (a network of minute blood vessels) and Bowman's capsule (an epithelial sac surrounding the glomerulus that's part of the tubular system). The renal corpuscle has a vascular pole, where the afferent arteriole enters and the efferent arteriole emerges, and a urinary pole that narrows to form the beginning of the tubular system. The tubular system includes the proximal convoluted tubule, the loop of Henle, and the distal convoluted tubule. The last portion of the nephron consists of the collecting duct.

INNERVATION AND VASCULATURE

The kidneys are innervated by sympathetic branches from the celiac plexus, upper lumbar splanchnic and thoracic nerves, and the intermesenteric and superior hypogastric plexuses, which

form a plexus around the kidneys. Similar numbers of sympathetic and parasympathetic nerves from the renal plexus, superior hypogastric plexus, and intermesenteric plexus innervate the ureters. Nerves that arise from the inferior hypogastric plexuses innervate the bladder. The parasympathetic nerve supply to the bladder controls micturition.

The ureters receive their blood supply from the renal, vesical, gonadal, and iliac arteries, and the abdominal aorta. The ureteral veins follow the arteries and drain into the renal vein. The bladder receives blood through vesical arteries. Vesical veins unite to form the pudendal plexus, which empties into the iliac veins. A rich lymphatic system drains the renal cortex, the kidneys, the ureters, and the bladder.

HOMEOSTASIS

Through the production and elimination of urine, the kidneys maintain homeostasis. These vital organs regulate the volume, electrolyte concentration, and acid–base balance of body fluids; detoxify the blood and eliminate wastes; regulate blood pressure; and aid in erythropoiesis. The kidneys eliminate wastes from the body through urine formation (by glomerular filtration, tubular reabsorption, and tubular secretion) and excretion. Glomerular filtration, the process of filtering the blood flowing through the kidneys, depends on the permeability of the capillary walls, vascular pressure, and filtration pressure. The normal glomerular filtration rate (GFR) is about 120 mL/minute.

CLEARANCE MEASURES FUNCTION

Clearance is the volume of plasma that can be cleared of a given substance per unit of time, and depends on how renal tubular cells handle the substance that has been filtered by the glomerulus:

- If the tubules don't reabsorb or secrete the substance, clearance equals the GFR.
- If the tubules reabsorb it, clearance is less than the GFR.
- If the tubules secrete it, clearance is greater than the GFR.
- If the tubules reabsorb and secrete it, clearance is less than, equal to, or greater than the GFR.

The most accurate measure of glomerular function is creatinine clearance, because this substance is filtered only by the glomerulus and isn't reabsorbed by the tubules.

The transport of filtered substances in tubular reabsorption or secretion may be active (requiring the expenditure of energy) or passive (requiring none). For example, energy is required to move sodium across tubular cells (active transport), but none is required to move urea (passive transport). The amount of reabsorption or secretion of a substance depends on the maximum tubular transport capacity for that substance; that is, the greatest amount of a substance that can be reabsorbed or secreted per minute without saturating the system.

ELDER TIP After age 40, a person's renal function begins to diminish; if the person lives to age 90, it may have decreased by as much as 50%. This change is reflected in a decreased GFR; it's caused by age-related changes in the renal vasculature that disturb glomerular hemodynamics as well as by reduced cardiac output and atherosclerotic changes that reduce renal blood flow by more than 50%.

WATER REGULATION

Hormones partially control water regulation by the kidneys. Hormonal control depends on the response of osmoreceptors to changes in osmolality. The two hormones involved are antidiuretic hormone (ADH), produced by the pituitary gland, and aldosterone, produced by the adrenal

cortex. ADH alters the collecting tubules' permeability to water. When plasma concentration of ADH is high, the tubules are very permeable to water, so a greater amount of water is reabsorbed, creating a high concentration but small volume of urine. The reverse is true if ADH concentration is low.

Aldosterone regulates sodium and water reabsorption from the distal tubules. High plasma aldosterone concentration promotes sodium and water reabsorption from the tubules and decreases sodium and water excretion in the urine; low plasma aldosterone concentration promotes sodium and water excretion. Aldosterone also helps control the distal tubular secretion of potassium. Other factors that determine potassium secretion include the amount of potassium ingested, number of hydrogen ions secreted, level of intracellular potassium, amount of sodium in the distal tubule, and the GFR.

The countercurrent mechanism—composed of a multiplication system and an exchange system that occur in the renal medulla via the limbs of the loop of Henle and the vasa recta—is the method by which the kidneys concentrate urine. It achieves active transport of sodium and chloride between the loop of Henle and the medullary interstitial fluid. Failure of the countercurrent mechanism produces polyuria and nocturia.

To regulate acid–base balance, the kidneys secrete hydrogen ions, reabsorb sodium and bicarbonate ions, acidify phosphate salts, and synthesize ammonia—which keep the blood at its normal pH of 7.37 to 7.43.

The kidneys assist in regulating blood pressure by synthesizing and secreting renin in response to an actual, or perceived, decrease in the volume of extracellular fluid. Renin, in turn, acts on a substrate to form angiotensin I, which is converted to angiotensin II. Angiotensin II increases arterial blood pressure by peripheral vasoconstriction and stimulation of aldosterone secretion. The resulting increase in the aldosterone level promotes the reabsorption of sodium and water to correct the fluid deficit and renal ischemia.

The kidneys secrete erythropoietin in response to decreased oxygen tension in the renal blood supply. Erythropoietin then acts on the bone marrow to increase the production of red blood cells (RBCs).

Renal tubular cells synthesize active vitamin D and help regulate calcium balance and bone metabolism.

CLINICAL ASSESSMENT

Assessment of the renal and urologic systems begins with an accurate patient history and requires a thorough physical examination and certain laboratory data and test results from invasive and noninvasive procedures. When obtaining a patient history, ask about symptoms that pertain specifically to the pathology of the renal and urologic systems, such as frequency or urgency, and about the presence of any systemic diseases that can produce renal or urologic dysfunction, such as hypertension, diabetes mellitus, or bladder infections. Family history may also suggest a genetic predisposition to certain renal diseases, such as glomerulonephritis or polycystic kidney disease. Also, ask what medications the patient has been taking; abuse of analgesics or antibiotics may cause nephrotoxicity.

PHYSICAL EXAMINATION FOR RENAL DISEASE

The first step in physical examination is careful observation of the patient's overall appearance because renal disease affects all body systems. Examine the patient's skin for color, turgor, intactness, and texture; mucous membranes for color, secretions, odor, and intactness; eyes for

periorbital edema and vision; general activity for motion, gait, and posture; muscle movement for motor function and general strength; and mental status for level of consciousness, orientation, and response to stimuli. (See *Common renal symptoms*.)

Common renal symptoms

Symptom	Possible cause
Dribbling	Prostatic enlargement, strictures
Dysuria	Infection, inflammation of bladder or urethra
Edema	Nephrotic syndrome, failure
Frequency	Infection, diabetes, bladder tumors, medications
Hematuria	Glomerular diseases, trauma, neoplasms, renal calculi
Hesitancy	Neurogenic bladder, infection
Incontinence	Infection, neoplasms, prolapsed uterus
Nocturia	Infection, nephrotic syndrome, diabetes, medications
Oliguria	Failure, insufficiency, neoplasms
Proteinuria	Glomerular diseases, infection
Pyuria	Infection
Renal colic	Calculi
Urgency	Infection, prostatic disease, medications

Renal disease causes distinctive changes in vital signs: hypertension due to fluid and electrolyte imbalances and hyperactivity of the renin–angiotensin system; a strong, fast, irregular pulse due to fluid and electrolyte imbalances; hyperventilation to compensate for metabolic acidosis; and an increased susceptibility to infection due to overall decreased resistance. Palpation and percussion may reveal little because the kidneys and bladder are difficult to palpate unless they are enlarged or distended.

NONINVASIVE TESTS AND MONITORING

Laboratory tests analyze serum levels of chemical substances such as uric acid, creatinine, and blood urea nitrogen; tests also determine urine characteristics, including the presence of RBCs, white blood cells (WBCs), casts, or bacteria; specific gravity and pH; and physical properties, such as clarity, color, and odor. (See *Serum and urine values in renal disease*, page 337.)

Serum and urine values in renal disease

	Normal serum value	Deviation	Normal urine value	Deviation
Sodium	135 to 145 mEq/L	↑ or N	30 to 280 mEq/L	V
Potassium	3.8 to 5.5 mEq/L	↑	25 to 100 mEq/L	↓
Chloride	100 to 108 mEq/L	↑	110 to 250 mEq/24 hour	↓
Calcium	8.9 to 10.1 mg/dL	↓	*Female:* <250 mg/24 hour	↓
			Male: <275 mg/24 hour	
Phosphorus	2.5 to 4.5 mg/dL	↑ or N	1 g/24 hour	V
Magnesium	1.7 to 2.1 mEq/L	↑	<150 mg/24 hour	↓
Carbon dioxide combining power	22 to 34 mEq/L	↓		
Specific gravity			1.005 to 1.035	↓
pH			4.5 to 8	↑

Blood urea nitrogen	8 to 20 mg/dL	↑	10 to 20 g/L	↓
Creatinine	*Female:* 0.6 to 0.9 mg/dL	↑	*Female:* 0 to 80 mg/24 hour	↓
	Male: 0.8 to 1.2 mg/dL		*Male:* 0 to 40 mg/24 hour	
Osmolality	280 to 295 mOsm/kg	V	500 to 1,400 mOsm/kg	↓
Uric acid	*Female:* 2.3 to 6 mg/dL	↑		
	Male: 4.3 to 8 mg/dL			
Glucose	70 to 100 mg/dL	N	0	N
Protein	6.9 to 7.9 g/dL	↓ or N	0	V
Hematocrit	*Female:* 38% to 46%	↓		
	Male: 42% to 54%			
Hemoglobin	*Female:* 12 to 16 g/dL	↓		
	Male: 14 to 18 g/dL			
White blood cells	4,000 to 10,000/µL		None	V
Red blood cells			None	V
Casts			None	V
Bacteria			None	V
Alkaline phosphatase	*Female age 24 to 65:* 82 to 282 U/L	↑		
	Male age 19 or older: 98 to 251 U/L			

Key: ↑, increased; ↓, decreased; N, normal; V, varies.

- Intake and output assessment: Fluid intake and output measurement helps determine the patient's hydration status but isn't a reliable method of evaluating renal function because urine output varies with different types of renal disorders. To provide the most useful and accurate information, use calibrated containers, establish baseline values for each patient, compare measurement patterns, and validate intake and output measurements by checking the patient's weight daily. Monitor all fluid losses—including blood, vomitus, and diarrhea. Also assess wound and stoma drainage daily.
- Specimen collection: Meticulous specimen collection is vital for valid laboratory data. If the patient is collecting the specimen, explain the importance of cleaning the meatal area thoroughly. The culture specimen should be caught midstream, in a sterile container; a specimen for urinalysis, in a clean container, preferably at the first voiding of the day. Begin a 24-hour specimen collection after discarding the first voiding; such specimens often necessitate special handling or preservatives. When obtaining a urine specimen from a catheterized patient, remember to avoid taking the specimen from the collection bag; instead, aspirate a sample through the collection port in the catheter, with a sterile needle and a syringe.
- Kidney–ureter–bladder radiography: This test assesses size, shape, position, and areas of calcification of these organs.
- Ultrasonography: This safe, painless procedure allows for visualization of the renal parenchyma, calyces, pelvis, ureters, and bladder. Because the test doesn't depend on renal function, it's useful in patients with renal failure and in detecting complications after kidney transplantation.
- Invasive tests: See *Invasive diagnostic tests for assessing the renal and urologic systems,* pages 338 and 339.

Invasive Diagnostic Tests for Assessing the Renal and Urologic Systems

Several invasive tests are available to assist in the diagnosis of renal and urologic problems. The most serious complication that occurs with many of these procedures is hypersensitivity to the contrast media. Symptoms may include increased pulse rate, itching, hives, chills, fever, dyspnea, and shock.

Procedure	Purpose	Special considerations
Computed tomography scan (CT) or magnetic resonance imaging (MRI)	Although CT scan and MRI can be noninvasive, I.V. contrast material is often given to enhance the views obtained. These tests are especially helpful in evaluating renal or bladder mass lesions.	Before: Check for prior history of contrast sensitivity. After: After using I.V. contrast medium, observe for hypersensitivity reaction and hematoma at injection site.
Cystoscopy	A fiberoptic scope is used to visualize the inside of the bladder in cystoscopy.	Before: Give sedatives as ordered. After: Offer increased fluids; administer analgesics; watch for hematuria and signs of perforation, hemorrhage, and infection (chills, fever, increased pulse rate, shock).
Cystourethrography	In cystourethrography, X-rays and I.V. contrast material are used to determine size and shape of the bladder and urethra.	Before: Check for prior history of contrast sensitivity. During: Catheterize the patient. After: Offer increased fluids; observe for hypersensitivity reaction.
Cystometry	Cystometry is used to evaluate bladder pressure, sensation, and capacity. A catheter is introduced into the bladder, and saline solution is instilled. Results are shown on a computer at the time of testing.	Before: Observe voiding; catheterize for residual urine. After: Remove catheter; watch for stress incontinence when patient coughs; watch voiding; catheterize for residual urine.
Excretory urography	Excretory urography uses X-rays and I.V. contrast material to allow visualization of renal parenchyma, calyces, pelves, ureters, bladder, and stones.	Before: Check for prior history of contrast sensitivity. After: Observe for hypersensitivity reaction; watch for hematomas at injection site.
Nephrotomography	In nephrotomography, I.V. contrast material and tomography are used to visualize parenchyma, calyces, and pelves in layers.	Before: Check for prior history of contrast sensitivity. After: Observe for hypersensitivity reaction.
Renal angiography	Renal angiography uses contrast material injected into a catheter in the femoral artery or vein to allow visualization of the arterial tree and capillaries as well as venous drainage of the kidney.	Before: Check for prior history of contrast sensitivity. After: Observe for hypersensitivity reaction, hematomas and hemorrhage at injection site, and nephrotoxicity. Offer increased fluids.
Renal scan	In renal scan, radioisotopes are administered I.V., and images of the kidney are taken at intervals to determine renal function.	Before: Check for prior history of sensitivity. After: Observe for hypersensitivity reaction.
Renal biopsy	The specimen obtained in renal biopsy is used to develop histologic diagnosis and determine therapy and prognosis.	Before: Make sure the patient's clotting times, prothrombin times, and platelet count are recorded on his or her chart. After: Apply gentle pressure to the bandage site. Watch for hemorrhage and hematoma at the biopsy site, and look for hematuria.

TREATMENT METHODS

Treatment of intractable renal or urinary system dysfunction may require urinary diversion, dialysis, or kidney transplantation. Urinary diversion is the surgical creation of an outlet for excreting urine. The types of urinary diversion include ileal conduit, cutaneous ureterostomy, ureterosigmoidostomy, and creation of a rectal bladder.

In dialysis, a semipermeable membrane, osmosis, and diffusion imitate normal renal function by eliminating excess body fluids, maintaining or restoring plasma electrolyte and acid–base balance, and removing waste products and dialyzable poisons from the blood. Dialysis is most often used for patients with acute or chronic renal failure. The two most common types of dialysis are peritoneal dialysis and hemodialysis.

In peritoneal dialysis, a dialysate solution is infused into the peritoneal cavity. Substances then diffuse through the peritoneal membrane. Waste products remain in the dialysate solution and are removed.

Hemodialysis separates solutes by differential diffusion through a cellophane membrane placed between the blood and the dialysate solution, in an external receptacle. Because the blood must actually pass out of the body into a dialysis machine, hemodialysis requires an access route to the blood supply by an arteriovenous fistula or cannula or by a bovine or synthetic graft. When caring for a patient with such an access route, monitor the patency of the access route, prevent infection, and promote safety and adequate function. After dialysis, watch for such complications as headache, vomiting, agitation, and twitching.

Patients with end-stage renal disease may benefit from kidney transplantation, despite its limitations: a shortage of donor kidneys, the chance of transplant rejection, and the need for lifelong medications and follow-up care. After kidney transplantation, maintain fluid and electrolyte balance, prevent infection, monitor for rejection, and promote psychological well-being.

Congenital Anomalies

MEDULLARY SPONGE KIDNEY

In medullary sponge kidney, the collecting ducts in the renal pyramids dilate, and cavities, clefts, and cysts form in the medulla. This disease may affect only a single pyramid in one kidney or all pyramids in both kidneys. The kidneys are usually somewhat enlarged but may be of normal size; they appear spongy.

Because this disorder is usually asymptomatic and benign, it's often overlooked until the patient reaches adulthood. The prognosis is generally very good. Medullary sponge kidney is unrelated to medullary cystic disease; these conditions are similar only in the presence and location of the cysts.

Pathophysiology

Medullary sponge kidney may be transmitted as an autosomal dominant trait, but this remains unproven. Most nephrologists consider it a congenital abnormality.

Although medullary sponge kidney may be found in both sexes and in all age groups, it primarily affects males ages 40 to 70. It occurs in about 1 in every 5,000 to 20,000 persons.

Complications

- Calcium oxalate calculi
- Infection

Signs and Symptoms

Symptoms usually appear only as a result of complications and are seldom present before adulthood. Complications include formation of calcium oxalate stones, which lodge in the dilated cystic collecting ducts or pass through a ureter, and infection secondary to dilation of the ducts. These complications, which occur in about 30% of patients, are likely to produce severe colic, hematuria, lower urinary tract infection ([UTI]; burning on urination, urgency, frequency), and pyelonephritis. Secondary impairment of renal function from obstruction and infection occurs in only about 10% of patients.

Diagnosis

Excretory urography is usually the key to diagnosis, often showing a characteristic flowerlike appearance of the pyramidal cavities when they fill with contrast material. It may also show renal calculi. Urinalysis is generally normal unless complications develop; however, it may show a slight reduction in concentrating ability or hypercalciuria. Diagnosis must distinguish medullary sponge kidney from renal tuberculosis, renal tubular acidosis, and papillary necrosis.

Treatment

Treatment focuses on preventing or treating complications caused by stones and infection. Specific measures include increasing fluid intake and monitoring renal function and urine. New symptoms necessitate immediate evaluation.

Because medullary sponge kidney is a benign condition, surgery is seldom necessary, except to remove stones during acute obstruction. Only serious, uncontrollable infection or hemorrhage requires nephrectomy.

Special Considerations

Patient care includes explaining the disease to the patient and family and reassuring them that the condition is benign and the prognosis good.

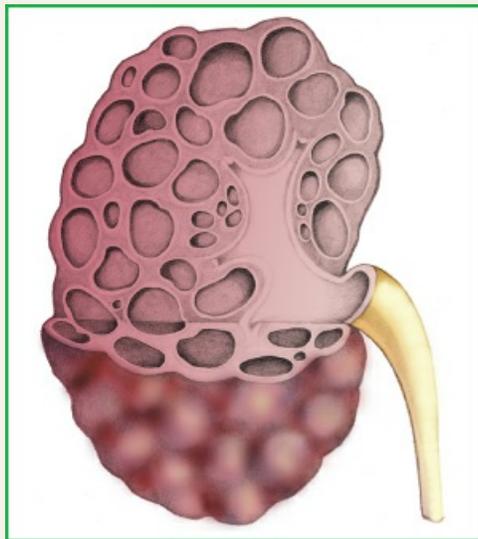
- To prevent infection, instruct the patient to bathe often and use proper toilet hygiene; this is especially important for a female patient because the proximity of the urinary meatus and the anus increases the risk of infection.
- If infection occurs, stress the importance of completing the prescribed course of antibiotic therapy.
- Emphasize the need for adequate fluid intake.
- Explain all diagnostic procedures, and provide emotional support. Teach the patient how to collect a clean-catch urine specimen for culture. Check for allergy to excretory urography dye.
- When the patient is hospitalized for a stone, strain all urine, administer analgesics as ordered, and force fluids. Before discharge, tell the patient to watch for and report any signs of stone passage and UTI.

POLYCYSTIC KIDNEY DISEASE

Polycystic kidney disease is an inherited disorder characterized by multiple, bilateral, grapelike

clusters of fluid-filled cysts that grossly enlarge the kidneys, compressing and eventually replacing functioning renal tissue. (See *Polycystic kidney,* page 341.) The disease appears in two distinct forms: The infantile form typically causes stillbirth or early neonatal death, although some infants may survive for 2 years, then develop fatal renal, cardiac, or respiratory failure. The adult form begins insidiously but usually becomes obvious between ages 30 and 50 years old; rarely, it causes no symptoms until the patient is in his 70s. In the adult form, renal deterioration is more gradual but, as in the infantile form, progresses relentlessly to fatal uremia.

Polycystic Kidney

In polycystic kidney disease, cysts are seen in grapelike clusters, as shown below.


The prognosis in adults is extremely variable. Progression may be slow, even after symptoms of renal insufficiency appear. However, after uremic symptoms develop, polycystic kidney disease is usually fatal within 4 years, unless the patient receives treatment with dialysis, kidney transplantation, or both.

Pathophysiology

Although both types of polycystic kidney disease are genetically transmitted, the incidence in two distinct age groups and different inheritance patterns suggest two unrelated disorders. The infantile type appears to be inherited as an autosomal recessive trait, whereas the adult type seems to be an autosomal dominant trait. The gene has been located on chromosome 6, supporting the premise that this is a single genetic disease with variable phenotype presentation.

Polycystic kidney disease reportedly affects 1 in every 1,000 Americans; that number may be even higher because some cases from patients who aren't symptomatic go unreported. Both types of polycystic kidney disease affect males and females equally.

Complications

- Hypertension
- UTI
- Kidney infection
- End-stage kidney disease
- Kidney stones
- Ruptured cysts

Signs and Symptoms

PEDIATRIC TIP *The neonate with infantile polycystic disease often has pronounced epicanthal folds, a pointed nose, a small chin, and floppy, low-set ears (Potter facies). At birth, the child has huge bilateral masses on the flanks that are symmetrical, tense, and can't be transilluminated. The patient characteristically shows signs of respiratory distress and heart failure. Eventually, the patient develops uremia and renal failure. Accompanying hepatic fibrosis may cause portal hypertension and bleeding varices to develop, requiring sclerotherapy or portacaval shunting.*

Adult polycystic kidney disease is commonly asymptomatic through the patient's 40s, but may induce nonspecific symptoms, such as hypertension, polyuria, and recurrent UTIs. Later, the patient develops overt symptoms related to the enlarging kidney mass, such as lumbar pain, widening girth, and swollen or tender abdomen. Abdominal pain is usually worsened by exertion and relieved by lying down. In advanced stages, this disease may cause recurrent hematuria, life-threatening retroperitoneal bleeding resulting from cyst rupture, proteinuria, and colicky abdominal pain from the ureteral passage of clots or calculi. Generally, about 10 years after symptoms appear, progressive compression of kidney structures by the enlarging mass produces renal failure and uremia. Hypertension is found in about 20% to 30% of children and up to 75% of adults due to intrarenal ischemia, which activates the renin–angiotensin system.

Diagnosis

A family history and a physical examination revealing large bilateral, irregular masses in the flanks strongly suggest polycystic kidney disease. In advanced stages, grossly enlarged and palpable kidneys make the diagnosis obvious. In patients with these findings, the following laboratory results are typical:

- Excretory urography reveals enlarged kidneys, with elongation of pelvis, flattening of the calyces, and indentations caused by cysts. Excretory urography of the neonate shows poor excretion of contrast medium.
- Ultrasound and computed tomography (CT) scan show kidney enlargement and the presence of cysts; tomography demonstrates multiple areas of cystic damage. Ultrasonography is the preferred imaging technique because it's less expensive, doesn't require contrast or radiation exposure, and is easily and safely performed on children and pregnant females.
- Urinalysis and creatinine clearance tests are nonspecific tests that evaluate renal function and reveal urine protein or blood in the urine.

Diagnosis must rule out the presence of renal tumors.

Treatment

Polycystic kidney disease can't be cured. The primary goal of treatment is preserving renal parenchyma and preventing infectious complications. Management of secondary hypertension will also help prevent rapid deterioration in function. Progressive renal failure requires treatment similar to that for other types of renal disease, including dialysis or, rarely, kidney transplantation.

When adult polycystic kidney disease is discovered in the asymptomatic stage, careful monitoring is required, including urine cultures and creatinine clearance tests every 6 months. Prompt and vigorous antibiotic treatment is needed when a urine culture reveals infection—even when the patient is asymptomatic. As renal impairment progresses, selected patients may undergo dialysis, transplantation, or both. Cystic abscess or retroperitoneal bleeding may require surgical drainage; intractable pain (a rare symptom) may also require surgery. However, because this disease affects both kidneys, nephrectomy usually isn't recommended because it increases the risk of infection in the remaining kidney.

Special Considerations

Because polycystic kidney disease is usually relentlessly progressive, comprehensive patient teaching and emotional support are essential.

- Refer the young adult patient or the parents of infants with polycystic kidney disease for genetic counseling. Parents will probably have many questions about the risk to other offspring.
- Provide supportive care to minimize any associated symptoms. Carefully assess the patient's lifestyle and his physical and mental status; determine how rapidly the disease is progressing. Use this information to plan individualized patient care.
- Acquaint yourself with all aspects of end-stage renal disease, including dialysis and transplantation, so you can provide appropriate care and patient teaching as the disease progresses.
- Explain all diagnostic procedures to the patient or to the family if the patient is an infant. Before beginning excretory urography or other procedures that use an iodine-based contrast medium, determine whether the patient has ever had an allergic reaction to iodine or shellfish. Even if the patient has no history of allergy, watch for an allergic reaction after performing the procedures.
- Administer antibiotics as ordered for UTI. Stress to the patient the need to take the medication exactly as prescribed, even if symptoms are minimal or absent.

Acute Renal Disorders

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) is the sudden interruption of kidney function due to obstruction, reduced circulation, or renal parenchymal disease. It's usually reversible with medical treatment; otherwise, it may progress to end-stage renal disease, uremic syndrome, and death.

Pathophysiology

The causes of AKI are classified as prerenal, intrinsic (or parenchymal), and postrenal. Prerenal failure is associated with diminished blood flow to the kidneys, possibly resulting from

hypovolemia, shock, severe anaphylaxis, embolism, blood loss, sepsis, pooling of fluid in ascites or burns, or from cardiovascular disorders, such as heart failure, arrhythmias, and tamponade.

Intrinsic renal failure results from damage to the kidneys themselves, usually due to acute tubular necrosis (ATN), but possibly due to acute poststreptococcal glomerulonephritis (APSGN), systemic lupus erythematosus, periarteritis nodosa, vasculitis, sickle cell disease, bilateral renal vein thrombosis, nephrotoxins, chronic misuse of nonsteroidal anti-inflammatory drugs, radiopaque contrast agents, ischemia, renal myeloma, acute pyelonephritis, and exposure to heavy metals, such as lead or mercury.

Postrenal failure results from bilateral obstruction of urinary outflow. Its multiple causes include kidney stones, blood clots, papillae from papillary necrosis, tumors, benign prostatic hyperplasia (BPH), strictures, and urethral edema from catheterization.

In the United States, the annual incidence of AKI is 100 cases for every million people. It's diagnosed in 1% of hospital admissions. Hospital-acquired AKI occurs in 4% of all admitted patients and 20% of patients who are admitted to critical care units.

Complications

- Volume overload
- Pulmonary edema
- Electrolyte imbalance
- Metabolic acidosis

Signs and Symptoms

AKI is a critical illness. Its early signs are oliguria, azotemia, and, rarely, anuria. Electrolyte imbalance, metabolic acidosis, and other severe effects follow, as the patient becomes increasingly uremic and renal dysfunction disrupts other body systems:

- *Gastrointestinal (GI):* anorexia, nausea, vomiting, diarrhea or constipation, stomatitis, bleeding, hematemesis, dry mucous membranes, uremic breath
- *Central nervous system (CNS):* headache, drowsiness, irritability, confusion, peripheral neuropathy, seizures, coma
- *Cutaneous:* dryness, pruritus, pallor, purpura and, rarely, uremic frost
- *Cardiovascular:* early in the disease, hypotension; later, hypertension, arrhythmias, fluid overload, heart failure, systemic edema, anemia, altered clotting mechanisms
- *Respiratory:* pulmonary edema, Kussmaul respirations.

Fever and chills indicate infection, a common complication.

Diagnosis

The patient's history may include a disorder that can cause renal failure. Blood test results indicating intrinsic renal failure include elevated blood urea nitrogen, serum creatinine, and potassium levels and low blood pH, bicarbonate, hematocrit (HCT), and hemoglobin (Hb) level. Urine specimens show casts, cellular debris, decreased specific gravity and, in glomerular diseases, proteinuria and urine osmolality close to serum osmolality. Urine sodium level is less than 20 mEq/L if oliguria is due to decreased perfusion; more than 40 mEq/L if due to an intrinsic problem. Other studies include renal ultrasonography, kidney–ureter–bladder X-rays, cautious use of excretory urography, renal scan, and nephrotomography.

Treatment

The goal of treatment is to correct or eliminate any reversible causes of kidney failure, such as obstructive uropathy, volume depletion, or the use of kidney-toxic medications. Supportive measures include a diet high in calories and low in protein, sodium, and potassium, with supplemental vitamins and restricted fluids. Meticulous electrolyte monitoring is essential to detect hyperkalemia. If hyperkalemia occurs, acute therapy may include dialysis, I.V. administration of hypertonic glucose, insulin infusion, and sodium bicarbonate, and administration of a potassium exchange resin (orally or by enema) to remove potassium from the body.

If measures fail to control uremic symptoms, hemodialysis or peritoneal dialysis may be necessary. Continuous arteriovenous hemodiafiltration and continuous venovenous hemodiafiltration are alternative hemodialysis techniques for the treatment of AKI. They're generally reserved for when intermittent dialysis fails to control hypervolemia or uremia, or for patients for whom peritoneal dialysis isn't possible.

Special Considerations

Patient care includes careful monitoring and dietary education.

- Measure and record intake and output, including all body fluids, such as wound drainage, nasogastric tube output, and diarrhea. Weigh the patient daily.
- Assess Hb levels and HCT and replace blood components, as indicated. *Don't* use whole blood if the patient is prone to heart failure and can't tolerate extra fluid volume. Packed RBCs deliver the necessary blood components without added volume.
- Monitor vital signs. Watch for and report any signs of pericarditis (pleuritic chest pain, tachycardia, pericardial friction rub), inadequate renal perfusion (hypotension), and acidosis.
- Maintain proper electrolyte balance. Strictly monitor potassium levels. Watch for symptoms of hyperkalemia (malaise, anorexia, paresthesia, or muscle weakness) and electrocardiogram changes (tall, peaked T waves, widening QRS segment, and disappearing P waves), and report them immediately. Avoid administering medications containing potassium.

ALERT *Assess the patient frequently, especially during emergency treatment to lower potassium levels. If the patient receives hypertonic glucose and insulin infusions, monitor potassium levels. If you give sodium polystyrene sulfonate rectally, make sure the patient doesn't retain it and become constipated, to prevent bowel perforation.*

- Maintain nutritional status. Provide a high-calorie, low-protein, low-sodium, and low-potassium diet, with vitamin supplements. Give the anorectic patient small, frequent meals.
- Use sterile technique, because the patient with AKI is highly susceptible to infection. Personnel with upper respiratory tract infections shouldn't provide care for the patient.
- Prevent complications of immobility by encouraging frequent coughing and deep breathing and by performing passive range-of-motion exercises. Help the patient walk as soon as possible.
- Provide good mouth care frequently because mucous membranes are dry. If stomatitis occurs, an antibiotic solution may be ordered. Have the patient swish the solution around in his mouth before swallowing.
- Monitor for GI bleeding by guaiac testing all stools for blood. Administer medications carefully, especially antacids and stool softeners. Use aluminum-hydroxide–based antacids;

magnesium-based antacids can cause serum magnesium levels to rise to critical levels.

◆ Use appropriate safety measures, such as side rails and restraints, because the patient with CNS involvement may be dizzy or confused.

◆ Provide emotional support to the patient and his family. Reassure them by clearly explaining all procedures.

◆ If the patient requires hemodialysis, check the blood access site (arteriovenous fistula, subclavian or femoral catheter) as per facility protocol or every 2 hours for patency and signs of clotting. Don't use the arm with the shunt or fistula for taking blood pressures or drawing blood. Weigh the patient before beginning dialysis. During dialysis, monitor vital signs, clotting times, blood flow, the function of the vascular access site, and arterial and venous pressures. Watch for complications, such as septicemia, embolism, hepatitis, and rapid fluid and electrolyte loss. After dialysis, monitor vital signs and the vascular access site; weigh the patient; watch for signs of fluid and electrolyte imbalances.

◆ During peritoneal dialysis, position the patient carefully. Elevate the head of the bed to reduce pressure on the diaphragm and aid respiration. Be alert for signs of infection (cloudy drainage, elevated temperature) and, rarely, bleeding. If pain occurs, reduce the amount of dialysate. Monitor the diabetic patient's blood glucose periodically, and administer insulin as ordered. Watch for complications, such as peritonitis, atelectasis, hypokalemia, pneumonia, and shock.

◆ Use standard precautions when handling all blood and body fluids.

PREVENTION

◆ *Evaluate all drugs the patient is taking and determine which drugs may be affected by or have an effect on renal function.*

◆ *Aggressively restore fluid volume after major surgery or trauma.*

ACUTE PYELONEPHRITIS

Acute pyelonephritis (also known as *acute infective tubulointerstitial nephritis*) is a sudden inflammation caused by bacteria that primarily affects the interstitial area and the renal pelvis or, less often, the renal tubules. It's one of the most common renal diseases. With treatment and continued follow-up care, the prognosis is good, and extensive permanent damage is rare. (See *Chronic pyelonephritis*, page 345.)

Chronic Pyelonephritis

Chronic pyelonephritis is a persistent kidney inflammation that can scar the kidneys and may lead to chronic renal failure. Its etiology may be bacterial, metastatic, or urogenous. This disease is most common in patients who are predisposed to recurrent acute pyelonephritis, such as those with urinary obstructions or vesicoureteral reflux.

Patients with chronic pyelonephritis may have a childhood history of unexplained fevers or bedwetting. Clinical effects may include flank pain, anemia, low urine specific gravity, proteinuria, waxy casts, leukocytes in urine and, especially in late stages, hypertension. Uremia rarely develops from chronic pyelonephritis unless structural abnormalities exist in the excretory system. Bacteriuria may be intermittent. When no bacteria are found in the urine, diagnosis depends on excretory urography (renal pelvis may appear small and

flattened) and renal biopsy.

Effective treatment of chronic pyelonephritis requires control of hypertension, elimination of the existing obstruction (when possible), and long-term antimicrobial therapy.

Pathophysiology

Acute pyelonephritis results from bacterial infection of the kidneys. Infecting bacteria usually are normal intestinal and fecal flora that grow readily in urine. The most common causative organism is *Escherichia coli,* but *Proteus, Pseudomonas, Staphylococcus aureus,* and *Enterococcus faecalis* (formerly *Streptococcus faecalis*) may also cause this infection.

Typically, the infection spreads from the bladder to the ureters, then to the kidneys, as in vesicoureteral reflux due to congenital weakness at the junction of the ureter and the bladder. Bacteria refluxed to intrarenal tissues may create colonies of infection within 24 to 48 hours. Infection may also result from instrumentation (such as catheterization, cystoscopy, or urologic surgery), from a hematogenic infection (as in septicemia or endocarditis), or possibly from lymphatic infection.

Pyelonephritis may also result from an inability to empty the bladder (e.g., in patients with neurogenic bladder), urinary stasis, or urinary obstruction due to tumors, strictures, or BPH.

Pyelonephritis occurs more commonly in women, probably because of a shorter urethra and the proximity of the urinary meatus to the vagina and the rectum—both of which allow bacteria to reach the bladder more easily—and a lack of the antibacterial prostatic secretions produced by men. Incidence increases with age and is higher in the following groups:

- *Sexually active women:* Intercourse increases the risk of bacterial contamination.
- *Pregnant women:* About 5% develop asymptomatic bacteriuria; if untreated, about 40% develop pyelonephritis.
- *Diabetics:* Neurogenic bladder causes incomplete emptying and urinary stasis; glycosuria may support bacterial growth in the urine.
- *Persons with other renal diseases:* Compromised renal function aggravates susceptibility.

Complications

- Recurrence of pyelonephritis
- Sepsis
- Perinephric abscess
- Renal failure

Signs and Symptoms

Typical clinical features include urgency, frequency, burning during urination, dysuria, nocturia, and hematuria (usually microscopic but may be gross). Urine may appear cloudy and have an ammonia-like or fishy odor. Other common symptoms include a temperature of 102° F (38.9° C) or higher, shaking chills, flank pain, anorexia, and general fatigue.

These symptoms characteristically develop rapidly over a few hours or a few days. Although these symptoms may disappear within days, even without treatment, residual bacterial infection is likely and may cause symptoms to recur later.

ELDER TIP Elderly patients may exhibit altered mental status or GI or pulmonary symptoms rather than the usual febrile responses to pyelonephritis.

Diagnosis

Diagnosis requires urinalysis and culture. Typical findings include:

- Pyuria (pus in urine): Urine sediment reveals the presence of leukocytes singly, in clumps, and in casts; and, possibly, a few RBCs.
- Significant bacteriuria: Urine culture reveals more than 100,000 organisms/mL of urine.
- Low specific gravity and osmolality: These findings result from a temporarily decreased ability to concentrate urine.
- Slightly alkaline urine pH.
- Proteinuria, glycosuria, and ketonuria: These conditions are less common.
- Costovertebral angle tenderness.

Excretory urography or CT scan of the kidneys, ureters, and bladder also help in the evaluation of acute pyelonephritis by revealing calculi, tumors, or cysts in the kidneys and the urinary tract. In addition, excretory urography may show asymmetrical kidneys.

Treatment

Treatment centers on antibiotic therapy appropriate to the specific infecting organism after identification by urine culture and sensitivity studies. When the infecting organism can't be identified, therapy usually consists of a broad-spectrum antibiotic. Urinary analgesics are also appropriate.

ALERT *If a woman is pregnant, antibiotics must be prescribed cautiously.*

Symptoms may disappear after several days of antibiotic therapy. Although urine usually becomes sterile within 48 to 72 hours, the course of such therapy is 10 to 14 days. Follow-up treatment may include reculturing urine 1 week after drug therapy stops, then periodically for the next year to detect residual or recurring infection. Most patients with uncomplicated infections respond well to therapy and don't suffer reinfection.

In infection from obstruction or vesicoureteral reflux, antibiotics may be less effective; treatment may then necessitate surgery to relieve the obstruction or correct the anomaly. Patients at high risk of recurring urinary tract and kidney infections, such as those with prolonged use of an indwelling catheter or maintenance antibiotic therapy, require long-term follow-up. Recurrent episodes of acute pyelonephritis can eventually result in chronic pyelonephritis.

Special Considerations

Patient care is supportive during antibiotic treatment of the underlying infection.

- Administer antipyretics for fever.
- Encourage fluids to achieve urine output of more than 2,000 mL/day. This helps to empty the bladder of contaminated urine. Don't encourage intake of more than 2 to 3 qt (2 to 3 L) because this may decrease the effectiveness of the antibiotics.
- Provide an acid-ash diet to prevent stone formation.
- Teach proper technique for collecting a clean-catch urine specimen. Be sure to refrigerate or

culture a urine specimen within 30 minutes of collection to prevent overgrowth of bacteria.
- Stress the need to complete prescribed antibiotic therapy, even after symptoms subside. Encourage long-term follow-up care for high-risk patients.

To prevent acute pyelonephritis:

PREVENTION

- *Observe strict sterile technique during catheter insertion and care.*
- *Instruct women to prevent bacterial contamination by wiping the perineum from front to back after defecation.*
- *Advise routine checkups for patients with a history of UTIs. Teach them to recognize signs of infection, such as cloudy urine, burning on urination, urgency, and frequency, especially when accompanied by a low-grade fever.*

ACUTE POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

APSGN, also known as *acute glomerulonephritis,* is a relatively common bilateral inflammation of the glomeruli. It usually follows a streptococcal infection of the respiratory tract or, less often, a skin infection such as impetigo.

Pathophysiology

APSGN results from the entrapment and collection of antigen–antibody complexes (produced as an immunologic mechanism in response to streptococcus) in the glomerular capillary membranes, inducing inflammatory damage and impeding glomerular function. Sometimes, the immune complement further damages the glomerular membrane. The damaged and inflamed glomerulus loses the ability to be selectively permeable, and allows RBCs and proteins to filter through as the GFR falls. Uremic poisoning may result.

APSGN is most common in boys ages 3 to 7, but it can occur at any age. Incidence is rising in the United States and Europe, with epidemics occurring in developing countries in Africa, the West Indies, and the Middle East.

Up to 95% of children and up to 70% of adults with APSGN recover fully; the rest may progress to chronic renal failure within months.

Complications

- AKI or chronic kidney failure
- End-stage renal disease
- Hypertension
- Heart failure
- Pulmonary edema
- Chronic glomerulonephritis
- Nephrotic syndrome

Signs and Symptoms

APSGN begins within 1 to 3 weeks after pharyngitis. Symptoms include mild to moderate edema, oliguria (<400 mL/24 hours), proteinuria, azotemia, hematuria, and fatigue. Mild to severe hypertension may result from either sodium or water retention (due to decreased GFR) or

inappropriate renin release. Heart failure from hypervolemia leads to pulmonary edema.

PEDIATRIC TIP *The presenting features of APSGN in children may be encephalopathy with seizures and focal neurologic deficits.*

Diagnosis

Diagnosis requires a detailed patient history and assessment of clinical symptoms and laboratory tests.

Urinalysis typically reveals proteinuria and hematuria. RBCs, WBCs, and mixed cell casts are common in urinary sediment. Elevated serum creatinine levels and low creatinine clearance accompany impaired glomerular filtration. Elevated antistreptolysin-O titers (in 80% of patients), elevated streptozyme and anti-DNase B titers, and low serum complement levels verify recent streptococcal infection. A throat culture may also show group A beta-hemolytic streptococcus. Renal ultrasound may show a normal or slightly enlarged kidney. A renal biopsy may confirm the diagnosis or assess renal tissue status.

Treatment

The goals of treatment are relief of symptoms and prevention of complications. Vigorous supportive care includes bed rest, fluid and dietary sodium restrictions, and correction of electrolyte imbalances (possibly with dialysis, although this is rarely necessary). Therapy may include diuretics to reduce extracellular fluid overload and an antihypertensive. The use of antibiotics is recommended for 7 to 10 days if staphylococcal infection is documented. Otherwise, antibiotic use is controversial.

Special Considerations

APSGN usually resolves within 2 weeks, so patient care is primarily supportive.

- Check vital signs and electrolyte values. Monitor intake and output and daily weight. Assess renal function daily through serum creatinine, blood urea nitrogen, and urine creatinine clearance levels. Watch for and immediately report signs of acute renal failure (oliguria, azotemia, and acidosis).
- Consult the dietitian to provide a diet high in calories and low in protein, sodium, potassium, and fluids.
- Protect the debilitated patient against secondary infection by providing good nutrition, using good hygienic technique, and preventing contact with infected persons.
- Bed rest is necessary during the acute phase. Allow the patient to *gradually* resume normal activities as symptoms subside.
- Provide emotional support for the patient and family. If the patient is on dialysis, explain the procedure fully.
- Advise the patient with a history of chronic upper respiratory tract infections to immediately report signs of infection (fever, sore throat).
- Tell the patient that follow-up examinations are necessary to detect chronic renal failure. Stress the need for regular blood pressure, urinary protein, and renal function assessments during the convalescent months to detect recurrence. After APSGN, gross hematuria may recur during nonspecific viral infections; abnormal urinary findings may persist for years.
- Encourage pregnant women with a history of APSGN to have frequent medical evaluations

because pregnancy further stresses the kidneys and increases the risk of chronic renal failure.

ACUTE TUBULAR NECROSIS

ATN, also known as *acute tubulointerstitial nephritis*, accounts for about 75% of all cases of AKI and is the most common cause of AKI in critically ill patients. ATN injures the tubular segment of the nephron, causing renal failure and uremic syndrome. Mortality ranges from 40% to 70%, depending on complications from underlying diseases. Nonoliguric forms of ATN have a better prognosis.

Pathophysiology

ATN results from ischemic or nephrotoxic injury, most commonly in debilitated patients, such as the critically ill or those who have undergone extensive surgery. In ischemic injury, disruption of blood flow to the kidneys may result from circulatory collapse, severe hypotension, trauma, hemorrhage, dehydration, cardiogenic or septic shock, surgery, anesthetics, or reactions to transfusions. Nephrotoxic injury may follow ingestion of certain chemical agents or result from a hypersensitive reaction of the kidneys. (See *Rise in nephrotoxic injury*.) Because nephrotoxic ATN doesn't damage the basement membrane of the nephron, it's potentially reversible. However, ischemic ATN can damage the epithelial and basement membranes and can cause lesions in the renal interstitium. ATN may result from:

Rise in Nephrotoxic Injury

The incidence of acute tubular necrosis (ATN) due to ingestion or inhalation of toxic substances is rising. ATN may occur in hospitalized patients following exposure to toxic agents, such as antibiotics, chemotherapeutic agents, or contrast material. Other nephrotoxic agents include pesticides, fungicides, heavy metals (e.g., mercury, arsenic, lead, bismuth, uranium), and organic solvents containing carbon tetrachloride or ethylene glycol, such as cleaning fluids or industrial solvents. Ingestion of these substances may be accidental or intentional.

- diseased tubular epithelium that allows leakage of glomerular filtrate across the membranes and reabsorption of filtrate into the blood
- obstruction of urine flow by the collection of damaged cells, casts, RBCs, and other cellular debris within the tubular walls
- ischemic injury to glomerular epithelial cells, resulting in cellular collapse and decreased glomerular capillary permeability
- ischemic injury to vascular endothelium, eventually resulting in cellular swelling and obstruction.

Complications

- Fluid and electrolyte imbalance
- Heart failure
- GI hemorrhage
- Pulmonary edema

Signs and Symptoms

Nephrotoxic injury causes multiple symptoms similar to those of renal failure, particularly azotemia, anemia, acidosis, overhydration, and hypertension. Some patients may also experience fever, rash, and eosinophilia. However, ATN is usually difficult to recognize in its early stages because effects of the critically ill patient's primary disease may mask the symptoms of ATN. (See *A close look at acute tubular necrosis*, page 348.) The first recognizable effect may be decreased urine output. Generally, hyperkalemia and the characteristic uremic syndrome soon follow, with oliguria (or, rarely, anuria) and confusion, which may progress to uremic coma. Other possible complications may include heart failure, uremic pericarditis, pulmonary edema, uremic lung, anemia, anorexia, intractable vomiting, and poor wound healing due to debilitation.

PATHOPHYSIOLOGY
A CLOSE LOOK AT ACUTE TUBULAR NECROSIS

In acute tubular necrosis caused by ischemia, patches of necrosis occur, usually in the straight portion of the proximal tubules as shown. In areas without lesions, tubules are usually dilated.

In acute tubular necrosis caused by nephrotoxicity, the tubules have a more uniform appearance, as shown in the second illustration.

ALERT *Fever and chills may signal the onset of an infection, which is the leading cause of death in ATN.*

Diagnosis

Diagnosis is usually delayed until the condition has progressed to an advanced stage. The most significant laboratory clues are urinary sediment containing RBCs and casts, and dilute urine of a low specific gravity (1.010), low osmolality (<400 mOsm/kg), and high sodium level (40 to 60 mEq/L). Blood studies reveal elevated blood urea nitrogen and serum creatinine levels, anemia, defects in platelet adherence, metabolic acidosis, and hyperkalemia. An electrocardiogram may show arrhythmias (due to electrolyte imbalances) and, with hyperkalemia, widening QRS segment, disappearing P waves, and tall, peaked T waves.

Treatment

Treatment consists of identifying the nephrotoxic substance, eliminating its use, and removing it from the body, possibly by hemodialysis or hemoperfusion in extreme cases. Initial treatment may include administration of diuretics and infusion of a large volume of fluids to flush tubules of cellular casts and debris and to replace fluid loss. However, this treatment carries a risk of fluid overload. Long-term fluid management requires daily replacement of projected and calculated losses (including insensible loss). Diet may be high in carbohydrates and low in protein, sodium, and potassium to minimize their buildup in the body. During the course of acute renal failure, treatment is supportive.

Other appropriate measures to control complications include transfusion of packed RBCs for anemia and administration of antibiotics for infection. Epoetin alfa may be given to stimulate RBC production as an alternative to blood transfusion. Hyperkalemia may require emergency I.V. administration of 50% glucose, regular insulin, and sodium bicarbonate. Sodium polystyrene

sulfonate with sorbitol may be given by mouth or by enema to reduce extracellular potassium levels. Peritoneal dialysis or hemodialysis may be needed if the patient is catabolic.

Special Considerations

Patient care is largely supportive.

- Maintain fluid balance. Watch for fluid overload, a common complication of therapy. Accurately record intake and output, including wound drainage, nasogastric tube output, and hemodialysis and peritoneal dialysis balances. Weigh the patient daily.
- Monitor Hb levels and HCT, and administer blood products as needed. Use fresh packed cells instead of whole blood to prevent fluid overload and heart failure.
- Maintain electrolyte balance. Monitor laboratory results and report imbalances. Enforce dietary restriction of foods containing sodium and potassium, such as bananas, orange juice, and baked potatoes. Check for potassium content in prescribed medications (e.g., potassium penicillin). Provide adequate calories and essential amino acids while restricting protein intake to maintain an anabolic state. Total parenteral nutrition may be indicated in the severely debilitated or catabolic patient.
- Use sterile technique, particularly when handling catheters, because the debilitated patient is vulnerable to infection. Immediately report fever, chills, delayed wound healing, or flank pain if the patient has an indwelling catheter in place.
- Watch for complications. If anemia worsens (pallor, weakness, lethargy with decreased Hb level), administer RBCs as ordered. For acidosis, give sodium bicarbonate or assist with dialysis in severe cases, as ordered. Watch for signs of diminishing renal perfusion (hypotension and decreased urine output). Encourage coughing and deep breathing to prevent pulmonary complications.
- Perform passive range-of-motion exercises. Provide good skin care; apply lotion or bath oil for dry skin. Help the patient to walk as soon as possible, but guard against exhaustion.
- Provide reassurance and emotional support. Encourage the patient and family to express their fears. Fully explain each procedure; repeat the explanation each time the procedure is done. Help the patient and family set realistic goals according to individual prognosis.
- To prevent ATN, make sure patients are well hydrated before surgery or after X-rays that use a contrast medium. Administer mannitol, as ordered, to high-risk patients before and during these procedures. Carefully monitor patients receiving blood transfusions to detect early signs of transfusion reaction (fever, rash, and chills), and discontinue such transfusion immediately.

PREVENTION

- *Immediately treat disorders that cause a decrease in blood flow and oxygenation to the kidneys, such as severe hypotension and cardiogenic or septic shock.*
- *Proper hydration before surgery is very important. Adequate hydration after administration of radiocontrast dyes may allow for their excretion and reduce the risk of kidney damage.*
- *Proper typing and crossmatching before blood transfusions reduces the risk of incompatibility reactions.*
- *When a patient is exposed to drugs toxic to the renal system, monitor carefully by checking levels regularly.*
- *Patients with diseases, such as diabetes, liver disease, and cardiac disorders, are at higher risk for ATN. These patients need to be well controlled in order to prevent the risk of ATN.*

RENAL INFARCTION

Renal infarction is the formation of a coagulated, necrotic area in one or both kidneys that results from renal blood vessel occlusion. The location and size of the infarction depend on the site of vascular occlusion; most often, infarction affects the renal cortex, but it can extend into the medulla. Residual renal function after infarction depends on the extent of the damage from the infarction.

Pathophysiology

In 75% of patients, renal infarction results from renal artery embolism secondary to mitral stenosis, infective endocarditis, atrial fibrillation, microthrombi in the left ventricle, rheumatic valvular disease, or recent myocardial infarction. The embolism reduces the rate of blood flow to renal tissue and leads to ischemia. The rate and degree of blood flow reduction determine whether or not the insult will be acute or chronic as arterial narrowing progresses. Less common causes of renal infarction are atherosclerosis, with or without thrombus formation, and thrombus from flank trauma, sickle cell anemia, scleroderma, polyarteritis nodosa, and arterionephrosclerosis.

Complications

- End-stage renal disease
- Granular kidneys
- Severe hypertension
- Cardiac hypertrophy
- Heart failure

Signs and Symptoms

Although renal infarction may be asymptomatic, typical symptoms include severe upper abdominal pain or gnawing flank pain and tenderness, costovertebral tenderness, fever, anorexia, nausea, and vomiting. Gross hematuria may be present. When arterial occlusion causes infarction, the affected kidney is small and not palpable. Renovascular hypertension, a frequent complication that may occur several days after infarction, results from reduced blood flow, which stimulates the renin–angiotensin mechanism.

Diagnosis

A history of predisposing cardiovascular disease or other factors in a patient with typical clinical features strongly suggests renal infarction. Firm diagnosis requires appropriate laboratory tests:

- Urinalysis shows proteinuria and microscopic hematuria.
- Urine enzyme levels, especially lactate dehydrogenase (LDH) and alkaline phosphatase, are often elevated as a result of tissue destruction.
- Serum enzyme levels, especially aspartate aminotransferase, alkaline phosphatase, and LDH, are elevated. Blood studies may also show leukocytosis and increased erythrocyte sedimentation rate.
- Excretory urography shows diminished or absent excretion of contrast dye, indicating vascular occlusion or urethral obstruction.
- Isotopic renal scan, a benign, noninvasive technique, demonstrates absent or reduced blood flow to the kidneys.

CONFIRMING DIAGNOSIS *Renal arteriography provides absolute proof of infarction but is used as a last resort because it's a high-risk procedure.*

Treatment

Infection in the infarcted area or significant hypertension may require surgical repair of the occlusion or nephrectomy. Surgery to establish collateral circulation to the area can relieve renovascular hypertension. Persistent hypertension may respond to antihypertensives and a low-sodium diet. Additional treatments may include administration of intra-arterial streptokinase, lysis of blood clots, and heparin therapy. For bilateral emboli, intra-arterial streptokinase or transluminal angioplasty is recommended. If effective renal blood flow is obtained, long-term anticoagulation is recommended.

Special Considerations

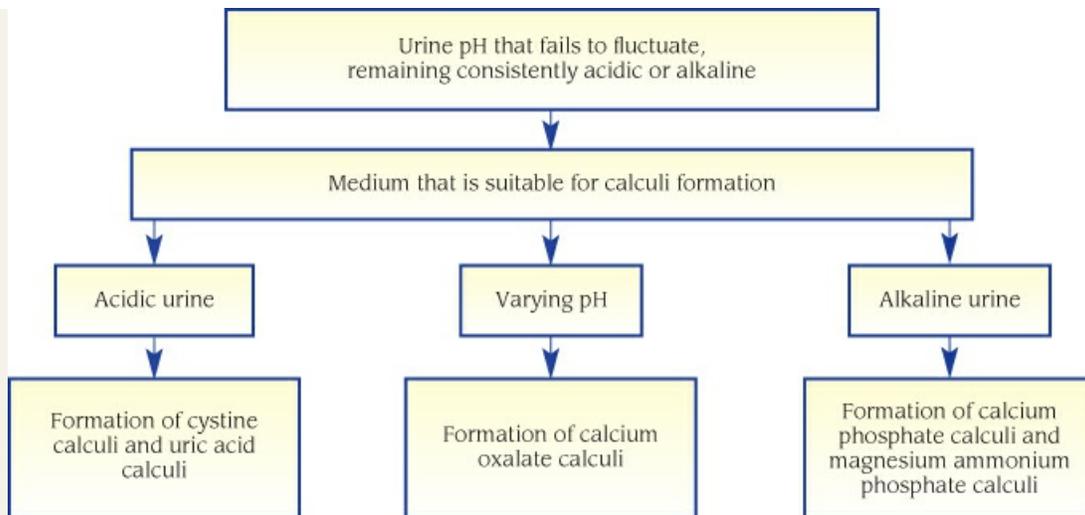
Assess the degree of renal function and offer supportive care to maintain homeostasis.

- Monitor intake and output, vital signs (particularly blood pressure), electrolytes, and daily weight. Watch for signs of fluid overload, such as dyspnea, tachycardia, pulmonary edema, and electrolyte imbalances.
- Carefully explain all diagnostic procedures.
- Provide reassurance and emotional support for the patient and family.
- Encourage the patient to return for follow-up examination, which usually includes excretory urography or a renal scan to assess regained renal function.

RENAL CALCULI

Renal calculi or nephrolithiasis (commonly called *kidney stones*) may form anywhere in the urinary tract but usually develop in the renal pelvis or the calyces of the kidneys. Calculi formation follows precipitation of substances normally dissolved in the urine, such as calcium oxalate, calcium phosphate, magnesium ammonium phosphate, or, occasionally, urate or cystine. (See *How urine pH affects calculi formation*.) Renal calculi vary in size and may be solitary or multiple. They may remain in the renal pelvis or enter the ureter and may damage renal parenchyma; large calculi cause pressure necrosis. In certain locations, calculi cause obstruction, with resultant hydronephrosis, and tend to recur.

PATHOPHYSIOLOGY
HOW URINE PH AFFECTS CALCULI FORMATION

The pH of the urine influences the types of calculi that may form.


Pathophysiology

Although the exact cause of renal calculi is unknown, predisposing factors include:

- *Dehydration:* Decreased urine production concentrates calculus-forming substances.
- *Infection:* Infected, damaged tissue serves as a site for calculus development; pH changes provide a favorable medium for calculus formation (especially for magnesium ammonium phosphate or calcium phosphate calculi); infected calculi (usually magnesium ammonium phosphate or staghorn calculi) may develop if bacteria serve as the nucleus in calculus formation. Infections may promote destruction of renal parenchyma.
- *Obstruction:* Urinary stasis (as in immobility from spinal cord injury) allows calculus constituents to collect and adhere, forming calculi. Obstruction also promotes infection, which, in turn, compounds the obstruction.
- *Metabolic factors:* These factors may predispose to renal calculi: hyperparathyroidism, renal tubular acidosis, elevated uric acid (usually with gout), defective metabolism of oxalate, genetic defect in metabolism of cystine, and excessive intake of vitamin D or dietary calcium.

Among Americans, renal calculi develop in 2% to 10% of the population, with people living in southeastern states having an increased risk. They're more common in men (especially those ages 30 to 40) than in women by a 3:1 ratio. They're rare in children.

Some types of calculi tend to be familial; some are associated with other conditions, such as bowel disease, bariatric surgery for obesity, or renal tubule defects. Calcium calculi are most common, accounting for more than 75% of all calculi, and are two to three times more common in males, usually appearing between 20 and 30 years old. The calcium may combine with other substances, such as oxalate (the most common substance), phosphate, or carbonate, to form the stone. Oxalate is present in certain foods. Diseases of the small intestine increase the tendency to form calcium oxalate calculi. Recurrence is likely.

Uric acid calculi are also more common in men and make up about 6% of all calculi. These calculi are associated with gout and chemotherapy. Cystine calculi, which make up about 2% of all calculi, may form in people with cystinuria, a hereditary disorder affecting both men and women. Struvite calculi, accounting for about 15% of all calculi, are mainly found in women as a result of a UTI. They can grow very large and may obstruct the kidney, ureter, or bladder.

Indinavir stones appear in patients with human immunodeficiency virus who are treated with the protease inhibitor indinavir.

Complications

- Damage or destruction of renal parenchyma
- Pressure necrosis
- Hydronephrosis
- Bleeding

Signs and Symptoms

Clinical effects vary with size, location, and etiology of the calculi. Pain, the key symptom, usually results from obstruction; large, rough calculi occlude the opening to the ureter and increase the frequency and force of peristaltic contractions. The pain of classic renal colic travels from the costovertebral angle to the flank, to the suprapubic region and external genitalia. The intensity of this pain fluctuates and may be excruciating at its peak. If calculi are in the renal pelvis and calyces, pain may be more constant and dull. Back pain (from calculi that produce an obstruction within a kidney) and severe abdominal pain (from calculi traveling down a ureter) may also occur. (See *Types of renal calculi*.) Nausea and vomiting usually accompany severe pain.

Types of renal calculi

Multiple small calculi may vary in size; they may remain in the renal pelvis or pass down the ureter.

A staghorn calculus (a cast of the calyceal and pelvic collecting system) may form from a stone that stays in the kidney.

Other associated signs include fever, chills, hematuria (when calculi abrade a ureter), abdominal distention, pyuria, and, rarely, anuria (from bilateral obstruction, or unilateral obstruction in the patient with one kidney).

Diagnosis

Diagnosis is based on the clinical picture and the following tests:

- CT scan (preferred study, non contrast) or magnetic resonance imaging (MRI) is highly sensitive for identifying hydronephrosis and detecting small renal and ureteral stones.
- Excretory urography may be used for diagnosis of obstruction by urinary calculus.
- Kidney–ureter–bladder X-rays reveal most renal calculi.
- Calculus analysis shows mineral content.
- Kidney ultrasonography is an easily performed, noninvasive, nontoxic test to detect obstructive changes such as hydronephrosis.
- Urine culture of midstream sample may indicate UTI.
- Urinalysis may be normal or may show increased specific gravity and acid or alkaline pH suitable for different types of stone formation. Other urinalysis findings include hematuria (gross or microscopic), crystals (urate, calcium, or cystine), casts, and pyuria with or without bacteria and WBCs.

- A 24-hour urine collection is evaluated for calcium oxalate, phosphorus, and uric acid excretion levels.
- Serial blood calcium and phosphorus levels detect hyperparathyroidism and show increased calcium level in proportion to normal serum protein.

Increased blood uric acid levels may indicate gout as the cause. Diagnosis must rule out appendicitis, cholecystitis, peptic ulcer, and pancreatitis as potential sources of pain.

CONFIRMING DIAGNOSIS *Excretory urography confirms the diagnosis, determines size and location of calculi, and is used only if noncontrast spiral CT is not confirmatory.*

Treatment

Because 90% of renal calculi are smaller than 5 mm in diameter, treatment usually consists of measures to promote their natural passage. Along with vigorous hydration, such treatment includes antimicrobial therapy (varying with the cultured organism) for infection, analgesics such as meperidine for pain, and diuretics to prevent urinary stasis and further calculus formation (thiazides decrease calcium excretion into the urine). Prophylaxis to prevent calculus formation includes a low-calcium diet for absorptive hypercalciuria, parathyroidectomy for hyperparathyroidism, allopurinol for uric acid calculi, and daily administration of ascorbic acid by mouth to acidify the urine. (See *Preventing renal calculi*.)

PREVENTION
PREVENTING RENAL CALCULI

The formation of kidney stones may be prevented by making certain lifestyle changes. If these lifestyles changes don't help in the prevention of kidney stone formation, drugs are needed. Advise your patient to make these changes.

Maintain Hydration

The most important lifestyle change is drinking plenty of fluids, especially water. An adult needs to drink at least 3½ qt/day. Drinking plenty of fluids helps to flush out the kidneys.

Adjust Diet

For a patient who tends to form calcium oxalate stones, suggest an oxalate-restricted diet. Foods that are high in oxalate should be avoided. These foods include rhubarb, star fruit, beets, beet greens, collards, okra, refried beans, spinach, Swiss chard, sweet potatoes, sesame seeds, almonds, and soy products. Restricting calcium in the diet doesn't seem to reduce the risk of kidney stones. Diets high in calcium actually help reduce the risk of oxalate stone formation. Calcium binds with oxalate so it can't be absorbed in the gastrointestinal tract and excreted by the kidneys.

All patients who form kidney stones should be on low-sodium diets. Sodium intake should be restricted to 3 to 4 g/day. Also, diets very low in animal proteins may help reduce the risk of stones.

Take Prescribed Drugs

Drugs can be helpful in preventing stone formation. The drugs prescribed depend on the type of stone. Some stones, such as calcium stones, develop more easily in more alkaline environments, and some stones, such as uric acid stones, develop in an acid environment. Patients with struvite stones are treated with antibiotics to prevent infection. Cystine stones are the hardest to treat, and they're treated with a urine alkalinizer and chelator (D-penicillamine and tiopronin).

Calculi too large for natural passage may require surgical removal. When a calculus is in the ureter, a cystoscope or ureteroscope may be inserted through the urethra and the calculus manipulated with the ureteroscope, catheters, ultrasonic lithotripter, Holmium laser wire, or other retrieval instruments. Extraction of calculi from other areas (kidney calyx, renal pelvis) may necessitate a flank or lower abdominal approach. Percutaneous ultrasonic lithotripsy and extracorporeal shock wave lithotripsy shatter the calculus into fragments for removal by suction or natural passage.

Special Considerations

Patient care includes confirming the diagnosis, facilitating passage of the stone, and prevention of future occurrences.

- ◆ To aid diagnosis, maintain a 24- to 48-hour record of urine pH, with nitrazine pH paper; strain all urine through gauze or a tea strainer, and save all solid material recovered for analysis.
- ◆ To facilitate spontaneous passage, encourage the patient to walk if possible. Also promote sufficient intake of fluids to maintain a urine output of 3 to 4 L/day (urine should be very dilute and colorless). Addition of Flowmax (tamsulosin) 0.4 mg daily can also help facilitate the spontaneous passage of ureteral stones. To help acidify urine, offer fruit juices, particularly cranberry juice. If the patient can't drink the required amount of fluid, supplemental I.V. fluids may be given. Record intake and output and daily weight to assess fluid status and renal function.
- ◆ Stress the importance of proper diet and compliance with drug therapy. For example, if the patient's stone is caused by a hyperuricemic condition, advise the patient (or whoever prepares meals for the patient) to avoid foods high in purine. Restrict protein to 60 g/day to decrease calcium and uric acid, and limit sodium to 3 to 4 g/day. Oxalate foods are restricted.
- ◆ If surgery is necessary, give reassurance by supplementing and reinforcing what the surgeon has told the patient about the procedure. The patient is apt to be fearful, especially if surgery includes removal of a kidney, so emphasize the fact that the body can adapt well to one kidney. If he's to have an abdominal or flank incision, teach deep breathing and coughing exercises.
- ◆ After surgery, the patient will probably have an indwelling catheter or a nephrostomy tube. Unless one of his kidneys was removed, expect bloody drainage from the catheter. Never irrigate the catheter without a physician's order. Check dressings regularly for bloody drainage, and know how much drainage to expect. Immediately report suspected hemorrhage (excessive drainage, rising pulse rate). Use sterile technique when changing dressings or providing catheter care.
- ◆ Watch for signs of infection (rising fever, chills), and give antibiotics as ordered. To prevent pneumonia, encourage frequent position changes, and ambulate the patient as soon as possible. Have the patient hold a small pillow over the operative site to splint the incision and

thereby facilitate deep breathing and coughing exercises.

- Before discharge, teach the patient and family the importance of following the prescribed dietary and medication regimens to prevent recurrence of calculi. Encourage increased fluid intake. If appropriate, show the patient how to check the urine pH, and instruct them to keep a daily record. Tell them to immediately report symptoms of acute obstruction (pain, inability to void).

RENAL VEIN THROMBOSIS

Renal vein thrombosis—clotting in the renal vein—results in renal congestion, engorgement and, possibly, infarction. Thrombosis may affect both kidneys and may occur in an acute or a chronic form. Chronic thrombosis usually impairs renal function, causing nephrotic syndrome. Abrupt onset of thrombosis that causes extensive damage may precipitate rapidly fatal renal infarction. If thrombosis affects both kidneys, the prognosis is poor. However, less severe thrombosis that affects only one kidney, or gradual progression that allows development of collateral circulation, may preserve partial renal function.

Pathophysiology

Renal vein thrombosis often results from a tumor that obstructs the renal vein (usually hypernephroma). Other causes include thrombophlebitis of the inferior vena cava (may result from abdominal trauma) or blood vessels of the legs, heart failure, and periarteritis.

PEDIATRIC TIP *In infants, renal vein thrombosis usually follows diarrhea that causes severe dehydration. Chronic renal vein thrombosis is often a complication of other glomerulopathic diseases, such as amyloidosis, systemic lupus erythematosus, diabetic nephropathy, and membranoproliferative glomerulonephritis.*

Complications

- Fatal renal infarction
- Disseminated intravascular coagulation

Signs and Symptoms

Clinical features of renal vein thrombosis vary with speed of onset. Rapid onset of venous obstruction produces severe lumbar pain and tenderness in the epigastric region and the costovertebral angle. Other characteristic features include fever, leukocytosis, pallor, hematuria, proteinuria, peripheral edema, and, when the obstruction is bilateral, oliguria and other uremic signs. The kidneys enlarge and become easily palpable. Hypertension is unusual but may develop.

Gradual onset causes symptoms of nephrotic syndrome. Peripheral edema is possible, but pain is generally absent. Other clinical signs include proteinuria, hypoalbuminemia, and hyperlipidemia.

Infants with this disease have enlarged kidneys, oliguria, and renal insufficiency that may progress to acute or chronic renal failure.

Diagnosis

A variety of tests are used to confirm diagnosis of renal vein thrombosis.

- CT scan with contrast is the procedure of choice because it reveals enlargement and distention of the affected renal vein with visualization of the clots within the vein.
- Excretory urography provides reliable diagnostic evidence. In acute renal vein thrombosis, the kidneys appear enlarged and excretory function diminishes. Contrast medium seems to "smudge" necrotic renal tissue. In chronic thrombosis, it may show ureteral indentations that result from collateral venous channels.
- Urinalysis reveals gross or microscopic hematuria, proteinuria (>2 g/day in chronic disease), casts, and oliguria.
- Blood studies show leukocytosis, hypoalbuminemia, and hyperlipidemia.
- MRI, abdominal X-ray, or abdominal ultrasound may show occlusion of the renal vein.

CONFIRMING DIAGNOSIS *Renal arteriography and biopsy may also confirm the diagnosis. Venography confirms thrombosis.*

Treatment

Treatment is most effective for gradual thrombosis that affects only one kidney. Anticoagulation therapy reduces the incidence of new thrombus formation and often reverses the deterioration of renal function. Heparin is the initial therapy of choice. After 5 to 7 days, warfarin (Coumadin) therapy can be instituted for long-term care. Streptokinase or urokinase infusion may be successful in early resolution of acute renal vein thrombosis. Surgery is rarely used; it must be performed within 24 hours of thrombosis but even then has limited success because thrombi often extend into the small veins. Extensive intrarenal bleeding may necessitate nephrectomy.

Patients who survive abrupt thrombosis with extensive renal damage develop nephrotic syndrome and require treatment for renal failure, such as dialysis and, possibly, transplantation.

PEDIATRIC TIP *Some infants with renal vein thrombosis recover completely following heparin therapy or surgery; others suffer irreversible kidney damage.*

Special Considerations

Patient care includes careful monitoring of symptoms for signs of improvement or worsening.

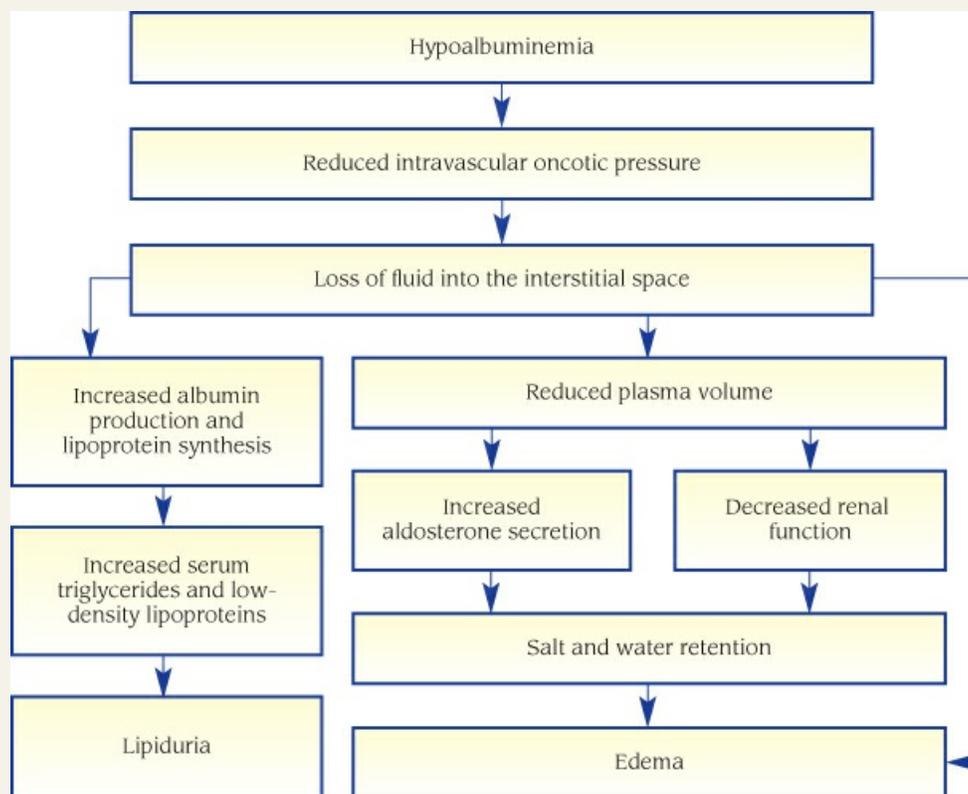
- Assess renal function regularly. Monitor vital signs, intake and output, daily weight, and electrolytes.
- Administer diuretics for edema as ordered, and enforce dietary restrictions of sodium and potassium intake.
- Monitor closely for signs of pulmonary emboli (chest pain, dyspnea).
- If heparin is given by constant I.V. infusion, frequently monitor partial thromboplastin time to determine the patient's response. Dilute the drug; administer it by infusion pump or controller, so the patient receives the least amount necessary.

ALERT *During anticoagulant therapy, watch for and report signs of bleeding, such as tachycardia, hypotension, hematuria, bleeding from nose or gums, ecchymoses, petechiae, and tarry stools. Instruct the patient on maintenance warfarin therapy to use an electric razor and a soft toothbrush, and to avoid trauma. Suggest that the patient wear a medical identification bracelet, and to avoid aspirin, which aggravates bleeding tendencies. Stress the need for close follow-up.*

Chronic Renal Disorders

NEPHROTIC SYNDROME

Nephrotic syndrome is a condition characterized by marked proteinuria, hypoalbuminemia, hyperlipidemia, and edema. (See *What happens in nephrotic syndrome,* page 355.) Although nephrotic syndrome isn't a disease itself, it results from a specific glomerular defect and indicates renal damage. The prognosis is highly variable, depending on the underlying cause. Some forms may progress to end-stage renal failure.

PATHOPHYSIOLOGY
WHAT HAPPENS IN NEPHROTIC SYNDROME


Pathophysiology

About 75% of nephrotic syndrome cases result from primary (idiopathic) glomerulonephritis. Classifications include:

- In *lipid nephrosis* (*nil lesions*), the main cause of nephrotic syndrome in children, the glomerulus looks normal by light microscopy. Some tubules may contain increased lipid deposits.
- *Membranous glomerulonephritis,* the most common lesion in adult idiopathic nephrotic syndrome, is characterized by uniform thickening of the glomerular basement membrane

containing dense deposits and eventually progresses to renal failure.

◆ *Focal glomerulosclerosis* can develop spontaneously at any age, follow renal transplantation, or result from heroin abuse. Reported incidence of this condition is 10% in children with nephrotic syndrome and up to 20% in adults. Lesions initially affect the deeper glomeruli, causing hyaline sclerosis, with later involvement of the superficial glomeruli. These lesions generally cause slowly progressive deterioration in renal function. Remissions occur occasionally.

◆ In *membranoproliferative glomerulonephritis*, slowly progressive lesions develop in the subendothelial region of the basement membrane. Lesions may follow infection, particularly streptococcal infection. This disease occurs primarily in children and young adults.

Other causes of nephrotic syndrome include metabolic diseases such as diabetes mellitus; collagen vascular disorders, such as systemic lupus erythematosus and periarteritis nodosa; circulatory diseases, such as heart failure, sickle cell anemia, and renal vein thrombosis; nephrotoxins, such as mercury, gold, and bismuth; allergic reactions; and infections, such as tuberculosis or enteritis. Other possible causes are pregnancy, hereditary nephritis, multiple myeloma, and other neoplastic diseases. These diseases increase glomerular protein permeability, leading to increased urinary excretion of protein, especially albumin, and subsequent hypoalbuminemia.

Nephrotic patients have an increased risk of infection, particularly of peritonitis.

PEDIATRIC TIP *Black children appear to be at greater risk for peritonitis.*

Complications

◆ Atherosclerosis
◆ Renal vein thrombosis
◆ Acute renal failure
◆ Chronic renal failure
◆ Infections
◆ Malnutrition
◆ Fluid overload

Signs and Symptoms

The dominant clinical feature of nephrotic syndrome is mild to severe dependent edema of the ankles or sacrum, or periorbital edema, especially in children. Edema may lead to ascites, pleural effusion, and swollen external genitalia. Accompanying symptoms may include orthostatic hypotension, lethargy, anorexia, depression, and pallor. Major complications are malnutrition, infection, coagulation disorders, thromboembolic vascular occlusion, and accelerated atherosclerosis.

Diagnosis

Consistent proteinuria in excess of 3.5 g for 24 hours strongly suggests nephrotic syndrome; examination of urine also reveals increased number of hyaline, granular, and waxy, fatty casts, and oval fat bodies. Serum values that support the diagnosis are increased cholesterol, phospholipids, and triglycerides and decreased albumin levels. Histologic identification of the lesion requires kidney biopsy. Other tests may be done to rule out metabolic causes.

Treatment

The goals of treatment of nephrotic syndrome are to relieve symptoms, prevent complications, and delay progressive kidney damage. Treatment of the causative disorder—possibly lifelong—is necessary to control nephrotic syndrome. Corticosteroid, immunosuppressive, antihypertensive, and diuretic medications may help control symptoms. Antibiotics may be needed to control infections. Angiotensin-converting enzyme inhibitors may significantly reduce the degree of protein loss in urine and are therefore typically prescribed for the treatment of nephrotic syndrome.

Treatment of hypertension and of high cholesterol and triglyceride levels are also recommended to reduce the risk of atherosclerosis and complications. Dietary limitation of cholesterol and saturated fats may be of little benefit because the high levels that accompany this condition seem to result from overproduction by the liver rather than from excessive fat intake. High-protein diets are of debatable value. In many patients, reducing the amount of protein in the diet produces a decrease in urine protein. In most cases, a moderate-protein diet (1 g/kg of body weight per day) is usually recommended. Sodium may be restricted to help control edema. Vitamin D may need to be replaced if nephrotic syndrome is chronic and unresponsive to therapy. Blood thinners may be required to treat or prevent clot formation.

Supportive treatment consists of protein replacement with infusion of salt-poor albumin or with a nutritional diet of 1.5 g protein/kg of body weight, with restricted sodium intake of 0.5 to 1 g/day; diuretics for edema; and antibiotics for infection.

Some patients respond to an 8-week course of corticosteroid therapy (such as prednisone), followed by a maintenance dose. Others respond better to a combination course of prednisone and azathioprine or cyclophosphamide.

Special Considerations

Patient care includes identification and treatment of the underlying cause accompanied by supportive care during treatment.

- Frequently check urine protein. (Urine containing protein appears frothy.)
- Measure blood pressure while the patient is supine and also while he's standing; immediately report a drop in blood pressure that exceeds 20 mm Hg.
- Monitor intake and output and check weight at the same time each morning—after the patient voids and before eating—and while they are wearing the same kind of clothing. Ask the dietitian to plan a high-protein, low-sodium diet.
- Provide good skin care because the patient with nephrotic syndrome usually has edema.
- To avoid thrombophlebitis, encourage activity and exercise, and provide antiembolism stockings as ordered.
- Watch for and teach the patient and family how to recognize adverse drug effects, such as bone marrow toxicity from cytotoxic immunosuppressants and cushingoid symptoms (muscle weakness, mental changes, acne, moon face, hirsutism, girdle obesity, purple striae, bone fractures, and amenorrhea) from long-term steroid therapy. Other steroid complications include masked infections, increased susceptibility to infections, ulcers, GI bleeding, and steroid-induced diabetes; a steroid crisis may occur if the drug is discontinued abruptly. To prevent GI complications, administer steroids with an antacid or with cimetidine or ranitidine. Explain that steroid adverse effects will subside when therapy stops.
- Offer the patient and family reassurance and support, especially during the acute phase, when edema is severe and the patient's body image changes.

ALERT *After kidney biopsy, watch for bleeding and shock.*

CHRONIC GLOMERULONEPHRITIS

A slowly progressive disease, chronic glomerulonephritis is characterized by inflammation of the glomeruli, which results in sclerosis, scarring, and eventual renal failure. This condition usually remains subclinical until the progressive phase begins, marked by proteinuria, cylindruria (presence of granular tube casts), and hematuria. By the time it produces symptoms, chronic glomerulonephritis is usually irreversible.

Pathophysiology

Common causes of chronic glomerulonephritis include primary renal disorders, such as membranoproliferative glomerulonephritis, membranous glomerulopathy, focal glomerulosclerosis, rapidly progressive glomerulonephritis, and, less often, poststreptococcal glomerulonephritis. Systemic disorders that may cause chronic glomerulonephritis include lupus erythematosus, Goodpasture syndrome, and hemolytic-uremic syndrome.

Chronic glomerulonephritis is twice as common in men as it is in women.

Complications

- End-stage renal disease
- Severe hypertension
- Heart failure
- Increased susceptibility to infections
- Nephrotic syndrome

Signs and Symptoms

Chronic glomerulonephritis typically develops insidiously and asymptomatically, usually over many years. At any time, however, it may suddenly become progressive, producing nephrotic syndrome, hypertension, proteinuria, and hematuria. In late stages of progressive chronic glomerulonephritis, it may accelerate to uremic symptoms, such as azotemia, nausea, vomiting, pruritus, dyspnea, malaise, and fatigability. Mild to severe edema and anemia may accompany these symptoms. Severe hypertension may cause cardiac hypertrophy, leading to heart failure, and may accelerate the development of advanced renal failure, eventually necessitating dialysis or transplantation.

Diagnosis

Patient history and physical assessment seldom suggest glomerulonephritis. Suspicion develops from urinalysis revealing proteinuria, hematuria, cylindruria (aka casts), and RBC casts. Rising blood urea nitrogen and serum creatinine levels indicate advanced renal insufficiency. X-ray or ultrasound shows smaller kidneys. Kidney biopsy identifies the underlying disease and provides data needed to guide therapy.

Treatment

Treatment is essentially nonspecific and symptomatic, with its goals to control hypertension with antihypertensives and a sodium-restricted diet, to correct fluid and electrolyte imbalances through restrictions and replacement, to reduce edema with diuretics such as furosemide, and to

prevent heart failure. Treatment may also include antibiotics (for symptomatic UTIs), dialysis, or transplantation.

Special Considerations

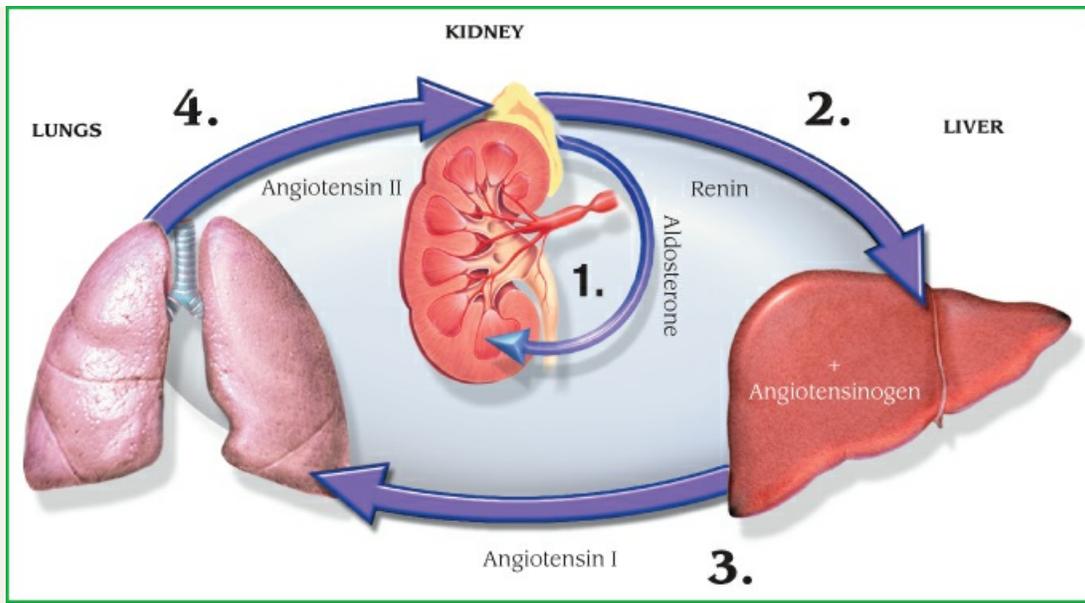
Patient care is primarily supportive, focusing on continual observation and sound patient teaching.

- Accurately monitor vital signs, intake and output, and daily weight to evaluate fluid retention. Observe for signs of fluid, electrolyte, and acid–base imbalances.
- Ask the dietitian to plan low-sodium, high-calorie meals with adequate protein.
- Administer medications as ordered, and provide good skin care (because of pruritus and edema) and oral hygiene. Instruct the patient to continue taking prescribed antihypertensives as scheduled, even if they are feeling better, and to report any adverse effects. Advise the patient to take diuretics in the morning, so they won't have to disrupt sleep to void. Teach them how to assess ankle edema.
- Warn the patient to report signs of infection, particularly UTI, and to avoid contact with persons who have infections. Urge follow-up examinations to assess renal function.
- Help the patient adjust to this illness by encouraging him or her to express his or her feelings. Explain all necessary procedures beforehand, and answer the patient's questions about them.

RENOVASCULAR HYPERTENSION

Renovascular hypertension is a rise in systemic blood pressure resulting from stenosis of the major renal arteries or their branches or from intrarenal atherosclerosis. This narrowing or sclerosis may be partial or complete, and the resulting blood pressure elevation, benign or malignant. (See *Mechanism of renovascular hypertension,* page 358.)

Mechanism of renovascular hypertension

(1) Renal artery stenosis causes a reduction in blood flow to the kidneys. (2) The kidneys secrete renin in response. (3) Renin combines with angiotensinogen in the liver to form angiotensin I. (4) In the lungs angiotensin I is converted to angiotensin II, a vasoconstrictor.


Pathophysiology

Stenosis or occlusion of the renal artery stimulates the affected kidney to release the enzyme renin, which converts angiotensinogen—a plasma protein—to angiotensin I. As angiotensin I circulates through the lungs and liver, it converts to angiotensin II, which causes peripheral vasoconstriction, increased arterial pressure and aldosterone secretion and, eventually, hypertension.

Atherosclerosis (especially in older men) and fibromuscular diseases of the renal artery wall layers—such as medial fibroplasia and, less commonly, intimal and subadventitial fibroplasia—are the primary causes in 95% of all patients with renovascular hypertension. Other causes include arteritis, anomalies of the renal arteries, embolism, trauma, tumor, and dissecting aneurysm. Less than 5% of patients with high blood pressure display renovascular hypertension; it's most common in persons younger than 30 years old or older than 50.

PEDIATRIC TIP *Fibromuscular dysplasia is the most common cause of renovascular hypertension in children. The surgical cure rate is very high.*

Complications

- Heart failure
- Myocardial infarction
- Stroke
- Renal failure (occasionally)

Signs and Symptoms

In addition to elevated systemic blood pressure, renovascular hypertension usually produces symptoms common to hypertensive states, such as headache, palpitations, tachycardia, anxiety, light-headedness, decreased tolerance of temperature extremes, retinopathy, and mental

sluggishness. Significant complications include heart failure, myocardial infarction, stroke, and, occasionally, renal failure.

Diagnosis

CONFIRMING DIAGNOSIS *The gold standard for diagnosing renal artery stenosis is renal arteriography. However, there are a variety of less invasive tests used for screening.*

- Gadolinium-enhanced magnetic resonance angiography can identify turbulent blood flow indicative of renal stenosis. However, patients with moderate to end-stage kidney disease or AKI should not receive gadolinium contrast agents.
- Duplex Doppler ultrasonography scans the renal artery and will reveal stenosis, but results vary.
- Oral captopril renography is the simplest, most noninvasive test for detection of renovascular hypertension but has a relatively high false-positive rate.

Treatment

Surgery, the treatment of choice, is performed to restore adequate circulation and to control severe hypertension or severely impaired renal function by renal artery bypass, endarterectomy, arterioplasty, or, as a last resort, nephrectomy. Balloon catheter renal artery dilation is used in selected cases to correct renal artery stenosis without the risks and morbidity of surgery. Symptomatic measures include antihypertensives, diuretics, and a sodium-restricted diet.

Medications that may be used in an attempt to control blood pressure include diuretics, beta-adrenergic blockers, calcium channel blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and alpha-adrenergic blockers. Diazoxide or nitroprusside may be given in the hospital if symptoms are acute. Response to medications is highly individual, and the dosage or specific drug used may need frequent adjustment.

Lifestyle changes may be recommended, including weight, exercise, and dietary adjustments; smoking cessation; and avoidance of alcohol. These habits add to the effects of hypertension in causing complications.

Special Considerations

The care plan must emphasize helping the patient and family understand renovascular hypertension and the importance of following the prescribed treatment.

- Accurately monitor intake and output and daily weight. Check blood pressure in both arms regularly, with the patient lying down and standing. A drop of 20 mm Hg or more on arising may necessitate an adjustment in antihypertensive medications. Assess renal function daily.
- Maintain fluid and sodium restrictions. Explain the purpose of a low-sodium diet.
- Explain the diagnostic tests, and prepare the patient appropriately; for example, adequately hydrate the patient before tests that use contrast media. Make sure the patient isn't allergic to the dye used in diagnostic tests. After excretory urography or arteriography, watch for complications.
- If a nephrectomy is necessary, reassure the patient that the remaining kidney is adequate for renal function.
- Provide a quiet, stress-free environment if possible. Urge the patient and family members to have regular blood pressure screenings.

HYDRONEPHROSIS

Hydronephrosis is an abnormal dilation of the renal pelvis and the calyces of one or both kidneys, caused by an obstruction of urine flow in the genitourinary tract. (See *Renal damage in hydronephrosis*.) Although partial obstruction and hydronephrosis may not produce symptoms initially, the pressure built up behind the area of obstruction eventually results in symptomatic renal dysfunction.

> **PATHOPHYSIOLOGY**
> **RENAL DAMAGE IN HYDRONEPHROSIS**
>
> In hydronephrosis, the ureters dilate and kink, the renal pelvis dilates, and the parenchyma and papilla atrophy.

Pathophysiology

Almost any type of obstructive uropathy can result in hydronephrosis. The most common causes are BPH, urethral strictures, and calculi; less common causes include strictures or stenosis of the ureter or bladder outlet, congenital abnormalities, abdominal tumors, blood clots, and neurogenic bladder. If obstruction is in the urethra or bladder, hydronephrosis is usually bilateral; if obstruction is in a ureter, it's usually unilateral. Obstructions distal to the bladder cause the bladder to dilate and act as a buffer zone, delaying hydronephrosis. Total obstruction of urine flow with dilation of the collecting system ultimately causes complete cortical atrophy and cessation of glomerular filtration.

Hydronephrosis occurs in 1 of every 100 people.

Complications

- Pyelonephritis
- Paralytic ileus
- Renal failure

Signs and Symptoms

Clinical features of hydronephrosis vary with the cause of the obstruction. In some patients, hydronephrosis produces no symptoms or only mild pain and slightly decreased urinary flow; in others, it may produce severe, colicky renal pain or dull flank pain that may radiate to the groin, and gross urinary abnormalities, such as hematuria, pyuria, dysuria, alternating oliguria and polyuria, or complete anuria. Other symptoms of hydronephrosis include nausea, vomiting, abdominal fullness, pain on urination, dribbling, or hesitancy. Unilateral obstruction may cause pain on only one side, usually in the flank area.

The most common complication of an obstructed kidney is infection (pyelonephritis) due to stasis that exacerbates renal damage and may create a life-threatening crisis. Paralytic ileus frequently accompanies acute obstructive uropathy.

Diagnosis

CONFIRMING DIAGNOSIS *While the patient's clinical features may suggest hydronephrosis, excretory urography, isotope renography (radioisotope scan of the kidneys), CT scan of the kidneys or abdomen, abdominal MRI, renal ultrasound, and renal function studies are necessary to confirm it.*

Treatment

The goals of treatment are to preserve renal function and prevent infection through surgical removal of the obstruction, such as dilation for stricture of the urethra or prostatectomy for BPH.

If renal function has already been affected, therapy may include a diet low in protein, sodium, and potassium. This diet is designed to stop the progression of renal failure before surgery. Inoperable obstructions may necessitate decompression and drainage of the kidney using a nephrostomy tube placed temporarily or permanently in the renal pelvis or placement of a ureteral stent to allow the ureter to drain. Concurrent infection requires appropriate antibiotic therapy.

Special Considerations

Explain hydronephrosis as well as the purpose of excretory urography and other diagnostic procedures. Check the patient for allergy to excretory urography dye.

- Administer medication for pain, as needed and prescribed.
- Postoperatively, closely monitor intake and output, vital signs, and fluid and electrolyte status. Watch for a rising pulse rate and cold, clammy skin, which indicate possible impending hemorrhage and shock. Monitor renal function studies daily.
- If a nephrostomy tube has been inserted, check it frequently for bleeding and patency. Irrigate the tube only as ordered, and don't clamp it.
- If the patient is to be discharged with a nephrostomy tube in place, teach them how to care for it properly.

PREVENTION *To prevent progression of hydronephrosis to irreversible renal disease, urge older men (especially those with family histories of BPH or prostatitis) to have routine medical checkups. Teach them to recognize and report symptoms of hydronephrosis (colicky pain, hematuria) or UTI.*

RENAL TUBULAR ACIDOSIS

Renal tubular acidosis (RTA)—a syndrome of persistent dehydration, hyperchloremia, hypokalemia, metabolic acidosis, and nephrocalcinosis—results from the kidneys' inability to conserve bicarbonate. This disorder occurs as distal RTA (Type I, or classic RTA) or proximal RTA (Type II). The prognosis is usually good but depends on the severity of renal damage that precedes treatment.

Pathophysiology

Metabolic acidosis usually results from renal excretion of bicarbonate. However, metabolic acidosis associated with RTA results from a defect in the kidneys' normal tubular acidification of urine.

Distal RTA results from an inability of the distal tubule to secrete hydrogen ions against established gradients across the tubular membrane. This results in decreased excretion of titratable acids and ammonium, increased loss of potassium and bicarbonate in the urine, and systemic acidosis. Prolonged acidosis causes mobilization of calcium from bone and, eventually, hypercalciuria, predisposing the kidney to the formation of renal calculi. Distal RTA may be classified as primary or secondary.

- *Primary distal RTA* may occur sporadically or through a hereditary defect and is most prevalent in women, older children, adolescents, and young adults.
- It can also be caused by certain drugs, such as amphotericin B, lithium, and analgesics.
- *Secondary distal RTA* has been linked to many renal or systemic conditions, such as starvation, malnutrition, hepatic cirrhosis, and several genetically transmitted disorders.

Proximal RTA results from defective reabsorption of bicarbonate in the proximal tubule. This causes bicarbonate to flood the distal tubule, which normally secretes hydrogen ions, and leads to impaired formation of titratable acids and ammonium for excretion. Ultimately, metabolic acidosis results. Proximal RTA occurs in two forms:

- In *primary proximal RTA*, the reabsorptive defect is idiopathic and is the only disorder present.
- In *secondary proximal RTA*, the reabsorptive defect may be one of several defects and is due to proximal tubular cell damage from a disease such as Fanconi syndrome.

Complications

- Pyelonephritis
- Hypercalciuria
- Renal calculi

Signs and Symptoms

PEDIATRIC TIP *In infants, RTA produces anorexia, vomiting, occasional fever, polyuria, dehydration, growth retardation, apathy, weakness, tissue wasting, constipation, nephrocalcinosis, and rickets.*

In children and adults, RTA may lead to UTI, rickets, and growth problems. Possible complications of RTA include nephrocalcinosis and pyelonephritis.

Diagnosis

℞ CONFIRMING DIAGNOSIS *Demonstration of impaired acidification of urine with systemic metabolic acidosis confirms distal RTA. Demonstration of bicarbonate wasting caused by impaired reabsorption confirms proximal RTA.*

Other relevant laboratory results show:

◆ decreased serum bicarbonate, pH, potassium, and phosphorus
◆ increased serum chloride and alkaline phosphatase
◆ alkaline pH, with low titratable acids and ammonium content in urine
◆ increased urinary bicarbonate and potassium
◆ low specific gravity

In later stages, X-rays may show nephrocalcinosis.

Treatment

Supportive treatment for patients with RTA requires replacement of those substances being abnormally excreted, especially bicarbonate, and may include sodium bicarbonate tablets or solution to control acidosis. Potassium may be given by mouth for dangerously low potassium levels. Vitamins D and calcium supplements are usually avoided because the tendency toward nephrocalcinosis persists even after bicarbonate therapy. If pyelonephritis occurs, treatment may include antibiotics as well.

Treatment for renal calculi secondary to nephrocalcinosis varies and may include supportive therapy until the calculi pass or until surgery for severe obstruction is performed.

Special Considerations

Urge compliance with all medication instructions. Inform the patient and family that the prognosis for RTA and bone lesion healing is directly related to the adequacy of treatment.

◆ Monitor laboratory values, especially potassium, for hypokalemia.
◆ Test urine for pH, and strain it for calculi.
◆ If rickets develops, explain the condition and its treatment to the patient and family.
◆ Teach the patient how to recognize signs and symptoms of calculi (hematuria, low abdominal or flank pain). Tell the patient to immediately report signs and symptoms.
◆ Instruct the patient with low potassium levels to eat foods with high potassium content, such as bananas, leafy green vegetables, and baked potatoes. Orange juice is also high in potassium.
◆ Because RTA may be caused by a genetic defect, encourage family members to seek genetic counseling or screening for this disorder.

CHRONIC RENAL FAILURE

Chronic renal failure is usually the end result of a gradually progressive loss of renal function; occasionally, it's the result of a rapidly progressive disease of sudden onset. Few symptoms develop until after more than 75% of glomerular filtration is lost; then the remaining normal parenchyma deteriorates progressively, and symptoms worsen as renal function decreases.

If this condition continues unchecked, uremic toxins accumulate and produce potentially fatal

physiologic changes in all major organ systems. If the patient can tolerate it, maintenance dialysis or kidney transplantation can sustain life. (See *Comparing peritoneal dialysis and hemodialysis*, page 362. Also see *Continuous ambulatory peritoneal dialysis*, page 363.)

Comparing Peritoneal Dialysis and Hemodialysis

Advantages, disadvantages, and complications of peritoneal dialysis and hemodialysis are described below.

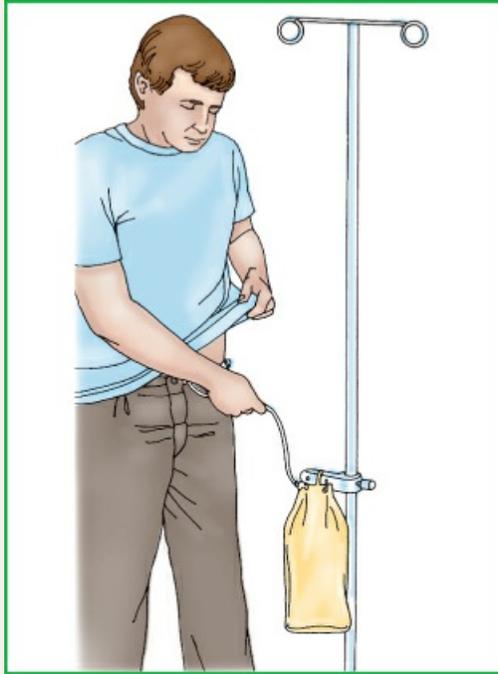
Type Advantages	Disadvantages	Possible complications
Peritoneal dialysis		
• Can be performed immediately • Requires less complex equipment and less specialized personnel than hemodialysis • Requires small amounts of heparin or none at all • No blood loss; minimal cardiovascular stress • Can be performed by patient anywhere (continuous ambulatory peritoneal dialysis), without assistance and with minimal patient teaching • Allows patient independence without long interruptions in daily activities because exchange may be done at night while he or she sleeps • Lower infection rate • Lower cost	• Contraindicated within 72 hours of abdominal surgery • Requires 48 to 72 hours for significant response to treatment • Severe protein loss necessitates high-protein diet (up to 100 g/day) • High risk of peritonitis; repeated bouts may cause scarring, preventing further treatments with peritoneal dialysis • Urea clearance less than with hemodialysis (60%)	• Bacterial or chemical peritonitis • Pain (abdominal, low back, shoulder) • Shortness of breath or dyspnea • Atelectasis and pneumonia • Severe loss of protein into the dialysis solution in the abdominal cavity (10 to 20 g/day) • Fluid overload • Excessive fluid loss • Constipation • Catheter site inflammation, infection, or leakage • Anorexia • Hypertriglyceridemia • Abdominal hernias
Hemodialysis		
• Takes only 3 to 5 hours per treatment • Faster results in an acute situation • Total number of hours of maintenance treatment that's only half that of peritoneal dialysis • In an acute situation, can use an I.V. route without a surgical access route	• Requires surgical creation of a vascular access between circulation and dialysis machine • Requires complex water treatment, dialysis equipment, and highly trained personnel • Requires administration of larger amounts of heparin • Confines patient to special treatment unit	• Septicemia • Air emboli • Rapid fluid and electrolyte imbalance (disequilibrium syndrome) • Hemolytic anemia • Metastatic calcification • Increased risk of hepatitis • Hypotension or hypertension • Itching • Pain (generalized or in chest) • Heparin overdose, possibly causing hemorrhage • Leg cramps • Nausea and vomiting • Headache

Continuous Ambulatory Peritoneal Dialysis

Continuous ambulatory peritoneal dialysis is a useful alternative to hemodialysis in patients with renal failure. Using the peritoneum as a dialysis membrane, it allows almost uninterrupted exchange of dialysis solution. With this method, four to six exchanges of fresh dialysis solution are infused each day. The approximate dwell-time for daytime exchanges is 5 hours; for overnight exchanges, the dwell-time is 8 to 10 hours. After each dwell-time, the patient removes the dialyzing solution by gravity drainage. This form of dialysis offers the unique advantages of a simple, easily taught procedure and patient independence from a special treatment center.

After applying a mask, the patient attaches a bag of dialysate to the tube entering his abdominal area so that the fluid flows into the peritoneal cavity. The patient can remove the mask when this step is completed.

While the dialysate remains in the peritoneal cavity, the patient rolls up the bag, places it under his shirt, and goes about his normal activities.

After applying a mask, the patient unrolls the bag and suspends it below his pelvis to allow the dialysate to drain from the peritoneal cavity back into the bag.


Pathophysiology

Diabetes and hypertension are the primary causes of chronic renal failure, accounting for two-thirds of cases. Other causes of chronic renal failure include:

- chronic glomerular disease such as glomerulonephritis
- chronic infections, such as chronic pyelonephritis or tuberculosis
- congenital anomalies such as polycystic kidneys
- vascular diseases such as renal nephrosclerosis
- obstructive processes such as calculi
- collagen diseases such as systemic lupus erythematosus
- nephrotoxic agents such as long-term aminoglycoside therapy.

These conditions gradually destroy the nephrons and eventually cause irreversible renal failure. Similarly, acute renal failure that fails to respond to treatment becomes chronic renal failure.

This syndrome may progress through the following stages:

- reduced renal reserve (GFR is 40 to 70 mL/minute)
- renal insufficiency (GFR 20 to 40 mL/minute)
- renal failure (GFR 10 to 20 mL/minute)
- end-stage renal disease (GFR < 10 mL/minute).

Chronic renal failure and end-stage renal disease affect about 2 of 1,000 people in the United States.

Complications

- Fatal physiologic changes in all major organs

- Anemia
- Peripheral neuropathy
- Cardiopulmonary complication
- GI complication
- Sexual dysfunction
- Dry skin
- Fractures

Signs and Symptoms

Chronic renal failure produces major changes in all body systems:

- *Renal and urologic:* Initially, salt-wasting and consequent hyponatremia produce hypotension, dry mouth, loss of skin turgor, listlessness, fatigue, and nausea; later, somnolence and confusion develop. As the number of functioning nephrons decreases, so does the kidneys' capacity to excrete sodium, resulting in salt retention and overload. Accumulation of potassium causes muscle irritability, then muscle weakness as the potassium level continues to rise. Fluid overload and metabolic acidosis also occur. Urine output decreases; urine is very dilute and contains casts and crystals.
- *Cardiovascular:* Renal failure leads to hypertension, arrhythmias (including life-threatening ventricular tachycardia or fibrillation), cardiomyopathy, uremic pericarditis, pericardial effusion with possible cardiac tamponade, heart failure, and periorbital and peripheral edema.
- *Respiratory:* Pulmonary changes include reduced pulmonary macrophage activity with increased susceptibility to infection, pulmonary edema, pleuritic pain, pleural friction rub and effusions, crackles, thick sputum, uremic pleuritis and uremic lung (or uremic pneumonitis), dyspnea due to heart failure, and Kussmaul respirations as a result of acidosis.
- *GI:* Inflammation and ulceration of GI mucosa cause stomatitis, gum ulceration and bleeding and, possibly, parotitis, esophagitis, gastritis, duodenal ulcers, lesions on the small and large bowel, uremic colitis, pancreatitis, and proctitis. Other GI symptoms include a metallic taste in the mouth, uremic fetor (ammonia smell to breath), anorexia, nausea, and vomiting.
- *Cutaneous:* Typically, the skin is pallid, yellowish bronze, dry, and scaly. Other cutaneous symptoms include severe itching; purpura; ecchymoses; petechiae; uremic frost (most often in critically ill or terminal patients); thin, brittle fingernails with characteristic lines; and dry, brittle hair that may change color and fall out easily.
- *Neurologic:* Restless leg syndrome, one of the first signs of peripheral neuropathy, causes pain, burning, and itching in the legs and feet, which may be relieved by voluntarily shaking, moving, or rocking them. Eventually, this condition progresses to paresthesia and motor nerve dysfunction (usually bilateral footdrop) unless dialysis is initiated. Other signs and symptoms include muscle cramping and twitching, shortened memory and attention span, apathy, drowsiness, irritability, confusion, coma, and seizures. EEG changes indicate metabolic encephalopathy.
- *Endocrine:* Common endocrine abnormalities include stunted growth patterns in children (even with elevated growth hormone levels), infertility and decreased libido in both sexes, amenorrhea and cessation of menses in females, and impotence, decreased sperm production, and testicular atrophy in males. Increased aldosterone secretion (related to increased renin production) and impaired carbohydrate metabolism (increased blood glucose levels similar to diabetes mellitus) may also occur.
- *Hematopoietic:* Anemia, decreased RBC survival time, blood loss from dialysis and GI

bleeding, mild thrombocytopenia, and platelet defects occur. Other problems include increased bleeding and clotting disorders, demonstrated by purpura, hemorrhage from body orifices, easy bruising, ecchymoses, and petechiae.

- *Skeletal:* Calcium-phosphorus imbalance and consequent parathyroid hormone imbalances cause muscle and bone pain, skeletal demineralization, pathologic fractures, and calcifications in the brain, eyes, gums, joints, myocardium, and blood vessels. Arterial calcification may produce coronary artery disease. In children, renal osteodystrophy (renal rickets) may develop.

Diagnosis

The diagnosis of chronic renal failure is based on clinical assessment, a history of chronic progressive debilitation, and gradual deterioration of renal function as determined by creatinine clearance tests. The following laboratory findings also aid in diagnosis:

- Blood studies show elevated blood urea nitrogen, serum creatinine, and potassium levels; decreased arterial pH and bicarbonate; and low Hb level and HCT.
- Urine specific gravity becomes fixed at 1.010; urinalysis may show proteinuria, glycosuria, RBCs, leukocytes, and casts, depending on the etiology.
- X-ray studies include kidney–ureter–bladder films, excretory urography, nephrotomography, renal scan, and renal arteriography.
- Renal or abdominal CT scan, MRI, or ultrasound indicates changes associated with chronic renal failure, including abnormally small size in both kidneys.
- Kidney biopsy allows histologic identification of the underlying pathology.

Treatment

Treatment focuses on controlling the symptoms, minimizing complications, and slowing the progression of the disease. Associated diseases that cause or result from chronic renal failure, such as hypertension, must be controlled. Conservative treatment aims to correct specific symptoms. A low-protein diet reduces the production of end products of protein metabolism that the kidneys can't excrete. (A patient receiving continuous peritoneal dialysis should have a high-protein diet.) A high-calorie diet prevents ketoacidosis and the negative nitrogen balance that results in catabolism and tissue atrophy, and restricts sodium and potassium.

Maintaining fluid balance requires careful monitoring of vital signs, weight changes, and urine volume (if present). If some renal function remains, administration of loop diuretics such as furosemide and fluid restriction can reduce fluid retention. Cardiac glycosides may be used to mobilize edema fluids; antihypertensives to control blood pressure and associated edema. Antiemetics taken before meals may relieve nausea and vomiting; cimetidine or ranitidine may decrease gastric irritation. Methylcellulose or docusate can help prevent constipation.

Treatment may also include regular stool analysis (guaiac test) to detect occult blood and, as needed, cleaning enemas to remove blood from the GI tract. Anemia necessitates iron and folate supplements; severe anemia requires infusion of fresh frozen packed cells or washed packed cells. However, transfusions relieve anemia only temporarily. Epoetin alfa (erythropoietin) increases RBC production.

Drug therapy often relieves associated symptoms: an antipruritic, such as trimeprazine or diphenhydramine, for itching and aluminum hydroxide gel to lower serum phosphate levels. The patient may also benefit from supplementary vitamins (particularly B vitamins and vitamin D) and essential amino acids.

Blood gas measurements may indicate acidosis; intensive dialysis and thoracentesis can relieve pulmonary edema and pleural effusions.

Hemodialysis or peritoneal dialysis (particularly continuous ambulatory peritoneal dialysis and continuous cyclic peritoneal dialysis) can help control most manifestations of end-stage renal disease; altering dialyzing bath fluids can correct fluid and electrolyte disturbances. But anemia, peripheral neuropathy, cardiopulmonary and GI complications, sexual dysfunction, and skeletal defects may persist. Maintenance dialysis itself may produce complications, such as protein wasting, refractory ascites, and dialysis dementia. Kidney transplantation may eventually be the treatment of choice for some patients with end-stage renal disease.

Special Considerations

Because chronic renal failure has such widespread clinical effects, it requires meticulous and carefully coordinated supportive care.

- Good skin care is important. Bathe the patient daily, using superfatted soaps, oatmeal baths, and skin lotion without alcohol to ease pruritus. Don't use glycerin-containing soaps because they'll cause skin drying. Give good perineal care, using mild soap and water. Pad the side rails to guard against ecchymoses. Turn the patient often, and use a convoluted foam mattress to prevent skin breakdown.
- Provide good oral hygiene. Brush the patient's teeth often with a soft brush or sponge tip to reduce breath odor. Sugarless hard candy and mouthwash minimize bad taste in the mouth and alleviate thirst.
- Offer small, palatable meals that are also nutritious; try to provide favorite foods within dietary restrictions. Encourage intake of high-calorie foods. Instruct the outpatient to avoid high-sodium foods and high-potassium foods. Encourage adherence to fluid and protein restrictions. To prevent constipation, stress the need for exercise and sufficient dietary bulk.
- Watch for hyperkalemia. Observe for cramping of the legs and abdomen, and diarrhea. As potassium levels rise, watch for muscle irritability and a weak pulse rate. Monitor the electrocardiogram for tall, peaked T waves, widening QRS segment, prolonged PR interval, and disappearance of P waves, indicating hyperkalemia.
- Assess hydration status carefully. Check for jugular vein distention, and auscultate the lungs for crackles. Measure daily intake and output carefully, including all drainage, emesis, diarrhea, and blood loss. Record daily weight, presence or absence of thirst, axillary sweat, dryness of tongue, hypertension, and peripheral edema.
- Monitor for bone or joint complications. Prevent pathologic fractures by turning the patient

carefully and ensuring his safety. Provide passive range-of-motion exercises for the bedridden patient.

◆ Encourage deep breathing and coughing to prevent pulmonary congestion. Listen often for crackles, rhonchi, and decreased breath sounds. Be alert for clinical effects of pulmonary edema (dyspnea, restlessness, and crackles). Administer diuretics and other medications, as ordered.

◆ Maintain strict sterile technique. Use a micropore filter during I.V. therapy. Watch for signs of infection (listlessness, high fever, and leukocytosis). Urge the outpatient to avoid contact with infected persons during the cold and flu season.

◆ Carefully observe and document seizure activity. Infuse sodium bicarbonate for acidosis, and sedatives or anticonvulsants for seizures, as ordered. Pad the side rails and keep an oral airway and suction setup at bedside. Assess neurologic status periodically, and check for Chvostek and Trousseau signs, indicators of low serum calcium levels.

◆ Observe for signs of bleeding. Watch for prolonged bleeding at puncture sites and at the vascular access site used for hemodialysis. Monitor Hb levels and HCT, and check stool, urine, and vomitus for blood.

◆ Report signs of pericarditis, such as a pericardial friction rub and chest pain.

◆ Schedule medications carefully. Give iron before meals, aluminum hydroxide gels after meals, and antiemetics, as necessary, a half hour before meals. Administer antihypertensives at appropriate intervals. If the patient requires a rectal infusion of sodium polystyrene sulfonate for dangerously high potassium levels, apply an emollient to soothe the perianal area. Be sure the sodium polystyrene sulfonate enema is expelled; otherwise, it will cause constipation and won't lower potassium levels. Recommend antacid cookies as an alternative to aluminum hydroxide gels needed to bind GI phosphate.

ALERT *Watch for the disappearance of friction rub, with a drop of 15 to 20 mm Hg in blood pressure during inspiration (paradoxical pulse)—an early sign of pericardial tamponade.*

If the patient requires dialysis:

◆ Prepare the patient by fully explaining the procedure. Be sure that they understand how to protect and care for the arteriovenous shunt, fistula, or other vascular access. Check the vascular access site per facility protocol or every 2 hours for patency and check the limb for adequate blood supply and intact nervous function (temperature, pulse rate, capillary refill, and sensation). If a fistula is present, feel for a thrill and listen for a bruit. Use a gentle touch to avoid occluding the fistula. Report signs of possible clotting. Don't use the arm with the vascular access site to take blood pressure readings, draw blood, or give injections as these procedures may rupture the fistula or occlude blood flow.

◆ Withhold the 6 a.m. (or morning) dose of antihypertensive on the morning of dialysis, and instruct the outpatient to do the same.

◆ Use standard precautions when handling body fluids and needles.

◆ Monitor Hb levels and HCT. Assess the patient's tolerance of these levels. Some individuals are more sensitive to lower levels than others. Instruct the anemic patient to conserve energy and to rest frequently.

◆ After dialysis, check for disequilibrium syndrome, a result of sudden correction of blood chemistry abnormalities. Symptoms range from a headache to seizures. Also, check for excessive bleeding from the dialysis site. Apply pressure dressing or absorbable gelatin

sponge, as indicated. Monitor blood pressure carefully after dialysis.

- A patient undergoing dialysis is under a great deal of stress, as is the family. Refer them to appropriate counseling agencies for assistance in coping with chronic renal failure.

Lower Urinary Tract Disorders

LOWER URINARY TRACT INFECTION

Cystitis and urethritis, the two forms of lower UTI, are nearly 10 times more common in women than in men and affect about 10% to 20% of all women at least once. Lower UTI is also a prevalent bacterial disease in children, with girls again most commonly affected. In men and children, lower UTIs are frequently related to anatomic or physiologic abnormalities and therefore require extremely close evaluation. UTIs often respond readily to treatment, but recurrence and resistant bacterial flare-up during therapy are possible.

PEDIATRIC TIP *Have a workup done on all children with proven UTI to exclude an abnormality of the urinary tract that would predispose them to renal damage.*

Pathophysiology

Most lower UTIs result from ascending infection by a single, gram-negative, enteric bacterium, such as *E. coli, Klebsiella, Proteus, Enterobacter, Pseudomonas,* or *Serratia.* However, in a patient with neurogenic bladder, an indwelling catheter, or a fistula between the intestine and the bladder, lower UTI may result from simultaneous infection with multiple pathogens. Infection can result from a breakdown in local defense mechanisms in the bladder that allow bacteria to invade the bladder mucosa and multiply. These bacteria can't be readily eliminated by normal micturition.

Bacterial flare-up during treatment is generally caused by the pathogenic organism's resistance to the prescribed antimicrobial therapy. The presence of even a small number (<10,000/mL) of bacteria in a midstream urine sample obtained during treatment casts doubt on the effectiveness of treatment.

In 99% of patients, recurrent lower UTI results from reinfection by the same organism or from some new pathogen; in the remaining 1%, recurrence reflects persistent infection, usually from renal calculi, chronic bacterial prostatitis, or a structural anomaly that may become a source of infection.

The high incidence of lower UTI among women may result from the shortness of the female urethra (1¼″ to 2″ [3 to 5 cm]), which predisposes women to infection caused by bacteria from the vagina, perineum, rectum, or a sexual partner. (See *Preventing UTIs,* page 368.) Men are less vulnerable because their urethras are longer (7¼″ [18.4 cm]) and because prostatic fluid serves as an antibacterial shield. However, in men older than age 60, incidence rates match those of women. In both men and women, infection usually ascends from the urethra to the bladder.

PREVENTION
PREVENTING UTIS

Following a few simple steps can help reduce the risk of developing a urinary tract infection (UTI). Women in particular may benefit from these suggestions.

Maintain Hydration

Suggest drinking plenty of liquids, especially water. Cranberry juice may have infection-unfighting properties.

Urinate Promptly

Tell the patient to urinate promptly when the urge arises; urination shouldn't be restricted for a long time after the urge to void is felt.

Maintain Hygiene

Wiping from front to back after urinating and after a bowel movement helps prevent bacteria in the anal region from spreading to the vagina and urethra. Also, after intercourse, the bladder should be emptied as soon as possible. Drinking a glass of water also helps flush bacteria.

Avoid Irritation

Use of deodorant sprays or other feminine products, such as douches and powders, should be avoided because they can irritate the urethra.

ELDER TIP As a person ages, the bladder muscles weaken, which may result in incomplete bladder emptying and chronic urine retention—factors that predispose the older person to bladder infections.

Complications

- Chronic or recurrent UTI
- Complicated UTI
- Kidney infection

Signs and Symptoms

Lower UTI usually produces urgency, frequency, dysuria, cramps or spasms of the bladder, itching, a feeling of warmth during urination, nocturia, and possibly urethral discharge in males. Inflammation of the bladder wall also causes hematuria and fever. Other common features include low back pain, malaise, nausea, vomiting, abdominal pain or tenderness over the bladder area, chills, and flank pain.

ELDER TIP The most common initial symptoms of lower UTI in elderly patients are lethargy and a change in mental status.

Diagnosis

Characteristic clinical features and a microscopic urinalysis showing RBCs and WBCs greater than 10/high-power field suggest lower UTI.

CONFIRMING DIAGNOSIS A clean-catch midstream urine specimen revealing a bacterial count above 100,000/mL confirms the diagnosis.

Lower counts don't necessarily rule out infection, especially if the patient is voiding frequently because bacteria require 30 to 45 minutes to reproduce in urine. Careful midstream, clean-catch collection is preferred to catheterization, in men. In women catheterization is the preferred method of obtaining a truly representative sample of the bladder urine as clean catch, irrespective of how fastidiously it is performed, can show perineal bacteria and cellular material.

Culture identifies the infecting organism while sensitivity testing determines the appropriate therapeutic antimicrobial. If patient history and physical examination warrant, a blood test or a stained smear of the discharge rules out venereal disease. Voiding cystourethrography or excretory urography may detect congenital anomalies that predispose the patient to recurrent UTIs.

Treatment

Appropriate antimicrobials are the treatment of choice for most initial lower UTIs. A course of antibiotic therapy lasting from 7 to 10 days is standard, but recent studies suggest that a single dose of an antibiotic or an antibiotic regimen of 3 to 5 days length may be sufficient to render the urine sterile. After 3 days of antibiotic therapy, urine culture should show no organisms. If the urine isn't sterile, bacterial resistance has probably occurred, making the use of a different antimicrobial necessary. Single-dose antibiotic therapy with amoxicillin or trimethoprim and sulfamethoxazole may be effective in females with acute noncomplicated UTI. A urine culture taken 1 to 2 weeks later indicates whether or not the infection has been eradicated.

Recurrent infections due to infected renal calculi, chronic prostatitis, or structural abnormality may necessitate surgery; prostatitis also requires long-term antibiotic therapy. In patients without these predisposing conditions, long-term, low-dosage antibiotic therapy is the treatment of choice.

PEDIATRIC TIP *Fluoroquinolones aren't used for children because of possible adverse effects on developing cartilage*.

Special Considerations

The care plan should include careful patient teaching, supportive measures, and proper specimen collection.

- Explain the nature and purpose of antimicrobial therapy. Emphasize the importance of completing the prescribed course of therapy or, with long-term prophylaxis, of adhering strictly to the ordered dosage. Urge the patient to drink plenty of water (at least eight glasses a day). Stress the need to maintain a consistent fluid intake of about 2 qt (2 L)/day. More or less than this amount may alter the effect of the prescribed antimicrobial. Fruit juices, especially cranberry juice, and oral doses of vitamin C may help acidify the urine and enhance the action of the medication.
- Watch for GI disturbances from antimicrobial therapy. Nitrofurantoin macrocrystals, taken with milk or a meal, prevent such distress. If therapy includes phenazopyridine (might mention the new urinary analgesic Uribel and Urogesic Blue which turn the urine blue), warn the patient that this drug may turn urine red-orange.
- Suggest warm sitz baths for relief of perineal discomfort. If baths aren't effective, apply heat sparingly to the perineum but be careful not to burn the patient. Apply topical antiseptics, such as povidone-iodine ointment, on the urethral meatus as necessary.

- Collect all urine samples for culture and sensitivity testing carefully and promptly. Teach a woman how to clean the perineum properly and keep the labia separated during voiding. A noncontaminated midstream specimen is essential for accurate diagnosis.
- To prevent recurrent lower UTIs, teach a woman to carefully wipe the perineum from front to back and to clean it thoroughly with soap and water after defecation. Advise an infection-prone woman to void immediately after sexual intercourse. Stress the need to drink plenty of fluids routinely and to avoid postponing urination. Recommend frequent comfort stops during long car trips. Also stress the need to completely empty the bladder. To prevent recurrent infections in men, urge prompt treatment of predisposing conditions such as chronic prostatitis. Have the patient use a commode rather than a bedpan to promote sitting up, which assists in emptying the bladder.

VESICOURETERAL REFLUX

In vesicoureteral reflux, urine flows from the bladder back into the ureters and eventually into the renal pelvis or the parenchyma. Because the bladder empties poorly, UTI may result, possibly leading to acute or chronic pyelonephritis with renal damage.

Vesicoureteral reflux is most common during infancy in boys and during early childhood (ages 3 to 7) in girls. Primary vesicoureteral reflux that results from congenital anomalies is most prevalent in females and is rare in blacks. Up to 25% of asymptomatic siblings of children with diagnosed primary vesicoureteral reflux also show reflux.

Pathophysiology

In patients with vesicoureteral reflux, incompetence of the ureterovesical junction and shortening of intravesical ureteral musculature allow backflow of urine into the ureter when the bladder contracts during voiding. Incompetence may result from congenital anomalies of the ureters or bladder, including short or absent intravesical ureter, ureteral ectopia lateralis (greater-than-normal lateral placement of ureters), and gaping ureteral orifice; inadequate detrusor muscle buttress in the bladder, stemming from congenital paraureteral bladder diverticulum; acquired diverticulum (from outlet obstruction); flaccid neurogenic bladder; and high intravesical pressure from outlet obstruction or an unknown cause. Vesicoureteral reflux may also result from cystitis, with inflammation of the intravesical ureter, which causes edema and fixation of the intramural ureter and usually leads to reflux in persons with congenital ureteral or bladder anomalies or other predisposing conditions.

Reflux nephropathy occurs in about 4 of 1,000 asymptomatic people. However, in infants and children who experience UTIs, its prevalence approaches 40% to 50%. Reflux nephropathy may lead to chronic renal failure and end-stage renal disease.

Complications

- Recurrent UTI
- Chronic pyelonephritis
- Renal scarring
- Hypertension

Signs and Symptoms

Vesicoureteral reflux typically manifests itself as the signs and symptoms of UTI: frequency, urgency, burning on urination, hematuria, foul-smelling urine and, in infants, dark, concentrated

urine. With upper urinary tract involvement, signs and symptoms usually include high fever, chills, flank pain, vomiting, and malaise.

PEDIATRIC TIP *In children, fever, nonspecific abdominal pain, and diarrhea may be the only clinical effects. Rarely, children with minimal symptoms remain undiagnosed until puberty or later, when they begin to exhibit clear signs of renal impairment (anemia, hypertension, and lethargy).*

Diagnosis

Symptoms of UTI provide the first clues to diagnosis of vesicoureteral reflux. In infants, hematuria or strong-smelling urine may be the first indication; palpation may reveal a hard, thickened bladder (hard mass deep in the pelvis) if posterior urethral valves are causing an obstruction in male infants.

Cystoscopy, with instillation of a solution containing methylene blue or indigo carmine dye, may confirm the diagnosis. After the bladder is emptied and refilled with clear sterile water, color-tinged efflux from either ureter positively confirms reflux.

Other pertinent laboratory studies include the following:

- Clean-catch urinalysis shows a bacterial count greater than 100,000/mL. Microscopic examination may reveal WBCs, RBCs, and an increased urine pH in the presence of infection. Specific gravity less than 1.010 demonstrates inability to concentrate urine.
- Laboratory studies reveal elevated creatinine levels (>1.2 mg/dL) and elevated blood urea nitrogen levels (>18 mg/dL), indicating advanced renal dysfunction.
- Excretory urography may show dilated lower ureter, ureter visible for its entire length, hydronephrosis, calyceal distortion, and renal scarring.
- Voiding cystourethrography (either fluoroscopic or radionuclide) identifies and determines the degree of reflux and shows when reflux occurs. It may also pinpoint the causative anomaly. In this procedure, contrast material is instilled into the bladder, and X-rays are taken before, during, and after voiding. Nuclear cystography and renal ultrasound may also be used to detect reflux.
- Abdominal CT scan or ultrasound of the kidneys or abdomen shows hydronephrosis, reflux, a small kidney, or scarring.
- Catheterization of the bladder after the patient voids determines the amount of residual urine.

Treatment

The goal of treatment in a patient with vesicoureteral reflux is to prevent pyelonephritis and renal dysfunction with antibiotic therapy and, when necessary, vesicoureteral reimplantation. Appropriate surgical procedures create a normal valve effect at the junction by reimplanting the ureter into the bladder wall at a more oblique angle.

Antimicrobial therapy is usually effective for reflux that's secondary to infection, reflux related to neurogenic bladder and, in children, reflux related to a short intravesical ureter (which abates spontaneously with growth). Reflux related to infection generally subsides after the infection is cured. However, 80% of females with vesicoureteral reflux will have recurrent UTIs within a year. Recurrent infection requires long-term prophylactic antibiotic therapy and careful patient follow-up (cystoscopy and excretory urography every 4 to 6 months) to track the degree of reflux.

UTI that recurs despite adequate prophylactic antibiotic therapy necessitates vesicoureteral reimplantation or reconstructive repair. Bladder outlet obstruction in people with neurogenic bladder requires surgery only if renal dysfunction is present. After surgery, as after antibiotic therapy, close medical follow-up is necessary (excretory urography every 2 to 3 years and urinalysis once per month for 1 year), even if symptoms haven't recurred.

Special Considerations

Patient care includes education and postoperative support.

- To ensure complete emptying of the bladder, teach the patient with vesicoureteral reflux to double void (void once and then try to void again in a few minutes). Because the natural urge to urinate may be impaired, advise them to void every 2 to 3 hours whether or not they feel the urge.
- If surgery is necessary, explain postoperative care: suprapubic catheter in the male, indwelling catheter in the female; and, in both, one or two ureteral catheters or (stents) brought out of the bladder through a small abdominal incision. The suprapubic or indwelling catheter keeps the bladder empty and prevents pressure from stressing the surgical wound; ureteral catheters drain urine directly from the renal pelvis. After complicated reimplantations, all catheters remain in place for 7 to 10 days. Explain that the child will be able to move and walk with the catheters but must be very careful not to dislodge them.
- Postoperatively, closely monitor fluid intake and output. Give analgesics and antibiotics, as ordered. Make sure the catheters are patent and draining well. Maintain sterile technique during catheter care. Watch for fever, chills, and flank pain, which suggest a blocked catheter.
- Before discharging the patient, stress the importance of close follow-up care and adequate fluid intake throughout childhood.
- Instruct parents to watch for and report recurring signs of UTI (painful, frequent, burning urination; foul-smelling urine).
- If the child is taking antimicrobial drugs, make sure his parents understand the importance of completing the prescribed therapy or maintaining low-dose prophylaxis.

PEDIATRIC TIP *Because the diagnostic tests may frighten the child, encourage one of his parents to stay with the patient during all procedures. Explain the procedures to the parents and to the child, if he's old enough to understand.*

NEUROGENIC BLADDER

Neurogenic bladder (also known as *neuromuscular dysfunction of the lower urinary tract, neurologic bladder dysfunction*, and *neuropathic bladder*) refers to all types of bladder dysfunction caused by an interruption of normal bladder innervation. Subsequent complications include incontinence, residual urine retention, urinary infection, stone formation, and renal failure. A neurogenic bladder can be spastic (hypertonic, reflex, or automatic) or flaccid (hypotonic, atonic, nonreflex, or autonomous).

Pathophysiology

At one time, neurogenic bladder was thought to result primarily from spinal cord injury; now, it appears to stem from a host of underlying conditions:

- cerebral disorders, such as stroke, brain tumor (meningioma and glioma), Parkinson disease, multiple sclerosis, dementia, and incontinence caused by aging
- spinal cord disease or trauma, such as herniated vertebral disks, spina bifida, myelomeningocele, spinal stenosis (causing cord compression) or arachnoiditis (causing adhesions between the membranes covering the cord), cervical spondylosis, myelopathies from hereditary or nutritional deficiencies and, rarely, tabes dorsalis
- disorders of peripheral innervation, including autonomic neuropathies resulting from endocrine disturbances such as diabetes mellitus (most common)
- metabolic disturbances, such as hypothyroidism, porphyria, or uremia (infrequent)
- acute infectious diseases such as transverse myelitis
- heavy metal toxicity
- chronic alcoholism
- collagen diseases such as systemic lupus erythematosus
- vascular diseases such as atherosclerosis
- distant effects of cancer such as primary oat cell carcinoma of the lung
- herpes zoster
- syphilis
- sacral agenesis.

An upper motor neuron lesion causes spastic neurogenic bladder, with spontaneous contractions of detrusor muscles, elevated intravesical voiding pressure, bladder wall hypertrophy with trabeculation, and urinary sphincter spasms. A lower motor neuron lesion causes flaccid neurogenic bladder, with decreased intravesical pressure, increased bladder capacity and large residual urine retention, and poor detrusor contraction.

Complications

- Calculus formation
- Incontinence
- Renal failure
- Residual urine retention
- UTI
- Autonomic dysreflexia

Signs and Symptoms

Neurogenic bladder produces a wide range of clinical effects, depending on the underlying cause and its effect on the structural integrity of the bladder. Usually, this disorder causes some degree of incontinence, changes in initiation or interruption of micturition, and the inability to empty the bladder completely. Other effects of neurogenic bladder include vesicoureteral reflux, deterioration or infection in the upper urinary tract, and ureteral dilatation with hydronephrosis.

Depending on the site and extent of the spinal cord lesion, spastic neurogenic bladder may produce involuntary or frequent scanty urination, without a feeling of bladder fullness, and possibly spontaneous spasms of the arms and legs. Anal sphincter tone may be increased. Tactile stimulation of the abdomen, thighs, or genitalia may precipitate voiding and spontaneous contractions of the arms and legs. With cord lesions in the upper thoracic (cervical) level, bladder distention can trigger hyperactive autonomic reflexes, resulting in severe hypertension, bradycardia, and headaches.

Flaccid neurogenic bladder may be associated with overflow incontinence, diminished anal

sphincter tone, and a greatly distended bladder (evident on percussion or palpation), but without the accompanying feeling of bladder fullness due to sensory impairment.

Diagnosis

The patient's history may include a condition or disorder that can cause neurogenic bladder, incontinence, and disruptions of micturition patterns. Voiding cystourethrography evaluates bladder neck function, vesicoureteral reflux, and continence.

Urodynamic studies help evaluate how urine is stored in the bladder, how well the bladder empties, and the rate of movement of urine out of the bladder during voiding. These studies consist of five components:

- Urine flow study (uroflow) shows diminished or impaired urine flow.
- Cystometry evaluates bladder nerve supply, detrusor muscle tone, and intravesical pressures during bladder filling and contraction.
- Urethral pressure profile determines urethral function with respect to the length of the urethra and the outlet pressure resistance.
- Sphincter electromyelography correlates the neuromuscular function of the external sphincter with bladder muscle function during bladder filling and contraction. This evaluates how well the bladder and urinary sphincter muscles work together.
- Retrograde urethrography reveals the presence of strictures and diverticula. This test may not be performed on a routine basis.

Treatment

The goals of treatment are to maintain the integrity of the upper urinary tract, control infection, and prevent urinary incontinence through evacuation of the bladder, drug therapy, surgery or, less commonly, neural blocks and electrical stimulation.

Techniques of bladder evacuation include Credé's method, Valsalva's maneuver, and intermittent self-catheterization. Credé's method—application of manual pressure over the lower abdomen—promotes complete emptying of the bladder. After appropriate instruction, most patients can perform this maneuver themselves. Even when patients perform this maneuver properly, however, Credé's method isn't always successful and doesn't always eliminate the need for catheterization.

Intermittent self-catheterization—more effective than either Credé's method or Valsalva's maneuver—has proved to be a major advance in the treatment of neurogenic bladder because it allows complete emptying of the bladder without the risks that an indwelling catheter poses. Generally, men can perform this procedure more easily than women, but women can learn self-catheterization with the help of a mirror. Intermittent self-catheterization, in conjunction with a bladder-retraining program, is especially useful for patients with flaccid neurogenic bladder.

Drug therapy for neurogenic bladder may include bethanechol and phenoxybenzamine to facilitate bladder emptying and propantheline, methantheline, flavoxate, dicyclomine, and imipramine to facilitate urine storage.

When conservative treatment fails, surgery may correct the structural impairment through transurethral resection of the bladder neck, urethral dilatation, external sphincterotomy, or urinary diversion procedures. Implantation of an artificial urinary sphincter may be necessary if permanent incontinence follows surgery for neurogenic bladder.

Special Considerations

Care for patients with neurogenic bladder varies according to the underlying cause and method of treatment.

- Explain all diagnostic tests clearly so the patient understands the procedure, time involved, and possible results. Assure the patient that the lengthy diagnostic process is necessary to identify the most effective treatment plan. After the treatment plan is chosen, explain it to the patient in detail.
- Use strict sterile technique during insertion of an indwelling catheter (a temporary measure to drain the incontinent patient's bladder). Don't interrupt the closed drainage system for any reason. Obtain urine specimens with a syringe and small-bore needle inserted through the aspirating port of the catheter itself (below the junction of the balloon instillation site). Irrigate in the same manner if ordered.
- Clean the catheter insertion site with soap and water at least twice a day. Don't allow the catheter to become encrusted. Use a sterile applicator to apply antibiotic ointment around the meatus after catheter care. Keep the drainage bag below the tubing, and don't raise the bag above the level of the bladder. Clamp the tubing, or empty the bag before transferring the patient to a wheelchair or stretcher to prevent accidental urine reflux. If urine output is considerable, empty the bag more frequently than once every 8 hours because bacteria can multiply in standing urine and migrate up the catheter and into the bladder.
- Watch for signs of infection (fever, cloudy or foul-smelling urine). Encourage the patient to drink plenty of fluids to prevent calculus formation and infection from urinary stasis. Try to keep the patient as mobile as possible. Perform passive range-of-motion exercises if necessary.
- If a urinary diversion procedure is to be performed, arrange for consultation with an enterostomal therapist, and coordinate the care plans.
- Before discharge, teach the patient and family evacuation techniques as necessary (Credé's method, intermittent catheterization). Counsel regarding sexual activities. Remember, the incontinent patient feels embarrassed and distressed. Provide emotional support.

CONGENITAL ANOMALIES OF THE URETER, BLADDER, AND URETHRA

The most common congenital malformations of the ureter, bladder, and urethra include duplicated ureter, retrocaval ureter, ectopic orifice of the ureter, stricture or stenosis of the ureter, ureterocele, exstrophy of the bladder, congenital bladder diverticulum, hypospadias, and epispadias. Some of these abnormalities are obvious at birth; others aren't apparent and are recognized only after they produce symptoms. (See *Congenital urologic anomalies,* page 373.)

Congenital urologic anomalies

Duplicated ureter	Retrocaval ureter (preureteral vena cava)	Ectopic orifice of ureter
Pathophysiology	**Pathophysiology**	**Pathophysiology**
• Most common ureteral anomaly	• The right ureter passes behind the inferior vena cava before entering the bladder. Compression of the ureter between the vena cava and the spine causes dilation and elongation of the pelvis; hydroureter and hydronephrosis; and fibrosis and stenosis of the ureter in the compressed area.	• Ureters single or duplicated in females, ureteral orifice usually inserts in urethra or vaginal vestibule, beyond external urethral sphincter; in males, in prostatic urethra, or in seminal vesicles or vas deferens
• *Complete*, a double collecting system with two separate pelves, each with its own ureter and orifice	• Relatively uncommon; higher incidence in males	
• *Incomplete* (Y		**Clinical features**

type), two separate ureters join before entering bladder

Clinical features
- Persistent or recurrent infection
- Frequency, urgency, or burning on urination
- Diminished urine output
- Flank pain, fever, and chills

Diagnosis and treatment
- Excretory urography
- Voiding cystoscopy
- Cystourethrography
- Retrograde pyelography
- Surgery for obstruction, reflux, or severe renal damage

Clinical features
- Right flank pain
- Recurrent urinary tract infection
- Renal calculi
- Hematuria

Diagnosis and treatment
- Excretory urography demonstrates superior ureteral enlargement with spiral appearance
- Surgical resection and anastomosis of ureter with renal pelvis, or reimplantation into bladder

- Symptoms rare when ureteral orifice opens between trigone and bladder neck
- Obstruction, reflux, and incontinence (dribbling) in 50% of females
- In males, flank pain, frequency, urgency

Diagnosis and treatment
- Excretory urography
- Urethroscopy, vaginoscopy
- Voiding cystourethrography
- Resection and ureteral reimplantation into bladder for incontinence

---

Strictures or stenosis of ureter	*Ureterocele*	*Exstrophy of bladder*

Pathophysiology
- Most common site, the distal ureter above ureterovesical junction; less common, ureteropelvic junction; rare, the midureter
- Discovered during infancy in 25% of patients; before puberty in most
- More common in males

Clinical features
- Megaloureter or hydroureter (enlarged ureter), with hydronephrosis when stenosis occurs in distal ureter
- Hydronephrosis alone when stenosis occurs at ureteropelvic junction

Pathophysiology
- Bulging of submucosal ureter into bladder can be 1 or 2 cm, or can almost fill entire bladder
- Unilateral, bilateral, ectopic with resulting hydroureter and hydronephrosis

Clinical features
- Obstruction
- Persistent or recurrent infection

Pathophysiology
- Absence of anterior abdominal and bladder wall allows the bladder to protrude onto abdomen
- In males, undescended testes and epispadias; in females, cleft clitoris, separated labia, or absent vagina
- Skeletal or intestinal anomalies possible

Clinical features
- Obvious at birth, with urine seeping onto abdominal wall from abnormal ureteral orifices
- Surrounding skin excoriated; exposed bladder mucosa ulcerated; infection; related abnormalities

---

Strictures or stenosis of ureter	*Ureterocele*	*Exstrophy of bladder*

Diagnosis and treatment	Diagnosis and treatment	Diagnosis and treatment
• Ultrasound • Excretory urography • Voiding cystography • Surgical repair of stricture; nephrectomy for severe renal damage	• Voiding cystourethrography • Excretory urography and cystoscopy show thin, translucent mass • Surgical excision or resection of ureterocele, with reimplantation of ureter	• Excretory urography • Surgical closure of defect, and bladder and urethra reconstruction during infancy to allow pubic bone fusion; alternative treatment: protective dressing and diapering; urinary diversion eventually necessary for most patients
Congenital bladder diverticulum	**Hypospadias**	**Epispadias**
Pathophysiology • Circumscribed pouch or sac (diverticulum) of bladder wall • Can occur anywhere in bladder, usually lateral to ureteral orifice. Large diverticulum at orifice can cause reflux. *Clinical features* • Fever, frequency, and painful urination • Urinary tract infection • Cystitis, particularly in males • Diagnosis and treatmentExcretory urography shows diverticulum • Retrograde cystography shows vesicoureteral reflux in ureter • Surgical correction for reflux	*Pathophysiology* • Urethral opening on ventral surface of penis or, in females (rare), within vagina • Occurs in 1 in 300 live male births; genetic factor suspected in less severe cases *Clinical features* • Usually associated with chordee, making normal urination with penis elevated impossible • Absence of ventral prepuce • Vaginal discharge in females • Diagnosis and treatmentMild disorder requires no treatment • Surgical repair of severe anomaly usually necessary before child reaches school age	*Pathophysiology* • Urethral opening on dorsal surface of penis; in females, a fissure of the upper wall of urethra • A rare anomaly; usually more common in males; often accompanies bladder exstrophy *Clinical features* • In mild cases, orifice appears along dorsum of glans; in severe cases, along dorsum of penis • In females, bifid clitoris and short, wide urethra • Diagnosis and treatmentSurgical repair, in several stages, almost always necessary

Pathophysiology

Congenital anomalies of the ureter, bladder, and urethra are among the most common birth defects, occurring in about 5% of all births. Their causes are unknown; diagnosis and treatment vary.

Complications

- Calculi
- Hematuria
- Infections

Special Considerations

 PEDIATRIC TIP *Because these anomalies aren't always obvious at birth, carefully evaluate the newborn's urogenital function. Document the amount and color of urine, voiding pattern, strength of stream, and any indications of infection, such as fever and urine odor. Tell parents to watch for these signs at home. In all children, watch for signs of obstruction, such as dribbling, oliguria or anuria, abdominal mass, hypertension, fever, bacteriuria, or pyuria.*

- Monitor renal function daily; record intake and output accurately.
- Follow strict sterile technique in handling cystostomy tubes or indwelling urinary catheters.
- Make sure that ureteral, suprapubic, or urethral catheters remain in place and don't become contaminated. Document the type, color, and amount of drainage.
- Apply sterile saline pads to protect the exposed mucosa of the newborn with bladder exstrophy. Don't use heavy clamps on the umbilical cord, and avoid dressing or diapering the infant. Place the infant in an incubator, and direct a stream of saline mist onto the bladder to keep it moist. Use warm water and mild soap to keep the surrounding skin clean. Rinse well, and keep the area as dry as possible to prevent excoriation.
- Infant boys diagnosed with hypospadias and epispadias should not be circumcised because the foreskin can and typically is used in the surgical repair.
- Provide reassurance and emotional support to the parents. When possible, allow them to participate in their child's care to promote normal bonding. As appropriate, suggest or arrange for genetic counseling.

Prostate and Epididymis Disorders

PROSTATITIS

Prostatitis, inflammation of the prostate gland, may be acute or chronic. Acute prostatitis most often results from gram-negative bacteria and is easy to recognize and treat. However, chronic prostatitis, the most common cause of recurrent UTIs in males, is less easy to recognize.

Pathophysiology

About 80% of bacterial prostatitis cases result from infection by *E. coli*; the rest are due to infection by *Klebsiella, Enterobacter, Proteus, Pseudomonas, Streptococcus,* or *Staphylococcus.* These organisms probably spread to the prostate by the bloodstream or from ascending urethral infection, invasion of rectal bacteria via lymphatics, reflux of infected bladder urine into the prostate ducts or, less commonly, infrequent or excessive sexual intercourse or such procedures as cystoscopy or catheterization. Chronic prostatitis usually results from bacterial invasion from the urethra.

It's estimated that 2 of every 10,000 people who seek outpatient care do so because of prostatitis. As many as 35% of males older than age 50 have chronic prostatitis; about 50% of males will be diagnosed with prostatitis at some point in their lives.

Complications

- UTI

- Prostatic abscess
- Pyelonephritis
- Epididymitis

Signs and Symptoms

Acute prostatitis begins with fever, chills, low back pain, myalgia, perineal fullness, and arthralgia. Urination is frequent and urgent. Dysuria, nocturia, and urinary obstruction may also occur. The urine may appear cloudy. When palpated rectally, the prostate is tender, indurated, swollen, firm, and warm. If the patient has shaking chills and fever prostate manipulation should be deferred.

Chronic bacterial prostatitis sometimes produces no symptoms but usually elicits the same urinary symptoms as the acute form but to a lesser degree. UTI is a common complication. Other possible signs include painful ejaculation, hemospermia, persistent urethral discharge, and sexual dysfunction.

Diagnosis

Characteristic rectal examination findings suggest prostatitis (boggy, tender prostate). In some cases, a urine culture can identify the causative infectious organism which is most often *E. coli*. Expressed prostatic secretion (EPS) should be attempted during the prostate exam and any seminal fluid expressed should be examined microscopically looking for WBCs in clumps. Bacteria are seldom seen in an EPS.

CONFIRMING DIAGNOSIS *A firm diagnosis depends on a comparison of urine cultures of specimens obtained by the Meares and Stamey technique. This test requires three urine specimens and one specimen of prostatic secretions. Urine is collected when the patient starts voiding (sample 1); then at midstream (sample 2), after which the patient is asked to stop voiding with some urine remaining in the bladder; the physician massages the prostate and a specimen of EPS is obtained; and, finally, the first-voided urine after this prostatic massage is collected (sample 3). A significant increase in colony count in sample 3 compared with samples 1 and 2 confirms prostatitis.*

Treatment

Systemic antibiotic therapy chosen according to the infecting organism is the treatment of choice for acute prostatitis. If sepsis is likely, I.V. antibiotics may be given until sensitivity test results are known. If test results and clinical response are favorable, parenteral therapy continues for 48 hours to 1 week, after which an oral agent is substituted for 30 days. For infections caused by a sexually transmitted disease, injection of ceftriaxone followed by a 10-day course of doxycycline or floxacin is effective.

Supportive therapy includes bed rest, adequate hydration, and administration of analgesics, antipyretics, sitz baths, and stool softeners as necessary. Diet therapy includes avoiding substances that irritate the bladder, such as alcohol, caffeinated food and beverages, citrus juices, and hot or spicy foods. Increasing the intake of fluids (1.5 to 4 L/day) encourages frequent urination that will help flush the bacteria from the bladder. In symptomatic chronic prostatitis, regular massage of the prostate is most effective. Regular ejaculation may help promote drainage of prostatic secretions. Anticholinergics and analgesics may help relieve nonbacterial prostatitis symptoms.

If drug therapy is unsuccessful, treatment may include transurethral resection of the prostate (TURP), which requires removal of all infected tissue. However, this procedure usually isn't performed on young adults because it may cause retrograde ejaculation and sterility. Total prostatectomy is curative but may cause impotence and incontinence.

Special Considerations

Patient care is primarily supportive.

- Ensure bed rest and adequate hydration. Provide stool softeners and administer sitz baths, as ordered.
- As needed, prepare to assist with suprapubic needle aspiration of the bladder or a suprapubic cystostomy (rarely used).
- Emphasize the need for strict adherence to the prescribed drug regimen. Instruct the patient to drink at least eight glasses of water a day. Have the patient report adverse drug reactions (rash, nausea, vomiting, fever, chills, and GI irritation).
- Adding probiotics during prolonged antibiotic therapy can help prevent gut bacteria overgrowth.

EPIDIDYMITIS

This infection of the epididymis, the testicle's cordlike excretory duct, is one of the most common infections of the male reproductive tract. It usually affects adults and is rare before puberty. Epididymitis may spread to the testicle itself, causing orchitis; bilateral epididymitis may cause sterility. (See *Orchitis*.)

Orchitis

Orchitis, an infection of the testicles, is a serious complication of epididymitis. It may also result from mumps, which may lead to sterility. Orchitis may, rarely, result from other systemic infections, testicular torsion, or severe trauma. Its typical effects include unilateral or bilateral tenderness, sudden onset of pain, and swelling of the scrotum and testicles. The affected testicle may be red. Nausea and vomiting also occur. Sudden cessation of pain indicates testicular ischemia, which may result in permanent damage to one or both testicles.

Treatment consists of immediate antibiotic therapy; in orchitis due to mumps, diethylstilbestrol may be given to relieve pain, swelling, and fever. Severe orchitis may require surgery to incise and drain the hydrocele and improve testicular circulation. Other treatment is similar to that for epididymitis. To prevent orchitis due to mumps, stress the need for prepubertal males to receive mumps vaccine (or gamma globulin injection after contracting mumps).

Pathophysiology

Epididymitis is usually a complication of pyogenic bacterial infection of the urinary tract (urethritis or prostatitis). The pyogenic organisms, such as staphylococci, *E. coli*, streptococci, *Chlamydia trachomatis*, and *Neisseria gonorrhoeae*, reach the epididymis through the lumen of the vas deferens. Rarely, epididymitis is secondary to a distant infection, such as pharyngitis or tuberculosis, that spreads through the lymphatics or, less commonly, the bloodstream. Other

causes include trauma, gonorrhea, syphilis, or a chlamydial infection. Trauma may reactivate a dormant infection or initiate a new one. Epididymitis may be a complication of prostatectomy and may also result from chemical irritation by extravasation of urine through the vas deferens. The incidence is about 600,000 cases per year, with the highest prevalence in young males ages 19 to 35.

Complications

- ◆ Bilateral epididymitis can cause sterility
- ◆ Orchitis

Signs and Symptoms

The key symptoms are pain, extreme tenderness, and swelling in the groin and scrotum with erythema, high fever, malaise, and a characteristic waddle—an attempt to protect the groin and scrotum during walking. An acute hydrocele may also result from inflammation.

Diagnosis

Clinical features suggest epididymitis, but diagnosis is actually made with the aid of laboratory tests:

- ◆ urinalysis: increased WBC count indicates infection
- ◆ urine culture and sensitivity tests: may identify causative organism
- ◆ serum WBC count: more than 10,000/µL in infection.

ALERT *Scrotal ultrasonography may help differentiate acute epididymitis from other conditions, such as testicular torsion, which is a surgical emergency.*

Testicular scan (nuclear medicine scan) may be done to rule out torsion. In epididymitis, increased blood flow is also demonstrated.

Treatment

The goal of treatment is to reduce pain and swelling and combat infection. Therapy must begin immediately, particularly in the patient with bilateral epididymitis because sterility is always a threat. During the acute phase, treatment consists of bed rest, scrotal elevation with towel rolls or adhesive strapping, broad-spectrum antibiotics, and analgesics. An ice bag applied to the area may reduce swelling and relieve pain (heat is contraindicated because it may damage germinal cells, which are viable only at or below normal body temperature). When pain and swelling subside and allow walking, an athletic supporter may prevent pain. Occasionally, corticosteroids may be prescribed to help counteract inflammation, but their use is controversial.

ELDER TIP *In the older patient undergoing open prostatectomy, bilateral vasectomy may be necessary to prevent epididymitis as a postoperative complication; however, antibiotic therapy alone may prevent it. When epididymitis is refractory to antibiotic therapy, epididymectomy under local anesthetic is necessary.*

Special Considerations

Patient care includes support and monitoring for worsening of symptoms.

- ◆ Watch closely for abscess formation (localized, hot, red, tender area) or extension of infection

into the testes. Closely monitor temperature, and ensure adequate fluid intake.
- Because the patient is usually very uncomfortable, administer analgesics as necessary. During bed rest, check often for proper scrotum elevation.
- Before discharge, emphasize the importance of completing the prescribed antibiotic therapy, even after symptoms subside. Educate the patient regarding preventing the transmission of sexually transmitted diseases, as appropriate.
- If the patient faces the possibility of sterility, suggest supportive counseling as necessary.

BENIGN PROSTATIC HYPERPLASIA

Although most men older than age 50 have some prostatic enlargement, in BPH, also known as *benign prostatic hypertrophy*, the prostate gland enlarges sufficiently to compress the urethra and cause some overt urinary obstruction. Depending on the size of the enlarged prostate, the age and health of the patient, and the extent of obstruction, BPH is treated symptomatically or surgically.

Pathophysiology

Evidence suggests a link between BPH and hormonal activity. As men age, production of androgenic hormones decreases, causing an imbalance in androgen and estrogen levels, and high levels of dihydrotestosterone, the main prostatic intracellular androgen. Other causes include neoplasm, arteriosclerosis, diabetes, inflammation, and metabolic or nutritional disturbances.

Regardless of the cause, BPH begins with changes in periurethral glandular tissue. As the prostate enlarges, it may extend into the bladder and obstruct urinary outflow by compressing or distorting the prostatic urethra. BPH may also cause a pouch to form in the bladder that retains urine when the rest of the bladder empties. This retained urine may lead to calculus formation or cystitis.

The likelihood of developing an enlarged prostate increases with age. A small amount of prostate enlargement is present in many men older than age 40 (8%), up to 40% to 50% in men 51 to 60, and more than 80% to 90% of men older than age 80. Blacks, with an incidence of 224.3 cases per 100,000 people, are at the greatest risk, present with more advanced disease, and have a poorer prognosis. Whites, by comparison, have an incidence of 150.3 cases per 100,000 people, and Asians have an incidence of 82.2 cases per 100,000 people.

Complications

- Urinary stasis
- UTI
- Calculi (bladder and prostatic)
- Bladder wall trabeculation
- Detrusor muscle hypertrophy
- Bladder diverticula and saccules
- Urethral stenosis
- Hydronephrosis
- Paradoxical incontinence
- Acute or chronic renal failure
- Acute postobstructive diuresis

Signs and Symptoms

Clinical features of BPH depend on the extent of prostatic enlargement and the lobes affected.

Characteristically, the condition starts with a group of symptoms known as *prostatism*: reduced urine stream caliber and force, urinary hesitancy, and difficulty starting micturition (resulting in straining, feeling of incomplete voiding, and an interrupted stream). As the obstruction increases, it causes frequent urination with nocturia, dribbling, urine retention, incontinence, and possibly hematuria. Physical examination indicates a visible midline mass above the symphysis pubis that represents an incompletely emptied bladder; rectal palpation discloses an enlarged prostate. Examination may detect secondary anemia and, possibly, renal insufficiency secondary to obstruction.

As BPH worsens, complete urinary obstruction may follow infection or use of decongestants, tranquilizers, alcohol, antidepressants, or anticholinergics. Complications include infection, renal insufficiency, hemorrhage, and shock.

Diagnosis

Clinical features and a rectal examination are usually sufficient for diagnosis. Other findings help to confirm it:

- Excretory urography may indicate urinary tract obstruction, hydronephrosis, calculi or tumors, and filling and emptying defects in the bladder.
- Elevated blood urea nitrogen and serum creatinine levels suggest renal dysfunction.
- Urinalysis and urine culture show hematuria, pyuria and, when the bacterial count exceeds 100,000/mL, UTI.

When symptoms are severe, a cystourethroscopy is definitive, but this test is performed only immediately before surgery to help determine the best procedure. It can show prostate enlargement, bladder wall changes, and a raised bladder neck.

Treatment

Conservative therapy includes prostate massages, sitz baths, fluid restriction for bladder distention, and antimicrobials for infection. If symptoms are mild, methods for relief may include avoiding alcohol and caffeine, especially after dinner; urinating when the urge is first felt; avoiding over-the-counter cold and sinus medications that contain decongestants or antihistamines because they can increase BPH symptoms; keeping warm and exercising regularly because cold weather and lack of physical activity may worsen symptoms; performing pelvic strengthening exercises (Kegel exercises); and reducing stress because nervousness and tension can lead to more frequent urination. Some men have had success taking extracts of saw palmetto berries, a herb that has been used to ease prostate symptoms. Fat-soluble saw palmetto extract that has been standardized to contain 85% to 95% fatty acids and sterols is more effective. Regular ejaculation may help relieve prostatic congestion.

Urine flow rates can be improved with alpha$_1$-adrenergic blockers, which relieve bladder outlet obstruction by preventing contractions of the prostatic capsule and bladder neck. Finasteride (5-alpha reductase inhibitor) lowers levels of hormones produced by the prostate (dihydrotestosterone), reduces the size of the prostate gland, increases urine flow rate, and decreases symptoms of BPH. It may take 3 to 6 months before a significant improvement in symptoms occurs. Potential adverse effects related to finasteride include decreased sex drive and impotence. Recently Cialis 5 mg daily has shown some benefit in men who have failed alpha$_1$-adrenergic blockers such as Terazosin, Doxazosin, Tamsulosin, Alfuzosin, and/or Silodosin.

Surgery is the only effective therapy to relieve acute urine retention, hydronephrosis, severe

hematuria, recurrent UTIs, and other intolerable symptoms. A transurethral resection may be performed if the prostate weighs less than 2 oz (56.7 g). In TURP, a resectoscope removes tissue with a wire loop and electric current. In high-risk patients, postoperative continuous drainage with a three-way indwelling urinary catheter alleviates urine retention caused by clotting. Transurethral needle ablation (transurethral microwave thermotherapy) may be used to heat and destroy prostate tissue by radiofrequency; this helps spare surrounding tissue. Laser prostate ablation can also be used but pathologic specimens are vaporized and destroyed during the procedure.

The following procedures involve open surgical removal:

- *suprapubic (transvesical) resection:* most common and useful when prostatic enlargement remains within the bladder and the prostate is bigger than 60 g
- *retropubic (extravesical) resection:* allows direct visualization; potency and continence are usually maintained.

Balloon dilatation of the prostate has been used with varying degrees of success. Prostate stenting has also been used, again with varying degrees of success.

Special Considerations

Prepare the patient for diagnostic tests and surgery, as appropriate.

- Monitor and record the patient's vital signs, intake and output, and daily weight. Watch closely for signs of postobstructive diuresis (such as increased urine output and hypotension), which may lead to serious dehydration, lowered blood volume, shock, electrolyte loss, and anuria.
- Administer antibiotics, as indicated, for UTI, urethral instrumentation, and cystoscopy.
- If urine retention is present, insert an indwelling urinary catheter (although this is usually difficult in a patient with BPH). If the catheter can't be passed transurethrally, assist with suprapubic cystostomy (under local anesthetic). Avoid rapid bladder decompression.

After prostatic surgery:

- Maintain patient comfort, and watch for and prevent postoperative complications. Observe for immediate dangers of prostatic bleeding (shock and hemorrhage). Check the catheter often (every 15 minutes for the first 2 to 3 hours) for patency and urine color; check dressings for bleeding.
- Postoperatively, many urologists insert a three-way catheter and establish continuous bladder irrigation. Keep the catheter open at a rate sufficient to maintain returns that are clear and light pink. Watch for fluid overload from absorption of the irrigating fluid into systemic circulation. If a regular catheter is used, observe it closely. If drainage stops because of clots, irrigate the catheter, as indicated, usually with 80 to 100 mL of normal saline solution, while maintaining strict sterile technique.
- Administer anticholinergics, as indicated, to relieve painful bladder spasms that often occur after transurethral resection.
- Provide patient comfort measures after an open procedure: suppositories (except after perineal prostatectomy), analgesic medication to control incisional pain, and frequent dressing changes.
- Continue infusing I.V. fluids until the patient can drink sufficient fluids (2 to 3 L/day) to maintain adequate hydration.

- Administer stool softeners and laxatives, as needed, to prevent straining. Don't check for fecal impaction because a rectal examination may precipitate bleeding.
- After the catheter is removed, the patient may experience frequency, dribbling, and occasional hematuria. Reassure the patient that he'll gradually regain urinary control.
- Reinforce prescribed limits on activity. Warn the patient against lifting, strenuous exercise, and long automobile rides because these increase the risk of bleeding. Also caution the patient to restrict sexual activity for at least several weeks after discharge from the hospital.
- Instruct the patient to follow the prescribed oral antibiotic drug regimen, and discuss the indications for using gentle laxatives. Urge the patient to seek medical care immediately if they can't void, pass bloody urine, or develop a fever.

ALERT *Watch for septic shock, the most serious complication of prostatic surgery, which may cause severe chills, sudden fever, tachycardia, hypotension, or other signs of shock. Start rapid infusion of antibiotics I.V. as indicated. Watch for pulmonary embolus, heart failure, and renal shutdown. Monitor vital signs, central venous pressure, and arterial pressure continuously. The patient may need intensive supportive care in the intensive care unit.*

Immune Disorders

Introduction

The environment contains thousands of pathogenic microorganisms—viruses, bacteria, fungi, and parasites. Ordinarily, we protect ourselves from infectious organisms and other harmful invaders through an elaborate network of safeguards—the host defense system. Understanding how this system functions provides the framework for studying various immune disorders.

HOST DEFENSE SYSTEM

The host defense system includes physical and chemical barriers to infection, the inflammatory response, and the immune response. Physical barriers, such as the skin and mucous membranes, prevent invasion by most organisms. Those organisms that penetrate this first line of defense simultaneously trigger the inflammatory and immune responses. Both responses involve cells derived from a hematopoietic stem cell in the bone marrow.

Chemical barriers include lysozymes (found in body secretions, such as tears, mucus, and saliva) and hydrochloric acid (found in the stomach). Lysozymes destroy bacteria by removing cell walls. Hydrochloric acid breaks down food and mucus that contains pathogens.

The inflammatory response involves polymorphonuclear leukocytes, basophils, mast cells, platelets, and, to some extent, monocytes and macrophages.

The immune response primarily involves the interaction of lymphocytes (T and B cells), macrophages, and macrophage-like cells and their products. These cells may be circulating or may be localized in the immune system's tissues and organs, including the thymus, lymph nodes, spleen, and tonsils. The thymus participates in the maturation of T lymphocytes (cell-mediated immunity); here these cells are "educated" to differentiate "self" from "nonself." In contrast, B lymphocytes (humoral immunity) mature in the bone marrow. The key humoral effector mechanism is the production of immunoglobulin (Ig) by B cells and the subsequent activation of the complement cascade. The lymph nodes, spleen, liver, and intestinal lymphoid tissue help remove and destroy circulating antigens in the blood and lymph.

ANTIGENS

An antigen is any substance that can induce an immune response. T and B lymphocytes have specific receptors that respond to specific antigen molecular shapes (epitopes). In B

lymphocytes, or B cells, this receptor is an Ig (antibody) cell: IgD or IgM, sometimes referred to as a surface Ig. The T-cell antigen receptor recognizes antigens only in association with specific cell-surface molecules known as the major histocompatibility complex (MHC). (See *The major histocompatibility complex*, page 381.) MHC molecules, which differ among individuals, identify substances as self or nonself. Slightly different antigen receptors can recognize a phenomenal number of distinct antigens, which are coded by distinct, variable region genes.

The major histocompatibility complex

The major histocompatibility complex (MHC) is a cluster of genes on human chromosome 6 that plays a pivotal role in the immune response. Also known as *human leukocyte antigen* (*HLA*) *genes*, these genes are inherited in an autosomal codominant manner. That is, each individual receives one set of MHC genes (haplotype) from each parent, and both sets of genes are expressed on the individual's cells. These genes play a role in the recognition of self versus nonself and in the interaction of immunologically active cells by coding for cell-surface proteins.

HLA genes are divided into three classes. Class I molecules appear on the surface of nearly all of the body's cells and include HLA-A, HLA-B, and HLA-C genes. During tissue graft rejection, they're the chief antigens recognized by the host. When killer (CD8$^+$) T cells detect a virally infected antigen, they recognize it in the context of a class I molecule. Class II molecules only appear on B cells, macrophages, and activated T cells. They include the HLA-D and HLA-DR genes. Class II molecules promote efficient collaboration between immunocompetent cells.

Helper (CD4$^+$) T cells require that antigen be presented in the context of a class II molecule. Because these molecules also determine whether an individual responds to a particular antigen, they're also known as *immune response genes*. Class III molecules include certain complement proteins (C2, C4, and Factor B).

Groups, or clones, of lymphocytes exist with identical receptors for a specific antigen. The clone of a lymphocyte rapidly proliferates when exposed to the specific antigen. Some lymphocytes further differentiate, and others become memory cells, which allow a more rapid response—the memory or anamnestic response—to subsequent challenge by the antigen.

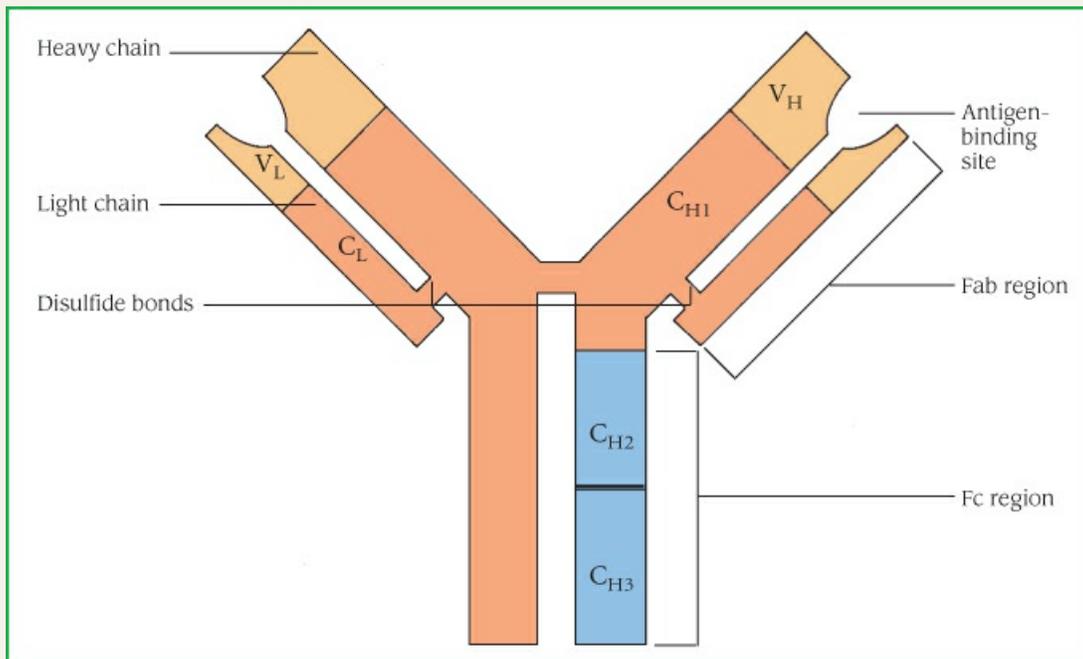
Many factors influence antigenicity. Among them are the antigen's physical and chemical characteristics, its relative foreignness, and the individual's genetic makeup, particularly the MHC molecules. Most antigens are large molecules, such as proteins or polysaccharides. (Smaller molecules such as drugs that aren't antigenic by themselves are known as *haptens*. These haptens can bind with larger molecules, or carriers, and become antigenic or immunogenic.) The antigen's relative foreignness influences the immune response's intensity. For example, little or no immune response may follow transfusion of serum proteins between humans; however, a vigorous immune response (serum sickness) commonly follows transfusion of horse serum proteins to a human. Genetic makeup may also determine why some individuals respond to certain antigens, whereas others don't. The genes responsible for this phenomenon encode the MHC molecules.

B LYMPHOCYTES

B lymphocytes and their products, Igs, contribute to humoral immunity. The binding of soluble antigen with B-cell antigen receptors initiates the humoral immune response. The activated B cells differentiate into plasma cells that secrete Igs or antibodies. This response is regulated by T lymphocytes and their products, lymphokines. These lymphokines, which include interleukin (IL)-2, IL-4, IL-5, and interferon (IFN) gamma, are important in determining the class of Igs made by B cells.

The Igs secreted by plasma cells are four-chain molecules with two heavy (H) and two light (L) chains. (See *Structure of the immunoglobulin molecule,* page 382.) Each chain has a variable (V) region and one or more constant (C) regions, which are coded by separate genes. The V regions of both L and H chains participate in the binding of antigens. The C regions of the H chain provide a binding site for crystallizable fragment (Fc) receptors on cells and govern other mechanisms.

Structure of the immunoglobulin molecule

The immunoglobulin (Ig) molecule consists of four polypeptide chains—two heavy (H) and two light (L) chains—held together by disulfide bonds. The H chain has one variable (V) and at least three constant (C) regions. The L chain has one V and one C regions. Together, the V regions of the H and L chains form a pocket known as the antigen-binding site. This site is located within the antigen-binding fragment (Fab) region of the molecule. Part of the C region of the H chains forms the crystallizable fragment (Fc) region of the molecule. This region mediates effector mechanisms such as complement activation and is the portion of the Ig molecule bound by Fc receptors on phagocytic cells, mast cells, and basophils. Each Ig molecule also has two antibody-combining sites (except for the IgM molecule, which has 10, and IgA, which may have two or more).


Any clone of B lymphocytes has one antigen specificity determined by the V regions of its L and H chains. However, the clone can change the class of Ig that it makes by changing the association between its V region genes and H chain C region genes (a process known as *isotype switching*). For example, a clone of B lymphocytes genetically preprogrammed to recognize tetanus toxoid initially will make an IgM antibody against tetanus toxoid and later an IgG or other antibody against it.

The five known classes of Igs—IgG, IgM, IgA, IgE, and IgD—are distinguished by the constant portions of their H chains. However, each class has a kappa or a lambda L chain, which gives rise to many subtypes. The almost limitless combinations of L and H chains give Igs their specificity.

- *IgG*, the smallest Ig, appears in all body fluids because of its ability to move across membranes as a single structural unit (a monomer). It constitutes 75% of total serum Igs and is the major antibacterial and antiviral antibody.
- *IgM*, the largest Ig, appears as a pentamer (five monomers joined by a J-chain). Unlike IgG—which is produced mainly in the secondary, or recall, response—IgM dominates in the primary, or initial, immune response. However, like IgG, IgM is involved in classic antibody reactions, including precipitation, agglutination, neutralization, and complement fixation. Because of its size, IgM can't readily cross membrane barriers and is usually present only in the vascular system. IgM constitutes 5% of total serum Igs.
- *IgA* exists in serum primarily as a monomer; in secretory form, IgA exists almost exclusively as a dimer (two monomer molecules joined by a J-chain and a secretory component chain). As a secretory Ig, IgA defends external body surfaces and is present in colostrum, saliva, tears, nasal fluids, and respiratory, gastrointestinal (GI), and genitourinary (GU) secretions. This antibody is considered important in preventing antigenic agents from attaching to epithelial surfaces. IgA makes up 20% of total serum Igs.
- *IgE*, present in trace amounts in serum, is involved in the release of vasoactive amines stored in basophils and tissue mast cell granules. When released, these bioamines cause the allergic effects characteristic of this type of hypersensitivity (erythema, itching, smooth-muscle contraction, secretions, and swelling).
- *IgD*, present as a monomer in serum in minute amounts, is the predominant antibody found on the surface of B lymphocytes and serves mainly as an antigen receptor. It may function in controlling lymphocyte activation or suppression.

T LYMPHOCYTES

T lymphocytes, or T cells, and macrophages are the chief participants in cell-mediated immunity. Immature T lymphocytes are derived from the bone marrow. Upon migration to the thymus, they undergo a maturation process that depends on the HLA genes. Thus, mature T cells can distinguish between self and nonself. T cells acquire certain surface molecules, or markers; these markers combined with the T-cell antigen receptor promote the particular activation of each type of T cell. T-cell activation requires presentation of antigens in the context of a specific HLA gene. Helper T cells require class II HLA genes; cytotoxic T cells require class I HLA genes. T-cell activation also involves IL-1, produced by macrophages, and IL-2, produced by T cells.

Natural killer (NK) cells are a discrete population of large lymphocytes, some of which resemble T lymphocytes. NK cells recognize surface changes on body cells infected with a virus; they then bind to and, in many cases, kill the infected cells.

MACROPHAGES

Important cells of the reticuloendothelial system, macrophages influence both immune and inflammatory responses. Macrophage precursors circulate in the blood. When they collect in various tissues and organs, they differentiate into macrophages with varying characteristics. Unlike B and T lymphocytes, macrophages lack surface receptors for specific antigens; instead, they have receptors for the C region of the H chain (Fc region) of Ig, for fragments of the third component of complement (C3), and for nonimmunologic factors such as carbohydrate molecules.

One of the most important functions of macrophages is the presentation of antigen to T lymphocytes. Macrophages ingest and process antigen, then deposit it on their own surfaces in association with HLA gene. T lymphocytes become activated upon recognizing this complex. Macrophages also function in the inflammatory response by producing IL-1, which generates fever. Additionally, macrophages synthesize complement proteins and other mediators that produce phagocytic, microbicidal, and tumoricidal effects.

CYTOKINES

Cytokines are low–molecular-weight proteins involved in communication between cells. Their purpose is to induce or regulate a variety of immune or inflammatory responses. However, disorders may occur if cytokine production or regulation is impaired. Cytokines are categorized as follows:

- *Colony-stimulating factors* function primarily as hematopoietic growth factors, guiding the division and differentiation of bone marrow stem cells. They also influence the functioning of mature lymphocytes, monocytes, macrophages, and neutrophils.
- *Interferons* act early to limit the spread of viral infections. They also inhibit tumor growth. Mainly, they determine how well tissue cells interact with cytotoxic cells and lymphocytes.
- *Interleukins* are a large group of cytokines. (Those produced primarily by T lymphocytes are called *lymphokines.* Those produced by mononuclear phagocytes are called *monokines*.) They have a variety of effects, but most direct other cells to divide and differentiate.
- *Tumor necrosis factor* is believed to play a major role in mediating inflammation and cytotoxic reactions (along with IL-1, IL-6, and IL-8).
- *Transforming growth factor* demonstrates both inflammatory and anti-inflammatory effects. It's believed to be partially responsible for tissue fibrosis associated with many diseases. It demonstrates immunosuppressive effects on T cells, B cells, and NK cells.

COMPLEMENT SYSTEM

The chief humoral effector of the inflammatory response, the complement system consists of more than 20 serum proteins that are synthesized primarily in the liver. When activated, these proteins interact in a cascadelike process that has profound biologic effects. Complement activation takes place through one of two pathways. In the classical pathway, binding of IgM or IgG and antigen forms antigen–antibody complexes that activate the first complement component, C1. This, in turn, activates C4, C2, and C3. In the alternative pathway, activating surfaces such as bacterial membranes directly amplify spontaneous cleavage of C3. Once C3 is activated in either pathway, activation of the terminal components—C5 to C9—follows.

The major biologic effects of complement activation include phagocyte attraction (chemotaxis) and activation, histamine release, viral neutralization, promotion of phagocytosis

by opsonization, and lysis of cells and bacteria. Other mediators of inflammation derived from the kinin and coagulation pathways interact with the complement system.

POLYMORPHONUCLEAR LEUKOCYTES

Besides macrophages and complement, other key participants in the inflammatory response are the polymorphonuclear leukocytes (also known as *granulocytes*)—neutrophils, eosinophils, and basophils.

Neutrophils, the most numerous of these cells, derive from bone marrow and increase dramatically in number in response to infection and inflammation. Highly mobile cells, neutrophils are attracted to areas of inflammation (chemotaxis); in fact, they're the primary constituent of pus.

Neutrophils have surface receptors for Ig and complement fragments, and they avidly ingest opsonized particles such as bacteria. Ingested organisms are then promptly killed by toxic oxygen metabolites and enzymes such as lysozyme. Unfortunately, neutrophils not only kill invading organisms, but may also damage host tissues.

Also derived from bone marrow, *eosinophils* multiply in both allergic disorders and parasitic infestations. Although their phagocytic function isn't clearly understood, evidence suggests that they participate in host defense against parasites. Their products may also diminish the inflammatory response in allergic disorders.

Two other types of cells that function in allergic disorders are basophils and mast cells. (Mast cells, however, aren't blood cells.) *Basophils* circulate in peripheral blood, whereas *mast cells* accumulate in connective tissue, particularly in the lungs, intestines, and skin. Both types of cells have surface receptors for IgE. When cross-linked by an IgE–antigen complex, they release mediators characteristic of the allergic response.

IMMUNE DISORDERS

Because of their complexity, the processes involved in host defense and immune response may malfunction. When the body's defenses are exaggerated, misdirected, or either absent or depressed, the result may be a hypersensitivity disorder, autoimmunity, or immunodeficiency, respectively. Some forms of immunodeficiency are iatrogenic. (See *Iatrogenic immunodeficiency*.)

Iatrogenic immunodeficiency

Iatrogenic immunodeficiency may be a complicating adverse effect of chemotherapy or other treatments. At times, though, it's the goal of therapy—for example, to suppress immune-mediated tissue damage in autoimmune disorders or to prevent rejection of an organ transplant.

As explained below, iatrogenic immunodeficiency may be induced by immunosuppressive drugs, radiation therapy, or splenectomy.

Immunosuppressive Drug Therapy

Immunosuppressive drugs fall into several categories:

- Cytotoxic drugs. These drugs kill immunocompetent cells while they're replicating. However, most cytotoxic drugs aren't selective and thus interfere with all rapidly

proliferating cells. As a result, they reduce the number of lymphocytes as well as phagocytes. Besides depleting their number, cytotoxic drugs interfere with lymphocyte synthesis and release of immunoglobulins (Igs) and lymphokines.

Cyclophosphamide, a potent and commonly used immunosuppressant, initially depletes the number of B cells, suppressing humoral immunity. However, chronic therapy also depletes T cells, suppressing cell-mediated immunity as well. Cyclophosphamide may be used in systemic lupus erythematosus, Wegener granulomatosis, other systemic vasculitides, and in certain autoimmune disorders. Because it nonselectively destroys rapidly dividing cells, this drug can cause severe bone marrow suppression with neutropenia, anemia, and thrombocytopenia; gonadal suppression with sterility; alopecia; hemorrhagic cystitis; and nausea, vomiting, and stomatitis. It may also increase the risk of lymphoproliferative neoplasms.

Among other cytotoxic drugs used for immunosuppression are azathioprine (commonly used in kidney transplantation) and methotrexate (occasionally used in rheumatoid arthritis [RA] and other autoimmune disorders).

If the patient is receiving cytotoxic drugs, monitor the white blood cell (WBC) count. If it falls too low, the drug dosage may need to be adjusted. Also monitor urine output and watch for signs of cystitis, especially if the patient is taking cyclophosphamide. Ensure adequate fluid intake (2 qt [about 2 L] daily). Give mesna as ordered to help prevent hemorrhagic cystitis. Provide antiemetics to relieve nausea and vomiting as ordered. Give meticulous oral hygiene and report signs of stomatitis.

Teach the patient about the early signs and symptoms of infection. If the WBC count falls too low, granulocyte colony-stimulating factor may be used to boost the count. Make sure the male patient understands the risk of sterility; advise sperm banking if appropriate.

Young women may take hormonal contraceptives to minimize ovarian dysfunction and to prevent pregnancy during administration of these potentially teratogenic drugs.

♦ Corticosteroids. These adrenocortical hormones are used to treat immune-mediated disorders because of their potent anti-inflammatory and immunosuppressive effects. Corticosteroids stabilize the vascular membrane, blocking tissue infiltration by neutrophils and monocytes, thus inhibiting inflammation. They also "kidnap" T cells in the bone marrow, causing lymphopenia. Because these drugs aren't cytotoxic, lymphocyte concentration can return to normal within 24 hours after they're withdrawn. Corticosteroids also appear to inhibit Ig synthesis and to interfere with the binding of Ig to antigen or to cells with crystallizable fragment (Fc) receptors. These drugs have many other effects as well.

The most commonly used oral corticosteroid is prednisone. For long-term therapy, prednisone is best given early in the morning to minimize exogenous suppression of cortisol production and with food or milk to minimize gastric irritation. After the acute phase, it's usually reduced to an alternate-day schedule and then gradually withdrawn to minimize potentially harmful adverse effects. Other corticosteroids used for immunosuppression include hydrocortisone, methylprednisolone, and dexamethasone.

Chronic corticosteroid therapy can cause numerous adverse effects, which are sometimes more harmful than the disease itself. Neurologic adverse effects include euphoria, insomnia, or psychosis; cardiovascular effects include hypertension and edema; and GI effects include gastric irritation, ulcers, and increased appetite with weight gain. Other possible effects are cataracts, hyperglycemia, glucose intolerance, muscle weakness, osteoporosis, delayed

wound healing, and increased susceptibility to infection.

During corticosteroid therapy, monitor the patient's blood pressure, weight, intake and output, and blood glucose. Instruct the patient to eat a well-balanced, low-salt diet or to follow the specially prescribed diet to prevent excessive weight gain. Remember that even though the patient is more susceptible to infection, the patient shows fewer or less dramatic signs of inflammation.

Cyclosporine. Cyclosporine selectively suppresses the proliferation and development of helper T cells, resulting in depressed cell-mediated immunity. This drug is used primarily to prevent rejection of kidney, liver, and heart transplants but is also being investigated for use in several other disorders. Significant toxic effects of cyclosporine primarily involve the liver and kidney, so treatment with this drug requires regular evaluation of renal and hepatic function. Adjusting the dose or the duration of therapy helps minimize certain adverse effects.

♦ Antilymphocyte serum or antithymocyte globulin (ATG). This anti–T-cell antibody reduces T-cell number and function, thus suppressing cell-mediated immunity. It has been used effectively to prevent cell-mediated rejection of tissue grafts or transplants. Usually, ATG is administered immediately before the transplant and continued for some time afterward. Potential adverse effects include anaphylaxis and serum sickness. Occurring 1 to 2 weeks after injection of ATG, serum sickness is characterized by fever, malaise, rash, arthralgias, and, occasionally, glomerulonephritis or vasculitis. It presumably results from the deposition of immune complexes throughout the body.

Radiation Therapy

Because irradiation is cytotoxic to proliferating and intermitotic cells, including most lymphocytes, radiation therapy may induce profound lymphopenia, resulting in immunosuppression. Irradiation of all major lymph node areas—a procedure known as *total nodal irradiation*—is used to treat certain disorders such as Hodgkin lymphoma. Its effectiveness in severe RA, lupus nephritis, and the prevention of kidney transplant rejection is still under investigation.

Splenectomy

Splenectomy may be performed to manage various disorders, including splenic injury or trauma, tumor, Hodgkin lymphoma, hairy cell leukemia, Felty syndrome, Gaucher disease, idiopathic thrombocytopenic purpura, hereditary spherocytosis and hereditary elliptocytosis, thalassemia major, and chronic lymphocytic leukemia.

After splenectomy, the patient has increased susceptibility to infection. These patients should receive the pneumococcal vaccine polyvalent (Pneumovax) for prophylaxis and be warned to avoid exposure to infection and trauma.

HYPERSENSITIVITY DISORDERS

An exaggerated or inappropriate immune response may lead to various hypersensitivity disorders. Such disorders are classified as type I through type IV, although some overlap exists. (See *Classification of hypersensitivity reactions*, pages 386 and 387.)

Classification of hypersensitivity reactions

Type	Cause	Antibody or cell involved	Pathophysiology	Clinical examples
I—Immediate hypersensitivity (anaphylaxis, atopy)	Foreign protein (antigen)	Immunoglobulin (Ig) E	IgE attaches to the surface of the mast cell and specific antigen, and triggers release of intracellular granules from mast cells	Extrinsic asthma, allergic rhinitis, anaphylaxis, reactions to stinging insects, some food and drug reactions
II—Cytotoxic hypersensitivity	Foreign protein (antigen)	IgG or IgM	IgG or IgM reacts with antigen, activates complement, and causes cytolysis or phagocytosis	Transfusion reaction, hemolytic drug reaction, Goodpasture syndrome, hemolytic disease of the neonate
III—Immune complex disease	Foreign protein (antigen) Endogenous antigens	IgG, IgM, IgA	Antigen–antibody complexes precipitate in tissue, activate complement, and cause inflammatory reaction	Rheumatoid arthritis, systemic lupus erythematosus, serum sickness to some drugs or viral hepatitis antigen, glomerulonephritis
IV—Delayed cell-mediated	Foreign protein, cell, or tissue	T lymphocytes	Sensitized T cells react with specific antigen to induce inflammatory process by direct cell action or by activity of lymphokines	Contact dermatitis, graft-versus-host disease, granulomatous diseases

Type I Hypersensitivity (Allergic Disorders)

In individuals with type I hypersensitivity, certain antigens (allergens) activate T cells. These, in turn, induce B-cell production of IgE, which binds to the Fc receptors on the surface of mast cells. When these cells are re-exposed to the same antigen, the antigen binds with the surface IgE, cross-links the Fc receptors, and causes mast cell degranulation with release of various mediators. (Degranulation may also be triggered by complement-derived anaphylatoxins—C3a and C5a—or by certain drugs such as morphine.)

Some of these mediators are preformed, whereas others are newly synthesized upon activation of mast cells. Preformed mediators include heparin, histamine, proteolytic and other enzymes, and chemotactic factors for eosinophils and neutrophils. Newly synthesized mediators include prostaglandins and leukotrienes. Mast cells also produce a variety of cytokines. The effects of these mediators include smooth-muscle contraction, vasodilation, bronchospasm, edema, increased vascular permeability, mucus secretion, and cellular infiltration by eosinophils and neutrophils. Among classic associated signs and symptoms are hypotension, wheezing, swelling, urticaria, and rhinorrhea.

Examples of type I hypersensitivity disorders are anaphylaxis, atopy (an allergic reaction related to genetic predisposition), hay fever (allergic rhinitis), and, in some cases, asthma.

Type II Hypersensitivity (Antibody-Dependent Cytotoxicity)

In type II hypersensitivity, antibody is directed against cell-surface antigens. (Alternatively, though, antibody may be directed against small molecules adsorbed to cells or against cell-surface receptors rather than against cell constituents themselves.) Type II hypersensitivity then causes tissue damage through several mechanisms. Binding of antigen and antibody activates complement, which ultimately disrupts cellular membranes.

Another mechanism is mediated by various phagocytic cells with receptors for Ig (Fc region) and complement fragments. These cells envelop and destroy (phagocytize) opsonized targets, such as red blood cells (RBCs), white blood cells (WBCs), and platelets. Antibody against these cells may be visualized by immunofluorescence. Cytotoxic T lymphocytes and NK cells may

contribute to tissue damage in type II hypersensitivity.

Examples of type II hypersensitivity include transfusion reactions, hemolytic disease of the neonate, autoimmune hemolytic anemia, Goodpasture syndrome, and myasthenia gravis.

Type III Hypersensitivity (Immune Complex Disease)

In type III hypersensitivity, excessive circulating antigen–antibody complexes (immune complexes) result in the deposition of these complexes in tissue—most commonly in the kidneys, joints, skin, and blood vessels. (Normally, immune complexes are effectively cleared by the reticuloendothelial system.) These deposited immune complexes activate the complement cascade, resulting in local inflammation. They also trigger platelet release of vasoactive amines that increase vascular permeability, augmenting deposition of immune complexes in vessel walls.

Type III hypersensitivity may be associated with infections, such as hepatitis B and bacterial endocarditis; certain cancers in which a serum sickness-like syndrome may occur; and autoimmune disorders such as lupus erythematosus. This hypersensitivity reaction may also follow drug or serum therapy.

Type Iv Hypersensitivity (Delayed Hypersensitivity)

In type IV hypersensitivity, also known as *cell-mediated hypersensitivity*, antigen is processed by macrophages and presented to T cells. The sensitized T cells then release lymphokines, which recruit and activate other lymphocytes, monocytes, macrophages, and polymorphonuclear leukocytes. The coagulation, kinin, and complement pathways also contribute to tissue damage in this type of reaction.

Examples of type IV hypersensitivity include tuberculin reactions, contact hypersensitivity, and sarcoidosis.

AUTOIMMUNE DISORDERS

Autoimmunity is characterized by a misdirected immune response in which the body's defenses become self-destructive. Autoimmune diseases aren't transmitted from one person to another, and the causes of autoimmunity aren't clearly understood. However, the process of autoimmunity is related to genes or a combination of genes, hormones, and environmental stimuli. Individuals with specific genes or gene combinations may be at a higher risk for developing autoimmune disorders, which may be triggered by outside stimuli, such as sun exposure, infection, drugs, or pregnancy.

Recognition of self through the MHC is of primary importance in an immune response. However, how an immune response against self is prevented and which cells are primarily responsible isn't well understood.

Many autoimmune disorders are characterized by B-cell hyperactivity, marked by proliferation of B cells and autoantibodies and by hypergammaglobulinemia. B-cell hyperactivity is probably related to T-cell abnormalities, but the molecular basis of autoimmunity is poorly understood. Hormonal and genetic factors strongly influence the incidence of autoimmune disorders; for example, lupus erythematosus predominantly affects females of childbearing age, and certain HLA haplotypes are associated with an increased risk of specific autoimmune disorders.

Autoimmune diseases may not follow a clear pattern of symptoms; therefore, a definitive diagnosis may be delayed. Diagnosis may rely on the patient's medical history; family history; physical examination, including signs and symptoms; and laboratory tests. Autoantibodies are

usually found with such disorders as rheumatoid arthritis (RA) or systemic lupus erythematosus (SLE), but confusion may occur because individuals with these disorders may have false-negative results on laboratory tests.

Treatment for autoimmune disorders focuses on relieving symptoms, preserving organ function, and providing medication that can target the immune system, such as cyclophosphamide and cyclosporine. Autoimmune and immunologic disorders are being researched. Websites for the National Institutes of Health (www.nih.gov) and other organizations offer substantial healthcare information relevant to both the patient and the physician.

IMMUNODEFICIENCY

In immunodeficiency, the immune response is absent or depressed, resulting in increased susceptibility to infection. This disorder may be primary or secondary. Primary immunodeficiency reflects a defect involving T cells, B cells, or lymphoid tissues. The National Primary Immunodeficiency Resource Center is a source of information on primary immunodeficiency syndromes.

Secondary immunodeficiency results from an underlying disease or factor that depresses or blocks the immune response. The most common forms of immunodeficiency are caused by viral infection (as in acquired immunodeficiency syndrome [AIDS]).

Allergy

ASTHMA

Asthma is a lung disease characterized by reversible obstruction or narrowing of the airways.

Causes and Incidence

Asthma that results from sensitivity to specific external allergens is known as *extrinsic*. In cases in which the allergen isn't obvious, asthma is referred to as *intrinsic*. Allergens that cause extrinsic asthma include pollen, animal dander, house dust or mold, kapok or feather pillows, food additives containing sulfites, and any other sensitizing substance. Extrinsic (atopic) asthma usually begins in childhood and is accompanied by other manifestations of atopy (type I, IgE-mediated allergy), such as eczema and allergic rhinitis. In intrinsic (nonatopic) asthma, no extrinsic allergen can be identified. Most cases are preceded by a severe respiratory infection. Irritants, emotional stress, fatigue, exposure to noxious fumes as well as changes in endocrine function, temperature, and humidity may aggravate intrinsic asthma attacks. In many asthmatics, intrinsic and extrinsic asthma coexist.

Several drugs and chemicals may provoke an asthma attack without using the IgE pathway. Apparently, they trigger release of mast cell mediators by way of prostaglandin inhibition. Examples of these substances include aspirin, various nonsteroidal anti-inflammatory drugs (NSAIDs such as indomethacin and mefenamic acid), and tartrazine, a yellow food dye. Exercise may also provoke an asthma attack. In exercise-induced asthma, bronchospasm may follow heat and moisture loss in the upper airways.

The allergic response has two phases. When the patient inhales an allergenic substance, sensitized IgE antibodies trigger mast cell degranulation in the lung interstitium, releasing histamine, cytokines, prostaglandins, thromboxanes, leukotrienes, and eosinophil chemotactic factors. Histamine then attaches to receptor sites in the larger bronchi, causing irritation,

inflammation, and edema. In the late phase, inflammatory cells flow in. The influx of eosinophils provides additional inflammatory mediators and contributes to local injury.

Although this common condition can strike at any age, half of all cases first occur in children younger than age 10; in this age group, asthma affects twice as many males as females. In the United States, 14 million adults and 6 million children have asthma. Emergency department visits, hospitalizations, and mortality from asthma have been increasing for more than 20 years, especially among children and blacks.

Pathophysiology

Asthma is characterized by reversible obstruction or narrowing of the airways, which are typically inflamed and hyperresponsive to a variety of stimuli. It may resolve spontaneously or with treatment. Its symptoms range from mild wheezing and dyspnea to life-threatening respiratory failure. (See *Determining asthma's severity*, page 389.) Symptoms of bronchial airway obstruction may persist between acute episodes.

Determining asthma's severity

Asthma is classified by severity using these features:
- frequency, severity, and duration of symptoms
- degree of airflow obstruction (spirometry measure) or peak expiratory flow (PEF)
- frequency of nighttime symptoms and the degree to which the asthma interferes with daily activities

Severity can change over time, and even milder cases can become severe in an uncontrolled attack. Long-term therapy depends on whether the patient's asthma is classified as mild intermittent, mild persistent, moderate persistent, or severe persistent. For all patients, quick relief can be obtained by using a short-acting bronchodilator (2 to 4 puffs of short-acting inhaled beta$_2$-adrenergic agonists as needed for symptoms). However, the use of a short-acting bronchodilator more than twice a week in patients with intermittent asthma or daily or increasing use in patients with persistent asthma may indicate the need to initiate or increase long-term control therapy.

Mild Intermittent Asthma

The signs and symptoms of mild intermittent asthma include:
- daytime symptoms no more than twice a week
- nighttime symptoms no more than twice a month
- lung function testing (either PEF or forced expiratory volume in 1 second) is 80% of predicted value or higher
- PEF varies no more than 20%

Severe exacerbations, separated by long, symptomless periods of normal lung function, indicate mild intermittent asthma. A course of systemic corticosteroids is recommended for these exacerbations; otherwise, daily medication isn't required.

Mild Persistent Asthma

The signs and symptoms of mild persistent asthma include:
- daytime symptoms 3 to 6 days a week

- nighttime symptoms three to four times a month
- lung function testing 80% of predicted value or higher
- PEF between 20% and 30%

The preferred treatment for mild, persistent asthma is low-dose inhaled corticosteroids, but alternative treatments include cromolyn, a leukotriene modifier, nedocromil, or sustained-release theophylline.

Moderate Persistent Asthma

The signs and symptoms of moderate persistent asthma include:
- daily daytime symptoms
- at least weekly nighttime symptoms
- lung function testing 60% to 80% of predicted value
- PEF varying more than 30%

The preferred treatment for moderate persistent asthma is low- or medium-dose inhaled corticosteroids combined with a long-acting inhaled $beta_2$-adrenergic agonist. Alternative treatments include increasing inhaled corticosteroids within the medium-dose range or low- or medium-dose inhaled corticosteroids with either a leukotriene modifier or theophylline.

For recurring exacerbations, the preferred treatment is to increase inhaled corticosteroids within the medium-dose range and add a long-acting inhaled $beta_2$-adrenergic agonist. The alternative treatment is to increase inhaled corticosteroids within the medium-dose range and add either a leukotriene modifier or theophylline.

Severe Persistent Asthma

The signs and symptoms of severe persistent asthma include:
- continual daytime symptoms
- frequent nighttime symptoms
- lung function testing 60% of predicted value or lower
- PEF varying more than 30%

The preferred treatment for severe, persistent asthma includes high-dose inhaled corticosteroids combined with long-acting inhaled $beta_2$-adrenergic agonists. Long-term administration of corticosteroid tablets or syrup (2 mg/kg/day, not to exceed 60 mg/day) may be used to reduce the need for systemic corticosteroid therapy.

Complications

- Status asthmaticus
- Respiratory failure

Signs and Symptoms

An asthma attack may begin dramatically, with simultaneous onset of many severe symptoms, or insidiously, with gradually increasing respiratory distress. It typically includes progressively worsening shortness of breath, cough, wheezing, and chest tightness or some combination of these signs or symptoms.

During an acute attack, the cough sounds tight and dry. As the attack subsides, tenacious mucoid sputum is produced (except in young children, who don't expectorate). Characteristic wheezing may be accompanied by coarse rhonchi, but fine crackles aren't heard unless

associated with a related complication. Between acute attacks, breath sounds may be normal.

The intensity of breath sounds in symptomatic asthma is typically reduced. A prolonged phase of forced expiration is typical of airflow obstruction. Evidence of lung hyperinflation (use of accessory muscles, for example) is particularly common in children. Acute attacks may be accompanied by tachycardia, tachypnea, and diaphoresis. In severe attacks, the patient may be unable to speak more than a few words without pausing for breath. Cyanosis, confusion, and lethargy indicate the onset of respiratory failure.

Diagnosis

Laboratory studies in patients with asthma commonly show these abnormalities:

- Pulmonary function studies reveal signs of airway obstruction (decreased peak expiratory flow rates and forced expiratory volume in 1 second), low-normal or decreased vital capacity, and increased total lung and residual capacity. However, pulmonary function studies may be normal between attacks.
- Pulse oximetry may reveal decreased arterial oxygen saturation (Sao_2).
- Arterial blood gas (ABG) analysis provides the best indications of an attack's severity. In acutely severe asthma, the partial pressure of arterial oxygen is less than 60 mm Hg, the partial pressure of arterial carbon dioxide ($Paco_2$) is 40 mm Hg or more, and pH is usually decreased.
- Complete blood count (CBC) with differential reveals increased eosinophil count.
- Chest X-rays may show hyperinflation with areas of focal atelectasis.

Before initiating tests for asthma, rule out other causes of airway obstruction and wheezing. In children, such causes include cystic fibrosis, tumors of the bronchi or mediastinum, and acute viral bronchitis; in adults, other causes include obstructive pulmonary disease, heart failure, and epiglottitis.

Treatment

Treatment of acute asthma aims to decrease bronchoconstriction, reduce bronchial airway edema, and increase pulmonary ventilation. After an acute episode, treatment focuses on avoiding or removing precipitating factors, such as environmental allergens or irritants.

If asthma is known to be caused by a particular antigen, it may be treated by desensitizing the patient through a series of injections of limited amounts of the antigen. The aim is to curb the patient's immune response to the antigen.

If asthma results from an infection, antibiotics are prescribed. Drug therapy is most effective when begun soon after the onset of signs and symptoms. For relief of symptoms in adults and children older than age 5, short-acting inhaled beta$_2$-adrenergic agonists for bronchodilation may be used, and a course of systemic corticosteroids may be needed. Other control drugs that may be used are leukotriene inhibitors, theophylline, zileuton, omalizumab, or cromolyn sodium. The goal of therapy is asthma control with minimal or no adverse effects from medication.

Acute attacks that don't respond to self-treatment may require hospital care, beta$_2$-adrenergic agonists by inhalation or subcutaneous injection (in three doses over 60 to 90 minutes), and, possibly, oxygen for hypoxemia. If the patient responds poorly, systemic corticosteroids and, possibly, subcutaneous epinephrine may help. Beta$_2$-adrenergic agonist inhalation continues hourly. I.V. theophylline, although rarely used, may be added to the regimen and I.V. fluid therapy is started. Patients who don't respond to this treatment, whose airways remain

obstructed, and who have increasing respiratory difficulty are at risk for status asthmaticus and may require mechanical ventilation.

Treatment of status asthmaticus consists of aggressive drug therapy with a beta$_2$-adrenergic agonist by nebulizer every 30 to 60 minutes, possibly supplemented with subcutaneous epinephrine, I.V. corticosteroids, I.V. theophylline, oxygen administration, I.V. fluid therapy, and intubation and mechanical ventilation for hypercapnic respiratory failure (Paco$_2$ of 40 mm Hg or more). (See *How status asthmaticus progresses*, pages 390 and 391.)

PATHOPHYSIOLOGY
HOW STATUS ASTHMATICUS PROGRESSES

A potentially fatal complication, status asthmaticus arises when impaired gas exchange and heightened airway resistance increase the work of breathing. This flow chart shows the stages of status asthmaticus.

| Obstructed airways hamper gas exchange and increase airway resistance, leading to labored breathing. | The patient hyperventilates, lowering partial pressure of arterial carbon dioxide (PaCo$_2$). | Respiratory alkalosis and hypoxemia develop. | Hypoxia and labored breathing tire the patient. His respiratory rate drops to normal. | PaCo$_2$ rises to a higher-than-baseline level (an asthmatic patient's PaCo$_2$ usually is low). | The patient hypoventilates from exhaustion. | Respiratory acidosis begins as partial pressure of oxygen in arterial blood drops and PaCo$_2$ continues to rise. | Without treatment, the patient experiences acute respiratory failure. |

Special Considerations

During an acute attack, proceed as follows:

- First, assess the severity of asthma.
- Administer the prescribed treatments and assess the patient's response.
- Place the patient in high Fowler's position. Encourage pursed-lip and diaphragmatic breathing. Help the patient to relax.
- Administer prescribed humidified oxygen by nasal cannula at 2 L/minute to ease breathing and to increase Sao$_2$. Later, adjust oxygen according to the patient's vital signs and ABG levels.
- Anticipate intubation and mechanical ventilation if the patient fails to maintain adequate oxygenation.
- Monitor serum theophylline levels to ensure they're in the therapeutic range. Observe your patient for signs and symptoms of theophylline toxicity (vomiting, diarrhea, and headache), as well as for signs of subtherapeutic dosage (respiratory distress and increased wheezing).
- Observe the frequency and severity of your patient's cough, and note whether it's productive. Then auscultate the lungs, noting adventitious or absent breath sounds. If the cough isn't productive and rhonchi are present, teach the patient effective coughing techniques. If the patient can tolerate postural drainage and chest percussion, perform these procedures to clear secretions. Suction an intubated patient as needed.
- Treat dehydration with I.V. fluids until the patient can tolerate oral fluids, which will help loosen secretions.
- If conservative treatment fails to improve the airway obstruction, anticipate bronchoscopy or bronchial lavage when a lobe or larger area collapses.

ALERT *Monitor the patient's vital signs. Keep in mind that developing or increasing tachypnea may indicate worsening asthma or drug toxicity. Blood pressure readings may reveal pulsus paradoxus, indicating severe asthma. Hypertension may indicate asthma-related hypoxemia.*

During long-term care, proceed as follows:

- Monitor the patient's respiratory status to detect baseline changes, to assess response to treatment, and to prevent or detect complications.
- Auscultate the lungs frequently, noting the degree of wheezing and quality of air movement.
- Review ABG levels, pulmonary function test results, and Sao$_2$ readings.
- If the patient is taking systemic corticosteroids, observe for complications, such as elevated blood glucose levels and friable skin and bruising.
- Cushingoid effects resulting from long-term use of corticosteroids may be minimized by alternate-day dosage or use of prescribed inhaled corticosteroids.
- If the patient is taking corticosteroids by inhaler, watch for signs of candidal infection in the mouth and pharynx. Using an extender device and rinsing the mouth afterward may prevent this.
- Observe the patient's anxiety level. Keep in mind that measures that reduce hypoxemia and breathlessness should help relieve anxiety.
- Keep the room temperature comfortable and use an air conditioner or a fan in hot, humid weather.
- Control exercise-induced asthma by instructing the patient to use a bronchodilator or cromolyn 30 minutes before exercise. Also instruct the patient to use pursed-lip breathing while exercising.

All patients should know the following:

- Teach the patient and family to avoid known allergens and irritants.
- Describe to the patient prescribed drugs, including their names, dosages, actions, adverse effects, and special instructions.
- Teach the patient how to use a metered-dose inhaler. If the patient has difficulty using an inhaler, the patient may need an extender device to optimize drug delivery and lower the risk of candidal infection with orally inhaled corticosteroids.
- If the patient has moderate to severe asthma, explain how to use a peak flow meter to measure the degree of airway obstruction. Tell the patient to keep a record of peak flow readings and to bring it to medical appointments. Explain the importance of calling the physician at once if the peak flow drops suddenly (may signal severe respiratory problems).
- Tell the patient to notify the physician if developing a fever above 100° F (37.8° C), chest pain, shortness of breath without coughing or exercising, or uncontrollable coughing. An uncontrollable asthma attack requires immediate attention.
- Teach the patient diaphragmatic and pursed-lip breathing as well as effective coughing techniques.
- Urge the patient to drink at least 3 qt (3 L) of fluids daily to help loosen secretions and maintain hydration.

ALLERGIC RHINITIS

Allergic rhinitis is a reaction to airborne (inhaled) allergens. Depending on the allergen, the

resulting rhinitis and conjunctivitis may occur seasonally (hay fever) or year-round (perennial allergic rhinitis).

Causes and Incidence

In most cases, it's induced by windborne pollens: in the spring by tree pollens (oak, elm, maple, alder, birch, and cottonwood), in the summer by grass pollens (sheep sorrel and English plantain), and in the fall by weed pollens (ragweed). Occasionally, hay fever is induced by allergy to fungal spores. In addition to individual sensitivity and geographic differences in plant population, the amount of pollen in the air can be a factor in determining whether symptoms develop. Hot, dry, windy days have more pollen than cool, damp, rainy days.

The major perennial allergens and irritants include dust mites, feather pillows, mold, cigarette smoke, upholstery, and animal dander. Seasonal pollen allergy may exacerbate signs and symptoms of perennial rhinitis.

Allergic rhinitis is the most common atopic allergic reaction, affecting more than 20 million Americans. It's most prevalent in young children and adolescents but can occur in all age groups.

Pathophysiology

Hay fever reflects an IgE-mediated type I hypersensitivity response to an environmental antigen (allergen) in a genetically susceptible individual.

In perennial allergic rhinitis, inhaled allergens provoke antigen responses that produce recurring symptoms year-round. The allergens trigger antibody production and histamine release, producing itching, swelling, and mucus.

Complications

- Secondary sinus and middle ear infections
- Nasal polyps
- Nasal obstruction

Signs and Symptoms

In seasonal allergic rhinitis, the key signs and symptoms are paroxysmal sneezing, profuse watery rhinorrhea, nasal obstruction or congestion, and pruritus of the nose and eyes. It's usually accompanied by pale, cyanotic, edematous nasal mucosa; red and edematous eyelids and conjunctivae; excessive lacrimation; and headache or sinus pain. Some patients also complain of itching in the throat and malaise.

In perennial allergic rhinitis, conjunctivitis and other extranasal effects are rare, but chronic nasal obstruction is common. In many cases, this obstruction extends to eustachian tube obstruction, particularly in children.

In both types of allergic rhinitis, dark circles may appear under the patient's eyes ("allergic shiners") because of venous congestion in the maxillary sinuses. The severity of signs and symptoms may vary from season to season and from year to year.

Diagnosis

Microscopic examination of sputum and nasal secretions reveals large numbers of eosinophils. Blood chemistry shows normal or elevated IgE. A definitive diagnosis is based on the patient's personal and family history of allergies as well as physical findings during a symptomatic phase. Skin testing paired with tested responses to environmental stimuli can pinpoint the responsible

allergens given the patient's history. In patients who can't tolerate skin testing, the radioallergosorbent test may be helpful in determining specific allergen sensitivity.

To distinguish between allergic rhinitis and other nasal mucosa disorders, remember these differences:

- In chronic vasomotor rhinitis, eye symptoms are absent, rhinorrhea is mucoid, and seasonal variation is absent.
- In infectious rhinitis (the common cold), the nasal mucosa is beet red; nasal secretions contain polymorphonuclear, not eosinophilic, exudate; and signs and symptoms include fever and sore throat. This condition isn't a recurrent seasonal phenomenon.
- In rhinitis medicamentosa, which results from excessive use of nasal sprays or drops, nasal drainage and mucosal redness and swelling disappear when such medication is withheld.

PEDIATRIC TIP *In children, differential diagnosis involves ruling out a nasal foreign body, such as a bean or a button.*

Treatment

Treatment aims to control symptoms by eliminating the environmental antigen, if possible, and providing drug therapy and immunotherapy.

Antihistamines block histamine effects but commonly produce anticholinergic adverse effects (sedation, dry mouth, nausea, dizziness, blurred vision, and nervousness). Antihistamines, such as cetirizine, loratadine, and fexofenadine, produce fewer adverse effects and are less likely to cause sedation.

Inhaled intranasal steroids produce local anti-inflammatory effects with minimal systemic adverse effects. The most commonly used intranasal steroids are beclomethasone, flunisolide, fluticasone, mometasone, and triamcinolone. These drugs are effective when symptoms aren't relieved by antihistamines alone.

Advise the patient to use intranasal steroids regularly as prescribed for optimal effectiveness. Oral or parenteral steroids may be used for 6 to 8 weeks when conventional therapy isn't working. Cromolyn may be helpful in treating hay fever, but this drug may take up to 4 weeks to produce a satisfactory effect and must be taken regularly during allergy season. Eye drop versions of cromolyn and antihistamines are available for itchy, bloodshot eyes.

Long-term management includes immunotherapy, or desensitization with injections of extracted allergens, administered before or during allergy season or perennially. Seasonal allergies require particularly close dosage regulation.

Special Considerations

- Before desensitization injections, assess the patient's symptom status. Afterward, watch for adverse reactions, including anaphylaxis and severe localized erythema.

ALERT *Keep epinephrine and emergency resuscitation equipment available, and observe the patient for 30 minutes after the injection. Instruct the patient to call the physician if a delayed reaction should occur.*

The following protocol is recommended for allergic rhinitis:

- Monitor the patient's compliance with prescribed drug treatment regimens. Also, carefully

note any changes in the control of symptoms or any signs of drug misuse.

◆ To reduce environmental exposure to airborne allergens, suggest that the patient sleep with the windows closed, avoid the countryside during pollination seasons, use air-conditioning to filter allergens and minimize moisture and dust, and eliminate dust-collecting items, such as wool blankets, deep-pile carpets, and heavy drapes, from the home.

◆ In severe and resistant cases, suggest that the patient consider drastic changes in lifestyle such as relocation to a pollen-free area either seasonally or year-round.

◆ Be aware that some patients may develop chronic complications, including sinusitis and nasal polyps.

ATOPIC DERMATITIS

Atopic dermatitis is a chronic type I immediate hypersensitivity skin disorder that's characterized by superficial skin inflammation and intense itching. Although this disorder may appear at any age, it typically begins during infancy or early childhood. It may then subside spontaneously, followed by exacerbations in late childhood, adolescence, or early adulthood. Atopic dermatitis affects 2.5% of the population.

Causes and Incidence

The cause of atopic dermatitis is still unknown.

Exacerbating factors of atopic dermatitis include irritants, infections (commonly caused by *Staphylococcus aureus*), and some allergens. Although no reliable link exists between atopic dermatitis and exposure to inhalant allergens (such as house dust and animal dander), exposure to food allergens (such as soybeans, fish, or nuts) may coincide with flare-ups of atopic dermatitis.

Pathophysiology

Several theories attempt to explain its pathogenesis. One theory suggests an underlying metabolically or biochemically induced skin disorder that's genetically linked to elevated serum IgE levels. Another theory suggests defective T-cell function.

Complications

◆ Scarring
◆ Secondary infection

Signs and Symptoms

Scratching the skin causes vasoconstriction and intensifies pruritus, resulting in erythematous, weeping lesions. Eventually, the lesions become scaly and lichenified. Usually, they're located in areas of flexion and extension, such as the neck, antecubital fossa, popliteal folds, and behind the ears. Patients with atopic dermatitis are prone to unusually severe viral infections, bacterial and fungal skin infections, ocular complications, and allergic contact dermatitis.

Diagnosis

Typically, the patient has a history of atopy, such as asthma, hay fever, or urticaria; the family may have a similar history. Laboratory tests reveal eosinophilia and elevated serum IgE levels. A skin biopsy may be performed, but it isn't always required to make the diagnosis.

Treatment

Measures to ease this chronic disorder include meticulous skin care, environmental control of offending allergens, and drug therapy. Because dry skin aggravates itching, frequent application of nonirritating topical lubricants is important, especially after bathing or showering. Minimizing exposure to allergens and irritants, such as wools and harsh detergents, also helps control symptoms.

Drug therapy involves corticosteroids and antipruritics. Atopic dermatitis responds well to topical corticosteroids, which should be applied immediately after bathing for optimal penetration. Oral antihistamines are commonly used to help control itching. A bedtime dose may reduce involuntary scratching during sleep. If secondary infection develops, antibiotics are necessary. Topical immunomodulatory agents are a steroid-free treatment for itching and rash and have demonstrated an 80% success rate in studies.

Special Considerations

- Monitor the patient's compliance with drug therapy.
- Teach the patient when and how to apply topical corticosteroids.
- Emphasize the importance of regular personal hygiene using only water with little soap.
- Be alert for signs and symptoms of secondary infection; teach the patient how to recognize them as well.
- If the patient's diet is modified to exclude food allergens, monitor nutritional status.
- Offer support to help the patient and family cope with this chronic disorder.
- Discourage use of laundry additives.
- Dissuade the patient from scratching during urticaria to help prevent an infection.

LATEX ALLERGY

Latex is a substance found in an increasing number of products both on the job and in the home environment. Latex allergy is a hypersensitivity reaction to products that contain natural latex, which is derived from the sap of a rubber tree, not synthetic latex.

Causes and Incidence

About 1% of the population has a latex allergy. Anyone who is in frequent contact with latex-containing products is at risk for developing a latex allergy. (See *Products that contain latex*, page 395.) The more frequent the exposure, the higher the risk. The populations at highest risk are medical and dental professionals, workers in latex companies, and patients with spina bifida.

Products that contain latex

Many medical and everyday items contain latex, which can be a threat to the patient with latex allergy. The most common items that contain latex are listed below.

Medical Products
- Adhesive bandages
- Airways, nasogastric tubes
- Blood pressure cuff, tubing, and bladder
- Catheters

- Catheter leg straps
- Dental devices
- Elastic bandages
- Electrode pads
- Fluid-circulating hypothermia blankets
- Handheld resuscitation bag
- Hemodialysis equipment
- I.V. catheters
- Latex or rubber gloves
- Medication vials
- Pads for crutches
- Protective sheets
- Reservoir breathing bags
- Rubber airway and endotracheal tubes
- Stethoscopes
- Tape
- Tourniquets

Nonmedical Products

- Adhesive tape
- Balloons (excluding Mylar)
- Cervical diaphragms
- Condoms
- Dishwashing gloves
- Disposable diapers
- Elastic stockings
- Glue
- Latex paint
- Nipples and pacifiers
- Racquet handles
- Rubber bands
- Tires

Pathophysiology

There are two types of latex allergy. A type I hypersensitivity reaction involves mast cells releasing histamine and other secretory products. This leads to vasodilation and bronchoconstriction. A type IV delayed hypersensitivity reaction occurs as a reaction to chemicals involved in processing rather than to the latex itself. Sensitized T lymphocytes are triggered, which cause other lymphocytes and mononuclear cells to proliferate, resulting in tissue inflammation.

Other individuals at risk include:

- patients with a history of asthma or other allergies, especially to bananas, avocados, tropical fruits, or chestnuts
- patients with a history of multiple intra-abdominal or GU surgeries
- patients who require frequent intermittent urinary catheterization

Complications

- Respiratory obstruction
- Systemic vascular collapse

Signs and Symptoms

Type I symptoms can include rhinitis, conjunctivitis, asthma, and anaphylaxis. Type IV symptoms may include contact dermatitis with vesicular skin lesions, pruritus, edema, and erythema. Although type IV hypersensitivity is not life-threatening, those who are sensitized to latex are at increased risk for development of type I reactions.

Diagnosis

A patient who describes even the mildest symptoms during a history and physical assessment should be suspected of having a latex allergy. The patient may describe dermatitis or mild respiratory distress when using latex gloves, inflating a balloon, or coming in contact with other latex products.

CONFIRMING DIAGNOSIS *A blood test for latex sensitivity can confirm the diagnosis. This test, which measures specific IgE antibodies against latex, should be used only when latex allergy is suspected; it isn't recommended as a screening tool.*

Treatment

The best treatment of latex allergy is prevention; the more a latex-sensitive person is exposed to latex, the worse the symptoms will become. To avoid exposure, advise the patient to substitute products made of silicone and vinyl for those made of latex.

When a latex allergy is suspected or known, the patient may receive medications before and after surgery or other invasive procedures. Pre- and post-procedure medications may include corticosteroids, antihistamines, and H_2-receptor antagonists.

There's no known treatment for an allergic reaction to latex. Care is supportive in nature. The patient's airway, breathing, and circulation must be monitored. An artificial airway, oxygen therapy, cardiopulmonary resuscitation, and fluid management may be necessary. During an acute reaction, epinephrine, diphenhydramine, and hydrocortisone are commonly administered by I.V. infusion.

Special Considerations

- Urge the patient to wear an identification tag mentioning latex allergy.
- Teach the patient and family members how to use an epinephrine autoinjector.
- Teach the patient to be aware of all latex-containing products and to use vinyl or silicone products instead. Advise the patient that Mylar balloons don't contain latex.

PREVENTION

- *Make sure that items that aren't available in a latex-free form, such as stethoscopes and blood pressure cuffs, are wrapped in cloth before they come in contact with a hypersensitive patient's skin.*
- *Place the patient in a private room or with another patient who requires a latex-free*

environment.
- *When adding medication to an I.V. bag, inject the drug through the spike port, not the rubber latex port.*

ANAPHYLAXIS

Anaphylaxis is a dramatic, acute atopic reaction marked by the sudden onset of rapidly progressive urticaria and respiratory distress. A severe reaction may precipitate vascular collapse, leading to systemic shock, and, sometimes, death.

Causes and Incidence

The source of anaphylactic reactions is ingestion of, or other systemic exposure to, sensitizing drugs or other substances. Such substances may include animal serums, vaccines, allergen extracts, enzymes (L-asparaginase), hormones, penicillin and other antibiotics, sulfonamides, local anesthetics, salicylates, polysaccharides, diagnostic chemicals (sulfobromophthalein, sodium dehydrocholate, and radiographic contrast media), foods (especially legumes, nuts, berries, seafood, and egg albumin) and sulfite-containing food additives, insect venom (honeybees, wasps, hornets, yellow jackets, fire ants, mosquitoes, and certain spiders), and, rarely, ruptured hydatid cyst.

A common cause of anaphylaxis is penicillin, which induces anaphylaxis in 1 to 4 of every 10,000 patients treated with it. Penicillin is most likely to induce anaphylaxis after parenteral administration or prolonged therapy and in atopic patients with an allergy to other drugs or foods. (See *Preventing allergic response to penicillin*.)

PREVENTION
PREVENTING ALLERGIC RESPONSE TO PENICILLIN

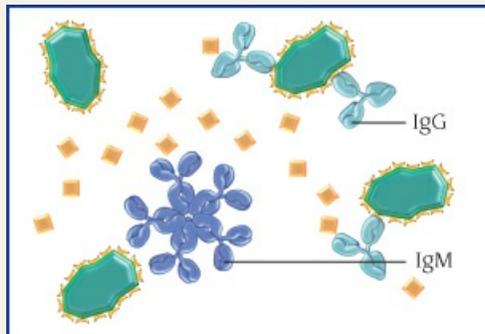
When administering penicillin or its derivatives, such as ampicillin or carbenicillin, follow these recommendations from the World Health Organization to prevent an allergic response:
- Have an emergency kit available to treat allergic reactions.
- Take a detailed patient history, including penicillin allergy and other allergies. In an infant younger than 3 months, check for penicillin allergy in the mother.
- Never give penicillin to a patient who has had an allergic reaction to it.
- Before giving penicillin to a patient with suspected penicillin allergy, refer the patient for skin and immunologic tests to confirm it.
- Always tell a patient he's going to receive penicillin before taking the first dose.
- Observe the patient carefully for adverse effects for at least half an hour after penicillin administration.
- Be aware that penicillin derivatives also may elicit an allergic reaction.

At the same time, two other chemical mediators, bradykinin and leukotrienes, induce vascular collapse by stimulating contraction of certain groups of smooth muscles and by increasing vascular permeability. In turn, increased vascular permeability leads to decreased peripheral resistance and plasma leakage from the circulation to extravascular tissues, which lowers blood volume, causing hypotension, hypovolemic shock, and cardiac dysfunction. (See *Understanding*

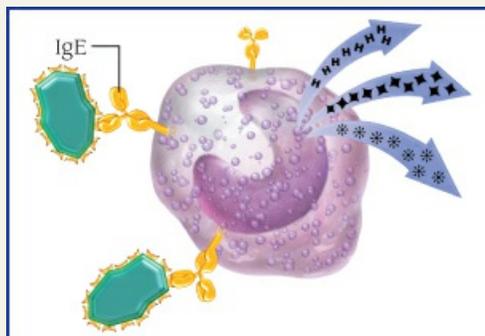
PATHOPHYSIOLOGY
UNDERSTANDING ANAPHYLAXIS

The illustrations below teach the development of anaphylaxis.

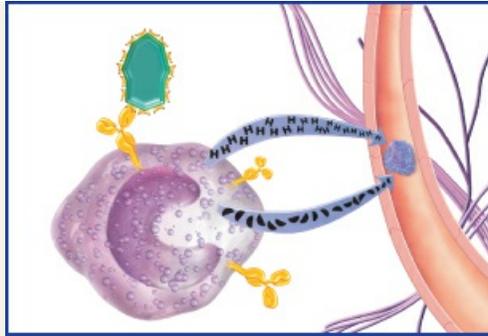
Response To Antigen

Immunoglobulins (Ig) M and G recognize and bind the antigen.


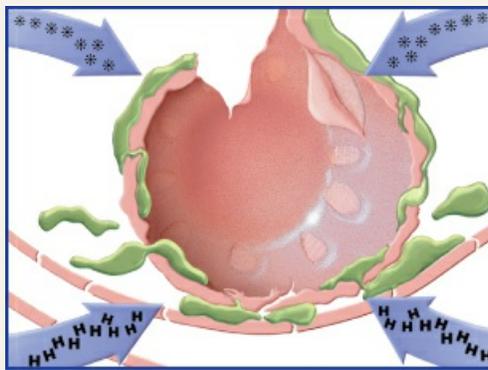
Release of Chemical Mediators

Activated IgE on basophils promotes the release of mediators: histamine, serotonin, and leukotrienes.


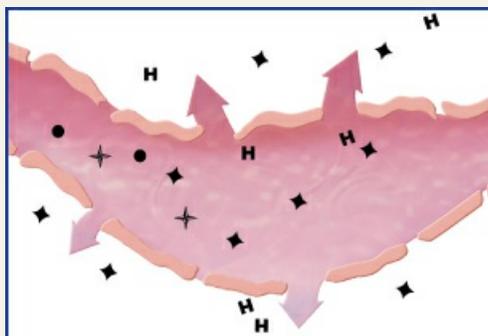
Intensified Response

Mast cells release more histamine and eosinophil chemotactic factor of anaphylaxis.


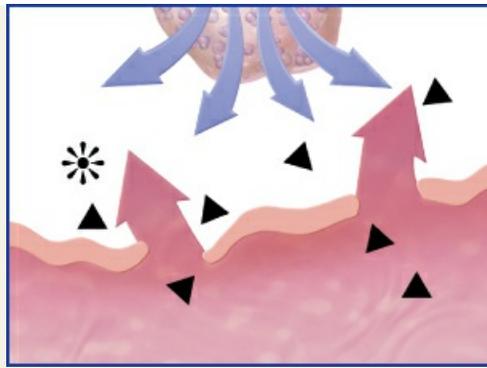
Respiratory Distress

In the lungs, histamine causes endothelial cell destruction and allows fluid to leak into alveoli.


Deterioration

Meanwhile, mediators increase vascular permeability, causing fluid to leak from the vessels.


Failure of Compensatory Mechanisms

Endothelial cell damage causes basophils and mast cells to release heparin and mediator-neutralizing substances. However, anaphylaxis is now irreversible.


KEY

Complement cascade ▪   Prostaglandins ✚
Histamine **H**   ECF-A ◗
Serotonin ◆   Bradykinin ●
Leukotrienes ✳   Heparin ▲

Pathophysiology

An anaphylactic reaction requires previous sensitization or exposure to the specific antigen, resulting in the production of specific IgE antibodies by plasma cells. This antibody production takes place in the lymph nodes and is enhanced by helper T cells. IgE antibodies then bind to membrane receptors on mast cells (found throughout connective tissue) and basophils.

On re-exposure, the antigen binds to adjacent IgE antibodies or cross-linked IgE receptors, activating a series of cellular reactions that trigger degranulation—the release of powerful chemical mediators (such as histamine and eosinophil chemotactic factor of anaphylaxis) from mast cell stores. IgG or IgM enters into the reaction and activates the release of complement fractions.

Complications

- Respiratory obstruction
- Systemic vascular collapse
- Death

Signs and Symptoms

An anaphylactic reaction produces sudden physical distress within seconds or minutes (although a delayed or persistent reaction may occur for up to 24 hours) after exposure to an allergen. The reaction's severity is inversely related to the interval between exposure to the allergen and the onset of symptoms. Usually, the first symptoms include a feeling of impending doom or fright, weakness, sweating, sneezing, shortness of breath, nasal pruritus, urticaria, and angioedema, followed rapidly by symptoms in one or more target organs.

Cardiovascular symptoms include hypotension, shock, and, sometimes, cardiac arrhythmias. If untreated, arrhythmia may precipitate circulatory collapse. Respiratory symptoms can occur at any level in the respiratory tract and commonly include nasal mucosal edema, profuse watery rhinorrhea, itching, nasal congestion, and sudden sneezing attacks. Edema of the upper

respiratory tract results in hypopharyngeal and laryngeal obstruction (hoarseness, stridor, and dyspnea). This is an early sign of acute respiratory failure, which can be fatal. GI and GU symptoms include severe stomach cramps, nausea, diarrhea, and urinary urgency and incontinence.

Diagnosis

Anaphylaxis can be diagnosed by the rapid onset of severe respiratory or cardiovascular signs and symptoms after ingestion or injection of a drug, vaccine, diagnostic agent, food, or food additive or after an insect sting. If these symptoms occur without a known allergic stimulus, rule out other possible causes of shock (acute myocardial infarction, status asthmaticus, or heart failure).

Tests that help determine a patient's risk of anaphylaxis include skin tests that may show hypersensitivity to a specific allergen and an elevated serum IgE level.

Treatment

Anaphylaxis is always an emergency. It requires an *immediate* injection of epinephrine 1:1,000 aqueous solution, 0.1 to 0.5 mL, repeated every 5 to 20 minutes as needed.

In the early stages of anaphylaxis, when the patient hasn't lost consciousness and is normotensive, give epinephrine I.M. or subcutaneously and help it move into circulation faster by massaging the injection site. In severe reactions, when the patient has lost consciousness and is hypotensive, give epinephrine I.V.

ALERT *Maintain airway patency. Observe the patient for early signs of laryngeal edema (hoarseness, stridor, and dyspnea), which will probably require endotracheal tube insertion or a tracheotomy and oxygen therapy.*

In case of cardiac arrest, begin cardiopulmonary resuscitation, including closed-chest heart massage, assisted ventilation, and other therapies as indicated by clinical response.

Watch for hypotension and shock, and maintain circulatory volume with volume expanders (plasma, plasma expanders, saline, and albumin) as needed. Stabilize blood pressure with the I.V. vasopressors norepinephrine and dopamine. Monitor blood pressure, central venous pressure, and urine output as a response index.

After the initial emergency, administer other medications as ordered: subcutaneous epinephrine, longer-acting epinephrine, corticosteroids, and I.V. diphenhydramine for long-term management and an inhaled beta-agonist for bronchospasm.

Special Considerations

PREVENTION

- *Teach the patient to avoid exposure to known allergens. A person allergic to certain foods or drugs must learn to avoid the offending food or drug in all its forms. A person allergic to insect stings should avoid open fields and wooded areas during the insect season. An anaphylaxis kit (epinephrine, antihistamine, and tourniquet) should also be carried whenever the patient with known severe allergic reactions goes outdoors. In addition, every patient prone to anaphylaxis should wear a medical identification bracelet identifying allergies.*

- *If a patient must receive a drug to which he or she's allergic, prevent a severe reaction by making sure the patient receives careful desensitization with gradually increasing doses of the antigen or advance administration of steroids. Of course, a person with a known allergic history should receive a drug with a high anaphylactic potential only after cautious pretesting for sensitivity. Closely monitor the patient during testing, and make sure you have resuscitative equipment and epinephrine ready. When any patient needs a drug with a high anaphylactic potential (particularly parenteral drugs), make sure they received each dose under close medical observation.*
- *Closely monitor a patient undergoing diagnostic tests that use radiographic contrast media, such as excretory urography, cardiac catheterization, and angiography.*

URTICARIA AND ANGIOEDEMA

Urticaria, commonly known as *hives*, is an episodic, usually self-limited skin reaction characterized by local dermal wheals surrounded by an erythematous flare. Angioedema is a subcutaneous and dermal eruption that produces deeper, larger wheals (usually on the hands, feet, lips, genitals, and eyelids) and a more diffuse swelling of loose subcutaneous tissue. Urticaria and angioedema can occur simultaneously, but angioedema may last longer.

Causes and Incidence

Urticaria and angioedema are common allergic reactions that may occur in 20% of the general population. The causes of these reactions include allergy to drugs, foods, insect bites and stings, and, occasionally, inhalant allergens (animal dander and cosmetics) that provoke an IgE-mediated response to protein allergens. However, certain drugs may cause urticaria without an IgE response. When urticaria and angioedema are part of an anaphylactic reaction, they almost always persist long after the systemic response has subsided. This occurs because circulation to the skin is the last to be restored after an allergic reaction, which results in slow histamine reabsorption at the reaction site.

Nonallergic urticaria and angioedema are also related to histamine release. External physical stimuli, such as cold (usually in young adults), heat, water, or sunlight, may also provoke urticaria and angioedema. *Dermographism urticaria*, which develops after stroking or scratching of the skin, occurs in as much as 20% of the population. Such urticaria develops with varying pressure, usually under tight clothing, and is aggravated by scratching.

Pathophysiology

Several different mechanisms and underlying disorders may provoke urticaria and angioedema. These include IgE-induced release of mediators from cutaneous mast cells; binding of IgG or IgM to antigen, resulting in complement activation; and such disorders as localized or secondary infections (such as respiratory infection), neoplastic diseases (such as Hodgkin lymphoma), connective tissue diseases (such as SLE), collagen vascular diseases, and psychogenic diseases.

Complications

- Infection from scratching
- Laryngeal edema (upper respiratory tract involvement)
- Severe abdominal colic (GI involvement)

Signs and Symptoms

The characteristic features of urticaria are distinct, raised, evanescent (temporary) dermal wheals surrounded by an erythematous flare. These lesions may vary in size. In cholinergic urticaria, the wheals may be tiny and blanched, surrounded by erythematous flares.

Angioedema characteristically produces nonpitted swelling of deep subcutaneous tissue, usually on the eyelids, lips, genitalia, and mucous membranes. These swellings don't usually itch but may burn and tingle.

Diagnosis

An accurate patient history can help determine the cause of urticaria. Such a history should include:

- drug history, including over-the-counter preparations (vitamins, aspirin, and antacids)
- frequently ingested foods (strawberries, milk products, fish)
- environmental influences (pets, carpet, clothing, soap, inhalants, cosmetics, hair dye, and insect bites and stings)

Diagnosis also requires physical assessment to rule out similar conditions as well as a CBC, urinalysis, erythrocyte sedimentation rate (ESR), and a chest X-ray to rule out inflammatory infections. Skin testing, an elimination diet, and a food diary (recording time and amount of food eaten and circumstances) can pinpoint provoking allergens. The food diary may also suggest other allergies. For instance, a patient allergic to fish may also be allergic to iodine contrast materials.

Recurrent angioedema without urticaria, along with a familial history, points to hereditary angioedema. (See *Hereditary angioedema*, page 400.) Decreased serum levels of complement 4 and complement 1 esterase inhibitors confirm this diagnosis.

Hereditary angioedema

A nonallergenic type of angioedema, hereditary angioedema results from an autosomal dominant trait—a hereditary deficiency of an alpha globulin, the normal inhibitor of C1 esterase (a component of the complement system). This deficiency allows uninhibited C1 esterase release, resulting in the vascular changes common to angioedema.

The clinical effects of hereditary angioedema usually appear in childhood with recurrent episodes of subcutaneous or submucosal edema at irregular intervals of weeks, months, or years, in many cases after trauma or stress. Hereditary angioedema is unifocal, without urticarial pruritus, but associated with recurrent edema of the skin and mucosa (especially of the GI and respiratory tracts). GI tract involvement may cause nausea, vomiting, and severe abdominal pain. Laryngeal angioedema may cause fatal airway obstruction.

Treatment of acute hereditary angioedema may require androgens such as danazol. Tracheotomy may be necessary to relieve airway obstruction resulting from laryngeal angioedema.

Treatment

Treatment aims to prevent or limit contact with triggering factors or, if this is impossible, to desensitize the patient to them and to relieve symptoms. During desensitization, progressively larger doses of specific antigens (determined by skin testing) are injected intradermally. After the

triggering stimulus has been removed, urticaria usually subsides in a few days—except for drug reactions, which may persist as long as the drug is in the bloodstream.

Diphenhydramine, hydroxyzine, or another antihistamine can ease itching and swelling in every kind of urticaria. Corticosteroid therapy may be necessary for some patients.

Special Considerations

- Inform the patient receiving antihistamines of the possibility of drowsiness.
- Suggest cool compresses to reduce swelling and pain. A cool bath may be used for large areas. Calamine lotion may be soothing as well.
- Avoid hot baths, which can cause hives to return.
- Advise the patient to avoid tight-fitting clothing.

BLOOD TRANSFUSION REACTION

Mediated by immune or nonimmune factors, a transfusion reaction accompanies or follows I.V. administration of blood components. Its severity varies from mild (fever and chills) to severe (acute renal failure or complete vascular collapse and death), depending on the amount of blood transfused, the type of reaction, and the patient's general health.

Causes and Incidence

- Mismatched blood
- Rh-incompatible blood
- Allergic reactions
- Febrile nonhemolytic reactions
- Transfusion-related acute lung injury (TRALI)
- Bacterial contamination

Pathophysiology

Acute hemolytic reactions follow transfusion of mismatched blood. Transfusion of serologically incompatible blood triggers the most serious reaction, marked by intravascular agglutination of RBCs. The recipient's antibodies (IgG or IgM) attach to the donated RBCs, leading to widespread clumping and destruction of the recipient's RBCs and, possibly, the development of disseminated intravascular coagulation (DIC) and other serious effects.

Transfusion of Rh-incompatible blood triggers a less serious reaction within several days to 2 weeks. Rh reactions are most common in females sensitized to RBC antigens by prior pregnancy or by unknown factors (such as bacterial or viral infection) and in people who have received more than five transfusions. (See *Understanding the Rh system*.)

Understanding the Rh System

The Rh system contains more than 30 antibodies and antigens. Eighty-five percent of the world's population is Rh-positive, which means that the red blood cells of most people carry the D or Rh antigen. The remaining 15% of the population, who are Rh-negative, don't carry this antigen.

When Rh-negative people receive Rh-positive blood for the first time, they become

sensitized to the D antigen but show no immediate reaction to it. If they receive Rh-positive blood a second time, they then develop a massive hemolytic reaction. For example, an Rh-negative mother who delivers an Rh-positive baby is sensitized by the baby's Rh-positive blood. During the next Rh-positive pregnancy, sensitized blood would cause a hemolytic reaction in fetal circulation. Thus, the Rh-negative mother should receive $Rh_o(D)$ immune globulin (human) I.M. within 72 hours after delivering an Rh-positive baby to prevent the formation of antibodies against Rh-positive blood.

Allergic reactions are fairly common but only occasionally serious. In this type of reaction, transfused soluble antigens react with surface IgE molecules on mast cells and basophils, causing degranulation and release of allergic mediators. Antibodies against IgA in an IgA-deficient recipient can also trigger a severe allergic reaction (anaphylaxis).

Febrile nonhemolytic reactions, the most common type of reaction, apparently develop when cytotoxic or agglutinating antibodies in the recipient's plasma attack antigens on transfused lymphocytes, granulocytes, or plasma cells.

TRALI occurs when acutely increased permeability of the pulmonary microcirculation causes massive leakage of fluids and protein into the alveolar spaces and interstitium, usually within 6 hours of transfusion. In many cases, it is associated with the presence of granulocyte antibodies in the donor or recipient, causing complement and histamine release.

Although uncommon, *bacterial contamination* of donor blood can occur during donor phlebotomy. Offending organisms are usually gram-negative, especially *Pseudomonas* species, *Citrobacter freundii,* and *Escherichia coli.*

Contamination of donor blood with viruses, such as hepatitis, cytomegalovirus, and malaria, is also possible.

Complications

- Bronchospasm
- Respiratory failure
- Acute tubular necrosis
- Acute renal failure
- Anaphylactic shock
- Vascular collapse
- DIC

Signs and Symptoms

Immediate effects of a hemolytic transfusion reaction develop within a few minutes or hours after the start of the transfusion and may include chills, fever, urticaria, tachycardia, dyspnea, nausea, vomiting, tightness in the chest, chest and back pain, hypotension, bronchospasm, angioedema, and signs and symptoms of anaphylaxis, shock, pulmonary edema, heart failure, and renal failure. In a surgical patient under anesthesia, these symptoms are masked, but blood oozes from mucous membranes or the incision site.

Delayed hemolytic reactions can occur up to several weeks after a transfusion, causing fever, an unexpected fall in serum hemoglobin (Hb) level, and jaundice.

Allergic reactions are typically afebrile and characterized by urticaria and angioedema, possibly progressing to cough, respiratory distress, nausea, vomiting, diarrhea, abdominal

cramps, vascular instability, shock, and coma.

The hallmark of febrile nonhemolytic reactions is mild to severe fever that may begin at the start of transfusion or within 2 hours after its completion.

Symptoms of TRALI include severe respiratory distress within 6 hours of transfusion, fever, chills, cyanosis, and hypotension.

Bacterial contamination produces a high fever, nausea, vomiting, diarrhea, abdominal cramps, and, possibly, shock. Symptoms of viral contamination may not appear for several weeks after transfusion.

Diagnosis

℞ **CONFIRMING DIAGNOSIS** *Confirming a hemolytic transfusion reaction requires proof of blood incompatibility and evidence of hemolysis, such as hemoglobinuria, anti-A or anti-B antibodies in the serum, low serum Hb levels, and elevated bilirubin levels.*

If you suspect such a reaction, have the patient's blood retyped and crossmatched with the donor's blood. After a hemolytic transfusion reaction, laboratory tests will show increased indirect bilirubin levels, decreased haptoglobin levels, increased serum Hb levels, and Hb in the urine. As the reaction progresses, tests may show signs of DIC (thrombocytopenia, increased prothrombin time, and decreased fibrinogen level) and acute tubular necrosis (increased blood urea nitrogen [BUN] and serum creatinine levels).

A blood culture to isolate the causative organism should be done when bacterial contamination is suspected.

Treatment

At the first sign of a hemolytic reaction, *stop the transfusion immediately*. Depending on the nature of the patient's reaction, prepare to:

- monitor vital signs every 15 to 30 minutes, watching for signs of shock.
- maintain a patent I.V. line with normal saline solution; insert an indwelling catheter and monitor intake and output.
- cover the patient with blankets to ease chills, and explain what's happening.
- deliver supplemental oxygen at low flow rates through a nasal cannula or bag-valve-mask (handheld resuscitation bag).
- give drugs as ordered: an I.V. antihypotensive drug (like dopamine) and normal saline solution to combat shock, epinephrine to treat dyspnea and wheezing, diphenhydramine to combat cellular histamine released from mast cells, corticosteroids to reduce inflammation, and mannitol or furosemide to increase renal blood flow ensure 30 to 100 mL/hour of urine output. Administer parenteral antihistamines and corticosteroids for allergic reactions. (Severe reactions such as anaphylaxis may require epinephrine.) Administer antipyretics for nonhemolytic febrile reactions and appropriate I.V. antibiotics for bacterial contamination.
- Treatment for TRALI usually requires aggressive respiratory support, which may include intubation and mechanical ventilation. Diuretics are not effective because the underlying pathology involves microvascular injury rather than fluid overload.

Special Considerations

- Remember to fully document the transfusion reaction on the patient's chart, noting the

transfusion's duration, the amount of blood absorbed, and a complete description of the reaction and of any interventions.

PREVENTION *Make sure you know your hospital's policy about giving blood before you give a transfusion. Then make sure you have the right blood and the right patient. Check and double-check the patient's name, hospital number, ABO blood group, and Rh status. If you find even a small discrepancy, don't give the blood. Notify the blood bank immediately and return the unopened unit.*

Autoimmunity

RHEUMATOID ARTHRITIS

A chronic, systemic, inflammatory disease, RA primarily attacks peripheral joints and surrounding muscles, tendons, ligaments, and blood vessels. Spontaneous remissions and unpredictable exacerbations mark the course of this potentially crippling disease. RA usually requires lifelong treatment and, sometimes, surgery. In most patients, the disease follows an intermittent course and allows normal activity, although 10% suffer total disability from severe articular deformity, associated extra-articular symptoms, or both. The prognosis worsens with the development of nodules, vasculitis, and high titers of rheumatoid factor (RF).

Causes and Incidence

RA occurs worldwide, striking three times more females than males. Although it can occur at any age, it begins most often between ages 25 and 55. This disease affects more than 7 million people in the United States alone.

What causes the chronic inflammation characteristic of RA isn't known, but various theories point to infectious, genetic, and endocrine factors.

Pathophysiology

It's believed that a genetically susceptible individual develops abnormal or altered IgG antibodies when exposed to an antigen. This altered IgG antibody isn't recognized as "self," and the individual forms an antibody against it—an antibody known as RF. By aggregating into complexes, RF generates inflammation. Eventually, cartilage damage by inflammation triggers additional immune responses, including activation of complement. This in turn attracts polymorphonuclear leukocytes and stimulates release of inflammatory mediators, which enhance joint destruction.

If unarrested, the inflammatory process within the joints occurs in four stages. First, synovitis develops from congestion and edema of the synovial membrane and joint capsule. Formation of pannus—thickened layers of granulation tissue—marks the second stage's onset. Pannus covers and invades cartilage and eventually destroys the joint capsule and bone. Progression to the third stage is characterized by fibrous ankylosis—fibrous invasion of the pannus and scar formation that occludes the joint space. Bone atrophy and malalignment cause visible deformities and disrupt the articulation of opposing bones, causing muscle atrophy and imbalance, and, possibly, partial dislocations or subluxations. In the fourth stage, fibrous tissue calcifies, resulting in bony ankylosis and total immobility. (See *The effects of rheumatoid arthritis on certain joints*, page

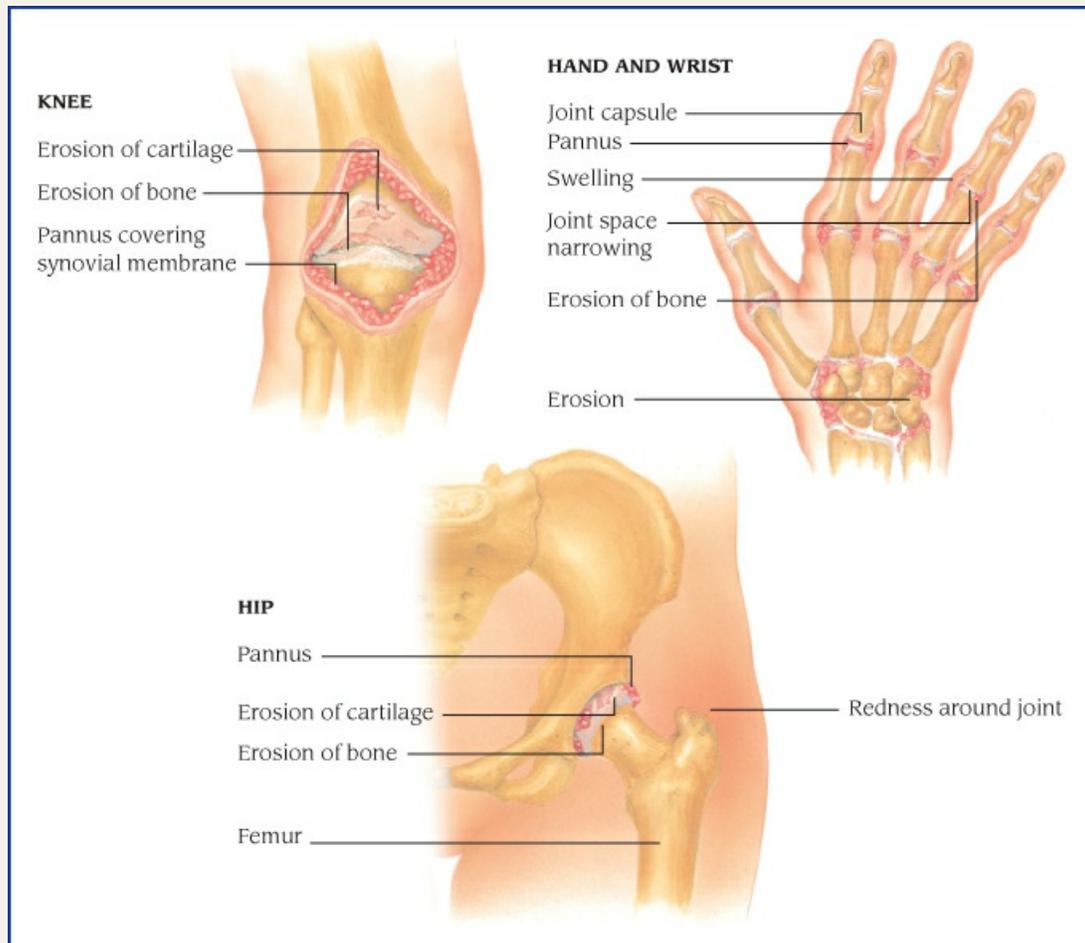
403.)

PATHOPHYSIOLOGY
THE EFFECTS OF RHEUMATOID ARTHRITIS ON CERTAIN JOINTS

Many joints can be affected by rheumatoid arthritis, including the knee, hand and wrist, and hip.

KNEE
- Erosion of cartilage
- Erosion of bone
- Pannus covering synovial membrane

HAND AND WRIST
- Joint capsule
- Pannus
- Swelling
- Joint space narrowing
- Erosion of bone
- Erosion

HIP
- Pannus
- Erosion of cartilage
- Erosion of bone
- Femur
- Redness around joint


Complications

- Fibrous or bony ankylosis
- Soft-tissue contractures
- Joint deformities
- Subluxations
- Carpal tunnel syndrome
- Popliteal (Baker's) cysts
- Osteoporosis

- Vasculitis
- Amyloidosis
- Cardiac and pulmonary disorders

Signs and Symptoms

RA usually develops insidiously and initially produces nonspecific signs and symptoms, such as fatigue, malaise, anorexia, persistent low-grade fever, weight loss, lymphadenopathy, and vague articular symptoms. Later, more specific localized articular symptoms develop, commonly in the fingers at the proximal interphalangeal, metacarpophalangeal, and metatarsophalangeal joints. These symptoms usually occur bilaterally and symmetrically and may extend to the wrists, knees, hips, elbows, and ankles. The affected joints stiffen after inactivity, especially on rising in the morning. The fingers may assume a spindle shape from marked edema and joint congestion. The joints become tender and painful, at first only when the patient moves them, but eventually even at rest. They commonly feel hot to the touch. Ultimately, joint function is diminished.

Deformities are common if active disease continues. Proximal interphalangeal joints may develop flexion deformities or become hyperextended. Metacarpophalangeal joints may swell dorsally, and volar subluxation and stretching of tendons may pull the fingers to the ulnar side ("ulnar drift"). The fingers may become fixed in a characteristic "swan's neck" appearance, or "boutonnière" deformity. The hands appear foreshortened, the wrists boggy; carpal tunnel syndrome from synovial pressure on the median nerve causes tingling paresthesia in the fingers.

The most common extra-articular finding is the gradual appearance of rheumatoid nodules—subcutaneous, round or oval, nontender masses—usually on pressure areas such as the elbows. Vasculitis can lead to skin lesions, leg ulcers, and multiple systemic complications. Peripheral neuropathy may produce numbness or tingling in the feet or weakness and loss of sensation in the fingers. Stiff, weak, or painful muscles are common. Other common extra-articular effects include pericarditis, pulmonary nodules or fibrosis, pleuritis, scleritis, and episcleritis.

Another complication is destruction of the odontoid process, part of the second cervical vertebra. Rarely, cord compression may occur, particularly in patients with long-standing deforming disease. Upper motor neuron signs and symptoms, such as a positive Babinski sign and muscle weakness, may also develop.

RA can also cause temporomandibular joint disease, which impairs chewing and causes earaches. Other extra-articular findings may include infection, osteoporosis, myositis, cardiopulmonary lesions, lymphadenopathy, and peripheral neuritis.

Diagnosis

Typical clinical features suggest this disorder, but a definitive diagnosis is based on laboratory and other test results:

- X-rays—in early stages, show bone demineralization and soft-tissue swelling; later, loss of cartilage and narrowing of joint spaces; finally, cartilage and bone destruction and erosion, subluxations, and deformities
- RF test—positive in 75% to 80% of patients, as indicated by a titer of 1:160 or higher
- Synovial fluid analysis—reveals increased volume and turbidity but decreased viscosity and complement (C3 and C4) levels; WBC count usually exceeds 10,000/μL
- ESR—elevated in 85% to 90% of patients (may be useful to monitor response to therapy because elevation commonly parallels disease activity)
- CBC—usually reveals moderate anemia and slight leukocytosis

A C-reactive protein test may be positive and can help monitor response to therapy. Antinuclear antibody (ANA) test results may also be positive.

The criteria for classifying RA developed by the American College of Rheumatology can also serve as guidelines for establishing a diagnosis. However, keep in mind that failure to meet these criteria—particularly early in the disease—doesn't exclude the diagnosis. (See *Classifying rheumatoid arthritis*.)

Classifying rheumatoid arthritis

The criteria established by the American College of Rheumatology allow for the classification of rheumatoid arthritis (RA).

Guidelines

A patient who meets four of the seven criteria is classified as having RA. The patient must experience the first four criteria for at least 6 weeks, and a physician must observe the second through fifth criteria.

A patient with two or more other clinical diagnoses can also be diagnosed with RA.

Criteria

- Morning stiffness in and around the joints that lasts for 1 hour before full improvement
- Arthritis in three or more joint areas, with at least three joint areas (as observed by a physician) exhibiting soft-tissue swelling or joint effusions, not just bony overgrowth (the 14 possible areas involved include the right and left proximal interphalangeal, metacarpophalangeal, wrist, elbow, knee, ankle, and metatarsophalangeal joints)
- Arthritis of hand joints, including the wrist, the metacarpophalangeal joint, or the proximal interphalangeal joint
- Arthritis that involves the same joint area on both sides of the body
- Subcutaneous rheumatoid nodules over bony prominences
- Demonstration of abnormal amounts of serum rheumatoid factor by any method that produces a positive result in less than 5% of patients without RA
- Radiographic changes, usually on posteroanterior hand and wrist X-rays; these changes must show erosions or unequivocal bony decalcification localized in or most notably adjacent to the involved joints

Treatment

Salicylates, particularly aspirin, are the mainstay of RA therapy because they decrease inflammation and relieve joint pain. Other useful medications include NSAIDs (such as indomethacin, fenoprofen, and ibuprofen), antimalarials (hydroxychloroquine), penicillamine (not as commonly used), gold salts (not as commonly used), Tofacitinib, and corticosteroids (prednisone). Immunosuppressants, such as cyclophosphamide, methotrexate, and azathioprine, are also therapeutic and are being used more commonly in early disease. (See *Drug therapy for rheumatoid arthritis*, pages 405 to 407.)

Drug therapy for rheumatoid arthritis

Drug and adverse effects	Clinical considerations
Analgesics	
Aspirin	
Prolonged bleeding time; gastrointestinal (GI) disturbances, including anorexia, nausea, dyspepsia, ulcers, and hemorrhage; hypersensitivity reactions ranging from urticaria to anaphylaxis; salicylism (mild toxicity: tinnitus, dizziness; moderate toxicity: restlessness, hyperpnea, delirium, marked lethargy; and severe toxicity: coma, seizures, severe hyperpnea)	◆ Don't use in patients with GI ulcers, bleeding, or hypersensitivity or in neonates. ◆ Tell the patient to take the drug with food, milk, antacid, or a large glass of water to reduce GI adverse effects. ◆ Monitor the patient's salicylate level. Remember that toxicity can develop rapidly in febrile, dehydrated children. ◆ Teach the patient to reduce the dose, one tablet at a time, if tinnitus occurs. ◆ Teach the patient to watch for signs of bleeding, such as bruising, melena, and petechiae.
Nonsteroidal anti-inflammatory drugs (NSAIDs)	
Celecoxib, fenoprofen, ibuprofen, naproxen, piroxicam, sulindac, and tolmetin	
Prolonged bleeding time; central nervous system (CNS) abnormalities (headache, drowsiness, restlessness, dizziness, and tremor); GI disturbances, including hemorrhage and peptic ulcer; increased blood urea nitrogen and liver enzyme levels	◆ Tell the patient taking NSAIDs that they may have a higher risk of having a heart attack or stroke than those not taking NSAIDs. ◆ Don't use in patients with renal disease, in patients with asthma who have nasal polyps, or in children. ◆ Use cautiously in patients with GI and cardiac disease or if a patient is allergic to other NSAIDs. ◆ Tell the patient to take the drug with milk or meals to reduce GI adverse effects. ◆ Tell the patient that the drug effect may be delayed for 2 to 3 weeks. ◆ Monitor the patient's kidney, liver, and auditory functions in long-term therapy. Stop the drug if abnormalities develop. ◆ Use cautiously in elderly patients; they may experience severe GI bleeding without warning.
Corticosteroids	
Prednisone	
Increased appetite, indigestion, GI irritation, nervousness, osteoporosis, easy bruising, fluid retention, weight gain, muscle weakness, onset or worsening of diabetes, cataracts, increased risk of infection, hypertension, arrhythmias, thromboembolism	◆ Use cautiously in patients with recent myocardial infarction (MI), GI ulcer, osteoporosis, diabetes mellitus, hypothyroidism, cirrhosis, diverticulitis, seizures, heart failure, ocular herpes simplex, emotional instability, and psychotic tendencies. ◆ Monitor patient's blood pressure, sleep patterns, and potassium level. ◆ Weigh patient daily; report sudden weight gain to prescriber. ◆ Monitor patient for cushingoid effects. ◆ Watch for depression or psychotic episodes, especially during high-dose therapy. ◆ Diabetic patients may need increased insulin; monitor level. ◆ Elderly patients may be more susceptible to osteoporosis with long-term use.

| | ◆ Drug may mask or worsen infection. |
| | ◆ Gradually reduce dosage after long-term therapy. |

Disease-modifying antirheumatic drugs (DMARDs)

Hydroxychloroquine and sulfasalazine
Blood dyscrasias, GI irritation, corneal opacities, and keratopathy or retinopathy

◆ Don't use in patients with retinal or visual field changes.
◆ Use cautiously in patients with hepatic disease, alcoholism, glucose-6-phosphate dehydrogenase deficiency, or psoriasis.
◆ Perform complete blood count (CBC) and liver function tests before therapy and during chronic therapy. The patient should also have regular ophthalmologic examinations.
◆ Tell the patient to take the drug with food or milk to minimize GI adverse effects.
◆ Warn the patient that dizziness may occur.

Gold (oral and parenteral)
Dermatitis, pruritus, rash, stomatitis, nephrotoxicity, blood dyscrasias and, with oral form, GI distress and diarrhea

◆ Watch for and report adverse effects. Observe for nitritoid reaction (flushing, fainting, and sweating).
◆ Check the patient's urine for blood and albumin before giving each dose. If positive, hold the drug and notify the physician. Stress to the patient the need for regular follow-up, including blood and urine testing.
◆ To avoid local nerve irritation, mix the drug well and give it via a deep I.M. injection in the buttock.
◆ Advise the patient not to expect improvement for 3 to 6 months.
◆ Tell the patient to report rash, bruising, bleeding, hematuria, or oral ulcers.

Methotrexate
Tubular necrosis, bone marrow depression, leukopenia, thrombocytopenia, pulmonary interstitial infiltrates, hyperuricemia, stomatitis, rash, pruritus, dermatitis, alopecia, diarrhea, dizziness, cirrhosis, and hepatic fibrosis

◆ Don't give to women who are pregnant or breastfeeding or to patients who are alcoholic.
◆ Monitor the patient's uric acid levels, CBC, and intake and output.
◆ Warn the patient to report any unusual bleeding (especially GI) or bruising promptly.
◆ Warn the patient to avoid alcohol, aspirin, and NSAIDs.
◆ Advise the patient to follow the prescribed regimen.

Biologic response modifiers

Etanercept, golimumab, infliximab, and adalimumab
Headache, dizziness, peripheral edema, rhinitis, pharyngitis, mouth ulcers, dyspepsia, abdominal pain, upper respiratory tract infections, cough, rash, alopecia, infections

◆ Use cautiously in patients with chronic or invasive infections, malignancies, heart failure, or CNS demyelination.
◆ Monitor patient closely for signs and symptoms of infection.
◆ Evaluate patient for latent tuberculosis (TB) with tuberculin skin test before initiating treatment. Monitor for active TB during treatment.

	◆ Monitor for new or worsening heart failure. ◆ Monitor patient for lymphomas and other malignancies. ◆ Monitor CBC regularly during therapy.
Anakinra Headache, sinusitis, abdominal pain, diarrhea, neutropenia, upper respiratory tract infection, ecchymosis, infection (cellulitis, pneumonia, bone and joint infection), flulike symptoms	◆ Use drug cautiously in immunosuppressed patients, those with chronic infections, the elderly, and breastfeeding women. ◆ Don't start treatment if patient has active infection. ◆ Monitor patient for infection and injection site reactions. ◆ Monitor patient for possible anaphylactic reactions. ◆ Obtain neutrophil count before treatment, monthly for the first 3 months of treatment, and then quarterly for up to 1 year.
Rituximab Asthenia, fever, headache, agitation, dizziness, insomnia, hypotension, arrhythmia, bradycardia, chest pain, edema, flushing, hypertension, tachycardia, conjunctivitis, sinusitis, abdominal pain or enlargement, anorexia, acute renal failure, leukopenia, neutropenia, thrombocytopenia, anemia, hyperglycemia, arthritis, bronchospasm, severe mucocutaneous reactions, angioedema, infusion reaction, tumor lysis syndrome	◆ Use cautiously in patients at high risk for hepatitis B viral infection. ◆ Monitor patient for infusion reaction complex, including hypoxia, pulmonary infiltrates, acute respiratory distress syndrome, MI, or cardiogenic shock. ◆ Monitor patient closely for signs of hypersensitivity. ◆ Monitor patient's blood pressure closely during infusion. If hypotension, bronchospasm, or angioedema occurs, stop infusion and restart at half the rate when symptoms resolve. ◆ Withhold antihypertensive 12 hours before infusion because transient hypotension may occur. ◆ If serious or life-threatening arrhythmias occur, stop infusion. ◆ Severe mucocutaneous reactions may occur 1 to 13 weeks after administration. Avoid further infusions and promptly start treatment of the skin reaction.
Abatacept Headache, dizziness, hypertension, nasopharyngitis, GI disturbances, including dyspepsia, nausea; urinary tract infection; back pain; respiratory system disturbances including upper respiratory infection, cough, exacerbation of chronic obstructive pulmonary disease (COPD); skin rash; infusion-related hypersensitivity reactions, infections, malignancy	◆ Don't give live vaccines during therapy and for 3 months after the end of treatment because it may decrease immune response to vaccine. ◆ Use cautiously in patients with active infections, history of chronic infection, or COPD or in women who are pregnant. ◆ Patients who test positive for TB should be treated before using abatacept. ◆ Contraindicated in patients taking a tumor necrosis factor antagonist.

Supportive measures include 8 to 10 hours of sleep every night, frequent rest periods between

daily activities, and splinting to rest inflamed joints. A physical therapy program that includes range-of-motion (ROM) exercises and carefully individualized therapeutic exercises forestalls joint function loss; application of heat relaxes muscles and relieves pain. Moist heat usually works best for patients with chronic disease. Ice packs are effective during acute episodes.

Advanced disease may require synovectomy, joint reconstruction, or total joint arthroplasty.

Useful surgical procedures in RA include metatarsal head and distal ulnar resectional arthroplasty, insertion of a Silastic prosthesis between the metacarpophalangeal and proximal interphalangeal joints, and arthrodesis (joint fusion). Arthrodesis sacrifices joint mobility for stability and pain relief. Synovectomy (removal of destructive, proliferating synovium, usually in the wrists, knees, and fingers) may halt or delay the course of this disease. Osteotomy (the cutting of bone or excision of a wedge of bone) can realign joint surfaces and redistribute stresses. Tendons may rupture spontaneously, requiring surgical repair. Tendon transfers may prevent deformities or relieve contractures. (See *When arthritis requires surgery*.)

When Arthritis Requires Surgery

Arthritis severe enough to warrant total knee or total hip arthroplasty calls for comprehensive preoperative teaching and postoperative care.

Before Surgery
- Explain preoperative and surgical procedures. Show the patient the prosthesis to be used if available.
- Teach the patient postoperative exercises such as isometrics, and supervise the practice. Also, teach deep-breathing and coughing exercises that will be necessary after surgery.
- Explain that total hip or knee arthroplasty requires frequent range-of-motion exercises of the leg after surgery; total knee arthroplasty requires frequent leg-lift exercises.
- Show the patient how to use a trapeze to move himself about in bed after surgery, and make sure there is a fracture bedpan handy.
- Tell the patient what kind of dressings to expect after surgery. After total knee arthroplasty, the patient's knee may be placed in a constant-passive-motion device to increase postoperative mobility and prevent emboli. After total hip arthroplasty, they'll have an abduction pillow between the legs to help keep the hip prosthesis in place.

After Surgery
- Closely monitor and record vital signs. Watch for complications, such as steroid crisis and shock in patients receiving steroids. Monitor distal leg pulses often, marking them with a waterproof marker to make them easier to find.
- As soon as the patient awakens, encourage active dorsiflexion; if unable, report this immediately. Supervise isometric exercises every 2 hours. After total hip arthroplasty, check traction for pressure areas and keep the bed's head raised between 30 and 45 degrees.
- Change or reinforce dressings, as needed, using sterile technique. Check wounds for hematoma, excessive drainage, color changes, or foul odor—all possible signs of hemorrhage or infection. (Wounds on rheumatoid arthritis patients may heal slowly.) Avoid contaminating dressings while helping the patient use the urinal or bedpan.
- Administer blood replacement products, antibiotics, and pain medication, as ordered.

- Monitor serum electrolyte and hemoglobin levels and hematocrit.
- Have the patient turn, cough, and deep-breathe every 2 hours; then percuss the chest.
- After total knee arthroplasty, keep the patient's leg extended and slightly elevated.
- After total hip arthroplasty, keep the patient's hip in abduction to prevent dislocation by using such measures as a wedge pillow. Prevent external rotation and avoid hip flexion greater than 90 degrees. Watch for and immediately report any inability to rotate the hip or bear weight on it, increased pain, or a leg that appears shorter—all may indicate dislocation.
- As soon as allowed, help the patient get out of bed and sit in a chair, keeping the weight on the unaffected side. When he's ready to walk, consult with the physical therapist for walking instruction and aids.

Special Considerations

- Assess all joints carefully. Look for deformities, contractures, immobility, and inability to perform everyday activities.
- Monitor the patient's vital signs and note weight changes, sensory disturbances, and level of pain. Administer analgesics as ordered and watch for adverse effects.
- Provide meticulous skin care. Check for rheumatoid nodules as well as pressure ulcers and breakdowns due to immobility, vascular impairment, corticosteroid treatment, or improper splinting. Use lotion or cleansing oil, not soap, for dry skin.
- Explain all diagnostic tests and procedures. Tell the patient to expect multiple blood samples to allow firm diagnosis and accurate monitoring of therapy.
- Monitor the duration, not the intensity, of morning stiffness because duration more accurately reflects the disease's severity. Encourage the patient to take hot showers or baths at bedtime or in the morning to reduce the need for pain medication.
- Apply splints carefully and correctly. Observe for pressure ulcers if the patient is in traction or wearing splints.
- Explain the nature of the disease. Make sure the patient and family understand that RA is a chronic disease that requires major changes in lifestyle. Emphasize that there are no miracle cures, despite claims to the contrary.
- Encourage a balanced diet, but make sure the patient understands that special diets won't cure RA. Stress the need for weight control because obesity adds further stress to joints.
- Urge the patient to perform activities of daily living (ADLs), such as practicing good hygiene and dressing and feeding oneself. Suggest ADL aids, such as a long-handled shoehorn; elastic shoelaces; zipper-pulls; button hooks; easy-to-handle cups, plates, and silverware; elevated toilet seats; and battery-operated toothbrushes. Household cleaning devices such as long-handled dustpans are also available. Patients who have trouble maneuvering fingers into gloves should wear mittens.
- ADLs that can be done in a sitting position should be encouraged. Allow the patient enough time to calmly perform these tasks.
- Provide emotional support. Remember that the patient with chronic illness easily becomes depressed, discouraged, and irritable. Encourage the patient to discuss fears concerning dependency, sexuality, body image, and self-esteem. Refer the patient to an appropriate social service agency as needed.
- Discuss sexual aids: alternative positions, pain medication, and moist heat to increase

mobility.

- Before discharge, make sure the patient knows how and when to take prescribed medication and how to recognize possible adverse effects.
- Teach the patient how to stand, walk, and sit correctly: upright and erect. Tell the patient to sit in chairs with high seats and armrests; the patient will find it easier to get up from a chair if the knees are lower than the hips. If the patient doesn't own a chair with a high seat, recommend putting blocks of wood under a favorite chair's legs. Suggest an elevated toilet seat.
- Mobility aids are very helpful. Many medical and commercial stores offer assistive and supportive devices that promote self-care, including an overhead grasping trapeze to get out of bed, easy-to-open drawers, handheld shower nozzles, handrails, and grab bars.
- Instruct the patient to pace daily activities, resting for 5 to 10 minutes out of each hour and alternating sitting and standing tasks. Adequate sleep and correct sleeping posture are important. The patient should sleep on their back on a firm mattress and should avoid placing a pillow under the knees, which encourages flexion deformity.
- Teach the patient to avoid putting undue stress on joints and to use the largest joint available for a given task, to support weak or painful joints as much as possible, to avoid positions of flexion and promote positions of extension, to hold objects parallel to the knuckles as briefly as possible, to always use hands toward the center of the body, and to slide—not lift—objects whenever possible. Enlist the aid of the occupational therapist to teach how to simplify activities and protect arthritic joints. Stress the importance of shoes with proper support.
- Refer the patient to the Arthritis Foundation for more information on coping with the disease.

ELDER TIP Reinforce safety precautions for elderly patients, such as the removal of throw rugs and the use of handrails and adequate night lighting. Recommend a step stool for elderly patients who need to reach in overhead cupboards. Suggest that the patient purchase medication without safety caps, if available, because these caps can be difficult to open. Medication administration should be designed to follow a standard regimen that fits with the patient's lifestyle.

JUVENILE RHEUMATOID ARTHRITIS

Affecting children younger than age 16, juvenile rheumatoid arthritis (JRA) is an inflammatory disorder of the connective tissues, characterized by joint swelling and pain or tenderness. It may also involve organs such as the skin, heart, lungs, liver, spleen, and eyes, producing extra-articular signs and symptoms.

JRA has three major types: systemic (Still disease or acute febrile type), polyarticular, and pauciarticular. Depending on the type, this disease can occur as early as age 6 weeks—although rarely before 6 months—with peaks of onset at ages 1 to 3 and 8 to 12.

The prognosis for JRA is generally good, although disabilities can occur. Long periods of spontaneous remission are common. Improvement or remission may occur at puberty.

Causes and Incidence

The cause of JRA remains puzzling. Research continues to test several theories, such as those linking the disease to genetic factors or to an abnormal immune response. Viral or bacterial (particularly streptococcal) infection, trauma, and emotional stress may be precipitating factors, but their relationship to JRA remains unclear.

Considered the major chronic rheumatic disorder of childhood, JRA affects an estimated 50 to

100 per 100,000 children in the United States; overall incidence is twice as high in females, with variation among the types of JRA.

Pathophysiology

The etiology and pathogenesis of JRA are not completely understood. Genetic susceptibility plays a major role, but there is significant overlap between loci associated with juvenile idiopathic arthritis and those associated with other autoimmune diseases.

Complications

- Ocular damage
- Loss of vision
- Growth disturbances

Signs and Symptoms

Signs and symptoms vary with the type of JRA. Affecting boys and girls almost equally, *systemic JRA* accounts for about 10% of cases. The affected children may have mild, transient arthritis or frank polyarthritis with fever and rash. Joint involvement may not be evident at first, but the child's behavior may clearly suggest joint pain. Such a child may constantly want to sit in a flexed position, may not walk much, or may refuse to walk at all. Young children with JRA are noticeably irritable and listless.

Fever in systemic JRA occurs suddenly and spikes to 103° F (39.4° C) or higher once or twice daily, usually in the late afternoon, then rapidly returns to normal or subnormal. (This "sawtooth" or intermittent spiking fever pattern helps differentiate JRA from other inflammatory disorders.) When fever spikes, an evanescent rheumatoid rash commonly appears, consisting of small pale or salmon pink macules, usually on the trunk and proximal extremities and occasionally on the face, palms, and soles. Massaging or applying heat intensifies this rash. It's usually most conspicuous where the skin has been rubbed or subjected to pressure such as the areas of skin covered by underclothing.

Other signs and symptoms of systemic JRA may include hepatosplenomegaly, lymphadenopathy, pleuritis, pericarditis, myocarditis, and nonspecific abdominal pain.

Polyarticular JRA accounts for about 40% of cases and is three times more common in females than in males; affected children may be seronegative or seropositive for RF. It involves five or more joints and usually develops insidiously. Most commonly involved joints are the wrists, elbows, knees, ankles, and small joints of the hands and feet. Polyarticular JRA can also affect larger joints, including the temporomandibular joints, cervical spine, hips, and shoulders. These joints become swollen, tender, and stiff. Usually, the arthritis is symmetrical; it may be remittent or indolent. The patient may run a low-grade fever with daily peaks. Listlessness and weight loss can occur, possibly with lymphadenopathy and hepatosplenomegaly. Other signs of polyarticular JRA include subcutaneous nodules on the elbows or heels and noticeable developmental retardation.

Seropositive polyarticular JRA, the more severe type, usually occurs late in childhood and can cause destructive arthritis that mimics adult RA.

Pauciarticular JRA involves few joints (usually no more than four), typically affecting the knees and other large joints. This form accounts for 50% of cases and has major subtypes. The first, pauciarticular JRA with chronic iridocyclitis, most commonly strikes females younger than age 6 and involves the knees, elbows, ankles, or iris. Inflammation of the iris and ciliary body is

commonly asymptomatic but may produce pain, redness, blurred vision, and photophobia.

The second subtype, pauciarticular JRA with sacroiliitis, usually strikes males (9:1) older than age 8, who tend to test positive for human leukocyte antigen (HLA)-B27. This subtype is characterized by lower-extremity arthritis that produces hip, sacroiliac, heel, and foot pain as well as Achilles tendinitis. These patients may later develop the sacroiliac and lumbar arthritis characteristic of ankylosing spondylitis. Some also experience acute iritis, but not as many as those with the first subtype.

The third subtype includes patients with joint involvement who are ANA and HLA-B27 negative and don't develop iritis. These patients have a better prognosis than those with the first or second subtype.

Common to all types of JRA is joint stiffness in the morning or after periods of inactivity. Back pain and limited ROM are common. Growth disturbances may also occur, resulting in uneven length of arms or legs due to overgrowth or undergrowth adjacent to inflamed joints.

Diagnosis

Persistent joint pain and the rash and fever clearly point to JRA. Laboratory tests are useful for ruling out other inflammatory or even malignant diseases that can mimic JRA. Disease activity and response to therapy can also be monitored through laboratory results.

- CBC shows decreased Hb levels, neutrophilia, and thrombocytosis.
- ESR and C-reactive protein, haptoglobin, Ig, and C3 complement levels may be elevated.
- ANA test may be positive in patients who have pauciarticular JRA with chronic iridocyclitis.
- RF is present in 15% of JRA cases, compared with 85% of RA cases.
- Positive HLA-B27 antigens may forecast later development of ankylosing spondylitis.
- X-rays in early stages reveal changes, including soft-tissue swelling, effusion, and periostitis in affected joints. Later, osteoporosis and accelerated bone growth may appear, followed by subchondral erosions, joint space narrowing, bone destruction, and fusion.

Treatment

Successful management of JRA usually involves administration of anti-inflammatory drugs, physical therapy, carefully planned nutrition and exercise, and regular eye examinations. Both child and parents must be involved in therapy.

NSAIDs, disease-modifying antirheumatic drugs (DMARDs), biologic agents, and corticosteroids are classifications of medications that may be used in treatment. Because of adverse effects, steroids are generally reserved for treatment of systemic complications, such as pericarditis or iritis, that are resistant to NSAIDs. Corticosteroids and mydriatic drugs are commonly used for iridocyclitis. If little relief is obtained from these drugs, biologic response modifiers may be used. These drugs work by blocking various actions of the inflammatory process.

Physical therapy promotes regular exercise to maintain joint mobility and muscle strength, thereby preventing contractures, deformity, and disability. Good posture, gait training, and joint protection are also beneficial. Splints help reduce pain, prevent contractures, and maintain correct joint alignment.

Surgery is usually limited to soft-tissue releases to improve joint mobility. Joint replacement is delayed until the child has matured physically and can handle vigorous rehabilitation.

Special Considerations

- Parents and healthcare professionals should encourage the child to be as independent as possible and to develop a positive attitude toward school, social development, and vocational planning.
- Regular slit-lamp examinations help ensure early diagnosis and treatment of iridocyclitis. Children with pauciarticular JRA with chronic iridocyclitis should be checked every 3 months during periods of active disease and every 6 months during remissions.

PSORIATIC ARTHRITIS

Psoriatic arthritis is a rheumatoid-like joint disease associated with psoriasis of nearby skin and nails. Although the arthritis component of this syndrome may be clinically indistinguishable from RA, the rheumatoid nodules are absent, and serologic tests for RF are negative. Psoriatic arthritis is usually mild, with intermittent flare-ups, but in rare cases may progress to crippling arthritis mutilans. This disease affects males and females equally; onset usually occurs between ages 30 and 35.

Causes and Incidence

Evidence suggests that predisposition to psoriatic arthritis is hereditary; 20% to 50% of patients are HLA-B27 positive. However, onset is usually precipitated by streptococcal infection or trauma.

About 5% to 8% of patients with psoriasis develop psoriatic arthritis. It occurs in up to 1% of the general population.

Signs and Symptoms

Psoriatic lesions usually precede the arthritic component; however, after the full syndrome is established, joint and skin lesions recur simultaneously. Arthritis may involve one joint or several joints symmetrically. Spinal involvement occurs in some patients. Peripheral joint involvement is most common in the distal interphalangeal joints of the hands, which have a characteristic sausagelike appearance. Nail changes include pitting, transverse ridges, onycholysis, keratosis, yellowing, and destruction. The patient may experience general malaise, fever, and eye involvement.

Diagnosis

Inflammatory arthritis in a patient with psoriatic skin lesions suggests psoriatic arthritis.

℞ **CONFIRMING DIAGNOSIS** *X-rays confirm joint involvement and show:*

- *erosion of terminal phalangeal tufts*
- *"whittling" of the distal end of the terminal phalanges*
- *"pencil-in-cup" deformity of the distal interphalangeal joints*
- *relative absence of osteoporosis*
- *sacroiliitis*
- *atypical spondylitis with syndesmophyte formation. Hyperostosis and paravertebral ossification result, which may lead to vertebral fusion*

Blood studies indicate negative RF and elevated ESR and uric acid levels.

Treatment

In mild psoriatic arthritis, treatment is supportive and consists of immobilization through bed rest or splints, isometric exercises, paraffin baths, heat therapy, and aspirin and other NSAIDs. Some patients respond well to low-dose systemic corticosteroids; topical steroids may help control skin lesions. DMARDs such as sulfasalazine and methotrexate therapy are effective in treating both the articular and cutaneous effects of psoriatic arthritis. Antimalarials are contraindicated because they can provoke exfoliative dermatitis. Tumor necrosis factor inhibitors such as adalimumab, etanercept, and infliximab block proteins in the inflammatory process, helping to reduce inflammation.

Special Considerations

- Explain the disease and its treatment to the patient and family.
- Encourage exercise, particularly swimming, to maintain strength and ROM.
- Teach the patient how to apply skin care products and medications correctly; explain possible adverse effects.
- Stress the importance of adequate rest and protection of affected joints.
- Encourage regular, moderate exposure to the sun.
- Refer the patient to the Arthritis Foundation for self-help and support groups.

ANKYLOSING SPONDYLITIS

A chronic, usually progressive inflammatory disease, ankylosing spondylitis primarily affects the sacroiliac, apophyseal, and costovertebral joints, along with adjacent soft tissue. The disease (also known as *rheumatoid spondylitis* and *Marie–Strümpell disease*) usually begins in the sacroiliac joints and gradually progresses to the spine's lumbar, thoracic, and cervical regions. Deterioration of bone and cartilage can lead to fibrous tissue formation with eventual fusion of the spine or peripheral joints.

Ankylosing spondylitis may be equally prevalent in both sexes. Progressive disease is well recognized in men, but the diagnosis is commonly overlooked or missed in females, who tend to have more peripheral joint involvement.

Pathophysiology

The pathophysiology remains quite unknown. However, new insights have been provided by the recent identification of susceptibility genes other than HLA-B27; evidence of a pivotal role for several proinflammatory cytokines including IL-23 and IL-17; and the recognition that inflammation and structural progression proceed separately from each other.

Causes and Incidence

Evidence strongly suggests a familial tendency in ankylosing spondylitis. The presence of HLA-B27 (positive in >90% of patients with this disease) and circulating immune complexes suggests immunologic activity.

One of 10,000 people has ankylosing spondylitis. It affects more males than females and usually emerges between ages 20 and 40, although it may develop in children younger than age 10.

Complication

- Atlantoaxial subluxation

Signs and Symptoms

The first indication of ankylosing spondylitis is intermittent low back pain that's usually most severe in the morning or after a period of inactivity. Other signs and symptoms depend on the disease stage and may include:

- hip deformity and associated limited ROM
- kyphosis in advanced stages, caused by chronic stooping to relieve symptoms
- mild fatigue, fever, anorexia, or weight loss; occasional iritis; aortic insufficiency and cardiomegaly; and upper lobe pulmonary fibrosis (mimics tuberculosis)
- pain and limited expansion of the chest due to involvement of the costovertebral joints
- peripheral arthritis involving shoulders, hips, and knees
- stiffness and limited motion of the lumbar spine
- tenderness over the inflammation site

These signs and symptoms progress unpredictably, and the disease can go into remission, exacerbation, or arrest at any stage.

Diagnosis

Typical symptoms, family history, and the presence of HLA-B27 strongly suggest ankylosing spondylitis.

℞ **CONFIRMING DIAGNOSIS** *Confirmation requires these characteristic X-ray findings:*

- *blurring of the bony margins of joints in the early stage*
- *bilateral sacroiliac involvement*
- *patchy sclerosis with superficial bony erosions*
- *eventual squaring of vertebral bodies*
- *bamboo spine with complete ankylosis*

ESR and alkaline phosphatase and serum IgG A levels may be elevated. A negative RF helps rule out RA, which produces similar symptoms.

Treatment

No treatment reliably stops progression of this disease, so management aims to delay further deformity through good posture, stretching and deep-breathing exercises and, in some patients, braces and lightweight supports. Anti-inflammatory analgesics, such as aspirin, indomethacin, sulfasalazine, and sulindac, control pain and inflammation.

Tumor necrosis factor inhibitors have been shown to improve symptoms. Corticosteroid therapy or medication to suppress the immune system may be prescribed to control various symptoms. DMARDs such as methotrexate and sulfasalazine have been used in patients who don't respond well to corticosteroids or those who are dependent on high doses of corticosteroids.

Severe hip involvement usually necessitates surgical hip replacement. Severe spinal involvement may require a spinal wedge osteotomy to separate and reposition the vertebrae. This surgery is performed only on selected patients because of the risk of spinal cord damage and the long convalescence involved.

Special Considerations

Ankylosing spondylitis can be an extremely painful and crippling disease, so your main responsibility is to promote the patient's comfort. When dealing with such a patient, keep in mind that limited ROM makes simple tasks difficult. Offer support and reassurance.

- Administer medications as ordered. Apply local heat and provide massage to relieve pain. Assess mobility and degree of discomfort frequently. Teach and assist with daily exercises as needed to maintain strength and function. Stress the importance of maintaining good posture.
- If treatment includes surgery, provide good postoperative care. Because ankylosing spondylitis is a chronic, progressively crippling condition, a comprehensive treatment plan should also reflect counsel from a social worker, visiting nurse, and dietitian.
- To minimize deformities, advise the patient to:

  - avoid any physical activity that places undue stress on the back, such as lifting heavy objects
  - stand upright; to sit upright in a high, straight chair; and to avoid leaning over a desk
  - sleep in a prone position on a hard mattress and to avoid using pillows under neck or knees
  - avoid prolonged walking, standing, sitting, or driving
  - perform regular stretching and deep-breathing exercises and to swim regularly, if possible
  - have height measured every 3 to 4 months to detect any tendency toward kyphosis
  - seek vocational counseling if work requires standing or prolonged sitting at a desk
  - contact the local Arthritis Foundation chapter for a support group

SJÖGREN SYNDROME

The second most common autoimmune rheumatic disorder after RA, Sjögren syndrome is characterized by diminished lacrimal and salivary gland secretion (sicca complex). Sjögren syndrome may be a primary disorder or it may be associated with connective tissue disorders, such as RA, scleroderma, SLE, and polymyositis. In some patients, the disorder is limited to the exocrine glands (glandular Sjögren syndrome); in others, it also involves other organs, such as the lungs and kidneys (extraglandular Sjögren syndrome).

Causes and Incidence

The cause of Sjögren syndrome is unknown, but genetic and environmental factors probably contribute to its development. Viral or bacterial infection or perhaps exposure to pollen may trigger Sjögren syndrome in a genetically susceptible individual. Tissue damage results from infiltration by lymphocytes or from the deposition of immune complexes. Lymphocytic infiltration may be classified as benign, malignant, or pseudolymphoma (nonmalignant, but tumorlike aggregates of lymphoid cells).

This syndrome occurs mainly in females (90% of patents); mean age of onset is 40 to 50.

Pathophysiology

The pathophysiology of Sjögren syndrome is not well understood. The presence of activated salivary gland epithelial cells expressing MHC class II molecules and the identification of inherited susceptibility markers suggest that environmental or endogenous antigens trigger a self-perpetuating inflammatory response in susceptible individuals. In addition, the continuing presence of active IFN pathways in Sjögren syndrome suggests ongoing activation of the innate immune system. Together, these findings suggest an ongoing interaction between the innate and acquired immune systems in Sjögren syndrome.

Complications

- Corneal ulceration
- Deafness
- Renal tubular necrosis
- Splenomegaly

Signs and Symptoms

About 50% of patients with Sjögren syndrome have confirmed RA and a history of slowly developing sicca complex. However, some patients seek medical help for rapidly progressive and severe oral and ocular dryness, in many cases accompanied by periodic parotid gland enlargement. Ocular dryness (xerophthalmia) leads to foreign body sensation (gritty, sandy eye), redness, burning, photosensitivity, eye fatigue, itching, and mucoid discharge. The patient may also complain of a film across the field of vision.

Oral dryness (xerostomia) leads to difficulty swallowing and talking; abnormal taste or smell sensation or both; thirst; ulcers of the tongue, buccal mucosa, and lips (especially at the corners of the mouth); and severe dental caries. Dryness of the respiratory tract leads to epistaxis, hoarseness, chronic nonproductive cough, recurrent otitis media, and increased incidence of respiratory infections.

Other effects may include dyspareunia and pruritus (associated with vaginal dryness), generalized itching, fatigue, recurrent low-grade fever, and arthralgia or myalgia. Lymph node enlargement may be the first sign of malignant lymphoma or pseudolymphoma.

Specific extraglandular findings in Sjögren syndrome include interstitial pneumonitis; interstitial nephritis, which results in renal tubular acidosis in 25% of patients; Raynaud phenomenon (20%); and vasculitis, usually limited to the skin and characterized by palpable purpura on the legs (20%). About 50% of patients show signs of hypothyroidism related to autoimmune thyroid disease. A few patients develop systemic necrotizing vasculitis.

Diagnosis

The diagnosis of Sjögren syndrome rests on the detection of two of the following three conditions: xerophthalmia, xerostomia (with salivary gland biopsy showing lymphocytic infiltration), and an associated autoimmune or lymphoproliferative disorder. Diagnosis must rule out other causes of oral and ocular dryness, including sarcoidosis, endocrine disorders, anxiety or depression, and effects of therapy such as radiation to the head and neck. More than 200 commonly used drugs also produce dry mouth as an adverse effect. In patients with salivary gland enlargement and severe lymphoid infiltration, diagnosis must rule out cancer.

Laboratory values include elevated ESR in most patients, mild anemia and leukopenia in 30%, and hypergammaglobulinemia in 50%. Autoantibodies are also common, including anti-Sjögren syndrome-A (anti-Ro) and anti-Sjögren syndrome-B (anti-La), which are antinuclear and antisalivary duct antibodies. From 75% to 90% of patients test positive for RF; 90%, for antinuclear antibodies.

Other tests help support this diagnosis. Schirmer tearing test and slit-lamp examination with rose Bengal dye are used to measure eye involvement. Salivary gland involvement is evaluated by measuring the volume of parotid saliva and by secretory sialography and salivary scintigraphy. Lower-lip biopsy shows salivary gland infiltration by lymphocytes.

Treatment

Treatment is usually symptomatic and includes conservative measures to relieve ocular or oral dryness. Mouth dryness can be relieved by using a methylcellulose swab or spray and by drinking plenty of fluids, especially at mealtime. Meticulous oral hygiene is essential, including regular flossing, brushing, at-home fluoride treatment, and frequent dental checkups.

Instill artificial tears as often as every half hour to prevent eye damage (corneal ulcerations and corneal opacifications) from insufficient tear secretions. Some patients may also benefit from instillation of an eye ointment at bedtime or from twice-a-day use of sustained-release cellulose capsules (Lacrisert). If infection develops, antibiotics should be given immediately; topical steroids should be avoided. Other treatment measures vary with associated extraglandular findings. Parotid gland enlargement requires local heat and analgesics. Pulmonary and renal interstitial disease necessitate corticosteroid use. Accompanying lymphoma is treated with a combination of chemotherapy, surgery, or radiation.

Special Considerations

- Stress the need to humidify home and work environments to help relieve respiratory dryness.
- Advise the patient to avoid drugs that decrease saliva production, such as atropine derivatives, antihistamines, anticholinergics, and antidepressants.
- If mouth lesions make eating painful, suggest high-protein, high-calorie liquid supplements to prevent malnutrition.
- Advise the patient to avoid sugar, which contributes to dental caries. Tobacco; alcohol; and spicy, salty, or highly acidic foods, which cause mouth irritation, should also be avoided.
- Suggest normal saline solution drops or aerosolized spray for nasal dryness.
- Advise the patient to avoid prolonged hot showers and baths and to use moisturizing lotions to help ease dry skin. Suggest K-Y lubricating jelly as a vaginal lubricant.
- Suggest the use of sunglasses to protect the patient's eyes from dust, wind, and strong light. Moisture chamber spectacles may also be helpful. Because dry eyes are more susceptible to infection, advise the patient to keep the face clean and to avoid rubbing the eyes.
- Refer the patient to the Sjögren's syndrome Foundation for additional information and support.

LUPUS ERYTHEMATOSUS

A chronic inflammatory disorder of the connective tissues, lupus erythematosus appears in two forms. *Discoid lupus erythematosus* (DLE) affects only the skin. (See *Discoid lupus erythematosus*.) SLE affects multiple organ systems as well as the skin and can be fatal. (See *Organs affected by systemic lupus erythematosus*, page 416.) Like RA, SLE is characterized by recurring remissions and exacerbations, especially common during the spring and summer. The prognosis improves with early detection and treatment, but remains poor for patients who develop cardiovascular, renal, or neurologic complications or severe bacterial infections.

Discoid lupus erythematosus

Discoid lupus erythematosus (DLE) is a form of lupus erythematosus marked by chronic skin eruptions that, if untreated, can lead to scarring and permanent disfigurement. About 1 of 20 patients with DLE later develops systemic lupus erythematosus (SLE). The exact cause of DLE is unknown, but some evidence suggests an autoimmune defect. An estimated 60% of

patients with DLE are women in their late 20s or older. This disease is rare in children.

DLE lesions are raised, red, scaling plaques, with follicular plugging and central atrophy. The raised edges and sunken centers give them a coinlike appearance. Although these lesions can appear anywhere on the body, they usually erupt on the face, scalp, ears, neck, and arms or on any part of the body that's exposed to sunlight. Such lesions can resolve completely or may cause hypopigmentation or hyperpigmentation, atrophy, and scarring. Facial plaques sometimes assume the butterfly pattern characteristic of SLE. Hair tends to become brittle or may fall out in patches.

As a rule, patient history and the appearance of the rash itself are diagnostic. Lupus erythematosus cell test is positive in fewer than 10% of patients. Skin biopsy of lesions reveals immunoglobulins or complement components. SLE must be ruled out.

Patients with DLE should avoid prolonged exposure to the sun, fluorescent lighting, or reflected sunlight. They should wear protective clothing, use sunscreening agents, avoid engaging in outdoor activities during periods of most intense sunlight (between 10 a.m. and 2 p.m.), and report any changes in the lesions. Drug treatment consists of topical, intralesional, or systemic medication, as in SLE.

Organs affected by systemic lupus erythematosus

Systemic lupus erythematosus affects multiple organ systems as well as the skin and can be fatal.

HAIR
- Patchy alopecia

BRAIN
- Seizures
- Psychosis

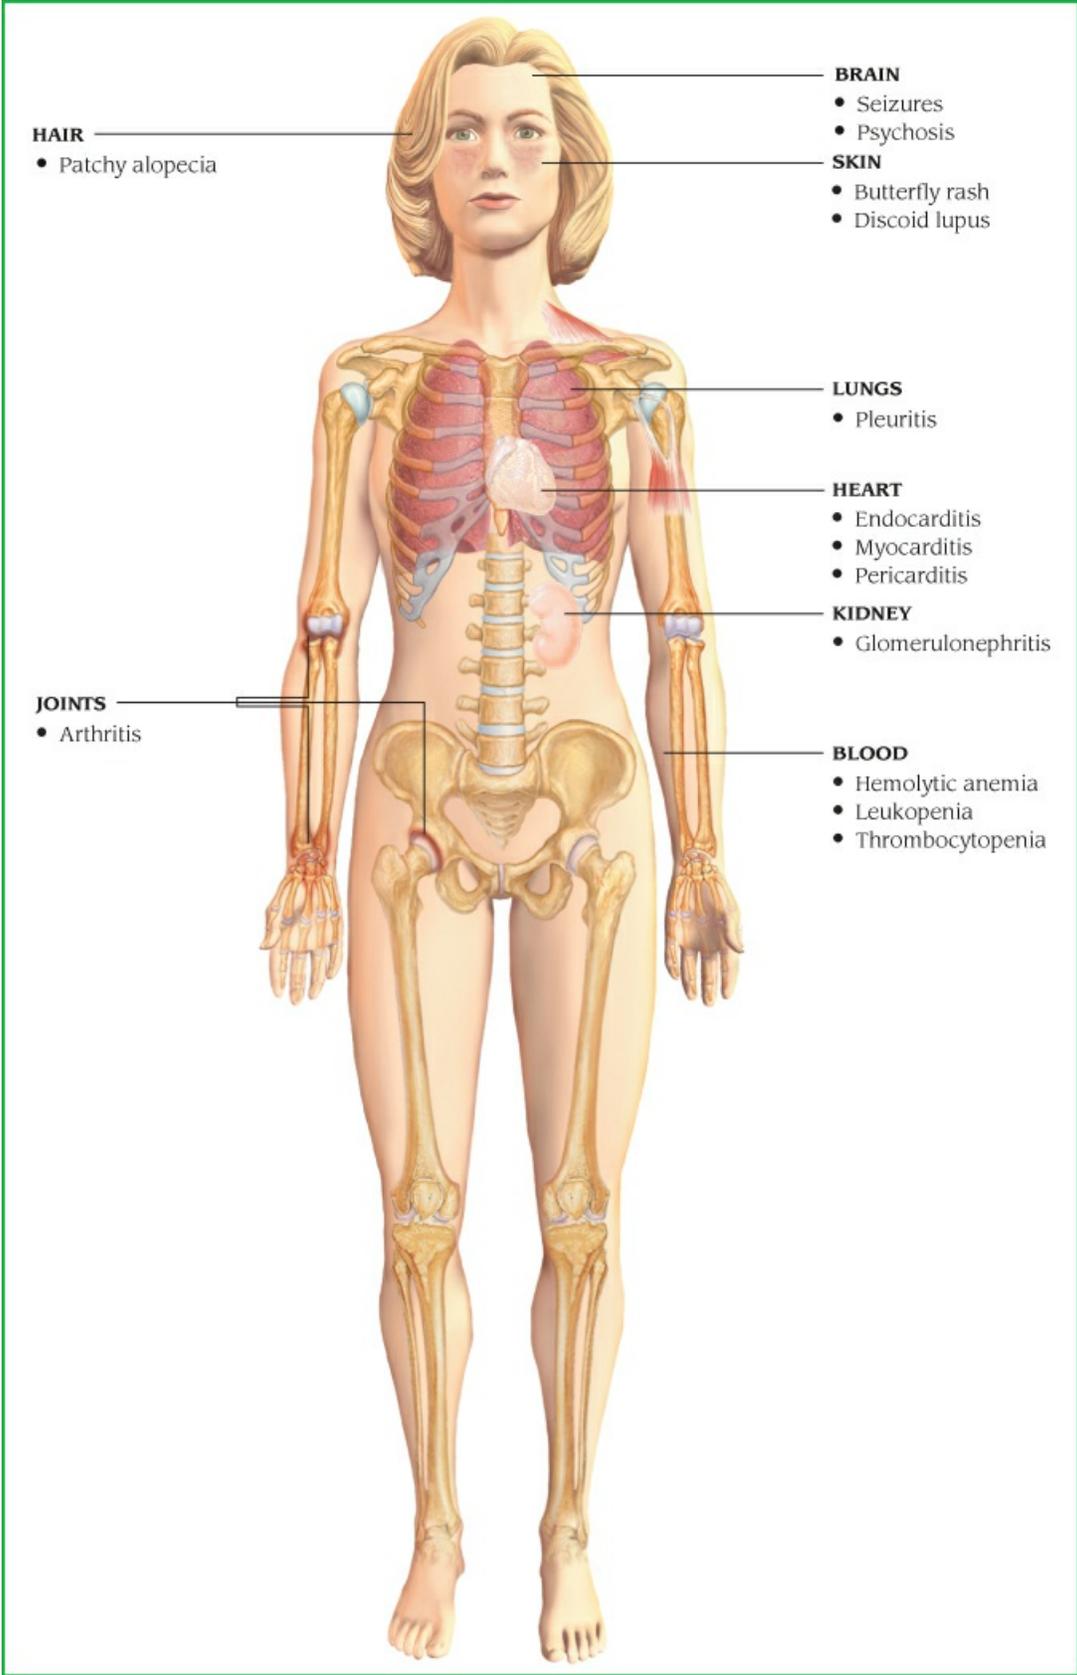
SKIN
- Butterfly rash
- Discoid lupus

LUNGS
- Pleuritis

HEART
- Endocarditis
- Myocarditis
- Pericarditis

KIDNEY
- Glomerulonephritis

JOINTS
- Arthritis

BLOOD
- Hemolytic anemia
- Leukopenia
- Thrombocytopenia


Causes and Incidence

The exact cause of SLE remains a mystery, but evidence points to interrelated immunologic, environmental, hormonal, and genetic factors. Autoimmunity is thought to be the prime causative mechanism.

Certain predisposing factors may make a person susceptible to SLE. Physical or mental stress, streptococcal or viral infections, exposure to sunlight or ultraviolet light, immunization, pregnancy, and abnormal estrogen metabolism may all affect this disease's development.

SLE may also be triggered or aggravated by treatment with certain drugs—for example, procainamide, hydralazine, anticonvulsants, and, less commonly, penicillins, sulfa drugs, and hormonal contraceptives.

SLE strikes 9 times more women than men, increasing to 15 times more during childbearing years. It occurs worldwide but is most prevalent among Asians and Blacks.

Pathophysiology

Autoimmunity is felt to be the culprit. In autoimmunity, the body produces antibodies against its own cells, such as the ANA. The formed antigen–antibody complexes can suppress the body's normal immunity and damage tissues. Patients with SLE produce antibodies against many different tissue components, such as RBCs, neutrophils, platelets, lymphocytes, or almost any organ or tissue in the body.

Complications

- Pleurisy
- Pleural effusions
- Pneumonitis
- Pulmonary hypertension
- Pericarditis
- Endocarditis
- Coronary atherosclerosis
- Renal failure

Signs and Symptoms

The onset of SLE may be acute or insidious and produces no characteristic clinical pattern. However, its symptoms commonly include fever, weight loss, malaise, and fatigue as well as rashes and polyarthralgia. SLE may involve every organ system. In 90% of patients, joint involvement is similar to that in RA. Skin lesions are most commonly erythematous rashes in areas exposed to light. The classic butterfly rash over the nose and cheeks occurs in fewer than 50% of the patients. (See *Butterfly rash*.) Ultraviolet rays often provoke or aggravate skin eruptions. Vasculitis can develop (especially in the digits), possibly leading to infarctive lesions, necrotic leg ulcers, or digital gangrene. Raynaud phenomenon appears in about 20% of patients. Patchy alopecia and painless ulcers of the mucous membranes are common.

Butterfly rash

In the classic butterfly rash, lesions appear on the cheeks and the bridge of the nose, creating a characteristic butterfly pattern. The rash may vary in severity from malar erythema to discoid lesions (plaque).

Constitutional symptoms of SLE include aching, malaise, fatigue, low-grade or spiking fever, chills, anorexia, and weight loss. Lymph node enlargement (diffuse or local, and nontender), abdominal pain, nausea, vomiting, diarrhea, and constipation may occur. Females may experience irregular menstrual periods or amenorrhea during the active phase of SLE.

About 50% of SLE patients develop signs of cardiopulmonary abnormalities, such as pleuritis, pericarditis, and dyspnea. Myocarditis, endocarditis, tachycardia, parenchymal infiltrates, and pneumonitis may occur. Renal effects may include hematuria, proteinuria, urine sediment, and cellular casts, which may progress to total kidney failure. Urinary tract infections may result from heightened susceptibility to infection. Seizure disorders and mental dysfunction may indicate neurologic damage. Central nervous system (CNS) involvement may produce emotional instability, psychosis, and organic mental syndrome. Headaches, irritability, and depression are common. (See *Signs of systemic lupus erythematosus*, page 417.)

Signs of Systemic Lupus Erythematosus

Diagnosing systemic lupus erythematosus (SLE) is difficult because SLE commonly mimics

other diseases; symptoms may be vague and vary greatly from patient to patient.

The revised criteria for SLE must include four or more of the following signs:

- abnormal titer of antinuclear antibody
- hemolytic disorder
- malar rash
- discoid rash
- arthritis
- oral ulcerations
- photosensitivity
- serositis
- renal disorder
- neurologic disorder
- immunologic disorder

Diagnosis

Diagnostic tests for patients with SLE include a CBC with differential (for signs of anemia and decreased WBC count); platelet count (may be decreased); ESR (commonly elevated); and serum electrophoresis (may show hypergammaglobulinemia).

Specific tests for SLE include:

- ANA panel, including anti-deoxyribonucleic acid (DNA) and anti-Smith antibodies—generally positive for lupus alone. (Because the anti-DNA test is rarely positive in other conditions, it's the most specific test for SLE. However, if the patient is in remission, anti-DNA may be reduced or absent [correlates with disease activity, especially renal involvement, and helps monitor response to therapy]. Other tests may be performed as needed to rule out other disorders.)
- urine studies—may show RBCs and WBCs, urine casts and sediment, and significant protein loss (>0.5 g/24 hours)
- blood studies—decreased serum complement (C3 and C4) levels indicate active disease
- chest X-ray—may show pleurisy or lupus pneumonitis
- electrocardiogram—may show conduction defect with cardiac involvement or pericarditis
- kidney biopsy—determines disease stage and extent of renal involvement

Some patients show a positive lupus anticoagulant test and a positive anticardiolipin test. Such patients are prone to antiphospholipid syndrome (thrombosis and thrombocytopenia).

Treatment

Patients with mild disease require little or no medication. NSAIDs, including aspirin, control arthritis symptoms in many patients. Skin lesions need topical treatment. Corticosteroid creams are recommended for acute lesions.

Refractory skin lesions are treated with intralesional corticosteroids or antimalarials such as hydroxychloroquine. Because hydroxychloroquine can cause retinal damage, such treatment requires ophthalmologic examination every 6 months.

Corticosteroids remain the treatment of choice for systemic symptoms of SLE, for acute generalized exacerbations, or for serious disease related to vital organ systems, such as pleuritis, pericarditis, lupus nephritis, vasculitis, and CNS involvement. Initial doses equivalent to 60 mg or more of prednisone often bring noticeable improvement within 48 hours. As soon as

symptoms are under control, steroid dosage is tapered slowly. (Rising serum complement levels and decreasing anti-DNA titers indicate patient response.) Diffuse proliferative glomerulonephritis, a major complication of SLE, requires treatment with large doses of steroids. If renal failure occurs, dialysis or kidney transplant may be necessary. In some patients, cytotoxic drugs may delay or prevent deteriorating renal status. Antihypertensive drugs and dietary changes may also be warranted in renal disease. Antimalarials are helpful in treating skin, musculoskeletal, and systemic effects. For more serious cases of SLE, immunosuppressants may aid patients who have not responded to other drugs.

The photosensitive patient should wear protective clothing (hat, sunglasses, long sleeves, and slacks) and use a screening agent, with a sun protection factor of at least 15, when outdoors. Because SLE usually strikes females of childbearing age, questions about pregnancy commonly arise. Available evidence indicates that a woman with SLE can have a safe, successful pregnancy if the patient has no serious renal or neurologic impairment.

Special Considerations

Careful assessment, supportive measures, emotional support, and patient education are all important parts of the care plan for patients with SLE.

- Watch for constitutional symptoms: joint pain or stiffness, weakness, fever, fatigue, and chills. Observe for dyspnea, chest pain, and any edema of the extremities. Note the size, type, and location of skin lesions. Check urine for hematuria, scalp for hair loss, and skin and mucous membranes for petechiae, bleeding, ulceration, pallor, and bruising.
- Provide a balanced diet. Renal involvement may mandate a low-sodium, low-protein diet.
- Urge the patient to get plenty of rest. Schedule diagnostic tests and procedures to allow adequate rest. Explain all tests and procedures. Tell the patient that several blood samples are needed initially, then periodically, to monitor progress.
- Apply heat packs to relieve joint pain and stiffness. Encourage regular exercise to maintain full ROM and prevent contractures. Teach ROM exercises as well as body alignment and postural techniques. Arrange for physical therapy and occupational counseling as appropriate.
- Explain the expected benefit of prescribed medications. Watch for adverse effects, especially when the patient is taking high doses of corticosteroids.
- Advise the patient receiving cyclophosphamide to maintain adequate hydration. If prescribed, give mesna to prevent hemorrhagic cystitis and ondansetron to prevent nausea and vomiting.
- Monitor vital signs, intake and output, weight, and laboratory reports. Check pulse rates and observe for orthopnea. Check stools and GI secretions for blood.
- Observe for hypertension, weight gain, and other signs of renal involvement.
- Assess for signs of neurologic damage: personality change, paranoid or psychotic behavior, ptosis, or diplopia. Take seizure precautions. If Raynaud phenomenon is present, warm and protect the patient's hands and feet.
- Offer cosmetic tips such as suggesting the use of hypoallergenic makeup and refer the patient to a hairdresser who specializes in scalp disorders.
- Advise the patient to purchase medications in quantity, if possible. Warn against "miracle" drugs for relief of arthritis symptoms.
- Refer the patient to the Lupus Foundation of America and the Arthritis Foundation as needed.

FIBROMYALGIA SYNDROME

Fibromyalgia syndrome (FMS), previously called fibrositis, is a diffuse pain syndrome and one

of the most common causes of chronic musculoskeletal pain. It's characterized by diffuse musculoskeletal pain, daily fatigue, and poor-quality sleep, along with multiple tender points on examination (in specific areas). More women than men are affected, and although FMS may occur at almost any age, the peak incidence is in patients between ages 20 and 60.

FMS has also been reported in children, who have more diffuse pain and a higher incidence of sleep disturbances than adult patients. They may have fewer tender points and typically improve after 2 to 3 years of follow-up.

Causes and Incidence

The cause of FMS is unknown, but it may be a primary disorder or occur in association with an underlying disease, such as SLE, RA, osteoarthritis, and sleep apnea syndrome.

The pain is located mainly in muscle areas, but no distinct abnormalities have been documented on microscopic evaluation of biopsies of tender points when compared with normal muscle. One theory suggests that blood flow to the muscle is decreased (because of poor muscle aerobic conditioning, rather than other physiologic abnormalities); another suggests cerebral blood flow in the thalamus and caudate nucleus is decreased, leading to a lowered pain threshold. Still other theories suggest that the cause lies in endocrine dysfunction, such as abnormal pituitary–adrenal axis responses, or in abnormal levels of the neurotransmitter serotonin in brain centers, which affect pain and sleep. Abnormal functioning of other pain-processing pathways may also be involved.

Considerable overlap of symptoms with other pain syndromes, such as chronic fatigue syndrome (CFS), raises the question of association with microbial infection, such as parvovirus B19.

The development of FMS may be multifactorial and influenced by stress (physical and mental), physical conditioning, poor-quality sleep, neuroendocrine factors, psychiatric factors, and possibly, hormonal factors (explaining the predominance in women).

Pathophysiology

Fibromyalgia is currently understood to be a disorder of central pain processing or a syndrome of central sensitivity. Research has provided evidence for altered functional connectivity and chemistry in the pain-processing system of the brain.

Complications

- Mental fog
- Constant pain
- Fatigue
- Lack of sleep
- Depression
- Death from suicide or injury

Signs and Symptoms

The primary symptom is diffuse, dull, aching pain that's typically concentrated across the neck and shoulders as well as in the lower back and proximal limbs. It can involve all body quadrants (bilateral upper trunk and arms, and bilateral lower trunk and legs) and typically is worse in the morning, when it's associated with stiffness. The pain can vary from day to day and can be exacerbated by stress, lack of sleep, weather changes, and inactivity.

Sleep disturbance and fatigue are commonly reported. The patient awakens feeling fatigued and remains so throughout the day. Fatigue is commonly present from a half hour to several hours after rising in the morning and can last for the rest of the day.

Other associated features that can occur with FMS include irritable bowel syndrome, tension headaches, puffy hands (sensation of hand swelling, especially in the morning), and paresthesia.

Diagnosis

FMS is diagnosed in a patient with characteristic symptoms, multiple tender points on examination, and exclusion of other illnesses that can cause similar features. Tender points are elicited by applying a moderate amount of pressure to specific locations. This examination can be fairly subjective, but many FMS patients with true tender points wince or withdraw when pressure is applied at a certain intensity. Nontender control points can also be tested to assess for conversion reactions (psychogenic rheumatism), in which patients hurt everywhere or exhibit other psychosomatic illnesses. (See *Tender points of fibromyalgia*.)

Tender points of fibromyalgia

The patient with fibromyalgia may report specific areas of tenderness. These areas are indicated in the illustrations below.

Occiput
(suboccipital
muscle insertions)

Trapezius
(midpoint of the
upper border)

Supraspinatus
(above the med-
ial border of the
scapular spine)

Gluteal
(upper
outer
quadrants
of buttocks)

Greater
trochanter
(posterior of the
trochanteric
prominence)

Low cervical
(anterior
aspects of the
intertransverse
spaces
at C5 to C7)

Second rib
(second
costochondral
junctions)

Lateral
epicondyle
(¾″ [2 cm]
distal to the
epicondyles)

Knee (medial
fat pad
proximal to
the joint line)

Treatment

NSAIDs and acetaminophen may help relieve the pain and stiffness of fibromyalgia. Antidepressants such as duloxetine and milnacipran may be used to lessen pain and fatigue. Antiseizure drugs, including gabapentin and pregabalin, may aid in reducing fibromyalgia pain.

A physical therapist may assist in the management of FMS through the use of education, injection of tender points, massage therapy, and ultrasound treatments for particular problem areas. In a few studies, acupuncture, phototherapy, and mind-body exercises (such as yoga and tai chi) have been somewhat beneficial.

Special Considerations

◆ The most important aspect of FMS management is patient education. Patients must understand that although FMS pain can be severe and is often chronic, the syndrome is common and doesn't lead to deforming or life-threatening complications.

◆ A regular, low-impact aerobic exercise can be effective in improving the patient's muscle conditioning, energy level, and overall sense of well-being. The FMS patient should be taught

preexercise and postexercise stretching to minimize injury. Strongly encourage a low-intensity exercise program, such as walking, bicycling, or swimming, and to increase level of intensity as tolerated.

GOODPASTURE SYNDROME

In Goodpasture syndrome, hemoptysis and rapidly progressive glomerulonephritis follow the deposition of antibody against the alveolar and glomerular basement membrane (GBM). The prognosis improves with aggressive immunosuppressive and antibiotic therapy along with dialysis or renal transplantation.

Causes and Incidence

The cause of Goodpasture syndrome is unknown. Although some cases have been associated with exposure to hydrocarbons or type 2 influenza, many have no precipitating events. The high incidence of HLA DRW2 in these patients suggests a genetic predisposition.

This syndrome may occur at any age but is most common in men between ages 20 and 30. A second peak incidence occurs between ages 50 and 70, with men and women in this age group affected equally.

Pathophysiology

Abnormal production and deposition of antibody against GBM and alveolar basement membrane activate the complement and inflammatory responses, resulting in glomerular and alveolar tissue damage.

Complications

- Renal failure
- Pulmonary edema and hemorrhage

Signs and Symptoms

Goodpasture syndrome may initially cause malaise, fatigue, and pallor associated with severe iron deficiency anemia. Pulmonary findings range from slight dyspnea and cough with blood-tinged sputum to hemoptysis and frank pulmonary hemorrhage. Subclinical pulmonary bleeding may precede overt hemorrhage and renal disease by months or years. Usually, renal findings are subtler, although some patients note hematuria and peripheral edema.

Diagnosis

CONFIRMING DIAGNOSIS *Confirmation of Goodpasture syndrome requires measurement of circulating anti-GBM antibody by radioimmunoassay and linear staining of GBM and alveolar basement membrane by immunofluorescence.*

Immunofluorescence of alveolar basement membrane shows linear deposition of Ig as well as complement 3 and fibrinogen. Immunofluorescence of GBM also shows linear deposition of Ig combined with detection of circulating anti-GBM antibody. This finding distinguishes Goodpasture from other pulmonary-renal syndromes, such as Wegener granulomatosis, polyarteritis, and SLE.

A lung biopsy reveals interstitial and intra-alveolar hemorrhage with hemosiderin-laden

macrophages. Chest X-ray reveals pulmonary infiltrates in a diffuse, nodular pattern, and renal biopsy commonly shows focal necrotic lesions and cellular crescents.

Creatinine and BUN levels typically increase two to three times normal. Urinalysis may reveal RBCs and cellular casts, which typify glomerular inflammation. Granular casts and proteinuria may also be observed.

Treatment

Treatment aims to remove antibody by plasmapheresis and to suppress antibody production with immunosuppressive drugs, such as cyclophosphamide, to stop attacks by immune cells on the kidneys and lungs. Patients with renal failure may benefit from dialysis or transplantation. Aggressive ultrafiltration helps relieve pulmonary edema that may aggravate pulmonary hemorrhage. High-dose I.V. steroids also help control pulmonary hemorrhage.

Special Considerations

- Promote adequate oxygenation by elevating the bed's head and administering humidified oxygen. Encourage the patient to conserve their energy. Assess respirations and breath sounds regularly; note sputum quantity and quality.
- Monitor vital signs, ABGs, hematocrit, and coagulation studies.
- Transfuse blood and administer steroids as ordered. Observe closely for drug adverse effects.
- Assess renal function by monitoring symptoms, intake and output, daily weights, creatinine clearance, and BUN and creatinine levels.
- Tell the patient and the family what signs and symptoms to expect and how to relieve them. Carefully describe other treatment measures such as dialysis.

REACTIVE ARTHRITIS

A self-limiting syndrome associated with polyarthritis (dominant feature), urethritis, balanitis (inflammation of the glans penis), conjunctivitis, and mucocutaneous lesions, reactive arthritis (ReA), previously known as *Reiter syndrome*, appears to be related to infection, either venereal or enteric.

Causes and Incidence

The cause of ReA is unknown, but most cases follow venereal or enteric infection. Because 75% to 85% of patients with ReA test positive for the HLA-B27, genetic susceptibility is likely. ReA has followed infections caused by *Campylobacter, Salmonella, Yersinia,* and *Chlamydia* organisms.

This disease usually affects young males (ages 20 to 40); it's rare in females and children. However, due to the uncertainty of diagnosis and variations in the definition of this disorder, incidence is estimated at approximately 3.5 per 100,000 people. About 1% to 3% of all patients with nonspecific urethritis develop an episode of arthritis.

Pathophysiology

ReA is usually triggered by a GU or GI infection. Evidence indicates that a preceding *Chlamydia* respiratory infection may also trigger ReA. The frequency of ReA after enteric infection averages 1% to 4% but varies greatly, even among outbreaks of the same organism. Although severely symptomatic GI infections are associated with an increased risk of ReA, asymptomatic venereal infections more frequently cause this disease.

Complications

- Chronic heel pain
- Ankylosing spondylitis
- Persistent joint pain and swelling

Signs and Symptoms

The patient with ReA may complain of dysuria, hematuria, urgent and frequent urination, and mucopurulent penile discharge, with swelling and reddening of the urethral meatus. Small painless ulcers may erupt on the glans penis (balanitis). These coalesce to form irregular patches that cover the penis and scrotum. The patient may also experience suprapubic pain, fever, anorexia with weight loss, and other GU complications, such as prostatitis and hemorrhagic cystitis.

Arthritic symptoms usually follow GU or enteric symptoms and last from 2 to 4 months. Asymmetrical and extremely variable polyarticular arthritis is most common, with a tendency to develop in weight-bearing joints of the legs and sometimes in the low back or sacroiliac joints. The arthritis is usually acute, with warm, erythematous, and painful joints, but it may be mild, with minimal synovitis. Muscle wasting is common near affected joints. Fingers and toes may swell and appear sausagelike.

Ocular symptoms include mild bilateral conjunctivitis, possibly complicated by keratitis, iritis, retinitis, or optic neuritis. In severe cases, burning, itching, and profuse mucopurulent discharge are possible.

In 30% of patients, skin lesions (keratoderma blennorrhagica) develop 4 to 6 weeks after onset of other symptoms and may last for several weeks. These macular to hyperkeratotic lesions commonly resemble those of psoriasis. They usually occur on the palms and soles but can develop anywhere on the trunk, extremities, or scalp. Nails become thick, opaque, and brittle; keratic debris accumulates under the nails. In many patients, painless, transient ulcerations erupt on the buccal mucosa, palate, and tongue.

Diagnosis

Nearly all patients with ReA test positive for HLA-B27 and have an elevated WBC count and ESR. Mild anemia may develop. Urethral discharge and synovial fluid contain many WBCs, mostly polymorphonuclear leukocytes. Synovial fluid is high in complement and protein and is grossly purulent. Cultures of discharge and synovial fluid rule out other causes such as gonococci.

During the first few weeks, X-rays are normal and may remain so, but some patients may show osteoporosis in inflamed areas. If inflammation persists, X-rays may show erosions of the small joints, periosteal proliferation (new bone formation) of involved joints, and calcaneal spurs.

Treatment

No specific treatment exists for ReA. Most patients recover in 2 to 16 weeks. About 50% of patients have recurring acute attacks, whereas the rest follow a chronic course, experiencing continued synovitis and sacroiliitis. In acute stages, limited weight bearing or complete bed rest may be necessary.

Any underlying infection should be treated with antibiotics. Arthritis is treated with nonsteroidal anti-inflammatory agents and pain relievers. Local administration of corticosteroids

may help relieve persistent inflammation in one joint. Physical therapy includes ROM and strengthening exercises and the use of padded or supportive shoes to prevent contractures and foot deformities. Therapy to suppress the immune system may be considered in severe cases but is limited due to toxic adverse effects.

Special Considerations

- Explain ReA. Discuss the medications and their possible adverse effects. Warn the patient to take medications with meals or milk to prevent GI bleeding.
- Encourage normal daily activity and moderate exercise. Suggest a firm mattress and encourage good posture and body mechanics.
- Arrange for occupational counseling if the patient has severe or chronic joint impairment.

SCLERODERMA

Scleroderma, also known as *systemic sclerosis*, is a diffuse connective tissue disease characterized by fibrotic, degenerative, and occasionally inflammatory changes in skin, blood vessels, synovial membranes, skeletal muscles, and internal organs (especially the esophagus, intestinal tract, thyroid, heart, lungs, and kidneys).

This disease can be classified as systemic (involving skin, blood vessels, and internal organs) or localized (limited to skin and tissues). Each classification has distinctive forms.

Systemic forms include:

- *limited cutaneous systemic sclerosis* (*or CREST syndrome*)—a benign form characterized by calcinosis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia
- *diffuse cutaneous systemic sclerosis*—characterized by generalized skin thickening and invasion of internal organs
- *systemic sine scleroderma*—a rare form of the disease, includes involvement of internal organs but does not have skin involvement

Localized forms include:

- *morphea*—characterized by patchy skin changes with a droplike appearance
- *linear scleroderma*—characterized by a band of thickened skin on the face or extremities that severely damages underlying tissues, causing atrophy and deformity (most common in childhood)

Other forms include *chemically induced localized scleroderma, eosinophilia myalgia syndrome* (recently associated with ingestion of L-tryptophan), *toxic oil syndrome* (associated with contaminated oil), and *graft-versus-host disease*.

Causes and Incidence

The cause of scleroderma is unknown. Risk factors include exposure to silica dust and polyvinyl chloride.

Scleroderma affects 300,000 people in the United States, more women than men, especially between ages 30 and 50. About 30% of patients with scleroderma die within 5 years of onset.

Complications

- Arrhythmias
- Dyspnea

- Malignant hypertension

Pathophysiology

The pathogenesis of systemic sclerosis is complex. Increasing evidence suggests an interaction between environmental and genetic factors, with a regulatory epigenetic mechanism involving changes in the expression of DNA and microRNA.

The clinical and pathologic manifestations result from three distinct processes: (1) severe fibroproliferative vascular lesions of small arteries and arterioles, (2) excessive and often progressive deposition of collagen and other extracellular matrix macromolecules in skin and various internal organs, and (3) alterations in humoral and cellular immunity. It is not clear which of these processes is of primary importance or how they are temporally related during the development and progression of the disease.

Complications

- Compromised circulation due to thickened vessels
- Decreased food intake or weight loss due to GI symptoms
- Arrhythmias
- Dyspnea
- Malignant hypertension

Signs and Symptoms

Scleroderma typically begins with Raynaud phenomenon—blanching, cyanosis, and erythema of the fingers and toes in response to stress or exposure to cold. Progressive phalangeal resorption may shorten the fingers.

Compromised circulation, which results from abnormal thickening of the arterial intima, may cause slowly healing ulcerations on the tips of the fingers or toes that may lead to gangrene. Raynaud phenomenon may precede scleroderma by months or years.

Later symptoms include pain, stiffness, and finger and joint swelling. Skin thickening produces taut, shiny skin over the entire hand and forearm. Facial skin also becomes tight and inelastic, causing a masklike appearance and "pinching" of the mouth. As tightening progresses, contractures may develop.

GI dysfunction causes frequent reflux, heartburn, dysphagia, and bloating after meals. These symptoms may cause the patient to decrease food intake and lose weight. Other GI effects include abdominal distention, diarrhea, constipation, and malodorous floating stools.

Diagnosis

Typical cutaneous changes provide the first clue to diagnosis. Results of diagnostic tests include:

- blood studies—slightly elevated ESR, positive RF in 25% to 35% of patients, and positive ANA test
- chest X-rays—bilateral basilar pulmonary fibrosis
- electrocardiogram—possible nonspecific abnormalities related to myocardial fibrosis
- GI X-rays—distal esophageal hypomotility and stricture, duodenal loop dilation, small-bowel malabsorption pattern, and large diverticula
- hand X-rays—terminal phalangeal tuft resorption, subcutaneous calcification, and joint space narrowing and erosion

- pulmonary function studies—decreased diffusion and vital capacity and restrictive lung disease
- skin biopsy—may show changes consistent with the disease's progress, such as marked thickening of the dermis and occlusive vessel changes
- urinalysis—proteinuria, microscopic hematuria, and casts (with renal involvement)

Treatment

Currently, no cure exists for scleroderma. Treatment aims to preserve normal body functions and minimize complications. Use of an immunosuppressant is a common palliative measure. Corticosteroids, NSAIDs, cyclooxygenose-2 inhibitors, and analgesics help to alleviate joint pain and stiffness. Blood platelet levels need to be monitored throughout drug therapy.

Other treatments vary according to symptoms:

- chronic digital ulcerations—a digital plaster cast to immobilize the area, minimize trauma, and maintain cleanliness; possibly surgical debridement
- esophagitis with stricture—antacids, histamine-2 (H_2) receptor agonists, proton pump inhibitors, periodic esophageal dilation, and a soft, bland diet
- hand debilitation—physical therapy to maintain function and promote muscle strength, heat therapy to relieve joint stiffness, and patient teaching to make performance of daily activities easier
- Raynaud phenomenon—various vasodilators and antihypertensive agents (such as calcium channel blockers, angiotensin II receptor antagonists, or angiotensin-converting enzyme inhibitors), intermittent cervical sympathetic blockade, or, rarely, thoracic sympathectomy
- scleroderma kidney (with malignant hypertension and impending renal failure)—dialysis, antihypertensives, and calcium channel blockers
- small-bowel involvement (diarrhea, pain, malabsorption, and weight loss)—broad-spectrum antibiotics, such as erythromycin or tetracycline, to counteract bacterial overgrowth in the duodenum and jejunum related to hypomotility

Special Considerations

- Assess the patient's motion restrictions, pain, vital signs, intake and output, respiratory function, and daily weight.
- Because of compromised circulation, warn against finger-stick blood tests.
- Remember that air-conditioning may aggravate Raynaud phenomenon.
- Help the patient and family adjust to the patient's new body image and to the limitations and dependence that these changes cause.
- Teach the patient to avoid fatigue by pacing activities and organizing schedules to include necessary rest.
- Stress to the patient and family the need to accept the fact that this condition is incurable. Encourage them to express their feelings and help them cope with their fears and frustrations by offering information about the disease, its treatment, and relevant diagnostic tests.
- Whenever possible, let the patient participate in treatment by measuring their own intake and output, planning their own diet, assisting in dialysis, performing their own heat therapy, and doing prescribed exercises.
- Direct the patient to seek out support groups, which can be found in every state. Instruct the patient to call 1-800-722-HOPE or go to www.scleroderma.org.

VASCULITIS

Vasculitis includes a broad spectrum of disorders characterized by inflammation and necrosis of blood vessels. Its clinical effects, which reflect tissue ischemia caused by blood flow obstruction, and confirming laboratory procedures depend on the vessels involved. The prognosis is variable. For example, hypersensitivity vasculitis is usually a benign disorder limited to the skin, but more extensive polyarteritis nodosa can be rapidly fatal. Vasculitis can occur at any age, except for mucocutaneous lymph node syndrome, which occurs only during childhood. Vasculitis may be a primary disorder or occur secondary to other disorders, such as RA or SLE.

Causes and Incidence

How vascular damage develops in vasculitis isn't well understood. It has been associated with a history of serious infectious disease, such as hepatitis B or bacterial endocarditis, and high-dose antibiotic therapy.

Pathophysiology

Current theory holds that it's initiated by excessive circulating antigen, which triggers the formation of soluble antigen–antibody complexes. These complexes can't be effectively cleared by the reticuloendothelial system, so they're deposited in blood vessel walls (type III hypersensitivity). Increased vascular permeability associated with the release of vasoactive amines by platelets and basophils enhances such deposition. The deposited complexes activate the complement cascade, resulting in chemotaxis of neutrophils, which release lysosomal enzymes. In turn, these enzymes cause vessel damage and necrosis, which may precipitate thrombosis, occlusion, hemorrhage, and ischemia.

   Another mechanism that may contribute to vascular damage is the cell-mediated (T-cell) immune response. In this response, circulating antigen triggers the release of soluble mediators by sensitized lymphocytes, which attracts macrophages. The macrophages release intracellular enzymes, which cause vascular damage. They can also transform into the epithelioid and multinucleated giant cells that typify the granulomatous vasculitides. Phagocytosis of immune complexes by macrophages enhances granuloma formation.

Complications

- Renal failure
- Renal hypertension
- Glomerulitis
- Fibrous scarring of lung tissue
- Stroke
- GI bleeding
- Necrotizing vasculitis
- Spontaneous hemorrhage
- Intestinal obstruction
- Myocardial infarction
- Pericarditis
- Rupture of mesenteric aneurysms

Signs and Symptoms

The clinical effects of vasculitis vary according to the blood vessels involved.

Diagnosis

Laboratory tests performed to confirm a diagnosis of vasculitis depend on the blood vessels involved. (See *Types of vasculitis*, pages 426 to 428.)

Types of vasculitis

Vasculitis occurs in various forms; diagnosis depends on the presenting signs and symptoms.

Type	Vessels involved	Signs and symptoms	Diagnosis
Polyarteritis nodosa	Small to medium arteries throughout the body (Lesions tend to be segmental, occur at bifurcations and branchings of arteries, and spread distally to arterioles. In severe cases, lesions circumferentially involve adjacent veins.)	Hypertension, abdominal pain, myalgias, headache, joint pain, and weakness	History of symptoms; elevated erythrocyte sedimentation rate (ESR) and blood urea nitrogen and creatinine levels; leukocytosis; anemia; thrombocytosis; depressed C3 complement; rheumatoid factor > 1:60; circulating immune complexes; tissue biopsy showing necrotizing vasculitis
Allergic angiitis and granulomatosis (Churg–Strauss syndrome)	Small to medium arteries (including arterioles, capillaries, and venules), mainly of the lungs, kidneys, but also other organs	Resembles polyarteritis nodosa with hallmark of severe pulmonary involvement	History of asthma; eosinophilia; increased immunoglobulin (Ig) E level; tissue biopsy showing granulomatous inflammation with eosinophilic infiltration
Polyangiitis overlap syndrome (microscopic polyangiitis)	Small to medium arteries (including arterioles, capillaries, and venules) of the lungs and other organs	Combines symptoms of polyarteritis nodosa, allergic angiitis, and granulomatosis	Possible history of allergy; eosinophilia; tissue biopsy showing granulomatous inflammation with eosinophilic infiltration
Wegener granulomatosis	Medium to large vessels of the respiratory tract and kidney; may also involve small arteries and veins	Fever, pulmonary congestion, cough, malaise, anorexia, weight loss, and mild to severe hematuria	Tissue biopsy showing necrotizing vasculitis with granulomatous inflammation; leukocytosis; elevated ESR and immunoglobulin IgA and IgG levels; low titer rheumatoid factor; circulating immune complexes; antineutrophil cytoplasmic antibody in >90% of patients
Temporal arteritis (giant cell arteritis)	Medium to large arteries, most commonly branches of the carotid artery	Fever, myalgia, jaw claudication, visual changes, and headache (associated with polymyalgia rheumatica syndrome)	Decreased hemoglobin (Hb) level; elevated ESR; tissue biopsy showing panarteritis with infiltration of mononuclear cells, giant cells within vessel wall, fragmentation of internal elastic lamina, and proliferation of intima
Takayasu arteritis (aortic arch syndrome)	Medium to large arteries, particularly the aortic arch, its branches and, possibly, the pulmonary artery	Malaise, pallor, nausea, night sweats, arthralgias, anorexia, weight loss, pain or paresthesia distal to affected area, bruits, loss of distal pulses, syncope and, if a carotid artery is involved, diplopia and transient blindness; may progress to	Decreased Hb level; leukocytosis; positive lupus erythematosus cell preparation and elevated ESR; arteriography showing calcification and obstruction of affected vessels; tissue biopsy showing inflammation of adventitia and intima of vessels, and thickening of vessel walls

		heart failure or stroke	
Hypersensitivity vasculitis	Small vessels, especially of the skin	Palpable purpura, papules, nodules, vesicles, bullae, ulcers, or chronic or recurrent urticaria	History of exposure to antigen, such as a microorganism or drug; tissue biopsy showing leukocytoclastic angiitis, usually in postcapillary venules, with infiltration of polymorphonuclear leukocytes, fibrinoid necrosis, and extravasation of erythrocytes
Mucocutaneous lymph node syndrome (Kawasaki disease)	Small to medium vessels, primarily of the lymph nodes; may progress to involve coronary arteries	Fever; nonsuppurative cervical adenitis; edema; congested conjunctivae; erythema of oral cavity, lips, and palms; and desquamation of fingertips; may progress to arthritis, myocarditis, pericarditis, myocardial infarction, and cardiomegaly	History of symptoms; elevated ESR; tissue biopsy showing intimal proliferation and infiltration of vessel walls with mononuclear cells; echocardiography necessary
Behçet disease	Small vessels, primarily of the mouth and genitalia, but also of the eyes, skin, joints, GI tract, and central nervous system	Recurrent oral ulcers, eye lesions, genital lesions, and cutaneous lesions	History of symptoms
Henoch–Schönlein purpura	Any blood vessel in the skin	Red to purple papule skin lesions, pain, infarction, joint pain, numbness, weakness, fever, fatigue, dysmenorrhea, heartburn, dysphonia, and dysphagia	History of symptoms; biopsy showing leukocytoclastic vasculitis; abdominal imaging studies demonstrating decreased motility and dilated loops of bowel; and elevated ESR
Rheumatoid vasculitis	Small and medium vessels, especially of the eyes, skin, hands, and feet	Digital ischemia of fingers and toes, scleritis, fever, weight loss, wrist drop	History of rheumatoid arthritis, symptoms; elevated ESR or C-reactive protein and rheumatoid factors; low antinuclear antibody

Treatment

Treatment of vasculitis aims to minimize irreversible tissue damage associated with ischemia. In primary vasculitis, treatment may involve removal of an offending antigen or use of anti-inflammatory or immunosuppressant drugs. For example, antigenic drugs, food, and other environmental substances should be identified and eliminated, if possible.

Drug therapy in primary vasculitis commonly involves low-dose cyclophosphamide (2 mg/kg orally daily) with daily corticosteroids. In rapidly fulminant vasculitis, cyclophosphamide dosage may be increased to 4 mg/kg daily for the first 2 to 3 days, followed by the regular dose. Prednisone should be given in a dose of 1 mg/kg/day in divided doses for 7 to 10 days, with consolidation to a single morning dose by 2 to 3 weeks. When the vasculitis appears to be in remission or when prescribed cytotoxic drugs take full effect, corticosteroids are tapered down to a single daily dose. Finally, an alternate-day schedule of steroids may continue for 3 to 6 months before slow discontinuation of steroids.

In secondary vasculitis, treatment focuses on the underlying disorder.

Special Considerations

◆ Assess patients with Wegener granulomatosis for dry nasal mucosa. Instill nose drops to

lubricate the mucosa and help diminish crusting, or irrigate the nasal passages with warm normal saline solution.

◆ Monitor vital signs. Use a Doppler ultrasonic flowmeter, if available, to auscultate blood pressure in patients with Takayasu arteritis, whose peripheral pulses are generally difficult to palpate.

◆ Monitor intake and output. Check daily for edema. Keep the patient well hydrated (3 L daily) to reduce the risk of hemorrhagic cystitis associated with cyclophosphamide therapy.

◆ Provide emotional support to help the patient and family cope with an altered body image—the result of the disorder or its therapy (e.g., Wegener granulomatosis may be associated with saddle nose, steroids may cause weight gain, and cyclophosphamide may cause alopecia).

◆ Teach the patient how to recognize drug adverse effects. Monitor the patient's WBC count during cyclophosphamide therapy to prevent severe leukopenia.

POLYMYOSITIS AND DERMATOMYOSITIS

Diffuse, inflammatory myopathies of unknown cause, polymyositis and dermatomyositis produce symmetrical weakness of striated muscle—primarily proximal muscles of the shoulder and pelvic girdles, neck, and pharynx. In dermatomyositis, such muscle weakness is accompanied by cutaneous involvement. These diseases usually progress slowly, with frequent exacerbations and remissions. They occur in twice as many females as males (except dermatomyositis with malignant tumor, which is most common in males older than age 40).

The prognosis usually worsens with age. Death commonly occurs from associated cancer, respiratory disease, or heart failure or from the adverse effects of drug therapy. On the other hand, 80% to 90% of affected children regain normal function with proper treatment. However, if untreated, childhood dermatomyositis may progress rapidly to disabling contractures and muscle atrophy.

Causes and Incidence

Although the cause of polymyositis remains puzzling, researchers believe that it may result from an autoimmune reaction. Polymyositis and dermatomyositis may be associated with other disorders, such as allergic reactions; SLE; scleroderma; RA; Sjögren syndrome; carcinomas of the lung, breast, or other organs; and systemic viral infection; or D-penicillamine administration.

Annual incidence is 5 to 10 in 100,000 people.

Pathophysiology

Presumably, the patient's T cells inappropriately recognize muscle fiber antigens as foreign and attack muscle tissue, causing diffuse or focal muscle fiber degeneration. (Regeneration of new muscle cells then follows, producing remission.)

Complications

◆ Rhabdomyolysis
◆ Interstitial lung disease
◆ Cardiovascular disease
◆ Infection
◆ Dysphagia
◆ Overlapping autoimmune diseases

Signs and Symptoms

Polymyositis begins acutely or insidiously with muscle weakness, tenderness, and discomfort. It affects proximal muscles more than distal muscles and impairs performance of ordinary activities. The patient may have trouble getting up from a chair, combing their hair, reaching into a high cupboard, climbing stairs, or even raising their head from a pillow. Other muscular symptoms include inability to move against resistance, proximal dysphagia, dysphonia, and difficulty breathing.

In dermatomyositis, an erythematous rash usually erupts on the face, neck, upper back, chest, and arms as well as around the nail beds. A characteristic heliotrope rash appears on the eyelids, accompanied by periorbital edema. Gottron papules (violet, flat-topped lesions) may appear on the interphalangeal joints.

Diagnosis

CONFIRMING DIAGNOSIS *Diagnosis requires a muscle biopsy that shows necrosis, degeneration, regeneration, and interstitial chronic lymphocytic infiltration. Magnetic resonance imaging and an electrocardiogram, as well as the use of electromyography, aid in diagnosis.*

Other tests differentiate polymyositis from diseases that cause similar muscular or cutaneous symptoms, such as muscular dystrophy, advanced trichinosis, psoriasis, seborrheic dermatitis, and SLE.

Typical laboratory results in polymyositis include elevated ESR, elevated WBC count, and elevated muscle enzyme levels (creatine kinase, aldolase, and serum aspartate aminotransferase) not attributable to hemolysis of RBCs or hepatic or other diseases. Other laboratory results include increased urine creatine level (>150 mg/24 hours), decreased creatinine level, and positive antinuclear antibodies. Electromyography shows polyphasic short-duration potentials, fibrillation (positive spike waves), and bizarre high-frequency repetitive changes.

Treatment

High-dose corticosteroid therapy relieves inflammation and lowers muscle enzyme levels. Within 2 to 6 weeks after treatment, serum muscle enzyme levels usually return to normal, and muscle strength improves, permitting a gradual tapering down of corticosteroid dosage. If the patient responds poorly to corticosteroids, treatment may include cytotoxic or immunosuppressant drugs. Supportive therapy includes bed rest during the acute phase, ROM exercises to prevent contractures, analgesics and application of heat to relieve painful muscle spasms, and diphenhydramine to relieve itching. Patients older than age 40 need thorough assessment for coexisting cancer.

Special Considerations

- Assess level of pain, muscle weakness, and ROM daily. Give analgesics as needed.
- If the patient is confined to bed, prevent pressure ulcers by giving good skin care. To prevent footdrop and contractures, apply high-topped sneakers, and assist with passive ROM exercises at least four times daily. Teach the patient's family how to perform these exercises on the patient.
- If 24-hour urine collection for creatine or creatinine is necessary, make sure your coworkers

understand the procedure. When you assist with muscle biopsy, make sure the biopsy isn't taken from an area of recent needle insertion.

- If the patient has a rash, warn the patient not to scratch, as it may cause infection. If antipruritic medication doesn't relieve severe itching, apply tepid sponges or compresses.
- Encourage the patient to feed and dress to the best of their ability but to ask for help when needed. Advise the patient to pace activities to counteract muscle weakness. Encourage the patient to express anxiety. Ease the fear of dependence by reassuring the patient that muscle weakness is probably temporary.
- Explain the disease to the patient and family. Prepare them for diagnostic procedures and possible adverse effects of corticosteroid therapy (weight gain, hirsutism, hypertension, edema, amenorrhea, purplish striae, glycosuria, acne, and easy bruising). Advise a low-sodium diet to prevent fluid retention. Emphatically warn against abruptly discontinuing corticosteroids. Reassure the patient that steroid-induced weight gain will diminish when the drug is discontinued.

Immunodeficiency

AGAMMAGLOBULINEMIA

Agammaglobulinemia is a recessive, congenital disorder in which all five Igs—IgM, IgG, IgA, IgD, and IgE—and circulating B cells are absent or deficient but T cells are intact. It's also called *Bruton agammaglobulinemia* and *X-linked agammaglobulinemia*. Affecting males almost exclusively, this disorder causes severe, recurrent infections during infancy. Prognosis is good with early treatment, except in infants who develop polio or persistent viral infection. Infection usually causes some permanent damage, especially in the neurologic or respiratory system.

Causes and Incidence

Humoral (B-cell) immune deficiencies account for 50% of all primary immunodeficiencies. IgA deficiency is the most common antibody deficiency syndrome, followed by common variable immunodeficiency (CVID). The incidence of these two disorders is 1 in 700 persons. Selective IgM deficiency is rare. IgG4 deficiency occurs in 10% to 15% of the population.

Pathophysiology

B cells and B-cell precursors may be present in the bone marrow and peripheral blood, but a mutation in the B-cell protein tyrosine kinase keeps B cells from maturing and secreting Ig. Without protective Igs, the affected person develops repeated infections.

Complications

- Chronic otitis media
- Chronic sinusitis
- Encephalitis
- Failure to thrive
- Hepatitis
- Enteroviral infections
- Meningitis

Signs and Symptoms

Typically, the infant with agammaglobulinemia is asymptomatic until age 6 months, when transplacental maternal Igs that provided immunity have been depleted. The patient then develops recurrent bacterial otitis media, pneumonia, dermatitis, bronchitis, and meningitis—usually caused by pneumococci, streptococci, *Haemophilus influenzae*, or other gram-negative organisms. Purulent conjunctivitis, abnormal dental caries, and polyarthritis resembling RA may also occur. Severe malabsorption associated with infestation by *Giardia lamblia* may retard development. Despite recurrent infections, lymphadenopathy and splenomegaly are usually absent.

Diagnosis

The diagnosis of agammaglobulinemia can be especially difficult because recurrent infections are common even in normal infants (many of whom don't start producing their own antibodies until age 18 to 20 months). Immunoelectrophoresis and quantitative Igs (nephelometry) confirm decreased levels, or a total absence, of IgM, IgA, and IgG in the serum. IgG is usually less than 200 mg/dL, and IgA and IgM are almost unmeasurable. However, diagnosis by this method usually isn't possible until the infant is 9 months old. Antigenic stimulation confirms an inability to produce specific antibodies, although cellular immunity remains intact. Flow cytometry may be helpful in measuring circulating B lymphocytes.

Treatment

Treatment aims to prevent or control infections and to boost the patient's immune response. Injection of immune serum globulin (gamma globulin, IV Ig) helps maintain immune response. Because these injections are painful, give them deep into a large muscle mass, such as the gluteal or thigh muscles, and massage well. If the dosage is more than 1.5 mL, divide it and inject it into more than one site; for frequent injections, rotate the injection sites. Because immune globulin is composed primarily of IgG, the patient may also need fresh frozen plasma infusions to provide IgA and IgM. Mucosal secretory IgA can't be replaced by therapy, resulting in crippling pulmonary disease in many patients.

The judicious use of antibiotics also helps combat infection; in some cases, chronic broad-spectrum antibiotics may be indicated. During acute infection, monitor the patient closely. Maintain adequate nutrition and hydration. Perform chest physiotherapy if required.

Special Considerations

- Carefully explain all treatment measures, and make sure the patient and family understand the disorder.
- Teach the patient and family how to recognize early signs of infection and counsel them to report such signs promptly. Advise them to have cuts and scrapes cleaned immediately. Warn them to avoid crowds and people who have active infections.
- Advise parents that live-virus vaccines are contraindicated due to the potential to cause infections.
- Suggest genetic counseling if parents have questions about vulnerability of future offspring.

COMMON VARIABLE IMMUNODEFICIENCY

CVID is characterized by progressive deterioration of B-cell (humoral) immunity, resulting in

increased susceptibility to infection.

Causes and Incidence

The cause of CVID is unknown.

Unlike agammaglobulinemia, this disorder (also known as *acquired hypogammaglobulinemia*) usually causes symptoms after infancy and childhood, between ages 25 and 40. It affects males and females equally and usually doesn't interfere with normal life span or normal pregnancy and offspring.

Pathophysiology

Most patients have a normal circulating B-cell count but defective synthesis or release of Igs. Many also exhibit progressive deterioration of T-cell (cell-mediated) immunity revealed by delayed hypersensitivity skin testing.

Complications

- Conjunctivitis
- Chronic sinusitis
- *Giardia lamblia* GI infestation
- Upper and lower respiratory tract infections
- Encephalitis
- Meningitis
- Hemolytic anemia

Signs and Symptoms

In CVID, pyogenic bacterial infections are characteristic but tend to be chronic rather than acute (as in agammaglobulinemia). Recurrent sinopulmonary infections, chronic bacterial conjunctivitis, and malabsorption (associated with infestation by *G. lamblia*) are usually the first clues to immunodeficiency.

CVID may be associated with autoimmune diseases, such as SLE, RA, hemolytic anemia, and pernicious anemia, and with cancers, such as leukemia and lymphoma.

Diagnosis

Characteristic diagnostic markers in this disorder are decreased serum Ig (IgM, IgA, and IgG) levels detected by immunoelectrophoresis, along with a normal circulating B-cell count. Antigenic stimulation confirms an inability to produce specific antibodies; cell-mediated immunity may be intact or delayed. X-rays usually show signs of chronic lung disease or sinusitis.

Treatment

Treatment and care of patients with CVID are essentially the same as for those with agammaglobulinemia.

Injection of immune globulin (usually weekly to monthly) helps maintain the immune response. Because these injections are painful, give them deep into a large muscle mass, such as the gluteal or thigh muscles, and massage well. If the dosage is more than 1.5 mL, divide the dose and inject it into more than one site; for frequent injections, rotate the injection sites. Because immune globulin is composed primarily of IgG, the patient may also need fresh frozen

plasma infusions to provide IgA and IgM.

Antibiotics are the mainstay for combating infection. Regular X-rays and pulmonary function studies help monitor lung infection; chest physiotherapy may be ordered to forestall or help clear such infection.

Special Considerations

- Teach the patient and family how to recognize early signs of infection and counsel them to report such signs promptly. Advise the patient to avoid crowds and people who have active infections.
- Stress the importance of good nutrition and regular follow-up care.

IGA DEFICIENCY

Total absence or severe deficiency of IgA, also known as *selective IgA deficiency*, is the most common primary Ig deficiency, appearing in as many as 1 in 400 to 1,000 people. IgA—the major Ig in human saliva, nasal and bronchial fluids, and intestinal secretions—guards against bacterial and viral reinfections. Consequently, IgA deficiency leads to chronic sinopulmonary infections, allergies, chronic diarrhea, GI diseases, and other disorders. The prognosis is good for patients who receive correct treatment, especially if they have no associated disorders.

Causes and Incidence

IgA deficiency seems to be linked to autosomal dominant or recessive inheritance. The disorder has familial trends and occurs frequently in immediate relatives of individuals with CVID. Congenital intrauterine infection with rubella, toxoplasmosis, or cytomegalovirus can result in selective IgA deficiency. Treatment for seizures with phenytoin and hydantoin, as well as Wilson disease (an inherited disorder treated with penicillamine), can result in temporarily acquired selective IgA deficiency. When the medications are stopped, the IgA level returns to normal. Some drugs, such as anticonvulsants, may cause transient IgA deficiency.

Pathophysiology

The presence of normal numbers of peripheral blood lymphocytes carrying IgA receptors and of normal amounts of other Igs suggests that B cells may not be secreting IgA, as they haven't matured into IgA-producing plasma cells.

Signs and Symptoms

Some IgA-deficient patients have no symptoms, possibly because they have extra amounts of low–molecular-weight IgM. This Ig takes over IgA function and helps maintain immunologic defenses. Among patients who develop symptoms, chronic sinopulmonary infection is the most common. Other effects are respiratory allergy, often triggered by infection; GI tract diseases, such as celiac disease, ulcerative colitis, and regional enteritis; autoimmune diseases, such as RA, SLE, immunohemolytic anemia, and chronic hepatitis; and malignant tumors, such as squamous cell carcinoma of the lungs, reticulum cell sarcoma, and thymoma.

Age of onset varies. Some IgA-deficient children with recurrent respiratory disease and middle ear inflammation may begin to synthesize IgA spontaneously as recurrent infections subside and their condition improves.

Diagnosis

Serum immunoelectrophoresis and quantitative immunologic analyses of patients with IgA deficiency show serum IgA levels below 7 mg/dL. Although IgA is usually absent from secretions in patients with IgA deficiency, levels may be normal in rare cases. IgE is normal, whereas IgM may be normal or elevated in serum and secretions. Normally absent low–molecular-weight IgM may be present.

Tests may also indicate autoantibodies and antibodies against IgG (RF), IgM, and bovine milk. Cell-mediated immunity and secretory piece (the glycopeptide that transports IgA) are usually normal, and most circulating B cells appear normal.

Treatment

Selective IgA deficiency has no known cure. Treatment aims to control symptoms of associated diseases, such as respiratory and GI infections, and is generally the same as for a patient with normal IgA.

> **ALERT** *Don't give an IgA-deficient patient immune globulin (IV Ig) because sensitization may lead to anaphylaxis during future administration of blood products.*

If transfusion with blood products is necessary, minimize the risk of adverse reaction by using washed RBCs or avoid the reaction completely by crossmatching the patient's blood with that of an IgA-deficient donor.

Special Considerations

Because this is a lifelong disorder, teach the patient to prevent infection, to recognize its early signs, and to seek treatment promptly.

DIGEORGE SYNDROME

DiGeorge syndrome (DGS), also called *22q11.2 deletion syndrome*, is a disorder caused by a large deletion from chromosome 22. This deletion means that several genes from this region are not present in DGS patients. The variation in the symptoms of the disease appears to be related to the amount of genetic material lost in the chromosomal deletion. DGS can affect a few or many body systems. Problems that are commonly associated with this syndrome include heart defects, cleft palate, and developmental and behavioral disorders.

In addition, some neonates may present with immunologic problems. Errors during fetal development of the third and fourth pharyngeal pouches interfere with thymus formation; the thymus may be completely absent or partially present in an abnormal location, causing deficient T-cell (cell-mediated) immunity. (See *Role of the thymus in immune response*.) As a result, recurrent infections or difficulty with vaccinations may occur. Many children outgrow these problems by age 1 year. However, some continue with problems throughout childhood and into adulthood. These immunodeficiency problems include Graves disease, idiopathic thrombocytopenia, and juvenile arthritis.

Role of the thymus in immune response

The thymus provides an environment in which T cells develop and learn to distinguish self from nonself during fetal and early postnatal stages. Most cells that enter the thymus are

destroyed. T-cell clones that react strongly to self and those that don't recognize self are deleted (negative selection). T-cell clones that recognize self but don't react strongly against self are positively selected.

After early life, mature T cells reside primarily in peripheral lymph organs and recirculate in blood and lymph.

Causes and Incidence

DGS is caused by a genetic defect on chromosome 22. This syndrome is present in 1 in 4,000 live births. It may also be found in 1 in 68 children with congenital heart defects, and 5% to 8% of children born with a cleft palate.

Pathophysiology

The 22q11.2 deletion results in a range of embryonic developmental disruptions involving the head, neck, brain, skeleton, and kidneys. Portions of the heart, head and neck, thymus, and parathyroids derive from the third and fourth pharyngeal pouches, and this developmental field is disrupted due to the chromosomal microdeletion. This, in turn, leads to hypocalcemia and variable T-cell deficiency. A combined T- and B-cell deficiency in part results from lack of T-helper cell function as seen in cases of complete 22q11.2DS.

Complications

- Hypocalcemia (life-threatening)
- Seizures
- CNS damage
- Failure to thrive
- Anorexia
- Diarrhea
- Weight loss
- Cardiac failure

Signs and Symptoms

Symptoms are usually obvious at birth or shortly thereafter. An infant with DGS may have low-set prominent ears, notched ear pinnae, a mouth without the usual bow-shaped lip, an undersized jaw, and abnormally wide-set eyes (hypertelorism) that are low-set and posteriorly angulated. Additionally, an infant may have a bifid uvula and a high, arched palate. Congenital heart anomalies are common. Cardiovascular abnormalities include great blood vessel anomalies (these may also develop soon after birth) and tetralogy of Fallot.

An infant with thymic hypoplasia (rather than aplasia) may experience a spontaneous return of cell-mediated immunity but can develop severe T-cell deficiencies later in life. This allows exaggerated susceptibility to viral, fungal, or bacterial infections, which may be overwhelming. Hypoparathyroidism, usually associated with DGS, typically causes tetany, hyperphosphatemia, and hypocalcemia. Hypocalcemia (calcium levels <7 mg/dL) develops early and is unusually resistant to treatment. It can lead to tetany, seizures, CNS damage, and early heart failure.

Diagnosis

Immediate diagnosis is difficult unless the infant has typical facial anomalies—normally the first

clues to the disorder. A definitive diagnosis depends on successful treatment of hypocalcemia and other life-threatening birth defects during the first few weeks of life. Such diagnosis rests on proof of decreased or absent T lymphocytes (sheep cell test, lymphopenia), partial B-cell immunodeficiency, and of an absent thymus (chest X-ray). Fluorescent in situ hybridization test can reveal the chromosomal 22 deletion.

Additional tests showing low serum calcium level, elevated serum phosphorus level, and missing parathyroid hormone confirm hypoparathyroidism.

Treatment

ALERT *Life-threatening hypocalcemia must be treated immediately, but it's unusually resistant and requires aggressive treatment, for example, with rapid I.V. infusion of a 10% solution of calcium gluconate.*

During such an infusion, monitor heart rate and watch carefully to avoid infiltration. Remember that calcium supplements *must* be given with vitamin D, or sometimes also with parathyroid hormone, to ensure effective calcium utilization. After hypocalcemia is under control, a fetal thymus transplant or hematopoietic cell transplant may restore normal cell-mediated immunity. Cardiac anomalies require surgical repair when possible.

Special Considerations

- Instruct the patient with DGS to follow a low-phosphorus diet, and educate about measures to prevent infection.
- Teach the parents of an infant with DGS to watch for signs of infection and have it treated immediately, to keep the infant away from crowds or any other potential sources of infection, and to provide good hygiene and adequate nutrition and hydration.
- Advise the parents to schedule and keep regular follow-up visits to the infant's pediatrician.

ACQUIRED IMMUNODEFICIENCY SYNDROME

AIDS is a serious secondary immunodeficiency disorder caused by the human immunodeficiency virus (HIV). Immunodeficiency makes the patient susceptible to opportunistic infections, unusual cancers, and other abnormalities. (See *Common infections and neoplasms in HIV and AIDS,* page 434.)

Common infections and neoplasms in HIV and AIDS

This is a list of commonly seen disorders with human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS). AIDS is diagnosed when a patient diagnosed with HIV has a CD4$^+$ T-cell count of less than 200 cells/µL.

- Common infections in a patient with a CD4$^+$ count less than 350 cells/µL include:
- herpes simplex virus
- herpes zoster
- *Mycobacterium tuberculosis*
- non-Hodgkin lymphoma
- oral or vaginal thrush
- Common infections in a patient with a CD4$^+$ count less than 200 cells/µL include:

- *esophagitis*
- *Pneumocystis jiroveci* (*carinii*) pneumonia
- Common infections in a patient with a CD4$^+$ count less than 100 cells/μL include:
- AIDS dementia
- cryptococcal meningitis
- progressive multifocal leukoencephalopathy
- toxoplasmosis encephalitis
- wasting syndrome
- Common infections in a patient with a CD4$^+$ count less than 50 cells/μL include:
- *Cytomegalovirus* infection
- *Mycobacterium avium*
- Common neoplasms in patients with HIV and AIDS include:
- Hodgkin lymphoma
- Kaposi sarcoma
- malignant lymphoma

The Centers for Disease Control and Prevention (CDC) first described AIDS in 1981. Since then, the CDC has declared a case surveillance definition for AIDS and modified it several times, most recently in 2008.

Causes and Incidence

AIDS results from infection with HIV, which has two forms: HIV-1 and HIV-2. Both forms of HIV have the same modes of transmission and similar opportunistic infections associated with AIDS, but studies indicate that HIV-2 develops more slowly and presents with milder symptoms than HIV-1.

Transmission occurs through contact with infected blood or body fluids and is associated with identifiable high-risk behaviors. It's disproportionately represented in:

- homosexual and bisexual men
- persons who use illicit I.V. drugs
- neonates of infected females
- recipients of contaminated blood or blood products (incidence dramatically decreased since mid-1985)
- heterosexual partners of persons in the former groups

Pathophysiology

The disease is characterized by the progressive destruction of cell-mediated (T-cell) immunity with subsequent effects on humoral (B-cell) immunity because of the pivotal role of the CD4$^+$ helper T cells in immune reactions.

Complications

- Opportunistic infections
- Certain cancers

Signs and Symptoms

A person with HIV may remain asymptomatic for months or years. Initially, laboratory evidence

of seroconversion to HIV antibodies may be the only clinical evidence of infection. However, as the disease progresses, the patient may develop generalized adenopathy and nonspecific signs and symptoms, such as weight loss, fatigue, night sweats, and fevers. As the patient's T-cell count lowers further, neurologic symptoms, opportunistic infections, and certain normally rare cancers may develop. (See *Manifestations of HIV infection and AIDS*, page 435.) HIV also destroys lymph nodes and immunologic organs, leading to major dysfunctions of the immunologic system. Eventually, HIV advances to AIDS. (Some individuals, termed *nonprogressors*, develop AIDS very slowly or not at all. They seem to have genetic differences that prevent the virus from attaching to certain immune receptors.)

PATHOPHYSIOLOGY
MANIFESTATIONS OF HIV INFECTION AND AIDS

A person infected with human immunodeficiency virus (HIV) may remain asymptomatic for months or years. However, if the disease progresses, it will eventually advance to acquired immunodeficiency syndrome (AIDS).

SYMPTOMS OF HIV INFECTION

Memory loss, disorientation, inability to think clearly

Persistent headaches

High fever

White patches on tongue

Swollen lymph nodes in neck, armpits, and groin

Heavy night sweats

Loss of appetite

Severe weight loss

Cryptosporidiosis: severe diarrhea, weight loss

Chronic diarrhea

Fatigue and muscle weakness

AIDS-RELATED ILLNESSES AND OPPORTUNISTIC INFECTIONS

Cryptococcal meningitis: inflammation in and around brain and central nervous system (CNS)

Toxoplasmosis encephalitis: most common opportunistic infection of CNS

Cytomegalovirus retinitis: leads to blindness

Herpes simplex virus: sores around the mouth and genitals

Oral candidiasis (thrush): white fungal growth on tongue and mouth

Candida esophagitis: painful ulcerations

Pneumocystis jiroveci pneumonia: fever, cough, and shortness of breath

Pulmonary tuberculosis: cough, sputum, difficulty breathing

Kaposi sarcoma: purplish brown skin lesions

Malignant lymphoma

PEDIATRIC TIP *The clinical course varies slightly in children, who have a shorter incubation time (mean, 17 months). Signs and symptoms resemble those in adults, except for findings related to sexually transmitted disease (STD). Children show virtually all of the opportunistic infections observed in adults, with a higher incidence of bacterial infections: otitis media, pneumonias other than that caused by* Pneumocystis carinii, *sepsis, chronic salivary gland enlargement, and lymphoid interstitial pneumonia.*

Diagnosis

CONFIRMING DIAGNOSIS *Signs and symptoms may occur at any time after infection with HIV, but AIDS isn't officially diagnosed until the patient's CD4$^+$ T-cell count falls below 200 cells/µL or the associated clinical conditions or disease are present.*

The most commonly performed tests, antibody tests, indicate HIV infection indirectly by revealing HIV antibodies. The recommended protocol requires initial screening of individuals and blood products with an enzyme-linked immunosorbent assay (ELISA). A positive ELISA should be repeated and then confirmed by an alternate method, usually the Western blot or an immunofluorescence assay. The radioimmunoprecipitation assay is considered more sensitive and specific than the Western blot, but because it requires radioactive materials, it's a poor choice for routine screening. In addition, antibody testing isn't reliable. Because people produce detectable levels of antibodies at different rates—a "window" varying from a few weeks to as long as 35 months in one documented case—an HIV-infected person can test negative for HIV antibodies. Antibody tests are also unreliable in neonates because transferred maternal antibodies persist for 6 to 10 months. To overcome these problems, direct tests are used, including antigen tests (p24 antigen), HIV cultures, nucleic acid probes of peripheral blood lymphocytes, and the polymerase chain reaction. (See *Laboratory tests for diagnosing and tracking HIV and assessing immune status*, page 436.)

Laboratory tests for diagnosing and tracking HIV and assessing immune status

Test	Findings in HIV infection
HIV antibody tests	
Enzyme-linked immunosorbent assay (ELISA)	Positive test results must be confirmed by Western blot
Western blot	Positive
Indirect immunofluorescence assay (IFA)	Positive test results must be confirmed by Western blot
Radioimmunoprecipitation assay (RIPA)	Positive, more sensitive and specific than Western blot
Home sample collection (dried blood spot, oral mucosa fluid, urine)	Findings confirmed with ELISA or Western blot
HIV tracking	
p24 antigen	Positive for free viral protein
Polymerase chain reaction (PCR)	Detection of HIV ribonucleic acid (RNA) or DNA
Branch deoxyribonucleic acid (bDNA)	Detection of HIV RNA
Nucleic acid sequence-based amplification (NASBA)	Detection of HIV RNA
Peripheral blood mononuclear cell (PBMC) culture for HIV-1	Positive when two consecutive assays detect reverse transcriptase or p24 antigen in increasing magnitude
Quantitative cell culture	Measures viral load within cells
Quantitative plasma culture	Measures viral load by free infectious virus in the plasma
Beta2–microglobulin	Protein is increased with disease progression
Serum neopterin	Increased levels seen with disease progression
Immune status	
Number of CD4$^+$ cells	Decreased
Percentage of CD4$^+$ cells	Decreased
CD4$^+$:CD8$^+$ ratio	Decreased
White blood cell count	Normal to decreased
Immunoglobulin levels	Increased
CD4$^+$ cell function tests	CD4$^+$ T cells have decreased ability to respond to antigen
Skin test sensitivity reaction	Decreased to absent

Additional tests to support the diagnosis and help evaluate the severity of immunosuppression include $CD4^+$ and $CD8^+$ T-lymphocyte subset counts, ESR, complete blood cell count, serum beta$_2$-microglobulin, p24 antigen, neopterin levels, and anergy testing. Because many opportunistic infections in AIDS patients are reactivations of previous infections, patients are also tested for associated neoplasms, infections, and STDs.

Treatment

There is no cure for either HIV or AIDS. However, significant advances have been made to help patients control signs and symptoms and impair disease progression. Because HIV can become resistant to any drug, healthcare professionals use combination treatments and multiple drug regimens to suppress the virus. Patients receiving medication remain infectious.

An effective method of treatment is highly active antiretroviral therapy (HAART), which combines three or more anti-HIV medications in a daily regimen. HAART aims to reduce the number of HIV particles in the blood as measured by viral load, thus increasing T-cell counts and improving the immunologic system's functioning. A regular and vigilant medication regimen is critical or resistance will develop because HIV strains mutate and can become resistant to HAART relatively easily.

The *nucleoside reverse transcriptase inhibitors* have been the mainstay of AIDS therapy in recent years. These drugs interfere with viral reverse transcriptase, which impairs HIV's ability to turn its ribonucleic acid into DNA for insertion into the host cell.

Antiretroviral therapy typically begins when the patient's $CD4^+$ T-cell count drops to less than 500/µL or when the patient develops an opportunistic infection. Most clinicians recommend starting the patient on a combination of these drugs in an attempt to gain the maximum benefit and to inhibit the production of resistant mutant strains of HIV. The drug combinations and dosages are then altered, depending on the patient's response.

Increasingly, physicians are basing changes in therapy on the patient's viral load rather than on the $CD4^+$ T-cell count. Because the $CD4^+$ count is influenced by the total WBC count, changes in the $CD4^+$ count may have nothing to do with changes in the patient's HIV status. Many physicians suggest that patients on antiretroviral therapy have their viral load checked every 3 months.

The increasing use of protease inhibitors (PIs) has greatly increased the life expectancy of patients with AIDS. These drugs block the enzyme protease, which HIV needs to produce virions, the viral particles that spread the virus to other cells. The use of PIs dramatically reduces viral load—sometimes to undetectable levels—while producing a corresponding increase in the $CD4^+$ T-cell count and, because they act at a different site than nucleoside analogues, the PIs don't produce additional adverse effects when added to a patient's regimen.

Antiviral therapy includes the use of multiple combined drug therapies that suppress the replication of the HIV virus in the body. Entry/fusion inhibitors are a class of antiviral drugs that work by blocking HIV entry into cells and can be used as part of the HAART regimen. In addition, integrase inhibitors, which stop the protein integrase from allowing HIV to place its genetic material into an infected cell, may also be added to the treatment regimen. After antiviral therapy is initiated, treatment should be aggressive. Initially, HAART, consisting of a triple-drug therapy regimen—a PI and two non-nucleoside reverse transcriptase inhibitors—is recommended. In addition to these primary treatments, anti-infectives are used to combat opportunistic infections (some are used prophylactically to help patients resist opportunistic

infections), and antineoplastic drugs are used to fight associated neoplasms. Supportive treatments help maintain nutritional status and relieve pain and other distressing physical and psychological symptoms.

Special Considerations

◆ Advise healthcare workers and the public to use precautions in all situations that risk exposure to blood, body fluids, and secretions. Diligently practicing standard precautions can prevent the inadvertent transmission of AIDS and other infectious diseases that are transmitted by similar routes. (See *Preventing AIDS transmission*.)

PREVENTION
PREVENTING AIDS TRANSMISSION

Healthcare workers and the public are advised to use precautions in all situations that risk exposure to blood, body fluids, and secretions. These precautions include:

◆ Educate the patient and family, sexual partners, and friends about disease transmission and prevention of extending the disease to others.
◆ Inform the patient not to donate blood, blood products, organs, tissue, or sperm.
◆ If the patient uses I. V. drugs, caution them not to share needles.
◆ Inform the patient that high-risk sexual practices for AIDS transmission are those that exchange body fluids, such as vaginal or anal intercourse without a condom.
◆ Discuss safer sexual practices, such as hugging, petting, mutual masturbation, and protected sexual intercourse. Abstaining is the most protective method of not transmitting the disease.
◆ Advise female patients of childbearing age to avoid pregnancy. Explain that an infant may become infected before birth, during delivery, or during breastfeeding.

◆ Recognize that a diagnosis of AIDS is profoundly distressing because of the disease's social impact and discouraging prognosis. The patient may lose his or her job and financial security as well as the support of family and friends. Do your best to help the patient cope with an altered body image, the emotional burden of serious illness, and the threat of death, and encourage and assist the patient in learning about AIDS societies and support programs.

CHRONIC MUCOCUTANEOUS CANDIDIASIS

Chronic mucocutaneous candidiasis is a form of candidiasis (moniliasis) that usually develops during the first year of life but occasionally occurs as late as the 20s, affecting males and females. In some patients, an autoimmune response affecting the endocrine system may induce various endocrinopathies.

Despite chronic candidiasis, these patients seldom die of systemic infection. Instead, they usually die of hepatic or endocrine failure. The prognosis for chronic mucocutaneous candidiasis depends on the severity of the associated endocrinopathy. Patients with associated endocrinopathy seldom live beyond their 30s.

Causes and Incidence

No characteristic immunologic defects have been identified in this infection, but many patients have a diminished response to various antigens or to *Candida* alone. In some patients, anergy may result from deficient migration inhibition factor, a mediator normally produced by lymphocytes.

Candida species infections are the most common causes of fungal infections in patients who are immunocompromised. About three of every four females have at least one bout of vulvovaginal candidiasis during their lifetimes. In individuals who are HIV-positive, more than 90% experience oropharyngeal candidiasis and 10% have at least one episode of esophageal candidiasis.

Pathophysiology

Chronic mucocutaneous candidiasis is characterized by repeated infection with *Candida albicans* that may result from an inherited defect in cell-mediated (T-cell) immunity. (Humoral [B-cell] immunity remains intact and provides a normal antibody response to *C. albicans*.)

Complications

- Addison disease
- Nephrotoxicity
- Hypoparathyroidism
- Hypocalcemia with seizures
- Diabetes mellitus
- Pernicious anemia
- Corticotropin deficiency
- Ovarian failure

Signs and Symptoms

Chronic candidal infections can affect the skin, mucous membranes, nails, and vagina, usually causing large, circular lesions. These infections seldom produce systemic symptoms but in late stages may be associated with recurrent respiratory tract infections. Other associated conditions include severe viral infections that may precede the onset of endocrinopathy and, sometimes, hepatitis. Involvement of the mouth, nose, and palate may cause speech and eating difficulties.

Symptoms of endocrinopathy are peculiar to the organ involved. Tetany and hypocalcemia are most common and are associated with hypoparathyroidism. Addison disease, hypothyroidism, diabetes, and pernicious anemia are also connected with chronic mucocutaneous candidiasis. Psychiatric disorders are likely because of disfigurement and multiple endocrine aberrations.

Diagnosis

Laboratory findings usually show a normal circulating T-cell count, although it may be decreased. Skin tests don't usually show delayed hypersensitivity to *Candida*, even during the infectious stage. Migration inhibiting factor that indicates the presence of activated T cells may not respond to *Candida*.

Nonimmunologic abnormalities resulting from endocrinopathy may include hypocalcemia, abnormal hepatic function studies, hyperglycemia, iron deficiency, and abnormal vitamin B_{12} absorption (pernicious anemia). Diagnosis must rule out other immunodeficiency disorders associated with chronic *Candida* infection, especially DGS, ataxia-telangiectasia, and severe combined immunodeficiency disease (SCID), all of which produce severe immunologic defects.

After diagnosis, the patient needs evaluation of adrenal, pituitary, thyroid, gonadal, pancreatic, and parathyroid function as well as careful follow-up. The disease is progressive, and most patients eventually develop endocrinopathy.

Treatment

Treatment aims to control infection but isn't always successful. Topical antifungal agents, such as clotrimazole, miconazole, and nystatin, are useful. They may be prescribed as mouthwashes or troches (lozenges) for 5 to 10 days.

Systemic infections may not be fatal, but they're serious enough to warrant vigorous treatment. Ketoconazole and fluconazole have had some positive effect. Oral or I.M. iron replacement may also be necessary. Treatment may also include plastic surgery of the lesions, when possible, and counseling to help patients cope with their disfigurement.

Special Considerations

Teach the patient about the disease's progressive manifestations and emphasize the importance of seeing an endocrinologist for regular checkups.

CHRONIC FATIGUE SYNDROME

Sometimes called *chronic Epstein-Barr virus* or *myalgic encephalomyelitis*, chronic fatigue and immune dysfunction syndrome is typically marked by debilitating fatigue, neurologic abnormalities, and persistent symptoms that suggest chronic mononucleosis. It commonly occurs in adults younger than age 45, primarily in women.

Causes and Incidence

The cause of CFS is unknown, but researchers suspect that it may be found in human herpes virus-6 or in other herpesviruses, enteroviruses, or retroviruses. Recent studies have shown that inflammation of nervous system pathways, acting as an immune or autoimmune response, may play a role as well. CFS may also be associated with a reaction to viral illness that's complicated by dysfunctional immune response and by other factors that may include gender, age, genetic disposition, prior illness, stress, and environment.

Of the 4 million people with CFS in the United States, less than 20% have been diagnosed.

Pathophysiology

The immune system is upregulated in CFS and the levels of antibodies to various previously encountered antigens are increased. Although increased titers do not indicate a causal relationship in CFS, the titers are nonetheless useful as laboratory clues, which, when taken together, are common in patients with CFS.

Signs and Symptoms

CFS has specific symptoms and signs, based on the exclusion of other possible causes. Its characteristic symptom is prolonged, often overwhelming fatigue that's commonly associated with a varying complex of other symptoms that are similar to those of many infections, including myalgia and cephalgia. It may develop within a few hours and can last for 6 months or more. Fatigue isn't relieved by rest and is severe enough to restrict ADLs by at least 50%.

Diagnosis

Because the cause and nature of CFS are still unknown, no single test unequivocally confirms its presence. Therefore, physicians base this diagnosis on the patient's history and the CDC criteria. (See *Criteria for diagnosing chronic fatigue syndrome,* page 440.) Because the CDC's criteria are admittedly a working concept that may not include all forms of this disease and are based on symptoms that can result from other diseases, diagnosis is difficult and uncertain.

Criteria for diagnosing chronic fatigue syndrome

There is no blood test, brain scan, or other laboratory test to diagnose chronic fatigue syndrome (CFS); it's a diagnosis of exclusion. Following a detailed patient history, review of medications, and laboratory screening tests, the physician should consider a diagnosis of CFS if two of these criteria are met:

1. Unexplained, persistent fatigue that's not due to ongoing exertion, isn't substantially relieved by rest, is of new onset (not lifelong), and results in a significant reduction in previous levels of activity.
2. Four or more of the following symptoms are present for 6 months or more:
   - Impaired memory or concentration
   - Postexertional malaise (extreme, prolonged exhaustion and sickness following physical or mental activity)
   - Unrefreshing sleep
   - Muscle pain
   - Multijoint pain without swelling or redness
   - Headaches of a new type or severity
   - Sore throat that's frequent or recurring
   - Tender cervical or axillary lymph nodes

From: Centers for Disease Control and Prevention. Myalgic encephalomyelitis/chronic fatigue syndrome. Retrieved April 19, 2011 from www.cdc.gov/cfs/cfsdiagnosis.htm.

Treatment

No treatment is known to cure CFS. Symptomatic treatment may involve the use of medications to treat depression, anxiety, pain, discomfort, and fever. Hidden yeast infections may be present and should be treated. Endocrine abnormalities should be treated with replacement therapy when possible.

Special Considerations

- Some patients may benefit from avoiding environmental irritants and certain foods.
- Because patients with CFS may benefit from supportive contact with others who share this disease, refer the patient to the CFS Association for information and to local support groups. Patients may also benefit from psychological counseling.

CHRONIC GRANULOMATOUS DISEASE

Patients with chronic granulomatous disease (CGD) may develop granulomatous inflammation, which leads to ischemic tissue damage.

Causes and Incidence

CGD is inherited as a recessive X-linked trait in 50% to 60% of affected patients. Males are more likely to be affected. The genetic defect may be linked to deficiency of the enzyme nicotinamide adenine dinucleotide phosphate oxidase. The inability of phagocytic cells to kill certain bacteria and fungi leads to long-term and repeated infections.

Pathophysiology

Abnormal neutrophil metabolism impairs phagocytosis—one of the body's chief defense mechanisms—resulting in increased susceptibility to low-virulent or nonpathogenic organisms, such as *Staphylococcus epidermidis, E. coli, Aspergillus,* and *Nocardia.* Phagocytes attracted to sites of infection can engulf these invading organisms but are unable to destroy them.

Complications

- Bone damage and infections
- Pneumonia
- Lung damage
- Skin damage
- Chronic infections

Signs and Symptoms

Usually, the patient with CGD displays signs and symptoms associated with infections of the skin, lymph nodes, lung, liver, and bone by age 2. Skin infection is characterized by small, well-localized areas of tenderness. Seborrheic dermatitis of the scalp and axilla is also common. Lymph node infection typically causes marked lymphadenopathy with draining lymph nodes and hepatosplenomegaly. Many patients develop liver abscess, which may be recurrent and multiple; abdominal tenderness, fever, anorexia, and nausea point to abscess formation. Other common infections include osteomyelitis, which causes localized pain and fever, pneumonia, and gingivitis with severe periodontal disease.

Diagnosis

Clinical features of osteomyelitis, pneumonia, liver abscess, or chronic lymphadenopathy in a young child provide the first clues to CGD diagnosis.

℞ **CONFIRMING DIAGNOSIS** *An important tool for confirming this diagnosis is the nitroblue tetrazolium (NBT) test. A clear yellow dye, NBT is normally reduced by neutrophil metabolism, resulting in a color change from yellow to blue. Quantifying this color change estimates the degree of neutrophil metabolism.*

Patients with CGD show impaired NBT reduction, indicating abnormal neutrophil metabolism. Another test measures the rate of intracellular killing by neutrophils; in CGD, killing is delayed or absent.

Other laboratory values may support the diagnosis or help monitor disease activity. Osteomyelitis typically causes elevated WBC count and ESR; bone scans help locate and size such infections. Recurrent liver or lung infection may eventually cause abnormal function studies. Cell-mediated and humoral immunity are usually normal in CGD, although some patients have hypergammaglobulinemia.

Treatment

Early, aggressive treatment of infection is the chief goal in caring for a patient with CGD. Areas of suspected infection should be biopsied or cultured, and broad-spectrum antibiotics are usually started immediately—without waiting for results of cultures. Confirmed abscesses may be drained or surgically removed. Provide meticulous wound care after such treatment, including irrigation or packing.

Many patients with CGD receive a combination of I.V. antibiotics, in many cases extended beyond the usual 10- to 14-day course. However, for fungal infections with *Aspergillus* or *Nocardia*, treatment involves amphotericin B in gradually increasing doses to achieve a maximum cumulative dose. During I.V. drug therapy, monitor vital signs frequently and rotate the I.V. site every 48 to 72 hours.

To help treat antibiotic-resistant or life-threatening infection, or to help localize infection, the patient may receive granulocyte transfusions—usually once daily until the crisis has passed. During such transfusions, watch for fever and chills (these effects can sometimes be prevented by premedication with acetaminophen). Transfusions shouldn't be given for 6 hours before or after amphotericin B to avoid severe pulmonary edema and, possibly, respiratory arrest.

IFN-gamma may help reduce the number of severe infections. Bone marrow transplantation is also promising.

Special Considerations

- If prophylactic antibiotics are ordered, teach the patient and family how to administer them properly and how to recognize adverse effects. Advise them to promptly report any signs or symptoms of infection.
- Stress the importance of good nutrition and hygiene, especially meticulous skin and mouth care.
- During hospitalizations, encourage the patient to continue ADLs as much as possible.
- If the patient is a child, arrange for a tutor to help them keep up with schoolwork.

SEVERE COMBINED IMMUNODEFICIENCY DISEASE

In SCID, both cell-mediated (T-cell) and humoral (B-cell) immunity are deficient or absent, resulting in susceptibility to infection from all classes of microorganisms during infancy. It's the most severe form of T-cell and B-cell deficiency.

Pathophysiology

At least three types of SCID exist: reticular dysgenesis, the most severe type, in which the hematopoietic stem cell fails to differentiate into lymphocytes and granulocytes; Swiss-type agammaglobulinemia, in which the hematopoietic stem cell fails to differentiate into lymphocytes alone; and enzyme deficiency, such as adenosine deaminase (ADA) deficiency, in which the buildup of toxic products in the lymphoid tissue causes damage and subsequent dysfunction.

Causes and Incidence

SCID is usually transmitted as an autosomal recessive trait, although it may be X-linked. In most cases, the genetic defect seems associated with failure of the stem cell to differentiate into T and B lymphocytes. Many molecular defects, such as mutation of the kinase ZAP-70, can cause

SCID. X-linked SCID is due to a mutation of a subunit of the IL-2, IL-4, and IL-7 receptors. Less commonly, it results from an enzyme deficiency.

SCID affects more males than females. Its estimated incidence is 1 in every 100,000 to 500,000 births. Most untreated patients die from infection within 1 year of birth.

Complications

- Infection
- Pneumonia
- Oral ulcers
- Failure to thrive
- Dermatitis

Signs and Symptoms

An extreme susceptibility to infection becomes obvious in the infant with SCID in the first months of life. The infant fails to thrive and develops chronic otitis; sepsis; watery diarrhea (associated with *Salmonella* or *E. coli*); recurrent pulmonary infections (usually caused by *Pseudomonas*, cytomegalovirus, or *P. jiroveci* [formerly *carinii*]); persistent oral candidiasis, sometimes with esophageal erosions; and possibly fatal viral infections such as chickenpox.

Pneumocystis jiroveci pneumonia usually strikes a severely immunodeficient infant in the first 3 to 5 weeks after birth. Onset is typically insidious, with gradually worsening cough, low-grade fever, tachypnea, and respiratory distress. Chest X-ray characteristically shows bilateral pulmonary infiltrates.

Diagnosis

Diagnosis is generally made clinically because most SCID infants suffer recurrent overwhelming infections within 1 year of birth. Some infants are diagnosed after a severe reaction to vaccination.

Defective humoral immunity is difficult to detect before age 5 months. Before that period, even normal infants have very small amounts of serum IgM and IgA. Normal IgG levels merely reflect maternal IgG.

℞ **CONFIRMING DIAGNOSIS** *Severely diminished or absent T-cell number and function, as well as lymph node biopsy showing absence of lymphocytes, can confirm the diagnosis of SCID.*

Treatment

Treatment aims to restore the immune response and prevent infection. Histocompatible bone marrow transplantation is the only satisfactory treatment available to correct immunodeficiency. Because bone marrow cells must be HLA and mixed leukocyte culture matched, the most common donors are histocompatible siblings. However, because bone marrow transplant can produce a potentially fatal graft-versus-host (GVH) reaction, newer methods of bone marrow transplant that eliminate GVH reaction (such as lectin separation and the use of monoclonal antibodies) are being evaluated.

Fetal thymus and liver transplants have achieved limited success. Immune globulin administration may also play a role in treatment. Some SCID infants have received long-term protection by being isolated in a completely sterile environment. However, this approach isn't effective if the infant already has had recurring infections.

The standard treatment for ADA deficiency is enzyme therapy. The enzyme used, PEG-ADA, is 90% effective in children. Gene therapy is also being used to treat ADA deficiency.

Special Considerations

Patient care is primarily preventive and supportive.

- Constantly monitor the infant for early signs of infection. If infection develops, provide prompt and aggressive drug therapy as ordered. Watch for adverse effects of any medications given.
- Avoid vaccinations and give only irradiated blood products if a transfusion is ordered.
- Although SCID infants must remain in strict protective isolation, try to provide a stimulating atmosphere to promote growth and development. Encourage the parents to visit their child often, to hold the child, and to bring toys that can be easily sterilized. If the parents can't visit, call them often to report on the infant's condition. Explain all procedures, medications, and precautions to them. Maintain a normal day and night routine for the child and talk to the child as much as possible.
- Because the parents will have questions about the vulnerability of future offspring, refer them for genetic counseling.
- Arrange for psychological and spiritual support for the parents and siblings to help them cope with the child's inevitable long-term illness and early death.

COMPLEMENT DEFICIENCIES

Complement is a series of circulating enzymatic serum proteins with nine functional components, labeled C1 through C9. (The first four complement components are numbered out of sequence, in order of their discovery—C1, C4, C2, and C3—but the remaining five are numbered sequentially.)

Complement deficiency or dysfunction may increase susceptibility to infection and also seems related to certain autoimmune disorders. Theoretically, any complement component may be deficient or dysfunctional, and many such disorders are under investigation. Inherited or primary complement deficiencies are rare. The most common are C2, C4, C6, and C8 deficiencies and C5 familial dysfunction. More common secondary complement abnormalities have been confirmed in patients with lupus erythematosus, in some with dermatomyositis, in some with scleroderma, and in a few with gonococcal and meningococcal infections. The prognosis varies with the abnormality and the severity of associated diseases.

Pathophysiology

When IgG or IgM reacts with antigens as part of an immune response, it activates C1, which then combines with C4, initiating the classic complement pathway, or cascade. (An alternative complement pathway involves the direct activation of C3 by the serum protein properdin, bypassing the initial components [C1, C4, and C2] of the classic pathway.) Complement then combines with the antigen–antibody complex and undergoes a sequence of reactions that amplify the immune response against the antigen. This complex process, which is vital to normal immune response, is called *complement fixation;* it's necessary to promote chemotaxis, opsonization, phagocytosis, bacteriolysis, and anaphylaxis reactions.

Causes and Incidence

Primary complement deficiencies are inherited as autosomal recessive traits, except for deficiency of C1 esterase inhibitor, which is autosomal dominant. Secondary deficiencies may follow complement-fixing (complement-consuming) immunologic reactions, such as drug-induced serum sickness, acute streptococcal glomerulonephritis, and acute active SLE.

Inherited deficiency is rare in the general population, with an incidence of 0.03%. C2 protein deficiency disorder occurs in 1 in 10,000 persons.

Complications

- Systemic lupus erythematosus
- Glomerulonephritis
- JRA

Signs and Symptoms

Clinical effects vary with the specific deficiency. C2 and C3 deficiencies and C5 familial dysfunction increase susceptibility to bacterial infection (which may involve several body systems simultaneously). C2 and C4 deficiencies are also associated with collagen vascular disease such as lupus erythematosus and with chronic renal failure. C5 dysfunction, a familial defect in infants, causes failure to thrive, diarrhea, and seborrheic dermatitis. C1 esterase inhibitor deficiency (hereditary angioedema) may cause periodic swelling in the face, hands, abdomen, or throat, with potentially fatal laryngeal edema.

Diagnosis

Diagnosis of a complement deficiency is difficult, requiring careful interpretation of both clinical features and laboratory results. Total serum complement level (CH50) is low in various complement deficiencies. In addition, specific assays may be done to confirm deficiency of specific complement components. For example, detection of complement components and IgG by immunofluorescent examination of glomerular tissues in glomerulonephritis strongly suggests complement deficiency.

Treatment

Primary complement deficiencies have no known cure. Associated infection, collagen vascular disease, or renal disease requires prompt, appropriate treatment. Transfusion of fresh frozen plasma to provide replacement of complement components is controversial because replacement therapy doesn't cure complement deficiencies, and any beneficial effects are transient. A bone marrow transplant may be helpful but can cause a potentially fatal reaction (graft-versus-host-rejection). Anabolic steroids such as danazol and antifibrinolytic agents are often used to reduce acute swelling in patients with C1 esterase inhibitor deficiency.

Special Considerations

- Teach the patient (or his/her family, if the patient is a child) the importance of avoiding infection, how to recognize its early signs and symptoms, and the need for prompt treatment if it occurs.
- After a bone marrow transplant, monitor the patient closely for signs of a transfusion reaction or GVH reaction.
- Meticulous patient care can speed recovery and prevent complications. For example, a patient

with renal infection needs careful monitoring of intake and output, tests for serum electrolytes and acid–base balance, and observation for signs of renal failure.

◆ When caring for a patient with hereditary angioedema, be prepared for emergency management of laryngeal edema; keep airway equipment on hand.

Hematologic Disorders

Introduction

Blood, one of the body's major fluid tissues, continuously circulates through the heart and blood vessels, carrying vital elements to every part of the body.

Blood Basics

Blood performs several vital functions through its special components: the liquid portion (plasma) and the formed constituents (erythrocytes, leukocytes, and thrombocytes) that are suspended in it. Erythrocytes (red blood cells [RBCs]) carry oxygen to the tissues and remove carbon dioxide from them. Leukocytes (white blood cells [WBCs]) act in inflammatory and immune responses. Plasma (a clear, straw-colored fluid) carries antibodies and nutrients to tissues and carries waste away; plasma coagulation factors and thrombocytes (platelets) control clotting. (See *Coagulation factors*.)

Coagulation Factors

Factor	Synonym
Factor I	Fibrinogen
Factor II	Prothrombin
Factor III	Tissue thromboplastin
Factor IV	Calcium ion
Factor V	Labile factor
Factor VII	Stable factor
Factor VIII	Antihemophilic globulin or antihemophilic factor A
Factor IX	Plasma thromboplastin component, Christmas factor
Factor X	Stuart–Prower factor
Factor XI	Plasma thromboplastin antecedent
Factor XII	Hageman factor
Factor XIII	Fibrin-stabilizing factor

Typically, the average person has 5 to 6 L of circulating blood, which constitutes 5% to 7% of body weight (as much as 10% in premature neonates). Blood is three to five times more viscous than water, with an alkaline pH of 7.35 to 7.45, and is either bright red (arterial blood) or dark red (venous blood), depending on the degree of oxygen saturation and the hemoglobin (Hb) level.

Formation and Characteristics

Hematopoiesis, the process of blood formation, occurs primarily in the bone marrow of the femur, sternum, and vertebrae, where primitive blood cells (stem cells) produce the precursors of erythrocytes (normoblasts), leukocytes, and thrombocytes. During embryonic development, blood cells are derived from mesenchyma and form in the yolk sac. As the fetus matures, blood cells are produced in the liver, the spleen, and the thymus; by the fifth month of gestation, blood cells also begin to form in bone marrow. After birth, blood cells are usually produced only in the marrow.

Blood'S Function

The most important function of blood is to *transport oxygen* (bound to RBCs inside Hb) from the lungs to the body tissues and to *return carbon dioxide* from these tissues to the lungs. Blood also performs the following functions:

- production and delivery of antibodies (by WBCs) formed by plasma cells and lymphocytes
- transportation of granulocytes and monocytes to defend the body against pathogens by phagocytosis
- immunity against viruses and cancer cells through sensitized lymphocytes
- provision of complement, a group of immunologically important protein substances in plasma essential for immune and inflammatory responses

Blood's other functions include control of hemostasis by platelets, plasma, and coagulation factors that repair tissue injuries and prevent or halt bleeding; acid–base and fluid balance; regulation of body temperature by carrying off excess heat generated by the internal organs for dissipation through the skin; and transportation of nutrients and regulatory hormones to body tissues and of metabolic wastes to the organs of excretion (kidneys, lungs, and skin).

Blood Dysfunction

Because of the rapid reproduction of bone marrow cells and the short life span and minimal storage in the bone marrow of circulating cells, bone marrow cells and their precursors are particularly vulnerable to physiologic changes that can affect cell production, or *hematopoiesis*. Resulting blood disorders may be primary or secondary, quantitative or qualitative, or both; they may involve some or all blood components. Quantitative blood disorders result from increased or decreased cell production or cell destruction; qualitative blood disorders stem from intrinsic cell abnormalities or plasma component dysfunction. Specific causes of blood disorders include trauma, chronic disease, surgery, malnutrition, drugs, exposure to toxins and radiation, and

genetic and congenital defects that disrupt production and function. For example, depressed bone marrow production or mechanical destruction of mature blood cells can reduce the number of RBCs, platelets, and granulocytes, resulting in pancytopenia (anemia, thrombocytopenia, and granulocytopenia). Increased production of multiple bone marrow components can follow myeloproliferative disorders.

Erythropoiesis

The tissues' demand for oxygen and the blood cells' ability to deliver it regulate RBC production, or *erythropoiesis*. Consequently, hypoxia (or tissue anoxia) stimulates RBC production by triggering the formation and release of erythropoietin, a hormone (produced by the kidneys) that activates bone marrow to produce RBCs. Erythropoiesis may also be stimulated by androgens (which accounts for the higher RBC counts in men). RBCs have a life span of approximately 120 days.

The actual formation of an erythrocyte begins with an uncommitted stem cell that may eventually develop into an RBC or a WBC. Such formation requires certain vitamins—B_{12} and folic acid—and minerals, such as copper, cobalt, and especially iron, which is vital to Hb's oxygen-carrying capacity. Iron is obtained from various foods and is absorbed in the duodenum and upper jejunum, leaving the excess for temporary storage in reticuloendothelial cells, especially those in the liver. Iron excess is stored as ferritin and hemosiderin until it's released for use in the bone marrow to form new RBCs.

ELDER TIP In older adults, fatty bone marrow replaces some active cell-forming marrow— first in the long bones and later in the flat bones. The altered bone marrow can't increase erythrocyte production as readily as before in response to such stimuli as hormones, anoxia, hemorrhage, and hemolysis.

RBC Disorders

RBC disorders include quantitative and qualitative abnormalities. Deficiency of RBCs (anemia) can follow any condition that destroys or inhibits the formation of these cells. Common factors leading to this deficiency include:

- chronic illnesses, such as renal disease, cancer, and chronic infections, chronic inflammation (rheumatoid arthritis)
- congenital or acquired defects that cause bone marrow aplasia and suppress general hematopoiesis (aplastic anemia) or erythropoiesis
- deficiencies of vitamins (vitamin B_{12} deficiency or pernicious anemia) or minerals (iron, folic acid, copper, and cobalt deficiency anemias) that cause inadequate RBC production
- drugs, toxins, and ionizing radiation
- excessive chronic or acute blood loss (posthemorrhagic anemia)
- intrinsically or extrinsically defective RBCs (sickle cell anemia and hemolytic transfusion reaction)
- metabolic abnormalities (sideroblastic anemia)

Comparatively few conditions lead to excessive numbers of RBCs:

- abnormal proliferation of all bone marrow elements (polycythemia vera), especially RBC mass
- a single-element abnormality (for instance, an increase in RBCs that results from erythropoietin excess, which in turn results from hypoxemia, hypertension, or pulmonary disease)
- decreased plasma cell volume, which produces a corresponding relative increase in RBC concentration (such as through the use of drugs)

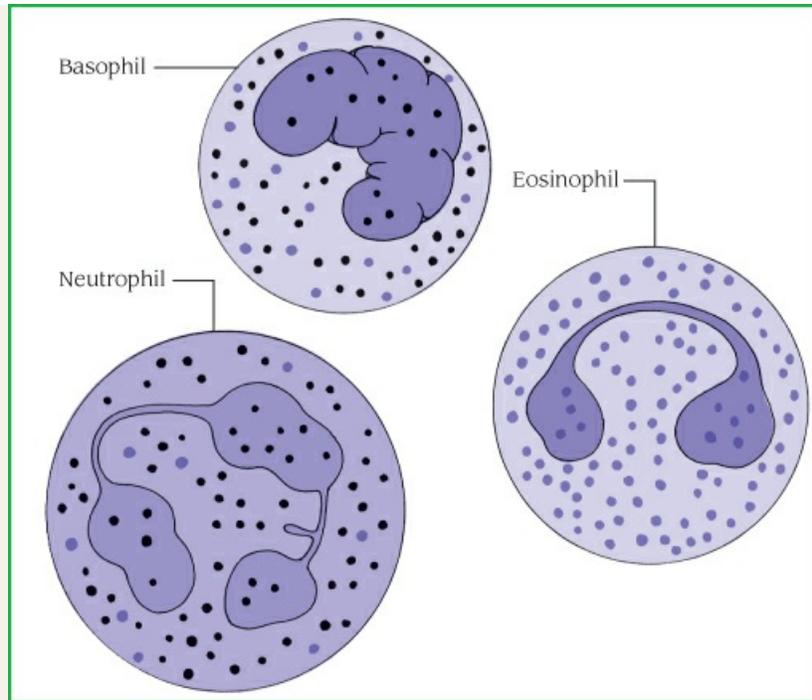
Function of WBCs

WBCs, or leukocytes, protect the body against harmful bacteria and infection and are classified as granular leukocytes (basophils, neutrophils, and eosinophils) or nongranular leukocytes (lymphocytes, monocytes, and plasma cells). (See *Two types of leukocytes*, page 447.) Usually, WBCs are produced in bone marrow; lymphocytes and plasma cells are produced in lymphoid tissue as well. Neutrophils have a circulating half-life of less than 6 hours; some lymphocytes may survive for weeks or months. Normally, WBCs number between 5,000 and 10,000/µL.

Two types of leukocytes

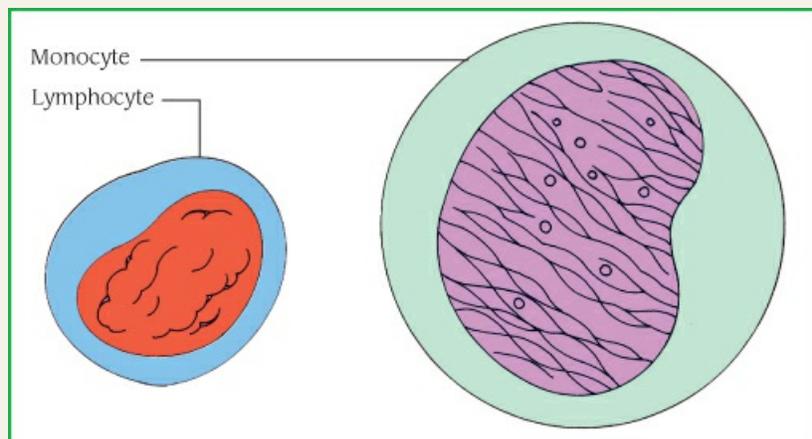
Leukocytes vary in size, shape, and number.

Granular Leukocytes

Granular leukocytes (granulocytes) are the most numerous and include basophils, containing cytoplasmic granules that stain readily with alkaline dyes; eosinophils, which stain with acidic dyes; and neutrophils, which are finely granular and recognizable by their multinucleated appearance.


Granular Leukocytes

Nongranular Leukocytes

Lymphocytes and monocytes have few, if any, granulated particles in the cytoplasm.


Nongranular Leukocytes

There are six types of WBCs:

- *Neutrophils*, the predominant form of granulocyte, make up about 60% of WBCs; they help devour invading organisms by phagocytosis.
- *Eosinophils*, minor granulocytes, may defend against parasites and lung and skin infections and act in allergic reactions. They account for 1% to 5% of the total WBC count.
- *Basophils,* minor granulocytes, may release heparin and histamine into the blood and

participate in delayed hypersensitivity reactions. They account for 0% to 1% of the total WBC count.

◆ *Monocytes*, along with neutrophils, help devour invading organisms by phagocytosis. They help process antigens for lymphocytes and form macrophages in the tissues; they account for 1% to 6% of the total WBC count.

◆ *Lymphocytes* occur as B cells and T cells. B cells aid antibody synthesis; T cells regulate cell-mediated immunity. They account for 20% to 40% of the total WBC count.

◆ *Plasma cells* develop from lymphocytes, reside in the tissue, and produce antibodies. Plasma cells do not normally circulate in the blood.

A temporary increase in production and release of mature WBCs (leukemic reaction) is a normal response to infection. However, an excessive number of immature WBC precursors and their accumulation in bone marrow or lymphoid tissue are characteristic of leukemia. These nonfunctioning WBCs (blasts) provide no protection against infection; crowd out RBCs, platelets, and mature WBCs; and spill into the bloodstream, sometimes infiltrating organs and impairing function.

WBC deficiencies may reflect inadequate cell production, drug reactions, ionizing radiation, infiltrated bone marrow (cancer), congenital defects, aplastic anemia, folic acid deficiency, or hypersplenism. The major WBC deficiencies are granulocytopenia, lymphocytopenia, and monocytopenia.

Platelets, Plasma, and Clotting

Platelets are small (2 to 4 µm in diameter), colorless, disk-shaped cytoplasmic fragments split from cells in bone marrow called *megakaryocytes*. The normal platelet concentration is 150,000 to 400,000/µL. These fragments, which have a life span of approximately 10 days, perform three vital functions:

◆ initiate vasoconstriction of damaged blood vessels to minimize blood loss
◆ form hemostatic plugs in injured blood vessels
◆ with plasma, provide materials that accelerate blood coagulation—notably platelet factor III

Plasma consists mainly of proteins (chiefly albumin, globulin, and fibrinogen) held in aqueous suspension. Other components of plasma include glucose, lipids, amino acids, electrolytes, pigments, hormones, respiratory gases (oxygen and carbon dioxide), and products of metabolism, such as urea, uric acid, creatinine, and lactic acid. Its fluid characteristics—including osmotic pressure, viscosity, and suspension qualities—depend on its protein content. Plasma components regulate acid–base balance and immune responses and mediate coagulation and nutrition.

In a complex process called *hemostasis*, platelets, plasma, and coagulation factors interact to control bleeding.

Hemostasis and The Clotting Mechanism

Hemostasis is the complex process by which the body controls bleeding. When a blood vessel ruptures, local vasoconstriction and platelet clumping (aggregation) at the injury site initially help prevent hemorrhage. This activation of the coagulation system, called *extrinsic cascade*,

requires release of tissue thromboplastin from the damaged cells. However, formation of a more stable clot requires initiation of the complex clotting mechanism known as the *intrinsic cascade system*. When endothelial vessel injury or a foreign body in the bloodstream activates this system, *activating factor XII* triggers clotting. In the final common pathway, prothrombin is converted to thrombin. Thrombin acts on fibrinogen to form fibrin, the basis of a clot.

Therapy With Blood Components

Because of improved methods of collection, component separation, and storage, blood transfusions are being used more effectively than ever. Separating blood into components permits a single unit of blood to benefit several patients with different hematologic abnormalities. Component therapy allows replacement of a specific blood component without risking reactions from other components.

Blood typing, crossmatching, and human leukocyte antigen (HLA) typing are compatibility tests used to ensure safe, effective replacement therapy and minimize the risk of transfusion reactions. Blood typing determines the antigens present in the patient's RBCs by reaction with standardized sera. (Critical antigen groups are those of ABO and Rh factor.) Crossmatching the patient's blood with transfusion blood provides some assurance that the patient doesn't have antibodies against donor red cells. HLA typing may be helpful for the patient who needs long-term transfusion therapy or frequent platelet transfusions, but usually, only family members can provide an appropriate match because antigenic properties are genetically determined.

Bone Marrow Transplantation

Bone marrow transplantation is used to treat acute leukemia, aplastic anemia, severe combined immunodeficiency disease (SCID), Nezelof syndrome, and Wiskott–Aldrich syndrome. In this procedure, marrow from a twin or another HLA-identical donor (usually a sibling) is transfused in an attempt to repopulate the recipient's bone marrow with normal cells.

A hematologic disorder can affect nearly every aspect of the patient's life, perhaps resulting in life-threatening emergencies that require prompt medical treatment. This is particularly true of patients with such diseases as hemophilia and thalassemia major, diseases for which no cure is available. Astute, sensitive care founded on a firm understanding of hematologic basics can help the patient survive such illnesses. In situations with poor prognoses, the patient may need to make many adjustments to maintain an optimal quality of life.

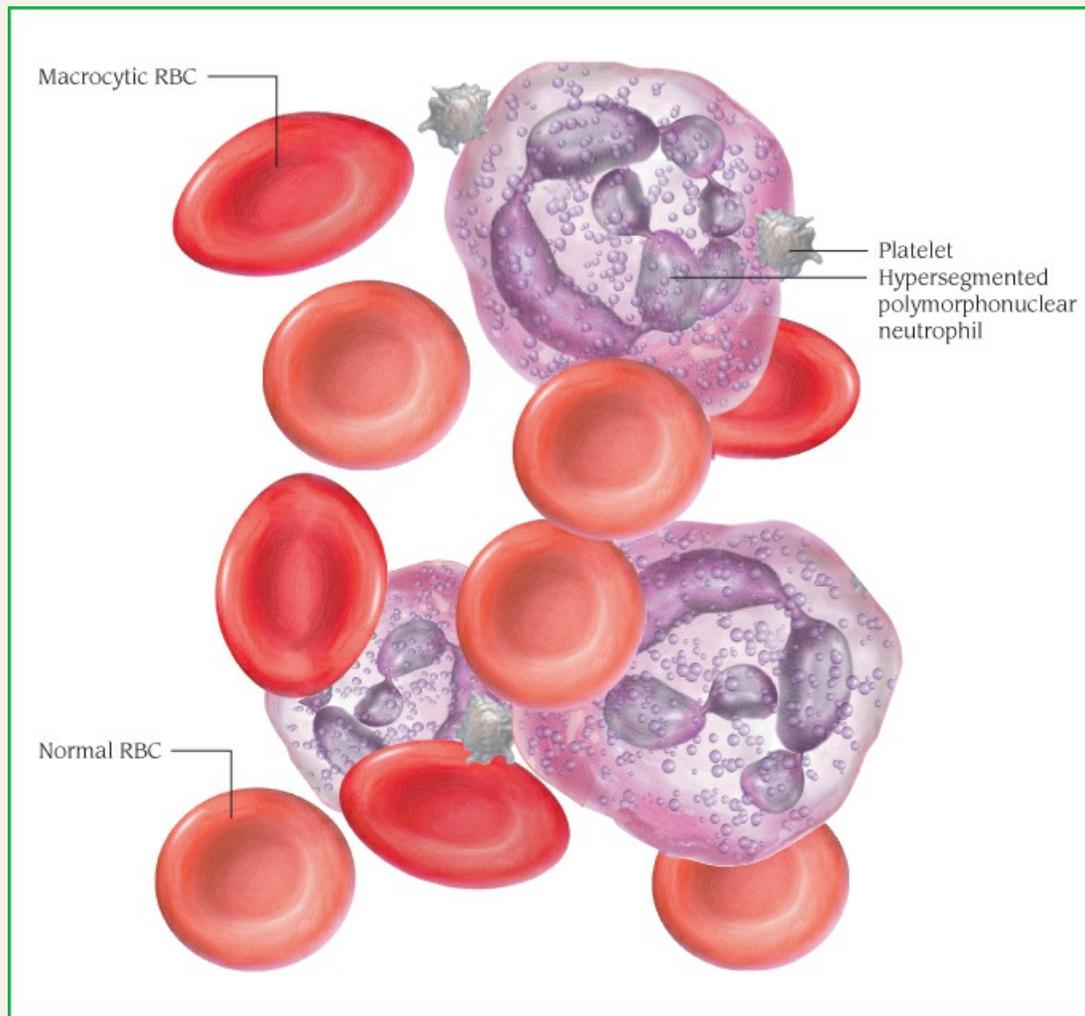
Anemias

PERNICIOUS ANEMIA

Pernicious anemia, also known as *vitamin B_{12} deficiency*, is a type of megaloblastic anemia characterized by decreased gastric production of hydrochloric acid and deficiency of intrinsic factor (IF), a substance normally secreted by the parietal cells of the gastric mucosa that's essential for vitamin B_{12} absorption in the ileum. The resulting deficiency of vitamin B_{12} causes serious neurologic, gastric, and intestinal abnormalities. Untreated pernicious anemia may lead to

permanent neurologic disability and death. (See *Peripheral blood smear in pernicious anemia*, page 449.)

Peripheral blood smear in pernicious anemia

Pernicious anemia is caused by malabsorption of vitamin B_{12}.


Pathophysiology

Familial incidence of pernicious anemia suggests a genetic predisposition. (It may involve an inherited single dominant autosomal factor.) Significantly higher incidence in patients with immunologically related endocrine diseases, such as thyroiditis, myxedema, and Graves disease, seems to support a widely held theory that an inherited autoimmune response causes gastric mucosal atrophy and, therefore, deficiency of hydrochloric acid and IF. IF deficiency impairs vitamin B_{12} absorption. The resultant vitamin B_{12} deficiency inhibits cell growth, particularly of RBCs, leading to insufficient and deformed RBCs with poor oxygen-carrying capacity. It also

impairs myelin formation, causing neurologic damage. Iatrogenic induction can follow partial gastrectomy and/or bypass for obesity.

PEDIATRIC TIP *Juvenile pernicious anemia, occurring in children younger than age 10, stems from a congenital stomach disorder that causes secretion of abnormal IF.*

ELDER TIP *With age, vitamin B_{12} absorption may also diminish, resulting in reduced erythrocyte mass and decreased Hb levels and hematocrit (HCT).*

Pernicious anemia primarily affects people of northern European ancestry. It's rare in children and infants. Onset typically occurs after age 35, and incidence increases with age. It affects about 2% of people older than age 60.

Complications

- Paralysis
- Psychotic behavior
- Loss of bowel and bladder sphincter control

Signs and Symptoms

Characteristically, pernicious anemia has an insidious onset but eventually causes an unmistakable triad of symptoms: weakness, sore tongue, and numbness and tingling in the extremities. The lips, gums, and tongue appear markedly bloodless. Hemolysis-induced hyperbilirubinemia may cause faintly jaundiced sclera and pale to bright yellow skin. In addition, the patient may become highly susceptible to infection, especially of the genitourinary (GU) tract.

Other systemic symptoms of pernicious anemia include the following:

- *Gastrointestinal* (*GI*)—Gastric mucosal atrophy and decreased hydrochloric acid production disturb digestion and lead to nausea, vomiting, anorexia, weight loss, flatulence, diarrhea, and constipation. Gingival bleeding and tongue inflammation may hinder eating and intensify anorexia.
- *Central nervous system* (*CNS*)—Demyelination caused by vitamin B_{12} deficiency initially affects the peripheral nerves but gradually extends to the spinal cord. Consequently, the neurologic effects of pernicious anemia may include neuritis; weakness in extremities; peripheral numbness and paresthesia; disturbed position sense; lack of coordination; ataxia; impaired fine finger movement; positive Babinski and Romberg signs; light-headedness; altered vision (diplopia and blurred vision), taste, and hearing (tinnitus); optic muscle atrophy; loss of bowel and bladder control; and, in males, impotence. Its effects on the nervous system may also produce irritability, poor memory, headache, depression, and delirium. Although some of these symptoms are temporary, irreversible CNS changes may have occurred before treatment.
- *Cardiovascular*—Increasingly fragile cell membranes induce widespread destruction of RBCs, resulting in low Hb levels. The impaired oxygen-carrying capacity of the blood secondary to lowered Hb leads to weakness, fatigue, and light-headedness. Compensatory increased cardiac output results in palpitations, wide pulse pressure, dyspnea, orthopnea, tachycardia, premature beats and, eventually, heart failure.

◆ *Musculoskeletal*—Scissors gait can also occur as a late sign of untreated anemia.

Diagnosis

A positive family history, typical ethnic heritage, and results of blood studies, bone marrow aspiration, gastric analysis, and the Schilling test establish the diagnosis. (See *Tests for blood composition, production, and function,* page 451.) Laboratory screening must rule out other anemias with similar symptoms, such as folic acid deficiency anemia, because treatment differs. Diagnosis must also rule out vitamin B_{12} deficiency resulting from malabsorption due to GI disorders, gastric surgery including obesity gastric bypass surgery, radiation, or drug therapy.

Tests for blood composition, production, and function

Overall Composition

◆ Peripheral blood smear shows maturity and morphologic characteristics of blood elements and determines qualitative abnormalities.
◆ Complete blood count (CBC) determines the actual number of blood elements in relation to volume and quantifies abnormalities.
◆ Bone marrow aspiration or biopsy allows evaluation of hematopoiesis by showing blood elements and precursors, and abnormal or malignant cells.

Red Blood Cell Function

◆ Hematocrit, or packed cell volume, measures the percentage of red blood cells (RBCs) per fluid volume of whole blood.
◆ Hemoglobin (Hb) measures the amount (grams) of Hb per deciliter of blood, to determine oxygen-carrying capacity.
◆ Reticulocyte count assesses RBC production by determining concentration of this erythrocyte precursor.
◆ Schilling test determines absorption of vitamin B_{12} (necessary for erythropoiesis) by measuring excretion of radioactive B_{12} in the urine.
◆ Mean corpuscular volume describes the RBC in terms of size.
◆ Mean corpuscular Hb determines the average amount of Hb per RBC.
◆ Mean corpuscular Hb concentration establishes the average Hb concentration in 1 dL of packed RBCs.
◆ Sucrose hemolysis test assesses the susceptibility of RBCs to hemolyze with complement.
◆ Direct Coombs test demonstrates the presence of immunoglobulin G (IgG) antibodies (such as antibodies to Rh factor) or, possibly, complement on circulating RBCs.
◆ Indirect Coombs test, a two-step test, detects the presence of IgG antibodies in the serum.
◆ Sideroblast test detects stainable iron (available for Hb synthesis) in normoblastic RBCs.
◆ Hb electrophoresis demonstrates abnormal Hb such as sickle cell anemia.

Hemostasis

◆ Platelet count determines the number of platelets.
◆ Bleeding time (Ivy bleeding time) assesses the capacity for platelets to stop bleeding in capillaries and small vessels.
◆ Prothrombin time (Quick test, pro time) assists in evaluation of thrombin generation

(extrinsic clotting mechanism).
- Partial thromboplastin time aids evaluation of the adequacy of plasma-clotting factors (intrinsic clotting mechanism).
- International normalized ratio normalizes ratios between labs.
- Fibrin degradation products (fibrin split products, FDPs) test the amount of clot breakdown products in serum.
- Thrombin time detects abnormalities in thrombin fibrinogen reaction.
- Fibrinogen (factor I) measures this coagulation factor in plasma.
- D-dimer test determines if FDPs are from normal mechanisms or excessive fibrinolysis and is commonly used to diagnose disseminated intravascular coagulation (DIC).

White Blood Cell Function
- White blood cell (WBC) count and differential establishes quantity and maturity of WBC elements (neutrophils [called polymorphonuclear granulocytes or bands], basophils, eosinophils, lymphocytes, monocytes).
- Quantified $CD4^+$:$CD8^+$ T lymphocytes determines helper:suppressor ratio, which is important to immune function and is decreased in HIV infection.

Plasma
- Erythrocyte sedimentation rate measures the rate of RBCs settling from plasma and may reflect infection.
- Electrophoresis of serum proteins determines the amount of various serum proteins (classified by mobility in response to an electrical field). It's commonly used to diagnose plasma cell myeloma.
- Immunoelectrophoresis of serum proteins separates and classifies serum antibodies (immunoglobulins) through specific antisera.
- Warn the patient with a sensory deficit not to use a heating pad, because it may cause burns.
- If the patient is incontinent, establish a regular bowel and bladder routine. After the patient is discharged, a home healthcare nurse should follow up on this schedule and make adjustments, as needed.
- If neurologic damage causes behavioral problems, assess mental and neurologic status often; if needed, give tranquilizers, as ordered, and apply wrist or jacket restraint and utilize bed alert alarm at night.
- Stress that vitamin B_{12} replacement isn't a permanent cure and that these injections *must* be continued for life, even after symptoms subside.

Blood study results that suggest pernicious anemia include:
- decreased Hb levels (4 to 5 g/dL) and decreased RBC count
- increased mean corpuscular volume (>120/µL); because larger-than-normal RBCs *each* contain increased amounts of Hb, mean corpuscular Hb concentration is also increased
- possible low WBC and platelet counts and large, malformed platelets
- serum vitamin B_{12} assay levels less than 0.1 µg/mL
- elevated serum lactate dehydrogenase levels

Bone marrow aspiration reveals erythroid hyperplasia (crowded red bone marrow), with increased numbers of megaloblasts but few normally developing RBCs. Gastric analysis shows absence of free hydrochloric acid after histamine or pentagastrin injection.

CONFIRMING DIAGNOSIS *The Schilling test was once the definitive diagnostic test for pernicious anemia. It is rarely used now because it involves the injection of radioactive vitamin B_{12}. Now, vitamin B_{12} levels are measured along with tests for the presence of IF and antiparietal cell antibodies.*

In addition, a complete blood count (CBC) with decreased Hb level and RBC count will reveal anemia. Elevated homocysteine and methylmalonic acid levels may indicate pernicious anemia. In some cases, bone marrow aspiration may be performed. If pernicious anemia is present, the aspirate will show erythroid hyperplasia, increased numbers of megaloblasts but few normally developing RBCs.

Treatment

Early parenteral vitamin B_{12} replacement can reverse pernicious anemia, minimize complications and, possibly, prevent permanent neurologic damage. An initial high dose of parenteral vitamin B_{12} causes rapid RBC regeneration. Within 2 weeks, Hb levels should rise to normal, and the patient's condition should markedly improve. Because rapid cell regeneration increases the patient's iron and folate requirements, concomitant iron and folic acid replacement is necessary to prevent iron deficiency anemia.

After the patient's condition improves, the vitamin B_{12} dosage can be decreased to maintenance levels and given monthly. Because such injections must be continued for life, the patient should learn self-administration of vitamin B_{12}.

A new vitamin B_{12} nasal gel that is applied once a week may be used in place of injections to maintain vitamin B_{12} levels.

If anemia causes extreme fatigue, the patient may require bed rest until Hb levels rise. If Hb levels are dangerously low, the patient may need blood transfusions. Digoxin, a diuretic, and a low-sodium diet may be necessary for a patient with heart failure. Most important is the replacement of vitamin B_{12} to control the condition that led to this failure. Antibiotics help combat accompanying infections.

Special Considerations

Supportive measures minimize the risk of complications and speed recovery. Patient and family teaching can promote compliance with lifelong vitamin B_{12} replacement.

- If the patient has severe anemia, plan activities, rest periods, and necessary diagnostic tests to conserve his energy. Monitor pulse rate often; tachycardia means activities are too strenuous.
- To ensure accurate Schilling test results, make sure that all urine over a 24-hour period is collected and that the specimens are uncontaminated.
- Warn the patient to guard against infections and tell them to report signs of infection

promptly, especially pulmonary and urinary tract infections, because the patient's weakened condition may increase susceptibility.

◆ Provide a well-balanced diet, including foods high in vitamin B_{12} (meat, liver, fish, eggs, and milk). Offer between-meal snacks and encourage the family to bring favorite foods from home.

◆ Because a sore mouth and tongue make eating painful, ask the dietitian to avoid giving the patient irritating foods. If these symptoms make talking difficult, supply a pad and pencil or some other aid to facilitate nonverbal communication; explain this problem to the family. Provide diluted mouthwash or, with severe conditions, swab the patient's mouth with tap water or warm saline solution or use topical anesthetic mouthwash.

PREVENTION *To prevent vitamin B_{12} deficiency, emphasize the importance of vitamin B_{12} supplements for patients who have had extensive gastric resections or who follow strict vegetarian or vegan diets.*

FOLIC ACID DEFICIENCY ANEMIA

Folic acid is a water-soluble vitamin that is rapidly excreted; body stores are limited to a few weeks. It is therefore relatively easy to develop a folic acid deficiency.

Folic acid deficiency anemia is a common, slowly progressive, megaloblastic anemia. It usually occurs in infants, adolescents, pregnant and lactating females, alcoholics, elderly people, and people with malignant or intestinal diseases.

Pathophysiology

Folic acid deficiency anemia may result from:

◆ alcohol abuse (alcohol may suppress metabolic effects of folate)
◆ poor diet (common in alcoholics, elderly people living alone, and infants, especially those with infections or diarrhea)
◆ impaired absorption (due to intestinal dysfunction from disorders such as celiac disease, tropical sprue, regional jejunitis, or bowel resection and bariatric surgery)
◆ bacteria competing for available folic acid
◆ excessive cooking, which can destroy a high percentage of folic acids in foods (See *Preventing folic acid deficiency anemia*.)

> **PREVENTION**
> **PREVENTING FOLIC ACID DEFICIENCY ANEMIA**
>
> Folic acid (pteroylglutamic acid, folacin) is found in most body tissues, where it acts as a coenzyme in metabolic processes involving one carbon transfer. It's essential for formation and maturation of red blood cells and for synthesis of deoxyribonucleic acid. Although its body stores are relatively small (about 70 mg), this vitamin is plentiful in most well-balanced diets.
>
> However, because folic acid is water-soluble and heat-labile, it's easily destroyed by cooking. Also, approximately 20% of folic acid intake is excreted unabsorbed. Insufficient daily folic acid intake (<50 µg/day) usually induces folic acid deficiency within 4 months.

To prevent folic acid deficiency anemia, foods high in folic acid content should be chosen, such as those listed below:

Food	µg/100 g
Asparagus spears	109
Beef liver	294
Broccoli spears	54
Collards (cooked)	102
Mushrooms	24
Oatmeal	133
Peanut butter	57
Red beans	180
Wheat germ	305

- limited storage capacity in infants
- prolonged drug therapy (anticonvulsants and estrogens)
- increased folic acid requirements during pregnancy; during rapid growth in infancy (common because of recent increase in survival of premature infants); during childhood and adolescence (because of general use of folate-poor cow's milk); and in patients with neoplastic diseases and some skin diseases (chronic exfoliative dermatitis)

It's estimated that 10% of the United States population has low folate stores.

Signs and Symptoms

Folic acid deficiency anemia gradually produces clinical features characteristic of other megaloblastic anemias, without the neurologic manifestations: progressive fatigue, shortness of breath, palpitations, weakness, glossitis, mouth ulcers, nausea, anorexia, headache, fainting, irritability, forgetfulness, pallor, and slight jaundice. Folic acid deficiency anemia doesn't cause neurologic impairment unless it's associated with vitamin B_{12} deficiency, as in pernicious anemia.

Diagnosis

CONFIRMING DIAGNOSIS *A CBC with significant findings including macrocytosis, decreased reticulocyte count, abnormal platelets, low Hb level, normal or high vitamin B_{12} level, and serum folate less than 3 ng/mL confirm the diagnosis.*

Treatment

Treatment consists primarily of folic acid supplements and elimination of contributing causes. Folic acid supplements may be given orally or parenterally (to patients who are severely ill, have malabsorption, or are unable to take oral medication). Many patients respond favorably to a well-balanced diet. Vitamin B_{12} deficiency should be ruled out before administering folic acid. If the patient has combined B_{12} and folate deficiencies, folic acid replenishment alone may aggravate neurologic dysfunction.

Special Considerations

- Teach the patient to meet daily folic acid requirements by including a food from each food

group in every meal. If they have a severe deficiency, explain that diet only reinforces folic acid supplementation and isn't therapeutic by itself. Urge compliance with the prescribed course of therapy. Advise them not to stop taking the supplements when they begin to feel better.

◆ If the patient has glossitis, emphasize the importance of good oral hygiene. Suggest regular use of mild or diluted mouthwash and a soft toothbrush.

◆ Watch fluid and electrolyte balance, particularly in the patient who has severe diarrhea and is receiving parenteral fluid replacement therapy.

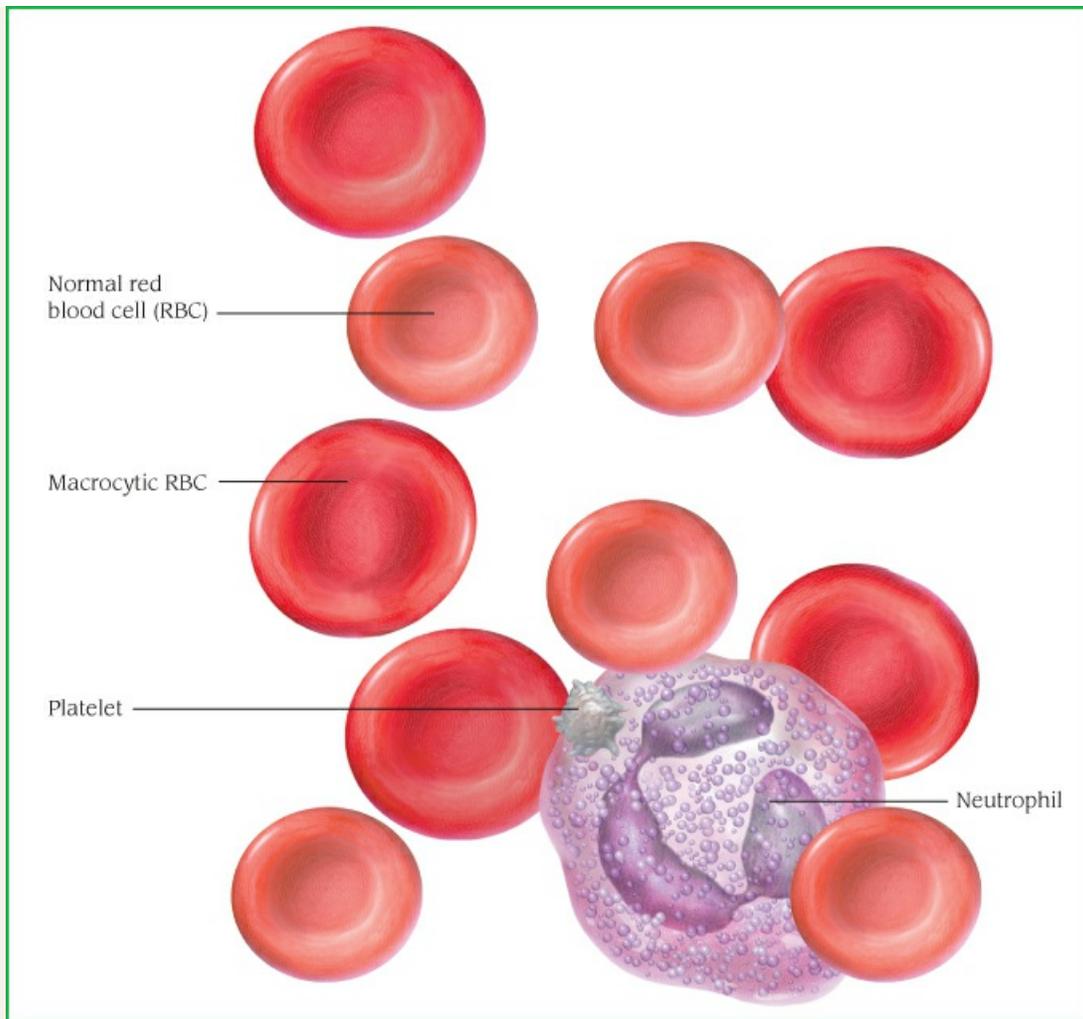
◆ Because anemia causes severe fatigue, schedule regular rest periods until the patient is able to resume normal activity.

PREVENTION *Emphasize the importance of a well-balanced diet high in folic acid. Identify alcoholics with poor dietary habits and try to arrange for appropriate counseling. Tell mothers who aren't breast-feeding to use commercially prepared formulas.*

APLASTIC ANEMIAS

Aplastic, or hypoplastic, anemias result from injury to or destruction of stem cells in bone marrow or the bone marrow matrix, causing pancytopenia (anemia, granulocytopenia, and thrombocytopenia) and bone marrow hypoplasia. (See *Peripheral blood smear in aplastic anemia*, page 454.) Although commonly used interchangeably with other terms for bone marrow failure, *aplastic anemia* properly refers to pancytopenia resulting from the decreased functional capacity of a hypoplastic, fatty bone marrow. These disorders generally produce fatal bleeding or infection, particularly when they're idiopathic or stem from chloramphenicol or from infectious hepatitis. Mortality for aplastic anemias with severe pancytopenia is 80% to 90%.

Peripheral Blood Smear in Aplastic Anemia

Aplastic anemia results from injury to or destruction of stem cells in the bone marrow or the bone marrow matrix, causing pancytopenia.


Pathophysiology

Aplastic anemias usually develop when damaged or destroyed stem cells (which develop into RBCs, WBCs, and platelets) inhibit RBC production. Less commonly, they develop when damaged bone marrow microvasculature creates an unfavorable environment for cell growth and maturation. About one-half of such anemias result from drugs (antibiotics, anticonvulsants, anti-inflammatory drugs, antineoplastics, diuretics, phenothiazines, antidiabetics, and antithyroid drugs), toxic agents (such as benzene and chloramphenicol), or radiation. The rest may result from immunologic factors (unconfirmed), severe disease (especially hepatitis), viral infection (especially in children), or preleukemic and neoplastic infiltration of bone marrow.

Idiopathic anemias may be congenital. Two such forms of aplastic anemia have been identified: Congenital hypoplastic anemia (Blackfan–Diamond anemia) develops between ages 2 and 3 months; Fanconi syndrome, between birth and age 10. In Fanconi syndrome, chromosomal abnormalities are usually associated with multiple congenital anomalies, such as dwarfism, and hypoplasia of the kidneys and spleen. In the absence of a consistent familial or genetic history of aplastic anemia, researchers suspect that these congenital abnormalities result from an induced change in the fetus' development.

Incidence is 0.6 to 6.1 cases per 1 million people in the United States. There is no racial predilection.

Complications

- Life-threatening hemorrhage
- Secondary opportunistic infections

Signs and Symptoms

Clinical features of aplastic anemias vary with the severity of pancytopenia but develop insidiously in many cases. Anemic symptoms include progressive weakness and fatigue, shortness of breath, headache, pallor and, ultimately, tachycardia and heart failure. Thrombocytopenia leads to ecchymosis, petechiae, and hemorrhage, especially from the mucous membranes (nose, gums, rectum, and vagina) or into the retina or CNS. Neutropenia may lead to infection (fever, oral and rectal ulcers, and sore throat) but without characteristic inflammation.

Diagnosis

Confirmation of aplastic anemia requires a series of laboratory tests:

- RBCs are usually normochromic and normocytic (although macrocytosis [larger-than-normal erythrocytes] and anisocytosis [excessive variation in erythrocyte size] may exist), with a total count of 1 million/µL or less. Absolute reticulocyte count is very low.
- Serum iron level is elevated (unless bleeding occurs), but total iron-binding capacity is normal or slightly reduced. Hemosiderin (a derivative of Hb) is present, and tissue iron storage is visible microscopically.
- Platelet, neutrophil, and WBC counts fall.
- Coagulation tests (bleeding time), reflecting decreased platelet count, are abnormal.
- Bone marrow aspiration from several sites may yield a "dry tap," and biopsy will show severely hypocellular or aplastic marrow with varied amounts of fat, fibrous tissue, or gelatinous replacement; absence of tagged iron (because iron is deposited in the liver rather than bone marrow) and megakaryocytes (platelet precursors); and depression of erythroid elements.

Differential diagnosis must rule out paroxysmal nocturnal hemoglobinuria and other diseases in which pancytopenia is common.

Treatment

Effective treatment must eliminate any identifiable cause and provide vigorous supportive measures, such as packed RBCs, platelets, and experimental histocompatibility locus antigen-matched leukocyte transfusions. Even after elimination of the cause, recovery can take months. Bone marrow or stem cell transplantation is the treatment of choice for anemia due to severe aplasia and for patients who need constant RBC transfusions. (See *Bone marrow transplantation*, pages 455 and 456.)

Bone marrow transplantation

In bone marrow transplantation, usually 500 to 700 mL of marrow is aspirated from the

pelvic bones of a human leukocyte antigen (HLA)-compatible donor (allogeneic) or of the recipient himself during complete remission (autologous). The aspirated marrow is filtered and then infused into the recipient in an attempt to repopulate the patient's marrow with normal cells. This procedure has effected long-term, healthy survival in about 50% of patients with severe aplastic anemia. Bone marrow transplantation may also be effective in patients with acute leukemia, certain immunodeficiency diseases, and solid tumor neoplasms.

Because bone marrow transplantation carries serious risks, it requires strict adherence to infection control and strict sterile techniques, and a primary nurse to provide consistent care and continuous monitoring of the patient's status.

Before Transplantation

- Explain that the success rate depends on the stage of the disease and an HLA-identical match.
- After bone marrow aspiration is completed under a local anesthetic, apply pressure dressings to the donor's aspiration sites. Observe the sites for bleeding. Relieve pain with analgesics and ice packs, as needed.
- Assess the patient's understanding of bone marrow transplantation. If necessary, correct any misconceptions about this procedure and provide additional information, as appropriate. Prepare the patient to expect an extended hospital stay. Explain that chemotherapy and possible radiation treatments are necessary to destroy cells that may cause the body to reject the transplant.
- Various treatment protocols are used. For example, I.V. cyclophosphamide may be used with additional chemotherapeutic agents or total body irradiation. This treatment requires aggressive hydration to prevent hemorrhagic cystitis. Control nausea and vomiting with an antiemetic, such as ondansetron (Zofran) or metoclopramide (Reglan), as needed. Give allopurinol, as prescribed, to prevent hyperuricemia resulting from tumor breakdown products. Because alopecia is a common adverse effect of high-dose cyclophosphamide therapy, encourage the patient to choose a wig or scarf before treatment begins.
- Total body irradiation may follow chemotherapy, inducing total marrow aplasia. Warn the patient that cataracts, GI disturbances, and sterility are possible adverse effects.
- Assess venous access. If necessary, the patient may have an indwelling central venous catheter inserted.

During Marrow Infusion

- Monitor vital signs every 15 minutes.
- Watch for complications of marrow infusion, such as pulmonary embolus, hypersensitivity reactions, and volume overload.
- Reassure the patient throughout the procedure.

After The Infusion

- Continue to monitor the patient's vital signs every 15 minutes for 2 hours after infusion, then every 4 hours. Watch for fever and chills, which may be the only signs of infection. Give prophylactic antibiotics as prescribed. To reduce the possibility of bleeding, don't administer medications rectally or I.M.
- Administer methotrexate or cyclosporine, as prescribed, to prevent graft-versus-host (GVH) reaction, a potentially fatal complication of allogeneic transplantation. Watch for

signs or symptoms of GVH reaction, such as maculopapular rash, pancytopenia, jaundice, joint pain, and generalized edema.
- Administer vitamins, steroids, and iron and folic acid supplements, as appropriate. Administration of blood products, such as platelets and packed red blood cells, may also be indicated, depending on the results of daily blood studies.
- Provide good mouth care every 2 hours. Use hydrogen peroxide and nystatin mouthwash or oral fluconazole, for example, to prevent candidiasis and other mouth infections. Also provide meticulous skin care, paying special attention to pressure points and open sites, such as those from the marrow aspiration and I.V. insertion.

Patients with low leukocyte counts need special measures to prevent infection. The infection itself may require specific antibiotics; however, these aren't given prophylactically because they tend to encourage resistant strains of organisms. Patients with low Hb levels may need respiratory support with oxygen in addition to blood transfusions.

For older patients, or for those who don't have a matched bone marrow donor, antithymocyte globulin (ATG) is an alternative treatment. ATG is a horse serum that contains antibodies against human T cells. It may be used in an attempt to suppress the body's immune system, allowing the bone marrow to resume its blood cell-generating function. Other immunosuppressant agents, such as cyclosporine, may also be used.

Other treatments may include corticosteroids to stimulate erythroid production, marrow-stimulating agents such as androgens (which remain controversial), and colony stimulation factors to encourage growth of specific cellular components.

Special Considerations

- If the platelet count is low (<20,000/μL), prevent bleeding by avoiding I.M. injections, suggesting the use of an electric razor and a soft toothbrush, humidifying oxygen to prevent drying of mucous membranes, avoiding enemas and rectal temperatures, and promoting regular bowel movements through the use of a stool softener and a proper diet to prevent constipation. Also, apply pressure to venipuncture sites until bleeding stops. Detect bleeding early by checking for blood in urine and stool, and assessing skin for petechiae.
- Take safety precautions to prevent falls that could lead to prolonged bleeding or hemorrhage.
- Help prevent infection by washing your hands thoroughly before entering the patient's room, by making sure they are receiving a nutritious diet (high in vitamins and proteins) to improve resistance, and by encouraging meticulous mouth and perianal care.
- Watch for life-threatening hemorrhage, infection, adverse effects of drug therapy, or blood transfusion reaction. Make sure routine throat, urine, nose, rectal, and blood cultures are done regularly and correctly to check for infection. Teach the patient to recognize signs of infection, and tell to report any abnormal signs immediately.
- If the patient has a low Hb level, which causes fatigue, schedule frequent rest periods. Administer oxygen therapy as needed. If blood transfusions are necessary, assess for a transfusion reaction by checking the patient's temperature and watching for the development of other signs and symptoms, such as rash, hives, itching, back pain, restlessness, and shaking chills.
- Reassure and support the patient and their family by explaining the disease and its treatment, particularly if they have recurring acute episodes. Explain the purpose of all prescribed drugs and discuss possible adverse effects, including which ones they should report promptly.

Encourage the patient who doesn't require hospitalization to continue their normal lifestyle, with appropriate restrictions (such as regular rest periods), until remission occurs.

◆ To prevent aplastic anemia, monitor blood studies carefully in the patient receiving anemia-inducing drugs.

◆ Support efforts to educate the public about the hazards of toxic agents. Tell parents to keep toxic agents out of the reach of children. Encourage people who work with radiation to wear protective clothing and a radiation-detecting badge, and to observe plant safety precautions. Those who work with benzene (solvent) should know that 10 parts per million is the highest safe environmental level and that a delayed reaction to benzene may develop.

SIDEROBLASTIC ANEMIAS

Sideroblastic anemias are a group of heterogeneous disorders with a common defect; they fail to use iron in Hb synthesis, despite the availability of adequate iron stores. These anemias may be hereditary or acquired; the acquired form, in turn, can be primary or secondary. Hereditary sideroblastic anemia may respond to treatment with pyridoxine. Correction of the secondary acquired form depends on the causative disorder; the primary acquired (idiopathic) form, however, resists treatment and usually proves fatal within 10 years after onset of complications or a concomitant disease.

Pathophysiology

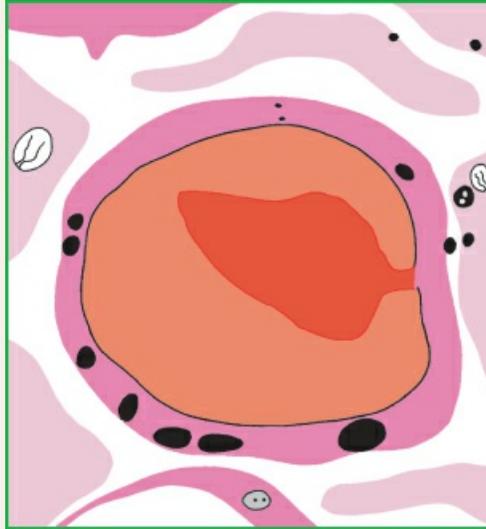
Hereditary sideroblastic anemia appears to be transmitted by X-linked inheritance, occurring mostly in young males; females are carriers and usually show no signs of this disorder.

The acquired form may be secondary to ingestion of or exposure to toxins, such as alcohol and lead, or to certain drugs, such as isoniazid used to treat tuberculosis. It can also occur as a complication of other diseases, such as rheumatoid arthritis, lupus erythematosus, multiple myeloma, tuberculosis, and severe infections.

The primary acquired form, known as *refractory anemia with ringed sideroblasts*, is most common in elderly people. It's commonly associated with thrombocytopenia or leukopenia as part of a myelodysplastic syndrome.

In sideroblastic anemia, normoblasts fail to use iron to synthesize Hb. As a result, iron is deposited in the mitochondria of normoblasts, which are then termed *ringed sideroblasts*. (See *Ringed sideroblast*.)

Ringed sideroblast

Electron microscopy shows large iron deposits in the mitochondria that surround the nucleus, forming the characteristic ringed sideroblast.


Complications

- Severe cardiac, hepatic, and pancreatic disease
- Respiratory complications

Signs and Symptoms

Sideroblastic anemias usually produce nonspecific clinical effects, which may exist for several years before being identified. Such effects include anorexia, fatigue, weakness, dizziness, pale skin and mucous membranes and, occasionally, enlarged lymph nodes. Heart and liver failure may develop due to excessive iron accumulation in these organs, causing dyspnea, exertional angina, slight jaundice, and hepatosplenomegaly. Hereditary sideroblastic anemia is associated with increased GI absorption of iron, causing signs of hemosiderosis. Additional symptoms in secondary sideroblastic anemia depend on the underlying cause.

Diagnosis

℞ CONFIRMING DIAGNOSIS *Ringed sideroblasts on microscopic examination of bone marrow aspirate, stained with Prussian blue or alizarin red dye, confirm this diagnosis.*

Microscopic examination of blood shows erythrocytes to be hypochromic or normochromic and slightly macrocytic. Red cell precursors may be megaloblastic, with anisocytosis (abnormal variation in RBC size) and poikilocytosis (abnormal variation in RBC shape). Unlike iron deficiency anemia, sideroblastic anemia lowers Hb levels and raises serum iron and transferrin levels. In turn, faulty Hb production raises urobilinogen and bilirubin levels. Platelets and leukocytes remain normal, but, occasionally, thrombocytopenia or leukopenia occurs.

Treatment

Treatment of sideroblastic anemias depends on the underlying cause. The hereditary form usually responds to several weeks of treatment with high doses of pyridoxine (vitamin B$_6$). The acquired secondary form generally subsides after the causative drug or toxin is removed or the

underlying condition is adequately treated. Folic acid supplements may also be beneficial when concomitant megaloblastic nuclear changes in RBC precursors are present. Elderly patients with sideroblastic anemia (usually the primary acquired form) are less likely to improve quickly and are more likely to develop serious complications. Deferoxamine may be used to treat chronic iron overload in selected patients.

Carefully crossmatched transfusions (providing needed Hb) or high doses of androgens are effective palliative measures for some patients with the primary acquired form of sideroblastic anemia. However, this form is essentially refractory to treatment and usually leads to death from acute leukemia or from respiratory or cardiac complications.

Some patients with sideroblastic anemia may benefit from phlebotomy to prevent hemochromatosis (the accumulation of iron in body tissues). Phlebotomy steps up the rate of erythropoiesis and uses up excess iron stores; thus, it reduces serum and total body iron levels.

Special Considerations

- Administer medications as indicated. Teach the patient the importance of continuing prescribed therapy, even after they begin to feel better.
- Provide frequent rest periods if the patient becomes easily fatigued.
- If phlebotomy is scheduled, explain the procedure thoroughly to help reduce anxiety. If this procedure must be repeated frequently, provide a high-protein diet to help replace the protein lost during phlebotomy. Encourage the patient to follow a similar diet at home.
- Always inquire about the possibility of exposure to lead in the home (especially for children) or on the job.
- Identify patients who abuse alcohol; refer them for appropriate therapy.

THALASSEMIA

Thalassemia, a hereditary group of hemolytic anemias, is characterized by defective synthesis in the polypeptide chains necessary for Hb production. Consequently, RBC synthesis is also impaired. (See *Peripheral blood smear in thalassemia major*.)

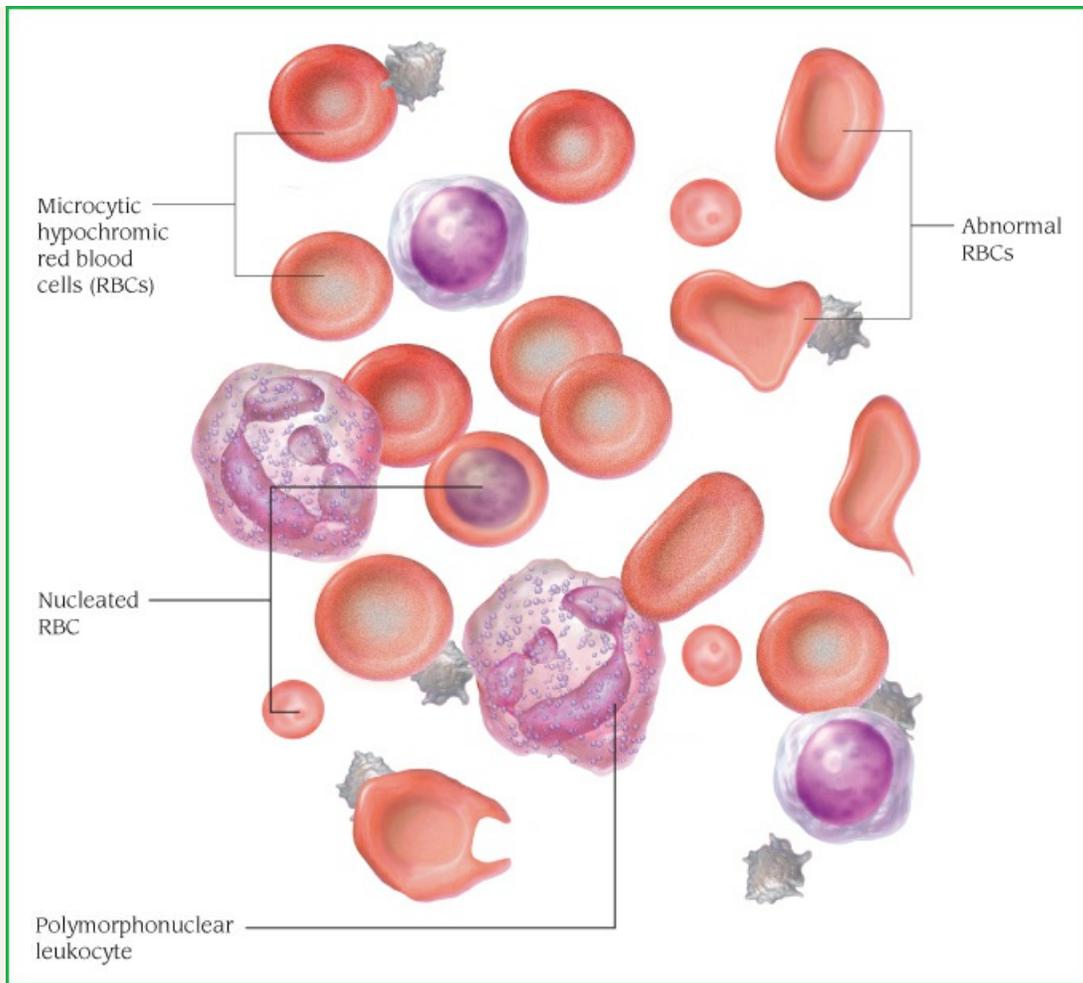
Peripheral blood smear in thalassemia major

Thalassemia major is a hereditary group of hemolytic anemias. It is characterized by defective synthesis in the polypeptide chains necessary for hemoglobin production that results in impairment of red blood cell production.

Microcytic hypochromic red blood cells (RBCs)

Abnormal RBCs

Nucleated RBC

Polymorphonuclear leukocyte


Beta-thalassemia is the most common form of this disorder. It results from defective beta polypeptide chain synthesis and occurs in three clinical forms: major, intermedia, and minor. The resulting anemia's severity depends on whether the patient is homozygous or heterozygous for the thalassemic trait. The prognosis for beta-thalassemia varies. People with thalassemia major seldom survive to adulthood; children with thalassemia intermedia develop normally into adulthood, although puberty is usually delayed; people with thalassemia minor can expect a normal life span.

Pathophysiology

Thalassemia major and *thalassemia intermedia* result from homozygous inheritance of the partially dominant autosomal gene responsible for this trait. *Thalassemia minor* results from heterozygous inheritance of the same gene. In these disorders, total or partial deficiency of beta polypeptide chain production impairs Hb synthesis and results in continual production of fetal Hb, lasting even past the neonatal period.

Thalassemia is most common in people of Mediterranean ancestry (especially Italian and Greek) but also occurs in blacks and people from southern China, Southeast Asia, and India.

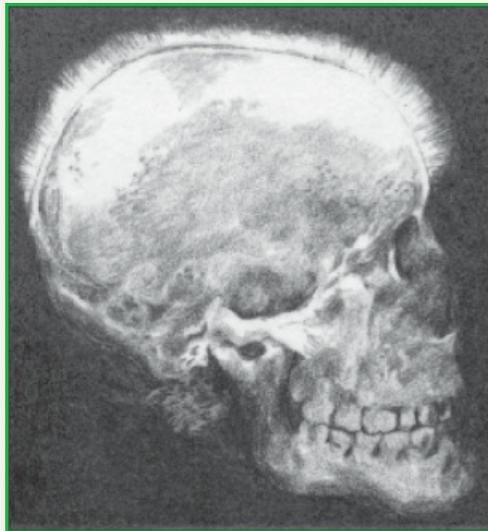
Complications

- Pathologic fractures
- Cardiac arrhythmias
- Heart failure

Signs and Symptoms

In thalassemia major (also known as *Cooley anemia, Mediterranean disease,* and *erythroblastic anemia*), the neonate is well at birth but develops severe anemia, bone abnormalities, failure to thrive, and life-threatening complications. (See *Thalassemia major*.) In many cases, the first signs are pallor and yellow skin and sclera in infants ages 3 to 6 months. Later clinical features, in addition to severe anemia, include splenomegaly or hepatomegaly, with abdominal enlargement, frequent infections, bleeding tendencies (especially toward epistaxis), and anorexia.

Thalassemia major

X-ray shows a characteristic skull abnormality in thalassemia major: diploetic fibers extending from the internal lamina.


Children with thalassemia major typically have small bodies and large heads and may also be mentally retarded. Infants may have mongoloid features because bone marrow hyperactivity has thickened the bone at the base of the nose. As these children grow older, they become susceptible to pathologic fractures as a result of expansion of the marrow cavities with thinning of the long bones. They're also subject to cardiac arrhythmias, heart failure, and other complications that result from iron deposits in the heart and in other tissues from repeated blood transfusions.

Thalassemia intermedia comprises moderate thalassemic disorders in homozygotes. Patients with this condition show some degree of anemia, jaundice, and splenomegaly and, possibly, signs of hemosiderosis due to increased intestinal absorption of iron.

Thalassemia minor may cause mild anemia but usually produces no symptoms and is

commonly overlooked. It should be differentiated from iron deficiency anemia.

Diagnosis

In the infant, the development of anemia with the characteristic bone abnormalities suggests the diagnosis of thalassemia major. Laboratory results show lowered RBC count and Hb level, microcytosis, and elevated reticulocyte, bilirubin, and urinary and fecal urobilinogen levels. A low serum folate level indicates increased folate utilization by the hypertrophied bone marrow. A peripheral blood smear reveals target cells, microcytes, pale nucleated RBCs, and marked anisocytosis. X-rays of the skull and long bones show thinning and widening of the marrow space because of overactive bone marrow. The bones of the skull and vertebrae may appear granular; long bones may show areas of osteoporosis. The phalanges may also be deformed (rectangular or biconvex). Quantitative Hb studies show a significant rise in HbF and a slight increase in HbA_2. Diagnosis must rule out iron deficiency anemia, which also produces hypochromia (slightly lowered Hb level) and microcytic (notably small) RBCs.

In thalassemia intermedia, laboratory results show hypochromia and microcytic RBCs, but the anemia is less severe than that in thalassemia major. In thalassemia minor, laboratory results show hypochromia and microcytic RBCs. Quantitative Hb studies show a significant increase in HbA_2 levels and a moderate rise in HbF levels.

Treatment

Treatment of thalassemia major is essentially supportive. For example, infections require prompt treatment with appropriate antibiotics. Folic acid supplements help maintain folic acid levels in the face of increased requirements. Transfusions of packed RBCs raise Hb levels but must be used judiciously to minimize iron overload. In addition, patients who receive blood transfusions should avoid iron supplements and oxidative drugs because iron levels can become toxic. Those who receive significant numbers of blood transfusions may require chelation therapy to remove iron from the body. Bone marrow transplantation is performed only in severe cases due to riskiness of the procedure and difficulty finding a good donor match.

Thalassemia intermedia and thalassemia minor generally don't require treatment.

Iron supplements are contraindicated in all forms of thalassemia.

Special Considerations

- During and after RBC transfusions for thalassemia major, watch for adverse reactions—shaking chills, fever, rash, itching, and hives.
- Stress the importance of good nutrition, meticulous wound care, periodic dental checkups, and other measures to prevent infection.
- Discuss with the parents of a young patient various options for healthy physical and creative outlets. Such a child must avoid strenuous athletic activity because of increased oxygen demand and the tendency toward pathologic fractures, but may participate in less stressful activities.
- Teach parents to watch for signs of hepatitis and iron overload, which are always possible with frequent transfusions.
- Because parents may have questions about the vulnerability of future offspring, refer them for genetic counseling. Also refer adult patients with thalassemia minor and thalassemia intermedia for genetic counseling; they need to recognize the risk of transmitting thalassemia major to their children if they marry another person with thalassemia. If such people choose to

marry and have children, their children should be evaluated for thalassemia by age 1. Be sure to tell people with thalassemia minor that their condition is benign.

IRON DEFICIENCY ANEMIA

Iron deficiency anemia is caused by an inadequate supply of iron for optimal formation of RBCs, resulting in smaller (microcytic) cells with less color on staining. (See *Peripheral blood smear in iron deficiency anemia,* page 461.) Body stores of iron, including plasma iron, decrease, as do levels of transferrin, which binds with and transports iron. Insufficient body stores of iron lead to a depleted RBC mass and, in turn, to a decreased Hb concentration (hypochromia) and decreased oxygen-carrying capacity of the blood. (See *Absorption and storage of iron,* page 461.)

Peripheral blood smear in iron deficiency anemia

Iron deficiency anemia is caused by an inadequate supply of iron for the formation of red blood cells, resulting in smaller (microcytic) cells with less color on staining.

Pathophysiology

Iron deficiency anemia may result from:

- inadequate dietary intake of iron (<1 to 2 mg/day), such as in prolonged unsupplemented breast-feeding or bottle-feeding of infants or during periods of stress such as rapid growth in children and adolescents
- iron malabsorption, such as in chronic diarrhea, partial or total gastrectomy, chronic diverticulosis, and malabsorption syndromes, such as celiac disease and pernicious anemia. Can also see iron deficiency in patient who have had bariatric surgery
- blood loss secondary to drug-induced GI bleeding (from anticoagulants, aspirin, and steroids) or due to heavy menses, hemorrhage from trauma, GI ulcers, esophageal varices, or cancer
- pregnancy, which diverts maternal iron to the fetus for erythropoiesis
- intravascular hemolysis-induced hemoglobinuria or paroxysmal nocturnal hemoglobinuria
- mechanical erythrocyte trauma caused by a prosthetic heart valve or vena cava filters
- anemia of chronic inflammation (as in rheumatoid arthritis)

A common disease worldwide, iron deficiency anemia affects 10% to 30% of the adult population of the United States. It occurs most commonly in premenopausal women, infants (particularly premature or low–birth-weight neonates), children, and adolescents (especially girls). Persons who are at increased risk for iron deficiency include those of low socioeconomic status who don't get a well-balanced diet that includes iron-rich foods.

Complications

- Infection
- Pneumonia
- Pica (in children)
- Bleeding
- Hemochromatosis (from excess iron treatment in children)

Signs and Symptoms

Because of the gradual progression of iron deficiency anemia, many patients are initially asymptomatic except for symptoms of any underlying condition. They tend not to seek medical treatment until anemia is severe. At advanced stages, decreased Hb levels and the consequent decrease in the blood's oxygen-carrying capacity cause the patient to develop dyspnea on exertion, fatigue, listlessness, pallor, inability to concentrate, irritability, headache, and a susceptibility to infection. Decreased oxygen perfusion causes the heart to compensate with increased cardiac output and tachycardia.

In chronic iron deficiency anemia, nails become spoon-shaped and brittle, the mouth's corners crack, the tongue turns smooth, and the patient complains of dysphagia or may develop pica. Associated neuromuscular effects include vasomotor disturbances, numbness and tingling of the extremities, and neuralgic pain.

Diagnosis

Blood studies (serum iron levels, total iron-binding capacity, and ferritin levels) and stores in bone marrow may confirm iron deficiency anemia. However, the results of these tests can be misleading because of complicating factors, such as infection, pneumonia, blood transfusion, or iron supplements. Characteristic blood test results include:

- low Hb levels (in males, <12 g/dL; in females, <10 g/dL)
- low HCT (in males, <39%; in females, <35%)
- low serum iron levels, with elevated total iron-binding capacity
- low serum ferritin levels
- low RBC count, with microcytic and hypochromic cells (in early stages, RBC count may be normal, except in infants and children)
- decreased mean corpuscular volume in severe anemia

Although rarely used, bone marrow studies provide a definitive diagnosis by revealing depleted or absent iron stores (done by staining) and normoblastic hyperplasia.

Diagnosis must rule out other forms of anemia, such as those that result from thalassemia minor, cancer, and chronic inflammatory, hepatic, and renal disease.

Treatment

The first priority of treatment is to determine the underlying cause of anemia. Once this is determined, iron replacement therapy can begin. Treatment of choice is an oral preparation of iron or a combination of iron and ascorbic acid (which enhances iron absorption). However, in some cases, iron may have to be administered parenterally—for instance, if the patient is noncompliant to the oral preparation, needs more iron than can be taken orally, if malabsorption prevents adequate iron absorption, or if a maximum rate of Hb regeneration is desired.

Because total dose I.V. infusion of supplemental iron is painless and requires fewer injections, it's usually preferred to I.M. administration. Pregnant patients and geriatric patients with severe anemia, for example, should receive a total dose infusion of iron dextran in normal saline solution over 8 hours. To minimize the risk of an allergic reaction to iron, an I.V. test dose of 0.5 mL should be given first. For more patient care information, see *Supportive management of patients with anemia*, above.

Supportive management of patients with anemia

To meet the anemic patient's nutritional needs:

- If the patient is fatigued, urge them to eat small, frequent meals throughout the day.
- If the patient has oral lesions, suggest soft, cool, bland foods.
- If the patient has dyspepsia, eliminate spicy foods, and include milk and dairy products in his diet.
- If the patient is anorexic and irritable, encourage the family to bring their favorite foods from home (unless the diet is restricted) and to keep them company during meals, if possible.

To set limitations on activities:

- Assess the effect of a specific activity by monitoring pulse rate during the activity. If the patient's pulse accelerates rapidly and the patient develops hypotension with hyperpnea, diaphoresis, light-headedness, palpitations, shortness of breath, or weakness, the activity is too strenuous.
- Tell the patient to pace his activities and to allow for frequent rest periods.

To decrease susceptibility to infection:

- Use strict sterile technique.
- Isolate the patient from infectious persons.
- Instruct the patient to avoid crowds and other sources of infection. Encourage them to practice good hand-washing technique. Stress the importance of receiving necessary immunizations and prompt medical treatment for any sign of infection.

To prepare the patient for diagnostic testing:

- Explain erythropoiesis, the function of blood, and the purpose of diagnostic and therapeutic procedures.
- Tell the patient how they can participate in diagnostic testing. Give them an honest description of the pain or discomfort they will probably experience.
- If possible, schedule all tests to avoid disrupting the patient's meals, sleep, and visiting hours.

To prevent complications:

- Observe for signs of bleeding that may exacerbate anemia. Check stool for occult bleeding. Assess for ecchymoses, gingival bleeding, and hematuria. Monitor vital signs frequently.
- If the patient is confined to strict bed rest, assist with range-of-motion exercises and frequent turning, coughing, and deep breathing.
- If blood transfusions are needed for severe anemia (hemoglobin level <5 g/dL), give washed red blood cells, as ordered, in partial exchange if evidence of pump failure is present. Carefully monitor for signs of circulatory overload or transfusion reaction. Watch for a change in pulse rate, blood pressure, or respiratory rate, or onset of fever, chills, pruritus, or edema. If any of these signs develop, stop the transfusion and notify the physician.
- Warn the patient to move about or change positions slowly to minimize dizziness induced by cerebral hypoxia.

Special Considerations

- Monitor the patient's compliance with the prescribed iron supplement therapy. Advise the patient not to stop therapy even if they feel better, because replacement of iron stores takes

time. Iron supplementation must be continued for at least 1 year after Hb has risen to normal levels.

◆ Tell the patient they may take iron supplements with a meal to decrease gastric irritation. Advise them to avoid fiber, milk, and milk products, and antacids because they interfere with iron absorption; however, vitamin C can increase absorption.

◆ Warn the patient that iron supplements may result in dark green or black stools and can cause constipation.

◆ Instruct the patient to drink liquid supplemental iron through a straw to prevent staining his teeth.

◆ Tell the patient to report reactions, such as nausea, vomiting, diarrhea, constipation, fever, or severe stomach pain, which may require a dosage adjustment.

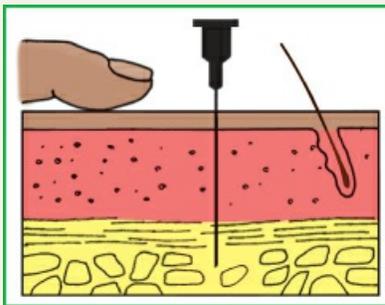
◆ Use the Z-track injection method when administering iron I.M. to prevent skin discoloration, scarring, and irritating iron deposits in the skin. (See *How to inject iron solutions*, page 463.)

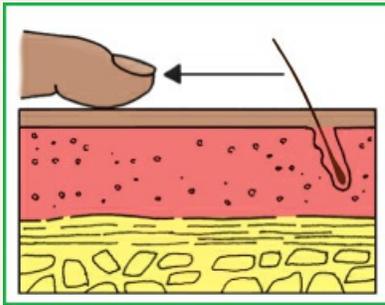
How to inject iron solutions

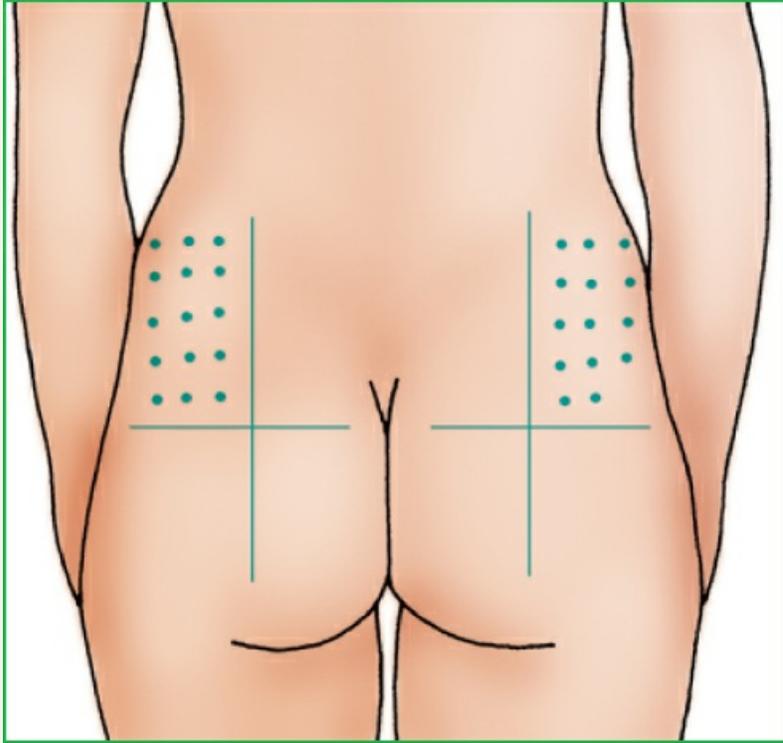
For deep I.M. injections of iron solutions, use the Z-track technique to avoid subcutaneous irritation and discoloration from leaking medication.

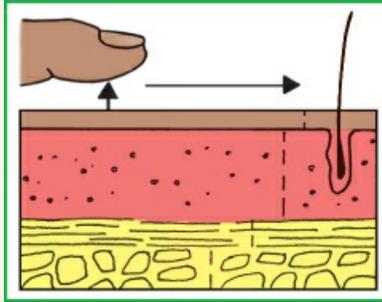
Choose a 19G to 20G, 2″ to 3″ needle. After drawing up the solution, change to a fresh needle to avoid tracking the solution through to subcutaneous tissue. Draw 0.5 mL of air into the syringe as an "air lock."

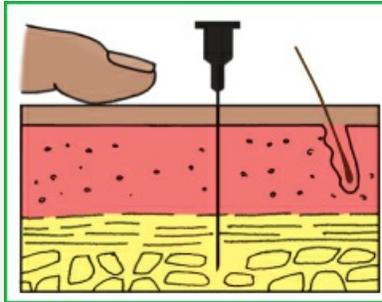
Displace the skin and fat at the injection site (in the upper outer quadrant of the buttocks or the ventrogluteal site only) firmly to one side. Clean the area and insert the needle. Aspirate to check for entry into a blood vessel. Inject the solution slowly, followed by the 0.5 mL of air in the syringe. Wait 10 seconds, then pull the needle straight out, and release tissues.

Apply direct pressure to the site but don't massage it. Caution the patient against vigorous exercise for 15 to 30 minutes.










- Because an iron deficiency may recur, advise regular checkups and blood studies. (See *Preventing iron deficiency anemia,* page 464.)

PREVENTION
PREVENTING IRON DEFICIENCY ANEMIA

Play a vital role in preventing iron deficiency anemia in your patients by encouraging the following actions:

Include Iron-Rich Foods In Diet

Teach the basics of a nutritionally balanced diet by having your patients include foods rich in iron, such as those listed below, in their diet:
- Meat (especially liver)
- Egg yolks
- Dried beans or peas
- Green leafy vegetables
- Dried fruits
- Cream of wheat cereal
- Molasses

Include Vitamin C-Rich Foods In Diet

Encourage your patients to consume foods high in vitamin C (ascorbic acid) at the same time they're eating iron-rich foods. The vitamin C aids in the absorption of the iron. These foods are rich in vitamin C:
- Citrus fruit or juice

- Tomatoes
- Broccoli
- Melons
- Strawberries
- Red peppers

Include Prophylactic Oral Iron

Emphasize the need for high-risk individuals, such as premature infants, children younger than age 2, and pregnant women, to receive prophylactic oral iron, as ordered by a physician. (Children younger than age 2 should also receive supplemental cereals and formulas high in iron.)

Assess Dietary Habits

Assess a family's dietary habits for iron intake and note the influence of childhood eating patterns, cultural food preferences, and family income on adequate nutrition.

Assess Medication History

Carefully assess your patients' drug histories because certain drugs, such as pancreatic enzymes and vitamin E, may interfere with iron metabolism and absorption and because aspirin, steroids, and other drugs may cause GI bleeding. (Teach patients who must take medications that are gastric irritants to take these medications with meals or milk.)

ALERT *If the patient receives I.V. iron, monitor the infusion rate carefully and observe for an allergic reaction. Stop the infusion and begin supportive treatment immediately if the patient shows signs of an adverse reaction. Also, watch for dizziness and headache and for thrombophlebitis around the I.V. site.*

Polycythemias

POLYCYTHEMIA VERA

Polycythemia vera is a chronic, myeloproliferative disorder characterized by increased RBC mass. In addition, there may also be leukocytosis, thrombocytosis, and increased Hb concentration, with normal or increased plasma volume. This disease is also known as *primary polycythemia, erythremia, polycythemia rubra vera, splenomegalic polycythemia,* and *Vaquez–Osler disease.* (See *Peripheral blood smear in polycythemia vera.*)

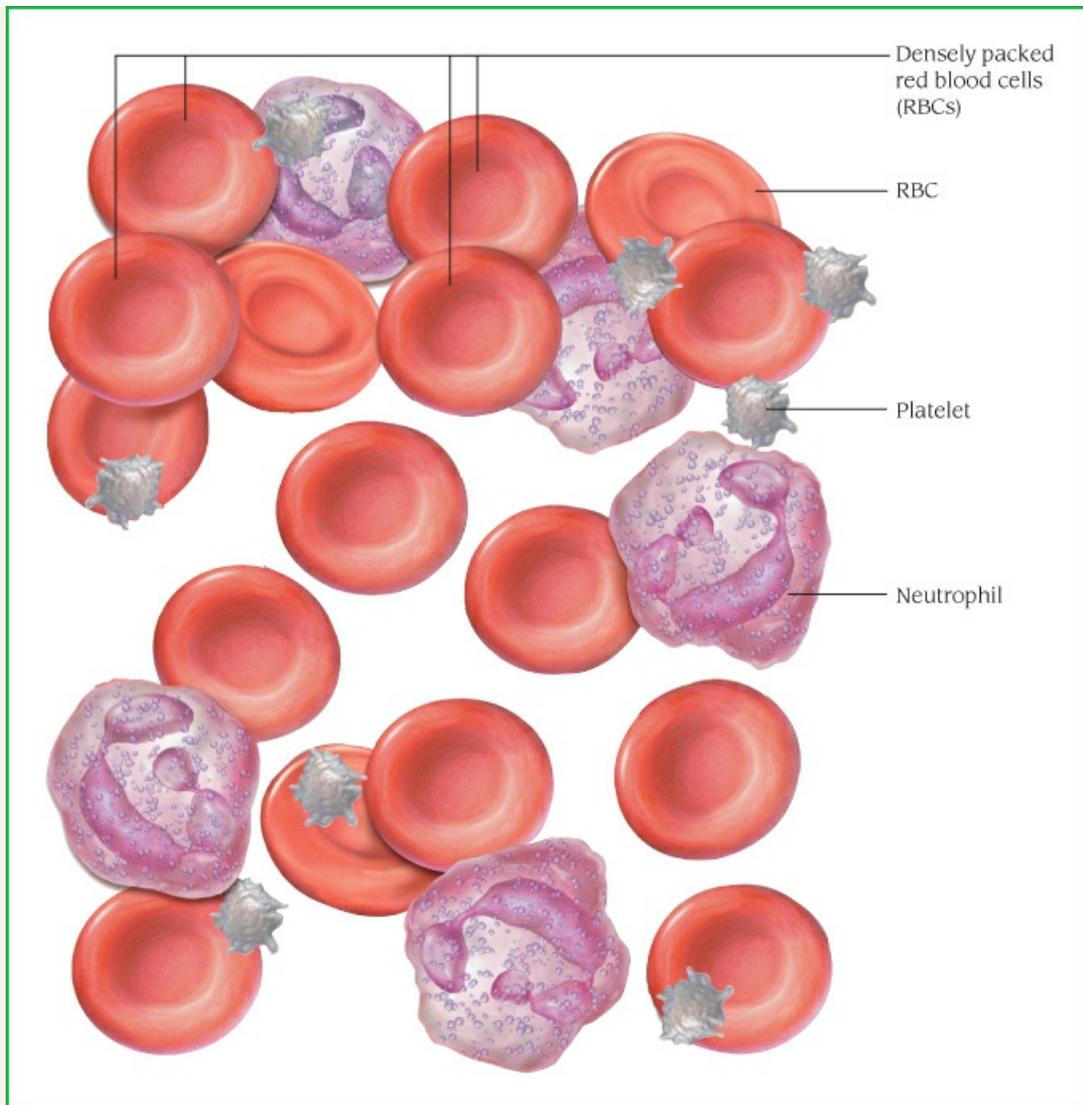
Peripheral Blood Smear in Polycythemia Vera

Polycythemia vera is a chronic, myeloproliferative disorder characterized by increased red blood cell mass, leukocytosis, thrombocytosis, and increased hemoglobin concentration, with normal or increased plasma volume.

Densely packed red blood cells (RBCs)

RBC

Platelet

Neutrophil


Clinical Features of Polycythemia Vera

Signs and symptoms	*Causes*
Eye, ear, nose, and throat	
◆ Visual disturbances (blurring, diplopia, scotoma, engorged veins of fundus and retina) and congestion of conjunctiva, retina, retinal veins, oral mucous membrane ◆ Epistaxis or gingival bleeding	◆ Hypervolemia and hyperviscosity ◆ Engorgement of capillary beds
Central nervous system	
◆ Headache or fullness in the head, lethargy, weakness, fatigue, syncope, tinnitus, paresthesia of digits, and impaired mentation	◆ Hypervolemia and hyperviscosity leading to decreased cerebral blood flow
Cardiovascular system	
◆ Hypertension ◆ Intermittent claudication, thrombosis and emboli, angina, thrombophlebitis ◆ Hemorrhage	◆ Hypervolemia and hyperviscosity ◆ Hypervolemia, thrombocytosis, and vascular disease ◆ Engorgement of capillary beds

Skin	
• Pruritus (especially after hot bath)	• Basophilia (secondary histamine release)
• Urticaria	• Altered histamine metabolism
• Ruddy cyanosis	• Hypervolemia and hyperviscosity due to congested vessels, increased oxyhemoglobin, and reduced hemoglobin
• Night sweats	
• Ecchymosis	• Hypermetabolism
	• Hemorrhage
GI system	
• Epigastric distress	• Hypervolemia and hyperviscosity
• Early satiety and fullness	• Hepatosplenomegaly
• Peptic ulcer pain	• Gastric thrombosis and hemorrhage
• Hepatosplenomegaly	• Congestion, extramedullary hematopoiesis, and myeloid metaplasia
• Weight loss	
	• Hypermetabolism
Respiratory system	
• Dyspnea	• Hypervolemia and hyperviscosity
Musculoskeletal system	
• Joint symptoms	• Increased urate production secondary to nucleoprotein turnover

The prognosis depends on the patient's age at diagnosis, the type of treatment used, and complications. Mortality is high if polycythemia is untreated or progresses to leukemia or myeloid metaplasia.

Pathophysiology

In polycythemia vera, uncontrolled and rapid cellular reproduction and maturation cause proliferation or hyperplasia of all bone marrow cells (panmyelosis). The cause of such uncontrolled cellular activity is unknown but it's probably due to a mutation in the protein *JAK2*.

Polycythemia vera usually occurs between ages 40 and 60, most commonly among males and those with a family history; it seldom affects children or blacks and doesn't appear to be familial. The disease may manifest itself in women after menopause.

Complications

- Thrombosis of small vessels
- Ruddy cyanosis of nose
- Clubbing
- Splenomegaly
- Renal calculus formation
- Abdominal thrombosis
- Hemorrhage

Signs and Symptoms

Increased RBC mass results in hyperviscosity and retards blood flow to microcirculation. Subsequently, increased viscosity, diminished velocity, and thrombocytosis promote intravascular thrombosis. In early stages, polycythemia vera usually produces no symptoms. (Increased HCT may be an incidental finding.) However, as altered circulation secondary to increased RBC mass produces hypervolemia and hyperviscosity, the patient may complain of a feeling of fullness in the head, headache, dizziness, and other symptoms, depending on the body

system affected. The patient may also complain of severe itching after a warm or hot shower. Hyperviscosity may lead to thrombosis of smaller vessels with ruddy cyanosis of the nose and clubbing of the digits. Splenomegaly is present in about one-third of patients at the time of diagnosis.

Paradoxically, hemorrhage is a complication of polycythemia vera. It may be due to defective platelet function or to hyperviscosity and the local effects from excess RBCs exerting pressure on distended venous and capillary walls. (See *Clinical features of polycythemia vera*, page 466.)

Diagnosis

Laboratory studies confirm polycythemia vera by showing increased RBC mass and normal arterial oxygen saturation in association with splenomegaly or two of the following: thrombocytosis, leukocytosis, elevated leukocyte alkaline phosphatase level, or elevated serum vitamin B_{12} level or unbound B_{12}-binding capacity. A low serum erythropoietin level will also confirm diagnosis.

Another common finding is increased uric acid production, leading to hyperuricemia and hyperuricuria. Other laboratory results include increased blood histamine levels, decreased serum iron concentration, and decreased or absent urinary erythropoietin. Bone marrow biopsy reveals panmyelosis and possibly a genetic mutation of *JAK2*.

Treatment

Phlebotomy can reduce RBC mass promptly. The frequency of phlebotomy and the amount of blood removed each time depend on the patient's condition. Typically, 350 to 500 mL of blood can be removed every other day until the HCT is reduced to the low-normal range. After repeated phlebotomies, the patient develops iron deficiency, which stabilizes RBC production and reduces the need for phlebotomy. Pheresis permits the return of plasma to the patient, diluting the blood and reducing hypovolemic symptoms.

Phlebotomy doesn't reduce the WBC or platelet count and won't control the hyperuricemia associated with marrow cell proliferation. For severe symptoms, myelosuppressive therapy may be used. Chemotherapeutic agents may be used to suppress the bone marrow, but these agents may cause leukemia and should be reserved for older patients and those with problems uncontrolled by phlebotomy. The current preferred myelosuppressive agent is hydroxyurea, which isn't associated with leukemia. Patients who have had previous thrombotic problems should be considered for myelosuppressive therapy. The use of antiplatelet therapy is controversial because it may cause gastric bleeding. Allopurinol may be given for hyperuricemia.

Special Considerations

If the patient requires phlebotomy, explain the procedure, and provide reassurance that it will relieve distressing symptoms. Check blood pressure, pulse rate, and respiratory rate. During phlebotomy, make sure the patient is lying down comfortably to prevent vertigo and syncope. Stay alert for tachycardia, clamminess, or complaints of vertigo. If these effects occur, the procedure should be stopped.

- Immediately after phlebotomy, check blood pressure and pulse rate. Have the patient sit up for about 5 minutes before allowing them to walk; this prevents vasovagal attack or orthostatic hypotension. Also, have them drink 24 oz (710 mL) of juice or water.
- Tell the patient to watch for and report signs or symptoms of iron deficiency (pallor, weight loss, asthenia [weakness], and glossitis).

- Keep the patient active and ambulatory to prevent thrombosis. If bed rest is absolutely necessary, prescribe a daily program of both active and passive range-of-motion exercises.
- Watch for complications: hypervolemia, thrombocytosis, and signs or symptoms of an impending stroke (decreased sensation, numbness, transitory paralysis, fleeting blindness, headache, and epistaxis).
- Regularly examine the patient closely for bleeding. Tell them which are the most common bleeding sites (such as the nose, gingiva, and skin) so they can check for bleeding. Advise them to report any abnormal bleeding promptly.
- To compensate for increased uric acid production, give additional fluids, administer allopurinol, and alkalinize the urine to prevent uric acid calculi.
- If the patient has symptom-producing splenomegaly, suggest or provide small, frequent meals, followed by a rest period, to prevent nausea and vomiting.
- Report acute abdominal pain immediately; it may signal splenic infarction, renal calculi, or abdominal organ thrombosis.

  During myelosuppressive treatment:

- Monitor CBC and platelet count before and during therapy. Warn the outpatient who develops leukopenia that his resistance to infection is low; advise the patient to avoid crowds and watch for the symptoms of infection. If leukopenia develops in a hospitalized patient who needs reverse isolation, follow hospital guidelines. If thrombocytopenia develops, tell the patient to watch for signs of bleeding (blood in urine, nosebleeds, and black stool).
- Tell the patient about possible reactions (nausea, vomiting, and risk of infection) to alkylating agents. Alopecia may follow the use of busulfan, cyclophosphamide, and uracil mustard; sterile hemorrhagic cystitis may follow the use of cyclophosphamide (forcing fluids can prevent it). Watch for and report all reactions. If nausea and vomiting occur, begin antiemetic therapy and adjust the patient's diet.

SPURIOUS POLYCYTHEMIA

Spurious polycythemia, also known as *relative polycythemia, stress erythrocytosis, stress polycythemia, benign polycythemia, Gaisböck syndrome,* and *pseudopolycythemia,* is characterized by increased HCT and normal or decreased RBC total mass; it results from decreasing plasma volume and subsequent hemoconcentration.

Pathophysiology

There are three possible causes of spurious polycythemia:

- Dehydration—Conditions that promote severe fluid loss decrease plasma levels and lead to hemoconcentration. Such conditions include persistent vomiting or diarrhea, burns, adrenocortical insufficiency, aggressive diuretic therapy, decreased fluid intake, diabetic acidosis, and renal disease.
- Hemoconcentration due to stress—Nervous stress leads to hemoconcentration by some unknown mechanism (possibly by temporarily decreasing circulating plasma volume or vascular redistribution of erythrocytes). This form of erythrocytosis (chronically elevated HCT) is particularly common in the middle-aged man who's a chronic smoker and a type A personality (tense, hard driving, and anxious).
- High normal RBC mass and low-normal plasma volume—In many patients, an increased HCT merely reflects a normally high RBC mass and low plasma volume. This is particularly

common in patients who don't smoke, aren't obese, and have no history of hypertension.

Other factors that may be associated with spurious polycythemia include hypertension, thromboembolic disease, elevated serum cholesterol and uric acid levels, and familial tendency. It usually affects middle-aged people and occurs more commonly in men than in women.

Complications

- Hypercholesterolemia
- Hyperlipidemia
- Hyperuricemia

Signs and Symptoms

The patient with spurious polycythemia usually has no specific symptoms but may have vague complaints, such as headaches, dizziness, and fatigue. Less commonly, the patient may develop diaphoresis, dyspnea, and claudication.

Typically, the patient has a ruddy appearance, a short neck, slight hypertension, and a tendency to hypoventilate when recumbent. The patient shows no associated hepatosplenomegaly but may have cardiac or pulmonary disease.

Diagnosis

Hb levels, HCT, and RBC count are elevated; RBC mass, arterial oxygen saturation, and bone marrow are normal. Plasma volume may be decreased or normal. Hypercholesterolemia, hyperlipidemia, or hyperuricemia may be present.

℞ **CONFIRMING DIAGNOSIS** *Spurious polycythemia is distinguishable from true polycythemia vera by its characteristic normal RBC mass, elevated HCT, and the absence of leukocytosis and thrombocytosis.*

Treatment

The principal goals of treatment are to prevent life-threatening thromboembolism and to correct dehydration. Rehydration with appropriate fluids and electrolytes is the primary therapy for spurious polycythemia secondary to dehydration. Therapy must also include appropriate measures to prevent further fluid loss such as antidiarrheals, if needed, and avoiding dietary diuretics.

Special Considerations

- During rehydration, carefully monitor intake and output to maintain fluid and electrolyte balance.
- Whenever appropriate, suggest counseling about the patient's work habits and lack of relaxation. If the patient smokes, make sure they understand how important it is to stop. Refer the patient to a smoking-cessation program if necessary.
- Emphasize the need for follow-up examinations every 3 to 4 months after leaving the hospital.
- Thoroughly explain spurious polycythemia, diagnostic measures, and therapy. The hard-driving person predisposed to spurious polycythemia is likely to be more inquisitive and anxious than the average patient. Answer questions honestly, but take care to reassure that they can effectively control symptoms by complying with the prescribed treatment.

SECONDARY POLYCYTHEMIA

Secondary polycythemia (also called *reactive polycythemia* or *secondary erythrocytosis*) is a disorder characterized by excessive production of circulating RBCs due to hypoxia, tumor, or disease.

Pathophysiology

Secondary polycythemia may result from increased production of erythropoietin. This hormone, which is possibly produced and secreted in the kidneys, stimulates bone marrow production of RBCs. Increased production may be a compensatory physiologic response to hypoxemia, which may result from:

- chronic obstructive pulmonary disease
- Hb abnormalities (such as carboxyhemoglobinemia, which is seen in heavy smokers)
- heart failure (causing a decreased ventilation–perfusion ratio)
- right-to-left shunting of blood in the heart (as in transposition of the great vessels)
- central or peripheral alveolar hypoventilation (as in barbiturate intoxication or pickwickian syndrome)
- low oxygen content at high altitudes

Increased production of erythropoietin may also be an inappropriate (pathologic) response to renal disease (such as renal vascular impairment, renal cysts, or hydronephrosis), to CNS disease (such as encephalitis and parkinsonism), to neoplasms (such as liver tumors, adrenal adenoma, renal tumors, uterine myomas, or cerebellar hemangiomas), or to endocrine disorders (such as Cushing syndrome, Bartter syndrome, or pheochromocytomas). Rarely, secondary polycythemia results from a recessive genetic trait.

Secondary polycythemia occurs in about 2 out of every 100,000 people living at or near sea level; incidence rises among those living at high altitudes.

Complications

- Hemorrhage
- Thromboemboli

Signs and Symptoms

In the hypoxic patient, suggestive physical findings include ruddy cyanotic skin, emphysema, and hypoxemia without hepatosplenomegaly or hypertension. Clubbing of the fingers may occur if the underlying disease is cardiovascular. When secondary polycythemia isn't caused by hypoxemia, it's usually an incidental finding during treatment of an underlying disease.

Diagnosis

℞ CONFIRMING DIAGNOSIS *Laboratory values for secondary polycythemia include increased RBC mass (increased HCT, Hb levels, and mean corpuscular volume and mean corpuscular Hb values) and serum and urinary erythropoietin and blood histamine levels, with decreased or*

normal arterial oxygen saturation. Bone marrow biopsies reveal hyperplasia confined to the erythroid series.

Unlike polycythemia vera, secondary polycythemia isn't associated with leukocytosis or thrombocytosis.

Treatment

The goal of treatment is correction of the underlying disease or environmental condition. In severe secondary polycythemia in which altitude is a contributing factor, relocation may be advisable. If secondary polycythemia has produced hazardous hyperviscosity or if the patient doesn't respond to treatment of the primary disease, reduction in blood volume by phlebotomy or pheresis may be effective. Emergency phlebotomy is indicated for prevention of impending vascular occlusion or before emergency surgery. In the latter case, it's usually advisable to remove excess RBCs and reinfuse the patient's plasma.

ALERT *Because a patient with polycythemia has an increased risk of hemorrhage during and after surgery, elective surgery should be avoided until polycythemia is controlled.*

Typically, secondary polycythemia disappears when the primary disease is corrected.

Special Considerations

- Keep the patient as active as possible to decrease the risk of thrombosis due to increased blood viscosity.
- Reduce calorie and sodium intake to counteract the tendency toward hypertension.
- Before and after phlebotomy, check blood pressure with the patient lying down. After the procedure, have the patient drink 24 oz (710 mL) of water or juice. To prevent syncope, have them sit upright for about 5 minutes before walking.
- Emphasize the importance of regular blood studies (every 2 to 3 months), even after the disease is controlled.
- Teach the patient and their family about the underlying disorder. Help them understand its relationship to polycythemia and the measures needed to control both.
- Teach the patient to recognize symptoms of recurring polycythemia and the importance of reporting them promptly.

Hemorrhagic Disorders

ALLERGIC PURPURAS

Allergic purpura, a nonthrombocytopenic purpura, is an acute or chronic vascular inflammation affecting the skin, joints, and GI and GU tracts, in association with allergy symptoms. When allergic purpura primarily affects the GI tract, with accompanying joint pain, it's called *Henoch–Schönlein syndrome*, or *anaphylactoid purpura*. However, the term *allergic purpura* applies to purpura associated with many other conditions, such as erythema nodosum. An acute attack of allergic purpura can last for several weeks and is potentially fatal (usually from renal failure); however, most patients do recover.

Fully developed allergic purpura is persistent and debilitating, possibly leading to chronic

glomerulonephritis (especially following a streptococcal infection).

Pathophysiology

The most common identifiable cause of allergic purpura is probably an autoimmune reaction directed against vascular walls, triggered by a bacterial infection (particularly streptococcal infection). Typically, upper respiratory tract infection occurs 1 to 3 weeks before the onset of symptoms. Other possible causes include allergic reactions to some drugs and vaccines, to insect bites, and to some foods (such as wheat, eggs, milk, and chocolate).

Allergic purpura affects males more than females and is most prevalent in children ages 3 to 7. The prognosis is more favorable for children than adults.

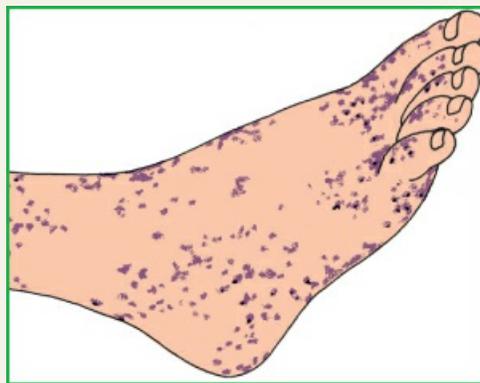
Complications

- Renal failure
- Acute glomerulonephritis

Signs and Symptoms

Characteristic skin lesions of allergic purpura are purple, macular, ecchymotic, and of varying size. They're caused by vascular leakage into the skin and mucous membranes. (See *Purpuric lesions*.) The lesions usually appear in symmetric patterns on the arms, legs, and buttocks and are accompanied by pruritus, paresthesia and, occasionally, angioneurotic edema. In children, skin lesions are generally urticarial and expand and become hemorrhagic. Scattered petechiae may appear on the legs, buttocks, and perineum.

Purpuric lesions

Lesions of allergic purpura, such as those pictured on the foot and leg below, characteristically vary in size.


Henoch–Schönlein syndrome commonly produces transient or severe colic, tenesmus (spasmodic contraction of the anal sphincter) and constipation, vomiting, and edema or hemorrhage of the mucous membranes of the bowel, resulting in GI bleeding, occult blood in the stool and, possibly, intussusception. Such GI abnormalities may *precede* overt, cutaneous signs

of purpura. Musculoskeletal symptoms, such as rheumatoid pains and periarticular effusions, mostly affect the legs and feet.

In 25% to 50% of patients, allergic purpura is associated with GU signs and symptoms: nephritis; renal hemorrhages that may cause microscopic hematuria and disturb renal function; bleeding from the mucosal surfaces of the ureters, bladder, or urethra; and, occasionally, glomerulonephritis. Also possible are moderate and irregular fever, headache, anorexia, and localized edema of the hands, feet, or scalp.

Diagnosis

No laboratory test clearly identifies allergic purpura (although WBC count and erythrocyte sedimentation rate may be elevated). Diagnosis therefore necessitates careful clinical observation, in many cases during the second or third attack. Except for a positive tourniquet test (a test to assess the capillaries' ability to withstand increased pressure), coagulation and platelet function tests are usually normal. Small-bowel X-rays may reveal areas of transient edema; in many cases, tests for blood in the urine and stool are positive. Increased blood urea nitrogen and creatinine levels may indicate renal involvement. Diagnosis must rule out other forms of nonthrombocytopenic purpura.

Treatment

Treatment is generally symptomatic; for example, severe allergic purpura may require steroids to relieve edema and analgesics to relieve joint and abdominal pain. Some patients with chronic renal disease may benefit from immunosuppressive therapy with azathioprine along with identification of the provocative allergen. *An accurate allergy history is essential.*

Special Considerations

- Encourage maintenance of an elimination diet to help identify specific allergenic foods so these foods can be eliminated from the patient's diet.
- Monitor skin lesions and level of pain. Provide analgesics as needed.
- Watch carefully for complications: GI and GU tract bleeding, edema, nausea, vomiting, headache, hypertension (with nephritis), abdominal rigidity and tenderness, and absence of stool (with intussusception).
- To prevent muscle atrophy in the bedridden patient, provide passive or active range-of-motion exercises.
- Provide emotional support and reassurance, especially if florid skin lesions temporarily disfigure the patient.
- After the acute stage, stress the need for the patient to *immediately* report *any* recurrence of symptoms (recurrence is most common about 6 weeks after initial onset) and to return for follow-up urinalysis as scheduled.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

Hereditary hemorrhagic telangiectasia (also called *Osler–Weber–Rendu syndrome*) is an inherited vascular disorder in which venules and capillaries dilate and form fragile masses of thin convoluted vessels (telangiectases), resulting in an abnormal tendency to hemorrhage. This disorder affects both sexes but may cause less severe bleeding in girls and women.

Complication

- Secondary iron deficiency anemia

Pathophysiology

Hereditary hemorrhagic telangiectasia is transmitted by autosomal dominant inheritance. It seldom skips generations. In its homozygous state, it may be lethal. It affects 1 in 5,000 to 1 in 10,000 people worldwide.

Signs and Symptoms

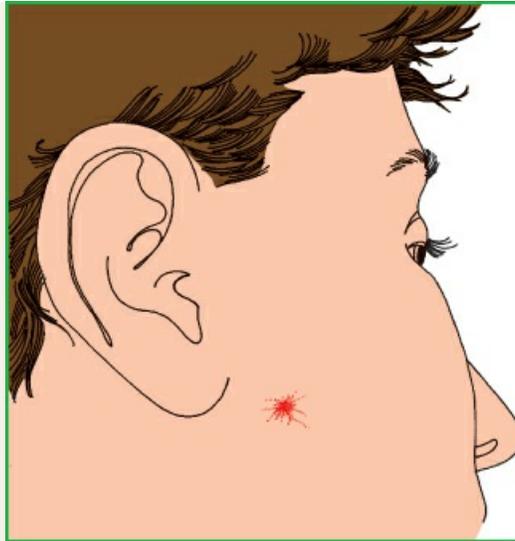
Signs of hereditary hemorrhagic telangiectasia are present in childhood but increase in severity with age. Localized aggregations of dilated capillaries appear on the skin of the face, ears, scalp, hands, arms, and feet; under the nails; and on the mucous membranes of the nose, mouth, and stomach. These dilated capillaries cause frequent epistaxis, hemoptysis, and GI bleeding, usually leading to iron deficiency anemia. (In children, epistaxis is usually the first symptom.)

Characteristic telangiectases are violet, bleed spontaneously, may be flat or raised, blanch on pressure, and are nonpulsatile. They may be associated with vascular malformations such as arteriovenous fistulas. Visceral telangiectases are common in the liver, bladder, respiratory tract, and stomach. The type and distribution of these lesions are generally similar among family members.

Generalized capillary fragility, as evidenced by spontaneous bleeding, petechiae, ecchymoses, and spider hemangiomas of varying sizes, may exist without overt telangiectasia. (See *Typical lesions of hereditary hemorrhagic telangiectasia*, page 472.) Rarely, vascular malformation may cause pulmonary arteriovenous fistulas; then, shunting of blood through the fistulas may lead to hypoxemia, recurring cerebral embolism, brain abscess, and clubbing of digits.

Typical Lesions of Hereditary Hemorrhagic Telangiectasia

Dilated capillaries, either flat or raised, appear in localized aggregations, as on the fingers.

On the face, spider hemangiomas reflect capillary fragility.


Diagnosis

Diagnosis is based principally on an established familial pattern of bleeding disorders and on clinical evidence of telangiectasia and hemorrhage. Hypochromic, microcytic anemia is common; abnormal platelet function may also be found.

Treatment

Supportive therapy includes blood transfusions for acute hemorrhage and supplemental iron administration to replace iron lost in repeated mucosal bleeding. Ancillary treatments consist of applying pressure and topical hemostatic agents to bleeding sites, using electrocautery or laser surgery on bleeding sites not readily accessible, and protecting the patient from trauma and unnecessary bleeding. Endovascular embolization may be used to treat abnormal blood vessels in the brain and other parts of the body.

Oral and, rarely, parenteral administration of supplemental iron enhances absorption to maintain adequate iron stores and prevents gastric irritation. Administering antipyretics or antihistamines before blood transfusions, and using saline-washed cells, frozen blood, or other types of leukocyte-poor blood instead of whole blood may prevent febrile transfusion reactions.

The administration of estrogen has proved effective in some patients, especially when used to control epistaxis.

Special Considerations

⚠️ **ALERT** *During the first 15 minutes of a blood transfusion, stay with the patient to watch for adverse reactions. Afterward, check again every 15 minutes for signs and symptoms of a febrile or an allergic transfusion reaction (flushing, shaking chills, fever, headache, rash, tachycardia, and hypertension) because patients with this disorder are quite susceptible to this type of reaction.*

- ◆ Observe the patient for indications of GI bleeding, such as hematemesis and melena. Instruct them to watch for and report such signs as well.

- If the patient requires an iron supplement, stress the importance of following dosage instructions and of taking oral iron with meals to minimize gastric irritation. Warn them that iron turns stools dark green or black and may cause constipation.
- Provide emotional and psychological support. Encourage the patient to express concerns they may have about the disease and its treatment. As much as possible, include them in care decisions.
- Encourage fluid intake, when possible, if the patient is experiencing a bleeding episode or is hypovolemic. Monitor intake and output.
- Provide good skin care and hygiene, and use sterile technique when caring for the patient. Lesions bleed easily, which may result in infection and skin breakdown.
- Monitor the patient's organ function through physical examination and the comparison of laboratory tests to detect renal, hepatic, or respiratory failure.
- Teach the patient and their family how to manage minor bleeding episodes, especially recurrent epistaxis, and how to recognize major episodes that necessitate emergency intervention.
- Teach the patient and their family about the disease's hereditary nature. Refer for genetic counseling, as appropriate, and to the Hereditary Hemorrhagic Telangiectasia Foundation International for support and information.

THROMBOCYTOPENIA

The most common cause of hemorrhagic disorders, thrombocytopenia is characterized by deficiency of circulating platelets. Because platelets play a vital role in coagulation, this deficiency poses a serious threat to hemostasis. (See *What happens in thrombocytopenia*, page 474.) The prognosis is excellent in drug-induced thrombocytopenia if the offending drug is withdrawn; in such cases, recovery may be immediate. In other types, the prognosis depends on the patient's response to treatment of the underlying cause.

PATHOPHYSIOLOGY
WHAT HAPPENS IN THROMBOCYTOPENIA

Thrombocytopenia is the most common cause of bleeding disorders and is characterized by a severe decrease in platelets. This platelet decrease can result from hematologic malignancy, radiation or drug therapy, idiopathic causes, blood transfusions, disseminated intravascular coagulation (DIC), or splenomegaly. Excessive hemorrhaging can lead to shock if interventions are delayed. This chart shows how these conditions and treatments develop into thrombocytopenic hemorrhage.

HEMATOLOGIC MALIGNANCY (such as leukemia)	→	Immature white blood cells crowd out normal bone marrow cells.	
RADIATION THERAPY	→	Bone marrow activity is suppressed.	→ Platelet production decreases.
DRUG THERAPY (thiazides, chemotherapy agents, estrogens)	→	Bone marrow aplasia or hypoplasia occurs; fat or fibrous tissue replaces blood-cell precursors.	
DRUG THERAPY (antibiotics, sulfonamides, gold salts)			Thrombocytopenic hemorrhage
IDIOPATHIC CAUSES	→	Antibodies form and attack platelets.	
BLOOD TRANSFUSIONS			Platelet destruction increases.
DIC	→	Clotting factors are consumed, including platelets.	
SPLENOMEGALY	→	Platelets collect in spleen; platelet circulation decreases.	→ Platelets are distributed abnormally.

Causes

Thrombocytopenia may be congenital or acquired; the acquired form is more common. In either case, it usually results from decreased or defective production of platelets in the marrow (such as occurs in leukemia, aplastic anemia, or toxicity with certain drugs) or from increased destruction outside the marrow caused by an underlying disorder (such as cirrhosis of the liver, disseminated intravascular coagulation [DIC], or severe infection). Less commonly, it results from sequestration (hypersplenism and hypothermia) or platelet loss. Acquired thrombocytopenia may result from certain drugs, such as sulfonamides, antibiotics, gold salts, estrogens, or chemotherapeutic agents. (See *Causes of decreased circulating platelets*.)

Causes of Decreased Circulating Platelets

Diminished Or Defective Platelet Production

Congenital
- Wiskott–Aldrich syndrome
- Maternal ingestion of thiazides
- Neonatal rubella

- Polycythemia

Acquired
- Aplastic anemia
- Marrow infiltration (acute and chronic leukemias, tumor)
- Nutritional deficiency (vitamin B_{12}, folic acid)
- Myelosuppressive agents
- Drugs that directly influence platelet production (thiazides, alcohol, hormones)
- Radiation
- Viral infections (measles, dengue)

Increased Peripheral Platelet Destruction

Congenital
- Nonimmune (prematurity, erythroblastosis fetalis, infection)
- Immune (drug sensitivity, maternal idiopathic thrombocytopenic purpura [ITP])

Acquired
- Nonimmune (infection, disseminated intravascular coagulation, thrombotic thrombocytopenic purpura)
- Immune (drug-induced, especially with quinine and quinidine; posttransfusion purpura; acute and chronic ITP; sepsis; alcohol)
- Invasive lines and devices
- Intra-aortic balloon pump
- Prosthetic heart valves
- Heparin

Platelet Sequestration
- Hypersplenism
- Hypothermia

Platelet Loss
- Hemorrhage
- Extracorporeal perfusion

ELDER TIP In older adults, platelet characteristics change. Granular constituents decrease and platelet-release factors increase. These changes may reflect diminished bone marrow and increased fibrinogen levels.

An idiopathic form of thrombocytopenia commonly occurs in children. A transient form may follow viral infection (such as Epstein–Barr virus or infectious mononucleosis).

Complication
- Acute hemorrhage

Signs and Symptoms

Thrombocytopenia typically produces a sudden onset of petechiae or ecchymoses in the skin or bleeding into any mucous membrane. Nearly all patients are otherwise asymptomatic, although some may complain of malaise, fatigue, and general weakness. In adults, large, blood-filled bullae characteristically appear in the mouth. In severe thrombocytopenia, hemorrhage may lead to tachycardia, shortness of breath, loss of consciousness, and death.

Diagnosis

Diagnosis is based on the results of the patient history (especially a drug history), physical examination, and laboratory tests. Coagulation tests and CBC reveal a decreased platelet count (in adults, <100,000/µL), prolonged bleeding time (although this doesn't always indicate platelet quality), and normal prothrombin time and partial thromboplastin time. If increased destruction of platelets is causing thrombocytopenia, bone marrow studies will reveal a greater number of megakaryocytes (platelet precursors) and shortened platelet survival (several hours or days rather than the usual 7 to 10 days).

Treatment

Treatment varies with the underlying cause and severity and may include corticosteroids or immune globulin to increase platelet production. The treatment of choice is removal of the offending agents in drug-induced thrombocytopenia or treatment of the underlying cause. Platelet transfusions are helpful only in treating complications of severe hemorrhage. In cases of severe thrombocytopenia where medications fail to work, a splenectomy may be performed.

Special Considerations

When caring for the patient with thrombocytopenia, take every possible precaution against bleeding.

◆ Protect the patient from trauma. Keep the side rails up and pad them, if possible. Promote the use of an electric razor and a soft toothbrush. Avoid invasive procedures, such as venipuncture or urinary catheterization, if possible. When venipuncture is unavoidable, be sure to exert pressure on the puncture site for at least 20 minutes or until the bleeding stops.
◆ Monitor platelet count daily.
◆ Test stool for guaiac; dipstick urine and vomitus for blood.
◆ Watch for bleeding (petechiae, ecchymoses, surgical or GI bleeding, and menorrhagia).
◆ Warn the patient to avoid aspirin in any form and other drugs that impair coagulation. Teach them how to recognize aspirin or ibuprofen compounds on labels of over-the-counter remedies.
◆ Advise the patient to avoid straining at stool or coughing, as both can lead to increased intracranial pressure, possibly causing cerebral hemorrhage in the patient with thrombocytopenia. Provide a stool softener to avoid constipation.
◆ During periods of active bleeding, maintain the patient on strict bed rest if necessary.
◆ When administering platelet concentrate, remember that platelets are extremely fragile, so infuse them quickly. Don't give platelets to a patient with a fever.
◆ Histocompatibility locus antigen-typed platelets may be ordered to prevent febrile reaction. A patient with a history of minor reactions may benefit from acetaminophen and diphenhydramine before transfusion.

- If thrombocytopenia is drug-induced, stress the importance of avoiding the offending drug.
- If the patient must receive long-term steroid therapy, teach them to watch for and report cushingoid signs (acne, moon face, hirsutism, buffalo hump, hypertension, girdle obesity, thinning arms and legs, glycosuria, and edema). Emphasize that steroid doses must be discontinued gradually. During steroid therapy, monitor fluid and electrolyte balance, and watch for infection, pathologic fractures, and mood changes.

ALERT *During platelet transfusion, monitor the patient for febrile reaction (flushing, chills, fever, headache, tachycardia, and hypertension).*

IDIOPATHIC THROMBOCYTOPENIC PURPURA

Idiopathic thrombocytopenic purpura (ITP), thrombocytopenia that results from immunologic platelet destruction, may be acute (post viral thrombocytopenia) or chronic (Werlhof disease, purpura hemorrhagica, essential thrombocytopenia, and autoimmune thrombocytopenia). The prognosis for acute ITP is excellent; nearly four out of five patients recover without treatment. The prognosis for chronic ITP is good; remissions lasting weeks or years are common, especially among women. Other names for ITP include immune thrombocytopenic purpura and autoimmune thrombocytopenic purpura.

Pathophysiology

ITP may be an autoimmune disorder, because antibodies that reduce the life span of platelets have been found in nearly all patients. The spleen probably helps to remove platelets modified by the antibody. Acute ITP usually follows a viral infection, such as rubella or chickenpox, and can follow immunization with a live-virus vaccine. Chronic ITP seldom follows infection and is commonly linked to immunologic disorders such as systemic lupus erythematosus. It's also linked to drug reactions. ITP frequently occurs in patients who have abused alcohol, heroin, or morphine, and in patients with acquired immunodeficiency syndrome who are exposed to the rubella virus.

Acute ITP usually affects children between ages 2 and 6; chronic ITP mainly affects adults younger than age 50, especially women between ages 20 and 40.

Complications

- Cerebral hemorrhage
- Fatal purpuric lesions in vital organs

Signs and Symptoms

Clinical features of ITP common to all forms of thrombocytopenia include petechiae, ecchymoses, and mucosal bleeding from the mouth, nose, or GI tract. Generally, hemorrhage is a rare physical finding. Purpuric lesions may occur in vital organs, such as the lungs, kidneys, or brain, and may prove fatal. In acute ITP, which commonly occurs in children, onset is usually sudden, causing easy bruising, epistaxis, and bleeding gums. The onset of chronic ITP is insidious.

Diagnosis

Platelet count less than 20,000/μL and prolonged bleeding time suggest ITP. Platelet size and morphologic appearance may be abnormal; anemia may be present if bleeding has occurred. As

in thrombocytopenia, bone marrow studies show an abundance of megakaryocytes and a shortened circulating platelet survival time (hours or days). Occasionally, platelet antibodies may be found in vitro, but this diagnosis is usually inferred from platelet survival data and the absence of an underlying disease.

Treatment

Acute ITP may be allowed to run its course without intervention or may be treated with glucocorticoids or immune globulin. For chronic ITP, corticosteroids such as prednisone may be the initial treatment of choice. Patients who fail to respond within 4 months or who need high steroid dosage are candidates for splenectomy, which may be successful in 50% of cases. Alternative treatments include immunosuppression, high-dose gamma globulin injections, and immunoabsorption apheresis using staphylococcal protein-A columns, which filter antibodies out of the bloodstream. Anti-RhD therapy can also be useful in people with specific blood types. Eltrombopag and romiplostim are thrombopoietin receptor agonists that are used to increase the number of platelets in patients with chronic ITP. These drugs should only be used in those who have not responded to other treatments, including splenectomy.

Before splenectomy, the patient may require blood, blood components, and vitamin K to correct anemia and coagulation defects. After splenectomy, they may need blood and component replacement and platelet concentrate. Normally, platelet counts increase spontaneously after splenectomy.

Special Considerations

Patient care for ITP is essentially the same as for other types of thrombocytopenia, with emphasis on teaching the patient to observe for petechiae, ecchymoses, and other signs of recurrence. Monitor patients receiving immunosuppressants for signs of bone marrow depression, infection, mucositis, GI ulcers, and severe diarrhea or vomiting. Tell the patient to avoid aspirin, ibuprofen, and warfarin, as these drugs interfere with platelet function and blood clotting.

PLATELET FUNCTION DISORDERS

Platelet function disorders are similar to thrombocytopenia but result from platelet dysfunction rather than platelet deficiency. They characteristically cause defects in platelet adhesion or procoagulation activity (ability to bind coagulation factors to their surface to form a stable fibrin clot). Such disorders may also create defects in platelet aggregation and thromboxane A_2 and may produce abnormalities by preventing the release of adenosine diphosphate (defective platelet-release reaction). The prognosis varies widely.

Pathophysiology

Abnormal platelet function disorders may be inherited (autosomal recessive) or acquired. Inherited disorders cause bone marrow production of platelets that are ineffective in the clotting mechanism. Acquired disorders result from the effects of such drugs as aspirin, nonsteroidal anti-inflammatory drugs, or carbenicillin; from such systemic diseases as uremia; or from other hematologic disorders such as myelofibrosis or polycythemia vera.

Complication

◆ Hemorrhage

Signs and Symptoms

Generally, the sudden appearance of petechiae or purpura or excessive bruising and bleeding of the nose and gums are the first overt signs of platelet function disorders. More serious signs are external hemorrhage, internal hemorrhage into the muscles and visceral organs, or excessive bleeding during surgery.

Diagnosis

Prolonged bleeding time in a patient with both a normal platelet count and normal clotting factors suggests this diagnosis. Determination of the defective mechanism requires a blood film and a platelet function test to measure platelet-release reaction and aggregation. Depending on the type of platelet dysfunction, some or all of the test results may be abnormal.

Other typical laboratory findings are poor clot retraction and decreased prothrombin conversion. Baseline testing includes CBC and differential and appropriate tests to determine hemorrhage sites. In platelet function disorders, plasma-clotting factors, platelet counts, prothrombin and partial thromboplastin times, and thrombin times are usually normal.

Treatment

Platelet replacement is the only satisfactory treatment for inherited platelet dysfunction. However, acquired platelet function disorders respond to adequate treatment of the underlying disease or discontinuation of damaging drug therapy. Plasmapheresis effectively controls bleeding caused by a plasma element that's inhibiting platelet function. During this procedure, one or more units of whole blood are removed from the patient; the plasma is removed from the whole blood, and the remaining packed RBCs are reinfused. (See *Facts about platelet concentrate*, page 477.)

Facts About Platelet Concentrate

Contents
◆ Platelets, white blood cells, some plasma
◆ Random platelets (ABO matched)
◆ Human leukocyte antigen (HLA) platelets (HLA-typed for multiple transfusions)

Amount
◆ 30 to 50 mL per donor
◆ 4 to 8 donor units given each time (each unit should raise the platelet count by 5,000/μL)

Shelf Life
◆ 6 to 72 hours (best used within 24 hours)

Special Considerations

◆ Obtain an accurate patient history, including onset of bleeding, use of drugs (especially aspirin), and family history of bleeding disorders.

- Watch closely for bleeding from skin, nose, gums, GI tract, or an injury site.
- Help the patient avoid unnecessary trauma. Advise them to tell the dentist about this condition before undergoing oral surgery. (Also stress the need for good oral hygiene to help prevent the need for such surgery.)
- Alert other care team members to the patient's hemorrhagic potential, especially before they undergo diagnostic tests or surgery that may cause trauma and bleeding.
- Observe the patient undergoing plasmapheresis for hypovolemia, hypotension, tachycardia, and other signs of volume depletion.
- If platelet dysfunction is inherited, help the patient and family understand and accept the disorder's nature. Teach them how to manage potential bleeding episodes. Warn them that petechiae, ecchymoses, and bleeding from the nose, gums, and GI tract signal abnormal bleeding and should be reported immediately.
- Tell the patient with a known coagulopathy or hepatic disease to avoid aspirin, aspirin compounds, and other agents that impair coagulation.
- Advise the patient to wear a medical identification bracelet or to carry a card identifying them as a potential bleeder.

VON WILLEBRAND DISEASE

von Willebrand disease is a hereditary bleeding disorder characterized by prolonged bleeding time; moderate deficiency of von Willebrand factor (VWF), clotting factor VIII (antihemophilic factor) and, possibly, factor VIII coagulant protein (VIII:C); and impaired platelet function. This disease commonly causes bleeding from the skin or mucosal surfaces and, in females, excessive uterine bleeding. Bleeding may range from mild and asymptomatic to severe, potentially fatal hemorrhage. The prognosis, however, is usually good.

The three types of von Willebrand disease are:

- *Type 1:* the most common form; there's decreased VWF, and factor VIII may be below normal; this is the mildest form
- *Type 2:* the VWF contains a defect causing it to not function properly; there are four subtypes: 2A, 2B, 2M, and 2N; it's important to know which subtype is present because each is treated differently
- *Type 3:* this is the rarest and most severe form; there's no VWF and factor VIII is at low levels

Pathophysiology

Unlike hemophilia, von Willebrand disease is inherited as an autosomal dominant trait that affects males and females equally. One theory of pathophysiology holds that mild to moderate deficiency of factor VIII and defective platelet adhesion prolong coagulation time. Specifically, this results from a deficiency of the VWF, which stabilizes the factor VIII molecule and is needed for proper platelet function.

Defective platelet function is characterized by:

- decreased agglutination and adhesion at the bleeding site
- reduced platelet retention when filtered through a column of packed glass beads
- diminished ristocetin-induced platelet aggregation

Recently, an acquired form has been identified in patients with cancer and immune disorders. von Willebrand disease, which doesn't have any racial or ethnic associations, affects about 1%

of the population.

Complication

- Severe, potentially life-threatening hemorrhage

Signs and Symptoms

von Willebrand disease produces easy bruising, epistaxis, and bleeding from the gums. Petechiae are rarely seen. Severe forms of this disease may cause hemorrhage after laceration or surgery, menorrhagia, and GI bleeding. Excessive postpartum bleeding is uncommon because factor VIII levels and bleeding time abnormalities become less pronounced during pregnancy. Massive soft-tissue hemorrhage and bleeding into joints seldom occur. Severity of bleeding may lessen with age, and bleeding episodes occur sporadically—a patient may bleed excessively after one dental extraction but not after another.

Diagnosis

Diagnosis is difficult because symptoms are mild, laboratory values are borderline, and factor VIII levels fluctuate. However, a positive family history and characteristic bleeding patterns and laboratory values help establish the diagnosis. Typical laboratory data include:

- prolonged bleeding time (>6 minutes)
- slightly prolonged partial thromboplastin time (>45 seconds)
- absent or reduced levels of factor VIII-related antigens and low factor VIII activity level
- defective in vitro platelet aggregation (using the ristocetin coagulation factor assay test)
- normal platelet count and normal clot retraction

Treatment

The goals of treatment are to shorten bleeding time by local measures and to replace factor VIII (and, consequently, VWF) by infusion of cryoprecipitate or blood fractions that are rich in factor VIII.

During bleeding and before surgery, I.V. infusion of cryoprecipitate or fresh frozen plasma (in quantities sufficient to raise factor VIII levels to 50% of normal) shortens bleeding time. Desmopressin given parenterally or intranasally is effective in raising serum levels of VWF in type 1 disease by releasing stores of VWF for 8 to 10 hours. Repeat doses are less effective unless stores of VWF are allowed to reaccumulate (about 48 hours). DDAVP is not effective in the other types of von Willebrand disease and may even be harmful.

For women with menorrhagia, oral contraceptives may be ordered to control heavy menstrual bleeding. Another treatment for menorrhagia is the intrauterine placement of a progesterone-containing contraceptive device. Antifibrinolytic medications, which help slow down clotting factor breakdown, may be given before or after surgical procedures.

Special Considerations

The care plan should include local measures to control bleeding and patient teaching to prevent bleeding, unnecessary trauma, and complications.

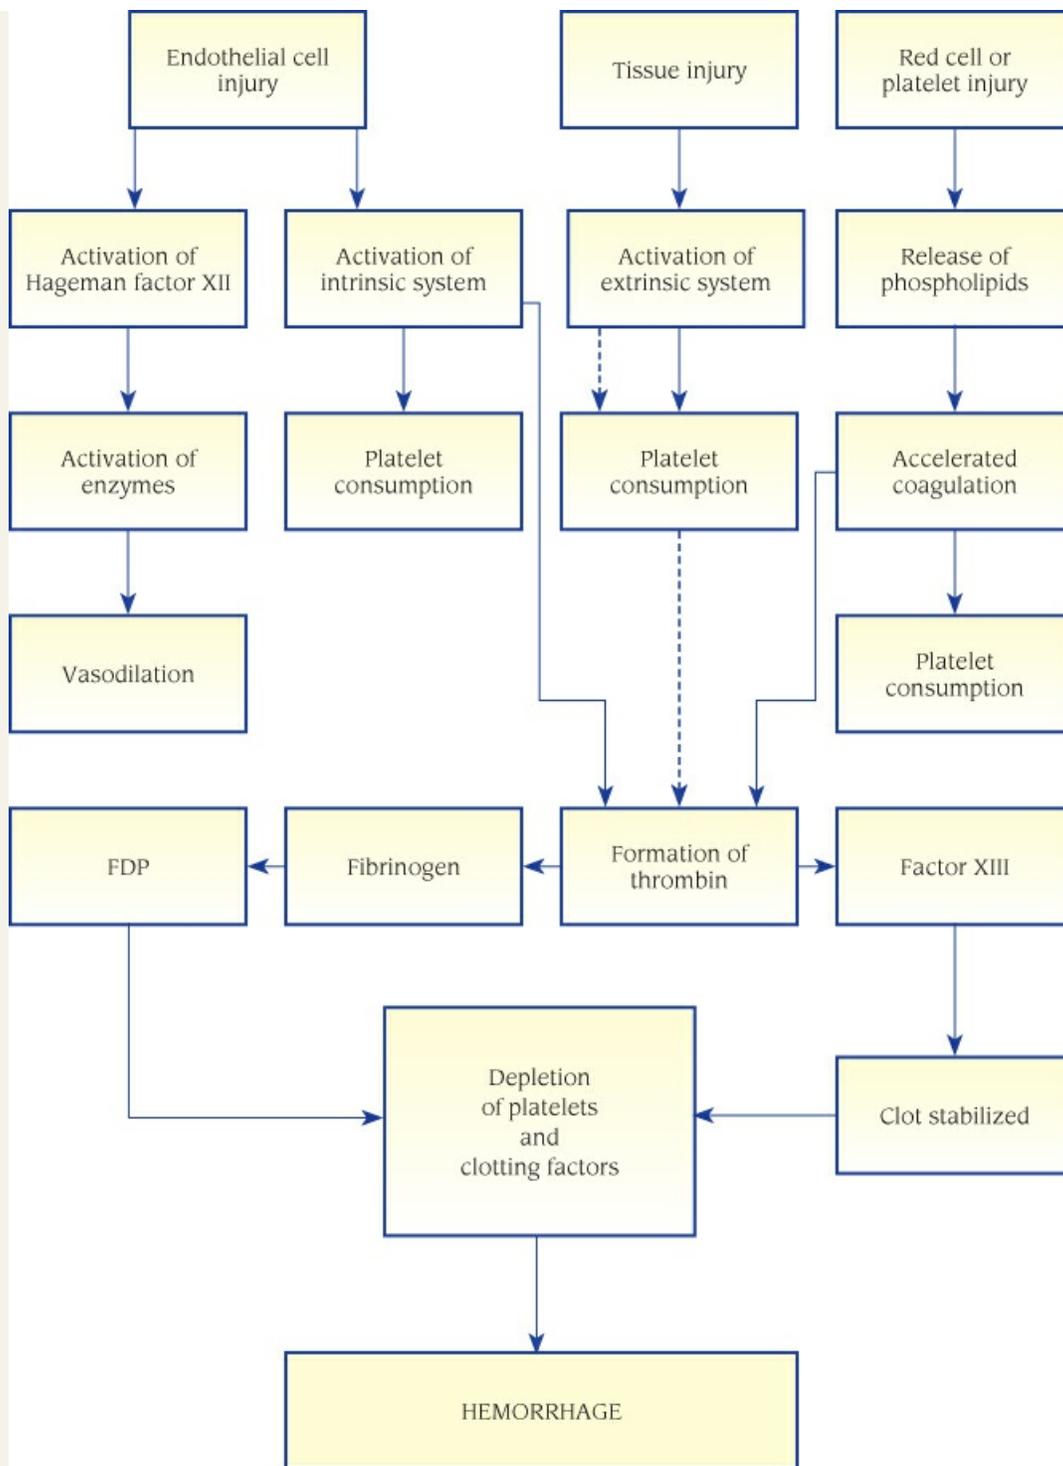
- After surgery, monitor bleeding time for 24 to 48 hours, and watch for signs of new bleeding.
- During a bleeding episode, elevate and apply cold compresses and gentle pressure to the bleeding site.

- Refer parents of affected children for genetic counseling.
- Advise the patient to consult the physician after even minor trauma and before all surgery to determine if replacement of blood components is necessary.
- Instruct the patient to watch for signs of hepatitis within 6 weeks to 6 months after transfusion.
- Warn the patient against using aspirin and other drugs that impair platelet function.
- Advise the patient who has a severe form to avoid contact sports.

DISSEMINATED INTRAVASCULAR COAGULATION

DIC occurs as a life-threatening complication of diseases and conditions that accelerate clotting, causing small blood vessel occlusion, organ necrosis, depletion of circulating clotting factors and platelets, and activation of the fibrinolytic system. This, in turn, can provoke severe hemorrhage. (See *Three mechanisms of DIC,* page 480.) Clotting in the microcirculation usually affects the kidneys and extremities but may occur in the brain, lungs, pituitary and adrenal glands, and GI mucosa. Other conditions, such as vitamin K deficiency, hepatic disease, and anticoagulant therapy, may cause a similar hemorrhage. DIC, also called *consumption coagulopathy* or *defibrination syndrome,* is generally an acute condition but may be chronic in cancer patients. The prognosis depends on early detection and treatment, the hemorrhage's severity, and treatment of the underlying disease or condition.

PATHOPHYSIOLOGY
THREE MECHANISMS OF DIC

However disseminated intravascular coagulation (DIC) begins, accelerated clotting (characteristic of DIC) usually results in excess thrombin, which in turn causes fibrinolysis with excess fibrin formation and fibrin degradation products (FDP), activation of fibrin-stabilizing factor (factor XIII), consumption of platelet and clotting factors and, eventually, hemorrhage.


Causes

DIC may result from:

◆ infection—gram-negative or gram-positive septicemia; viral, fungal, or rickettsial infection;

protozoal infection

- obstetric complications—abruptio placentae, amniotic fluid embolism, retained dead fetus, septic abortion, and eclampsia
- neoplastic disease—acute leukemia, metastatic carcinoma, and aplastic anemia
- disorders that produce necrosis—extensive burns and trauma, brain tissue destruction, transplant rejection, and hepatic necrosis
- other factors—heatstroke, shock, poisonous snakebite, cirrhosis, fat embolism, incompatible blood transfusion, cardiac arrest, surgery necessitating cardiopulmonary bypass, giant hemangioma, severe venous thrombosis, and purpura fulminans

It isn't clear why such disorders lead to DIC, nor is it certain that they lead to it through a common mechanism. In many patients, the triggering mechanisms may be the entrance of foreign protein into the circulation and vascular endothelial injury. Regardless of how DIC begins, the typical accelerated clotting results in generalized activation of prothrombin and a consequent excess of thrombin. Excess thrombin converts fibrinogen to fibrin, producing fibrin clots in the microcirculation. This process consumes exorbitant amounts of coagulation factors (especially fibrinogen, prothrombin, platelets, and factor V and factor VIII), causing hypofibrinogenemia, hypoprothrombinemia, thrombocytopenia, and deficiencies in factor V and factor VIII. Circulating thrombin activates the fibrinolytic system, which lyses fibrin clots into fibrin degradation products (FDPs). The hemorrhage that occurs may be due largely to the anticoagulant activity of FDPs, as well as depletion of plasma coagulation factors.

Complications

- Ischemia of legs, arms, or organs
- Severe bleeding
- Stroke

Signs and Symptoms

The most significant feature of DIC is abnormal bleeding, *without* a history of a serious hemorrhagic disorder. Almost always, this complication occurs in the setting of a serious underlying illness. Principal signs of such bleeding include cutaneous oozing, petechiae, ecchymoses, and hematomas caused by bleeding into the skin. Bleeding from surgical or I.V. sites and from the GI tract are equally significant signs, as are acrocyanosis (cyanosis of the extremities) and signs of acute tubular necrosis. Related signs, symptoms, and other effects include nausea, vomiting, dyspnea, oliguria, seizures, coma, shock, major organ failure, confusion, epistaxis, hemoptysis, and severe muscle, back, abdominal, and chest pain.

Diagnosis

Abnormal bleeding in a patient with severe illness and in the absence of a known hematologic disorder suggests DIC. Initial laboratory findings reflect coagulation factor deficiencies:

- decreased platelet count: less than 100,000/μL
- decreased fibrinogen level: less than 150 mg/dL

As the excessive clot breaks down, hemorrhagic diathesis occurs, and test results reflect coagulation abnormalities:

- prolonged prothrombin time: more than 15 seconds

- prolonged partial thromboplastin time: more than 60 seconds
- increased FDPs: commonly more than 45 μg/mL

Other supportive data include positive fibrin monomers, diminished levels of factors V and VIII, fragmentation of RBCs, and decreased Hb level (<10 g/dL). Assessment of renal status demonstrates reduction in urine output (<30 mL/hour) and elevated blood urea nitrogen (>25 mg/dL) and serum creatinine (>1.3 mg/dL) levels.

A positive D-dimer test (results < 1:8 dilution and decreased levels of factors V and VIII) is specific for DIC. Confirming the diagnosis may be difficult because many of these test results also occur in other disorders (e.g., primary fibrinolysis).

Treatment

Successful management of DIC necessitates prompt recognition and adequate treatment of the underlying disorder. Treatment may be supportive when the underlying disorder is self-limiting or highly specific. If the patient isn't bleeding, supportive care alone may reverse DIC. However, bleeding may require administration of blood, fresh frozen plasma, platelets, or packed RBCs to support hemostasis. Cryoprecipitate may also be used if fibrinogen is significantly decreased. Heparin is used in the early stages to prevent microclotting and is sometimes used in combination with replacement therapy.

Special Considerations

Patient care must focus on early recognition of abnormal bleeding, prompt treatment of the underlying disorders, and prevention of further bleeding.

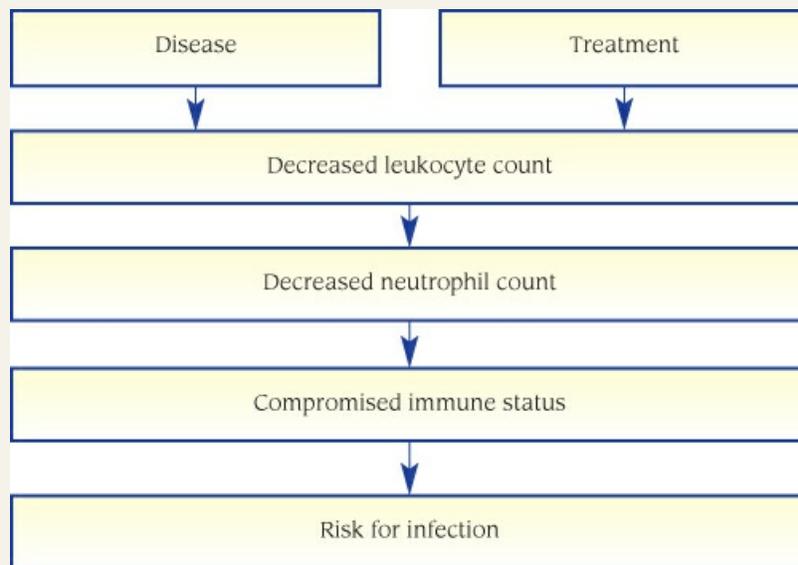
- To avoid dislodging clots and causing fresh bleeding, don't scrub bleeding areas. Use pressure, cold compresses, and topical hemostatic agents to control bleeding.
- To prevent injury, enforce complete bed rest during bleeding episodes. If the patient is agitated, pad the side rails.
- Check all I.V. and venipuncture sites frequently for bleeding. Apply pressure to injection sites for at least 20 minutes. Alert other personnel to his tendency to hemorrhage.
- Monitor intake and output hourly in acute DIC, especially when administering blood products. Watch for transfusion reactions and signs of fluid overload. To measure the amount of blood lost, weigh dressings and linen, and record drainage. Weigh the patient daily, particularly if there's renal involvement.
- Watch for bleeding from the GI and GU tracts. If you suspect intra-abdominal bleeding, measure the patient's abdominal girth at least every 4 hours, and monitor closely for signs of shock.
- Monitor the results of serial blood studies (particularly HCT, Hb levels, and coagulation times).
- Explain all diagnostic tests and procedures. Allow time for questions.
- Inform the patient's family of the progress. Prepare them for the presence of I.V. lines, nasogastric tubes, bruises, and dried blood. Provide emotional support for the patient and family. As needed, enlist the aid of a social worker, chaplain, and other members of the healthcare team in providing such support.

Miscellaneous Disorders

NEUTROPENIA AND LYMPHOCYTOPENIA

Granulocytopenia (commonly referred to as *neutropenia*) is characterized by a marked reduction in the number of circulating granulocytes. Although this implies all the granulocytes (neutrophils, basophils, and eosinophils) are reduced, granulocytopenia usually refers to decreased neutrophils. (See *Understanding neutropenia*, page 483.) This disorder, which can occur at any age, is associated with infections and ulcerative lesions of the throat, GI tract, other mucous membranes, and skin. The severest form is known as *agranulocytosis*.

PATHOPHYSIOLOGY
UNDERSTANDING NEUTROPENIA

Neutropenia, a deficiency in the number of mature neutrophils, is the most common immune system deficiency. It can result from a disease or from radiation or drug therapy. Common infections that occur secondary to neutropenia include aerobic gram-negative bacilli and *Staphylococcus aureus* and certain fungal infections, such as candidiasis and aspergillosis.


Lymphocytopenia (sometimes called *lymphopenia*), a rare disorder, is a deficiency of circulating lymphocytes (leukocytes produced mainly in lymph nodes).

In both granulocytopenia and lymphocytopenia, the total leukocyte count (WBC count) may reach dangerously low levels, leaving the body unprotected against infection. The prognosis in both disorders depends on the underlying cause and whether it can be treated. Untreated, severe granulocytopenia can be fatal in 3 to 6 days.

Causes

Granulocytopenia may result from diminished production of granulocytes in bone marrow, increased peripheral destruction of granulocytes, or greater utilization of granulocytes.

Diminished production of granulocytes in bone marrow generally stems from radiation or drug therapy; it's a common adverse effect of antimetabolites and alkylating agents and may occur in the patient who is hypersensitive to phenothiazine, sulfonamides (and some sulfonamide derivatives), antibiotics, and antiarrhythmic drugs. Drug-induced granulocytopenia usually develops slowly and typically correlates with the dosage and duration of therapy. Production of granulocytes also decreases in conditions such as aplastic anemia and bone marrow malignancies and in some hereditary disorders (infantile genetic agranulocytosis).

The growing loss of peripheral granulocytes is due to increased splenic sequestration, diseases that destroy peripheral blood cells (viral and bacterial infections), and drugs that act as haptens (carrying antigens that attack blood cells and causing acute idiosyncratic or non-dose–related drug reactions). Infections such as infectious mononucleosis may result in granulocytopenia because of increased utilization of granulocytes.

Similarly, lymphocytopenia may result from decreased production, increased destruction, or loss of lymphocytes. Decreased production of lymphocytes may be secondary to a genetic or a thymic abnormality or to immunodeficiency disorders, such as thymic dysplasia or ataxia-telangiectasia. Increased destruction of lymphocytes may be secondary to radiation, chemotherapy, or human immunodeficiency virus infection. Loss of lymphocytes may follow postsurgical thoracic duct drainage, intestinal lymphangiectasia, or impaired intestinal lymphatic drainage (as in Whipple disease).

Lymphocyte depletion can also result from elevated plasma corticoid levels (due to stress, corticotropin or steroid treatment, or heart failure). Other disorders associated with lymphocyte depletion include Hodgkin disease, leukemia, aplastic anemia, sarcoidosis, myasthenia gravis, lupus erythematosus, protein-calorie malnutrition, renal failure, terminal cancer, tuberculosis and, in infants, SCID.

Complication

- Infection

Signs and Symptoms

Patients with granulocytopenia, if the disease is associated with anemia, experience slowly progressive fatigue and weakness; however, if they develop an infection, they can exhibit sudden onset of fever and chills and mental status changes. Overt signs of infection (pus formation) are usually absent. Localized infection can quickly become systemic (bacteremia) or spread throughout an organ (pneumonia). All patients should be meticulously evaluated for even subtle signs of infection because untreated infections can lead to septic shock in 8 to 24 hours. If granulocytopenia results from an idiosyncratic drug reaction, signs of infection develop abruptly, without slowly progressive fatigue and weakness.

Patients with lymphocytopenia may exhibit enlarged lymph nodes, spleen, and tonsils and signs of an associated disease.

Diagnosis

Diagnosis of granulocytopenia necessitates a thorough patient history to check for precipitating factors. Physical examination for clinical effects of underlying disorders is also essential.

CONFIRMING DIAGNOSIS *A markedly decreased absolute neutrophil count (<500/µL leads to severe bacterial infections) and a WBC count lower than 2,000/µL, with few observable*

granulocytes on CBC, confirm granulocytopenia.

Bone marrow examination shows a scarcity of granulocytic precursor cells beyond the most immature forms, but this may vary, depending on the cause.

A lymphocyte count below 1,500/μL in adults or below 3,000/μL in children indicates lymphocytopenia. Identifying the cause by evaluation of clinical status, bone marrow and lymph node biopsies, or other appropriate diagnostic tests helps establish the diagnosis.

Treatment

Effective management of granulocytopenia must identify and eliminate the cause and control infection until the bone marrow can generate more leukocytes. In many cases, this means drug or radiation therapy must be stopped and antibiotic treatment begun immediately, even while awaiting test results. Treatment may also include antifungal preparations. Administration of granulocyte colony-stimulating factor (CSF) or granulocyte-macrophage CSF is a newer treatment used to stimulate bone marrow production of neutrophils. Spontaneous restoration of leukocyte production in bone marrow generally occurs within 1 to 3 weeks.

Treatment of lymphocytopenia includes eliminating the cause and managing any underlying disorders. For infants with SCID, therapy may include bone marrow transplantation.

Special Considerations

- Monitor vital signs frequently. Obtain cultures from blood, throat, urine, mouth, nose, rectum, vagina, and sputum, as ordered. Give antibiotics as scheduled.
- Explain the necessity of infection protection procedures to the patient and their family. Teach proper hand-washing technique and the correct use of gowns and masks. Prevent patient contact with staff or visitors with respiratory infections.
- Maintain adequate nutrition and hydration because malnutrition aggravates immunosuppression. Make sure the patient with mouth ulcerations receives a high-calorie liquid diet. Offer a straw to make drinking less painful.
- Provide warm saline water gargles and rinses, analgesics, and anesthetic lozenges. Good oral hygiene promotes comfort and facilitates healing.
- Ensure adequate rest, which is essential to the mobilization of the body's defenses against infection. Provide good skin and perineal care.
- Monitor CBC and differential, blood culture results, serum electrolyte levels, intake and output, and daily weight.
- To help detect granulocytopenia and lymphocytopenia in the early, most treatable stages, monitor the WBC count of any patient receiving radiation or chemotherapy. After the patient has developed bone marrow depression, they must zealously avoid exposure to infection.
- Advise the patient with known or suspected sensitivity to a drug that may lead to granulocytopenia or lymphocytopenia to alert medical personnel to this sensitivity in the future.

HYPERSPLENISM

Hypersplenism is a syndrome marked by exaggerated splenic activity and, in the majority of patients, splenomegaly. This disorder results in peripheral blood cell deficiency as the spleen traps and destroys peripheral blood cells.

Causes

Hypersplenism may be idiopathic (primary) or secondary to an extrasplenic disorder, such as chronic malaria, polycythemia vera, rheumatoid arthritis, or liver disease. (See *Causes of splenomegaly*.) In hypersplenism, the spleen's normal filtering and phagocytic functions accelerate indiscriminately, automatically removing antibody-coated, aging, and abnormal cells, even though some cells may be functionally normal. The spleen may also temporarily sequester normal platelets and RBCs, withholding them from circulation. In this manner, the enlarged spleen may trap as much as 90% of the body's platelets and up to 45% of its RBC mass.

Causes of splenomegaly

Infectious

- Acute (abscesses, subacute infective endocarditis), chronic (tuberculosis, malaria, Felty syndrome)

Congestive

- Cirrhosis, thrombosis

Hyperplastic

- Hemolytic anemia, polycythemia vera

Infiltrative

- Gaucher disease, Niemann–Pick disease

Cystic Or Neoplastic

- Cysts, leukemia, lymphoma, myelofibrosis

Signs and Symptoms

Most patients with hypersplenism develop anemia, leukopenia, or thrombocytopenia, in many cases with splenomegaly. They may contract bacterial infections frequently, bruise easily, hemorrhage spontaneously from the mucous membranes and GI or GU tract, and suffer ulcerations of the mouth, legs, and feet. They commonly develop fever, weakness, and palpitations. Patients with secondary hypersplenism may have other clinical abnormalities, depending on the underlying disease.

Diagnosis

Diagnosis requires evidence of abnormal splenic destruction or sequestration of RBCs or platelets and splenomegaly.

CBC shows decreased Hb level (as low as 4 g/dL), WBC count (<4,000/μL), and platelet count (<125,000/μL), and an elevated reticulocyte count (>75,000/μL). Splenic biopsy, scan, and angiography may be useful; biopsy is hazardous and should be avoided if possible. In sequestration, the spleen is palpable. Use abdominal palpation cautiously because it may create

injury, bleeding, or rupture.

Treatment

Splenectomy is indicated only in transfusion-dependent patients who are refractory to medical therapy. Splenectomy seldom cures the patient, but it does correct the effects of cytopenia. Postoperative complications may include infection and thromboembolic disease. Occasionally, splenectomy may result in accelerated blood cell destruction in the bone marrow and liver. Secondary hypersplenism necessitates treatment of the underlying disease.

Special Considerations

- If splenectomy is scheduled, administer preoperative transfusions of blood or blood products (fresh frozen plasma and platelets) to replace deficient blood elements. Also treat symptoms or complications of any underlying disorder.
- Postoperatively, monitor vital signs. Check for any excessive drainage or apparent bleeding. Watch for infection, thromboembolism, and abdominal distention. Keep the nasogastric tube patent; listen for bowel sounds. Instruct the patient to perform deep-breathing exercises, and encourage early ambulation to prevent respiratory complications and venous stasis.

ELDER TIP Older adults may be at higher risk for infection because of decreased leukocyte and lymphocyte production. Fewer and weaker lymphocytes and immune system changes diminish the antigen–antibody response in older adults.

Metabolic and Nutritional Disorders

Introduction

Metabolism is the physiologic process that allows cells to transform food into energy and continually rebuild body cells. Metabolism has two phases: catabolism and anabolism. In *catabolism*, the energy-producing phase of metabolism, the body breaks down large food molecules into smaller ones; in *anabolism*, the tissue-building phase, the body converts small molecules into larger ones (such as antibodies to keep the body capable of fighting infection). Both phases are accomplished by means of a chemical process using energy. A wide range of nutrients is metabolized to meet the body's needs. (See *Essential nutrients and their functions*, page 487.)

ELDER TIP A person's protein, vitamin, and mineral requirements usually remain the same as they age, although calorie needs decline. Diminished activity may lower energy requirements by almost 200 calories/day for men and women ages 51 to 75, 400 calories/day for women older than age 75, and 500 calories/day for men older than age 75.

Essential nutrients and their functions

Nutrients are required for the body to work properly and avoid disease.

Nutrients	Functions
Carbohydrates	◆ Energy source
Fats and essential fatty acids	◆ Energy source; essential for growth, normal skin, and membranes
Proteins and amino acids	◆ Synthesis of all body proteins, growth, and tissue maintenance
Water-soluble vitamins	
◆ Ascorbic acid (C)	◆ Collagen synthesis, wound healing, antioxidation
◆ Thiamine (B1)	◆ Coenzyme in carbohydrate metabolism
◆ Riboflavin (B2)	◆ Coenzyme in energy metabolism
◆ Niacin	◆ Coenzyme in carbohydrate, fat, energy metabolism, and tissue metabolism
◆ Vitamin B12	◆ Deoxyribonucleic acid (DNA) and ribonucleic acid synthesis; erythrocyte formation
◆ Folic acid	◆ Coenzyme in amino acid metabolism; heme and hemoglobin formation; DNA synthesis; lowering homocysteine levels
Fat-soluble vitamins	

◆ Vitamin A	◆ Vision in dim light, mucosal epithelium integrity, tooth development, endocrine function
◆ Vitamin D	◆ Regulation of calcium and phosphate absorption and metabolism; renal phosphate clearance; musculoskeletal function
◆ Vitamin E	
◆ Vitamin K	◆ Antioxidation; essential for muscle, liver, and red blood cell integrity
	◆ Blood clotting (catalyzes synthesis of prothrombin by liver); skeletal function

CARBOHYDRATES: PRIMARY ENERGY SOURCE

The body gets most of its energy by metabolizing carbohydrates, especially glucose. Glucose catabolism proceeds in three phases:

- *Glycolysis*, a series of chemical reactions, converts glucose molecules into pyruvic or lactic acid.
- The *citric acid cycle* removes ionized hydrogen atoms from pyruvic acid and produces carbon dioxide.
- *Oxidative phosphorylation* traps energy from the hydrogen electrons and combines the hydrogen ions and electrons with oxygen to form water and the common form of biological energy, adenosine triphosphate (ATP).

Other essential processes in carbohydrate metabolism include glycogenesis—the formation of glycogen, a storage form of glucose—which occurs when cells become saturated with glucose-6-phosphate (an intermediate product of glycolysis); glycogenolysis, the reverse process, which converts glycogen into glucose-6-phosphate in muscle cells and liberates free glucose in the liver; and gluconeogenesis, or "new" glucose formation from protein amino acids or fat glycerols.

A complex interplay of hormonal and neural controls regulates glucose metabolism. Hormone secretions of five endocrine glands dominate this regulatory function:

- Alpha cells of the islets of Langerhans secrete glucagon, which increases the blood glucose level by stimulating phosphorylase activity to accelerate liver glycogenolysis.
- Beta cells of the islets of Langerhans secrete the glucose-regulating hormone insulin, which assists in glucose transport across cell membranes and storage of excess glucose as fat.
- The adrenal medulla, as a physiologic response to stress, secretes epinephrine, which stimulates liver and muscle glycogenolysis to increase the blood glucose level.
- Corticotropin and glucocorticoids also increase blood glucose levels. Glucocorticoids accelerate gluconeogenesis by promoting the flow of amino acids to the liver, where they're synthesized into glucose.
- Human growth hormone (hGH) limits the fat storage and favors fat catabolism; consequently, it inhibits carbohydrate catabolism and thus raises blood glucose levels.
- Thyroid-stimulating hormone and thyroid hormone have mixed effects on carbohydrate metabolism and may raise or lower blood glucose levels.

FATS: CATABOLISM AND ANABOLISM

The breaking up of triglycerides—*lipolysis*—yields fatty acids and glycerol. Beta oxidation breaks down fatty acids into acetyl coenzyme A, which can then enter the citric acid cycle; glycerol can also undergo gluconeogenesis or enter the glycolytic pathways to produce energy. Conversely, *lipogenesis* is the chemical formation of fat from excess carbohydrates and proteins or from the fatty acids and glycerol products of lipolysis. Adipose tissue is the primary storage site for excess fat and thus is the greatest source of energy reserve. Certain unsaturated fatty

acids are necessary for the synthesis of vital body compounds. Because the body can't produce these essential fatty acids, they must be provided through diet. Insulin, hGH, catecholamines, corticotropin, and glucocorticoids control fat metabolism in an inverse relationship with carbohydrate metabolism; large amounts of carbohydrates promote fat storage, and deficiency of available carbohydrates promotes fat breakdown for energy needs.

PROTEINS: ANABOLISM

The primary process in protein metabolism is anabolism. Catabolism is relegated to a supporting role in protein metabolism—a reversal of the roles played by these two processes in carbohydrate and fat metabolisms. By synthesizing proteins—the tissue-building foods—the body derives substances essential for life (such as plasma proteins) and can reproduce, control cell growth, and repair itself. However, when carbohydrates or fats are unavailable as energy sources, or when energy demands are exceedingly high, protein catabolism converts protein into an available energy source. Protein metabolism consists of many processes, including:

- *Deamination*—a catabolic and energy-producing process occurring in the liver with the splitting off of the amino acid to form ammonia and a keto acid
- *Transamination*—anabolic conversion of keto acids to amino acids
- *Urea formation*—a catabolic process occurring in the liver, producing urea, the end product of protein catabolism

The male hormone testosterone and hGH stimulate protein anabolism; corticotropin prompts secretion of glucocorticoids, which, in turn, facilitate protein catabolism. Normally, the rate of protein anabolism equals the rate of protein catabolism—a condition known as *nitrogen balance* (because ingested nitrogen equals nitrogen waste excreted in urine, feces, and sweat). When excessive catabolism causes the amount of nitrogen excreted to exceed the amount ingested, a state of *negative nitrogen balance* exists—usually the result of starvation and cachexia or surgical stress.

FLUID AND ELECTROLYTE BALANCE

A critical component of metabolism is fluid and electrolyte balance. Water is an essential body substance and constitutes almost 60% of an adult's body weight and more than 75% of a neonate's body weight. In both older and obese adults, the ratio of water to body weight drops; children and lean people have a higher proportion of water in their bodies.

Body fluids can be classified as intracellular (or cellular) or extracellular. Intracellular fluid constitutes about 40% of total body weight and 60% of all body fluid; it contains large quantities of potassium and phosphates but very little sodium and chloride. Conversely, extracellular fluid (ECF) contains mostly sodium and chloride but very little potassium and phosphates. Incorporating interstitial, cerebrospinal, intraocular, and gastrointestinal (GI) fluids and plasma, ECF supplies cells with nutrients and other substances needed for cellular function. The many components of body fluids have the important function of preserving osmotic pressure and acid–base and anion–cation balance.

Homeostasis is a stable state—the equilibrium of chemical and physical properties of body fluid. Body fluids contain two kinds of dissolved substances: those that dissociate in solution (electrolytes) and those that don't. For example, glucose, when dissolved in water, doesn't break down into smaller particles; but sodium chloride dissociates in solution into sodium cations (+) and chloride anions (−). The composition of these electrolytes in body fluids is electrically

balanced so the positively charged ions (cations: sodium, potassium, calcium, and magnesium) equal the negatively charged ions (anions: chloride, bicarbonate, sulfate, phosphate, proteinate, and carbonic and other organic acids). Although these particles are present in relatively low concentrations, any deviation from their normal levels can have profound physiologic effects.

ELDER TIP Institutionalized older people are at particularly high risk for dehydration because of their diminished thirst perception and any combination of physical, cognitive, speech, mobility, and visual impairment.

In homeostasis—an ever-changing but balanced state—water and electrolytes and other solutes move continually between cellular and extracellular compartments. Such motion is made possible by semipermeable membranes that allow diffusion, filtration, and active transport. *Diffusion* refers to the movement of particles or molecules from an area of greater concentration to one of lesser concentration. Normally, particles move randomly and constantly until the concentrations within given solutions are equal. Diffusion also depends on permeability, electrical gradient, and pressure gradient. Particles, however, can't diffuse against any of these gradients without energy and a carrier substance (active transport). ATP is released from cells to aid particles needing energy to pass through the cell membrane.

The diffusion of water from a solution of low concentration to one of high concentration is called *osmosis.* The pressure that develops when a selectively permeable cell membrane separates solutions of different strengths of concentrations is known as *osmotic pressure,* expressed in terms of osmoles or milliosmoles (mOsm). Osmotic activity is described in terms of *osmolality*—the osmotic pull exerted by all particles per unit of water, expressed in mOsm/kg of water—or *osmolarity,* when expressed in mOsm/L of solution.

The normal range of body fluid osmolality is 285 to 295 mOsm/kg. Solutions of 50 mOsm above or below the high and low points of this normal range exert little or no osmotic effect (iso-osmolality). A solution below 240 mOsm contains a lower particle concentration than plasma (hypo-osmolar), whereas a solution over 340 mOsm has a higher particle concentration than plasma (hyperosmolar).

Rapid I.V. administration of iso-osmolar solutions to patients who are debilitated, are very old or very young, or have cardiac or renal insufficiency could lead to ECF volume overload and induce pulmonary edema and heart failure because particulate concentration is the same as plasma, so fluid shifting into and out of cells will occur.

Continuous I.V. administration of hypo-osmolar solutions decreases serum osmolality and leads to excess intracellular fluid volume (water intoxication), whereas continuous I.V. administration of hyperosmolar solutions results in intracellular dehydration, increased serum osmolality and, eventually, ECF volume deficit due to excessive urinary excretion. These states occur because of fluid diffusion and the cell's attempt to balance the particulate concentrations inside and outside the cell.

REGULATION OF PH

Primarily through the complex chemical regulation of carbonic acid by the lungs and of base bicarbonate by the kidneys, the body maintains the hydrogen ion concentration to keep the ECF pH between 7.35 and 7.45. Nutritional deficiency or excess, disease, injury, or metabolic disturbance can interfere with normal homeostatic mechanisms and raise pH (acidosis) or lower it (alkalosis).

ASSESSING HOMEOSTASIS

The goal of metabolism and homeostasis is to maintain the complex environment of ECF—the plasma—which nourishes and supports every body cell. This special environment is subject to multiple interlocking influences and readily reflects any disturbance in nutrition, chemical or fluid content, and osmotic pressure. Such disturbances can be detected by various laboratory tests. For example, measurements of albumin, prealbumin, and other blood proteins; electrolyte concentration; enzyme and antibody levels; and urine and blood chemistry levels (lipoproteins, glucose, blood urea nitrogen [BUN], creatinine, and creatinine-height index [CHI]) reflect the state of metabolism, homeostasis, and nutrition throughout the body. (See *Laboratory tests: Assessing nutritional status,* page 490.) Results of such laboratory tests, of course, supplement the information obtained from dietary history and physical examination—which offer gross clinical information about the quality, quantity, and efficiency of metabolic processes. To support clinical information, anthropometry, height-weight ratio, and skinfold thickness determinations specifically define tissue nutritional status.

Laboratory tests: Assessing nutritional status

Blood and urine tests provide the most precise data about nutritional status, often revealing nutritional problems before they're clinically apparent. The list below explains some common tests and what their results mean.

Serum Vitamins and Minerals

Vitamin and mineral deficiencies commonly screened for include deficiencies in A, B, B_{12}, folic acid, ascorbic acid, beta-carotene, riboflavin and, sometimes, zinc, calcium, magnesium, iron, and other minerals.

Serum Nutrients

Glucose levels help assess suspected diabetes or hypoglycemia. Glucose may be elevated with stress, acromegaly, Cushing syndrome, corticosteroid use, liver disease, sepsis, or overfeeding. Glucose may be decreased with fluid overload, adrenal insufficiency, liver disease, severe sepsis, insulinoma, or pancreatic disorders. Cholesterol and triglyceride levels help differentiate the type of hyperlipoproteinemia.

Nitrogen Balance

A negative nitrogen balance indicates inadequate intake of protein or calories.

Hemoglobin and Hematocrit

Decreased levels can occur in protein-calorie malnutrition, iron deficiency, overhydration, hemorrhage, and hemolytic disease; elevated levels in dehydration, polycythemia, and folate and vitamin B_{12} deficiency.

Serum Albumin

Reduced levels may indicate overhydration or visceral protein depletion because of GI disease, liver disease, or nephrotic syndrome. Elevated levels occur in dehydration.

Creatinine-Height Index (Chi)

This calculated value reflects muscle mass and estimates muscle protein depletion. Reduced CHI may indicate protein-calorie malnutrition or impaired renal function.

Serum Prealbumin

This carrier protein for thyroxine is a sensitive indicator of visceral protein.

Total Lymphocyte Count

This provides an indication of immune status. Counts are low in malnutrition and acquired immunodeficiency syndrome.

The following measures can help you maintain your patient's homeostasis:

- Obtain a complete dietary history and nutritional assessment, including weight history and GI symptoms, to determine if carbohydrate, fat, protein, vitamin, mineral, and water intake are adequate for energy production and for tissue repair and growth. Remember that during periods of rapid tissue synthesis (growth, pregnancy, healing), protein needs increase.
- Consult a dietitian about any patient who may be malnourished because of malabsorption syndromes, renal or hepatic disease, or clear-liquid diets or who may possibly receive nothing by mouth for more than 5 days. Planned meals that provide adequate carbohydrates, fats, and protein are necessary for convalescence. Supplementary carbohydrates are often needed to spare protein and achieve a positive nitrogen balance.
- Accurately record intake and output to assess fluid balance (this includes intake of oral liquids or I.V. solutions and urine, gastric, and stool output).
- Weigh the patient daily—at the same time, with the same-type clothing, and on the same scale. Remember, a weight loss of 2.2 lb (1 kg) is equivalent to the loss of 1 L of fluid.
- Observe the patient closely for insensible water or unmeasured fluid losses (such as through diaphoresis). Remember, fluid loss from the skin and lungs (normally 900 mL/day) can reach as high as 2,000 mL/day from hyperventilation or tachypnea, thus increasing insensible water losses.

ELDER TIP Teach elderly patients and others vulnerable to fluid imbalances the importance of maintaining adequate fluid intake.

- Recognize I.V. solutions that are hypo-osmolar, such as 0.45% NaCl (half-normal saline solution). Iso-osmolar solutions include normal saline solution (0.9% NaCl), 5% dextrose in 0.2% NaCl, Ringer solutions, and 5% dextrose in water. (The latter acts like a hypotonic solution because dextrose is quickly metabolized, leaving only free water.) Hyperosmolar solutions include 5% dextrose in normal saline solution, 10% dextrose in water, and 5% dextrose in Ringer lactate solution.
- When continuously administering hypo-osmolar solutions, watch for signs of water intoxication: headaches, behavior changes (confusion or disorientation), nausea, vomiting, rising blood pressure, and falling pulse rate.
- When continuously administering hyperosmolar solutions, be alert for signs of hypovolemia: thirst, dry mucous membranes, slightly falling blood pressure, rising pulse rate and respirations, low-grade fever (99° F [37.2° C]), and elevated hematocrit, hemoglobin, and BUN levels.

- Administer fluid cautiously, especially to the patient with cardiopulmonary or renal disease, and watch for signs of overhydration: constant and irritating cough, dyspnea, moist crackles, rising central venous pressure, and pitting edema (late sign). When the patient is in an upright position, neck and hand vein engorgement is a sign of fluid overload.

ELDER TIP Many older patients take drugs to treat a variety of conditions. Remember that drugs can affect the patient's nutritional status by altering nutrient absorption, metabolism, utilization, or excretion. Likewise, various foods, beverages, and mineral or vitamin supplements can affect the absorption and effectiveness of drugs. Be aware of these potential interactions when evaluating the patient's medication regimen and nutritional status.

Nutritional Imbalance

VITAMIN A DEFICIENCY

A fat-soluble vitamin absorbed in the GI tract, vitamin A maintains epithelial tissue and retinal function. Consequently, deficiency of this vitamin may result in night blindness, decreased color adjustment, keratinization of epithelial tissue, and poor bone growth. Healthy adults have adequate vitamin A reserves to last up to a year; children often don't.

Causes and Incidence

Vitamin A deficiency usually results from inadequate intake of foods high in vitamin A (liver, kidney, butter, milk, cream, cheese, and fortified margarine) or carotene, a precursor of vitamin A found in dark green leafy vegetables and yellow or orange fruits and vegetables. (Six milligrams of beta-carotene is equal to 1 mg of vitamin A.) The recommended daily allowance for vitamin A is 3,000 IU for adult males and 2,310 IU for adult females.

Less common causes of vitamin A deficiency include:

- malabsorption due to celiac disease, sprue, cirrhosis, obstructive jaundice, cystic fibrosis, giardiasis, or habitual use of mineral oil as a laxative
- massive urinary excretion caused by cancer, tuberculosis, pneumonia, nephritis, or urinary tract infection
- decreased storage and transport of vitamin A due to hepatic disease

Each year, more than 80,000 people worldwide—mostly children in underdeveloped countries—lose their sight from severe vitamin A deficiency. This condition is rare in the United States, although many disadvantaged children have substandard levels of vitamin A. With therapy, the chance of reversing symptoms of night blindness and milder conjunctival changes is excellent. When corneal damage is present, emergency treatment is necessary.

Pathophysiology

Once ingested, provitamins A are released from proteins in the stomach. These retinyl esters are then hydrolyzed to retinol in the small intestine, because retinol is more efficiently absorbed. Carotenoids are cleaved in the intestinal mucosa into molecules of retinaldehyde, which is subsequently reduced to retinol and then esterified to retinyl esters. The retinyl esters of retinoid and carotenoid origin are transported via micelles in the lymphatic drainage of the intestine to the blood and then to the liver as components of chylomicrons. In the body, 50% to 80% of vitamin A is stored in the liver, where it is bound to the cellular retinol-binding protein (RBP). The

remaining vitamin A is deposited into adipose tissue, the lungs, and the kidneys as retinyl esters, most commonly as retinyl palmitate.

Vitamin A can be mobilized from the liver to peripheral tissue by a process of deesterification of the retinyl esters. In blood, vitamin A is bound to RBP, which transports it as a complex with transthyretin. The hepatic synthesis of RBP is dependent on the presence of zinc and amino acids to maintain its narrow serum range of 40 to 50 µg/dL. Through a receptor-mediated process, the retinol is taken up by the peripheral tissues from the RBP-transthyretin complex.

Complication

- Corneal damage

Signs and Symptoms

Typically, the first symptom of vitamin A deficiency is night blindness (nyctalopia), which usually becomes apparent when the patient enters a dark place or is caught in the glare of oncoming headlights while driving at night. This condition can progress to xerophthalmia, or drying of the conjunctivas, with development of gray plaques (Bitot spots); if unchecked, perforation, scarring, and blindness may result. Keratinization of epithelial tissue causes dry, scaly skin; follicular hyperkeratosis; and shrinking and hardening of the mucous membranes, possibly leading to infections of the eyes and the respiratory or genitourinary tract. An infant with severe vitamin A deficiency shows signs of failure to thrive and apathy, along with dry skin and corneal changes, which can lead to ulceration and rapid destruction of the cornea.

Diagnosis

Dietary history and typical ocular lesions suggest vitamin A deficiency. Carotene levels less than 40 µg/dL also suggest vitamin A deficiency, but they vary with seasonal ingestion of fruits and vegetables.

CONFIRMING DIAGNOSIS *A serum level of vitamin A that falls below 10 µg/dL confirms the diagnosis. Levels between 10 and 19 µg/dL are also considered low, but the patient isn't likely to have developed significant symptoms.*

Treatment

Mild conjunctival changes or night blindness requires vitamin A replacement in the form of cod liver oil or halibut liver oil. Acute deficiency requires aqueous vitamin A solution I.M., or oral tablets, especially when corneal changes have occurred. Therapy for underlying biliary obstruction consists of administration of bile salts; for pancreatic insufficiency, pancreatin, or pancrelipase. Dry skin responds well to cream-based or petroleum-based products.

In patients with chronic malabsorption of fat-soluble vitamins, and in those with low dietary intake, prevention of vitamin A deficiency requires aqueous I.V. supplements or an oral water-miscible preparation.

Special Considerations

- Administer oral vitamin A supplements with or after meals or parenterally, as indicated. Watch for signs of hypercarotenemia (orange coloration of the skin and eyes) and hypervitaminosis A (rash, hair loss, anorexia, transient hydrocephalus, and vomiting in children; bone pain, hepatosplenomegaly, diplopia, and irritability in adults). If these signs

occur, discontinue supplements and notify the physician immediately. (Hypercarotenemia is relatively harmless; hypervitaminosis A may be toxic.)

PREVENTION *Because vitamin A deficiency usually results from dietary insufficiency, provide nutritional counseling. Tell the patient that vitamin A comes from animal sources, such as eggs, meat, milk, cheese, cream, liver, kidney, and cod and halibut fish oil, but that healthier choices, such as carrots, pumpkins, sweet potatoes, and most dark green, leafy vegetables are good sources of beta-carotene, vitamin A's precursor form. Instruct the patient to choose intense-colored fruit or vegetables, which have high beta-carotene content. Provide referrals to appropriate community agencies if necessary.*

VITAMIN B DEFICIENCIES

Vitamin B complex is a group of water-soluble vitamins essential to normal metabolism, cell growth, and blood formation. (See *Recommended daily allowance of B complex vitamins*.) The most common deficiencies involve thiamine (B_1), riboflavin (B_2), niacin (B_3), pyridoxine (B_6), and cobalamin (B_{12}).

Recommended daily allowance of B complex vitamins

Vitamin	Men (age 23 to 70)	Women (age 23 to 70)	Infants	Children (age 1 to 18)
B1*	1.2 mg	1.1 mg	0.2 to 0.3 mg	0.5 to 1.2 mg
B2*	1.3 mg	1.1 mg	0.3 to 0.4 mg	0.5 to 1.3 mg
Niacin*	16 mg	14 mg	2 to 4 mg	6 to 16 mg
B6	1.3 mg	1.3 mg	0.1 to 0.3 mg	0.5 to 1.3 mg
B12	2.4 µg	2.4 µg	0.4 to 0.5 µg	0.9 to 2.4 µg

*Requirements per 1,000 kcal of dietary intake.

Causes and Incidence

Thiamine deficiency results from malabsorption or inadequate dietary intake of vitamin B_1. It also results from alcoholism, prolonged diarrhea, or from increased requirement, which can occur in pregnancy, lactation, and hyperthyroidism. Beriberi, a serious thiamine deficiency disease, is most prevalent in Asians, who subsist mainly on diets of unenriched rice and wheat. Although this disease is uncommon in the United States, alcoholics may develop cardiac (wet) beriberi with high-output heart failure, neuropathy, and cerebral disturbances. In times of stress (e.g., pregnancy), malnourished young adults may develop beriberi; infantile beriberi may appear in infants on low-protein diets or in those breast-fed by thiamine-deficient mothers.

Riboflavin deficiency (ariboflavinosis) results from a diet deficient in milk, meat, fish, legumes, and green, leafy vegetables. Alcoholism or prolonged diarrhea may also induce riboflavin deficiency. Exposure of milk to sunlight or treatment of legumes with baking soda can destroy riboflavin.

Niacin deficiency, in its advanced form, produces pellagra, which affects the skin, central nervous system (CNS), and GI tract. (See *Recognizing pellagra*, page 493.) Although this deficiency is now seldom found in the United States, it was once common among Southerners who subsisted mainly on corn and consumed minimal animal protein. (Corn is low in niacin and in available tryptophan, the amino acid from which the body synthesizes niacin.) Niacin

deficiency is still common in parts of Egypt, Romania, Africa, Serbia, and Montenegro, where corn is the dominant staple food. Niacin deficiency can also occur secondary to carcinoid syndrome or Hartnup disease.

Recognizing pellagra

This patient with pellagra shows dark, scaly, advanced dermatitis. In advanced niacin deficiency, such dermatitis usually occurs on areas exposed to the sun.

Pyridoxine deficiency usually results from destruction of pyridoxine in infant formulas by autoclaving. A frank deficiency is uncommon in adults, except in patients taking pyridoxine antagonists, such as isoniazid and penicillamine.

Cobalamin deficiency most commonly results from an absence of intrinsic factor in gastric secretions, or an absence of receptor sites after ileal resection. Other causes include malabsorption syndromes associated with sprue, intestinal worm infestation, regional ileitis, and gluten enteropathy, and a diet low in animal protein.

Pathophysiology

Thiamine deficiency (B_1)—when healthy individuals are deprived of thiamine, thiamine stores are depleted within 1 month. However, within a week after thiamine intake stops, healthy people develop a resting tachycardia, weakness, and decreased deep tendon reflexes; some people develop a peripheral neuropathy.

Riboflavin deficiency (B_2)—riboflavin deficiency can alter iron absorption and cause an

anemia that leads to fatigue. Riboflavin is involved in red blood cell (RBC) production and transportation of oxygen to the cells. Improving the amount of riboflavin in the body can increase circulating hemoglobin levels and increase red cell production. Collagen is a protein found in most skin and hair, so riboflavin is necessary to maintain a good collagen level. Taking supplements of riboflavin is also a cure for migraines. Research showed that 400 mg of riboflavin a day had demonstrated efficacy in prevention of a migraine in adults, but it must be taken for a minimum of 3 months for good results. This is most likely because mitochondrial dysfunction has been shown to play a role in migraines, and riboflavin is a precursor of flavin cofactors of the electron transport chain.

Niacin deficiency (B_3)—niacin is essential for adequate cellular function because of its required roles in two similar but distinct coenzymes (i.e., nicotinamide adenine dinucleotide [NAD] and nicotinamide adenine dinucleotide phosphate [NADP]). Both of these are cofactors that can be recycled by serving as both oxidizing (NAD, NADP) and reducing (NADH, NADPH) agents.

During the oxidation of glucose and other intermediary metabolites, a substantial amount of chemical energy is released. NAD/NADH are able to transfer electrons in a process that captures the energy by generating high-energy phosphate bonds. The synthesized ATP then provides the energy necessary for other reactions of intermediary metabolism that simultaneously regenerate NAD from the reduced NADH. A portion of this cofactor is also converted to NADP/NADPH, which plays several distinct roles. Reduced NADPH is used in reactions that detoxify reactive oxygen species, that metabolize drugs in a cytochrome P450 system, and that support lipid biosynthesis.

Pyridoxine deficiency (B_6)—after absorption, pyridoxine, pyridoxamine, and pyridoxal are transported into hepatic cells by facilitated diffusion. Pyridoxal kinase phosphorylates pyridoxine and pyridoxamine, after which they are converted to pyridoxal 5′-phosphate (PLP) by a flavin-dependent enzyme. PLP either remains in the hepatocyte, where it is bound to an apoenzyme, or it is released into the serum, where it is tightly bound to albumin. Free pyridoxal is degraded by alkaline phosphatase, hepatic and renal aldehyde oxidases, and pyridoxal dehydrogenase.

Pyridoxine 5′-phosphate is an essential cofactor in various transamination, decarboxylation, and synthesis pathways involving carbohydrates, sphingolipids, sulfur-containing amino acids, heme, and neurotransmitters. PLP is a coenzyme of tryptophan, methionine, and gamma aminobutyric acid (GABA) metabolism. With methionine deficiency, *S*-adenosylmethionine accumulates, resulting in the inhibition of sphingolipid and myelin synthesis. Tryptophan is a precursor to several neurotransmitters and is required for niacin production. Thus, pyridoxine deficiency can cause a syndrome indistinguishable from pellagra. PLP is a cofactor for glutamic acid decarboxylase, the enzyme that produces GABA, such that PLP deficiency results in insufficient GABA. Since GABA is the major inhibitor cortical neurotransmitter, PLP deficiency can lead to seizures. Interestingly, pyridoxine-dependent seizures are not caused by a pyridoxine deficiency per se but rather due to an increased depletion of PLP.

The neurotransmitters dopamine, serotonin, epinephrine, norepinephrine, glycine, glutamate, and GABA also require PLP for their production. Homocysteine metabolism is dependent on pyridoxine, and high homocysteine levels can result from pyridoxine deficiency.

Cobalamin deficiency (B_{12})—cobalamin deficiency is caused by the failure of gastric parietal cells to produce sufficient IF (a gastric protein secreted by parietal cells) to permit the absorption of adequate quantities of dietary vitamin B_{12}. Other disorders that interfere with the absorption and metabolism of vitamin B_{12} can produce cobalamin deficiency, with the development of a

macrocytic anemia and neurologic complications.

Complications

- heart failure
- neuropathy
- pellagra
- anemia
- seizures

Signs and Symptoms

Thiamine deficiency causes polyneuritis and, possibly, Wernicke encephalopathy and Korsakoff psychosis. In infants (infantile beriberi), this deficiency produces edema, irritability, abdominal pain, pallor, vomiting, loss of voice and, possibly, seizures. In wet beriberi, severe edema starts in the legs and moves up through the body; dry beriberi causes multiple neurologic symptoms and an emaciated appearance. Thiamine deficiency may also cause cardiomegaly, palpitations, tachycardia, dyspnea, and circulatory collapse. Constipation and indigestion are common; ataxia, nystagmus, and ophthalmoplegia are also possible.

Riboflavin deficiency characteristically causes cheilosis (cracking of the lips and corners of the mouth), sore throat, and glossitis. It may also cause seborrheic dermatitis in the nasolabial folds, scrotum, and vulva and, possibly, generalized dermatitis involving the arms, legs, and trunk. This deficiency can also affect the eyes, producing burning, itching, light sensitivity, tearing, and vascularization of the corneas. Late-stage riboflavin deficiency causes neuropathy, mild anemia and, in children, growth retardation.

Niacin deficiency in its early stages produces fatigue, anorexia, muscle weakness, headache, indigestion, mild skin eruptions, weight loss, and backache. In advanced stages (pellagra), it produces dark, scaly dermatitis, especially on exposed body parts, that makes the patient appear to be severely sunburned. The mouth, tongue, and lips become red and sore, which may interfere with eating. Common GI symptoms include nausea, vomiting, and diarrhea. Associated CNS aberrations—confusion, disorientation, and neuritis—may become severe enough to induce hallucinations and paranoia. Because of this triad of symptoms, pellagra is sometimes called a "3-D" syndrome—dementia, dermatitis, and diarrhea. If not reversed by therapeutic doses of niacin, pellagra can be fatal.

Pyridoxine deficiency in infants causes a wide range of symptoms: dermatitis, occasional cheilosis or glossitis unresponsive to riboflavin therapy, abdominal pain, vomiting, ataxia, and seizures. This deficiency can also lead to CNS disturbances.

Cobalamin deficiency causes pernicious anemia, which produces anorexia, weight loss, abdominal discomfort, constipation, diarrhea, and glossitis; peripheral neuropathy; and, possibly, ataxia, spasticity, and hyperreflexia.

Diagnosis

The following values confirm vitamin B deficiency.

- *Thiamine deficiency*—commonly measured as micrograms per deciliter in a 24-hour urine collection. Deficiency levels are age-related: 1 to 3 years, less than 120; 4 to 6 years, less than 85; 7 to 9 years, less than 70; 10 to 12 years, less than 60; 13 to 15 years, less than 50; adults, less than 27; pregnant women, less than 23 (second trimester), less than 21 (third trimester).

- *Riboflavin deficiency*—measured as micrograms per gram of creatinine in a 24-hour urine collection. Deficiency levels are age-related: 1 to 3 years, less than 150; 4 to 6 years, less than 100; 7 to 9 years, less than 85; 10 to 15 years, less than 70; adults, less than 27; pregnant women, less than 39 (second trimester), less than 30 (third trimester).
- *Niacin deficiency*—measured by *n*-methyl nicotinamide in a 24-hour urine collection as micrograms per gram of creatinine. Deficiency levels in adults are less than 0.5; in pregnant women, less than 0.5 (first trimester), less than 0.6 (second trimester), and less than 0.8 (third trimester).
- *Pyridoxine deficiency*—xanthurenic acid more than 50 mg/day in 24-hour urine collection after administration of 10 g of L-tryptophan; decreased levels of serum and RBC transaminases; reduced excretion of pyridoxic acid in urine.
- *Cobalamin deficiency*—cobalamin serum levels less than 170 pg/mL. Tests to discover the deficiency's cause include gastric analysis and hemoglobin studies. In addition, the Schilling test measures absorption of radioactive cobalamin with and without intrinsic factor; however, it is rarely used.

Treatment

Diet and supplementary vitamins can correct or prevent vitamin B deficiencies, as follows.

- *Thiamine deficiency*—a high-protein diet, with adequate calorie intake, possibly supplemented by B complex vitamins for early symptoms. Thiamine-rich foods include pork, peas, wheat bran, oatmeal, and liver. Alcoholic beriberi may require thiamine supplements or thiamine hydrochloride as part of a B complex concentrate.
- *Riboflavin deficiency*—supplemental riboflavin in patients with intractable diarrhea or increased need for riboflavin related to growth, pregnancy, lactation, or wound healing. Good sources of riboflavin are meats, enriched flour, milk and dairy products, eggs, cereal, and green, leafy vegetables. Acute riboflavin deficiency requires daily oral doses of riboflavin alone or with other B complex vitamins. Riboflavin phosphate can also be administered I.V. or I.M.
- *Niacin deficiency*—supplemental B complex vitamins and dietary enrichment in patients at risk because of marginal diets or alcoholism. Meats, fish, peanuts, brewer's yeast, enriched breads, and cereals are rich in niacin; milk and eggs, in tryptophan. Confirmed niacin deficiency requires daily doses of niacinamide orally or I.V.
- *Pyridoxine deficiency*—prophylactic pyridoxine therapy in infants and in children with a seizure disorder; supplemental B complex vitamins in patients with anorexia, malabsorption, or those taking isoniazid or penicillamine. Some women who take hormonal contraceptives may have to supplement their diets with pyridoxine. Confirmed pyridoxine deficiencies require oral or parenteral pyridoxine. Children with seizures stemming from metabolic dysfunction may require daily doses of 200 to 600 mg pyridoxine.
- *Cobalamin deficiency*—parenteral cobalamin in patients with reduced gastric secretion of hydrochloric acid, lack of intrinsic factor, some malabsorption syndromes, or ileum resections. Strict vegetarians may have to supplement their diets with oral vitamin B_{12}. Depending on the deficiency's severity, supplementary cyanocobalamin or methylcobalamin is usually given parenterally for 5 to 10 days, followed by monthly or daily vitamin B_{12} supplements.

Special Considerations

An accurate dietary history provides a baseline for effective dietary counseling.

- Identify and observe patients who are at risk for vitamin B deficiencies—alcoholics, the elderly, pregnant women, oral hormonal contraceptive users (vitamins B_6 and B_{12}), and people on limited diets.
- Administer prescribed supplements. Make sure patients understand how important it is that they adhere strictly to their prescribed treatment for the rest of their lives. Watch for adverse effects from large doses of niacinamide, such as a flushed sensation or hot flashes, in patients with niacin deficiency. Remember, prolonged intake of niacin can cause hepatic dysfunction. Caution patients with Parkinson disease receiving pyridoxine that this drug can impair response to levodopa therapy.
- Explain all tests and procedures. Reassure patients that, with treatment, the prognosis is good. Refer patients to appropriate assistance agencies if their diets are inadequate due to adverse socioeconomic conditions.

PREVENTION

- *Encourage the patient to follow a well-balanced diet.*
- *Vitamin B_{12} injections can prevent anemia after surgeries known to cause vitamin B_{12} deficiency.*

VITAMIN C DEFICIENCY

Vitamin C (ascorbic acid) deficiency leads to scurvy or inadequate production of collagen, an extracellular substance that binds the cells of the teeth, bones, and capillaries. It's essential for wound healing and burn recovery. Vitamin C is also an important factor in metabolizing such amino acids as tyrosine and phenylalanine. It also acts as a reductant, activating enzymes in the body, as well as converting folic acid into useful components.

Severe vitamin C deficiency results in scurvy, evidenced by hemorrhagic tendencies and abnormal osteoid and dentin formation.

Causes and Incidence

This deficiency's primary cause is a diet lacking in vitamin C-rich foods, such as citrus fruits, tomatoes, cabbage, broccoli, spinach, and berries. Because the body can't store this water-soluble vitamin in large amounts, the supply needs to be replenished daily. Other causes include:

- destruction of vitamin C in foods by overexposure to air or by overcooking
- excessive ingestion of vitamin C during pregnancy, which causes the neonate to require large amounts of the vitamin after birth
- marginal intake of vitamin C during periods of physiologic stress—caused by infectious disease, for example—which can deplete tissue saturation of vitamin C

Historically common among sailors and others deprived of fresh fruits and vegetables for long periods of time, vitamin C deficiency is uncommon today in the United States, except in alcoholics, people on restricted-residue diets, and infants weaned from breast milk to cow's milk without a vitamin C supplement.

Pathophysiology

Humans, other primates, and guinea pigs are unable to synthesize L-ascorbic acid (vitamin C); therefore, they require it in their diet. The enzyme L-gulonolactone oxidase, which would usually catalyze the conversion of L-gluconogammalactone to L-ascorbic acid, is defective due to a mutation or inborn error in carbohydrate metabolism.

Ascorbic acid is metabolized in the liver by oxidation and sulfation. The renal threshold for excretion by the kidney in urine is approximately 1.4 mg/100 mL plasma. Excess amounts of ascorbic acid are excreted unchanged or as metabolites. When body tissue or plasma concentrations of vitamin C are low, excretion of the vitamin is decreased. Scurvy occurs after vitamin C has been eliminated from the diet for at least 3 months and when the body pool falls below 350 mg.

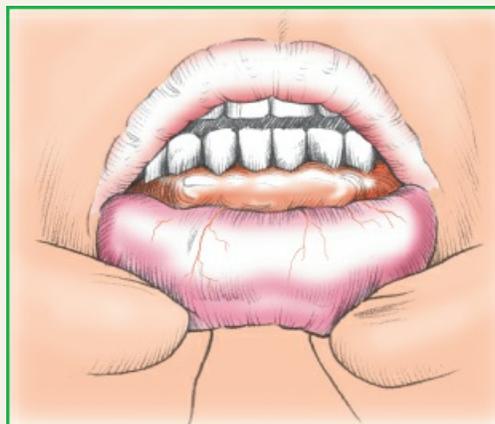
Complication

- ◆ Scurvy

Signs and Symptoms

Clinical features of vitamin C deficiency appear as capillaries become increasingly fragile. In an adult, it produces petechiae, ecchymoses, follicular hyperkeratosis (especially on the buttocks and legs), anemia, anorexia, limb and joint pain (especially in the knees), pallor, weakness, swollen or bleeding gums, loose teeth, lethargy, insomnia, poor wound healing, and ocular hemorrhages in the bulbar conjunctivae. (See *Scurvy's effect on gums and legs*.) Vitamin C deficiency can also cause beading, fractures of the costochondral junctions of the ribs or epiphysis, and such psychological disturbances as irritability, depression, hysteria, and hypochondriasis.

Scurvy's effect on gums and legs

In adults, scurvy causes swollen or bleeding gums and loose teeth.


It also causes follicular hyperkeratosis, usually on the legs.

In a child, vitamin C deficiency produces tender, painful swelling in the legs, causing the child to lie with the legs partially flexed. Other symptoms include fever, diarrhea, and vomiting.

Diagnosis

CONFIRMING DIAGNOSIS *Serum ascorbic acid levels less than 0.2 mg/dL and white blood cell ascorbic acid levels less than 30 mg/dL help confirm the diagnosis.*

Dietary history revealing an inadequate intake of ascorbic acid suggests vitamin C deficiency. A capillary fragility test may be performed on the patient's forearm with a blood pressure cuff; it's positive if more than 10 petechiae form after 5 minutes of pressure.

Treatment

Because scurvy may be fatal, treatment begins immediately to restore adequate vitamin C intake with daily doses of 100 to 200 mg synthetic vitamin C or orange juice in mild disease and with doses as high as 500 mg/day in severe disease. Symptoms usually subside in 2 to 3 days; hemorrhages and bone disorders, in 2 to 3 weeks.

Special Considerations

- Administer ascorbic acid orally or by slow I.V. infusion, as indicated. Avoid moving the patient unnecessarily to avoid irritating painful joints and muscles. Encourage the patient to drink orange juice.
- Explain the importance of supplemental ascorbic acid. Counsel the patient and family about good dietary sources of vitamin C.

- Advise against taking too much vitamin C. Explain that excessive doses of ascorbic acid may cause nausea, diarrhea, and renal calculi formation and may also interfere with anticoagulant therapy.

PREVENTION *Patients unable or unwilling to consume foods rich in vitamin C or those facing surgery should take daily supplements of ascorbic acid. The recommended daily allowance is 75 to 90 mg/day. Vitamin C supplementation may also prevent this deficiency in recently weaned infants or those drinking formula not fortified with vitamin C.*

VITAMIN D DEFICIENCY

Vitamin D deficiency, commonly called *rickets*, causes failure of normal bone calcification, which occurs through several mechanisms: decreased calcium and phosphorus (the major components of bone) from the intestines, increased excretion of calcium from renal tubules, and increased parathyroid secretion resulting in increased release of calcium from the bone. The deficiency results in rickets in infants and young children and osteomalacia in adults. With treatment, the prognosis is good. However, in rickets, bone deformities usually persist, whereas in osteomalacia, such deformities may disappear.

Causes and Incidence

Vitamin D deficiency results from inadequate dietary intake of preformed vitamin D, malabsorption of vitamin D, or too little exposure to sunlight.

Once a common childhood disease, rickets is now rare in the United States but occasionally appears in breast-fed infants who don't receive a vitamin D supplement or in infants receiving a formula with a nonfortified milk base. This deficiency may also occur in overcrowded urban areas in which smog limits sunlight penetration. Incidence is highest in black children who, because of their skin color, absorb less sunlight. (Solar ultraviolet rays irradiate 7-dehydrocholesterol, a precursor of vitamin D, to form calciferol.)

Osteomalacia, also uncommon in the United States, is most prevalent in Asia, among young multiparas who eat a cereal diet and have minimal exposure to sunlight. Other causes include:

- vitamin D-resistant rickets (refractory rickets, familial hypophosphatemia) from an inherited impairment of renal tubular reabsorption of phosphate (from vitamin D insensitivity)
- conditions that lower absorption of fat-soluble vitamin D, such as chronic pancreatitis, celiac disease, Crohn disease, cystic fibrosis, gastric or small-bowel resections, fistulas, colitis, and biliary obstruction
- hepatic or renal disease, which interferes with the formation of hydroxylated calciferol, necessary to initiate the formation of a calcium-binding protein in intestinal absorption sites
- malfunctioning parathyroid gland (decreased secretion of parathyroid hormone [PTH]), which contributes to calcium deficiency (normally, vitamin D controls calcium and phosphorus absorption through the intestine) and interferes with activation of vitamin D in the kidneys

Pathophysiology

Inadequate circulation of 25(OH)D is associated with elevated PTH; this condition is called secondary hyperparathyroidism. The rise in PTH may result in increased mobilization of calcium from the bone, which leads to decreased mineralization of the bone.

Of note, prolonged exposure to the sun does not cause vitamin D toxicity. This is because after

prolonged UVB radiation exposure, the vitamin D made in the skin is further degraded to the inactive vitamin D metabolites tachysterol and lumisterol.

Complications

- ◆ Chronic skeletal pain
- ◆ Skeletal deformities
- ◆ Skeletal fractures

Signs and Symptoms

Early indications of vitamin D deficiency are profuse sweating, restlessness, and irritability. Chronic deficiency induces numerous bone malformations due to softening of the bones: bowlegs, knock-knees, rachitic rosary (beading of ends of ribs), enlargement of wrists and ankles, pigeon breast, delayed closing of the fontanels, softening of the skull, and bulging of the forehead. (See *Recognizing bowlegs*.)

Recognizing bowlegs

This infant with rickets shows characteristic bowing of the legs.

Other rachitic features are poorly developed muscles (potbelly) and infantile tetany. Bone deformities may cause difficulty in walking and in climbing stairs, spontaneous multiple fractures, and lower back and leg pain.

Diagnosis

Physical examination, dietary history, and laboratory tests establish the diagnosis. Test results

that suggest vitamin D deficiency include plasma calcium serum levels less than 7.5 mg/dL, serum inorganic phosphorus levels less than 3 mg/dL, serum citrate levels less than 2.5 mg/dL, and alkaline phosphatase levels less than 4 Bodansky U/dL.

℞ CONFIRMING DIAGNOSIS *X-rays confirm the diagnosis by showing characteristic bone deformities and abnormalities such as Looser zones (pseudofractures).*

Treatment

For osteomalacia and rickets—except when caused by malabsorption—treatment consists of oral doses of vitamin D or sources such as fish, liver, and processed milk. Exposure to sunlight is encouraged. For rickets refractory to vitamin D or in rickets accompanied by hepatic or renal disease, treatment includes 25-hydroxycholecalciferol, 1,25-dihydroxycholecalciferol, or a synthetic analog of active vitamin D. Replacement of deficient calcium and phosphorus also helps to eliminate most symptoms of rickets. Positioning or bracing may be used to reduce or prevent deformities; some skeletal deformities may require corrective surgery.

Special Considerations

- Obtain a dietary history to assess the patient's current vitamin D intake. Encourage the patient to eat foods high in vitamin D—fortified milk, fish liver oils, herring, liver, and egg yolks— and get sufficient sun exposure. If deficiency is due to socioeconomic conditions, refer the patient to appropriate community agencies.
- If the patient must take vitamin D for a prolonged period, tell the patient to watch for signs of vitamin D toxicity (headache, nausea, constipation and, after prolonged use, renal calculi).

PREVENTION

- *Administer supplementary aqueous preparations of vitamin D for chronic fat malabsorption, hydroxylated cholecalciferol for refractory rickets, and supplemental vitamin D for breast-fed infants.*
- *Consider genetic counseling for a patient with a family history of inherited disorders that can cause rickets.*

VITAMIN E DEFICIENCY

Vitamin E (tocopherol) appears to act primarily as an antioxidant, preventing intracellular oxidation of polyunsaturated fatty acids and other lipids. It protects body tissue from damage caused by unstable substances called *free radicals*, which can harm cells, tissues, and organs and are believed to be one of the causes of aging's degenerative process. Vitamin E is also important in the formation of RBCs and helps the body to use vitamin K. Vitamin E deficiency usually manifests as hemolytic anemia in low–birth-weight or premature neonates. With treatment, prognosis is good.

Causes and Incidence

Vitamin E deficiency in infants usually results from consuming formulas high in polyunsaturated fatty acids that are fortified with iron but not vitamin E. Such formulas increase the need for antioxidant vitamin E because the iron supplement catalyzes the oxidation of RBC lipids. A neonate has low tissue concentrations of vitamin E to begin with because only a small amount

passes through the placenta; the mother retains most of it. Because vitamin E is a fat-soluble vitamin, deficiency develops in conditions associated with fat malabsorption, such as kwashiorkor, celiac disease, or cystic fibrosis. These conditions may induce megaloblastic or hemolytic anemia and creatinuria, all of which are reversible with vitamin E administration.

Vitamin E deficiency is uncommon in adults but is possible in people whose diets are high in polyunsaturated fatty acids, which increase vitamin E requirements, and in people with vitamin E malabsorption, which impairs RBC survival.

Complication

- Hemolytic anemia

Signs and Symptoms

Vitamin E deficiency is difficult to recognize, but its early symptoms include edema and skin lesions in infants and muscle weakness or intermittent claudication in adults. In premature neonates, vitamin E deficiency produces hemolytic anemia, thrombocythemia, and erythematous papular skin eruption, followed by desquamation.

Diagnosis

CONFIRMING DIAGNOSIS *Dietary and medical histories suggest vitamin E deficiency. Serum alpha-tocopherol levels below 0.5 mg/dL in adults and below 0.2 mg/dL in infants confirm it. Creatinuria, increased creatine kinase levels, hemolytic anemia, and an elevated platelet count generally support the diagnosis.*

Treatment

Replacement of vitamin E with a water-soluble supplement, either oral or parenteral, is the only appropriate treatment.

Special Considerations

- As indicated, prevent deficiency by providing vitamin E supplements for low–birth-weight neonates receiving formulas not fortified with vitamin E and for adults with vitamin E malabsorption. Many commercial multivitamin supplements are easily absorbed by patients with vitamin E malabsorption.
- If vitamin E deficiency is related to socioeconomic conditions, refer the patient to appropriate community agencies.

PREVENTION

- *Inform new mothers who plan to breast-feed that human milk provides adequate vitamin E.*
- *Encourage adult patients to eat foods high in vitamin E; good sources include vegetable oils (corn, safflower, soybean, cottonseed); whole grains; dark green, leafy vegetables; nuts; and legumes. Tell them that heavy consumption of polyunsaturated fatty acids increases the need for vitamin E.*

VITAMIN K DEFICIENCY

Deficiency of vitamin K, an element necessary for formation of prothrombin and other clotting factors in the liver, produces abnormal bleeding. If the deficiency is corrected, the prognosis is excellent.

Causes and Incidence

Vitamin K deficiency is common among neonates in the first few days postpartum due to poor placental transfer of vitamin K and inadequate production of vitamin K-producing intestinal flora. Its other causes include prolonged use of drugs, such as the anticoagulant warfarin and antibiotics that destroy normal intestinal bacteria; decreased flow of bile to the small intestine from obstruction of the bile duct or bile fistula; malabsorption of vitamin K due to sprue, pellagra, bowel resection, ileitis, or ulcerative colitis; chronic hepatic disease, with impaired response of hepatic ribosomes to vitamin K; and cystic fibrosis, with fat malabsorption. Vitamin K deficiency seldom results from insufficient dietary intake of this vitamin.

Pathophysiology

Vitamin K is necessary for the formation of prothrombin and other blood-clotting factors in the liver, and it also plays a role in bone metabolism. A form of the vitamin is produced by bacteria in the colon and can be utilized to some degree. Vitamin K deficiency causes impaired clotting of the blood and internal bleeding, even without injury.

Complications

- Hemorrhagic disease
- Osteoporosis

Signs and Symptoms

The cardinal sign of vitamin K deficiency is an abnormal bleeding tendency, accompanied by prolonged prothrombin time (PT); these signs disappear with vitamin K administration. Without treatment, bleeding may be severe and, possibly, fatal.

Diagnosis

CONFIRMING DIAGNOSIS *A PT that's 25% longer than the normal range of 10 to 20 seconds, measured by the Quick method, confirms the diagnosis of vitamin K deficiency after other causes of prolonged PT (such as anticoagulant therapy or hepatic disease) have been ruled out. The international normalized ratio (normal value, 0.8 to 1.2) is the more common method of assessing PT adequacy.*

Repetition of testing in 24 hours (and regularly during treatment) monitors the therapy's effectiveness.

Treatment

Administration of vitamin K I.V. or I.M. corrects abnormal bleeding tendencies.

Special Considerations

PREVENTION

- *Administer vitamin K to neonates and patients with fat malabsorption or with prolonged diarrhea from colitis, ileitis, or long-term antibiotic drug therapy.*
- *If the deficiency has a dietary cause, help the patient and family plan a diet that includes important sources of vitamin K, such as cauliflower, tomatoes, cheese, egg yolks, liver, and green, leafy vegetables.*
- *Warn against self-medication with or overuse of antibiotics, because these drugs destroy the intestinal bacteria needed to generate significant amounts of vitamin K.*

HYPERVITAMINOSES A AND D

Hypervitaminosis A is excessive accumulation of vitamin A; hypervitaminosis D, of vitamin D. Although these are toxic conditions, they usually respond well to treatment. They're most prevalent in infants and children, usually as a result of accidental or misguided overdosage by parents. A related, benign condition called *hypercarotenemia* results from excessive consumption of carotene, a chemical precursor of vitamin A.

Causes and Incidence

Vitamins A and D are fat-soluble vitamins that accumulate in the body because they aren't dissolved and excreted in the urine. (See *Important facts about vitamins A and D.*) In most cases, hypervitaminoses A and D result from ingestion of excessive amounts of supplemental vitamin preparations. A single dose of more than 1 million units of vitamin A can cause acute toxicity; daily doses of 15,000 to 25,000 U taken over weeks or months have proven toxic in infants and children. For the same dose to produce toxicity in adults, ingestion over years is necessary. Doses of 100,000 IU of vitamin D daily for several months can cause toxicity in adults. Individuals who are at risk include those with hyperparathyroidism, kidney disease, sarcoidosis, tuberculosis, or histoplasmosis.

Important facts about vitamins A and D

This table illustrates good sources of vitamins A and D, their recommended daily allowances, and the actions they produce.

Vitamin	Sources	Recommended dietary allowance	Action
Vitamin A	Carrots; sweet potatoes; dark green, leafy vegetables; butter; margarine; liver; egg yolk	Ages 1 to 13: 1,000 to 2,000 IU Ages ≥14: 2,300 to 3,000 IU Lactating women: 4,000 to 4,300 IU	Produces retinal pigment and maintains epithelial tissue
Vitamin D	Ultraviolet light; fortified foods (especially milk)	600 IU daily	Promotes absorption and regulates metabolism of calcium and phosphorus

Pathophysiology

Vitamin A—The bioavailability of retinol is generally more than 80%, whereas the

bioavailability and bioconversion of carotenes (i.e., provitamin A) are lower. These may be affected by species, molecular linkage, amount of carotene, nutritional status, genetic factors, and other interactions.

While in general the body absorbs retinoids and vitamin A very efficiently, it lacks the mechanisms to destroy excessive loads. Thus, the possibility of toxicity exists unless intake is carefully regulated. It has been suggested that earlier estimates of daily human requirements of vitamin A be revised downward.

Vitamin D—The acute toxic dose for vitamin D has not been established. The chronic toxic dose is more than 50,000 IU/day in adults. In infants younger than 6 months, 1,000 IU/day may be considered unsafe. However, a wide variance in potential toxicity exists for vitamin D.

PEDIATRIC TIP *In infants, giving 40,000 IU daily of vitamin D can cause toxicity in 1 to 4 months*.

Hypervitaminosis A may occur in patients receiving pharmacologic doses of vitamin A for dermatologic disorders. Hypervitaminosis D may occur in patients receiving high doses of the vitamin as treatment for hypoparathyroidism, rickets, and the osteodystrophy of chronic renal failure, and in infants who consume fortified milk and cereals plus a vitamin supplement. Concentrations of vitamin A in common foods are generally too low to pose a danger of excessive intake. However, hypercarotenemia results from excessive consumption of vegetables high in carotene (a protovitamin that the body converts into vitamin A), such as carrots, sweet potatoes, and dark green, leafy vegetables.

Complications

- Liver damage
- Osteoporosis
- Excess calcium buildup (which could cause kidney damage)

Signs and Symptoms

Chronic hypervitaminosis A produces anorexia, irritability, headache, hair loss, malaise, itching, vertigo, bone pain, bone fragility, and dry, peeling skin. It may also cause hepatosplenomegaly and emotional lability. Acute toxicity may also produce transient hydrocephalus and vomiting. (Hypercarotenemia produces yellow or orange skin coloration.)

Hypervitaminosis D causes anorexia, headache, nausea, vomiting, weight loss, polyuria, and polydipsia. Because vitamin D promotes calcium absorption, severe toxicity can lead to hypercalcemia, including calcification of soft tissues, as in the heart, aorta, and renal tubules. Lethargy, confusion, and coma may accompany severe hypercalcemia.

Diagnosis

A thorough patient history suggests hypervitaminosis A.

CONFIRMING DIAGNOSIS *An elevated serum vitamin A level (over 90 μg/dL) confirms hypervitaminosis A.*

Patient history and an elevated serum calcium level (over 10.5 μg/dL) suggest hypervitaminosis D.

Rx **CONFIRMING DIAGNOSIS** *An elevated serum vitamin D level confirms hypervitaminosis D.*

In children, X-rays showing calcification of tendons, ligaments, and subperiosteal tissues support this diagnosis.

Rx **CONFIRMING DIAGNOSIS** *An elevated serum carotene level (over 250 µg/dL) confirms hypercarotenemia.*

Treatment

Withholding vitamin supplements usually corrects hypervitaminosis A quickly and hypervitaminosis D gradually. Hypercalcemia may persist for weeks or months after the patient stops taking vitamin D. Treatment for severe hypervitaminosis D may include glucocorticoids to control hypercalcemia and prevent renal damage. In the acute stage, diuretics or other emergency measures for severe hypercalcemia may be necessary. Hypercarotenemia responds well to a diet free of high-carotene foods.

Special Considerations

- Keep the patient comfortable, and reassure the patient that symptoms will subside after they stop taking the vitamin.
- Make sure the patient or the parents of a child with these conditions understand that vitamins aren't innocuous. Explain the hazards associated with excessive vitamin intake. Point out that vitamin A and D requirements can easily be met with a diet containing dark green, leafy vegetables; fruits; and fortified milk or milk products.

PREVENTION *Monitor serum vitamin A levels in patients receiving doses above the recommended daily allowance and serum calcium levels in patients receiving pharmacologic doses of vitamin D.*

IODINE DEFICIENCY

Iodine deficiency is the absence of sufficient levels of iodine to satisfy daily metabolic requirements. Because the thyroid gland uses most of the body's iodine stores, iodine deficiency is apt to cause hypothyroidism and thyroid gland hypertrophy (endemic goiter). Other effects of deficiency range from dental caries to cretinism in neonates born to iodine-deficient mothers. Iodine deficiency is most common in pregnant or lactating women due to their exaggerated metabolic need for this element. Iodine deficiency responds readily to treatment with iodine supplements.

Causes and Incidence

Iodine deficiency usually results from insufficient intake of dietary sources of iodine, such as iodized table salt, seafood, and dark green, leafy vegetables. (Normal iodine requirements range from 35 µg/day for infants to 150 µg/day for lactating women; the average adult needs 1 µg/kg of body weight.) Iodine deficiency may also result from an increase in metabolic demands during pregnancy, lactation, and adolescence.

Pathophysiology

Dietary iodine is taken up readily through the gut in the form of iodide. From the circulation, it is concentrated in the thyroid gland by means of an energy-dependent sodium iodide symporter. In the follicle cells of the thyroid gland, four atoms of iodine are incorporated into each molecule of thyroxine (T_4) and three atoms into each molecule of triiodothyronine (T_3).

Complications

- Hypothyroidism
- Goiter

Signs and Symptoms

Clinical features of iodine deficiency depend on the degree of hypothyroidism that develops (in addition to the development of a goiter). Mild deficiency may produce only mild, nonspecific symptoms, such as lassitude, fatigue, and loss of motivation. Severe deficiency usually generates the typically overt and unmistakable features of hypothyroidism: bradycardia; decreased pulse pressure and cardiac output; weakness; hoarseness; dry, flaky, inelastic skin; puffy face; thick tongue; delayed relaxation phase in deep tendon reflexes; poor memory; hearing loss; chills; anorexia; and nystagmus. In women, iodine deficiency may also cause menorrhagia and amenorrhea.

Cretinism—hypothyroidism that develops in utero or in early infancy—is characterized by failure to thrive, neonatal jaundice, and hypothermia. By age 3 to 6 months, the infant may display spastic diplegia and signs and symptoms similar to those seen in infants with Down syndrome.

Diagnosis

CONFIRMING DIAGNOSIS *Abnormal laboratory test results include low thyroxine (T_4) levels with high radioactive iodine (^{131}I) uptake, low 24-hour urine iodine levels, and high thyroid-stimulating hormone levels. Radioiodine uptake test traces ^{131}I in the thyroid 24 hours after administration; triiodothyronine-resin or T_4-resin uptake test shows values 25% below normal.*

Treatment

Severe iodine deficiency requires administration of iodine supplements (potassium iodide [SSKI]). Mild deficiency may be corrected by increasing iodine intake through the use of iodized table salt and consumption of iodine-rich foods (seafood and green, leafy vegetables).

Special Considerations

- Administer SSKI preparation in milk or juice to reduce gastric irritation and mask its metallic taste. To prevent tooth discoloration, tell the patient to drink the solution through a straw. Store the solution in a light-resistant container.

PREVENTION

- *Recommend the use of iodized salt and consumption of iodine-rich foods for high-risk patients —especially adolescents and pregnant or lactating women.*
- *Advise pregnant women that severe iodine deficiency may produce cretinism in neonates, and*

instruct them to watch for early signs of iodine deficiency, such as fatigue, lassitude, weakness, and decreased mental function.

ZINC DEFICIENCY

Zinc, an essential trace element that's present in the bones, teeth, hair, skin, testes, liver, and muscles, is also a vital component of many enzymes. The prognosis is good with correction of the deficiency.

Causes and Incidence

Zinc deficiency usually results from excessive intake of foods (containing iron, calcium, vitamin D, and the fiber and phytates in cereals) that bind zinc to form insoluble chelates that prevent its absorption. Occasionally, it results from blood loss due to parasitism and low intake of foods containing zinc. Alcohol and corticosteroids increase renal excretion of zinc.

Zinc deficiency is most common in people from underdeveloped countries, especially in the Middle East. Children are most susceptible to this deficiency during periods of rapid growth.

Pathophysiology

Zinc promotes synthesis of deoxyribonucleic acid, ribonucleic acid and, ultimately, protein, and maintains normal blood concentrations of vitamin A by mobilizing it from the liver.

Complications

- Mental lethargy
- Decreased wound healing
- Impaired immune function

Signs and Symptoms

Zinc deficiency produces hepatosplenomegaly, sparse hair growth, soft and misshapen nails, poor wound healing, anorexia, hypogeusesthesia (decreased taste acuity), dysgeusia (unpleasant taste), hyposmia (decreased odor acuity), dysosmia (unpleasant odor in nasopharynx), severe iron deficiency anemia, bone deformities and, when chronic, hypogonadism, dwarfism, and hyperpigmentation.

Diagnosis

℞ **CONFIRMING DIAGNOSIS** *Fasting serum zinc levels below 70 µg/dL confirm zinc deficiency and indicate altered phosphate metabolism, imbalance between aerobic and anaerobic metabolism, and decreased pancreatic enzyme levels.*

Treatment

Treatment consists of correcting the deficiency's underlying cause and administering zinc supplements, as necessary.

Special Considerations

- Advise the patient to take zinc supplements with milk or meals to prevent gastric distress and vomiting.

Encourage a balanced diet that includes seafood, oatmeal, bran, meat, eggs, nuts, and dry yeast and the correct use of calcium and iron supplements.

OBESITY

Obesity is an excess of body fat, generally 20% above ideal body weight. The prognosis for correction of obesity is poor: Fewer than 30% of patients succeed in losing 20 lb (9 kg), and only half of these maintain the loss over a prolonged period.

Causes and Incidence

Obesity results from excessive calorie intake and inadequate expenditure of energy. Rates of obesity are climbing, and the percentage of children and adolescents who are obese has doubled in the past 20 years.

Pathophysiology

Theories to explain this condition include hypothalamic dysfunction of hunger and satiety centers, genetic predisposition, abnormal absorption of nutrients, and impaired action of GI and growth hormones and of hormonal regulators such as insulin. An inverse relationship between socioeconomic status and the prevalence of obesity has been documented, especially in women. Obesity in parents increases the probability of obesity in children, from genetic or environmental factors, such as activity levels and learned patterns of eating. Psychological factors, such as stress or emotional eating, may also contribute to obesity.

Complications

- Respiratory difficulties
- Hypertension
- Cardiovascular disease
- Diabetes mellitus
- Renal disease
- Gallbladder disease
- Psychosocial difficulties
- Premature death

Signs and Symptoms

Obesity is a problem of too much weight typically resulting in a body mass index (BMI) of 30 or higher. (See *Diagnostic aids.*)

Diagnostic Aids

Weight categories, overweight and obesity, are determined by using a person's height and weight to calculate the BMI. *Overweight* is defined as a BMI between 25.0 and 29.9. *Obesity* is defined as a BMI of 30 or higher. Measurement of the thickness of subcutaneous fat folds with calipers provides an approximation of total body fat. Although this measurement is reliable and isn't subject to daily fluctuations, it has little meaning for the patient in monitoring subsequent weight loss.

Treatment

Successful management of obesity must decrease the patient's daily calorie intake while increasing their activity level. Effective treatment must be based on a balanced, low-calorie diet that eliminates foods high in fat or sugar. Lifelong maintenance of these improved eating and exercise patterns is necessary to achieve long-term benefits.

The popular low-carbohydrate diets offer no long-term advantage; rapid early weight reduction is due to loss of water, not fat. These and other crash or fad diets have the overwhelming drawback that they don't teach the patient long-term modification of eating patterns and often lead to the "yo-yo syndrome"—episodes of repeated weight loss followed by weight gain. This can be more detrimental than the obesity itself because of the severe stress it can place on the body.

Total fasting is an effective method of rapid weight reduction but requires close monitoring and supervision to minimize risks of ketonemia, electrolyte imbalance, hypotension, and loss of lean body mass. Prolonged fasting and very-low-calorie diets have been associated with sudden death, possibly resulting from cardiac arrhythmias caused by electrolyte abnormalities. These methods also neglect patient re-education, which is necessary for long-term weight maintenance. The best way to lose weight is to do so slowly, losing 1 to 2 lb/week.

Treatment may also include behavior modification techniques, which promote fundamental changes in eating habits and activity patterns.

Food and Drug Administration (FDA)-approved medications for chronic weight loss include Alli (orlistat), Qsymia (phentermine and topiramate), Belviq (lorcaserin), Contrave (naltrexone/bupropion), and Saxenda (liraglutide). These drugs promote weight loss by decreasing the absorption of dietary fat. They need to be combined with healthy eating and physical activity to be most effective.

Obesity may be treated surgically with restriction or malabsorptive procedures. Those with a BMI greater than 40 or with a BMI between 35 and 39.9 along with a weight-related health problem may qualify for weight-loss surgery. Vertical banded gastroplasty, gastric banding, and the sleeve procedure represent restrictive surgical procedures that aid in weight loss by decreasing the volume of food that the stomach can accommodate. Gastric bypass with a Roux-en-Y procedure produces weight loss by both restricting stomach capacity and inducing malabsorption; food is rerouted to bypass part of the small intestine. Nutrition counseling before and after these procedures is recommended to enhance safe weight loss, educate the patient about proper diet advancement, and monitor for nutritional deficiencies. Psychological and social support are also beneficial before and after surgery.

Special Considerations

- Obtain an accurate diet history to identify the patient's eating patterns and the importance of food to their lifestyle. Ask the patient to keep a careful record of what, where, and when they eat to help identify situations that normally provoke overeating.
- Explain the prescribed diet carefully, and encourage compliance to improve health status.
- To increase calorie expenditure, promote increased physical activity, including an exercise program. Recommend varying activity levels according to the patient's general condition and cardiovascular status.
- Teach the grossly obese patient the importance of good skin care to prevent breakdown in moist skin folds. Recommend the regular use of powder to keep skin dry.

PREVENTION

- *Teach parents to avoid overfeeding their infants and to familiarize themselves with actual nutritional needs and optimum growth rates. Discourage parents from using food to reward or console their children, from emphasizing the importance of "clean plates," and from allowing eating to prevent hunger rather than to satisfy it.*
- *Encourage physical activity and exercise, especially in children and young adults, to establish lifelong patterns. Suggest low-calorie snacks such as raw vegetables.*

PROTEIN-CALORIE MALNUTRITION

One of the most prevalent and serious depletion disorders, protein-calorie malnutrition (PCM) occurs as marasmus (protein-calorie deficiency), characterized by growth failure and wasting, and as kwashiorkor (protein deficiency), characterized by tissue edema and damage. Both forms vary from mild to severe and may be fatal, depending on the accompanying stress (particularly sepsis or injury) and duration of deprivation. PCM increases the risk of death from pneumonia, chickenpox, or measles.

Causes and Incidence

Both kwashiorkor (edematous PCM) and marasmus (nonedematous PCM) are common in underdeveloped countries and in areas in which dietary amino acid content is insufficient to satisfy growth requirements. Kwashiorkor typically occurs at about age 1, after infants are weaned from breast milk to a protein-deficient diet of starchy gruels or sugar water, but it can develop at any time during the formative years. Marasmus affects infants ages 6 to 18 months as a result of breast-feeding failure, or a debilitating condition such as chronic diarrhea.

In industrialized countries, PCM may occur secondary to chronic metabolic disease that decreases protein and calorie intake or absorption, or trauma that increases protein and calorie requirements.

ELDER TIP In the United States, PCM is estimated to occur to some extent in 50% of elderly people in nursing homes.

Those who aren't allowed anything by mouth for an extended period are at high risk of developing PCM. Conditions that increase protein-calorie requirements include severe burns and injuries, systemic infections, and cancer (accounts for the largest group of hospitalized patients with PCM). Conditions that cause defective utilization of nutrients include malabsorption syndrome, short-bowel syndrome, and Crohn disease.

Pathophysiology

Marasmus is an insufficient energy intake to match the body's requirements. As a result, the body draws on its own stores, resulting in emaciation. In kwashiorkor, adequate carbohydrate consumption and decreased protein intake lead to decreased synthesis of visceral proteins. The resulting hypoalbuminemia contributes to extravascular fluid accumulation. Impaired synthesis of B-lipoprotein produces a fatty liver.

Protein-energy malnutrition also involves an inadequate intake of many essential nutrients.

Complications

- Mental and physical disabilities
- Coma
- Shock

Signs and Symptoms

Children with chronic PCM are small for their chronological age and tend to be physically inactive, mentally apathetic, and susceptible to frequent infections. Anorexia and diarrhea are common.

In acute PCM, children are small, gaunt, and emaciated, with no adipose tissue. Skin is dry and "baggy," and hair is sparse and dull brown or reddish-yellow. Temperature is low; pulse rate and respirations are slowed. Such children are weak, irritable, and usually hungry, although they may have anorexia, with nausea and vomiting.

Unlike marasmus, chronic kwashiorkor allows the patient to grow in height, but adipose tissue diminishes as fat metabolizes to meet energy demands. Edema often masks severe muscle wasting; dry, peeling skin and hepatomegaly are common. Patients with secondary PCM show signs similar to marasmus, primarily loss of adipose tissue and lean body mass, lethargy, and edema. Severe secondary PCM may cause loss of immunocompetence.

Diagnosis

℞ **CONFIRMING DIAGNOSIS** *Clinical appearance, dietary history, and anthropometry confirm PCM. If the patient doesn't suffer from fluid retention, weight change over time is the best index of nutritional status.*

The following factors support the diagnosis:

- height and weight less than 80% of standard for the patient's age and sex, and below-normal arm circumference and triceps skinfold
- serum albumin level less than 2.8 g/dL (normal: 3.3 to 4.3 g/dL)
- urinary creatinine (24-hour) level used to show lean body mass status by relating creatinine excretion to height and ideal body weight, to yield CHI.

Treatment

The aim of treatment is to provide sufficient proteins, calories, and other nutrients for nutritional rehabilitation and maintenance. When treating severe PCM, restoring fluid and electrolyte balance parentally is the initial concern. Nutrition provision should not be increased until laboratory values, such as electrolyte level, stabilize. A patient who shows normal absorption may receive enteral nutrition after anorexia has subsided. When possible, the preferred treatment is oral feeding. Foods are introduced slowly due to the risk of refeeding syndrome. Carbohydrates are given first to supply energy, and then high-quality protein foods, especially milk, and protein-calorie supplements are given. A patient who's unwilling or unable to eat may require supplementary feedings through a nasogastric (NG) tube or total parenteral nutrition (TPN), which is given through a central venous catheter because of its higher osmolality. Peripheral parenteral nutrition, which has a lower osmolality than TPN and can be given through a peripheral I.V. line, is an alternative to TPN, but it's given less commonly. Accompanying infection must also be treated, preferably with antibiotics that don't inhibit protein synthesis. Cautious realimentation is essential to prevent complications from overloading the compromised metabolic system.

Special Considerations

- Encourage the patient with PCM to consume as much nutritious food and beverage as

possible. (It's often helpful to "cheer the patient on" as he or she eats.) Assist the patient with eating if necessary. Cooperate closely with the dietitian to monitor intake, and provide acceptable meals and snacks.

◆ If TPN is necessary, observe strict sterile technique when handling catheters, tubes, and solutions and during dressing changes.

PREVENTION

◆ *Watch for PCM in patients who have been hospitalized for a prolonged period, have had no oral intake for several days, or have cachectic disease.*

◆ *To help eradicate PCM in developing countries, encourage prolonged breast-feeding, educate mothers about their children's needs, and provide supplementary foods, as needed.*

ELDER TIP If the older patient is anorexic, consider asking family members and other visitors to bring in special foods from home that may improve the patient's appetite. In addition, encouraging the family to collaborate on feeding a dependent patient can help promote recovery, enhance feelings of well-being, and stimulate the patient to eat more.

Metabolic Disorders

GALACTOSEMIA

Galactosemia is any disorder of galactose metabolism. It produces symptoms ranging from cataracts and liver damage to mental retardation and occurs in two forms: classic galactosemia and galactokinase deficiency galactosemia. Although a galactose-free diet relieves most symptoms, galactosemia-induced mental impairment is irreversible; some residual vision impairment may also persist.

Causes and Incidence

Both forms of galactosemia are inherited as autosomal recessive defects and occur in about 1 in 60,000 births in the United States. Up to 1.25% of the population is heterozygous for the classic galactosemia gene. Classic galactosemia results from a defect in the enzyme galactose-1-phosphate uridyl transferase. (See *Metabolic pathway in galactosemia*.) Galactokinase deficiency galactosemia, the rarer form of this disorder, stems from a deficiency of the enzyme galactokinase. In both forms of galactosemia, the inability to normally metabolize the sugar galactose (which is mainly formed by digestion of the disaccharide lactose that's present in milk) causes galactose accumulation.

Glucose

Pathophysiology

An elevated blood galactose concentration is the result of altered metabolism of galactose due to a genetic deficiency in enzyme activity or secondary hypergalactosemia due to liver disease (congenital hepatitis, patent ductus venosus, congenital hepatic arteriovenous malformation).

Complications

- Ovarian dysfunction
- Cataracts

- Abnormal speech
- Cognitive impairment
- Motor delay
- Growth retardation

Signs and Symptoms

In children who are homozygous for the classic galactosemia gene, signs are evident at birth or begin within a few days after milk ingestion, and include failure to thrive, vomiting, and diarrhea. Other clinical effects include liver damage (which causes jaundice, hepatomegaly, cirrhosis, and ascites), splenomegaly, galactosuria, proteinuria, and aminoaciduria. Cataracts may also be present at birth or develop later. Pseudotumor cerebri may occur.

Continued ingestion of galactose- or lactose-containing foods may cause mental retardation, malnourishment, progressive hepatic failure, and death—from the still-unknown process of galactose metabolites accumulating in body tissues. Although treatment may prevent mental impairment, galactosemia can produce a short attention span, difficulty with spatial and mathematical relationships, and apathetic, withdrawn behavior. Cataracts may be the only sign of galactokinase deficiency, resulting from the accumulation of galactitol, a metabolic by-product of galactose, in the lens.

Diagnosis

CONFIRMING DIAGNOSIS *Deficiency of the enzyme galactose-1-phosphate uridyl transferase in RBCs confirms classic galactosemia; decreased RBC levels of galactokinase confirm galactokinase deficiency. Prenatal diagnosis may be made by direct measurement of galactose-1-phosphate uridyl transferase.*

Related laboratory results include increased galactose levels in blood (normal value in children is <20 mg/dL) and urine (must use galactose oxidase to avoid confusion with other reducing sugars). Galactose measurements in blood and urine must be interpreted carefully because some children who consume large amounts of milk have elevated plasma galactose concentrations and galactosuria but aren't galactosemic. Also, neonates excrete galactose in their urine for about a week after birth; premature infants, even longer.

Other test results include:

- liver biopsy—typical acinar formation
- liver enzymes (aspartate aminotransferase, alanine aminotransferase levels)—elevated
- urinalysis—albumin in urine
- ophthalmoscopy—punctate lesions in the fetal lens nucleus (with treatment, cataracts regress)
- amniocentesis—prenatal diagnosis of galactosemia (recommended for heterozygous and homozygous parents)

Treatment

Elimination of galactose and lactose from the diet causes most effects to subside. The infant is fed soy formula, meat-base formula, protein hydrolysate formula, or another lactose-free formula. The infant gains weight; liver anomalies, nausea, vomiting, galactosemia, proteinuria, and aminoaciduria disappear; and cataracts regress. As the child grows, a balanced, galactose-free diet must be maintained. Hormone replacement is sometimes necessary for puberty. A

pregnant woman who's heterozygous or homozygous for galactosemia should also follow a galactose-restricted diet. Such a diet supports normal growth and development and may delay symptoms in the neonate.

Special Considerations

- To eliminate galactose and lactose from an infant's diet, replace cow's milk formula or breast milk with a meat-base or soybean formula.
- Teach the parents about dietary restrictions and stress the importance of compliance. (See *Diet for galactosemia*.) Warn them to read medication labels carefully and avoid giving any medication that contains lactose fillers.

Diet for galactosemia

A patient with galactosemia must follow a lactose-free diet. It's important for the patient to carefully read food labels to avoid milk and milk products, including dry milk products. The patient may eat these foods:
- fish and animal products (except brains and mussels)
- fresh fruits and vegetables (except peas and lima beans)
- only bread and rolls made from cracked wheat.

He should avoid these foods:
- dairy products
- puddings, cookies, cakes, pies
- food coloring
- instant potatoes
- canned and frozen foods (if lactose is listed as an ingredient)

- If the child has a learning disability, help parents secure educational assistance. Refer parents who want to have other children for genetic counseling. In some states, screening of all neonates for galactosemia is required by law.
- Instruct the parents to contact support groups, such as Parents of Galactosemic Children, for further information and support if appropriate.

GLYCOGEN STORAGE DISEASES

Glycogen storage diseases consist of at least eight distinct errors of metabolism, all inherited, that alter the synthesis or degradation of glycogen, the form in which glucose is stored in the body. Normally, muscle and liver cells store glycogen. Muscle glycogen is used in muscle contraction; liver glycogen can be converted into free glucose, which can then diffuse out of the liver cells to increase blood glucose levels. Glycogen storage diseases manifest as dysfunctions of the liver, heart, or musculoskeletal system. Symptoms vary from mild and easily controlled hypoglycemia to severe organ involvement that may lead to heart failure and respiratory failure.

Causes and Incidence

Almost all glycogen storage diseases (types I through V and type VII) are transmitted as autosomal recessive traits. The transmission mode of type VI is unknown; type VIII may be an

X-linked trait.

Pathophysiology

The most common glycogen storage disease is type I—von Gierke, or hepatorenal glycogen storage disease—which results from a deficiency of the liver enzyme glucose-6-phosphatase. This enzyme converts glucose-6-phosphate into free glucose and is necessary for the release of stored glycogen and glucose into the bloodstream, to relieve hypoglycemia. Infants may die of acidosis before age 2; if they survive past this age, with proper treatment, they may grow normally and live to adulthood, with only minimal hepatomegaly. However, there's a danger of adenomatous liver nodules, which may be premalignant.

Complications

- Heat intolerance
- Easy bruising
- Slowed growth
- Incomplete sexual development
- Hepatic adenomas
- Multiple organ failure

Signs and Symptoms

Primary clinical features of the liver glycogen storage diseases (types I, III, IV, VI, and VIII) are hepatomegaly and rapid onset of hypoglycemia and ketosis when food is withheld. Symptoms of the muscle glycogen storage diseases (types II, V, and VII) include poor muscle tone; type II may result in death from heart failure. (See *Rare forms of glycogen storage disease,* pages 508 and 509.)

Rare forms of glycogen storage disease

Type	Clinical features	Diagnostic test results
II (Pompe)		
Absence of alpha-1,4-glucosidase (acid maltase)	• *Infants:* cardiomegaly, profound hypotonia and, occasionally, endocardial fibroelastosis (usually fatal before age 1 due to cardiac or respiratory failure) • *Some infants and young children:* muscle weakness and wasting, variable organ involvement (slower progression, usually fatal by age 19) • *Adults:* muscle weakness without organomegaly (slowly progressive but not fatal)	• *Muscle biopsy:* increased concentration of glycogen with normal structure; alpha-1,4-glucosidase deficiency • *Electrocardiogram (in infants):* large QRS complexes in all leads; inverted T waves; shortened PR interval • *Electromyography (in adults):* muscle fiber irritability; myotonic discharges • *Amniocentesis:* alpha-1,4-glucosidase deficiency • *Placenta or umbilical cord examination:* alpha-1,4-glucosidase deficiency
III (Cori)		
Absence of debranching enzyme (amylo-1,6-glucosidase) (*Note:* predominant cause of glycogen	• *Young children:* massive hepatomegaly, which may disappear by puberty; growth retardation; moderate splenomegaly;	• *Liver biopsy:* deficient debranching activity; increased glycogen concentration • *Laboratory tests (in children only):*

storage disease in Israel)	hypoglycemia ◆ *Adults:* progressive myopathy ◆ Occasionally, moderate cardiomegaly, cirrhosis, muscle wasting, hypoglycemia	elevated aspartate aminotransferase or alanine aminotransferase levels; increased erythrocyte glycogen levels
IV (Andersen)		
Deficiency of branching enzyme (amylo-1,4-1,6-transglucosidase) (*Note:* extremely rare)	◆ *Infants:* hepatosplenomegaly, ascites, muscle hypotonia; usually fatal before age 2 from progressive cirrhosis	◆ *Liver biopsy:* deficient branching enzyme activity; glycogen molecule has longer outer branches
V (McArdle)		
Deficiency of muscle phosphorylase	◆ *Children:* mild or no symptoms ◆ *Adults:* muscle cramps and pain during strenuous exercise, possibly resulting in myoglobinuria and renal failure ◆ *Older patients:* significant muscle weakness and wasting	◆ *Serum lactate:* no increase in venous levels in sample drawn from extremity after ischemic exercise ◆ *Muscle biopsy:* lack of phosphorylase activity; increased glycogen content
VI (Hers)		
Possible deficiency of hepatic phosphorylase	◆ Mild symptoms (similar to those of type I), requiring no treatment	◆ *Liver biopsy:* decreased phosphorylase b activity, increased glycogen concentration
VII (Tarui)		
Deficiency of muscle phosphofructokinase	◆ Muscle cramps during strenuous exercise, resulting in myoglobinuria and possible renal failure ◆ Reticulocytosis	◆ *Serum lactate:* no increase in venous levels in sample drawn from extremity after ischemic exercise ◆ *Muscle biopsy:* deficient phosphofructokinase; marked rise in glycogen concentration ◆ *Blood studies:* low erythrocyte phosphofructokinase activity; reduced half-life of red blood cells
VIII		
Deficiency of hepatic phosphorylase kinase	◆ Mild hepatomegaly ◆ Mild hypoglycemia	◆ *Liver biopsy:* deficient phosphorylase b kinase activity; increased glycogen concentration ◆ *Blood study:* deficient phosphorylase b kinase in leukocytes

In addition, type I may produce these symptoms:

◆ infants—acidosis, hyperlipidemia, GI bleeding, coma
◆ children—low resistance to infection and, without proper treatment, short stature
◆ adolescents—gouty arthritis and nephropathy; chronic tophaceous gout; bleeding (especially epistaxis); small superficial vessels visible in skin due to impaired platelet function; fat deposits in cheeks, buttocks, and subcutaneous tissues; poor muscle tone; enlarged kidneys; xanthomas over extensor surfaces of arms and legs; steatorrhea; multiple, bilateral, yellow lesions in fundi; and osteoporosis, probably secondary to negative calcium balance. Correct treatment of glycogen storage disease should prevent all of these effects.

Diagnosis

CONFIRMING DIAGNOSIS *Liver biopsy confirms the diagnosis by showing normal glycogen synthetase and phosphorylase enzyme activities but reduced or absent glucose-6-*

phosphatase activity. Glycogen structure is normal but amounts are elevated. Spectroscopy may be used to show abnormal muscle metabolism with the use of magnetic resonance imaging in specialized centers.

- Laboratory studies of plasma demonstrate low glucose levels but high levels of free fatty acids, triglycerides, cholesterol, and uric acid. Serum analysis reveals high pyruvic acid levels and high lactic acid levels. Prenatal diagnoses are available for types II, III, and IV.
- Injection of glucagon or epinephrine increases pyruvic and lactic acid levels but doesn't increase blood glucose levels. Glucose tolerance test curve typically shows depletional hypoglycemia and reduced insulin output. Intrauterine diagnosis is possible.

Treatment

For type I, treatment aims to maintain glucose homeostasis and prevent secondary consequences of hypoglycemia through frequent feedings and constant nocturnal enteral feeding with Polycose or Vivonex. Treatment includes a low-fat diet, with normal amounts of protein and calories; carbohydrates should contain glucose or glucose polymers only. Physically modified cornstarch is also used to prevent hypoglycemia.

Therapy for type III includes frequent feedings (every 3 to 4 hours) and a high-protein diet. Type IV requires a high-protein, high-calorie diet; bed rest; diuretics; sodium restriction; and paracentesis, if necessary, to relieve ascites. Ultimately treat with liver transplant. Types V and VII require no treatment except avoidance of strenuous exercise. No treatment is necessary for types VI and VIII; no effective treatment exists for type II.

Special Considerations

When managing type I disease:

- Advise the patient or parents to include carbohydrate foods containing mainly starch in the diet and to sweeten foods with glucose only.
- Before discharge, teach the patient or family member how to use the enteral feeding equipment, monitor blood glucose levels with glucose reagent strips, and recognize symptoms of hypoglycemia.
- Watch for and report signs of infection (fever, chills, myalgia) and of hepatic encephalopathy (mental confusion, stupor, asterixis, coma) due to increased blood ammonia levels.

When managing other types, do the following.

- *Type II:* Explain test procedures, such as electromyography and electroencephalography (EEG), thoroughly.
- *Type III:* Instruct the patient to eat a high-protein diet (eggs, nuts, fish, meat, poultry, and cheese).
- *Type IV:* Watch for signs of hepatic failure (nausea, vomiting, irregular bowel function, clay-colored stools, right upper quadrant pain, jaundice, dehydration, electrolyte imbalance, edema, and changes in mental status, progressing to coma).

When caring for patients with types II, III, and IV glycogen storage disease, offer the patient and parents reassurance and emotional support. Recommend and arrange for genetic counseling, if appropriate.

- *Types V through VIII:* Care for these patients is minimal. Explain the disorder to the patient

and his/her family, and help them accept the limitations imposed by the patient's particular type of glycogen storage disease.

HYPOGLYCEMIA

Hypoglycemia is an abnormally low glucose level in the bloodstream. It occurs when glucose burns up too rapidly, when the glucose release rate falls behind tissue demands, or when excessive insulin enters the bloodstream. Hypoglycemia is classified as reactive or fasting. *Reactive hypoglycemia* results from the reaction to the disposition of meals or the administration of excessive insulin. *Fasting hypoglycemia* causes discomfort during long periods of abstinence from food, for example, in the early morning before breakfast. Although hypoglycemia is a specific endocrine imbalance, its symptoms are often vague and depend on how quickly the patient's glucose levels drop. If not corrected, severe hypoglycemia may result in coma and irreversible brain damage.

Causes and Incidence

Reactive hypoglycemia may take several forms. In a diabetic patient, it may result from administration of too much insulin or too much oral antidiabetic medication. In a mildly diabetic patient (or one in the early stages of diabetes mellitus), reactive hypoglycemia may result from delayed and excessive insulin production after carbohydrate ingestion. Similarly, a nondiabetic patient may develop reactive hypoglycemia from a sharp increase in insulin output after a meal. Sometimes called *postprandial hypoglycemia*, this type of reactive hypoglycemia usually disappears when the patient eats something sweet. In some patients, reactive hypoglycemia has no known cause (idiopathic reactive) or may result from gastric dumping syndrome and from impaired glucose tolerance.

Hypoglycemia is at least as common in neonates and children as it is in adults and affects 1 out of 1,000 people. Usually, infants develop hypoglycemia because of an increased number of cells per unit of body weight and because of increased demands on stored liver glycogen to support respirations, thermoregulation, and muscular activity. In full-term neonates, hypoglycemia may occur 24 to 72 hours after birth and is usually transient. In neonates who are premature or small for gestational age, the onset of hypoglycemia is much more rapid (it can occur as soon as 6 hours after birth) because of their small, immature livers, which produce much less glycogen. Maternal disorders that can produce hypoglycemia in neonates within 24 hours after birth include diabetes mellitus, toxemia, erythroblastosis, and glycogen storage disease.

Pathophysiology

Fasting hypoglycemia usually results from an excess of insulin or insulin-like substance or from a decrease in counterregulatory hormones. It can be *exogenous*, resulting from external factors such as alcohol or drug ingestion, or *endogenous*, resulting from organic problems.

Endogenous hypoglycemia may result from tumors or liver disease. Insulinomas, small islet cell tumors in the pancreas, secrete excessive amounts of insulin, which inhibit hepatic glucose production. They're generally benign (in 90% of patients). Extrapancreatic tumors, though uncommon, can also cause hypoglycemia by increasing glucose utilization and inhibiting glucose output. Such tumors occur primarily in the mesenchyma, liver, adrenal cortex, GI system, and lymphatic system. They may be benign or malignant. Among nonendocrine causes of fasting hypoglycemia are severe liver diseases, including hepatitis, cancer, cirrhosis, and liver congestion associated with heart failure. All of these conditions reduce the uptake and release of

glycogen from the liver. Some endocrine causes include adrenocortical insufficiency, which contributes to hypoglycemia by reducing the production of cortisol and cortisone needed for gluconeogenesis; and pituitary insufficiency, which reduces corticotropin and growth hormone levels.

Complication

- ◆ Permanent brain damage

Signs and Symptoms

Signs and symptoms of reactive hypoglycemia include fatigue, malaise, nervousness, irritability, trembling, tension, headache, hunger, cold sweats, and rapid heart rate. These same clinical effects usually characterize fasting hypoglycemia. In addition, fasting hypoglycemia may also cause CNS disturbances; for example, blurry or double vision, confusion, motor weakness, hemiplegia, seizures, or coma.

In infants and children, signs and symptoms of hypoglycemia are vague. A neonate's refusal to feed may be the primary clue to underlying hypoglycemia. Associated CNS effects include tremors, twitching, weak or high-pitched cry, sweating, limpness, seizures, and coma.

Diagnosis

A blood glucose monitor or glucose reagent strips provide quick screening methods for determining the blood glucose level. A reading less than 50 mg/dL indicates the need for a venous blood sample. (See *Diagnosing hypoglycemia*, page 512.)

DIFFERENTIAL DIAGNOSIS
DIAGNOSING HYPOGLYCEMIA

THIS FLOWCHART LISTS POSSIBLE DIAGNOSTIC FINDINGS AND INTERPRETATIONS TO ASSIST WITH TREATMENT OF THE PATIENT WITH HYPOGLYCEMIA.

Determine diabetes mellitus status.

Present

Pharmacotherapy as appropriate, nonpharmacotherapy modalities, patient education and self-care measures, appropriate patient follow-up and monitoring

Absent

No evidence of medical illness

Fasting plasma glucose test

< 50 mg/dL

Obtain insulin level

< 6 µIU/mL

Consider tumor; further workup needed.

> 6 µIU/mL

Check C-peptide assay.

> 0.6 ng/L

Consider insulinoma, sulfonylurea use.

< 0.6 ng/L

Exogenous insulin use

Consider autoimmune hypoglycemia, factitious use of insulin.

50 mg/dL

History of extended fast

Typical mixed meal

Documentation of Whipple's triad

Present

Reactive hypoglycemia

Absent

No hypoglycemia

Evidence of medical illness

Consider prior gastric surgery, inherited metabolic disorders, medications, alcohol, growth or cortisol deficiencies, sepsis, end-stage renal or liver disease, non-B-cell tumors, medication-induced hypoglycemia, sulfonamides, insulin, alcohol.

Treat disorder or discontinue medication.

℞ **CONFIRMING DIAGNOSIS** *Laboratory testing confirms the diagnosis by showing decreased blood glucose levels. The following values indicate hypoglycemia:*

◆ *Full-term infants*

- less than 30 mg/dL before feeding
- less than 40 mg/dL after feeding

- *Preterm infants*

  - less than 20 mg/dL before feeding
  - less than 30 mg/dL after feeding

- *Children and adults*

  - less than 40 mg/dL before meal
  - less than 50 mg/dL after meal

In addition, a 5-hour glucose tolerance test may be administered to provoke reactive hypoglycemia. Following a 12-hour fast, laboratory testing to detect plasma insulin and plasma glucose levels may identify fasting hypoglycemia.

Treatment

Effective treatment of reactive hypoglycemia requires dietary modification to help delay glucose absorption and gastric emptying. Usually this includes small, frequent meals; ingestion of complex carbohydrates, fiber, and fat; and avoidance of simple sugars, alcohol, and fruit drinks. The patient may also receive anticholinergic drugs to slow gastric emptying and intestinal motility and to inhibit vagal stimulation of insulin release.

For fasting hypoglycemia, surgery and drug therapy are usually required. In patients with insulinoma, tumor removal is the treatment of choice. Drug therapy may include nondiuretic thiazides such as diazoxide to inhibit insulin secretion; streptozocin; and hormones, such as glucocorticoids and long-acting glycogen.

Therapy for neonates who have hypoglycemia or who are at risk of developing it includes preventive measures. A hypertonic solution of 10% dextrose, calculated at 5 to 10 mL/kg of body weight administered I.V. over 10 minutes and followed by 4 to 8 mg/kg/minute for maintenance, should correct a severe hypoglycemic state in neonates. To reduce the chance of hypoglycemia in high-risk neonates, they should receive feedings (either breast milk or a solution of 5% to 10% glucose and water) as soon after birth as possible.

Special Considerations

- Watch for and report signs of hypoglycemia, such as poor feeding, in high-risk neonates.
- Monitor infusion of hypertonic glucose in the neonate to avoid hyperglycemia, circulatory overload, and cellular dehydration. Terminate glucose solutions gradually to prevent hypoglycemia caused by hyperinsulinemia.
- Explain the purpose and procedure for any diagnostic tests. Collect blood samples at the appropriate times, as ordered.
- Monitor the effects of drug therapy and watch for the development of any adverse effects.
- Teach the patient or family which foods to include in the diet (complex carbohydrates, fiber, fat) and which foods to avoid (simple sugars, alcohol). Refer the patient and family for dietary counseling as appropriate.

HEREDITARY FRUCTOSE INTOLERANCE

Hereditary fructose intolerance is an inability to metabolize fructose. After fructose is eliminated from the diet, symptoms subside within weeks. Older children and adults with hereditary

fructose intolerance have normal intelligence and apparently normal liver and kidney function.

Causes and Incidence

Transmitted as an autosomal recessive trait, hereditary fructose intolerance results from a deficiency in the enzyme fructose-1-phosphate aldolase. The enzyme operates at only 1% to 10% of its normal biological activity, thus preventing rapid uptake of fructose by the liver after ingestion of fruit or foods containing cane sugar.

In some European countries, hereditary fructose intolerance may have an incidence as high as 1 in 20,000 people.

Pathophysiology

Affected individuals are completely asymptomatic until they ingest fructose. Thus, homozygous neonates remain clinically well until confronted with dietary sources of fructose. Although lactose is the carbohydrate base in most infant formulas, some (e.g., soy formulas) contain sucrose, a fructose-glucose disaccharide that may cause symptoms. The biochemistry of hereditary fructose intolerance is complex for two reasons: (1) Three isozymes of aldolase (A, B, C) exist, of which aldolase B is expressed exclusively in the liver, kidney, and intestine; and (2) aldolase B mediates three separate reactions (i.e., cleavage of fructose 1-phosphate [F-1-P]; cleavage of fructose 1,6-diphosphate; and condensation of the triose phosphates, glyceraldehyde phosphate, and dihydroxyacetone phosphate to form fructose 1,6-diphosphate).

In normal cellular conditions, the primary enzymatic activity of aldolase B is to cleave fructose diphosphate, which forms rather than condenses the triose phosphate compounds. Here, the enzyme is central to the glycolytic pathway. Because the reaction is reversible, aldolase B is an essential enzyme in the process of gluconeogenesis (which is, in some respects, a reversal of glycolysis). The absence of the latter function readily explains the clinical hypoglycemia in individuals with hereditary fructose intolerance.

Reduced cleavage of F-1-P leads to its cellular accumulation and fructokinase inhibition, causing free fructose accumulation in the blood. A generally accepted consequence of this sequence is a dramatic change in the ATP-adenosine monophosphate cellular ratio, with a resultant acceleration in production of uric acid. This accounts for the hyperuricemia observed during an acute episode. Competition between urate and lactate for renal tubule excretion accounts for the lactic acidemia.

The cause of severe hepatic dysfunction remains unknown but may be a manifestation of focal cytoplasmic degeneration and cellular fructose toxicity. The cause of renal tubular dysfunction also remains unclear; patients with renal tubular dysfunction primarily present with a proximal tubular acidosis complicated by aminoaciduria, glucosuria, and phosphaturia. Thus, in an infant who is homozygous for fructose 1-aldolase deficiency, fructose ingestion triggers a cascade of biochemical events that result in severe clinical disease.

Complications

- Kidney dysfunction
- Liver dysfunction
- Infants—failure to thrive

Signs and Symptoms

Typically, clinical features of hereditary fructose intolerance appear shortly after dietary

introduction of foods containing fructose or sucrose. Symptoms are more severe in infants than in older people and include hypoglycemia, nausea, vomiting, pallor, excessive sweating, cyanosis, and tremor. In neonates and young children, continuous ingestion of foods containing fructose may result in failure to thrive, hypoglycemia, jaundice, hyperbilirubinemia, ascites, hepatomegaly, vomiting, dehydration, hypophosphatemia, albuminuria, aminoaciduria, seizures, coma, febrile episodes, substernal pain, and anemia.

Diagnosis

A dietary history often suggests hereditary fructose intolerance.

℞ CONFIRMING DIAGNOSIS *A fructose tolerance test (using glucose oxidase or paper chromatography to measure glucose levels) usually confirms the diagnosis. However, liver biopsy showing a deficiency in fructose-1-phosphate aldolase may be necessary for a definitive diagnosis.*

Supportive values may include decreased serum inorganic phosphorus levels. Urine studies may show fructosuria and albuminuria.

Treatment

Treatment of hereditary fructose intolerance consists of exclusion of fructose and sucrose (cane sugar or table sugar) from the diet. Otherwise, treatment is supportive as the patient's progress is monitored.

Special Considerations

- Tell the patient to avoid fruits containing fructose and vegetables containing sucrose (sugar beets, sweet potatoes, and peas), because sucrose is digested to glucose and fructose in the intestine. Fruits containing the least amount of fructose include strawberries, blackberries, blueberries, oranges, and grapefruits; others low in fructose are cherries, pears, bananas, grapes, and apples.
- Refer the patient and family for genetic and dietary counseling as appropriate.

HYPERLIPOPROTEINEMIA

Hyperlipoproteinemia occurs as five distinct metabolic disorders, all of which may be inherited.

Causes and Incidence

This disorder affects lipid transport in serum and produces varied clinical changes, from relatively mild symptoms that can be corrected by dietary management to potentially fatal pancreatitis.

Pathophysiology

Types I and III are transmitted as autosomal recessive traits; types II, IV, and V are transmitted as autosomal dominant traits. (See *Types of hyperlipoproteinemia,* page 515.) About one in five persons with elevated plasma lipid and lipoprotein levels has hyperlipoproteinemia. It's marked by increased plasma concentrations of one or more lipoproteins. Hyperlipoproteinemia may also occur secondary to other conditions, such as diabetes, pancreatitis, hypothyroidism, or renal disease.

Types of hyperlipoproteinemia

Type	Causes and incidence	Diagnostic findings
I		
(Frederickson's hyperlipoproteinemia, fat-induced hyperlipemia, idiopathic familial)	◆ Deficient or abnormal lipoprotein lipase, resulting in decreased or absent post-heparin lipolytic activity ◆ Relatively rare ◆ Present at birth	◆ Chylomicrons (very-low-density lipoprotein [VLDL], low-density lipoprotein [LDL], high-density lipoprotein), in plasma 14 hours or more after last meal ◆ Highly elevated serum chylomicrons and triglyceride levels; slightly elevated serum cholesterol levels ◆ Lower serum lipoprotein lipase levels ◆ Leukocytosis
II		
(familial hyperbetalipoproteinemia, essential familial hypercholesterolemia)	◆ Deficient cell surface receptor that regulates LDL degradation and cholesterol synthesis, resulting in increased levels of plasma LDL over joints and pressure points ◆ Onset between ages 10 and 30	◆ Increased plasma concentrations of LDL ◆ Increased serum LDL and cholesterol levels ◆ Amniocentesis shows increased LDL levels
III		
(familial broad-beta disease, dysbetalipoproteinemia, remnant removal disease, xanthoma tuberosum)	◆ Unknown underlying defect results in deficient conversion of triglyceride-rich VLDL to LDL ◆ Uncommon; usually occurs after age 20 but can occur earlier in men	◆ Abnormal serum betalipoprotein ◆ Elevated cholesterol and triglyceride levels ◆ Slightly elevated glucose tolerance ◆ Hyperuricemia
IV		
(endogenous hypertriglyceridemia, hyperbetalipoproteinemia)	◆ Usually occurs secondary to obesity, alcoholism, diabetes, or emotional disorders ◆ Relatively common, especially in middle-age men	◆ Elevated VLDL levels ◆ Abnormal levels of triglycerides in plasma; variable increase in serum ◆ Normal or slightly elevated serum cholesterol levels ◆ Mildly abnormal glucose tolerance ◆ Family history ◆ Early coronary artery disease
V		
(mixed hypertriglyceridemia, mixed hyperlipidemia)	◆ Defective triglyceride clearance causes pancreatitis; usually secondary to another disorder, such as obesity or nephrosis ◆ Uncommon; onset usually occurs in late adolescence or early adulthood	◆ Chylomicrons in plasma ◆ Elevated plasma VLDL levels ◆ Elevated serum cholesterol and triglyceride levels

Complications

◆ Coronary artery disease
◆ Pancreatitis

Signs and Symptoms

◆ *Type I:* recurrent attacks of severe abdominal pain similar to pancreatitis, usually preceded by fat intake; abdominal spasm, rigidity, or rebound tenderness; hepatosplenomegaly, with liver or spleen tenderness; papular or eruptive xanthomas (pinkish-yellow cutaneous deposits of fat) over pressure points and extensor surfaces; lipemia retinalis (reddish-white retinal

vessels); malaise; anorexia; and fever

◆ *Type II:* tendinous xanthomas (firm masses) on the Achilles tendons and tendons of the hands and feet, tuberous xanthomas, xanthelasma, juvenile corneal arcus (opaque ring surrounding the corneal periphery), accelerated atherosclerosis and premature coronary artery disease, and recurrent polyarthritis and tenosynovitis

◆ *Type III:* peripheral vascular disease manifested by claudication or tuboeruptive xanthomas (soft, inflamed, pedunculated lesions) over the elbows and knees; palmar xanthomas on the hands, particularly the fingertips; premature atherosclerosis

◆ *Type IV:* predisposition to atherosclerosis and early coronary artery disease, exacerbated by excessive calorie intake, obesity, diabetes, and hypertension

◆ *Type V:* abdominal pain (most common), pancreatitis, peripheral neuropathy, eruptive xanthomas on extensor surfaces of the arms and legs, lipemia retinalis, and hepatosplenomegaly

Treatment

The first goal is to identify and treat any underlying problem such as diabetes. If no underlying problem exists, the primary treatment of types II, III, and IV is dietary management, especially restriction of cholesterol intake, possibly supplemented by drug therapy (cholestyramine, fenofibrate, gemfibrozil, atorvastatin, niacin) to lower plasma triglyceride or cholesterol level when diet alone is ineffective.

Type I hyperlipoproteinemia requires long-term weight reduction, with fat intake restricted to less than 20 g/day. A 20- to 40-g/day medium-chain triglyceride diet may be ordered to supplement calorie intake. The patient should also avoid alcoholic beverages, to decrease plasma triglyceride levels. The prognosis is good with treatment; without treatment, death can result from pancreatitis.

For type II, dietary management to restore normal lipid levels and decrease the risk of atherosclerosis includes restriction of cholesterol intake to less than 300 mg/day for adults and less than 150 mg/day for children; triglycerides must be restricted to less than 100 mg/day for children and adults. Diet should also be high in polyunsaturated fats. In familial hypercholesterolemia, nicotinic acid with a bile acid usually normalizes low-density lipoprotein (LDL) levels. For severely affected children, a portacaval shunt is a last resort to reduce plasma cholesterol levels. The prognosis remains poor regardless of treatment; in homozygotes, myocardial infarction usually causes death before age 30.

For type III, dietary management includes restriction of cholesterol intake to less than 300 mg/day; carbohydrates must also be restricted, while polyunsaturated fats are increased. Statins, fibrates, estrogens (in women) and niacin help lower blood lipid levels. Weight reduction is helpful. With strict adherence to prescribed diet, the prognosis is good.

For type IV, weight reduction may normalize blood lipid levels without additional treatment. Long-term dietary management includes restricted cholesterol intake, increased polyunsaturated fats, and avoidance of alcoholic beverages. Fenofibrate, gemfibrozil, and niacin may lower plasma lipid levels. The prognosis remains uncertain, however, because of predisposition to premature coronary artery disease.

The most effective treatment for type V is weight reduction and long-term maintenance of a low-fat diet. Alcoholic beverages must be avoided. Niacin, fenofibrate, gemfibrozil, and a 20- to 40-g/day medium-chain triglyceride diet may prove helpful. The prognosis is uncertain because of the risk of pancreatitis. Increased fat intake may cause recurrent bouts of illness, possibly

leading to pseudocyst formation, hemorrhage, and death.

Special Considerations

Nursing care for hyperlipoproteinemia emphasizes careful monitoring for adverse drug effects and teaching the importance of long-term dietary management.

◆ Administer cholestyramine before meals or before bedtime. This drug must not be given with other medications. (See *Using bile acid sequestrants*.) Watch for adverse effects, such as nausea, vomiting, constipation, steatorrhea, rashes, and hyperchloremic acidosis. Also watch for malabsorption of other medications and fat-soluble vitamins.

Using bile acid sequestrants

Before giving the patient a bile acid sequestrant, such as cholestyramine, to lower cholesterol levels, make certain the patient isn't taking a drug whose absorption is affected by bile acid sequestrants. For example, bile acid sequestrants decrease the absorption of diuretics such as chlorothiazide. Other drugs affected besides diuretics include:
- beta-adrenergic blockers
- digitoxin
- fat-soluble vitamins
- folic acid
- thiazides
- thyroxine
- warfarin

⚠️ **ALERT** *Don't administer niacin to patients with active peptic ulcers or hepatic disease. Use with caution in patients with diabetes. In other patients, watch for adverse effects, such as flushing, pruritus, hyperpigmentation, and exacerbation of inactive peptic ulcers.*

◆ Urge the patient to adhere to the ordered diet (usually 1,000 to 1,500 calories/day) and to avoid excess sugar and alcoholic beverages, to minimize the intake of saturated fats (higher in meats, coconut oil), and to increase the intake of polyunsaturated fats (vegetable oils).
◆ Instruct the patient, for the 2 weeks preceding serum cholesterol and serum triglyceride tests, to maintain a steady weight and to adhere strictly to the prescribed diet. The patient should also fast for 12 hours preceding the test.

GAUCHER DISEASE

Gaucher disease, the most common lysosomal storage disease, causes an abnormal accumulation of glucocerebrosides in reticuloendothelial cells. It occurs in three forms: type I (adult); type II (infantile); and type III (juvenile). Type II can prove fatal within 9 months of onset, usually from pulmonary involvement.

Causes and Incidence

The three forms of Gaucher disease are classified by age of onset and the presence or absence of neurologic involvement. Type I, characterized by lack of neurologic involvement, is the most

common form affecting both children and adults and is most prevalent in the Ashkenazi Jewish population, affecting anywhere from 1 of 500 to 1,000 births. Type II usually presents in infancy with severe neurologic involvement, resulting in seizures and CNS damage. Type II also presents with spleen and bone marrow damage. Type III typically has mild neurologic involvement and runs a slower, more favorable course. The incidence of types II and III is 1 of 50,000 to 100,000 births. The juvenile form can begin in childhood, typically in the teenage years, and causes spleen, bone marrow, and neurologic damage.

Pathophysiology

Gaucher disease results from an autosomal recessive inheritance, which causes decreased activity of the enzyme glucocerebrosidase. Glucocerebrosidase deficiency leads to an accumulation of glucosylceramide in the storage compartments (lysosomes) of certain body cells. Glucosylceramide buildup occurs in the liver, spleen, bones, and bone marrow, eventually leading to decreased production of RBCs (anemia) and thinning of the bones (osteopenia).

Complications

- Neurologic impairment
- Portal hypertension
- Pathologic fractures
- Anemia
- Respiratory failure (type II)

Signs and Symptoms

The key signs of all types of Gaucher disease are hepatosplenomegaly and bone lesions. In type I, bone lesions lead to thinning of cortices, pathologic fractures, collapsed hip joints and, eventually, vertebral compression. Severe episodic pain may develop in the legs, arms, and back but usually not until adolescence. (The adult form of Gaucher disease is generally diagnosed while the patient is in their teens; the word "adult" is used loosely here.) Other clinical effects of type I are fever, abdominal distention (from hypotonicity of the large bowel), respiratory problems (pneumonia or, rarely, cor pulmonale), easy bruising and bleeding, anemia and, rarely, pancytopenia. Older patients may develop a yellow pallor and brown-yellow pigmentation on the face and legs.

In type II, motor dysfunction and spasticity occur at age 6 to 7 months. Other signs of the infantile form of Gaucher disease include abdominal distention, strabismus, muscle hypertonicity, retroflexion of the head, neck rigidity, dysphagia, laryngeal stridor, hyperreflexia, seizures, respiratory distress, and easy bruising and bleeding.

Clinical effects of type III after infancy include seizures, hypertonicity, strabismus, poor coordination and mental ability and, possibly, easy bruising and bleeding.

Diagnosis

℞ **CONFIRMING DIAGNOSIS** *Bone marrow aspiration showing Gaucher cells and direct assay of glucocerebrosidase activity, which can be performed on venous blood, confirms this diagnosis.*

Supportive laboratory results include increased serum acid phosphatase level, decreased

platelets and serum iron level and, in type III, abnormal EEG after infancy.

Treatment

Treatment is mainly supportive and consists of vitamins, supplemental iron or liver extract to prevent anemia caused by iron deficiency and to alleviate other hematologic problems, blood transfusions for anemia, splenectomy for thrombocytopenia, and strong analgesics for bone pain. Injections of a replacement synthetic enzyme have proven helpful. Imiglucerase, a recombinant form of acid beta-glucosidase has been used to treat symptomatic Gaucher disease. The FDA has recently approved velaglucerase alfa for injection to treat children and adults as a long-term enzyme replacement therapy for type I Gaucher disease. Patients receiving imiglucerase can safely be switched to velaglucerase alfa.

Special Considerations

- In the patient confined to bed, prevent pathologic fractures by turning the patient carefully. If the patient is ambulatory, make sure that he's assisted when getting out of bed or walking.
- Observe closely for changes in pulmonary status.
- Explain all diagnostic tests and procedures to the patient or parents. Help the patient accept the limitations imposed by this disorder.
- Recommend genetic counseling for patients with a family history of Gaucher disease. Prenatal testing can determine if a fetus has the syndrome.

PORPHYRIAS

Classification of porphyrias depends on the site of excessive porphyrin production; they may be erythropoietic (erythroid cells in bone marrow), hepatic (in the liver), or erythrohepatic (in bone marrow and liver). (See *Types of porphyria,* pages 518 and 519.) An acute episode of intermittent hepatic porphyria may cause fatal respiratory paralysis. In the other forms of porphyrias, the prognosis is good with proper treatment.

Types of porphyria

Porphyria	Signs and symptoms	Treatment
Erythropoietic porphyria		
Günther disease		
• Usual onset before age 5	• Red urine (earliest, most characteristic sign); severe cutaneous photosensitivity, leading to vesicular or bullous eruptions on exposed areas and, eventually, scarring and ulceration • Hypertrichosis • Brown-stained or red-stained teeth • Splenomegaly, hemolytic anemia	• Oral beta-carotene to prevent photosensitivity reactions • Anti-inflammatory ointments • Oral activated charcoal to absorb excess porphyrins • Packed red cells to inhibit erythropoiesis and excreted porphyrins • Heme therapy for recurrent attacks • Splenectomy for hemolytic anemia • Topical dihydroxyacetone and lawsone sunscreen filter

Erythrohepatic porphyria		
Protoporphyria ◆ Usually affects children ◆ Occurs most often in males	◆ Photosensitive dermatitis ◆ Hemolytic anemia ◆ Chronic hepatic disease	◆ Avoidance of causative factors ◆ Beta-carotene to reduce photosensitivity
Toxic-acquired porphyria ◆ Usually affects children ◆ Significant mortality	◆ Acute colicky pain ◆ Anorexia, nausea, vomiting ◆ Neuromuscular weakness ◆ Behavioral changes ◆ Seizures, coma	◆ Chlorpromazine I.V. to relieve pain and GI symptoms ◆ Avoidance of lead exposure
Hepatic porphyria		
Acute intermittent porphyria ◆ Most common form ◆ Affects females most often, usually between ages 15 and 40	◆ Colicky abdominal pain with fever, general malaise, and hypertension ◆ Peripheral neuritis, behavioral changes, possibly leading to frank psychosis ◆ Possible respiratory paralysis	◆ Chlorpromazine I.V. to relieve abdominal pain and control psychic abnormalities ◆ Avoidance of barbiturates, sulfonamides, infections, alcohol, and fasting ◆ Heme therapy for recurrent attacks ◆ High-carbohydrate diet
Variegate porphyria ◆ Usual onset between ages 30 and 50 ◆ Occurs almost exclusively among South African whites ◆ Affects males and females equally	◆ Skin lesions, extremely fragile skin in exposed areas ◆ Hypertrichosis ◆ Hyperpigmentation ◆ Abdominal pain during acute attack ◆ Neuropsychiatric manifestations	◆ Avoidance of sunlight, or wearing protective clothing when avoidance isn't possible ◆ Heme therapy for recurrent attacks
Porphyria cutanea tarda ◆ Most frequent in men ages 40 to 60 ◆ Highest incidence in South Africans	◆ Facial pigmentation ◆ Red-brown urine ◆ Photosensitive dermatitis ◆ Hypertrichosis	◆ Avoidance of precipitating factors, such as alcohol and estrogens ◆ Phlebotomy at 2-week intervals to lower serum iron level
Hepatic porphyria		
Hereditary coproporphyria ◆ Rare ◆ Affects males and females equally	◆ Asymptomatic or mild neurologic, abdominal, or psychiatric symptoms	◆ High-carbohydrate diet ◆ Avoidance of barbiturates ◆ Heme therapy for recurrent attacks

Causes and Incidence

Porphyrias are inherited as autosomal dominant traits, except for Günther disease (autosomal recessive trait) and toxic-acquired porphyria (usually from ingestion of or exposure to lead). Menstruation often precipitates acute porphyria in premenopausal women. (See *Preventing porphyria*.)

Pathophysiology

Porphyrias are inborn errors of metabolism that affect the biosynthesis of heme (a component of hemoglobin) and cause excessive production and excretion of porphyrins or their precursors. Porphyrins, which are present in all protoplasm, figure prominently in energy storage and utilization.

Complications

- Neurologic and hepatic dysfunction (hepatic)
- Cholelithiasis
- Coma
- Flaccid paralysis, respiratory paralysis, and death (acute intermittent)
- Hemolytic anemia (erythropoietic)

Signs and Symptoms

Porphyrias are generally marked by photosensitivity, acute abdominal pain, and neuropathy. Hepatic porphyrias may produce a complex syndrome marked by distinct neurologic and hepatic dysfunction:

- Neurologic symptoms include chronic brain syndrome, peripheral neuropathy and autonomic effects, tachycardia, labile hypertension, severe colicky lower abdominal pain, and constipation.
- During an acute attack, fever, leukocytosis, and fluid and electrolyte imbalance may occur.
- Structural hepatic effects include fatty infiltration of the liver, hepatic sclerosis, and focal hepatocellular necrosis.
- Skin lesions may cause itching and burning, erythema, and altered pigmentation and edema in areas exposed to light. Some chronic skin changes include milia (white papules on the hands'

dorsal aspects) and hirsutism on the upper cheeks and periorbital areas.

Diagnosis

℞ CONFIRMING DIAGNOSIS *Generally, diagnosis requires screening tests for porphyrins or their precursors (such as aminolevulinic acid [ALA] and porphobilinogen [PBG]) in urine, stool, blood or, occasionally, skin biopsy. A urinary lead level of 0.2 mg/L confirms toxic-acquired porphyria.*

Other laboratory values may include increased serum iron levels in porphyria cutanea tarda; leukocytosis, syndrome of inappropriate antidiuretic hormone (SIADH), and elevated bilirubin and alkaline phosphatase levels in acute intermittent porphyria.

Treatment

Treatment for porphyrias includes avoiding overexposure to the sun and using beta-carotene to reduce photosensitivity, as well as support for acute and long-term management. Heme therapy (panhematin) is given to control recurrent attacks of acute intermittent porphyria, Günther disease, variegate porphyria, and hereditary coproporphyria. A high-carbohydrate diet decreases urinary excretion of ALA and PBG, with restricted fluid intake to inhibit release of antidiuretic hormone (ADH).

Special Considerations

- Warn the patient to avoid excessive sun exposure, use a sunscreen when outdoors, and take a beta-carotene supplement to reduce photosensitivity.
- Encourage a high-carbohydrate diet.
- Administer beta-carotene and hemin, as ordered.
- Advise the patient to avoid drugs that may precipitate signs and symptoms of porphyrias. (See *Drugs that aggravate porphyria*.)

Drugs that Aggravate Porphyria

Make sure the patient with porphyria doesn't receive any of the following drugs, which are known to precipitate signs and symptoms of porphyria:
- Alcohol
- Barbiturates
- Carbamazepine
- Carisoprodol
- Chloramphenicol
- Chlordiazepoxide
- Diazepam
- Ergot alkaloids
- Estrogens
- Griseofulvin
- Imipramine
- Meprobamate
- Methsuximide

- Methyldopa
- Pentazocine
- Phenytoin
- Progesterones
- Sulfonamides
- Tolbutamide

METABOLIC SYNDROME

Metabolic syndrome—also called *syndrome X, insulin resistance syndrome, dysmetabolic syndrome,* and *obesity syndrome*—is a cluster of conditions characterized by abdominal obesity, high blood glucose (type 2 diabetes mellitus), insulin resistance, high blood cholesterol and triglycerides, low levels of high-density lipoprotein (HDL); and high blood pressure. More than 22% of people in the United States meet three or more of these criteria, raising their risk of heart disease and stroke and placing them at high risk for dying of myocardial infarction.

Causes and Incidence

Abdominal obesity is a strong predictor of metabolic syndrome because abdominal fat tends to be more resistant to insulin than fat in other areas. This increases the release of free fatty acids into the portal system, leading to increased apolipoprotein B, increased LDL, decreased HDL, and increased triglyceride levels. As a result, the risk of cardiovascular disease is increased.

Type 2 diabetes mellitus is a risk factor because a hallmark for metabolic syndrome is a fasting glucose level greater than 100 mg/dL. People with diabetes develop atherosclerotic heart disease at a younger age than other people. They're also at increased risk of macrovascular disease (ischemic heart disease, stroke, and peripheral vascular disease). Diabetes is a coronary artery disease risk equivalent.

Insulin resistance and dyslipidemia are also risk factors because insulin resistance leads to hyperinsulinemia, hyperglycemia, abnormal glucose and lipid metabolism, damaged endothelium, and cardiovascular disease. Insulin is also responsible for reducing the amount of free fatty acids in the liver. However, people with insulin resistance have an increased amount of free fatty acids reaching the liver, resulting in high triglycerides and LDLs and producing an abnormal endothelium and atherosclerosis.

High blood pressure is a risk factor because the combination of insulin resistance, hyperinsulinemia, and abdominal obesity leads to hypertension and its harmful cardiovascular effects. Moreover, insulin resistance promotes salt sensitivity in people with high blood pressure.

Women who have a history of polycystic ovarian syndrome are also at increased risk for developing metabolic syndrome.

Research also indicates that there may be a genetic predisposition to metabolic syndrome.

Pathophysiology

In the normal digestion process, the intestines break down food into its basic components, one of which is glucose. Glucose provides energy for cellular activity, while excess glucose is stored in cells for future use. Insulin, a hormone secreted in the pancreas, guides glucose into storage cells. However, in people with metabolic syndrome, glucose is insulin-resistant and doesn't respond to insulin's attempt to guide it into storage cells. Excess insulin is then required to overcome this resistance. This excess in quantity and force of insulin causes damage to the lining of the arteries,

promotes fat storage deposits, and prevents fat breakdown. This series of events can lead to diabetes, blood clots, and coronary events.

Complications

- Coronary artery disease
- Diabetes mellitus
- Hyperlipidemia

Signs and Symptoms

Assessment commonly reveals a history of hypertension, abdominal obesity, sedentary lifestyle, poor diet, and a family history of metabolic syndrome. Physical findings include abdominal obesity (evidenced by a waist of more than 40″ [101.6 cm] in men and 35″ [88.9 cm] in women), blood pressure 130/85 mm Hg or higher, and a fasting blood glucose level that's 100 mg/dL or higher. The patient may feel tired, especially after eating, and may have difficulty losing weight. If left untreated, such complications as coronary artery disease, diabetes, hyperlipidemia, and premature death may develop.

Diagnosis

Blood studies commonly indicate elevated blood glucose levels, hyperinsulinemia, and elevated serum uric acid. Lipid profile studies reveal elevated LDL levels, low HDL levels, and elevated triglycerides. Further diagnostic procedures are nonspecific, but may be performed to detect hypertension, diabetes, hyperlipidemia, and hyperinsulinemia.

Treatment

Lifestyle modification, focusing on weight reduction and exercise, is an important part of the treatment regimen. Modest weight reduction through diet and exercise considerably improves hemoglobin A_{1c} levels, reduces insulin resistance, improves blood lipid levels, and decreases blood pressure—all elements of metabolic syndrome. Recent studies have shown that in patients with impaired glucose tolerance, losing an average of 7% of body weight reduced the risk of developing type 2 diabetes by 58%. A long-term target goal for BMI should aim for less than 25 kg/m^2.

To improve cardiovascular health, a diet rich in vegetables, fruits, whole grains, fish, and low-fat dairy products combined with regular exercise is recommended. Moreover, nutrient-dense, low-energy foods should replace low-nutrient, high-calorie foods. A healthy diet should also be low in saturated fat, trans fat, cholesterol, and sodium. (See *Therapeutic lifestyle-change diet*, page 522.)

Therapeutic lifestyle-change diet

The therapeutic lifestyle-change diet is low in saturated fats and cholesterol to reduce blood cholesterol levels and prevent development of heart disease and its complications.

Nutrient	Recommended intake
Saturated fat*	<7% of total calories
Polyunsaturated fat	Up to 10% of total calories

Monounsaturated fat	Up to 20% of total calories
Total fat	25% to 35% of total calories
Carbohydrate**	50% to 60% of total calories
Fiber	20 to 30 g/day
Protein	~15% of total calories
Cholesterol < 200 mg/day	Sodium ≤2,400 mg/day
Total calories***	Balance energy intake and expenditure to maintain desirable body weight and prevent weight gain

* Trans fatty acids are another low-density lipoprotein–raising fat that should be minimized or avoided.
** Carbohydrates should be derived predominantly from foods rich in complex carbohydrates, including grains—especially whole grains, fruits, and vegetables.
*** Daily expenditure should include at least moderate physical activity (contributing about 200 kcal/day).
Source: From National Heart, Lung, and Blood Institute; National Institutes of Health; U.S. Department of Health and Human Services.

A regular exercise program of moderate physical activity, in addition to dietary modifications, promotes weight loss, improves insulin sensitivity, and reduces blood glucose levels. According to the Surgeon General's Report on Physical Activity and Health, a person should exercise moderately for a minimum of 30 minutes on most (if not all) days of the week. The selected exercise program should improve cardiovascular conditioning, increase strength through resistance training, and improve flexibility.

Medications may be used in the treatment of metabolic syndrome for patients who have a BMI of 27 kg/m^2 or greater in the presence of other risk factors (such as diabetes, hypertension, and hyperlipidemia) or for patients with a BMI of 30 kg/m^2 or greater without other risk factors. Weight-loss drugs may also be added to lifestyle changes if the patient hasn't achieved significant weight loss after 12 weeks.

Pharmacologic treatment may also be indicated. Phentermine is used for short-term treatment of obesity in conjunction with diet and exercise.

Surgical treatment of obesity, such as through gastric bypass procedures, produces a greater degree and duration of weight loss than other therapies and improves or resolves most of the factors of metabolic syndrome. Candidates for surgical intervention include patients with a BMI greater than 40 kg/m^2 or those with a BMI greater than 35 kg/m^2 with obesity-related medical conditions. Gastric bypass procedures produce permanent weight loss in the majority of patients.

Special Considerations

◆ Monitor the patient's blood pressure, blood glucose, blood cholesterol, and insulin levels.
◆ Because research indicates that longer lifestyle modification programs are associated with improved weight-loss maintenance, encourage patients with metabolic syndrome to begin an exercise and weight-loss program with a friend or family member. Assist the patient in exploring options and support their efforts.
◆ To improve compliance, schedule frequent follow-up appointments with the patient. At that time, review food diaries and exercise logs. Be positive and promote active participation and partnership in the treatment plan.
◆ A patient planning gastric bypass surgery should receive psychological and nutritional counseling before and after the surgery to assist with diet and lifestyle changes.

Homeostatic Imbalance
