In more severe EM major with significant painful oral lesions, supportive care might include a liquid diet, intravenous fluids, electrolytes, and nutritional support. Prednisone 40 to 60 mg per day tapered over 2 to 4 weeks may be required. In some cases, systemic steroids may only partially suppress the disease, and in fact, they may even prolong the duration of attacks.[62] For cases initiated by HSV in which attacks are recurrent and severe, continuous antiviral therapy with either acyclovir, 400 mg twice daily, valacyclovir, 500 mg twice daily, or famciclovir, 250 mg twice daily, is effective.[42,63,64] For patients who fail to respond to systemic antiviral therapy, azathioprine, 100 to 150 mg/d or 2 mg/kg/d, or mycophenolate mofetil, 1 gm twice per day, have been advocated.[17] Dapsone has been used for recurrent EM with mixed results. Complete resolution was reported in 23% to 33% of cases and partial resolution in 88%.[42,55,63]

Prognosis

The prognosis for EM is mainly related to the body surface and mucosal areas involved. Spontaneous healing of skin lesions is typically seen in 2 to 3 weeks for EM minor and 4 to 6 weeks for EM major. Mucosal lesions usually take longer to heal.[19,24] *(Print pagebreak 413)* Bacterial superinfections are a potential complication of skin or mucosal lesions.[18,19] Severe conjunctival mucosal lesions can cause synechia, which can result in blindness.

Histopathology

The histological features of cutaneous and mucous membrane lesions in EM are similar[65] and depend on the lesion's age and clinical appearance.[65,66,67,68,69] The earliest changes, in erythematous macules, are a sharply delimited perivascular infiltrate of predominantly lymphocytes in the upper dermis associated with endothelial cell swelling and thickened vessel walls.[67,68] Neutrophils, eosinophils, and plasma cells may be present, or there may be only lymphocytes and macrophages.[67] Dermal edema follows the perivascular inflammatory phase,[67] and then comes intercellular edema between keratinocytes, with some biopsies having epidermal necrosis with rounded and eosinophilic necrotic keratinocytes that may be anucleate or have pyknotic nuclei.[65,68] As macules progress to papules, inflammatory cells extend into the epidermis (“exocytosis”), keratinocyte intracellular edema advances leading to vacuolar (liquefactive) degeneration (Figure 62.3A), and subepidermal and intraepidermal bullae develop (Figure 62.3A and B) along with more necrotic keratinocytes (Figure 62.3C).[67,68] Lymphocytes may surround dying keratinocytes (“satellite cell necrosis”).[66] Target lesions (also known as iris lesions) have a central zone of subepidermal separation from the epidermis with necrotic keratinocytes in the overlying epidermis.[66] The periphery of target lesions has dermal changes similar to those in the macules.[66]

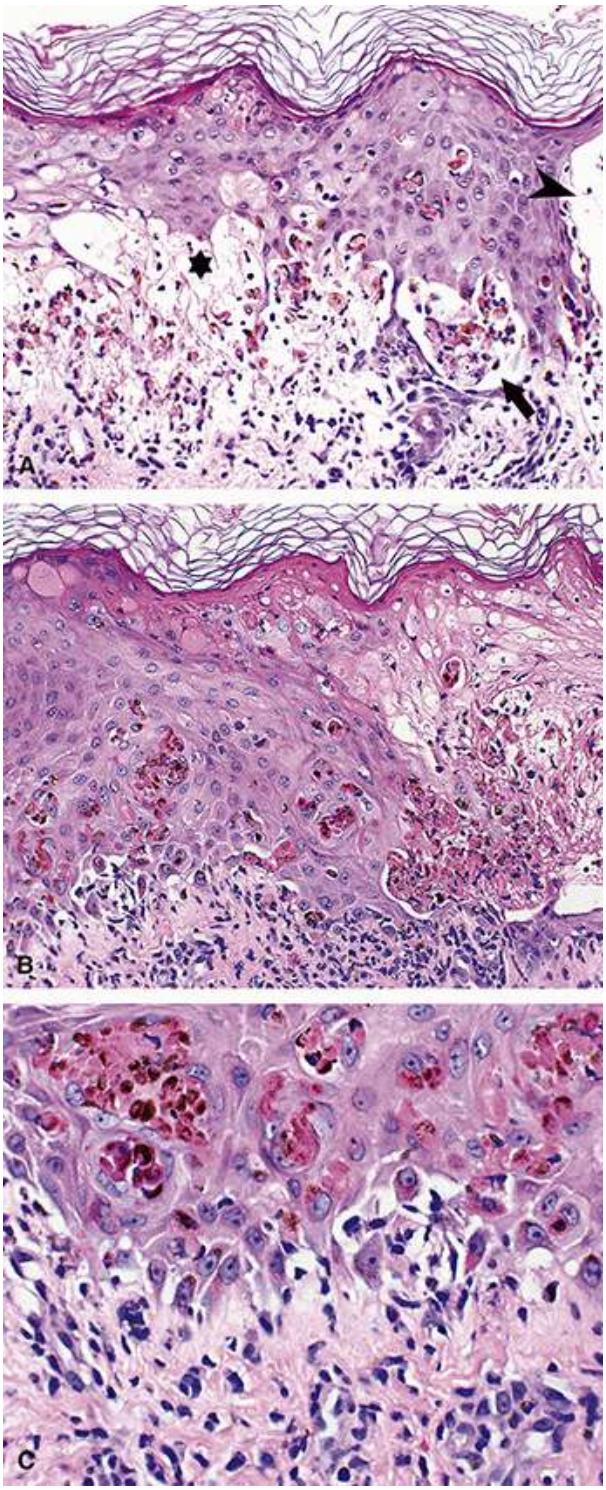

FIGURE 62.3 A, This erythema multiforme target lesion shows prominent vacuolar degeneration of basal keratinocytes (★), a small intraepidermal blister (vesicle) containing necrotic keratinocytes (arrow), and the edge of a larger intraepidermal blister (arrowhead). B, The target lesion has numerous brightly eosinophilic necrotic keratinocytes, along with an area of vacuolar degeneration occupying almost the full thickness of the epidermis. Macrophages and lymphocytes are in the papillary dermis with extension into the basal epidermis. C, Close-up view of the necrotic keratinocytes having brightly eosinophilic cytoplasm and pyknotic or absent nuclei. Melanin is in many of the necrotic cells of this black patient.

CHAPTER 63

Fibrous Histiocytoma

Key Points

- Fibrous histiocytoma (FH) is a soft-tissue tumor characterized by a proliferation of spindle-shaped cells, usually admixed with inflammatory cells
- It is believed to originate from a primitive mesenchymal cell with differentiation into fibroblast or histiocyte-like components
- This tumor can occur in any part of the body and can be benign or malignant
- Eyelid lesions usually present as a slow-growing, firm, painless, subcutaneous, or tarsal nodular mass, ranging from 4 mm to 1.5 cm in diameter
- Rarely they can be localized to the bulbar conjunctiva where they present as slow-growing, painless, vascular, yellow to pink elevated nodules that occasionally can infiltrate the cornea
- Local surgical excision is the treatment of choice
- Radiation therapy may be helpful as an adjuvant treatment in certain settings
- Local recurrence following surgical excision of benign FH has been reported between 5% and 11%
- Rates of local recurrence for malignant fibrous histiocytoma range from 25% to 75% with a 5-year overall survival rate of 48%

Fibrous histiocytoma (FH) is a common soft-tissue tumor characterized by a proliferation of spindle-shaped cells, usually admixed with inflammatory cells.[1,2] Lesions previously included under this name can be cutaneous or subcutaneous in location. In recent years, cutaneous tumors located in the dermis are more commonly referred to as dermatofibroma.[3,4] Deeper, subcutaneous tumors of this type are termed FH. These are less common than cutaneous forms and generally are larger and better circumscribed.[2,5,6,7]

FH was first described in 1961 by Kauffman and Stout.[8] It frequently involves muscular, fibrous, and fatty tissues.[9] Ocular involvement is infrequent and primarily limited to the orbit where it represents 0.5% of all benign orbital tumors and is considered to be the most common primary mesenchymal tumor of the orbit seen in adults.[10,11] Rarely, these tumors can arise in the conjunctiva, episclera, choroid, and lacrimal sac.[12,13,14,15,16,17,18,19,20,21,22,23,24,25] Its occurrence in the eyelid is rare.[4,19,26,27,28,29,30,31,32,33,34,35,36,37]

Malignant fibrous histiocytoma (MFH) was described in 1961 by Kauffman and Stout[8] and has been considered to be the most common adult soft-tissue sarcoma.[38,39] However, major advances in immunohistochemistry during the past several decades have led to a reclassification of many tumors once included under MFH,[40] so that nearly three-fourths of tumors previously diagnosed as MFH are now considered to represent alternative diagnoses.[41] Although controversial, some studies have indicated that the most probable cells of origin for MFH may be primitive mesenchymal or fibroblastic cells, rather than histiocytic cells. As a result, MFH is now frequently referred to as pleomorphic undifferentiated sarcoma.

MFH develops in males in approximately two-thirds of cases, arising most commonly during the sixth and seventh decades of life.[42,43] It most commonly occurs in the head and neck region, trunk, extremities, and retroperitoneum, but very rarely is seen in the eyelid.[37,44,45,46,47,48] It has a high potential for local muscle, perineural, and blood vessel invasion, and to progress to distant metastasis.

Etiology and Pathogenesis

FH is a soft-tissue neoplasm with both fibrocytic and histiocytic components. The tumor was initially thought to arise from two different cell types,[8] but it is now believed to originate from a primitive mesenchymal cell with differentiation into fibroblast or histiocyte-like components.[10] This tumor can occur in any part of the body and can be benign or malignant.[8] The orbit is the most common ocular site.[10] Case reports have described the occurrence of conjunctival FHs in individuals with a history of trauma, leukemia, chemotherapy, prednisone use, radiation, rheumatoid arthritis, and xeroderma pigmentosum.[49,50] There is also an association between systemic lupus erythematosis, multiple dermatofibromas, and FH in extraocular locations.[51]

Angiomatoid FH is a rare form with intermediate biologic potential most often arising in the extremities of children and young adults. Only one case has been described in the eyelid.[33] Genetic abnormalities have been described in angiomatoid FH, associated with three characteristic gene fusions, EWSR1-CREB1, EWSR1-ATF1, and, rarely, FUS-ATF1. Angiomatoid FH is now recognized in an increasing number of sites and is known to display a variety of unusual histologic features.[52,53,54]

(Print pagebreak 417)

For MFH, previous ionizing radiation therapy (RT) appears to be a risk factor in some cases.[55,56,57] It is the most commonly diagnosed sarcoma in patients with prior radiation exposure in the head or neck region, and patients with radiation-associated tumors in this region have a worse prognosis than those with tumors not associated with prior RT.[58,59,60,61] Genetic alterations in MFH include the p53 gene,[62] as well as H- and K-ras gene activation.[63]

Clinical Characteristics

Benign FHs involve subcutaneous tissue and generally are seen in adults older than 25 years, with a mean age of 40 years.[64] The majority occurs on the extremities, but they also rarely occur in the head and neck region. Clinically, deep FHs are usually painless, well-circumscribed, slowly enlarging encapsulated masses. Eyelid FH usually presents as a firm, painless, subcutaneous, or tarsal nodular mass, ranging from 4 mm to 1.5 cm in diameter. They are seen equally on the upper and lower eyelids, and rarely in the medial canthus.[4,26,28,32,35,65,66,67,68]

Eyelid lesions often grow slowly but can occasionally enlarge more rapidly over several weeks to months. Males are affected slightly more frequently than females, and the mean age at presentation is 37 years, with a range of 17 to 74 years. These tumors often are associated with local edema and erythema. Several cases have been localized to the bulbar conjunctiva,[14,69,70,71,72] where they present as slow-growing, painless, vascular, yellow to pink elevated nodules measuring 3 to 6 mm in diameter (Figure 63.1) Occasionally they can infiltrate the cornea.

For MFHs, the clinical presentation typically presents as a painless or painful, rapidly enlarging subcutaneous nodule that can be invasive and destructive of surrounding tissues (Figure 63.2). They are seen most commonly in the head and neck, extremities, and trunk.

Differential Diagnosis

The diagnosis of benign FH continues to be difficult and is frequently a diagnosis made through the exclusion of simulating lesions. The most important lesions in the differential diagnosis are malignant neoplasms, particularly MFH. MFH usually progresses more rapidly, is more likely to be painful, and generally affects younger males at a mean age of 26 years, compared with 47 years with a 60% male predominance for benign FH.[73] The recurrence rate for MFH is 40% with tumor-related mortality of 47%. Immunohistochemistry is important in distinguishing among these lesions.

Other lesions in the differential include xanthelasma, tuberous xanthoma, juvenile xanthogranuloma, and necrobiotic xanthogranuloma. Juvenile xanthogranuloma most commonly occurs in infants and children, while xanthelasma, *(Print pagebreak 418)* tuberous xanthoma, and necrobiotic xanthogranuloma are diseases of middle-aged and elderly patients.[74] Xanthelasmas are typically elevated, yellowish plaques, usually bilateral, and are located on the medial surfaces of the upper and lower eyelids.[74] Tuberous xanthomas appear as multiple, firm, nontender, yellowish nodules that can involve the upper and lower eyelids bilaterally.[75] Necrobiotic xanthogranuloma is characterized by indurated, nontender, dermal, or subcutaneous yellow nodules and plaques that infiltrate the eyelids and periorbital structures.[76]

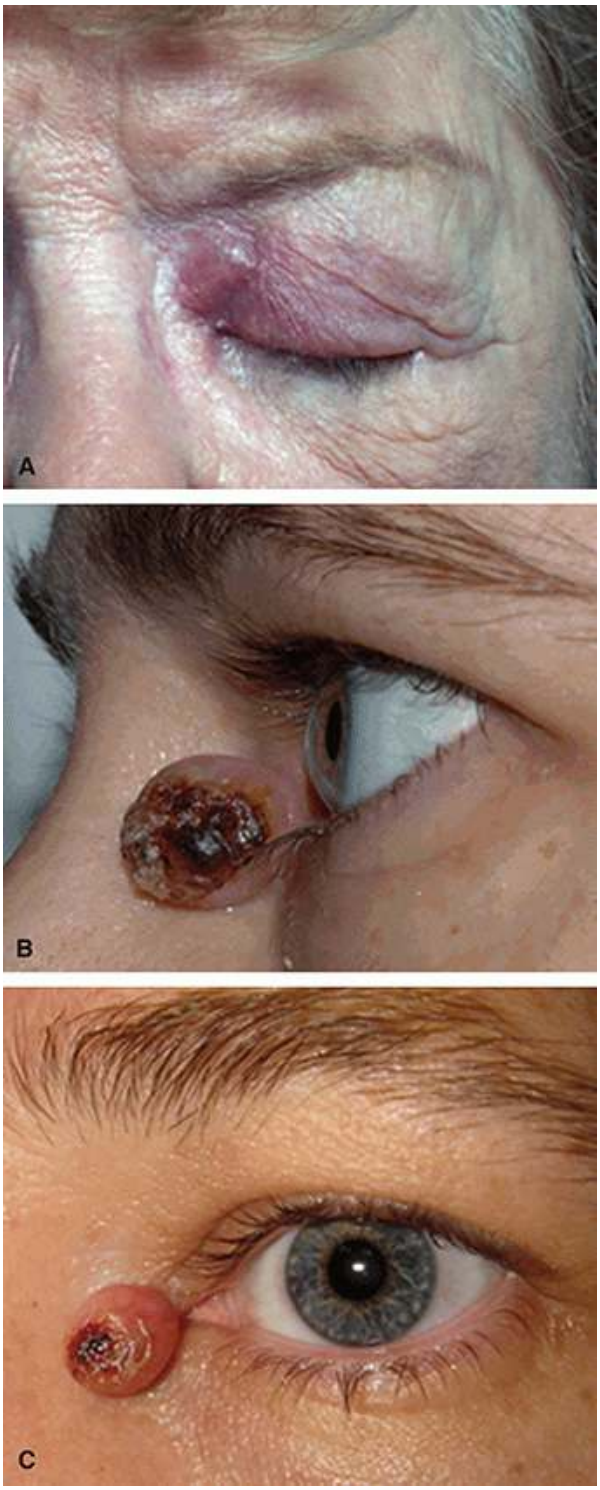

FIGURE 63.1 A-C, Nodular lesions of benign fibrous histiocytoma in the medial eyelid and medial canthus. (A, Courtesy of Dr. Robert Goldberg; B and C, Courtesy of Dr. Ramon Malhotra.)

FIGURE 63.2 Malignant fibrous histiocytoma of the upper eyelid following radiation therapy for retinoblastoma as a young child.

The differential diagnosis of conjunctival FH must include neoplastic lesions such as corneal intraepithelial neoplasia, squamous cell carcinoma, amelanotic melanoma, and conjunctival lymphoma. FH can also be misdiagnosed as pterygium, chalazia, leiomyoma, or nodular episcleritis.[16]

Treatment

Local surgical excision is the treatment of choice for FH without sacrificing structures that would cause major functional or cosmetic morbidity. Complete excision is often difficult due to the complexity of eyelid structure and function so that for MFH local recurrence rates are high, reported to range from 19% to 66%.[77,78,79,80] In a large study associated with the clinical size of operative margins with recurrence rate, 86% of patients treated with resections with margins less than 3 mm experienced local recurrence, compared with 66% following wider margins greater than 3 mm. Even with more radical resection with the clearance of regional lymph nodes, adjuvant RT, and chemotherapy or immunotherapy, 27% of patients can experience recurrence.[81]

RT may be helpful as an adjuvant treatment in certain settings.[82,83] Effective RT should employ a field that includes the tumor site and 5 cm or more of peripheral tissue, at doses ranging from 50 to 65 Gy.[84,85,86] In one study of patients with MFH of the extremities undergoing excisional surgery followed by postoperative RT, the 10-year relapse-free survival was 62% and the overall survival rate was 80%.[87] Other studies have suggested that preoperative RT may provide better overall survival rates than postoperative RT.[88] Traditional chemotherapy is typically recommended only for widespread disease, but several clinical trials have not shown a significant benefit.[89,90]

Prognosis

Local recurrence following surgical excision of benign FH has been reported between 5% and 11%,[2] mostly related to incompletely

resected, poorly defined infiltrative margins.[74,91]

For MFH, rates of local recurrence range from approximately 25% to 75%. Local recurrence may be attributed to insufficient primary tumor clearance, high rates of microsatellites, and in-transit metastases. MFH arising on the head and neck seem to exhibit more aggressive behavior than those occurring in other regions of the body. For patients with head and neck tumors, a 5-year overall survival rate of 48% has been reported compared with 77% for patients with tumors arising on the trunk and extremities.[92] Distant metastases are relatively common, primarily involving the lungs.

Histopathology

FHs of the skin are now classified by the World Health Organization (WHO) as dermatofibromas,[93] and their histopathological features are presented in Chapter 59. The WHO now classifies soft-tissue FHs as deep FHs.[94] Deep FHs are typically better circumscribed (Figures 63.3 and 63.4), are more cellular, and have a more prominent storiform pattern than their cutaneous counterparts.[94,95] There may be a vascular pattern reminiscent of a hemangiopericytoma/solitary fibrous tumor with thin-walled branching vessels (Figure 63.3A).[94,95,96] Tumor cells are plump, ovoid to spindle-shaped with oval or elongated, vesicular nuclei, and eosinophilic cytoplasm.[94,96] The tumors may lack foamy histiocytes or giant cells, and hyalinized stroma is common.[94,96] CD34 was expressed in 20 of 50 tumors (40%) examined by Gleason ad Fletcher, and 12 cases had CD34 expression by more than 50% of the cells.[96] Smooth muscle actin immunostaining was positive in 15 of 40 cases (38%). Deep FHs do not express STAT6 in their nucleus; this is useful for differentiating FHs that express CD34 from solitary fibrous tumors, which are $CD34^+$ and $STAT6^+$.[97,98]

(Print pagebreak 419)

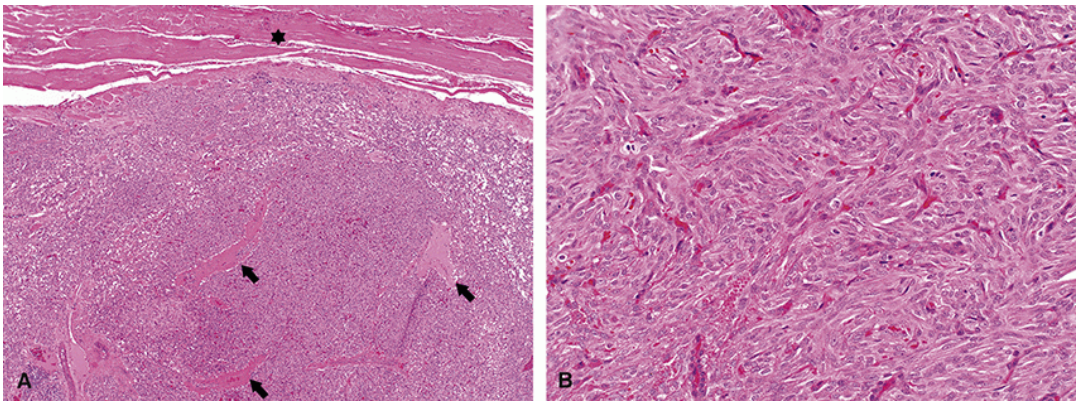

FIGURE 63.3 A, This fibrous histiocytoma arose in the left upper eyelid connective tissue between the orbicularis oculi muscle (★) and the tarsus. The tumor is circumscribed and has several large vessels (arrows) resembling those in solitary fibrous tumors. B, The plump spindle cells have a storiform configuration, which is typical in deep fibrous histiocytomas.

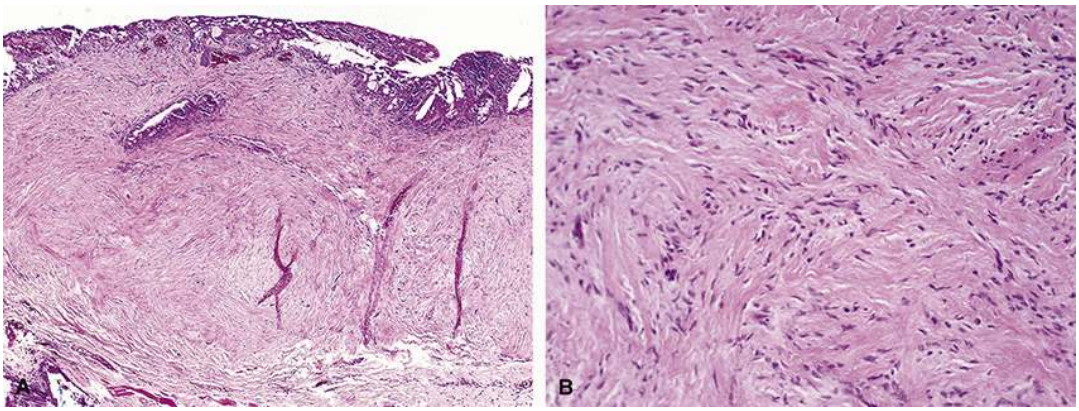

FIGURE 63.4 A, This fibrous histiocytoma arose approximately 30 years after radiation therapy for retinoblastoma as a young child. The tumor was well-circumscribed and located between the conjunctiva and the tarsus. B, The tumor cells are elongated spindle cells with pale eosinophilic cytoplasm. Though the tumor cells resemble those in solitary fibrous tumors and neurofibromas, they did not stain for either CD34 or S100 protein, thus ruling out those possibilities.

CHAPTER 64

Glomuvenous Malformation (Glomus Tumor)

Key Points

- Glomuvenous malformation is a rare benign hamartoma of the glomus body
- The pathogenesis and genetics of sporadic GVM are poorly understood but *BRAF* or *KRAS* mutations have been identified in some cases
- On the eyelids, lesions generally present as slow-growing, solitary or multiple, bluish to violaceous plaque-like, soft, spongy to firm to nodular lesions
- Solitary lesions appear in adults, and multiple tumors arise more commonly in childhood and may be familial
- The usual treatment of GVM of the eyelid is complete surgical excision
- External beam radiotherapy, stereotactic radiosurgery, and laser ablation have been used for unresectable or incompletely resected tumors
- All reported cases of eyelid GVM have been benign, and surgical excision carries an excellent prognosis with recurrence rates reported in 10% of cases

Glomuvenous malformation (GVM), previously termed glomus tumor or glomangioma, is a rare benign hamartoma of the glomus body,[1] distinct from venous malformations, and comprising less than 2% of all soft-tissue tumors. It occurs most commonly in adults between the fourth and seventh decades of life,[2] although it has been reported even in children.[3] This tumor most frequently subcutaneously occurs in the arms (14%) and legs (13%), with less common occurrence on the trunk (3%).[2]

Terminology in the literature is rather confusing and tumors can arise from both the glomus body and the glomus cell. A glomus cell is a peripheral chemoreceptor mainly located in the carotid bodies and aortic bodies, and less commonly in other organs. They are located along some blood vessels and nerves and help the body regulate breathing. It is able to detect changes in the blood's pH, oxygen saturation, and carbon dioxide levels. Clusters of glomus cells, of which the carotid bodies and aortic bodies are the most important, are called nonchromaffin or parasympathetic paraganglia. They are also present along the vagus nerve, in the inner ears, in the lungs, and at other sites. Tumors arising from glomus cells include glomus jugulare, glomus tympanicum, and paragangliomas in other deep sites. Some publications separate tumors from glomus cells and those from the glomus body as distinct, whereas others refer to both as glomus tumors. Deep-seated GVMs arise in locations that include the mouth, trachea, esophagus, stomach, lungs, colon, vagina, penis, and bones.

The glomus body was first described by Wood in 1812.[4] It is a normal intradermal arteriovenous shunt scattered in the dermis of the skin and is most frequently found in the pulps of the fingers and toes, the tip of the nose, and pinnae of the ears. Their primary function is thought to be thermoregulation.[5] The glomus body shunts blood away from the skin surface when exposed to cold temperature, thus preventing heat loss, and allowing maximum heat flow to the skin in warm weather to allow heat to dissipate. This structure is composed of an afferent arteriole that gives rise to several preglomic arterioles, and these anastomose with venules that are surrounded by a thick sheath with an S-shaped lumen, known as a Sucquet-Hoyer canal.[6,7,8,9,10] The Sucquet-Hoyer canals are lined by endothelial cells, which are surrounded by smooth muscle cells. The glomus bodies are interspersed within the smooth muscle. Hyperplasia of any of the structures composing the glomus body, glomus cells, vasculature, and smooth muscle cells will result in a GVM.[8] Malignant and atypical GVMs have been classified into several subtypes,[11] but none of these have been reported to occur in the eyelids.

Etiology and Pathogenesis

The pathogenesis and genetics of sporadic GVM are poorly understood, and it is unclear what molecular genetic changes might be

involved in their pathogenesis. One study identified *BRAF* or *KRAS* mutations in 4/28 cases (14.3%) of GVM.[12] There is also an association of GVM with neurofibromatosis type 1,[13] and loss of NF1 results in the upregulation of signaling through the mitogen-activated protein kinase (MAPK) pathway. *KRAS* and *BRAF* mutations also signal through this pathway, suggesting a possible role of MAPK in the growth regulation of GVM.

A gene associated with a familial variant of GVM has been localized to chromosome 1p21-22 and involves truncating mutations in the glomulin gene.[14,15] In the familial autosomal dominant form, most affected family members have small multiple lesions on the body. However, occasionally one member will suffer from a more severe form of the disease, having extensive congenital lesions in a segmental *(Print pagebreak 423)* distribution. It has been proposed that such a segmental manifestation of an autosomal dominant skin disorder suggests a postzygotic mutation early in embryogenesis, with loss of heterozygosity.[16]

Clinical Presentation

Only 19 cases of GVM have been described involving the eyelids.[7,8,9,10,17,18,19,20,21,22,23] In two of these cases, similar tumors were mentioned in five additional family members, but no details were given.[8,18] They generally present as slow-growing, bluish to violaceous plaque-like to nodular lesions that often extend over large areas of the face. They may be well defined or diffuse, solitary or multiple, and discreet or confluent. On palpation, they are usually soft, spongy, and compressible, but several have been described as firm. Lesions appear highly vascular, similar to hemangiomas, but are nonpulsatile and without a bruit. Lesions may be associated with tenderness on pressure,[7,8,9,23] which may be caused by pressure on adjacent Pacinian corpuscles associated with the dilatation of the walls of the glomus body.[9] Rarely, lesions may be pigmented and confused with melanoma. Tumors may be present at birth, or appear in childhood or teens,[8,9,23] or later in adult life.[9,17]

GVMs are seen in two forms, as a solitary lesion, which is the more common type (Figure 64.1), and as multiple familial lesions.[7,8,24,25,26,27,28] Solitary lesions tend to appear in adults, are encapsulated, and have extensive numbers of glomus cells.[17] Multiple tumors arise more commonly in childhood, are generally not tender or painful, and may have a familial occurrence.[7,8] They tend not to be encapsulated and to have fewer glomus cells. Several authors have noted the familial occurrence of multiple GVM with an autosomal dominant pattern of inheritance.[26,27,28]

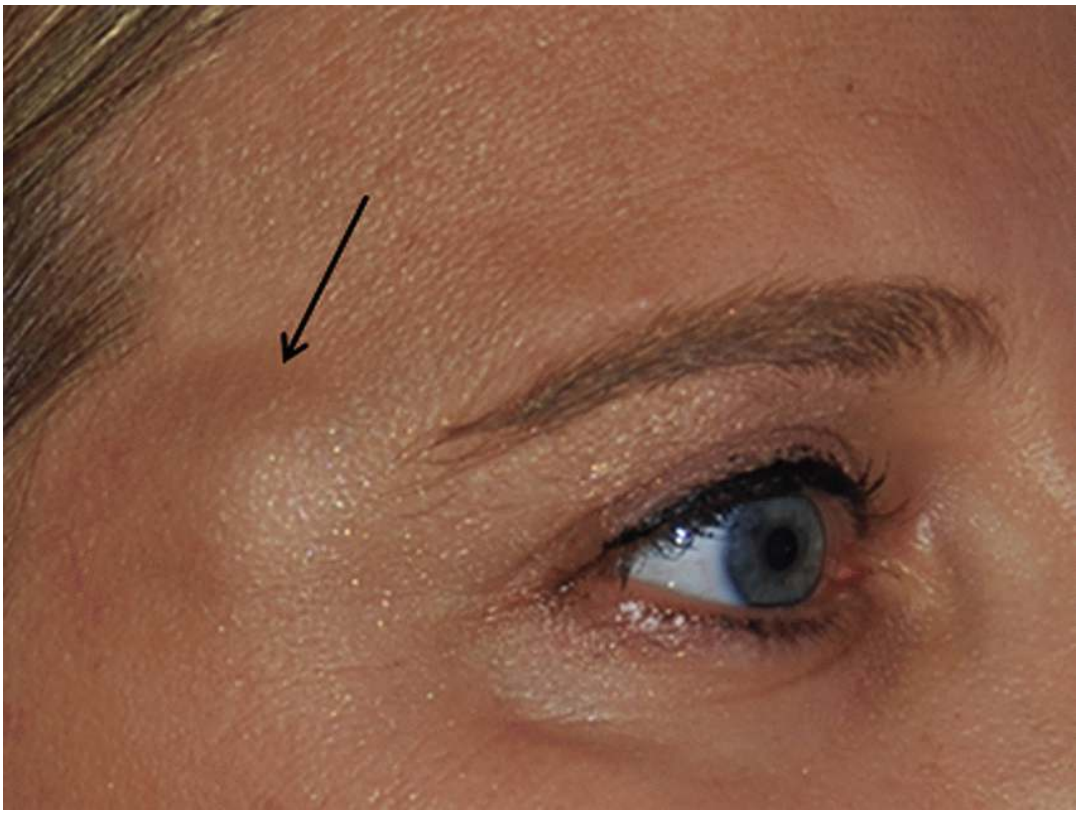

FIGURE 64.1 Solitary subcutaneous glomuvenous malformation in the lateral brow (arrow). (Courtesy of Dr. Kyle Godfrey.)

While these lesions have been reported in the orbit,[29,30,31] only one case of eyelid GVM was found at surgery to be penetrating the orbital septum, but without deep orbital invasion.[7]

Differential Diagnosis

GVMs can easily be diagnosed microscopically, but the clinical diagnosis is often difficult. A variety of solid violaceous tumors are often confused with it, including Merkel cell tumor, capillary, and cavernous hemangioma, varix, Kaposi sarcoma, pyogenic granuloma, lymphangioma, and angiosarcoma.[8]

Treatment

The usual treatment of GVM of the eyelid is complete surgical excision (Figure 64.2).[8] However, surgical removal is not always possible and depends on the tumor location, any involvement of critical vascular or neural structures, and the details of vascular supply to the tumor. More extensive facial and head and neck lesions may present significant challenges for good functional and aesthetic outcomes. In these cases, management options include surgical resection, radiotherapy, or combinations of both.[32]

Preoperative angiography and embolization have been helpful in some cases of glomus faciale and other glomus tumors.[33,34] It has been used to achieve significant preoperative tumor devascularization to decrease blood loss during surgical resection.[35] While this is not considered to be a curative treatment, it has been advocated as a beneficial preoperative surgical adjunct in selected cases.[36,37]

External beam radiotherapy (45-50 Gy) and stereotactic radiosurgery have been used for unresectable or incompletely resected tumors. Local tumor control rates of 74% *(Print pagebreak 424) (Print pagebreak 425)* to 97%, with complication rates from 4% to 20%, have been reported.[38,39,40,41,42,43,44]

FIGURE 64.2 Surgical excision of the lesion in Figure 64.1. (Courtesy of Dr. Kyle Godfrey.)

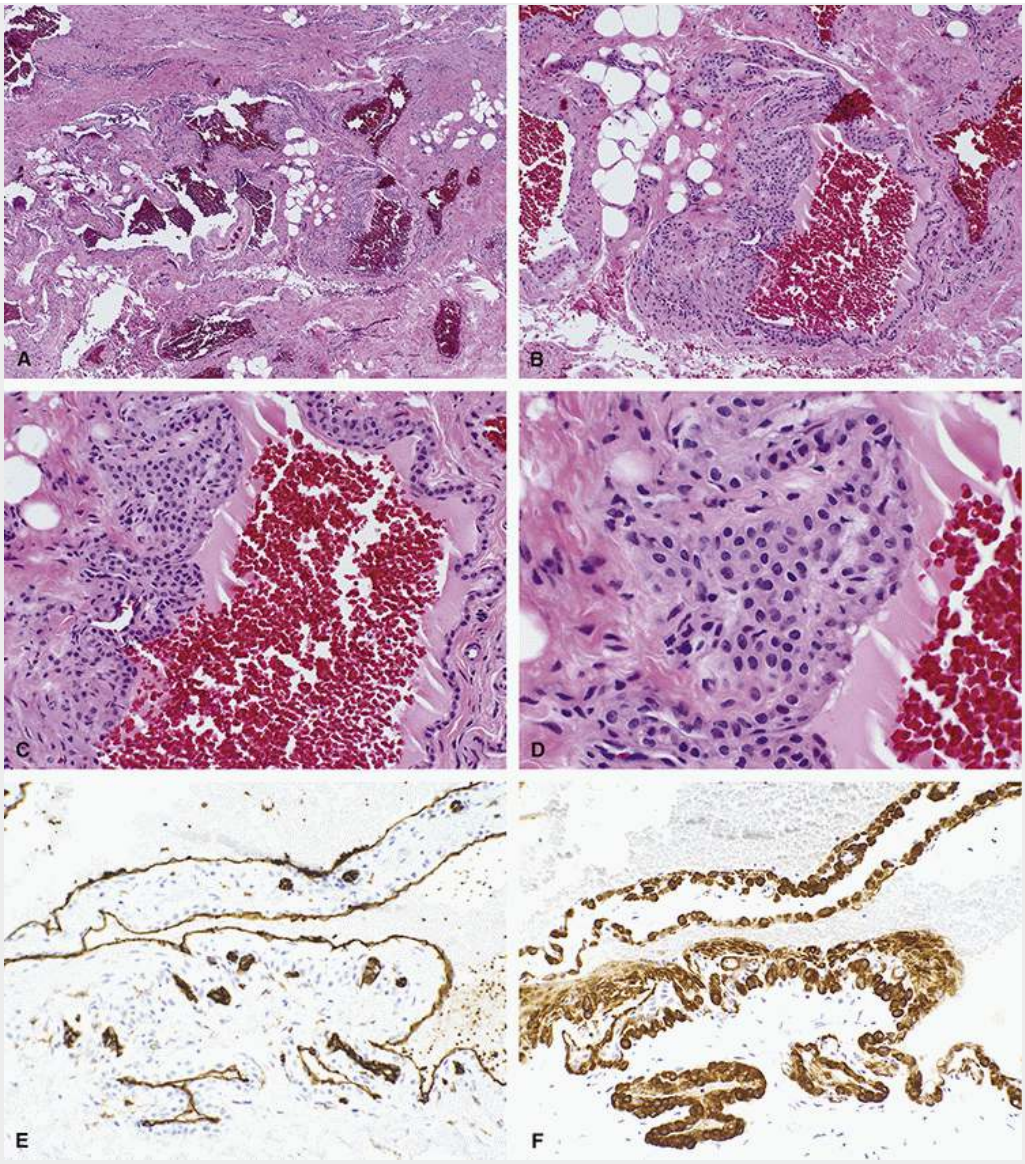

FIGURE 64.3 This glomuvenous malformation (GVM) of the eyelid was part of a larger lesion involving the face. A, At low magnification, the GVM resembles a cavernous hemangioma with interlacing, contorted, dilated blood vessels. B and C, A variably thick layer of glomus cells ensheaths the blood vessels. D, The glomus cells are uniform, large, round or cuboidal cells with a round nucleus, a rim of pale, lightly eosinophilic cytoplasm, and a distinct cell membrane that is slightly more eosinophilic than the cytoplasm. E, Immunohistochemical staining using antibodies to CD31 highlights the endothelial cells but not the glomus cells. F, The glomus cells are immunoreactive using antibodies to α-smooth muscle actin.

In a series of 17 patients, treatment with dual-wavelength PDL-Nd: YAG laser was shown to provide an excellent clinical response with a low risk of adverse events for GVMs.[45] The rationale behind sequential laser therapy was that the dual administration with pulsed dye laser allowed a greater absorption of the Nd:YAG laser due to the production of methemoglobin via hemoglobin, requiring less fluencies of the latter and therefore a decreased risk of adverse effects.

Prognosis

All reported cases of eyelid GVM have been benign, and surgical excision resulted in a cure. For most benign glomus tumors elsewhere in the body, the postsurgical recurrence rate is approximately 10%, usually associated with incomplete resection.[46] An exceptionally rare phenomenon, malignant transformation after recurrence or dedifferentiation of a benign glomus tumor has been described, but this has not been reported in the eyelid.[47]

Histopathology

The histopathology of the GVM variant of glomus tumor[48,49] was described in elegant detail in the 1920s and 1930s.[50,51,52,53] At low magnification, GVM resembles a cavernous hemangioma with interlacing, contorted, dilated blood vessels (Figure 64.3A and B).[50,51,53] The vessels are ensheathed by a variably thick layer of glomus cells (termed "epithelioid cells" in the earlier literature) that are uniform, large, round, or cuboidal cells with a round nucleus, a rim of clear or pale cytoplasm, and a distinct cell membrane best seen using Masson trichrome stain.[50,53] The blood vessels in GVM are of two types.[50,51] The first type has one or two layers of smooth muscle cells arranged circularly and separated from the endothelium by a collagenous membrane.[50,51] The circularly oriented smooth muscle cells are surrounded by "muscle cells less regularly arranged, branching, clearer, less rich in muscle fibrils, and each with a short ovoid nucleus. Proceeding peripherally, these cells are seen to pass through every gradation to typical epithelioid cells supported in a collagenous medium."[51] The second vessel type in GVM has glomus cells bordering endothelial cells without the interposition of smooth muscle cells.[50,51] Glomus cell ensheathed blood vessels are separated by connective tissue containing nonmyelinated nerve fibers that terminate around the glomus cells.[50,53] The endothelial cells in GVM can be highlighted using antibodies to CD31 (Figure 64.3E), CD34, or factor VIII-related antigen, while the glomus cells are highlighted using antibodies to α-smooth muscle actin (Figure 64.3F) and muscle-specific actin.[2] The glomus cells do not express CD31, cytokeratins, or S100 protein.[2,3]

CHAPTER 65

Granuloma Annulare

Key Points

- Granuloma annulare is a benign dermatological condition that occurs in healthy children
- It occurs clinically as several different forms, including generalized, subcutaneous, and perforating variants
- The etiology remains unknown, but inciting triggers include local trauma, insect bites, ultraviolet light exposure, viral infections, red tattoos, and tuberculin skin tests
- GA is characterized by necrobiotic granulomas with blood vessel thickening suggesting an immunoglobulin-mediated vasculitis
- Eyelid lesions usually present as a painless, flesh to yellow-tan-colored nodule commonly in the lateral aspect of the upper eyelid and the lateral canthal region but can show a more diffuse distribution of small multiple nodules
- GA lesions are benign and often self-limited with approximately 50% of cases resolving spontaneously within 2 years
- When symptoms are present or lesions are of cosmetic concern, lesions can be treated with local surgical excision, cryotherapy, laser ablation, intralesional corticosteroids, and psoralen plus ultraviolet A (PUVA) light therapy
- The prognosis for GA is generally excellent

Granuloma annulare (GA) is a benign dermatological condition that occurs in healthy children.[1] It was first described in 1895 by Fox,[2] who referred to it as an inflammatory dermatosis. The term “granuloma annulare” was later introduced by Radcliffe Crocker in 1902.[3] Mesara et al.[4] studied deep periocular nodular lesions and in 1964 named them pseudorheumatoid nodules because they appeared pathologically identical to rheumatoid nodules. Similar lesions identified as pseudorheumatoid nodules were identified in the periorbital region of 21 patients by Rao et al. in 1975.[5] Later, in 1994, Burnstine et al.[6] referred to similar periocular lesions as GA, and since then, this has been the preferred terminology.[7]

GA is characterized by firm papules, plaques, or nodules that are usually organized in a ringlike fashion, with normal overlying skin.[8] The distribution of GA lesions in children is located on the hands or arms in 60% of cases, on the feet and legs in 20%, on both upper and lower extremities in 7%, and on the trunk or head in 5% each.[8] However, Coskey et al.[9] reported a significantly higher incidence of facial GA occurring in adults.

The skin manifestations of GA are varied due to the many variants of this disease. The localized variant accounts for about 75% of GA cases. In this form, lesions are skin colored or erythematous and occur in annular groups of papules most commonly on the dorsal hands and feet. It is typically seen in patients younger than 30 years, with a female predilection in a ratio of 2:1.[10]

Generalized GA represents 8% to 10% of GA cases and is characterized by the simultaneous occurrence of multiple widespread annular plaques.[11,12] It has been reported that this variant is more likely to occur in middle-aged or older individuals,[13] but in a retrospective study involving 54 cases of generalized GA, this disease occurred predominantly in patients younger than 10 years or older than 40 years.[14] Subcutaneous GA is more common in children and presents as firm subcutaneous nodules, more commonly on the lower legs.[15] The perforating variant of GA differs from the other variants in that lesions show a central umbilication.

In addition to the classic variants, other rare subtypes of GA have been described. These include macular, patch, or pustular forms[16,17]; a palmar distribution[18,19,20]; and a form localized in photo-exposed skin.[21,22,23] Rare subtypes have been based on their clinical appearance, anatomic location, and patient demographics. These include localized, generalized, perforating, and subcutaneous deep variants.[8,24]

Generalized GA is characterized by small, 1- to 2-mm diffuse papules on the trunk. Perforating GA most frequently presents as small papules on the hands or fingers, which may have central umbilication. Subcutaneous GA occurs almost exclusively in children

and young adults presenting as an asymptomatic subcutaneous or deep dermal nodule. They are typically located in the pretibial skin, and less commonly on the hands, scalp, and eyelids.[8,24] Most reported cases of periorbital and orbital GA are the subcutaneous variant.

Etiology and Pathogenesis

The etiology of GA remains unknown. Several inciting triggers have been recognized, which include local trauma, insect bites, ultraviolet light exposure, viral infections, red tattoos, and tuberculin skin tests.[7,8,25,26] GA has also been seen at sites of healing herpes zoster and verruca vulgaris lesions, suggesting a possible viral etiology.[6] GA developing at sites of direct local trauma possibly results from primary degeneration of the connective tissue at the site of injury that can stimulate a granulomatous inflammation, a lymphocyte-mediated immune reaction with macrophage activation, and cytokine-mediated degradation of connective tissue with increased deposition of mucin.[27]

GA is characterized by necrobiotic granulomas and biopsy specimens frequently show blood vessel thickening, suggesting *(Print pagebreak 428)* that occlusion or other events involving blood vessels may partially be responsible for the necrobiosis. In 1977, Dahl et al.[28] studied GA specimens by conventional light and immunofluorescence microscopy. In 30% of blood vessels in involved skin, they identified IgM, and in 50%, they found complement C3. IgM, C3, or fibrinogen was also observed at the dermal-epidermal junction of 8 out of 20 GA patients, and necrobiotic areas contained fibrinogen. The authors suggested that an immunoglobulin-mediated vasculitis may be involved in the pathogenesis of GA. In an earlier study by Umbert and Winkelmann in 1976,[29] deposition of fibrin and circulating macrophage migration inhibition factors were found in the granulomas and necrobiotic lesions of 11 GA patients, suggesting an etiology of delayed hypersensitivity with involvement of the clotting factors. Thornsberry et al. and Mempel et al.[30,31] studied GA biopsies and reported increased production of interleukin-2, suggesting a T helper 1 cell-mediated process. Elastic fiber degeneration was demonstrated by electron microscopy by Hanna et al.,[32] suggesting that the elastic tissue may be a target tissue in GA.

The role of ultraviolet light in the pathogenesis of GA is unclear, but generalized GA in sun-exposed areas has been described in several cases.[33,34,35]

FIGURE 65.1 Granuloma annulare (GA) involving the eyelids. A, Nodular subcutaneous lesion in the lateral upper eyelid. B, GA nodule in the upper medial canthus. C and D, Small nodules of GA in the upper and lower eyelids. Arrows indicated the subcutaneous lesions.

Some systemic associations have also been reported with generalized GA, including diabetes mellitus, thyroid disease, rheumatoid

arthritis, lipid abnormalities, malignancy, human immunodeficiency virus, and hepatitis B and C.[36,37,38,39,40,41,42,43,44,45,46,47]

Clinical Characteristics

Lesions of GA most often involve the dorsal surfaces of the hands or feet, arms, legs, and trunk, and less frequently the scalp, face, and eyelids. They often present as a localized, erythematous, skin-colored, or violaceous cutaneous annular plaque, nodule, or papule with an elevated border.[48]

Fewer than 30 cases have been described involving the eyelids and periorbital region.[1,6,7,8,25,48,49,50,51,52,53,54,55,56,57,58,59,60,61] The typical presentation is as a painless, flesh to yellow-tan-colored nodule present for 3 months to 4 years. Eyelid lesions most commonly involve the lateral aspect of the upper eyelid and the lateral canthal region but can show a more diffuse distribution of small multiple nodules (Figure 65.1). Females predominate in a ratio of 3:1, and in 40% of reported cases, the patients are of African heritage. The age range is from 2 to 69 years, with a mean age at presentation of 21 years. However, two-thirds *(Print pagebreak 429)* of cases are younger than 18 years, and the median age is 11 years old. Lesions typically present as small 1 to 5 mm diameter nodules, but in rare cases can be up to 1.5 cm. In 40% of reported cases, lesions can be multiple on the same eyelid, and in 35%, they can be bilateral.

Eyelid lesions may be limited to the ocular adnexa, but similar lesions can concurrently be present on the extremities or trunk.[5,24,61] Other areas of ophthalmic involvement include the episclera,[6,62] orbit,[63] and choroid,[64] and one case was located beneath the periosteum of the orbital rim.[25] GA rarely can be associated with uveitis, retinal vasculitis, and cystoid macular edema with permanent decreased visual acuity.[65,66,67]

Differential Diagnosis

Periorbital GA can mimic many different lesions and the differential is broad because lesions do not always demonstrate the characteristic annular pattern.[68] The diagnosis usually becomes clear only after histologic examination. The most important lesions in the differential are malignant tumors, with basal cell carcinoma representing the most frequent misdiagnosis. Other lesions include eosinophilic granuloma, solitary fibrous tumor, rheumatoid nodules, systemic lupus erythematosus, sarcoidosis, tinea, nummular eczema, psoriasis, verruca vulgaris, granulomatous mycosis fungoides, chalazia, epidermal inclusion cyst, papilloma, pyogenic granuloma, nevus, pilomatrixoma, neurofibroma, and infection.[7,8,9,53,69,70,71] Basal cell carcinoma usually occurs in older adults, and typical lesions have a raised pearly border with a central cratered ulcer. Eosinophilic granuloma usually has typical although somewhat variable features. Like GA, it usually presents in the first decade of life as a tender, erythematous swelling in the superotemporal aspect of the orbit. Solitary fibrous tumor is more common in adults located in the orbit, but can occasionally be seen in the eyelid. It presents as a painless soft to hard diffuse slow-growing mass. Rheumatoid nodules are a common extra-articular manifestation of rheumatoid arthritis. They usually have a characteristic appearance as a well-defined, nontender, firm to hard, mobile subcutaneous mass. Cutaneous systemic lupus erythematosus rarely involves the periorbital skin. It is more common in middle-aged adults and presents as a pink to violaceous, unilateral erythematous swelling, mostly occurring in the upper eyelid. Sarcoidosis is a major cause of inflammatory eye disease. It can involve any ocular or periocular tissue. Eyelid lesions usually present as one or more irregular, firm subcutaneous nodules associated with multiple conjunctival granulomas, uveitis, episcleritis/scleritis, optic neuritis, and enlarged lacrimal gland. Tinea faciei is a fungal infection most often seen in children with an animal contact history. The leading organisms responsible are *Trichophyton mentagrophytes, Trichophyton verrucosum,* and *Microsporum canis*. The lesions start as a well-demarcated annular erythematous scaly patch, which progresses to a confluent thick-crusted plaque with purulent discharge over a period of days. A chalazion is a noninfectious inflammatory lesion of sebaceous glands, typically presenting as a painful, erythematous mass in the eyelid tarsus. The diagnosis is usually easily made, although some lesions may have an atypical presentation that is more diffuse with breakdown of the superficial skin or extension onto the conjunctiva.

Treatment

GA lesions are benign and often self-limited. Approximately 50% of cases resolve spontaneously within 2 years so that treatment is often not necessary.[72,73] When symptoms are present or lesions are of cosmetic concern, a number of treatment options have been used. These include local surgical excision, cryotherapy, laser ablation, intralesional corticosteroids, and psoralen plus ultraviolet A (PUVA) light therapy. However, there is no generally accepted treatment and results have yielded varying degrees of success.[24] Localized GA is most commonly treated with topical or intralesional corticosteroids.

Efficacy or optimal dosing regimen has not been established,[30,74] and steroids carry a risk of local skin atrophy and pigmentation alterations. Cryosurgery is another option and has been reported to result in the resolution of lesions with only one treatment.[75] However, there is a risk of localized pain, pigmentary changes, and scar formation during treatment. Topical

tacrolimus 1% ointment twice daily also has been reported to be successful.[50,76,77,78] Intralesional recombinant interferon gamma has been reported to be successful, but as with steroids, the optimal dosage has not been established.[79]

Phototherapy with local PUVA therapy is another option. Treatment four times a week for 17 to 40 treatments has shown partial or complete response in patients who have failed topical corticosteroids.[80,81,82]

Only a small number of reports have used laser ablation for GA.[73,83,84,85] In a series of 59 lesions in 13 patients, Passeron et al. reported >50% clearance in 56% of localized GA and 14% of generalized GA. There was a 17% recurrence rate after 6 to 12 months.[86]

Intravenous infliximab has been used successfully for generalized GA,[87,88] and adalimumab at an initial subcutaneous dose of 80 mg followed by 40 mg every 2 weeks has also resulted in positive response in several case reports.[89,90,91] Imiquimod 5% cream applied once a day for 6 to 12 weeks was reported to achieve complete resolution of GA lesions in four patients with no recurrence after a follow-up of 10 to 19 to 8 months.[92]

Prognosis

The prognosis for GA is generally excellent. It usually is self-limited over months to several years, but in about 20% of patients, lesions can recur in the same location, and in 15% to 40%, they can develop elsewhere on the body.[5,6,48]

Histopathology

There are three histological patterns of cutaneous GA: palisading granulomas, interstitial histocytes, and epithelioid (sarcoidal) nodules.[93] All patterns have normal epidermis.[34,94] *(Print pagebreak 430)* Pathological abnormalities localize to the middle and upper dermis.[93,94] Umbert and Winkelmann identified palisading granulomas in 53 of 207 (26%) cases of GA: histiocytes and lymphocytes surrounded altered collagen with their long axes perpendicular to the collagen bundles (Figure 65.2A and B).[93] Altered collagen, often termed "necrobiotic," may exhibit fragmentation of collagen bundles into fibrillary clumps; hyalinization with loss of discernible fibrillary structure in collagen bundles; basophilia with loss of distinct collagen bundle outlines accompanied by basophilic staining of the same area; sclerosis featuring densely packed collagen with little separation between individual bundles, along with a normal or decreased number of fibroblasts; and vacuolar change having clear round spaces between collagen bundles.[34] Mucin (glycosaminoglycans) may be present in the zone of abnormal collagen,[34,93,94,95,96] though its amount varies widely. The mucin is light blue in sections stained with hematoxylin and eosin, and its presence can be confirmed using Alcian blue (Figure 65.2C) or colloidal iron stains. Wood and Beerman found a "*considerable quantity*" of mucin in 13 of 25 specimens using Alcian blue stain, and occasional strands or small foci of mucin in 6 other cases.[95] When mucin is plentiful, it helps distinguish GA from rheumatoid nodules and necrobiosis lipoidica, which usually, but not always, have only slight amounts of mucin.[95] Other features that may help to distinguish the palisading granulomas in GA from those in rheumatoid nodules or necrobiosis lipoidica are delineated in the review by Muhlbauer.[94]

The infiltrative or interstitial type of GA has collections of histiocytes "*scattered between and around collagen bundles and blood vessels in the papillary and mid dermis*."[96] This was the most frequent pattern in the study by Umbert and Winkelmann, occurring in 147 of 207 (71%) cases.[93] There is minimal necrobiosis, but pericollagenous mucin is present.[93] Clinical correlation is vital for diagnosing the infiltrative/interstitial form of GA.[93] Epithelioid nodules were identified in only 7 of the 207 (3%) cases of Umbert and Winkelmann.[93] The epithelioid nodules were composed of histiocytes and "*some giant cells*"[93] and have been deemed "sarcoidal."[34,96]

Dabski and Winkelmann compared the histological findings in biopsies from 100 patients with localized and 100 patients with generalized GA, with generalized GA defined as "*involvement of at least the trunk and the upper or lower extremities.*"[34] They identified collagen changes in 79% and 53% of localized and generalized GA, respectively.[34] Most biopsies had a mixture of histological patterns, though there were differences between localized and generalized GA. Localized GA had interstitial histocytes in 75% of patients, palisading granulomas in 57%, and sarcoidal nodules in 11%.[34] Generalized GA had interstitial histiocytic infiltrates in 88% of patients, palisading granulomas in 31%, and sarcoidal nodules in 18%.[34] Despite the differences observed, Dabski and Winkelmann could not identify a pattern or feature that would allow localized and generalized GA to be diagnosed on histological grounds alone.[34]

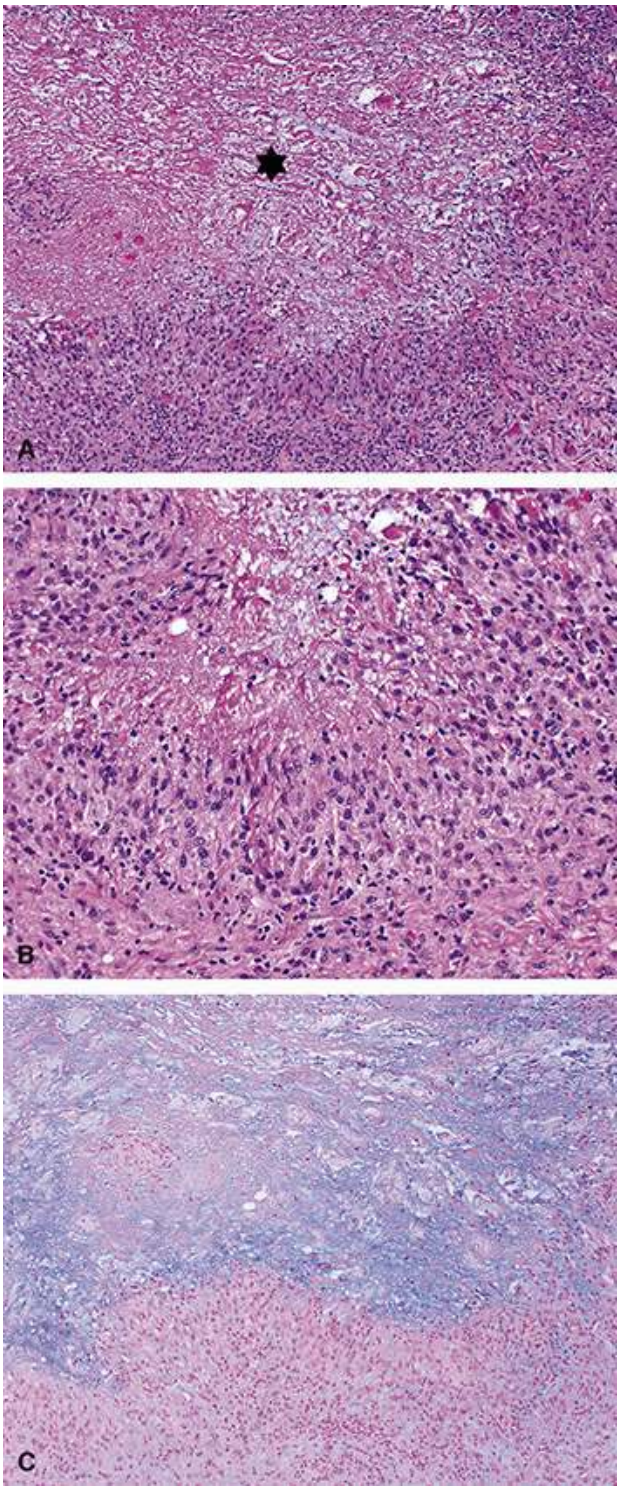

FIGURE 65.2 Granuloma annulare of the eyelid. A, A large zone of altered (necrobiotic) collagen (★) has fragmented collagen bundles, hyalinization, and basophilia. B, Palisading histiocytes and lymphocytes surround the necrobiotic collagen. The long axes of the histiocytes are perpendicular to the necrotic zone creating the palisading. C, Alcian blue stain highlights abundant mucin (glycosaminoglycan) accompanying the necrobiosis.

CHAPTER 66

Granulomatosis With Polyangiitis

Key Points

- Granulomatosis with polyangiitis (GPA) is a chronic multisystem vasculitic autoimmune disease that is more common in older white males
- It was previously referred to as Wegener granulomatosis
- GPA is part of the spectrum of ANCA-associated vasculitis (AAV)
- c-ANCA is positive in 85% of patients with generalized disease, but the figures are lower in patients with limited disease
- Roughly 10% of patients are ANCA negative, and another 10% are p-ANCA positive
- Eyelid findings include blepharitis, edema, entropion, ectropion, retraction, necrotic lesions, or nasocutaneous fistulas
- Orbital/sinus bony destruction on radiology should raise the clinical suspicion of GPA
- Sarcoidosis and orbital IgG4-related disease should be distinguished from GPA by clinical, radiologic, and serologic findings
- The relatively high mortality of the disease is attributable to disease-related organ damage, to the development of malignancies, and as a complication of treatment regimens
- Systemic immune suppression remains the cornerstone of therapy
- Cyclophosphamide or rituximab is used for induction of remission
- GPA is a chronic disease that may require years of long-term maintenance therapy
- Rituximab, azathioprine, or methotrexate may be used for maintenance therapy

Granulomatosis with polyangiitis (GPA, formerly called Wegener granulomatosis) is a multisystem autoimmune vasculitis of the small- and medium-sized blood vessels hallmarked clinically by a triad of necrotizing granulomas of the upper and lower respiratory tracts, small vessel vasculitis, and focal necrotizing glomerulonephritis.[1,2,3,4,5,6,7,8,9,10,11,12,13,14] The disease falls under the rubric of the antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV), a category of vasculitis that also includes eosinophilic granulomatosis with polyangiitis (EGPA, formerly called Churg-Strauss disease) and microscopic polyangiitis (MPA).[1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18] Following the discovery of ANCA in 1982,[15] AAV was identified as a separate entity usually characterized by ANCAs in the blood, which are directed against two main autoantigens, proteinase 3 (PR3) and myeloperoxidase (MPO).[5,6,9,14,16]

Etiology and Pathogenesis

The three main entities that constitute AAV (GPA, EGPA, and MPA) share the same underlying pathology with the involvement of small/medium-sized vessels (arteries, arterioles, venules, and veins) without the typical vessel wall immune complex depositions that hallmark primary systemic vasculitis.[5,6,7,8,9,14] GPA is a complex disease, and similar to most autoimmune diseases, the pathogenesis is multifactorial.[7] Although the exact etiology remains elusive, it has a strong underlying autoimmune diathesis, which usually develops in genetically predisposed individuals where infectious, epigenetic, and environmental factors all contribute to the full spectrum of the pauci-immune necrotizing vasculitis that is universally observed with these disease entities.[7,8,9,10,11,12,13,14] Although GPA, MPA, and to a lesser extent EGPA share fairly similar underlying etiopathogenetic events, orbital/periocular

involvement in EGPA is rare and is even rarer in MPA, which rarely if ever involves the orbit or the upper respiratory tract.[17]

The pathogenesis of GPA passes through three phases. First is the acute phase, in which an aberrant autoimmune response is generated. This phase is championed by an initiating agent, which may be infectious. This is followed by an active injury phase mediated by ANCA antibodies directed against PR3 and MPO autoantigens, the expression of which on the surface of neutrophils appears to be genetically determined. The final phase is the response-to-injury phase, which predominantly involves monocytes, macrophages, and T lymphocytes.[7]

During the acute phase, several exogenous and endogenous agents can initiate a pathological ANCA response. Microbial agents such as *Staphylococcus aureus* as well as the Ross River virus have been implicated in the pathogenesis of AAV, which is probably attributable to the molecular mimicry between these microbial peptides and ANCA autoantigens particularly PR3.[7,8] Drugs (propylthiouracil, cocaine, hydralazine, D-penicillamine, allopurinol, minocycline, and anti-TNF agents) and environmental factors (silica dust) can also trigger the development of GPA.[5,7,8,9,10,11,12,13,14]

During the active injury phase, neutrophils appear to be the major effector cells in the pathogenesis of GPA. Normally, *(Print pagebreak 434)* resting neutrophils have ANCA autoantigens (MPO and PR3) sequestered within the cell.[7] Upon exposure to an infectious or an exogenous agent, dendritic cells present the antigen to naïve T cells, which initiates a complex cascade of events that ultimately results in the priming of neutrophils, with the release of MPO and PR3 onto the surface of neutrophils as well as in the microenvironment around the cells.[14]

One of the quintessential steps in the pathogenesis of ANCA vasculitis is antigen presentation, and it is at this point in the pathogenetic cascade of AAV where genetic predisposition probably comes into play.[14] The genetic basis of GPA is undisputed and many of the genes described so far encode proteins that are involved in the immune response.[7,8,9,10,11,12,13,14,15,16] Genome-wide association studies have repeatedly provided evidence that the most convincing or strongest genetic association has been with major histocompatibility complex class II (MHC II) genes.[14,16] Susceptibility to GPA, therefore, is strongly associated with the expression of specific MHC II genotypes that are apt to present MPO or PR3 antigens to the immune system, which results in the production of ANCA.[14] Therefore, specific MHC II genetic traits correlate with certain types of ANCA autoantigens, which results in their increased membrane expression. Antibodies thus bind to the specific autoantigen presented at the surface of the cell, which ultimately directs the clinicopathologic expression of the disease.[5,7,14]

Although new associations between GPA and genetic polymorphisms continue to be reported and updated frequently in the literature, the HLA-DP locus has the strongest association with GPA.[19] Other genetic loci associated with GPA include SERPINA1 and PRTN3.[11,14] Animal models, clinical observations, and histopathologic studies have repeatedly demonstrated the central role played by ANCA antibodies in the pathogenesis of the disease.[7,8,9,10,11,12,13,14,15] The two major target antigens for ANCA autoantibodies in patients with AAV vasculitis are MPO and PR3, which are located within the granules of neutrophils, in the lysosomes of monocytes, and on the surface of neutrophils.[13] GPA is hallmarked by ANCA autoantibodies, which are more commonly directed against the PR3 and less commonly against MPO.[11] However, MPA is more commonly associated with MPO-ANCA than with PR3-ANCA.[11,12] Overall, about 10% of AAV patients are ANCA negative, a feature which is more commonly encountered in EGPA, where almost 30% to 50% of patients are ANCA negative, but the pathologic manifestations in ANCA-negative patients are similar to those of ANCA-positive patients.[7,11,12,20]

This binding of autoantibodies to primed neutrophils results in excessive activation of neutrophils.[7,14] Those activated neutrophils adhere to and penetrate vessel walls, and later undergo leukocytoclasis, a process whereby neutrophils undergo degeneration (karyorrhexis), with the formation of nuclear dust, subsequently releasing inflammatory cytokines, reactive oxygen species, and lytic enzymes in the extracellular milieu, and then the neutrophils finally disappear, to be replaced by mononuclear leukocytes including macrophages, monocytes, as well as T lymphocytes in later phases of the disease.[7,8,9,10,11,12,14,15,16,21] Furthermore, during the acute phase, the excessive activation of neutrophils by ANCAs induces the formation of neutrophil extracellular traps (NETs). The formation of NETs, which are a normal element of innate immunity, is a remarkable process by which neutrophils eject nuclear DNA impregnated with lethal antimicrobial agents into the extracellular space, creating what looks like a net trapping potential pathogens. NETs are subsequently eliminated later by an enzyme called the DNase I enzyme.[7,14] Although this is a normal physiologic process, if it exists in excessive amounts or if the NETs are insufficiently eliminated by the enzyme, NET formation in itself becomes harmful to small vessels. Interestingly, NETs are involved not only in ANCA-mediated vascular injury but also in the production of ANCAs by impairing DNase I activity; therefore, a NET-ANCA vicious cycle is accomplished, and further ANCA production is established, which contributes further to the pathogenesis of AAV.[7,14] Because ANCAs also bind to PR3 and MPO antigens on endothelial cells and other tissue sites of injury, ultimately, this entire process results not only in the apoptosis and destruction of neutrophils but also in the destruction of vessel walls and involved tissues.[5,7]

There is an ongoing debate as to whether GPA and MPA represent distinct diseases or are part of a single disease spectrum, but the consensus is that they are distinct autoimmune syndromes.[11,16] The abovementioned genetic data do support the notion that GPA does appear to be genetically distinct from MPO and other AAV-associated diseases. Confusingly, newer genetic data strongly

suggest that the HLA genomic signature of AAV vasculitides is strongly associated with ANCA specificity (PR3-ANCA vs MPO-ANCA) rather than the clinical manifestations (GPA, MPA, or EGP).[14,16] Whether this means a new classification of AAV is on the horizon remains to be determined.

Clinical Presentation

GPA has an annual incidence of 5 to 10 per million per year and a prevalence of 3/100,000.[22] The disease is more common in middle-aged white males older than 50 years, but it is rarely reported in children and the elderly.[17,23,24] Ocular/adnexal involvement is usually unilateral, but it may be bilateral in 14% to 58% of patients.[25,26,27] Ocular and adnexal disease is usually observed in up to 87% of generalized GPA patients at some point during their lifetime and may be the presenting feature of the disease in up to 16% of patients.[28,29]

The spectrum of symptoms varies from mild, nonspecific symptoms (ocular redness, eyelid swelling, epiphora, or inflamed eyelids) to more serious symptoms (painful proptosis, paralytic diplopia, or deterioration of vision). The more severe manifestations are the main presenting symptoms when the orbit is involved.[24,30,31]

GPA can be broadly classified into two distinct clinical presentations: limited (localized disease) and systemic or generalized disease.[26] It is currently unknown whether the *(Print pagebreak 435)* limited form of GPA is a subtype of generalized disease or is an entirely separate entity. Limited GPA is more common in the head and neck region including the orbit, and it also has a predilection for the upper respiratory tract, but it does not involve the kidneys. Some authors identify limited orbital/ophthalmic GPA as a separate entity that may or may not progress to generalized disease and maintain that this type is, in fact, more frequently encountered in the orbit than the generalized form.[17,23,26,31,32,33]

Ophthalmic and ocular adnexal manifestations are much more common in GPA than other ANCA-associated vasculitides like EGPA or MPA,[24] but eyelid involvement in GPA patients is relatively rare.[22] Patients with GPA may present with blepharitis with or without conjunctival chemosis, eyelid edema, ectropion, entropion trichiasis, necrotic lid lesions, and preseptal cellulitis and may rarely masquerade as a chalazion (Figure 66.1A-C).[24,26,31,34,35,36,37] The majority of patients with upper or lower eyelid edema may have an underlying orbital mass or dacryoadenitis.[31,34] Lacrimal gland enlargement may be one of the presenting features of the disease, and these patients usually present with mechanical ptosis together with an S-shaped eyelid deformity.[27] Ectropion is another early sign of the disease and usually signifies underlying bony destruction with loss of the structural bony support to the eyelids.[22] Tarsal findings include tarsoconjunctival necrosis, an early active fibrovascular proliferation of the tarsus, which may be followed by an inactive fibrous scar simulating trachomatous scarring in later stages of the disease.[28] This reparative scarring process ultimately results in symblepharon formation or frank tarsal deformities, which are the underlying cause of entropion and trichiasis that is occasionally observed in GPA patients.[28]

FIGURE 66.1 A-C, Granulomatosis with polyangiitis with eyelid erythema, edema, entropion, and periocular cellulitis. D, Nasocutaneous fistula in the medial canthus. (A-C, Courtesy of Dr. Charles Soparkar; D, Courtesy of Dr. Alan McNab.)

Ectropion may progress to one of the rarer cutaneous manifestations of GPA in the periocular region, that is *(Print pagebreak 436)* the development of a nasocutaneous fistula, which is more commonly observed in the medial canthal region. A nasocutaneous fistula usually develops as a result of the extensive advancement of an underlying sinus disease together with attendant bony destruction (destructive rhinosinusitis) (Figure 66.1D).[22] If a nasocutaneous fistula is still evolving, a Valsalva bubble test can be tried to support the diagnosis.[22]

Orbital involvement affects around 20% to 60% of GPA patients.[17,24] Patients may either present with orbital myositis, an orbital inflammatory disease with painful proptosis ("pseudotumor"), or an orbital infiltrating mass due to direct granulomatous orbital involvement.[24,27,30,38] Alternatively, secondary orbital involvement, extending from purulent or granulomatous inflammatory sinonasal disease, may also be observed.[23,38] This may manifest with globe displacement, eye movement restriction, or the formation of a nasoconjunctival fistula.[27] Lacrimal gland inflammatory enlargement may be acute, or chronic nonspecific, and is usually bilateral.[27] Dacryocystitis may also be observed in around 5% of patients.[27,39]

Ocular manifestations occur in around 30% of GPA patients and include conjunctivitis (52%), episcleritis (39%), marginal keratitis (7%), oculomotor nerve palsy (4%), scleritis (2%), or optic neuropathy (0.8%).[24,38,40] Of note is that scleritis usually manifests with sectoral vasodilatation of the deep scleral vessels in a typical crisscross pattern, which is not pathognomonic of the disease but may be highly suggestive.[24] Oculomotor nerve palsy is usually the result of compression by orbital tissue rather than being vasculitic in nature.[24]

Systemically, the clinical spectrum of GPA is broad. The presentation can be quite varied, ranging from a skin rash to fulminant multisystem disease, but typical features include upper respiratory tract involvement (95%), as well as renal impairment (75%).[1,26] Several disease activity scores such as the Birmingham Vasculitis Activity Score (BVAS) can act as a useful aide to record and measure disease activity, but these disease scores are complicated and require special training, so this job is beyond the context of ophthalmic practice.[1] Typical features of ear, nose, and throat manifestations in patients with GPA include nasal stuffiness and crusting or the occasional bout of epistaxis. Other features of GPA include the destruction of facial bones or soft tissues, which is highly suggestive of the disease, and if left untreated may lead to the development of a saddle-nose deformity.[22,27]

Because of the relative rarity of the condition and the nonspecific presentations, GPA usually poses a diagnostic challenge. Unfortunately, explicit diagnostic criteria are not available in the literature,[1,22] and the clue to the diagnosis may not lie in the eye or the periocular region. As a result, the diagnosis is generally based on a high index of clinical suspicion of a vasculitic condition, a positive ANCA serology, and histological evidence of necrotizing vasculitis.[22] The serological testing of ANCA is of utmost importance in the diagnosis and follow-up of GPA, as it is generally considered a sensitive and specific marker for the disease.[1,2,3,4,5,6,7,8,9,10,11,12,13,14] The two major types of ANCA have different cellular localization patterns that may be detected using indirect immunofluorescence on ethanol-fixed neutrophils.[14] Their nomenclature is prefixed (c-ANCA and p-ANCA) based on their immunofluorescence localization pattern.[17] The first fluoroscopic pattern that can be recognized is associated with diffuse cytoplasmic staining and is called c-ANCA, while the other type is associated with staining around the nucleus or perinuclear staining (p-ANCA).[14,41] Around 90% of c-ANCA is directed against PR3-ANCA, while 80% to 90% of p-ANCA is used to recognize MPO-ANCA.[17,22,41] The consensus is that c-ANCA (PR3-ANCA) is more commonly associated with GPA where it is observed in 85% of patients and is highly sensitive (91%), and specific (99%) for active disease as well, but the association is far from absolute as 5% to 10% of GPA patients are ANCA negative, and another 10% are p-ANCA positive.[22,41] However, p-ANCA (MPO-ANCA) positivity raises the possibility that the patient suffers from MPA. Of note is that in patients with limited forms of ANCA, ANCA positivity is lower than in generalized disease and varies between 32% and 67% of patients.[23,31]

Although ANCA levels are useful to monitor disease activity, they should not be used by themselves to guide treatment. The use of serial ANCA measurements as a tool to follow-up the treatment outcome during remission remains controversial,[1,14] nevertheless, a significant increase in ANCA titers, or the reappearance of ANCA, should alert the clinician to exercise a stricter control of the disease.[41] Besides ANCA, antinuclear antibodies as well as antiglomerular basement membrane antibodies should be ordered to exclude systemic lupus erythematosus and Goodpasture syndrome.[1] Other laboratory investigations include the assessment of kidney function (urea and electrolytes, with urine dip assessment, quantification of urine protein leak, and urine microscopy for red cell casts).[1]

Imaging (computed tomography) signs of sinonasal involvement that may help in establishing the diagnosis of GPA include opacification of the sinuses, sinus mucosal thickening, and bony changes, which include erosion or destruction of the sinus walls or turbinates. Destruction of the nasal septum and orbital walls may also be seen. Loss of the nasal septum is highly suggestive of GPA.[26]

Chest x-ray should be undertaken, but computerized tomography or magnetic resonance imaging may be more relevant to assess not just the chest but the brain, orbits, ear, nose, and throat structures as well.[1]

Differential Diagnosis

There are significant clinical, serologic, and histopathologic challenges that need to be addressed before a diagnosis of GPA is established; therefore, maintaining an open approach in the differential diagnosis is paramount. However, it is important not to rush to the diagnosis of GPA in any patient with vasculitis of uncertain etiology if the clinical findings and the *(Print pagebreak 437)* serological tests do not fit the typical features of GPA.[42] The diagnostic challenge is further exacerbated by the fact that the clinical manifestations of GPA can simulate many infectious, inflammatory, or neoplastic conditions.[38] Inflammatory or autoimmune diseases that may be confused with GPA are on top of the list of simulating lesions and include sarcoidosis, idiopathic dacryoadenitis, lymphoid hyperplasia, IgG4-related disease, sclerosing idiopathic orbital inflammatory disease, atypical thyroid eye disease, polyarteritis nodosa, Kawasaki disease, and very rarely CREST syndrome.[30,43,44] One differentiating feature that may help distinguish GPA from most of the abovementioned conditions is the presence of significant sinonasal pathology on imaging,[26] but in the end, a biopsy is usually required to clinch the diagnosis except in very rare situations when the clinical picture, radiologic findings, and serologic tests are strongly suggestive of a certain disorder like thyroid eye disease.[22]

Sarcoidosis in particular may cause a diagnostic dilemma. Clinical correlation with radiologic pulmonary involvement and angiotensin-converting enzyme levels can be helpful to establish the diagnosis, but only a biopsy is definitive. The presence of caseating granulomas on histopathology should raise the possibility of sarcoidosis.[43] There is considerable overlap between GPA and EGPA patients because they share the same small to medium vessel size pathology; however, in contrast to GPA, patients with EGPA typically present with a multisystem disease on a background of asthma, nasal polyposis, and peripheral blood eosinophilia, but orbital involvement is rare.[1]

Orbital IgG4-related disease should also be distinguished from GPA. The hallmark of this disease is an increase in IgG4-positive plasma cells, with reported IgG4 to IgG ratios that range from 30% to 90%.[43] Curiously, an increase in $IgG4^+$ cells or IgG4 to IgG ratios (greater than 40%) has been repeatedly reported in sinonasal or orbital/periorbital GPA biopsies, and this phenomenon may also be observed in other GPA biopsies from the head and neck region.[43,45,46] Although the significance of this finding is not yet known, this histopathological mimicry could cause a pitfall in the diagnosis of GPA. As these findings strongly suggest, an increased number of IgG4-positive plasma cells in an orbital biopsy is not enough evidence on its own to establish a diagnosis of orbital IgG4-related disease. Instead, complementary clinicopathologic information as well as additional histopathologic features of

IgG4-related disease such as the storiform fibrosis, dense lymphoplasmacytic infiltrate, and the paucity of inflammation, necrosis, microabscesses, or vasculitis may help rule out GPA.[43]

Some infectious etiologies (mycobacterial infections or invasive fungal sinusitis) should also be included in the differential diagnosis. Fungal infection is most commonly from *Aspergillus* or *Mucor* species, which can primarily involve the sinuses and secondarily invade the orbit especially in immunocompromised individuals, and it may be difficult to differentiate these infectious conditions from GPA. Several primary and secondary neoplasms, ranging from benign to malignant, need to be ruled out when considering a diagnosis of GPA, particularly orbital/adnexal lymphoma.[43]

Other causes of nasocutaneous fistulas should be excluded. The commonest cause may be iatrogenic due to thermal injury during transcanalicular laser dacryocystorhinostomy, or less commonly following external dacryocystorhinostomy. These fistulas are self-limiting and rarely require surgical intervention. Nasocutaneous fistula formation has also been reported after radiotherapy for sinonasal malignancy, following trauma to the periorbital region, frontal sinus disease, or tuberculosis.[22,47,48]

Because destruction of the nasal septum is a frequent finding in patients with GPA, other etiologies causing midline destructive lesions (previously called midline lethal granulomas) should be considered. The list includes non-Hodgkin lymphoma, foreign body, trauma, toxic agents (including cocaine), and infectious agents (fungal infections).[49]

It is important to consider the possible diagnosis of GPA in the differential diagnosis of any patient who presents with atypical lid edema.[31] Also, necrotizing fasciitis should also be excluded if the patient presents with eyelid necrosis.[36] Of note is that ANCA positivity may be found in a variety of conditions other than AAV, including inflammatory bowel diseases, other autoimmune diseases, and some infections, but the clinical significance is unclear.[41]

Treatment

In the presence of limited periocular disease, with no detectable c-ANCA levels, and no systemic disease activity, it may be difficult to recommend systemic treatment.[40] Topical corticosteroids may help reduce non-vision-threatening ocular surface inflammation.[34] Prompt referral to an ophthalmologist is mandatory for careful monitoring of the serious ocular complications that might be encountered during the disease. Orbital granulomas may not respond well to systemic chemotherapy and may require debulking or even orbital decompression.[34] Recently, the ultrasonic aspirator was successfully used to debulk an infiltrative orbital GPA mass because of limited surgical access.[50] Because of the small number of cases, the experience in treating eyelid and conjunctival GPA is limited.[40] Eyelid deformities such as ectropion, entropion, or eyelid retraction are treated according to the basic surgical principles.[34] A nasocutaneous fistula, if it occurs, is repaired with the appropriate flap.[22]

Control of systemic disease remains the cornerstone in the management of GPA.[22] From a therapeutic point of view, the traditional approach in the management of systemic AAV, particularly GPA and MPO, was to view both entities as a single group and treat them as such.[16] Treatment strategies and entry criteria for most major European and American trials have specified a general diagnosis of AAV and treated both conditions in a similar fashion.[16] There is an ongoing controversy whether both conditions (GPA & MPO) should be treated separately or not, and more recently, whether PR3-ANCA positive vasculitis and MPO-ANCA positive vasculitis should be treated as separate entities.[16]

(Print pagebreak 438)

Treatment regimens differ depending on the stage of therapy as drugs used in the induction of remission are different from the gamut of drugs used as maintenance therapy. In the majority of patients, induction using cyclophosphamide or rituximab should be considered as a first-line measure probably in all patients with new-onset GPA to effect long-term remission.[1] Although cyclophosphamide is considered the gold standard, rituximab has been successfully tested recently in two large randomized trials (the RAVE and RITUXVAS trials), with positive results comparable to cyclophosphamide.[3,4] In both studies, a single weekly infusion of rituximab (375 mg/m^2 of body surface area) was found to be equivalent to a daily dose of cyclophosphamide (2 mg/kg) for 6 months and even proved superior for relapsing disease.[3,4] Rituximab is preferred in more severe life-threatening disease, in patients at risk of infertility, or in patients with a past history of uroepithelial malignancy, while cyclophosphamide is reserved when there is no evidence of serious organ damage.[1] In patients who present with a creatinine of >500 µmol/L, plasma exchange may be performed, or high-dose glucocorticoids may be added to the regimen.[1] In a certain subset of patients with a milder initial disease with no evidence of serious organ damage or life-threatening conditions, an alternative induction regimen composed of methotrexate or mycophenolate mofetil may be prescribed.[1]

After remission, maintenance therapy should include a shift to azathioprine or methotrexate followed by their gradual taper until complete remission is achieved. Alternatively, rituximab could be continued while the glucocorticoids are tapered until

the patient is off treatment altogether.[1] It should be noted that the MAINRITSAN trial demonstrated that rituximab 500 mg given at days 0, 14, and then every 6 months until the 18th month was more effective in remission maintenance than azathioprine.[1]

The duration of the maintenance regimen is controversial because the early cessation of therapy earlier than 1 year after commencing treatment has been associated with a higher incidence of relapse[51]; therefore, the general advice is that maintenance therapy should continue for 18 to 24 months before being gradually withdrawn. In general, attempts at reduction of glucocorticoids should be made before tapering off the main immunosuppressive remission maintenance agent.[1,51] It should be noted that changes in ANCA alone should not be used as the sole indication to effect a change in therapy. Instead, ANCA measurement should be accompanied by a regular and structured clinical assessment.[1]

Prognosis

Before the advent of systemic chemotherapy, generalized GPA was a uniformly fatal or life-threatening disease, and carried a very poor prognosis, with a mean survival of only 5 months and 82% mortality within 1 year.[17,31] However, morbidity and mortality have improved dramatically with modern immunosuppressive therapy.[17,26] The 5-year survival rate for GPA is currently estimated to be between 74% to 91%.[1,2] This relatively high rate of mortality that is still being observed is not just due to organ tissue damage inflicted by the disease itself but is also due to the complications from the therapy, and because GPA has a twofold higher predisposition to malignancies (bladder cancer, keratinocyte carcinoma, leukemia, and possibly lymphoma) than the general population.[52,53] Profound immunosuppression, an immune system dysfunction, or a longstanding immune hyperactivation may be causally associated with the higher incidence of cancer.[52]

Following the popularization of cytotoxic drugs in the management of GPA, it became a chronic disease with remissions and exacerbations. Maintenance therapy is therefore continued until complete remission is achieved.[1,54] Remission is defined as the absence of detectable disease activity using a recognized scoring tool such as BVAS.[54]

The search for the ultimate biomarker that reliably predicts GPA relapses is still elusive,[55] although evidence suggests that patients in whom the initial ANCA level was more than fourfold the normal are at greater risk of relapse.[1] The risk of relapse is also greater in patients who are PR3-ANCA (c-ANCA) positive at presentation or those who continue to remain PR3-ANCA positive even after they switch from induction to maintenance immunosuppression.[1]

Histopathology

The histopathological features of cutaneous GPA are variable.[56] Leukocytoclastic vasculitis, observed in 31%[56] to 80%[57] of biopsies, is the most common histological finding (Figure 66.2).[56,57,58,59] The cutaneous leukocytoclastic vasculitis appears similar to that considered characteristic of GPA in other organs.[56] Vasculitis involving small arteries and veins and capillaries is most common in the superficial and mid dermis, but it may involve subcutaneous vessels.[56,57] Neutrophils infiltrate and destroy the vessel wall with nuclear dust production (Figure 66.2B).[58] Fibrin thrombi form in the vessel lumen with fibrinoid material in and around the wall accompanied by erythrocyte extravasation.[56,58,59] While leukocytoclastic vasculitis is characteristic of GPA, it is also found in other cutaneous vasculitides and is thus not diagnostic of GPA.[60,61,62]

About 10% to 20% of skin biopsies in patients with GPA have palisading granulomatous inflammation surrounding degenerating (necrobiotic) collagen (Figure 66.2C and D).[56,57,58,59] The cutaneous extravascular granulomas are similar to those seen in the orbit[63] and elsewhere[64] and often have leukocytoclastic debris within them.[59] As is the case with leukocytoclastic vasculitis, palisading granulomatous dermatitis is a nonspecific finding in GPA.[65,66,67,68]

GPA skin biopsies may also exhibit lymphocytic (Figure 66.2E and F) and granulomatous (Figure 66.2G and H) vasculitis. Granulomatous vasculitis is uncommon, reported in from 0%[56] to 10% of biopsies.[58] A similar granulomatous vasculitis may be seen in other disorders, such as sarcoidosis, metastatic Crohn disease, ulcerative colitis, hepatitis *(Print pagebreak 439)* C, and postherpetic eruptions.[61] Chronic dermatitis (31% of biopsies), acute inflammation without vasculitis (9%), nonspecific ulceration (4%), erythema nodosum (2.7%), and epidermal and superficial dermal necrosis without inflammation (2.7%) were other histopathological findings in the study of 75 biopsies from 46 patients reported by Barksdale and colleagues.[56]

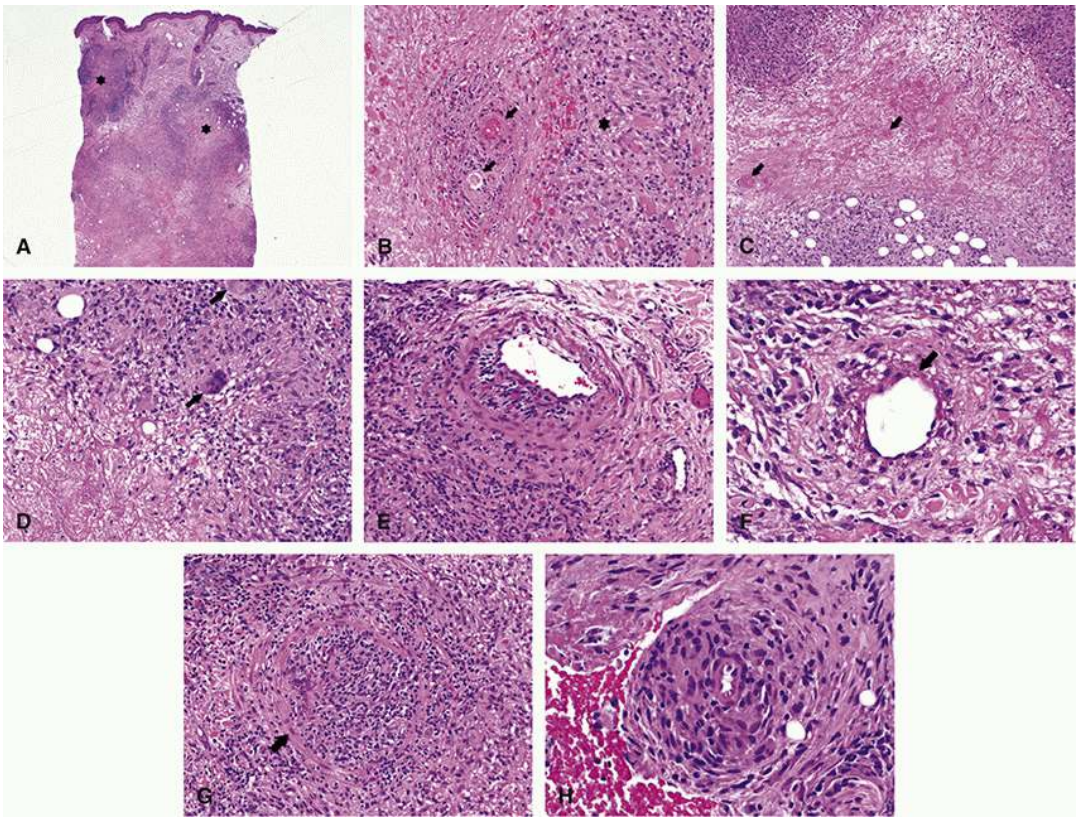

FIGURE 66.2 "Bumps" in the upper eyelid were the first manifestation of granulomatosis with polyangiitis (GPA) in this young woman. An increase in size and number of the nodules prompted this punch biopsy. A, At scanning magnification, the epidermis is normal while the superficial through deep dermis is inflamed. The most intense inflammation surrounds zones of necrosis (*). B, Palisading histiocytes (*) surround a zone of necrosis containing a small artery and vein with leukocytoclastic vasculitis (arrows). The small basophilic particles around the vessels are nuclear debris due to the disintegration of leukocytes. C, Palisading granulomatous inflammation surrounds a broad zone of collagen necrosis with several thrombosed small vessels (arrows). D, The palisading granulomatous inflammation consisted mostly of histiocytes, a lesser number of lymphocytes, and occasional multinucleated giant cells (arrows). E, This small artery has chronic lymphocytic vasculitis with lymphocytes infiltrating the tunica media and tunica intima. Lymphocytes and neovascularization expand the intima. The intimal neovascularization is indictive of chronicity. F, This small vein has lymphocytic vasculitis with fibrinoid necrosis (arrow). G, Granulomatous vasculitis is a rare finding in cutaneous GPA but is shown here involving a small artery (arrow). Lymphocytes and histiocytes disrupt the arterial wall and occlude the lumen. H, The wall of this small artery is effaced by granulomatous inflammation.

While there is no single histopathological feature diagnostic of GPA, the presence of leukocytoclastic vasculitis and/or granulomatous vasculitis together with palisading granulomatous inflammation should prompt clinical and laboratory evaluation for GPA. In Comfere, Macaron, and Gibson's study of 17 GPA patients with cutaneous manifestations, only 1 patient had a negative c-ANCA/p-ANCA at the time of cutaneous disease, and this became positive 1 year later.[59]

CHAPTER 67

Herpes Simplex Blepharitis

Key Points

- Herpes simplex is a virus transmitted chiefly by kissing or other forms of intimate contact
- Once the primary infection is over, the HSV-1 virus ascends in a retrograde manner to the trigeminal ganglion where it is sequestered from host immune surveillance
- When reactivated, it travels along sensory neurons to target sites in the eyelids, conjunctiva, cornea, or the uveal system and retina
- Recurrences may be spontaneous or predisposed by a variety of triggers including psychological stress; fatigue; exposure to heat, sunlight, or cold; menstruation or sexual intercourse; fever; diabetes; organ transplantation; immunosuppression; or corticosteroid administration
- Presentation is with an acute onset of eyelid swelling, erythema, and tenderness that may be associated with mechanical ptosis, tearing, or conjunctival follicles
- Eyelid infection may also present as erosive blepharitis with single or multiple eyelid margin ulcers or erosions
- The blepharitis is typically fleeting but HSV keratopathy can cause corneal scarring and blindness
- Systemic and local treatment of blepharitis is indicated in isolated cases to prevent spread to the cornea and conjunctiva
- Oral acyclovir is considered the gold standard of treatment
- Healing of isolated HSV blepharitis is the rule even without treatment but severe initial eyelid involvement is associated with more frequent recurrences

The family *Herpesviridae* has more than 100 viruses, but only 8 of which routinely infect humans. The herpes simplex virus types 1 and 2 (HSV-1 and HSV-2) belong to the α-herpesvirus subfamily. Both are ubiquitous pathogens that cause common infections with varied clinical manifestations in children as well as in adults. Although HSV-1 is a significant cause of corneal morbidity worldwide, herpetic cutaneous eyelid lesions due to HSV-1 or HSV-2 in neonates remain a minor concern.[1,2,3,4,5,6,7,8,9,10,11,12,13,14]

Etiology and Pathogenesis

HSV-1 and HSV-2 measure approximately 200 nm in diameter and contain a linear, double-stranded DNA core of approximately 150-kilo base pairs (Kbp) enclosed within a protein capsid. The DNA sequence of both HSV-1 and HSV-2 serotypes is similar but they are antigenically distinct because of a difference in the envelope proteins.[10] The majority of orofacial lesions are due to HSV-1 virus, while HSV-2 predominantly causes genital herpes. A notable exception is in neonates where exposure to HSV-2 during childbirth can result in the development of typical skin lesions during the first few days of life. It should be noted that both HSV-1 and HSV-2 are equally distributed in the trigeminal and sacral ganglia; therefore, the regional specificity of recurrent HSV infections is probably due to local host factors rather than a regional distribution of the latent virus.[12,14]

The chief mode of transmission is by kissing or other forms of intimate contact with an individual who has an active, usually recurrent, herpetic lesion, but asymptomatic patients shed the virus in the saliva as well, and accordingly are a more common source of infection.[10] Once the primary infection is over, HSV-1 ascends in a retrograde manner to the trigeminal ganglion, where the virus, which is now sequestered from host immune surveillance, safely replicates and establishes latency persisting in a dormant state for life. This predisposes the host to recurrent attacks of periodic viral reactivation. Once it is reactivated, the virus travels along sensory neurons to the target sites in the eyelids, conjunctiva, cornea, or the uveal system and retina.[10] These recurrences may

be spontaneous or predisposed by a variety of triggers including psychological stress; fatigue; exposure to heat, sunlight, or cold; menstruation; sexual intercourse; fever; diabetes; organ transplantation; immunosuppression; corticosteroid administration (oral, parenteral, topical, or even in inhaled form); and measles or HIV infection.[10,11,13,15]

Although direct viral toxicity to the eyelids is probably etiologically responsible for HSV blepharitis, the morbidity in primary HSV infections may also be immunopathogenic in origin.[7,8] After exposure to the viral antigen, there is a massive rise in the number of neutrophils (Gr-1$^+$ cells), which is the predominant infiltrating cell type and the likely source of inflammatory cytokines (IL-6, IL-10, IL-12, or IFN-γ), and therefore it could be a major effector of eyelid morbidity.[8] Shortly after that, the viral load begins to clear and CD4$^+$ T-cell count significantly increases in number. Although this immune response is essentially the same in the cornea and eyelids, it may play a different role in recurrent infections.[6] While an already primed immune system in recurrent HSV may cause an immune-mediated, potentially blinding stromal keratitis, the same immune mechanism may limit the spread of herpetic blisters in recurrent HSV, which may explain why herpetic blepharitis is an unusual occurrence in recurrent disease.[6,7,8]

(Print pagebreak 443)

Clinical Presentation

Incidence and prevalence data about HSV blepharitis are not directly available in the literature, but the data can be inferred indirectly from epidemiologic studies concerned with corneal HSV. Between 45% and 98% of the world population is seropositive for HSV-1,[12] the majority of whom are seroconverted by adolescence, particularly in children of lower socioeconomic groups.[13] Primary infections are typically subclinical and may go unrecognized, although they may be associated with constitutional signs and symptoms. However, even in the absence of symptoms, primary infections are associated with a longer duration of viral shedding.[12]

The first presentation of ocular HSV may not necessarily represent the primary site of infection in the body.[5,13] Clinical manifestations of ocular HSV may start at any age, but it generally is a disease of the young (mean age, 34 years). HSV-related blepharoconjunctivitis is one of the presenting signs in 35% to 54% of primary (initial) ocular attacks,[5,10,11,12,13] but monosymptomatic involvement of the eyelids and conjunctiva occurs only in 21% of patients.[10] However, recurrent HSV blepharoconjunctivitis is infrequent, and the incidence was as low as 4% in some studies.[2] The disease is predominantly unilateral, but bilateral occurrence is encountered in 7.5% to 29% of patients, particularly in children or in those with atopy.[13]

Two major presentations of HSV blepharitis are observed.[16] The classic presentation is with an acute onset of eyelid swelling, erythema, and a tingling sensation with local periocular tenderness in the involved side. This inflammatory swelling may cause mechanical ptosis if the upper eyelid is involved, or it may be accompanied by a red, tearing eye and conjunctival follicles if HSV simultaneously infects the conjunctiva (Figure 67.1).[6] This is quickly followed by the appearance of a cluster of relatively large umbilicated vesicles with a yellowish content that are usually grouped together with an underlying erythematous and edematous base along the eyelashes (Figure 67.2A-C). These vesicles eventually crust and then dry out causing spontaneous unroofing of the lesions.[5,17] In rare situations, particularly in atopic patients, these infections can be quite severe and could be secondarily infected. This is especially true when it is associated with eczema, where the condition has been termed eczema herpeticum (also referred to as Kaposi varicelliform eruption).[3,5] Regional lymph nodes are usually involved, and the condition may be associated with pathognomonic follicles around the mouth or the nasal cavity.

The second and reportedly more common type of eyelid infection is intermarginal HSV blepharitis (erosive-ulcerative type),[17] which is characterized by single or multiple eyelid margin ulcers or erosions each measuring 1 to several millimeters in length. These ulcers may be associated with localized swelling and tenderness but without the characteristic cutaneous follicular lesions or the acute inflammatory signs that hallmark the more typical presentation described above.[5,16,17,18,19] The absence of cutaneous vesicular eruptions on the palpebral surface and the presence of a crust that usually covers these lesions may make the diagnosis difficult.[18] If in doubt, staining the eyelid margin with fluorescein or rose bengal may help identify the ulcers and clinch the diagnosis.[18] Whether this is a distinct clinical type of HSV blepharitis or a normal sequela of deroofing of herpetic vesicles which later coalesce is unknown.[6] Of note is that the predilection of HSV to involve the eyelid margin is not unusual, and this is the typical behavior of a virus that favors orifices and mucocutaneous junctions.[18] Both forms of presentation (large blisters/eyelid margin ulcers) discussed above are a reliable sign of clinically manifest primary HSV blepharitis, since both are rare in recurrent disease, and even when encountered, they are usually observed in a milder clinical form.[6,17] As we mentioned earlier, this is likely due to immune reactions, which would limit the extent of HSV blepharitis.[6] Other rarer eyelid presentations include acquired entropion in children, complete acquired ankyloblepharon, and punctal or canalicular scarring.[15,20,21,22,23]

(Print pagebreak 444)

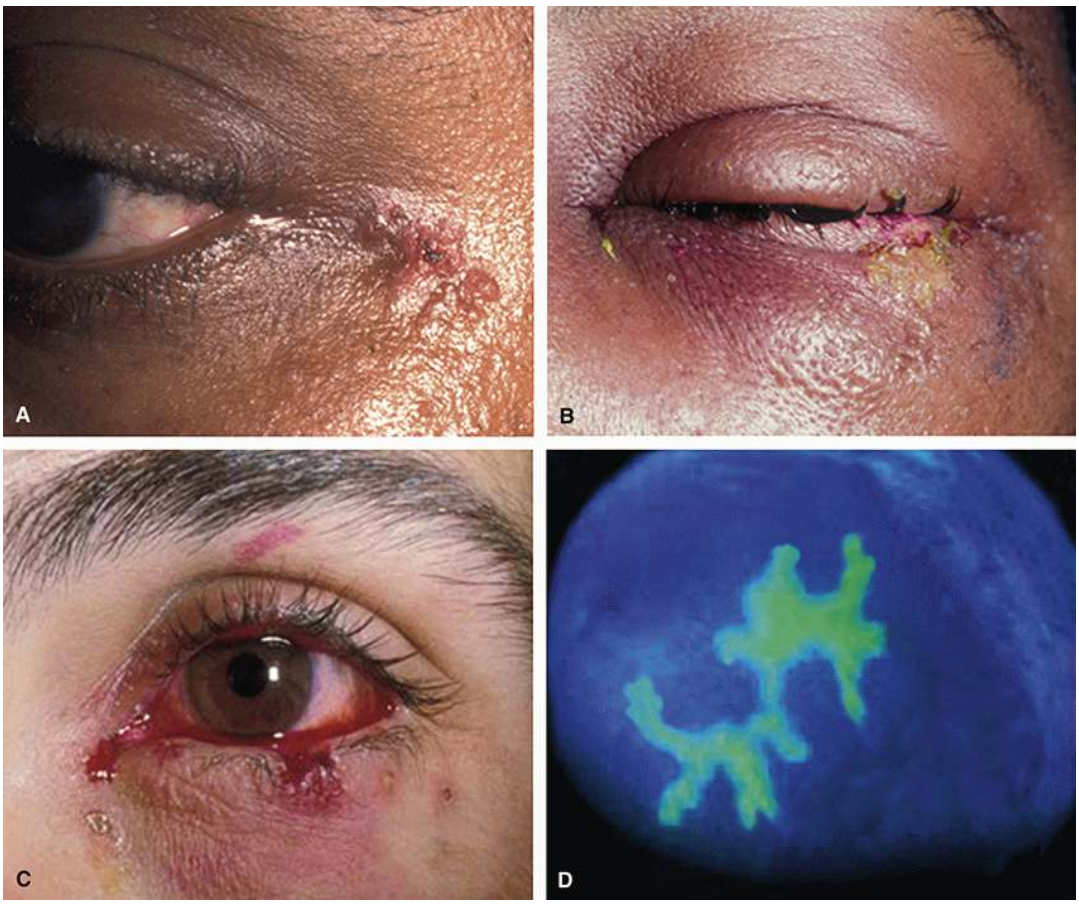

FIGURE 67.2 A-C, Herpes simplex eyelid vesicles and erosions. D, Herpetic dendritic keratitis. (A and B, Courtesy of Dr. Kenneth Cohen.)

While HSV blepharitis is typically fleeting and not of major clinical significance, HSV keratopathy is the hallmark of the disease and is a leading cause of corneal blindness.[3,4] HSV keratopathy takes many forms including epithelial disease (dendritic and geographic keratitis) (Figure 67.2D), stromal disease (stromal keratitis with or without ulceration), and endothelial disease (HSV endothelial keratitis or disciform keratitis).[13] Other rarer ocular presentations include scleritis, focal iritis, posterior uveitis, panuveitis, scleritis, trabeculitis, and glaucoma or retinitis.[17,24,25,26,27,28]

Laboratory investigations for the diagnosis of HSV are not routinely employed in clinical practice; however, if the diagnosis is in doubt, laboratory tests that could be ordered include electron microscopy, viral culture, cytological smear/Tzanck test, direct fluorescent antibody studies, tissue biopsy, or viral DNA detection by polymerase chain reaction (PCR).[12,20,29,30,31,32]

The Tzanck test is a rapid inexpensive diagnostic tool that is frequently employed by dermatologists where a smear is taken from the base of a freshly opened vesicle, stained by Papanicolaou or Giemsa stain, and examined under the light microscope. Positive smears usually show multinucleated giant cells and intranuclear eosinophilic inclusion bodies. Analysis of serum for anti-HSV antibodies may demonstrate high levels of IgM in patients with a primary infection, while elevated levels of IgG are suggestive of a nonprimary infection.[12,30,31] Herpes simplex vegetans is a rare variant of cutaneous HSV infection that can occur in immunocompromised patients (Figure 67.3). This can present as exophytic exudative or ulcerated growths that may mimic a cutaneous malignancy. These have occurred on digits, genitalia, and oral mucosa, and two cases were reported on the eyelids.[33,34] These lesions present as irregular, weeping, ulcerated, fungating masses with madarosis, and conjunctival inflammation.

Differential Diagnosis

HSV blepharitis can occasionally acquire a dermatomal distribution and may mimic herpes zoster virus lesions (zosteriform herpes simplex). If the characteristic HSV epithelial keratitis is absent, establishing the diagnosis may be difficult *(Print pagebreak 445)* and PCR may be needed to identify the specific causative virus because the Tzanck smear cannot differentiate a simplex from a zoster infection.[12,13,35,36] Patients with zosteriform herpes simplex should also be checked for HIV status.[37] Although both respond to the same antivirals, the distinction is important because the concentration of acyclovir, which is needed to inhibit the zoster virus, is 10 times more than what is needed to inhibit HSV.[37] Molluscum contagiosum typically presents with self-limiting dome-shaped papules that take 12 to 18 months to disappear. Acute inflammatory signs are generally absent in molluscum contagiosum except in HIV patients, and although central umbilication is a feature shared by both HSV and molluscum, it is more pronounced in patients with molluscum contagiosum (see Chapter 88, Figure 88.2).

FIGURE 67.3 Herpes simplex vegetans in a patient with congenital T-cell immunodeficiency. (Reprinted with permission from Blieden LS, Chévez-Barrios P, Yen MT. Herpes simplex vegetans presenting as an eyelid mass. *Ophthalmic Plast Reconstr Surg*. 2011; 27:e58-e59.)

In neonates, the use of gentamicin ophthalmic ointment is associated with the development of cutaneous eyelid ulcers simulating intermarginal HSV. A negative PCR can help establish the diagnosis.[29]

A bacterial rash on an eczematous skin area may also be difficult to discern from eczema herpeticum, and laboratory investigations to identify the infectious agent may be needed.[17] In rare situations, HSV blepharitis may need to be differentiated from staphylococcal blepharitis if it presents acutely with folliculitis. Loss of the eyelashes, which is not infrequently observed with staphylococcal blepharitis, is never a typical sign of HSV blepharitis. In addition, the infective pustules in patients with staphylococcal blepharitis lack umbilication.[17] Because of its rarity, HSV blepharitis may also be confused with the more ubiquitous meibomian gland dysfunction (MGD), but the chronicity and delayed age of onset, in addition to the absence of umbilicated vesicular eruptions on the cutaneous surface of the eyelid, may help establish a diagnosis of MGD.[3]

Treatment

Some authorities believe that no therapy is needed in patients with monosymptomatic HSV blepharitis since these lesions usually heal spontaneously, provided that eye rubbing is avoided. Rubbing or scratching can induce a mechanical injury that can cause exogenous HSV particles from the skin lesions to force their way into the corneal surface.[17] Of note, however, is that corneal disease more commonly develops simultaneously from the endogenous spreading of the virus to the ocular surface rather than from a surface superinfection.[17]

However, systemic and local treatment in monosymptomatic blepharitis is indicated in (1) isolated severe primary HSV blepharitis to prevent the spread of HSV to the cornea and conjunctiva, (2) in atopic patients with eczema herpeticum or intermarginal HSV, (3) in AIDS patients, or (4) in children where avoidance of eye rubbing cannot be ensured.[17,18] The situation is different when HSV blepharitis is associated with ocular disease where therapy is unequivocally required, and in such situations, therapy is tailored to the specific condition at hand.[17]

There are no clinical trials documenting the efficacy of oral antivirals in monosymptomatic HSV. However, if therapy is indicated in patients with isolated eyelid disease or patients with blepharoconjunctivitis, oral acyclovir (400 mg, 3-5 times/d orally for 5-7 days) is considered the gold standard of treatment.[17] Acyclovir is well tolerated by patients, has a good safety profile, and is also available in injectable form. However, because of its poor bioavailability and short plasma half-life, frequent daily dosing is required.[12] In patients with eczema herpeticum, therapy should be initiated with a maximal dose of oral antiviral agents (acyclovir 800 mg, 5 times/d), which is later reduced to 400 mg 5 times/d for at least 2 more weeks after the onset of healing.[17]

Other alternatives include penciclovir, valacyclovir, famciclovir, foscarnet, or cidofovir. Penciclovir has a longer half-life but is much less potent. Valacyclovir is a prodrug of acyclovir, which has up to five times greater bioavailability and subsequently requires less frequent dosing, and famciclovir has pharmacokinetic properties comparable to penciclovir.[12] Foscarnet is available in injectable form only and is indicated in immunocompromised hosts if the infection is resistant to acyclovir. Cidofovir is another antiviral agent that is indicated in patients with a double resistance to acyclovir and foscarnet.[12]

The use of topical agents in the management of HSV blepharitis is supported only by anecdotal reports[15,16,18,19,23]; however, topical therapy may be indicated if there is associated conjunctivitis or epithelial keratitis. Local treatment may especially be of value in cases presenting with intermarginal HSV and in eczema herpeticum. In the intermarginal HSV subtype, local antiviral agents have unrestricted access to the viral particles through the exposed ulcer and therefore logic dictates their use.[18] Eczema herpeticum should be aggressively treated not just with antivirals but with thorough local wound care and prophylactic topical antibiotic therapy as well to prevent secondary bacterial infection.[5,15] Topical *(Print pagebreak 446)* ophthalmic preparations include acyclovir 3% eye ointment, topical trifluridine 1% solution, and ganciclovir 0.15% ophthalmic gel, while topical skin preparations include acyclovir 5% cream, docosanol 10% cream, or penciclovir 1% cream. Topical ophthalmic preparations like acyclovir 3% eye ointment (5 times/d) may be the safer option for cutaneous periocular application.[1]

Prognosis

Cellular antiviral immunity is potent in the dermis and spontaneous healing of isolated HSV blepharitis is the rule even without the use of topical or systemic antivirals, which allegedly have no impact on the healing course.[17] The type and severity of the initial eyelid involvement may have a prognostic value. Severe initial eyelid involvement is associated with more frequent recurrences.[1,10] Intermarginal HSV blepharitis is of central importance not just because its presence is pathognomonic of primary HSV but because it is prognostically important as well, as it is also a predictor of more ominous anterior segment eye disease.[6,17] Eczema herpeticum is also of prognostic importance and is considered one of the dermatological emergencies as it is associated with a mortality rate of 6% to 10% if not treated, and may rarely progress to viral encephalitis.[38]

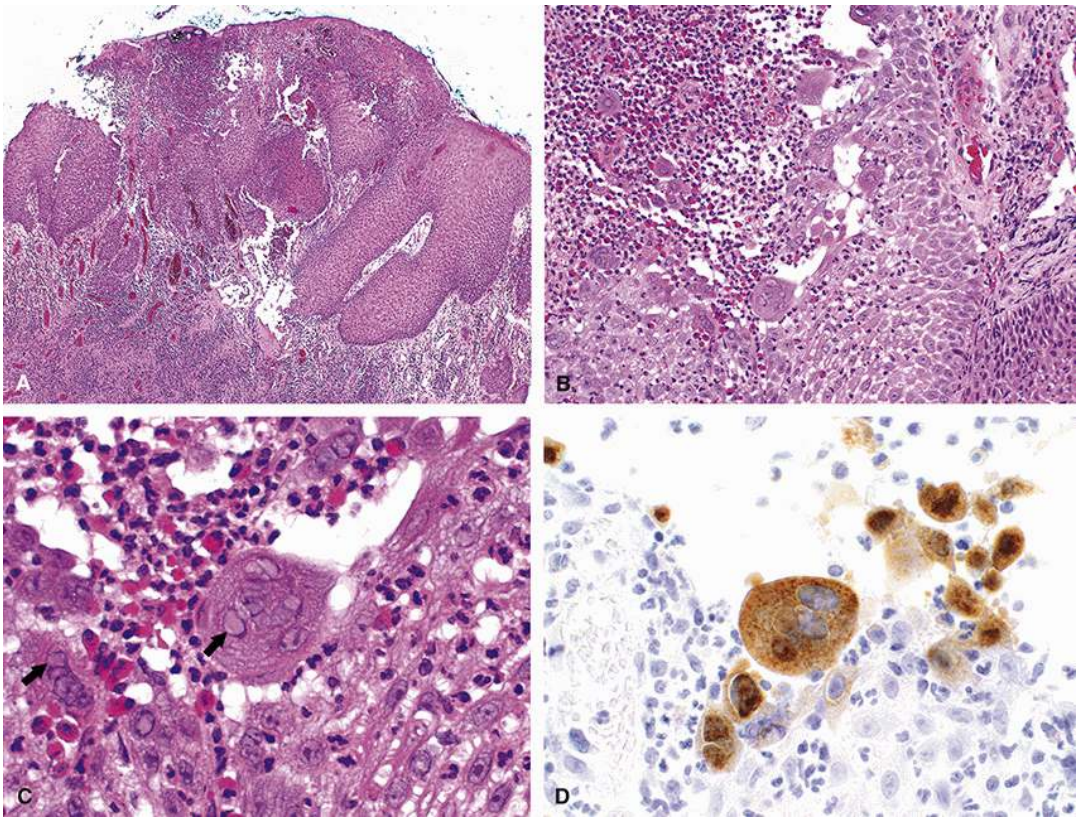

FIGURE 67.4 A, This herpes simplex virus (HSV) skin lesion preceded conjunctival and medial canthus HSV infection in a patient with HIV infection. The epidermis is ulcerated and acanthotic, and there are intraepidermal and subepidermal vesicles. The dermis has a marked infiltrate of lymphocytes, plasma cells, macrophages, and scattered eosinophils. B, The area of epidermal ulceration has infected keratinocytes mixed among numerous neutrophils. The infected cells are larger than the normal keratinocytes and have lost their cohesion with each other. C, Two enlarged, multinucleate, infected keratinocytes have eosinophilic nuclear inclusions (arrows). D, Immunohistochemical staining using antibodies specific for HSV antigen confirms the diagnosis. The infected cells are brown, while adjacent keratinocytes and inflammatory cells do not stain.

Histopathology

The histological features of skin infections by HSV (Figure 67.4), varicella, and herpes zoster virus are similar.[39,40,41,42,43] In HSV, the earliest changes are seen in the epidermal cell nuclei, which enlarge, develop a homogenous “ground glass” appearance, and have peripherally clumped chromatin.[44] Changes begin along the basal epidermal layer and progress to involve all *(Print pagebreak 447)* layers. Intraepidermal vesicles soon form secondary to ballooning and acantholysis of keratinocytes. Subepidermal vesicles may result from the destruction of the basal layer of the epidermis. Multinucleated keratinocytes are more conspicuous in lesions that have been present for several days. The histopathological clue to the diagnosis is eosinophilic nuclear inclusions, which are more common in the multinucleated cells. Diagnosis is confirmed using immunohistochemistry.[39]

In addition to the epidermal changes, HSV may infect hair follicles, sebaceous glands, and, more rarely, eccrine glands.[39,42] The histological changes of herpetic infection of dermal structures may occur in the absence of classic changes in the epidermis.[39,42] Dermal inflammation usually accompanies herpetic skin infections and may mimic lymphoma.[39,41,42]

CHAPTER 68

Herpes Zoster Ophthalmicus

Key Points

- The varicella-zoster virus is one of the three members of the α-herpesvirus subfamily and is the etiologic agent of varicella (chickenpox) and herpes zoster (shingles)
- Virus spread is believed to occur during childhood through the respiratory tract, where viral particle replication begins in the nasopharynx
- Viremia then progresses to the skin leading to the development of chickenpox, after which a latent infection develops in sensory neurons in the dorsal root ganglia
- Once reactivation occurs, the virus can move down the neurons to the skin where it triggers a local inflammatory immune response
- Eyelid lesions appear on or near the eyelid margin in the V1 dermatome. Various stages of evolution include a preeruptive phase, an acute eruptive phase, and a chronic or relapsing phase
- Ocular disease may include conjunctival injection, chemosis, and edema, scleritis, episcleritis, limbal vasculitis, punctate epithelial keratitis, anterior uveitis, or a transient palsy of the third, fourth, or sixth cranial nerves
- Treatment begins with oral acyclovir, valacyclovir, or famciclovir
- Between 10% and 12% of patients with HZO will develop vision impairment within 6 months from corneal scarring
- Postherpetic neuralgia is a major postinfection complication

The varicella-zoster virus (VZV) is one of the three members of the α-herpesvirus subfamily[1,2,3,4,5,6,7,8,9,10,11] and is the etiologic agent of two clinically distinct diseases: varicella (chickenpox) and herpes zoster (shingles). While a primary VZV infection causes chickenpox, reactivation of the latent virus, which usually occurs in adults, causes herpes zoster, manifesting as a vesicular rash with a dermatomal distribution and acute neuritis.[1,2]

Etiology and Pathogenesis

Like other members of the alphaherpesvirus subfamily, the VZV (also termed the human herpesvirus type 3) is an enveloped virus that has double-stranded DNA, a short reproductive cycle, the potential to cause major host cell destruction during active replication, and the ability to establish lifelong latency in sensory neural ganglia.[7] Several different genotypes vary geographically.[7]

The initial virus spread is believed to occur during childhood through the respiratory tract, where viral particle replication begins in the nasopharynx. Viremia then progresses from the nasopharynx to the skin through lymphatic spread leading to the development of varicella (chickenpox), which is characterized by an initial generalized rash, after which a latent infection develops in sensory neurons in the dorsal root ganglia.[7] T cell-mediated immune mechanisms keep the VZV in check within these sensory ganglia as evidenced by the fact that once the T cell-specific immunity is below a certain level, a person is at risk for VZV reactivation.[7,8]

Although the virulence of the specific strain that primarily infects an individual may have a pathogenetic impact, local host factors play the predominant role.[8] Established predisposing factors include old age, immunosuppression, pregnancy, and HIV infection. Certain malignancies, and lymphoproliferative disorders can compromise virus-specific cellular immunity causing a reactivation and replication of the latent virus that spreads through sensory neurons causing zoster (shingles) and zoster-associated pain (ZAP).[7,11]

Herpes zoster not only develops in individuals who have already contracted the virus through community-acquired infections (wild-type varicella) but also can occur through varicella vaccination in childhood (vaccine-type VZV).[8] Herpes zoster ophthalmicus

(HZO) occurs when VZV reactivation occurs in the ophthalmic division of the trigeminal nerve (V1).[9] Once reactivation occurs, the virus can move down the neurons and satellite cells along sensory axons to the skin. Virus spread results in viremia and triggers a local inflammatory immune response in the sensory nerves and the skin.[8,9] Therefore, the pathophysiology of acute and long-term complications of adnexal as well as ocular HZO may not solely be attributable to viremia, but immune mechanisms and tissue inflammation play a role as well.[8] Reactivation of the virus occurs repeatedly throughout the patient's life, but some of these reactivations may be subclinical, which helps to boost the immune response to VZV.[9]

Clinical Presentation

The mean age of onset of chickenpox is around 4.5 years (range, 4-13 years), but the incidence has sharply declined due to routine vaccination.[12] Following a brief (24-hour) period of prodromal symptoms, the rash rapidly develops *(Print pagebreak 449)* and quickly evolves. Although ocular involvement is seen in only 4% of chickenpox patients,[13] in those with ophthalmic symptoms, eyelid manifestations predominate and are seen in 62.5% of cases.[14] The eyelid lesions usually appear on or near the lid margin and are morphologically similar to the typical varicella vesicles elsewhere in the body.[14] They may be observed in various stages of evolution (vesicle, papule, or scab) surrounded by a distinct red base. But in contrast to the rash elsewhere in the body, the eyelid lesions are usually isolated rather than grouped.[14] Eyelid lesions heal without sequelae within 2 weeks.[1,7,12] Other ocular manifestations are rare but punctal and canalicular stenosis, dacryocystitis, conjunctivitis, disciform keratitis, iridocyclitis, panuveitis, glaucoma, cataract, chorioretinitis, neuroretinitis, optic neuritis, optic atrophy, and internal ophthalmoplegia also have been reported.[12,13,14,15,16,17] Although the disease is mild and self-limiting in most cases, it can have devastating consequences in immunocompromised hosts or during pregnancy.[7,12]

Out of the one million newly diagnosed cases of herpes zoster estimated to occur annually in the United States, HZO constitutes 10% to 20%,[9,18,19,20] and for the past 2 decades, the incidence of HZO has been rising at an alarming rate (3.6% per year).[20] The cause of this trend is unknown, but it is hypothesized that mass varicella vaccinations in children may have reduced the exposure to wild-type varicella in the general population.[20] Other alternative explanations include a rise in the number of patients with immunocompromised conditions, an improvement in health-seeking behavior, and an increasingly aging population.[8,20] HZO is indiscriminate of gender and has no seasonal preference, although the incidence and severity rise with increasing age, especially in patients older than 60 years. Age is a predictor of the severity of acute pain that accompanies HZO. More importantly, postherpetic neuralgia (PHN) is estimated to develop in 36.6% and 47.5% of patients older than 60 and 70 years, respectively.[8,21] A notable exception to this rule is in patients with an HIV infection where the age of onset of HZO is usually less than 50 years, although other factors causing immunosuppression could also be associated with a younger age of onset.[22]

The clinical manifestations of HZO are divided into three phases: a preeruptive phase, an acute eruptive phase, and a chronic or relapsing phase. The preeruptive phase is characterized by neuropathic pain, which is often described by patients as burning, tingling, or shooting in nature. The pain initially is mild, then gradually rises in crescendo, and usually follows the distribution of the ophthalmic division of the trigeminal nerve (V1). The pain may or may not be accompanied by viral prodromal symptoms.[9]

Following the preeruptive phase, the rash begins to appear.[8] The skin eruptions associated with acute HZO can be highly variable in severity and extent; however, the frontal nerve, which innervates the scalp, the forehead, and the upper eyelid, is almost invariably affected in all patients.[23] It is also the site where the most severe skin lesions are observed, while skin lesions at the nasociliary dermatome are seen less frequently, in 60% of patients.[23] The two terminal branches of the nasociliary nerve, the external nasal and the infratrochlear nerves, may be involved either alone or together.[23] Hutchinson sign is the acronym given to papulovesicular lesions on the side and top of the nose due to involvement of the external nasal nerve.[8,10,23] Clinically, the acute skin rash varies from a few scattered maculovesicular skin lesions (Figure 68.1) to severe confluent, hemorrhagic bullous eruptions,[23] and new skin lesions continue to appear for 3 to 5 days. The rash of HZO evolves through the same stages as the disease elsewhere in the body, with erythema, macules, papules, and vesicles, which subsequently pustulate and crust (Figure 68.2).[8] Periorbital edema and ptosis are commonly observed, and in some patients, both eyelids are severely edematous to the extent that the palpebral fissure can hardly be opened for ocular inspection.[24] Other adnexal manifestations include punctal and canalicular stenosis or even dacryocystitis.[25,26]

Once a skin rash appears in the V1 dermatome, ocular symptoms should be expected to develop after 1 to 4 weeks. However, the term HZO is not synonymous with ocular involvement,[27,28] and only 50% of HZO patients will suffer ocular involvement.[8,27,29] Ocular disease may be acute or chronic and takes many forms. It may involve the conjunctiva (injection, chemosis, boggy edema), the sclera (scleritis, episcleritis, sclerokeratitis, or limbal vasculitis), the cornea (punctate epithelial keratitis, transient pseudodendrites, nummular anterior stromal keratitis, lipid keratopathy, and keratouveitis or endotheliitis), uveal tissue (anterior uveitis, sectoral iris atrophy), and may result in glaucoma, or a transient palsy of the third, fourth, or sixth cranial nerves.[7,8,9,30,31] The retina may also be involved, albeit rarely. Posterior segment problems include retinal perivasculitis, ischemic optic neuritis, acute retinal necrosis, or progressive outer retinal necrosis. Orbital apex syndrome and potentially blinding acute optic neuritis also have been reported.[8,27,29,32]

Ocular and adnexal chronic sequelae of HZO can persist in 30% of HZO patients, but it is seen more frequently (70%) in patients older than 80 years.[8] Patients with chronic HZO may suffer from residual ptosis, entropion, ectropion, eyelid scarring, or even eyelid necrosis with resultant lagophthalmos or permanent depigmented scars in the eyelid or on the forehead (Figure 68.3).[8,33] Most of these complications are seen rarely today and predate the acyclovir era.[24] Cicatricial eyelid changes may lead to exposure keratopathy and subsequently corneal desiccation. The picture is compounded by corneal nerve damage, which is inherent to HZO and leads to neurotrophic keratopathy, characterized by decreased corneal sensation with subsequent loss of corneal epithelial integrity, and the development of sterile epithelial defects that may become secondarily infected.[7,8] Postherpetic neuralgia is one of the chronic sequelae of HZO that may negatively affect the quality of life and could lead to serious disability. It preferentially affects the elderly and the immunocompromised, and patients often experience recurrent severe shooting and sharp pain, which may last for months.[7,8]

(Print pagebreak 450)

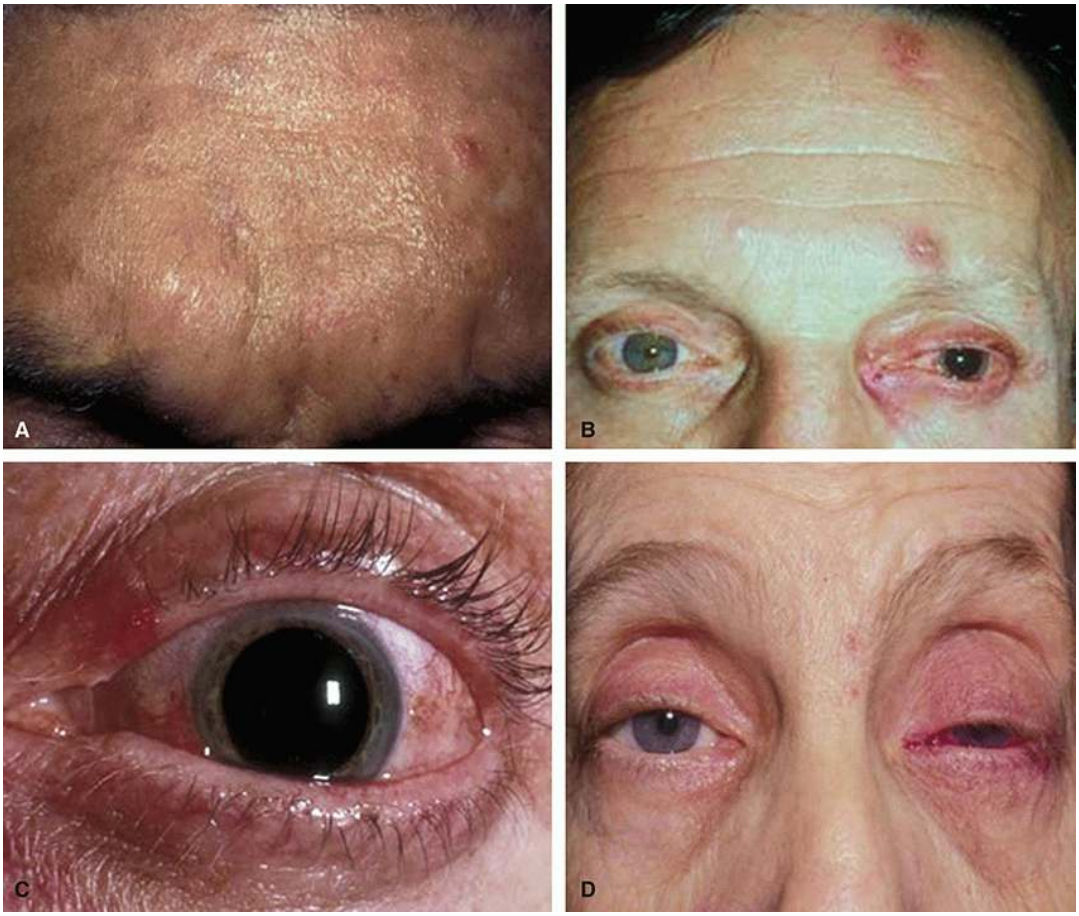

FIGURE 68.1 A-D, Early acute eruptive phase of *herpes zoster* ophthalmicus with scattered papulovesicular lesions and rash on the nose, forehead, and eyelids.

Recurrent herpes zoster is defined as the redevelopment of the characteristic vesicular rash accompanied by dermatomal pain or dysesthesia in V1, more than 3 months after the index episode.[28] It was recently estimated that the overall recurrence rates at 1, 3, and 5 years are 8%, 17%, and 25%, respectively,[28] and is counterintuitively far more common in immunocompetent patients. This suggests that recurrent disease may also be caused by an inflammatory response to the virus, rather than active viral replication.[28,29]

Occasionally, patients may suffer an acute unilateral neuropathic dermatomal pain with all the attendant complications of HZO, but the characteristic zoster rash is absent, a condition which is termed zoster sine herpete. Laboratory testing may help confirm the diagnosis.[8,34] Systemically, an affective mood disorder may follow HZO and persist for prolonged periods where patients suffer anorexia, insomnia, lassitude, severe depression, and occasionally antisocial behavior.[8]

In the presence of a strictly unilateral, unidermatomal rash of grouped vesicles on an erythematous background associated with the typical HZO pain, the clinical diagnosis of HZO is straightforward. However, laboratory testing may be needed whenever there is diagnostic uncertainty, chiefly to exclude herpes simplex.[11] Laboratory tests that are used for the diagnosis of HZV include antigen detection or virus isolation either with viral culture, electron microscopy, or one of the polymerase chain reaction (PCR) protocols. PCR is considered one of the most sensitive methods for viral diagnosis of VZV/herpes simplex virus (HSV).[11] A detailed discussion of the various PCR protocols available is beyond the scope of this chapter, but these include nested multiplex PCR, real-

time nested multiplex PCR, or reverse transcription PCR.[35,36,37] Serology *(Print pagebreak 451)* for detecting VZV-specific IgM, IgG, or IgA responses by ELISA is of little clinical value and is not routinely used in clinical practice.[8,11]

FIGURE 68.2 A and B, Late acute eruptive phase with bullous eruptions, eyelid erythema, edema, and ptosis.

FIGURE 68.3 A and B, Chronic posteruptive phase with skin necrosis, ectropion, and depigmentation.

Differential Diagnosis

Rarely, HSV may mimic the evolution and morphology of herpes zoster and present with zoster-like eruptions, which acquire an appearance and pattern that simulates the lesion caused by VZV. This has been referred to as zosteriform herpes simplex, which may be difficult to differentiate clinically from HZO.[38,39] The lack of pain or other neurosensory problems before the advent of the eruptions may help confirm the diagnosis. But if the diagnosis is still in doubt, laboratory investigations like PCR or viral cultures may be required.[38,39] In patients with HZO and facial pain, other causes of periorbital pain should be excluded if the characteristics of the associated pain are not typical of HZO, as it may be referred *(Print pagebreak 452)* pain, may originate from migraine headache, or may even originate from an undiagnosed orbital tumor.[40] Because HZO patients may acutely suffer from significant eyelid edema, the differential diagnosis in early cases is broad and should include orbital or preseptal cellulitis and occasionally acute dacryocystitis.

Treatment

Chickenpox is a self-limiting disease and vesicular lesions on the eyelids heal spontaneously without treatment. Therefore, no therapy is necessary except in the rare event of punctal/canalicular involvement where local treatment with antivirals may prevent long-term lacrimal complications.[16,17]

Because HZO is a serious and sight-threatening illness, widespread vaccination for individuals older than 50 years is pivotal in reducing disease incidence and morbidity.[7] Two forms of antizoster vaccines exist. The first is a lyophilized live attenuated VZV strain (Zostavax, zoster vaccine live), which is the same strain used in the varicella vaccine, but 14 times more potent, used to stimulate cellular immunity.[7] The live attenuated vaccine is routinely recommended for all patients older than 60 years, although the verdict is still out about recommending the vaccine in the age group between 50 and 59 years.[7] The live attenuated vaccine is contraindicated in pregnant females, immunocompromised patients, and patients allergic to any component of the vaccine. More recently, a recombinant subunit varicella vaccine containing VZV glycoprotein E (Shingrix, recombinant zoster vaccine) was introduced. It is given as two intramuscular injections 2 to 6 months apart and is currently recommended by the Advisory Committee for Immunization Practices for all adults older than 50 years, regardless of whether they already received the live attenuated vaccine or not.[41] At the time of writing of this chapter, the verdict is still out about the safety of the subunit vaccine in immunocompromised patients although preliminary evidence suggests its safety.[42]

Treatment of HZO has three main objectives: treatment of the acute viral infection, amelioration of the acute pain associated with the infection, and prevention of PHN. Antiviral agents, corticosteroids, and analgesics are prescribed to address all three objectives.[43] Treatment should start immediately with oral acyclovir (800 mg five times daily), valacyclovir (1 g three times daily), or famciclovir (500 mg three times daily) for 7 to 10 days, preferably within the 72-hour window after onset of the rash.[29,40] Although valacyclovir and famciclovir have better bioavailability and consequently require less frequent dosing than acyclovir, acyclovir is still considered the mainstay of treatment.[29] Patients with severe disease may also be started on oral prednisolone concurrently with antiviral therapy to accelerate healing and reduce acute zoster pain. However, there is a lack of consensus about their efficacy in reducing the progression of ZAP to postherpetic neuralgia, as this role is not supported by conclusive clinical evidence.[40,43]
Systemic steroids are contraindicated in immunocompromised patients. Long-term (7-12 months), low-dose treatment with valacyclovir (1 g daily) or acyclovir (800 mg twice daily) may help reduce recurrences after acute HZO.[29] Treatment of postherpetic neuralgia includes the prompt administration of antivirals, along with tricyclic antidepressants, gabapentin, pregabalin, and opioids to decrease neuropathic pain.[29,40] In the postacyclovir era, surgery is rarely required to address long-term structural eyelid deformities because they are seldom encountered in modern clinical practice. However, if they do occur, they should be managed accordingly.

At the time of writing this chapter, there is insufficient evidence to recommend any specific topical treatment for acute HZO.[11] Accordingly, several authors refrain from using any form of local therapy and simply recommend keeping the lesions clean and dry using sterile saline solution or mild antiseptics such as polyhexanide 20% solution, which are applied to the affected areas for 20 to 30 minutes four to six times daily.[11] The use of zinc oxide lotions or ozone therapy is commonly used by some clinicians, but these methods lack clinical validation.[11] The topical application of local anesthetics or capsaicin cream to treat neuropathic pain is not advocated and is not supported by scientific evidence.[11]

Surprisingly, and despite its widespread use in clinical practice, the use of topical antivirals in HZO remains controversial.[11] It seems that despite the presumably better local penetration of topical acyclovir, it appears to have no therapeutic value in the management of skin lesions in acute HZO, and scientific evidence for its efficacy has not so far been demonstrated.[33,44,45] Based on consensus alone, topical acyclovir may be applied to the affected areas as adjuvant therapy five times daily, but should never be used as monotherapy without systemic acyclovir.[33,46]

Prognosis

Varicella (chickenpox) is a self-limited disease, and lesions heal without treatment,[12] except in neonates or in immunocompromised individuals where it can lead to serious complications such as pneumonitis or encephalitis.[8,12] However, HZO can be a fatal disease because of the attendant viremia that particularly occurs in immunocompromised individuals. This may lead to visceral involvement in 10% to 50% of patients in the form of hepatitis, pneumonitis, or even encephalitis.[8] The mortality rate in patients with visceral involvement ranges from 5% to 15%, and the majority of deaths occur due to pneumonitis.[8]

Between 10% and 12% of patients with HZO will develop vision impairment within 6 months, which usually results from corneal scarring. It is not entirely clear why some patients develop long-term structural complications with a devastating visual outcome

and/or significant deterioration in the quality of life, while others do not suffer any complications at all. Strain virulence and/or local host factors probably play a role.[8,28] The greater pain burden of PHN significantly affects the quality of life in HZO patients and is one of the leading causes of suicide in patients older than 70 years suffering from chronic pain.[8,28,47]

(Print pagebreak 453)

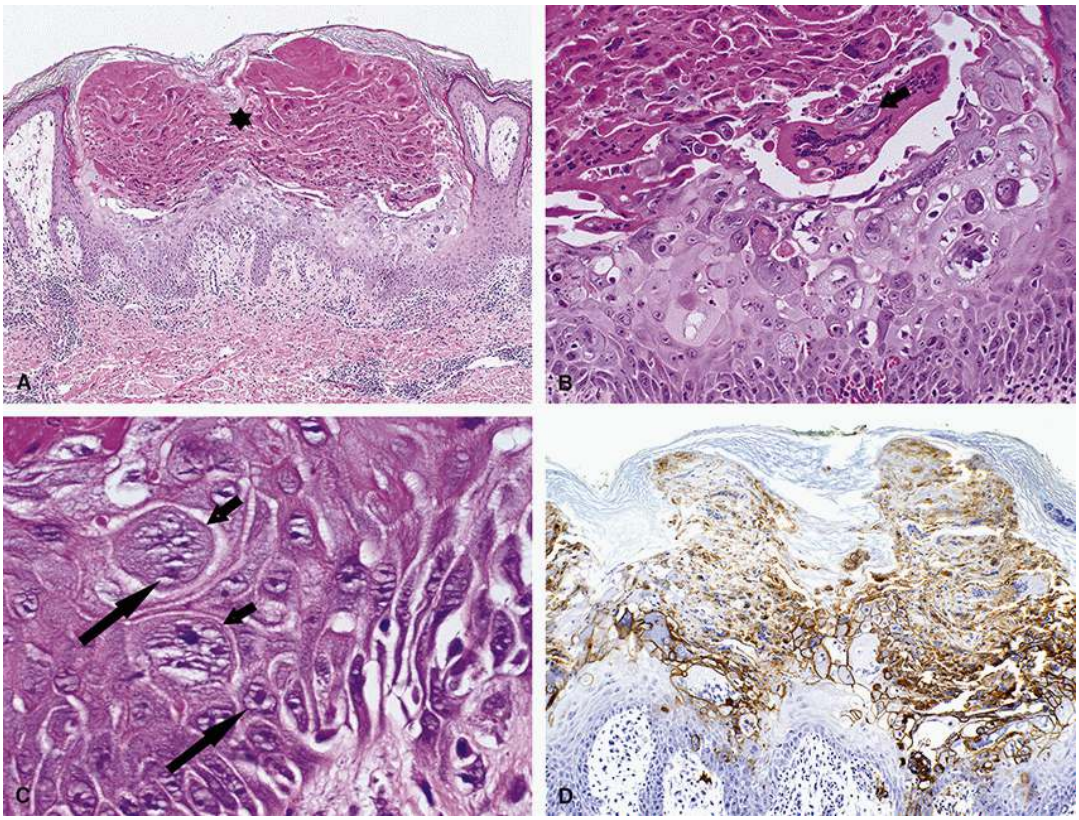

FIGURE 68.4 A, Varicella-zoster virus (VZV) infection has resulted in an intradermal vesicle (★). B, The vesicle contains infected cells, some of which are multinucleate (arrow). There are neutrophils among the infected keratinocytes. C, Close-up of multinucleated cells in the epidermis adjacent to the vesicle (short arrows). Eosinophilic intranuclear inclusions are in a multinucleated cell and a mononuclear keratinocyte (long arrows). D, Immunohistochemical staining using antibodies to VZV antigen confirms the diagnosis. Infected cells stain brown using diaminobenzidine as the chromogenic detection agent.

The classic dictum that Hutchinson sign is of special prognostic significance in acute HZO may not be entirely accurate. Involvement of the nasociliary nerve may indeed be a strong predictor for the development of sight-threatening ocular complications but only if both terminal branches of the nasociliary nerve (external nasal and infratrochlear nerves) are simultaneously involved.[8,10,23] It appears that the sparing of either of these branches is less predictive of serious ocular morbidity.[23] The severity and the extent of the skin rash may also be a predictor for the development of ocular complications because it underlies the immune status of the host.[23]

Histopathology

The histological features of skin infections by HSV and VZV are similar.[48,49,50,51] The characteristic lesion of herpes zoster infection is an intraepidermal vesicle (blister) with swollen multinucleate epidermal cells (Figure 68.4).[52] Swollen epidermal cells lose their attachment to adjacent cells and separate from them; a subepidermal vesicle may result if this process involves the basal epidermal cells. Eosinophilic nuclear inclusions are found in some of the multinucleated keratinocytes. Neutrophils are present within vesicles (Figure 68.4A and B) and within the subjacent dermis.[53] The lesions of herpes zoster resemble those of herpes simplex, but they can be distinguished using immunohistochemical stains (Figure 68.4D).[51]

Similar to cutaneous HSV infection, VZV may infect hair follicles, sebaceous glands, and, more rarely, eccrine glands.[49,50] The histological changes of herpetic infection of dermal structures may occur in the absence of classic changes in the epidermis.[49,50] Dermal inflammation usually accompanies herpetic skin infections and may mimic lymphoma.[49,50,51] Cutaneous reactions following VZV infection include granulomatous dermatitis, granuloma annulare, granulomatous vasculitis, and granulomatous

folliculitis.[54]

CHAPTER 69

Hidradenoma

Key Points

- Most hidradenomas are probably of *apocrine* rather than *eccrine* origin
- Fifty percent of hidradenomas harbor the t(11;19) translocation: the fusion of *MECT1 gene* on chromosome 19p13, with the *MAML2* genes on chromosome 11q21
- Definitive treatment is via complete excision with clear margins
- Hidradenomas are generally benign lesions
- Recurrences are possible if the lesion is incompletely excised
- The malignant potential is rare or negligible
- The malignant variety is called hidradenocarcinoma and may occur de novo, or less commonly on top of a benign hidradenoma

The human skin contains several million sweat glands (also termed “sudoriferous glands”), which are small tubular structures in the skin that are concerned with the production of sweat, and of which there are two types, the water-producing eccrine sweat glands, which express their secretion by exocytosis (merocrine secretion), and the oil-producing apocrine sweat glands, which express their secretions by a process of apical decapitation of the secretory cells.[1,2,3,4,5,6,7,8,9,10] The glandular portion of both types is located in the dermis. The eyelid apocrine-pilosebaceous glands (also termed apocrine glands of Moll) are only observed at the eyelid margin, and they open into the infundibulum of the pilosebaceous unit (the hair follicles) leading to the surface of the skin.[1,4,5,9,10] However, eccrine sweat glands are not associated with hair follicles, and they open directly onto the epidermal surface via a long straight ductule, which has an apical intraepidermal portion (the acrosyringium).[10] Eccrine sweat glands are located in the pretarsal and preseptal regions but not in the eyelid margin. Although the human skin contains far more eccrine sweat glands than their apocrine counterpart, the eyelid is one of the few regions in the body where apocrine sweat glands (glands of Moll) are abundant. Both glands could be a source of origin of several sweat gland cystic swellings and neoplasms that are mostly benign but may rarely be malignant.[1,2,3,4,5,6,7,8,9]

Hidradenomas are relatively rare benign adnexal neoplasms arising from the tubular secretory epithelium of the sweat glands, but they are of uncertain eccrine or apocrine derivation.[1,2,3,4,5,6,7,8,9] The condition is alternatively known in the literature as eccrine hidradenoma, apocrine hidradenoma, clear cell hidradenoma, nodular hidradenoma, eccrine acrospiroma, solid-cystic hidradenoma, or nodulocystic hidradenoma.[3,4,8,11] This nomenclatorial complexity, besides its uncertain origin (eccrine vs apocrine vs both), has led to significant confusion in the literature when dealing with the condition and probably reflects the different approaches between pathologists in interpreting the histologic features of the disease.[3]

Etiology and Pathogenesis

The cellular origin of hidradenoma is controversial. The understanding of this rare neoplasm and its ultrastructural features has evolved over the years from the more traditional outlook in older textbooks, which considered these neoplasms to be of an exclusive eccrine origin. Currently, the consensus is to separate adnexal neoplasms of glandular or ductal origin into eccrine or apocrine hidradenomas, even though it is sometimes impossible to identify whether a lesion is displaying eccrine or apocrine differentiation.[8,11] Although it is currently accepted that hidradenomas can show either an eccrine or apocrine architecture, the apocrine characteristics are the predominant histological subtype that is demonstrable in the majority of lesions.[4,5,8,11,12] This is particularly true in the periocular region where it has been demonstrated recently that apocrine tumors are far more common than their eccrine counterparts, a histological subtype that may turn out to be extremely rare in the eyelids.[4,5]

The common denominators of apocrine glandular differentiation are the presence of decapitation secretions and intracytoplasmic zymogen granules. However, the identification of glandular components in follicular or sebaceous neoplasms, even in the absence of either defining feature (decapitation or zymogen granules), almost certainly represents apocrine differentiation. This premise is supported by embryologic evidence because the apocrine glands, hair follicles, and sebaceous glands have a shared origin from pluripotential germinative cells present in the follicles. All three structures are histologically integrated as the apocrine-pilosebaceous unit.[3,8,11,13] However, there is no single microscopic finding that is ultimately specific for eccrine glandular differentiation. When the hallmarks of apocrine disease are absent (decapitation secretion, intracytoplasmic zymogen granules, or accompanying follicular or sebaceous differentiation), an eccrine origin may be suspected but the lack of *(Print pagebreak 457)* these findings is not definitive. It may not be entirely implausible to suggest that the diagnosis of an eccrine hidradenoma may be one of exclusion.[3,11] What complicates matters further is that neither enzymatic studies nor electron microscopy or even immunohistochemical studies are of much help to elucidate the subtype of hidradenoma.[11] Therefore, the current consensus supports a presumed apocrine morphological predominance of hidradenomas.[3,4,5,8,11]

The histogenesis of hidradenomas is largely unknown, and only one genetic mutation has ever been described in patients with hidradenoma.[14,15] Some hidradenomas feature a t(11;19) translocation, which involves the fusion of both the mucoepidermoid carcinoma translocated 1 gene (*MECT1*, 19p13) and the mastermind-like 2 gene (*MAML2*, 11q21).[11,14,15] It is estimated that about 50% of patients with hidradenoma have the *CRTC1-MAML2* gene fusion, which is particularly common in the clear cell variant of hidradenomas.[15] There are no other known predisposing factors, although some authors note that trauma may accelerate the rate of growth of hidradenoma.[3]

FIGURE 69.1 A-D, Hidradenoma. A (Courtesy of Dr. Bettina Meekins). B (Courtesy of Dr. David Jordan).

Clinical Presentation

Compared to hidrocystoma, eyelid hidradenoma is relatively rare. Most authorities agree that the disease has a 2:1 female preponderance,[7,8] although some authors suggest there is no sex predilection.[3] There is no specific age distribution although the maximum prevalence is generally observed between the fourth and the sixth decades.[3,8]

The clinical appearance of hidradenoma is nonspecific, and accurate diagnosis should rely on histopathology. Nevertheless, it generally presents as a solitary, well-circumscribed, slowly progressive pinkish or skin-colored solid nodule, which in the periocular region usually lies in close vicinity to the eyelid margin (Figure 69.1).[4] Occasionally, it may have a translucent appearance simulating a cystic lesion, with fine overlying telangiectatic vessels.[11]

The malignant variety is termed hidradenocarcinoma and is exceedingly rare, but if it does occur, it has a high potential for metastatic spread and is associated with low survival.[16] The malignant potential of benign hidradenomas *(Print pagebreak 458)* is unknown, and some authors consider it rare to negligible.[4,8] One large series identified the malignant counterpart of hidradenoma in 6.7% of excised lesions.[7] Whether hidradenocarcinomas represent a malignant transformation of a preexisting benign hidradenoma or a de novo lesion from the start is controversial. It should be noted that benign hidradenomas may exhibit a diverse morphological spectrum with variable differentiation; therefore, the original histology is not always an accurate predictor of the clinical behavior of their malignant potential.[8] Malignant transformation, if it occurs, is suggested by ulceration and infiltration around the borders of the lesion.[8,16,17]

Differential Diagnosis

Sweat gland lesions are ubiquitous in the periocular region, and as a result, any swelling involving the sweat glands, irrespective of its true nature, is usually dismissed as a trivial cystic swelling that may delay the proper diagnosis.[4,5] Therefore, it is important to make a clear distinction between hidradenomas, which are rare, and sweat gland cysts, including eccrine and apocrine cysts (hidrocystomas), which are ubiquitous.

Clinically, it may be difficult to differentiate hidradenomas from hidrocystomas, although other benign tumors arising from the eccrine ductal epithelium such as syringomas may be easier to discern based on clinical grounds alone. Eccrine hidrocystomas are retention cysts of the eccrine glands, whereas apocrine hidrocystomas probably represent cystic proliferations that arise from the apocrine secretory coil structure of the gland.[3] Syringomas are benign adnexal tumors derived from the intraepidermal eccrine ducts. They typically affect the lower eyelids and possibly the upper cheeks of middle-aged females more commonly than upper eyelid affection. By definition, they spare the eyelid margins, which points toward an eccrine origin.[4] They typically present with multiple soft to firm, skin-colored, yellowish, or translucent papules, 1 to 3 mm in diameter, which may coalesce together.[18] The differential diagnosis of hidradenoma should also include basal cell carcinoma and squamous cell carcinoma.[19]

Histologically, hidradenoma should be differentiated from tumors of the skin appendages, which exhibit follicular, sebaceous, or sweat gland differentiation including apocrine-mixed tumor, spiradenoma, cylindroma, chondroid syringoma, hidradenoma papilliferum, syringocystadenoma papilliferum, tubular apocrine adenoma, mucoepidermoid carcinoma, squamous cell carcinoma, as well as eyelid metastatic disease, particularly of renal origin.[3,8,12] Chondroid syringoma is a rare adnexal neoplasm that can arise in apocrine sweat glands and is an apocrine variant of pleomorphic adenoma.[20]

Hidradenoma papilliferum is an adenoma with apocrine differentiation, which almost exclusively involves the anogenital region in adult females, with few and rare reported ectopic exceptions in the periocular region or elsewhere.[21] It is not entirely clear in the literature whether ectopic hidradenoma papilliferum is indeed a true hidradenoma papilliferum or should simply be viewed as a hidradenoma with a definitive apocrine architecture, which is more likely because as we mentioned earlier, an apocrine architecture is probably the predominant histological form of most, if not all eyelid hidradenomas.[4,22,23]

Syringocystadenoma papilliferum is another benign eyelid lesion with a higher malignant potential than hidradenoma and should be differentiated from hidradenoma both clinically and histopathologically. This benign adnexal neoplasm is of apocrine origin; therefore, it arises almost exclusively near the eyelid margin. The condition is more common in females, the lesions are larger, with a rather more roughened or verrucous surface than typical hidradenomas, and the lesions may be more commonly encountered in clinical practice than hidradenoma.[19,24,25] Syringocystadenoma papilliferum may develop within a preexisting organoid nevus sebaceous, and basal cell carcinoma may occasionally develop on top.[24,25] The condition may coexist with hidrocystoma, tubular papillary adenoma, or hidradenomas,[24,25,26,27] and some authorities consider syringocystadenoma papilliferum, apocrine hidrocystoma, and tubular papillary adenoma with apocrine differentiation to represent a spectrum of the same disease rather than distinct entities.[6]

Eyelid tubular apocrine adenoma with apocrine differentiation is an extremely rare benign apocrine neoplasm, with only a few reported cases in the eyelids. Both lesions are clinically indistinguishable, and again, the distinction is usually morphological.[20,28] Although some authors make a clear distinction between apocrine papillary hidradenoma and the nonpapillary tubular variety with apocrine differentiation,[4] there are case descriptions in the literature of overlapping ultrastructural features.[29] It should be noted that apocrine *differentiation* does not automatically translate to apocrine *derivation*, and therefore both entities are perhaps indeed distinct.

Treatment

When removal is desired, complete surgical excision with clear margins is the treatment of choice to confirm the diagnosis

and prevent recurrences. Some authors have suggested Mohs micrographic surgery, although in most cases the lesion is well circumscribed and simple excision is all that is needed.[11]

Prognosis

Hidradenomas usually grow slowly, are generally considered benign lesions, and may exist for prolonged periods before the diagnosis is established because they may be initially dismissed as benign eyelid "cysts." Also, they may recur after inadequate surgical excision; therefore, regular follow-up is advised, particularly if the lesion is incompletely excised.

(Print pagebreak 459)

Because it may be difficult to establish the correct diagnosis of a sweat gland lesion based on clinical grounds alone, and because of the possibility of malignancy, it is generally preferred that any solitary sweat gland lesion that is excised from the periocular region should be routinely submitted to histopathology and should not be dismissed as a trivial cosmetic nuisance.[8,12,16,30]

Histopathology

These tumors, usually located in the dermis, are well circumscribed, solid or solid/cystic, and composed of lobules of cells forming acini and tubules or solid sheets.[3,8,31,32] The acini and tubules vary widely in luminal diameter and number, and cuboidal or columnar cells line them.[32] Solid areas of the tumor have a mixture of polyhedral cells with rounded nuclei and pale eosinophilic to slightly basophilic cytoplasm and round cells with clear cytoplasm due to glycogen dissolution during histological processing.[32,33,34] The proportion of the two cell types varies considerably between tumors.[32] Some authors consider clear cells the predominating cell type in hidradenomas,[31] but in a study of 41 hidradenomas by Winkelmann and Wolff, there were only 12 (29%) tumors of predominantly clear cells.[32] Polygonal squamoid cells with eosinophilic cytoplasm and occasional intercellular bridges are a common finding in hidradenomas, while less common cell types have mucinous or oncocytic features.[3,8,35,36,37] Apocrine cells with decapitation secretion are uncommon in hidradenomas.[8] In our experience, periocular hidradenomas most commonly have polyhedral cells with duct formation and small cystic spaces (Figure 69.2). We have seen only one eyelid hidradenoma with abundant clear cells (Figure 69.3).

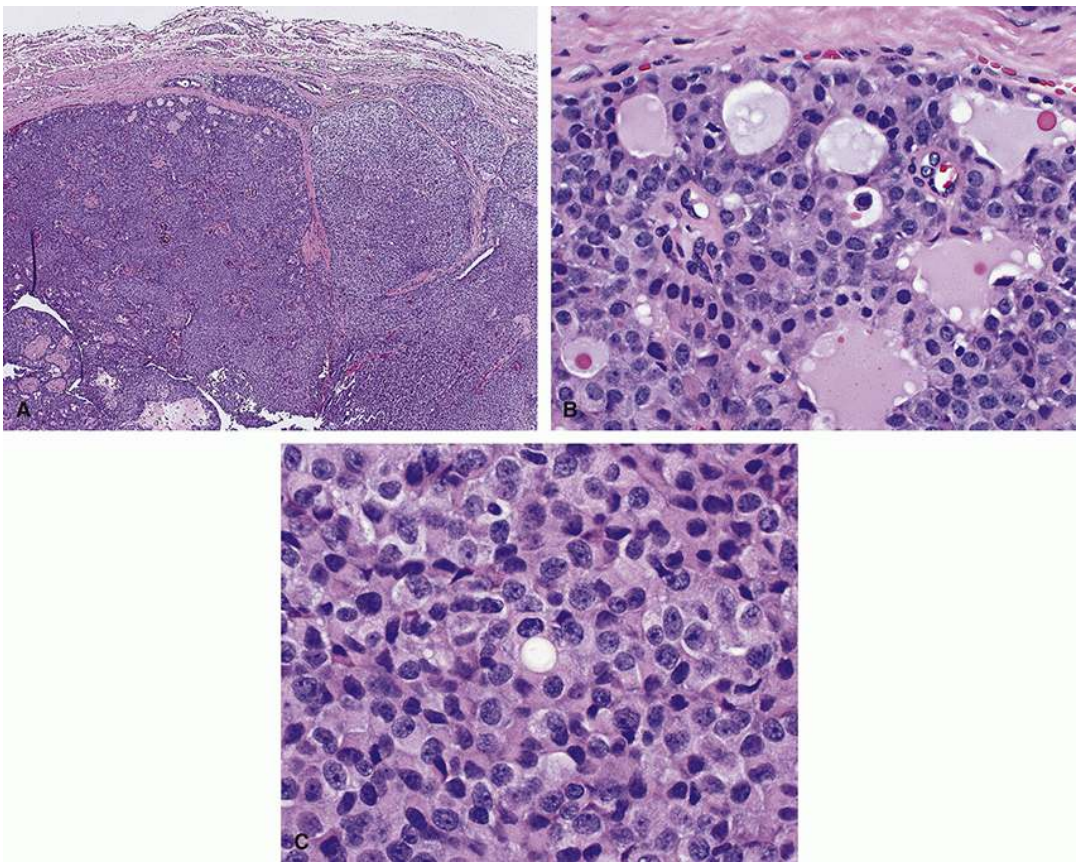

FIGURE 69.2 This hidradenoma of the right upper eyelid is typical of that we have encountered most often in the

periocular region. A, The tumor is based in the dermis, is well circumscribed, and has a lobular pattern. B, The tumor is predominantly solid with a few small cystic areas. C, Polygonal cells with pale eosinophilic cytoplasm form sheets or tubules.

A potential conundrum is a mucinous hidradenoma, which we have encountered several times in the eyelid (Figure 69.4). Mucinous hidradenomas are uncommon,[35,36] and they raise the specter of an endocrine mucin-producing sweat gland *(Print pagebreak 460) (Print pagebreak 461)* carcinoma (EMPSGC) when encountered in a periocular location.[38,39,40,41,42,43,44,45] EMPSGCs have a predilection for being periocular,[41] and 8 of 13 EMPSGCs in Shon and Salomão's study were classified originally as hidradenomas.[44] Expression of nuclear estrogen receptors cannot be depended on to distinguish EMPSGC from hidradenoma since some hidradenomas express estrogen receptors.[46,47] We recommend using a panel of immunostains including nuclear estrogen receptor, neuroendocrine markers (synaptophysin and chromogranin), and WT1 and classifying the tumor as an EMPSGC if the tumor expresses nuclear estrogen receptors, a neuroendocrine marker, and WT1.[38,39,41,43,44] We consider this prudent before diagnosing a tumor as hidradenoma because of the significant histological overlap with EMPSGC.

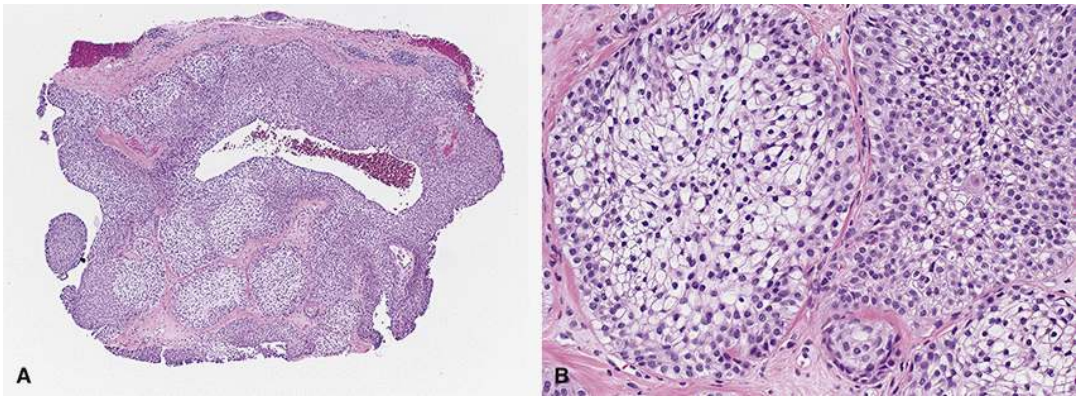

FIGURE 69.3 A and B, This hidradenoma of the left lower eyelid has a prominent population of clear cells containing glycogen. Much of the glycogen dissolves from the tissue during processing, leaving clear cytoplasm. Clear cells are often abundant in hidradenomas of other body sites, but they are uncommon in eyelid hidradenomas in our experience.

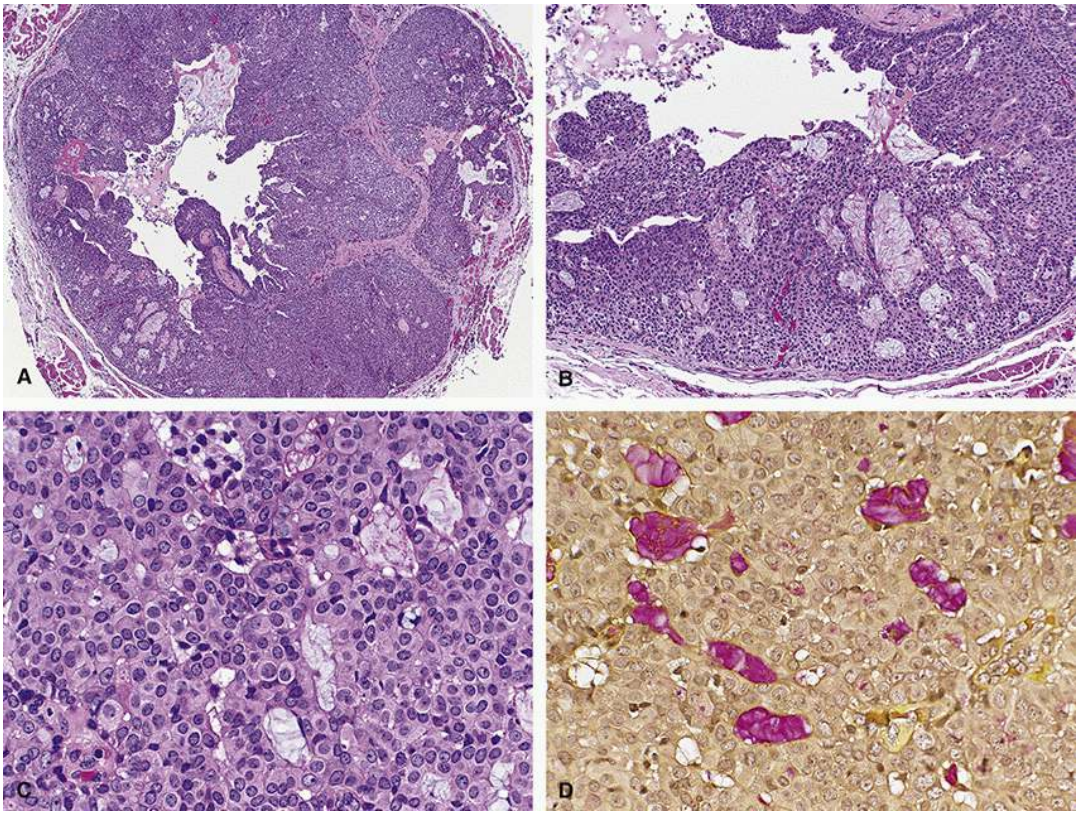

FIGURE 69.4 A, This hidradenoma of the right lower eyelid is well circumscribed with a solid and cystic pattern. B, There are scattered small pools of mucin among the sheets of polygonal cells. C, A majority of the cells are round or polygonal with lightly eosinophilic cytoplasm and round nuclei. Small pools of mucin are among the tumor cells. D, A mucicarmine stain highlights mucin pools and scattered small intracellular mucin globules.

A final consideration when evaluating hidradenomas is differentiating benign, atypical, and malignant tumors.[48,49] Hidradenocarcinomas have cytological atypia, infiltrative growth, deep extension, and ≥4 mitoses per 10 high-power fields.[48,49,50] Immunohistochemical stains using antibodies to Ki-67 and phosphorylated histone H3 may facilitate distinguishing benign and atypical hidradenomas from hidradenocarcinoma, with hidradenocarcinomas having much higher levels of Ki-67 and phosphohistone H3 expression.[49]

CHAPTER 70

Hidrocystoma

Key Points

- Hidrocystomas are benign cystic lesions of sweat glands seen most commonly on the face, especially on the eyelids
- Hidrocystomas are categorized into apocrine and eccrine types
- Apocrine glands are found only at the eyelid margin, whereas eccrine glands are sparsely present in the dermis of the pretarsal and preseptal eyelid skin
- Eccrine and apocrine hidrocystomas are believed to result from ectasias of sweat gland secretory ducts and glands
- Apocrine hidrocystomas are intradermal, dome-shaped, translucent cystic nodules with a white layered precipitate
- Eccrine lesions are dome-shaped cysts with a clear amber or bluish tint and no precipitate
- Treatment is mostly with surgical excision or electrodesiccation

Hidrocystomas are benign cystic lesions of sweat glands seen most commonly on the face, especially on the eyelids, in the medial canthus, and less commonly the lateral canthal angle.[1,2,3,4,5,6,7] In a large series of more than 5000 benign and malignant noninflammatory lesions excised from the eyelids, 5.9% were hidrocystomas, and these were equally distributed in the upper and lower eyelids.[4] Other studies reported hidrocystomas to account for 8% to 10.5% of benign eyelid lesions.[8,9]

Based on their histologic characteristics and presumed histogenic derivation, hidrocystomas are categorized into apocrine and eccrine types. Apocrine glands are found only at the eyelid margin in association with cilia, and nowhere else in the eyelid skin. Eccrine glands, however, are not present on either the upper or lower eyelid margins or in the perimarginal skin but are sparsely present in the dermis of the pretarsal and preseptal eyelid skin.[10] So eccrine hidrocystomas develop within the eyelid skin away from the eyelid margins and pericilial skin, whereas hidrocystomas on or near the eyelid margins are always apocrine in origin.[11,12,13] De Viragh et al[12] reported that apocrine or eccrine hidrocystomas are often misdiagnosed because the usual histological criteria are masked, probably secondary to intraluminal pressure in the cysts, which flattens their walls and abolishes decapitation secretions.

Apocrine sweat glands are composed of a coiled secretory portion located in the dermis. A short straight excretory duct inserts into the upper infundibular portion of the hair follicle.[14,15,16] The apocrine gland secretes an oily fluid with proteins, lipids, and steroids. Secretions appear on the skin surface mixed with sebum since sebaceous glands open into the same hair follicle.[17] Apocrine glands secrete in periodic spurts and release their products by “decapitation,” where membrane-bound cytoplasm from the apical surface of the secretory cells bud off into the lumen of the duct.

Apocrine hidrocystomas were first described by Mehregan in 1964[18] and are thought to derive from the secretory portion of the apocrine gland. They are usually solitary lesions, but can also be multiple,[19] and vary in size from 3 mm to about 15 mm.[20] Multiple apocrine hidrocystomas have been described in two rare ectodermal dysplasias. Goltz-Gorlin syndrome (focal dermal hypoplasia syndrome) is a sporadic or X-linked dominant disease most common in females and characterized by atrophic hyperpigmented and hypopigmented macules, linear skin atrophy, microcephaly, microphthalmia, midface hypoplasia, malformation of the ears, apocrine hidrocystoma of the eyelids, syndactyly, and mental retardation.[21,22] Schopf-Schulz-Passarge syndrome is an autosomal recessive condition characterized by hypotrichosis, hypodontia, palmar and plantar hyperkeratosis, nail fragility, hypotrichosis, and multiple eyelid apocrine hidrocystomas.[23,24]

Eccrine glands are composed of an intraepidermal spiral duct, a dermal duct consisting of a straight and coiled portion, and a coiled secretory tubule deep in the dermis.[17] The eccrine gland opens directly onto the skin surface through a sweat pore. These glands produce a clear odorless secretion, consisting primarily of water.

Eccrine hidrocystomas were first reported by Robinson in 1893[25] in workers laboring in humid and warm environments. The cysts tend to enlarge with exercise and in warm environments, due to increased sweat retention.[26] Eccrine hidrocystomas are most prevalent in adults between 30 and 70 years and present as small, tense, thin-walled cysts 1 to 6 mm in diameter and can occur as single or multiple lesions.[2,20] They are very rare in children, and when present can be associated with ptosis and astigmatism.[27,28] Solitary eccrine hidrocystomas occur equally among males and females, but multiple cysts are mainly seen in females.[29]

Graves disease has been associated with multiple eccrine hidrocystomas.[30] It is suggested that these are due to hyperhidrosis, which can be seen in hyperthyroid patients, and the cysts tend to disappear after treatment of the hyperthyroidism.[30]

(Print pagebreak 464)

Etiology and Pathophysiology

Eccrine and apocrine hidrocystomas are believed to result from ectasias of sweat gland secretory ducts and glands.[2,29,31,32,33,34,35] The apocrine sweat glands of Moll, which are present at the lid margin and empty into the infundibular portion of the lash follicles, give rise to cysts along the lash line.[10] These cysts derive from the secretory portion of apocrine glands in the dermis and are thought to develop as cystic proliferations of the coil structure of the gland, rather than as a simple retention cyst.[36,37,38] Eccrine hidrocystomas, however, are located in the dermis and empty directly onto the skin surface without any communication with the folliculosebaceous apparatus. Eccrine cysts are believed to result from blockage of the excretory duct, with sweat retention and cystic dilation of the eccrine gland.

Apocrine hidrocystomas differ from eccrine cysts by the presence of cyst content containing milky layered apical cytoplasmic decapitation debris. These represent shedding of adluminal snouts that become incorporated into the eosinophilic cyst secretions. Eccrine cysts contain a clear watery secretion with no snouts, and without cytoplasmic contributions.[10] Both of these types of cysts are distinguished from simple conjunctival cysts by the absence of goblet cells.

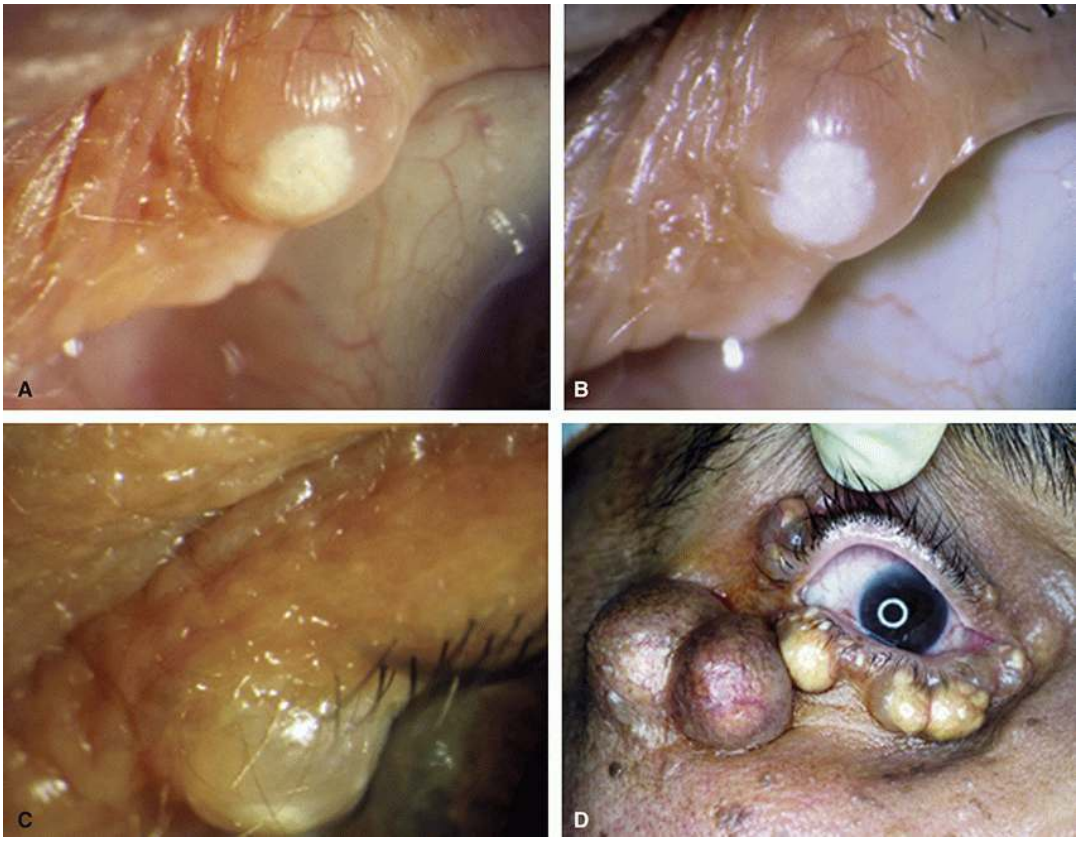

FIGURE 70.1 A-D, Apocrine hidrocystoma on the eyelid margins with a layered precipitate.

Clinical Presentation

Apocrine hidrocystomas are usually solitary lesions. They are found on the head and neck, commonly affecting the cheek and the medial canthus of the eyelid, but are also reported on the chest, shoulder, axilla, umbilicus, foreskin, penal shaft, vulva, and fingers. They typically are intradermal, moderately firm, dome-shaped, translucent, blue, bluish-black, grayish, or purple cystic nodules with

a white layered precipitant (Figure 70.1). Hidrocystomas on the eyelid margin are always of the apocrine type, may contain multiple loculated cystic spaces, and produce oily, foamy secretions. Peripheral linear vessels represent dilated vessels of the papillary dermis.[39,40,41] Cysts range in size from 3 to 15 mm in diameter, but occasionally can be larger. They may appear pigmented due to a Tyndall effect, but this may also occur due to the presence of lipofuscin pigments in the cystic fluid.[42,43]

Eccrine hidrocystomas can be solitary or multiple. They typically are dome shaped, have a clear amber or bluish tint, *(Print pagebreak 465)* and range from 1 to 6 mm in diameter. They are not located on the eyelid margins but can be seen on the pretarsal and preseptal eyelid skin. During hot or humid weather, these lesions tend to enlarge in size and can multiply in number due to increased sweat production and retention of secretions.[44] Eccrine cysts contain a single cyst cavity and produce a clear watery secretion (Figure 70.2).

FIGURE 70.2 A-D, Eccrine hidrocystoma containing a clear watery secretion.

Both apocrine and eccrine hidrocystomas are seen equally among men and women and generally present in adults at a mean age of about 64 years.[10]

Differential Diagnosis

Eccrine and apocrine hidrocystomas have very similar clinical presentations. For both, the differential diagnosis includes epidermoid cyst, epidermal inclusion cyst, sebaceous duct cyst, mucoid cyst, lymphatic or venolymphatic malformations, and hidradenomas. They can also occasionally resemble malignant tumors such as basal cell carcinoma, yellowish sebaceous carcinoma, endocrine mucin-producing sweat gland carcinoma, and, when pigmented, melanocytic nevi and melanoma.[11,45,46,47,48] When multiple, the differential also includes syringomas, milia, and trichoepitheliomas. For cysts that involve the conjunctiva, the differential also includes conjunctival inclusion cyst and canaliculops.

Treatment

The most common treatment of apocrine hidrocystoma is surgical excision with narrow margins, although surgery for larger or multiple lesions can result in scarring.[49] Incision and drainage is a simple procedure but results in a high recurrence rate. Recurrence can be reduced with cauterization of the remaining cyst wall.[2] Trichloroacetic acid injection after cyst puncture is an alternative to surgery,[50] as is hypertonic glucose as a sclerosant.[51]

Other therapeutic methods include electrodesiccation, radiofrequency ablation, and laser treatment for smaller lesions.[19,49,52] Multiple lesions have been treated successfully with topical 1% atropine or scopolamine creams, but some patients have discontinued treatment because of anticholinergic side effects.[53] Botulinum toxin A also has been used effectively because acetylcholine is an effector sudomotor *(Print pagebreak 466)* neurotransmitter, and this toxin reduced sweat secretion.[43,54,55] Other anticholinergic agents such as glycopyrrolate, clonidine, and oxybutynin exert an inhibitory effect on sweat glands and have also been used to treat multiple hidrocystomas.[26,53,56,57,58]

Prognosis

Hidrocystomas are benign lesions, and unless very large, usually are only of cosmetic concern. With appropriate treatment, recurrences can be minimal and the prognosis is excellent.

Histopathology

Hidrocystomas are classified routinely as apocrine or eccrine based on their appearance in hematoxylin and eosin sections.[58,59,60] However, cysts resembling eccrine hidrocystoma may have an immunophenotype indicative of an apocrine origin, making histological classification as apocrine or eccrine of dubious value.[9,12] Some dermatopathologists even question whether eccrine hidrocystomas even exist.[61]

Apocrine hidrocystomas may be unilocular or multilocular and are lined by two layers of cells (Figure 70.3A and B).[58,60] The inner lining is composed of columnar cells with eosinophilic cytoplasm and decapitation secretion (buds of cytoplasm detaching from the luminal surface). Myoepithelial cells compose the outer layer; the cells are flat to low cuboidal. The epithelium may form papillary projections into the lumen. When papillae are more profuse and have a fibrous core or the epithelium has an adenomatous appearance, the lesions are now classified as apocrine cystadenomas (Figure 70.3C and D).[60,62] Cyst contents, when present, are lightly eosinophilic proteinaceous material.

Cysts classified as eccrine hidrocystomas are unilocular. At low magnification, the cysts often have a convoluted profile due to cyst collapse during surgical removal. They are lined by two layers of epithelium: an inner layer of cuboidal cells and an outer layer of low cuboidal to flat cells (Figure 70.4).[58,59,60] The cyst contents are often absent from histological sections; they are lightly eosinophilic proteinaceous material if present.

The epithelium of hidrocystomas and apocrine cystadenomas may be pigmented (Figure 70.5), especially in lesions classified as apocrine.[63,64,65] In some cases, the pigment has the histochemical properties of melanin,[63,64,65] while in others, it does not.

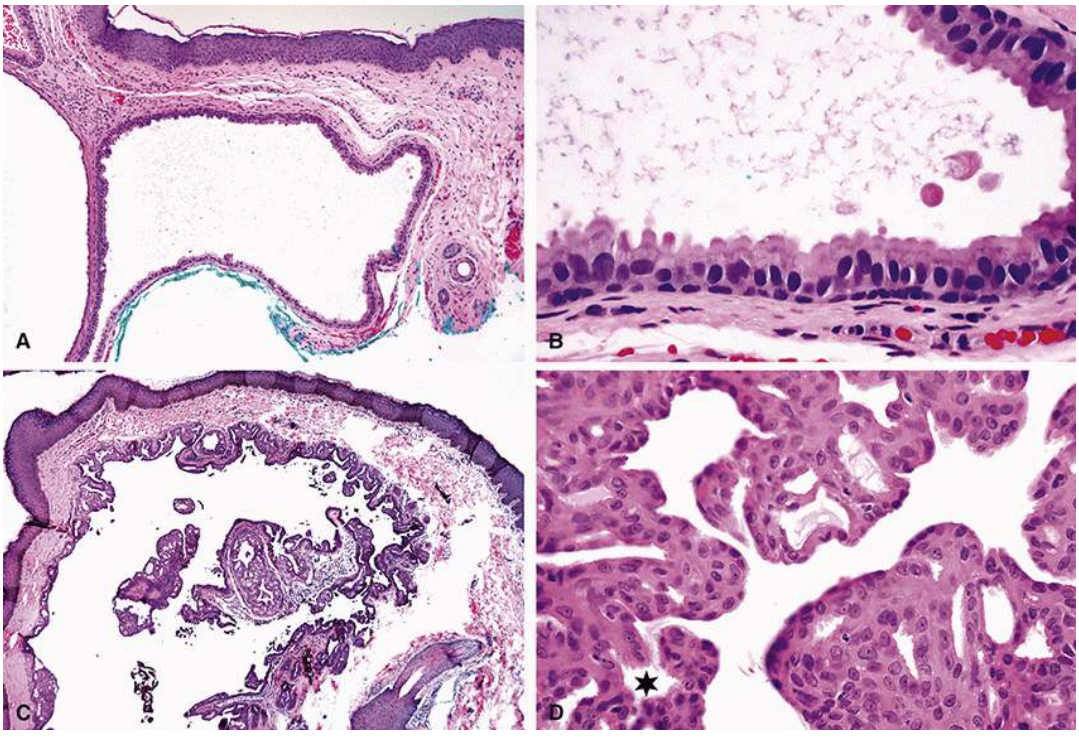

FIGURE 70.3 A, This left lower eyelid apocrine hidrocystoma is multiloculated. B, It is lined by two layers of cells. Columnar cells with eosinophilic cytoplasm and decapitation secretion form the inner layer. Flat to low cuboidal myoepithelial cells compose the outer layer. Lightly eosinophilic proteinaceous material is in the lumen. C and D, Apocrine cystadenomas have papillae with fibrous cores or an adenomatous appearance, as in this example from the right lower eyelid. Decapitation secretion is evident in some of the adenomatous glands (★).

(Print pagebreak 467)

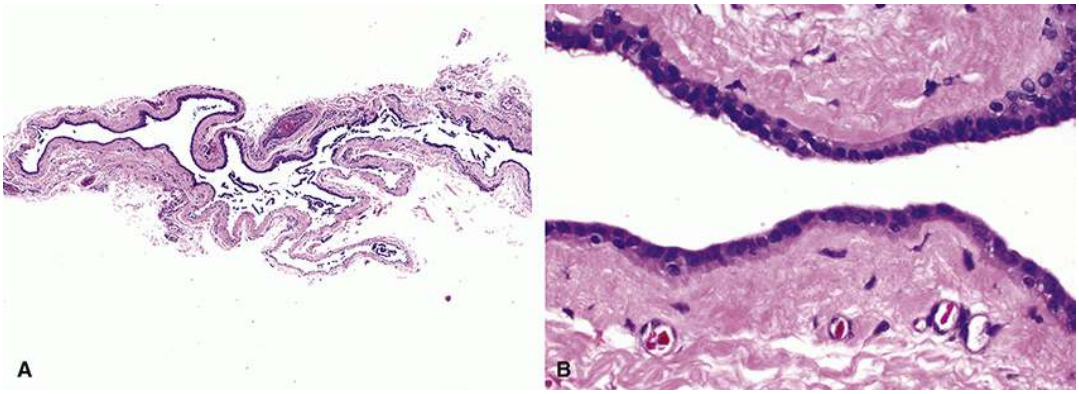

FIGURE 70.4 A, This cyst from the right lower eyelid was classified as an eccrine hidrocystoma since it was unilocular and lacked evidence of decapitation secretion by the inner lining of cells. At low magnification, the cyst has a convoluted profile due to collapse during surgical removal. B, The cyst is lined by two layers of epithelium: an inner layer of cuboidal cells and an outer layer of low cuboidal to flat cells.

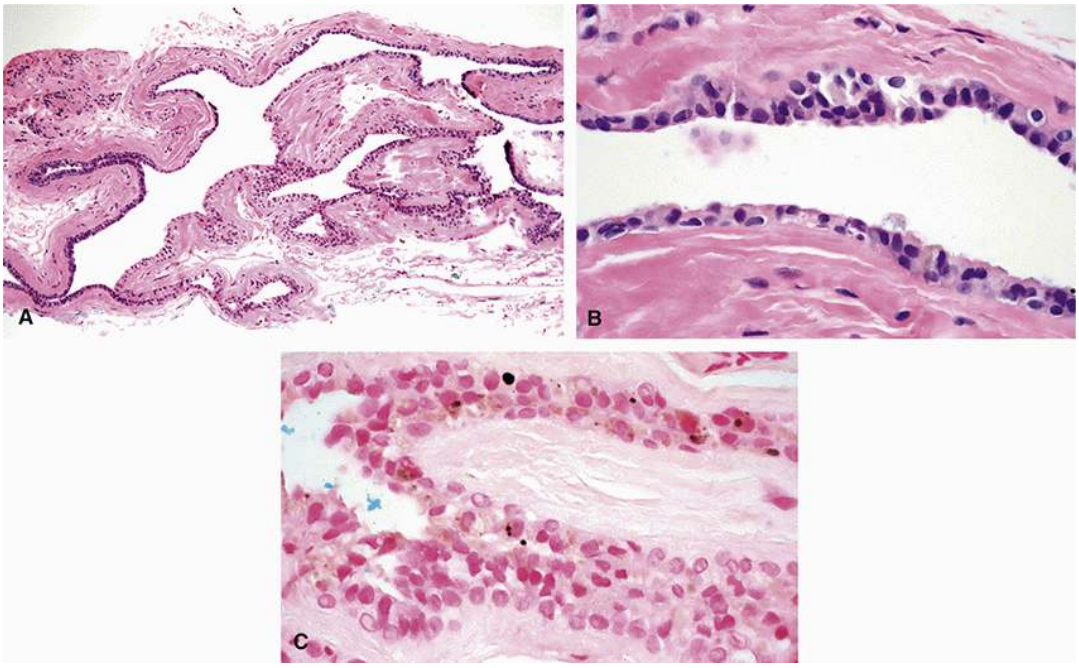

FIGURE 70.5 The epithelium of hidrocystomas and apocrine cystadenomas may be pigmented, as seen in this left medial canthus hidrocystoma. A, The cyst is unilocular with convolutions due to its collapse during removal. B, The cyst lining is two-layer thick, and the inner layer lacks features of decapitation secretion. The cells are less eosinophilic than a typical hidrocystoma and have a tan tinge. C, The intracytoplasmic pigment is more readily apparent in the section stained using the Fontana-Masson method for demonstrating melanin. The pigment has remained tan and brown, indicating that it is not melanin, which turns black utilizing this procedure.

CHAPTER 71

Ichthyosis

Key Points

- Ichthyosis is a heterogeneous group of disorders characterized by abnormal cutaneous keratinization with scale formation
- These are divided into nonsyndromic and syndromic forms of inherited ichthyoses and less common acquired ichthyoses
- Ichthyosis vulgaris is the most common and mildest form of nonsyndromic ichthyosis, presenting with dry skin with rough patches and/or tiny bumps, and trichomegaly
- Lamellar ichthyosis is characterized by hyperkeratosis and thick scales, eyelid ectropion, and corneal complications
- Harlequin ichthyosis the most severe form with a high mortality rate
- Syndromic forms include a number of uncommon conditions such as Netherton syndrome, Refsum syndrome, and KID syndrome and are usually more severe
- Most inherited forms result from mutations in genes involved with skin barrier homeostasis
- There is no cure and management is mostly supportive
- Genetic testing is essential to identify the subtype, predict the clinical course, and allow for family counselling
- Ectropion is treated with ocular lubricants and skin grafting
- The prognosis depends on the subtype and varies from very good to lethal

The term “ichthyosis” is derived from the Greek word ichthys, meaning fish, and the clinical features of the ichthyoses were noted in early medical writings dating back to antiquity describing them as diseases resembling snakeskin or the scales of a fish.[1] The first historic reference to ichthyosis, “Ekakushtha, skin disease like scales of a fish,” appears in an Indian text in 250 BCE.[2]

Ichthyosis refers to a clinically and genetically heterogeneous group of inherited congenital disorders characterized by abnormal cutaneous keratinization with scale formation.[3,4,5] It is a general term for more than 50 types of related cutaneous diseases.[6] These diseases can be inherited and congenital or acquired later in life.

In 2009, the First Ichthyosis Consensus Conference divided the inherited ichthyoses clinically into two groups: nonsyndromic and syndromic forms.[5] Nonsyndromic ichthyoses are phenotypically expressed only in the skin and represent the most commonly seen phenotypes,[7,8] whereas syndromic ichthyoses have phenotypes that involve the skin, as well as other organs.[9] Takeichi and Akiyama[7] classified the inherited nonsyndromic ichthyoses based on clinical features and genetic mutations as follows:

Common Ichthyosis

Ichthyosis vulgaris

Recessive X-linked ichthyosis

Autosomal recessive congenital ichthyosis

Major types

Harlequin ichthyosis

- Lamellar ichthyosis
- Congenital ichthyosiform erythroderma (collodion baby)
- Minor types
  - Self-healing collodion baby
  - Acral self-healing collodion baby
  - Bathing suit ichthyosis

Keratinopathic ichthyosis

- Major types
  - Epidermolytic ichthyosis
  - Superficial epidermolytic ichthyosis
- Minor types
  - Annular epidermolytic ichthyosis
  - Ichthyosis Curth-Macklin
  - Autosomal recessive epidermolytic ichthyosis
  - Epidermolytic nevi
  - Congenital reticular ichthyosiform erythroderma

Nonsyndromic Ichthyoses

Ichthyosis vulgaris is the most common and mildest form of nonsyndromic ichthyosis, having an incidence of 1:250 to 1:1000.[5] It is characterized by xerosis, scaling, pruritus, and eczema, and it is strongly associated with atopic manifestations.[5] The most commonly affected sites are the extensor surfaces of the lower legs and the back. Other cutaneous features include palmoplantar hyperlinearity and keratosis pilaris (dry, rough patches, and tiny bumps), usually on the upper arms, thighs, cheeks, or buttocks. Trichomegaly with elongated eyelashes has been reported as a cutaneous marker for this disease seen in 13% of patients.[10] The causative genetic mutation is in the *FLG* gene that encodes profilaggrin,[11] a precursor protein of filaggrin, a protein that *(Print pagebreak 471)* facilitates terminal differentiation of the epidermis, and the formation of the protective skin barrier.[12] In terminal differentiation, filaggrin is cross-linked to the cornified cell envelope, which constitutes an insoluble barrier in the stratum corneum to protect the organism against environmental agents and to prevent epidermal water loss.[13]

Recessive X-linked ichthyosis is the second most common ichthyosis. It affects males and is more severe than ichthyosis vulgaris, with a prevalence of 1:2000 to 1:6000. It is clinically characterized by generalized dark brown, polygonal scales and dryness on the back of the scalp, ears, neck, back, and legs with sparing of the face that appears shortly after birth. Symptoms begin at birth, and by childhood or adolescence patients become severely affected. The skin is often exacerbated in cold weather but dramatically improves during the summer.[14] It is caused by a deficiency of the enzyme steroid sulfatase.[8] Approximately 90% of patients have large deletions involving the *STS* (steroid sulfatase) gene and adjacent DNA.[7]

Autosomal recessive congenital ichthyosis is uncommon with a prevalence of 1:100,000. It presents at birth with erythrodermic, scaly skin over almost the entire body.[5] Clinical presentation and severity of presentation can vary significantly and fall on a continuum. Takeichi and Akiyama[7] clinically divided this group into three major and three minor subtypes. Harlequin ichthyosis, also known as alligator baby or malignant keratosis,[15] is the most severe form of nonsyndromic inherited ichthyosis. Clinically, these babies are usually born prematurely with thick, platelike scales that severely restrict movement, severe eyelid ectropion, eclabium (out-turned lips) flattening of the ears, and scarring alopecia of the scalp and eyebrows.[16] Life-threatening complications in the immediate postnatal period include respiratory distress, feeding problems, and systemic infection.[17] The disease is associated with mutations in any one of more than 12 genes involved in the biosynthesis that regulate epidermal lipid synthesis and cornified lipid envelopes.[6] These include *ABCA12, ALOX12B, ALOXE3, CASP14, CERS3, CYP4F22, LIPN, NIPAL4, PNPLA1, SDR9C7, TGM1*, and *SLC27A4,* but 15% of affected families do not have pathogenic variants in any of the known genes.[17]

Lamellar ichthyosis is another phenotype of autosomal recessive ichthyosis that is less severe than harlequin ichthyosis. The severity of the hyperkeratosis and scales varies from patient to patient. The scales covering most of the body are large, thickened, and dark gray or brown. Other signs may include eyelid ectropion, hair loss, palmoplantar hyperkeratosis, abnormally formed fingernails and toenails, lips that are turned outward, hypohidrosis, increased sensitivity to heat, dehydration, and respiratory difficulties.[18] Less frequently, affected individuals may have joint abnormalities and rickets.[19] In a series of 13 patients with lamellar ichthyosis and ectropion, 2 cases (15.4%) resulted in corneal scarring.[20,21] In another series of 10 patients, corneal leukoma was seen in 30%.[22] Cruz et al[22] postulate that the corneal damage is not directly linked to lower ectropion but is multifactorial. Cicatricial ectropion can involve both upper and lower eyelids with lagophthalmos exacerbating evaporative dry eye disease and decreased tear breakup time.[23] The risk of corneal scarring increases especially in cases where Bell phenomenon is absent. A rare case of spontaneous subconjunctival abscess was described in a child with lamellar ichthyosis.[24] Eight causative genes have been identified associated with lamellar ichthyosis: *ABCA12* (adenosine triphosphate-binding cassette subfamily A member 12); *ALOXE3* (lipoxygenase 3); *ALOX12B* (12R-lipoxygenase); CERS3 (ceramide synthase 3); *CYP4F22* (cytochrome P450, family 4, subfamily F, polypeptide 22); *NIPAL4/ICHTHYIN* (NIPA-like domain containing 4); *PNPLA1* (patatin-like phospholipase domain-containing protein 1); and *TGM1* (transglutaminase 1).[7]

Congenital ichthyosiform erythroderma, also known as collodion baby, is a form of autosomal recessive congenital ichthyosis characterized by generalized, red, dry, pruritic, and rough skin with large coarse and fine white scales.[7] Erythroderma and scaling appear after several weeks when the collodion membrane is shed. The scales are typically fine and white or light gray. Systemic erythroderma is present, but this may improve in infancy.[18,25] Mutations have been identified in several causative genes including *ABCA12, ALOX12B, ALOXE3, CERS3, CYP4F22, LIPN, NIPAL4/ICHTHYIN, PNPLA1,* and *TGM1*.[26]

Self-healing collodion baby is a minor variant of autosomal recessive congenital ichthyosis accounting for approximately 10% of all cases. It is characterized by nearly complete resolution of scaling within the first 3 months of life.[5,27] It is associated with *TGM1*, *ALOX12B*, and *ALOXE3* mutations,[28] and two cases were described associated with homozygous mutations in the gene *CYP4F22*.

Acral self-healing collodion baby is a very rare variant of autosomal recessive congenital ichthyosis where the patients are born with the typical membrane but limited to the hands and feet only, and after it sheds, the skin appears completely normal.[29] This variant is associated with a novel mutation in the *TGM1* gene.[30]

Bathing suit ichthyosis is another minor variant of autosomal recessive congenital ichthyosis characterized by a unique distribution of lesions on the trunk, the proximal parts of the upper limbs, the scalp, and the neck. The central face and extremities are not involved.[5,31,32] Twenty missense mutations of *TGM1* have been reported, nine of which occurred only in patients with this phenotype.

Keratinopathic ichthyosis was proposed as a general term for another group of rare phenotypes that include epidermolytic ichthyosis, superficial epidermolytic ichthyosis, annular epidermolytic ichthyosis, ichthyosis Curth-Macklin, autosomal recessive epidermolytic ichthyosis, epidermolytic nevi, and congenital reticular ichthyosiform erythroderma. They are all associated with mutations in the keratin family genes, *KRT1*, *KRT2*, and *KRT10*. Epidermolytic ichthyosis is the most prevalent form of the keratinopathic ichthyoses characterized by generalized erythroderma and blistering at birth, *(Print pagebreak 472)* followed by hyperkeratosis later in life.[5,7,33] The blistering and erythema diminish with age. Superficial epidermolytic ichthyosis is characterized by mild epidermal hyperkeratosis over flexural areas and blister formation with a more superficial pattern than epidermolytic ichthyosis. It is caused by mutations in *KRT2*, rather than *KRT1* or *KRT10*.[5] Annular epidermolytic ichthyosis is another rare distinct phenotypic variant of epidermolytic ichthyosis characterized by the intermittent development of annular, polycyclic, erythematous, scaly plaques over the proximal extremities and the trunk.[34] It is associated with a unique mutation in *KRT10*. Ichthyosis Curth-Macklin is an autosomal dominant disorder characterized by spiky or verrucous hyperkeratosis affecting the large joints and the trunk.[35,36] Mutations of *KRT1* have been identified in patients with this disorder.[37] Autosomal recessive epidermolytic ichthyosis is a phenotype where babies are born with collodion skin and generalized erythroderma. The collodion membrane is shed early. In the first months after birth, infants develop skin erosions after mild mechanical trauma and progressive ichthyosis with generalized hyperkeratosis most pronounced on the big joints, elbows, and knee bends and show phenotypic variability from mild to lethal forms.[38] The condition is caused by autosomal recessive mutations in *KRT10* leading to a complete absence of the protein.[39,40] Epidermolytic nevus is characterized by single or multiple circumscribed verrucous lesions frequently presenting following Blaschko lines.[41,42] Mutations in *KRT1* and *KRT10* have been reported. Congenital reticular ichthyosiform erythroderma (also referred to as ichthyosis with confetti) is a very rare skin disease in which babies are born with erythroderma, prominent scales, and palmoplantar keratoderma.[43,44] Hundreds to thousands of pale confetti-like spots appear on body surfaces and increase in number and size with advancing age. Mutations in *KRT10* and *CRIE* have been described.[45]

Syndromic Ichthyoses

Among the syndromic forms of ichthyosis, several uncommon syndromes have been described.[8] Netherton syndrome is a rare

autosomal recessive disorder that mostly affects females with an incidence of 1 in 200,000 individuals.[46] The syndrome is caused by mutations of the *SPINK5* gene and includes congenital ichthyosis with double-edged scales, bamboo hair, and atopic predisposition. Hair is short, sparse, and dry.[8,47,48] The syndrome also includes a predisposition to allergies, asthma, and eczema, with hypereosinophilia, trichorrhexis invaginata, and elevated serum IgE levels.

Sjögren-Larsson syndrome is an autosomal recessive error of lipid metabolism due to biallelic mutations in the *ALDH3A2* gene that result in a deficiency of fatty aldehyde dehydrogenase. Premature birth is common, seen in 73% of cases.[49,50,51,52] Affected patients show a classical triad of congenital ichthyosis, mental retardation, and spastic paralysis of the limbs.[50] A collodion membrane is not seen. The skin has an erythematous and hyperkeratotic appearance that transforms over days to the dry scaly appearance of ichthyosis. They may also show alopecia, eclabion, and eyelid ectropion.[51] Patients display sparse to florid perifoveal crystalline inclusions (glistening white dots) located in the inner retina and may show retinal thinning, cystic macular degeneration, retinal pigment epithelium atrophy, and deficiency of macular pigment.

Refsum syndrome is an autosomal recessive disease that develops from age 7 months to older than 50 years, and patients are usually normal at birth. It is characterized by ichthyosis, retinitis pigmentosa, progressive panretinal degeneration, cataract, sensorineural deafness, peripheral neuropathy, cerebellar ataxia, anosmia, hemeralopia, muscular atrophy, cardiomyopathy, progressive myelin degeneration, functional disorders of the nervous system, cochlear hearing loss, and renal failure, and an increase in the cerebrospinal fluid level of protein.[53,54,55] It is caused by biallelic pathogenic variants in either *PHYH* (encoding phytanoyl-CoA hydroxylase), which accounts for more than 90% of Refsum disease, or *PEX7* (encoding the PTS2 receptor), which accounts for less than 10% of the disease.[56]

Multiple sulfatase deficiency is a rare autosomal recessive lysosomal storage disorder due to a deficiency in a formylglycine-generating enzyme, encoded by the sulfatase-modifying factor 1 (*SUMF1*) gene. Clinical findings include ichthyosis, metachromatic leukodystrophy, acidic mucopolysaccharidosis, developmental regression, intellectual disability, periventricular white matter disease, and reduced tooth germ size and enamel thickness.[57] At 2 or 3 years of age, patients become unable to sit and also show symptoms of blindness and speech impairment.[58,59]

Keratitis ichthyosis deafness (KID) syndrome is a congenital ectodermal disorder considered to be an autosomal dominant inherited disease. The disorder is characterized by the thickened granular skin with keratotic scaly plaques, recurrent facial abscesses and blepharitis, dry eye, corneal edema, bilateral retinopathy, keratitis with corneal neovascularization, sensory hearing loss, nail deformities, dental abnormalities, loss of eyebrows, and scarring alopecia of the scalp.[60,61,62] Genetically, KID syndrome may be caused by mutations in the connexin gene *GJB2* and/or *GJB6*, which encode connexin proteins (Cx) 26 and 30, respectively.[63] Most of the cases are sporadic, but they can be familial as well.[64]

CHILD syndrome (congenital hemidysplasia, ichthyosiform erythroderma, or nevus and limb defects) is an extremely rare X-linked recessive or dominant disorder that is lethal to males, who die in utero. Most surviving patients are females. It is related to mutations in the *NSDHL* gene that encodes for the enzyme 3β-hydroxysteroid dehydrogenase that is involved in cholesterol pathways.[65]

Unilateral ichthyosiform erythroderma is present at the time of birth or appears within a few weeks after birth. Ipsilateral limb reduction, nail thickening, and hair abnormalities or alopecia concomitantly occur.[66]

(Print pagebreak 473)

IBIDS syndrome (ichthyosis, brittle hair, impaired intelligence, decreased fertility, and short stature) is an autosomal recessive complex neuroectodermal syndrome. It is associated with noncongenital ichthyosis that begins at several months of age, mild, brittle cystine-deficient hair, sparse eyelashes and eyebrows, impaired intelligence, neurologic disorders, and short stature. Cataract, retinal dystrophy, strabismus, and recurrent infections are additional features.[67,68] Patients have unusual facies that may include microphthalmia with apparent enophthalmos, receding chin, small and thin nose, small mouth, small ill-set teeth, and protruding ears. Some patients are born as collodion babies.[8] The specific genetic basis for this condition is unclear, but mutations in genes encoding subunits of the transcription/repair factor IIH (*TFIIH*) have been described.[69]

Conradi-Hünermann-Happle syndrome is a rare X-linked dominant ichthyosiform condition affecting approximately 1:400,000 births. It is caused by mutations in the *EBP* gene that result in a deficiency of 3β-hydroxysteroid-Δ8, Δ7-isomerase enzyme in the distal pathway of cholesterol biosynthesis.[70] This condition affects only females and manifests as ichthyosis following the lines of Blaschko, punctate cartilage aplasia, patchy scarring alopecia, and short stature.[71] Up to 67% of the patients have cataracts that are already present at birth or develop early in life. Occasionally, other eye findings such as microphthalmia, microcornea, glaucoma, or atrophy of the optic nerve have been reported.[70]

Etiology and Pathophysiology

Ichthyosis occurs when there is a disruption in the process of skin cornification, resulting in hyperkeratosis, scaling, and abnormalities of the stratum corneum barrier function.[72] A thickened stratum corneum results from an increased rate of cells entering this phase at an increased rate or of prolonged retention of corneocytes. All ichthyosiform dermatoses have abnormal cornification in common. Cornification and shedding of the stratum corneum is a complex and multistep process mediated by multiple enzymes operating in sequence. This process can be affected by a variety of genetic mutations that influence alterations in the water content or changes in the lipid composition of the intercellular material.[72]

The pathophysiology of most inherited forms of ichthyoses has been based on the identification of mutations in over 50 genes that encode structural proteins or enzymes involved in a variety of cellular functions from DNA repair to skin barrier homeostasis.[5] Abnormalities in these genes result in epidermal hyperplasia and increased stratum corneum accompanied by abnormal desquamation and visible accumulation of scales on the skin.[73]

Lamellar ichthyosis can be caused by mutations in any one of many genes. Mutations in the *TGM1* gene are responsible for approximately 90% of cases. The *TGM1* gene encodes for transglutaminase 1 that is involved in the formation of the cornified cell envelope and is essential for the development of the normal intercellular lipid layer formation in the stratum corneum.[4,74] This cell envelope is a structure that surrounds skin cells and helps form a protective barrier between the body and its external environment.[72] At least 14 different *TGM1* mutations have been identified,[75] which result in reduced or absent production of transglutaminase 1, which prevents the formation of the cornified cell envelope.[8] Epidermal turnover is accelerated resulting in proliferative hyperkeratosis.[4]

Acquired ichthyosis, usually appearing for the first time in adulthood, is a nonhereditary condition associated with a variety of internal diseases. These ichthyoses are rare and should elicit a search for an underlying systemic disease or cause. Acquired ichthyosis has been described in association with numerous malignancies, including Hodgkin disease, non-Hodgkin lymphoma, leiomyosarcoma, mycosis fungoides, multiple myeloma, Kaposi sarcoma, and carcinomas of the ovary, breast, gastrointestinal tract, lung, and cervix.[76,77,78,79,80]

When it is associated with malignancy, the severity of the cutaneous manifestations usually mirrors the course of the malignancy.[81] Acquired ichthyosis may represent a paraneoplastic syndrome from an underlying malignancy.[82,83,84]

Acquired ichthyosis also has been seen in the setting of infections such as active pulmonary tuberculosis[85] or associated with autoimmune disorders such as systemic lupus erythematosus[86] or autoimmune thyroiditis.[87] Cases have been attributed to the use of certain medications[88,89,90,91] and with nutritional deficiency.[92]

Clinical Presentation

Limbal stem cell deficiency can cause descemetocele and corneal perforation in ichthyosis.[61,62] Tarsorrhaphy with amniotic membrane transplantation can be used to treat persistent corneal epithelial defects.[93] Ichthyosis is associated with numerous eyelid and ocular manifestations.[94] Cicatricial ectropion is one of the most common findings, first reported by Arnold in 1834, resulting from shortening of the cutaneous anterior lamella (Figure 71.1).[4,95] The ectropion often results in ocular surface complications such as lagophthalmos, conjunctivitis, exposure keratopathy, corneal opacification, and rarely even corneal perforation (Figure 71.2). Photophobia, pain, epiphora, and foreign body sensation are prominent symptoms.[96] Symptoms usually begin at birth or in the first few months of life and persist throughout life.[6]

The severity of symptoms varies considerably depending upon the specific genotype of ichthyosis.[5,97,98] While the majority of patients have only mild to moderate skin symptoms, in some cases, they can be very severe with almost *(Print pagebreak 474)* complete ectropion and retraction of the lower eyelid (Figure 71.3).[98,99] Most patients have some degree of increased transepidermal water loss due to defects in the biosynthesis of proteins and lipids necessary for normal barrier formation.[100]

Once the diagnosis of ichthyosis is established or suspected, an underlying cause should be sought.[72] The most important initial step in evaluation is a detailed family history, review of symptoms, and a physical examination. Genetic testing is important to distinguish among the various subtypes of ichthyosis.

In adults with acquired ichthyosis, questioning should inquire about a history of malignancy, constitutional symptoms, history of liver or kidney impairment, medication use, and dietary history. Laboratory studies should be considered, biopsy specimens should be obtained, and genetic testing is undertaken to differentiate the various types of ichthyosis.[101]

(Print pagebreak 475)

Differential Diagnosis

The diagnosis of ichthyosis is usually obvious when it presents at birth or shortly thereafter. The major differential difficulty involves assigning the condition to one of the many subtypes. This is typically done with genetic testing of the child and family members, especially when the inheritance pattern is unclear.

Ichthyosis vulgaris is relatively mild and often mistaken for simple dry and scaly skin, so it can easily go undiagnosed. But this is an autosomal dominant congenital disease, so a positive family history is typical. The differential diagnosis for lamellar ichthyosis includes other ichthyoses, such as epidermolytic hyperkeratosis, self-healing collodion baby, Sjörgen-Larssen syndrome, X-linked ichthyosis, congenital ichthyosiform erythroderma, Comèl-Netherton syndrome, and trichothiodystrophy.[72] Later in life, lamellar ichthyosis is usually distinguished from other forms of ichthyoses based on history and clinical findings.[102]

Treatment

Genetic testing is an important tool in the successful management of congenital ichthyosis. Not only can it confirm the diagnosis but it also allows appropriate parental counseling.[103] Identifying the specific subtype of ichthyosis and its causative genetic mutations can help predict the clinical course of the disease.[100]

Currently, there is no cure for ichthyosis. Management is mostly supportive and must be based on individual signs and symptoms. In infants, a moist environment should be maintained to prevent infection.[8] Neonates should be monitored for fluid and electrolyte imbalances and temperature regulation. In older children and adults, humidification and lubrication may help to promote peeling and thinning of the stratum corneum.[8] The stratum corneum can absorb many times its weight in water so that emollients, such as petrolatum-based creams and ointments or water-in-oil preparations, should be applied after bathing while the skin is still wet.[8] Alpha hydroxy acids help reduce corneocyte adhesion and decrease the thickness of the epidermis, urea creams can help soften the scales, and topical retinoic acids can decrease thickened scales.[97,98] Tazarotene (Tazorac) 0.05% is a retinoid prodrug applied as a topical gel. Its active metabolite modulates the differentiation and proliferation of epithelial tissue, and it may also have anti-inflammatory and immunomodulatory properties.[8,104]

Ectropion can result in ocular sequellae including conjunctivitis, lagophthalmos, exposure keratopathy, and potentially vision-threatening side effects such as corneal perforation.[105] Therefore, cicatricial ectropion should be promptly managed either medically or surgically to aid in corneal protection. Early and extensive use of topical lubricants is the mainstay of initial ocular management. Definitive management of the ectropion is with surgery, usually with skin grafts to lengthen the anterior lamella. However, in many patients, healthy uninvolved skin may be difficult to find anywhere on the body.[96] The timing of surgery is also controversial. Whereas early surgery may be indicated to safeguard the cornea, the decision should be individualized according to the severity of the signs and symptoms because most forms of ichthyoses are progressive and the main postoperative issue after skin grafting is relapse.[103] Therefore, if early surgery is indicated, a close-followup, frequent wetting of the graft, as well as regular ocular lubrication are of paramount importance.[103] Oral mucus membrane grafts have been used as an alternative with good long-term results in preserving the functionality of the eyelid.[94,106] In a long-term follow-up of mucous membrane grafts for cicatricial ectropion, on histopathology the grafts showed evidence of acanthosis and mild metaplasia but no signs of dysplasia or marked fibrosis and contracture.[94] Human engineered skin was also reported to give good results.[105]

Prognosis

With appropriate care, mild cases of ichthyosis generally have an excellent prognosis, whereas patients with severe disease may be difficult to control. In cases of harlequin ichthyosis, the most severe form, there is a significant mortality rate and few children survive into young adulthood.

In the neonatal period, following the shedding of the collodion membrane, infants with ichthyosis are at risk for infection and dehydration. In childhood, hyperkeratosis interferes with normal sweat gland function, predisposing to heat intolerance.[4] The adhesion of platelike scales constricts and obstructs sweat ducts, causing heat intolerance, and contributes to caloric and water loss. In some children with ichthyosis vulgaris, the scales can become less noticeable during puberty or even disappear during childhood and return during the teen years or even adulthood. The patient may also suffer psychologically because of their physical appearance.

Eyelid ectropion, when not managed with lubricants and surgery when necessary, can result in lagophthalmos and exposure keratitis, and in some cases corneal scarring or perforation.

Histopathology

The histopathology of ichthyotic skin disorders depends on the disease variant.[7,107,108,109,110,111,112] The histopathological

features of ichthyosis vulgaris are seen best in biopsies from areas of maximum clinical hyperkeratosis.[110] The epidermis may be acanthotic, atrophic, or of normal thickness with mild to moderate orthohyperkeratosis forming a compact, laminated, eosinophilic stratum corneum (Figure 71.4A).[107,110] Parakeratosis is seen occasionally (Figure 71.4B),[111] especially when there is superimposed atopic dermatitis.[107] The granular cell layer is markedly thinned or absent, which is the key diagnostic feature of ichthyosis vulgaris.[107,109,110] Sebaceous glands are atrophic or absent, and there is a sparse lymphohistiocytic infiltrate around superficial dermal blood vessels.[110,111] Specimens from areas with only mild scales may be indistinguishable histologically from normal skin.[110]

(Print pagebreak 476)

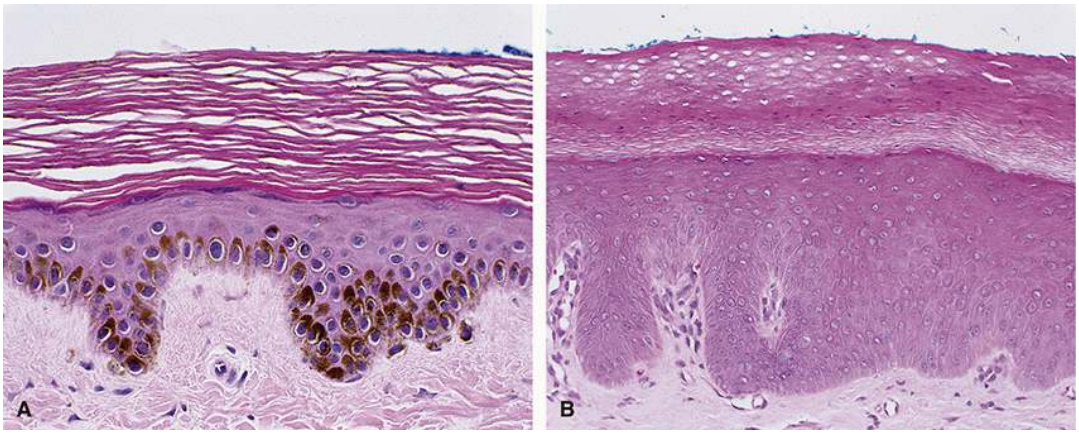

FIGURE 71.4 A, This example of ichthyosis vulgaris has an atrophic epidermis with a moderately thick layer of orthohyperkeratosis and a stratum granulosum reduced to one cell in thickness. B, This ichthyosis vulgaris biopsy has an acanthotic epidermis, an absent stratum granulosum, and a moderately to markedly thickened stratum corneum with a mixture of orthohyperkeratosis and parakeratosis.

CHAPTER 72

Impetigo

Key Points

- Impetigo is a highly contagious bacterial skin infection
- It is most common in warm tropical climates, with crowded living conditions, poor hygiene, and lower socioeconomic conditions
- Impetigo is caused by *Staphylococcus aureus* or group A beta-hemolytic *Streptococcus pyogenes*, or both
- There are two common forms of impetigo, nonbullous (70%) and bullous (30%) with distinct causes and clinical appearances
- Nonbullous impetigo is caused by *S. aureus* or *S. pyogenes* and is characterized by superficial honey-colored crusted lesions on the face and extremities in areas of compromised skin
- Bullous impetigo is caused by *S. aureus* and presents as large bullae located in intertriginous areas of the body that rupture and ooze yellow fluid
- Impetigo is usually a self-limiting infection and usually resolves within 3 weeks
- Antibiotic treatment is usually initiated for faster resolution and to prevent the spread to other individuals
- The prognosis is excellent, but a small percentage of cases can progress to renal failure, septic arthritis, scarlet fever, and sepsis

Impetigo is a highly contagious bacterial skin infection of the superficial layers of the epidermis most commonly caused by gram-positive bacteria.[1,2] Major risk factors include warm tropical climates, crowded living conditions, poor hygiene, lower socioeconomic conditions, daycare centers, crowded schools, close-contact sports, and poor immunity status.[1,3,4,5,6,7] Impetigo is less frequently seen in northern climates during the summer months.[8] It is seen most often in children, where it accounts for approximately 10% of skin disorders in pediatric patients.[2]

Normal skin is inhabited by large numbers of bacteria that usually do not lead to medical problems, but in susceptible skin with various predisposing factors, some bacteria can lead to cutaneous infections.[1,9,10,11,12] Impetigo is a contagious infectious dermatosis caused by *S. aureus* or group A β-haemolytic Streptococcus (GAS) or both.[4,13] The most common type of GAS is *Streptococcus pyogenes*. Individuals of any age can be affected, but children between 2 and 5 years of age are most often involved.[1,14] In children, there is no gender predilection, but in adults, men are more commonly affected.[2] Globally, the number of children suffering from impetigo at any one time has been estimated to be more than 162 million.[1]

There are two common forms of impetigo, nonbullous and bullous with distinct causes and clinical appearances.[15] A third type that is frequently mentioned in the literature is ecthyma which is basically a deeper ulcerative form of impetigo, although some authors believe it is a unique form of skin infection.[6,15] Nonbullous impetigo comprises approximately 70% of all cases and is caused by *S. aureus* or *S. pyogenes*.[4] Lesions are most often located on the face and extremities. Bullous impetigo is caused by *S. aureus* and usually takes the appearance of large bullae, which tend to be located in intertriginous areas of the body.[4]

Etiology and Pathophysiology

Studies have shown that the streptococcal strains responsible for impetigo colonize the unbroken normal skin before the development of skin lesions by an average interval of about 10 days.[8] Nonbullous impetigo, also known as impetigo contagiosa, is caused by *S. aureus* or *S. pyogenes*.[4,13] It is characterized by superficial honey-colored crusted lesions on the face and extremities. The infection is highly contagious and can spread to adjacent areas by auto-inoculation.[3,4,14,16] Lesions develop from intradermal

inoculation of surface bacteria into broken areas of skin from abrasions, minor trauma, or insect bites. Occasionally, the infection may spread from the skin to the upper respiratory tract after 2 to 3 weeks.[2]

Bullous impetigo is caused by a toxin produced by *S. aureus.* It is seen in infants and tends to affect the trunk, extremities, and moist intertriginous areas such as the axillae, neck fold, and diaper area. Lesions are characterized by rapidly enlarging, flaccid bullae that rupture and ooze, revealing a collarette of scales.[17] When extensive, skin lesions may be accompanied by systemic symptoms including fever, diarrhea, and generalized weakness.[3,4,14,16]

Clinical Presentation

Clinically, impetigo presents as either nonbullous or bullous lesions. The nonbullous type is more common and is seen principally in children, although it can occur in adults less frequently.[18] Nonbullous impetigo can develop as either a primary or secondary infection and is generally seen on the face or extremities in skin that has been compromised.[19] The primary form results from direct inoculation of bacteria into the skin,[4] whereas the secondary form is associated with disruption of skin integrity following trauma or underlying dermatologic conditions.[4] Lesions usually begin *(Print pagebreak 480)* as maculopapular pustules that evolve to thin-walled vesicles (Figure 72.1A). These tend to rupture, exuding a purulent exudate that forms a characteristic honey-colored crust on an erythematous base (Figure 72.2).[4,13] Without treatment, these lesions generally persist for 2 to 3 weeks before resolving without a scar.[4,13] Mild regional lymphadenopathy is commonly associated. Systemic symptoms such as fever are typically absent.

Bullous impetigo is caused by *S. aureus* and is seen more commonly on intact skin in intertriginous regions of the trunk, groin, axillae, neck, buttocks, and extremities in infants.[4,9,11,18] The exfoliative toxin A produced by *S. aureus* causes loss of cell adhesion in the superficial epidermis resulting in large, fragile, flaccid bullae that can rupture and ooze yellow fluid.[4,11] These rupture leaving an erythematous base with a scaly rim and a thick brown crust.[2,11,18] Unlike nonbullous impetigo, regional lymphadenopathy is not seen, but systemic symptoms, such as fever, are common.

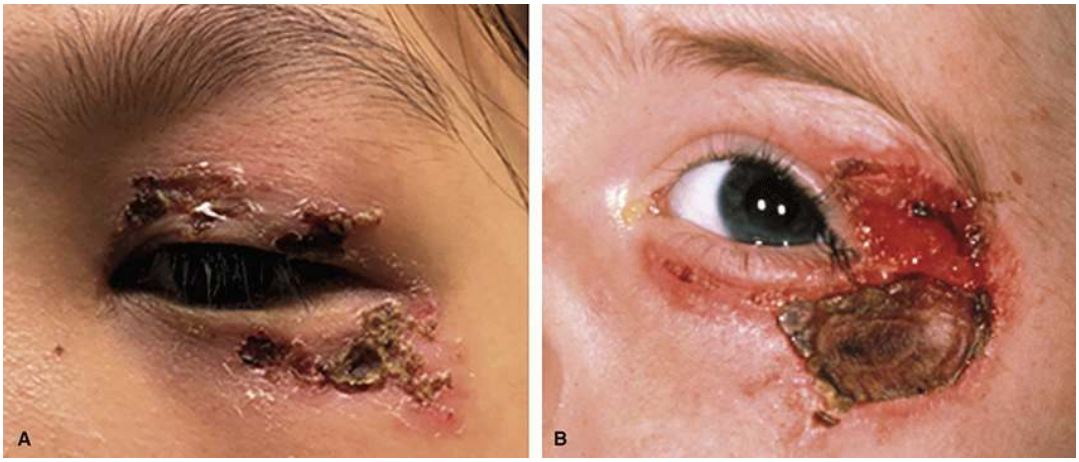

FIGURE 72.1 Eyelid impetigo. A, As maculopapular pustules. B, Ruptured bullae, exuding purulent exudate on an erythematous base. (A, Courtesy of Dr. Roman Shinder.)

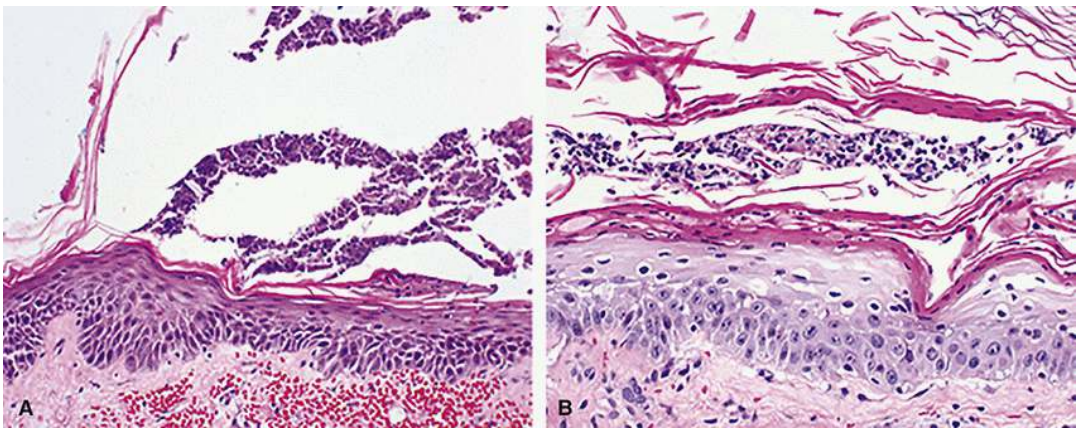

FIGURE 72.2 A, This example of bullous impetigo has a subcorneal blister containing neutrophils, debris, and bacteria. There is acute hemorrhage in the papillary dermis but no inflammation. B, Common impetigo has subcorneal accumulation of neutrophils and bacteria. In this example, there is parakeratosis, a feature of older lesions.

Differential Diagnosis

The differential diagnosis of impetigo includes a large variety of inflammatory and infectious cutaneous conditions and depends on whether the lesion is nonbullous or bullous.[14,20] For nonbullous impetigo, the differential includes lesions such as atopic dermatitis, contact dermatitis, scabies, *(Print pagebreak 481)* erysipelas, *Herpes simplex*, candidiasis, and tinea.[4,19] Atopic dermatitis is seen in children as thickening of the skin, with scaling and weeping papules. Contact dermatitis follows contact with a causative agent resulting in pruritic, edematous, erythematous papules and vesicles often with crusts and central erosions. Scabies is caused by the mite *Sarcoptes scabiei* that cause cutaneous burrows in which the mite deposits eggs. Lesions appear as intensely pruritic, pinhead-sized papules with punctate erosions, crusts, and scales, mostly in axillary folds, the umbilical region, and buttocks. The face is rarely involved. Erysipelas is a dermal streptococcal infection that spreads through superficial lymphatics forming a well-defined, painful, erythematous rash with raised edges and mostly affects older adults. *Herpes simplex* is a viral infection appearing as densely grouped pitted vesicles, blisters, and erosions associated with pain and pruritus. Candidiasis is a pathogenic yeast infection presenting as large confluent areas of scaly, erythematous lesions with satellite foci, and a collarette of scales, usually in intertriginous areas. Tinea is a mycotic infection appearing as sharply delineated scaling nummular patches and pustules.

For bullous impetigo, the differential diagnoses includes pemphigus vulgaris, insect bites, bullous pemphigoid, and second-degree thermal burns.[20] Bullous pemphigoid and pemphigus vulgaris are autoimmune conditions usually seen in older adults. Pemphigus vulgaris is characterized by generalized flaccid bullae and extensive erosions on an erythematous base. Bullous pemphigoid presents in elderly individuals as subepidermal blistering on normal or erythematous skin.

Treatment

Impetigo is usually a self-limiting infection and typically resolves within 3 weeks.[4] It is managed initially with general care beginning with proper hand hygiene, washing clothing, and not sharing towels to help limit the spread of the disease. Washing the lesions with soap and warm water can remove crusts and secretions.[11] However, impetigo may lead to secondary infection and occasionally can develop into more serious systemic conditions, so that some form of treatment is usually recommended. Antibiotic treatment is initiated for faster resolution, to prevent the spread to other individuals,[10,21] and to decrease the risk of complications involving the kidneys, joints, bones, and lungs.[21,22,23]

For localized nonbullous impetigo, mupirocin, retapamulin, and fusidic acid have been considered the agents of choice.[2,24,25,26] Mupirocin (pseudomonic acid A) is a metabolite of *Pseudomonas fluorescens* fermentation[11] and acts by inhibiting bacterial protein synthesis. Applied as a 2% cream or ointment, it is highly effective against *S. aureus*, *S. pyogenes*, and other species of streptococci.[11] Retapamulin 1% ointment is a novel pleuromutilin antibacterial drug derived from the fungus *Clitopilus passeckerianus*, with antibacterial activity against *S. aureus* (methicillin-susceptible isolates only) and *S. pyogenes*.[27] Ozenoxacin 1% cream is a novel nonfluorinated quinolone[17] approved for the topical treatment of nonbullous impetigo, with potent antimicrobial activity against staphylococci and streptococci, and a broad range of activity against methicillin-, mupirocin-, and ciprofloxacin-resistant strains of *S. aureus*.[28,29,30]

Systemic antibiotics are indicated for all cases of bullous impetigo and for cases of nonbullous impetigo with deep tissue involvement, signs of systemic infection, lymphadenopathy, oral lesions, or cases resistant to oral antibiotics.[2,16,31] Erythromycin and penicillin were standard treatments in the past, but they are no longer routinely used because of increasing drug resistance.[32] Beta-lactamase-resistant antibiotics such as cephalosporins, amoxicillin-clavulanate, and dicloxacillin are preferred for mixed infections. If MRSA infection is suspected, the recommended initial treatment is with trimethoprim/sulfamethoxazole, clindamycin, or a tetracycline (doxycycline or minocycline [Minocin]) pending culture results.[9]

Prognosis

Most cases of impetigo are expected to heal spontaneously in 2 to 3 weeks.[13] Scarring is uncommon but some patients may develop pigmentary changes. With antibiotic treatment, the resolution is faster, usually within 10 days.[2] In rare cases, neonates may develop meningitis and post-streptococcal glomerulonephritis seen more commonly with *Streptococcus* and appearing 7 to 14 days after onset of the skin infection. Other rare complications include septic arthritis, scarlet fever, sepsis, and staphylococcal scalded skin syndrome.[2]

Histopathology

The best descriptions of bullous impetigo histopathology (Figure 72.2A) are from Unna in 1896[33] and Kouskoukis and Ackerman in 1984.[34] Unna termed the entity "impetigo staphylogenes" and described pus, bacteria, and well-preserved individual and small groups of epithelial cells collecting between the epidermal horny and prickle layers with an outward expansion of the horny layer and flattening and posterior bowing of the posterior epidermis.[33] Kouskoukis and Ackerman examined biopsies from 42 patients.[34] They noted "blisters situated beneath the cornified layer, within the granular layer, or in the upper part of the spinous layer, acantholytic cells, and variable numbers of neutrophils within the blisters, epidermal hyperplasia, slight spongiosis, slight edema in the papillary dermis, and superficial perivascular and interstitial inflammatory cell infiltrates composed of lymphocytes, histiocytes, neutrophils, and eosinophils."[34] The feature that distinguished bullous impetigo from superficial pemphigoid was the presence of bacteria only within the blisters of bullous impetigo.[34] An adult case of bullous impetigo had intraepidermal cleavage beneath the granular layer with numerous acantholytic granular cells in the blister.[35]

(Print pagebreak 482)

Early lesions of common nonbullous impetigo have subcorneal accumulation of neutrophils and gram-positive cocci (Figure 72.2B), and a few acantholytic cells may be present.[36] Neutrophils often extend through the underlying epidermis.[36] As the lesions age, there is a surface crust of serum, neutrophils undergoing degeneration, and parakeratosis.[36]

CHAPTER 73

Infantile Hemangioma

Key Points

- Infantile hemangiomas are the most common benign soft-tissue tumors of infancy and childhood
- The pathogenesis of hemangiomas is not clearly understood
- Most cases are sporadic and are not inherited, but families with a Mendelian pattern of inheritance have been reported
- It is hypothesized that vascular stem cells that are normally present in the fetus occasionally persist and become dysregulated leading to hemangioma formation
- Infantile hemangiomas occur most frequently in the head and neck region
- They usually are not present at birth but may be preceded by a small area of pallor or a slightly purplish hue that gradually brightens and expands in size
- This is followed by a rapid proliferative phase for 6 to 12 months in which the tumor grows exponentially to a raised bright red lesion with a smooth or irregular outer surface
- The treatment of choice is systemic propranolol, which is believed to work by blocking the proangiogenic signaling of VEGF and bFGF, and also potentiates apoptosis
- Lesions tend to regress with time, but with treatment regression may be more rapid and dramatic

Infantile hemangiomas (IHs) are the most common benign soft-tissue tumors of infancy and childhood, with a prevalence that reportedly varies between 4% and 12%.[1,2,3,4,5,6,7,8,9,10,11] IH has unique growth characteristics with an explosive onset phase followed by regression. Although most hemangiomas tend to resolve spontaneously, some can cause life-threatening complications or may even lead to permanent disfigurement. Several synonyms for IH exist, some of which are no longer in use, and should be avoided including capillary hemangioma, strawberry hemangioma, strawberry nevus, juvenile hemangioma, angioma, or birthmarks.[2] Despite the repeated attempts by the International Society for the Study of Vascular Anomalies to simplify terminology,[12] hemangiomas remain a heterogeneous group and several of the aforementioned synonyms are still frequently used in the literature and in everyday medical practice. The term “hemangioma” or IH will be used predominantly throughout this chapter.

Etiology and Pathogenesis

Despite the considerable advances in our understanding of the pathogenesis of hemangiomas, many unanswered questions remain and the precise mechanisms dictating both proliferation and involution are not clearly understood.[3,13] Most cases are sporadic and are not inherited; however, families with a Mendelian pattern of inheritance have provided some insight into the genes that may one day prove to have a causal link or at least may be partially involved in the pathogenesis of IH through the proteins these genes encode.[9] These associations are mostly weak; however, candidate genes have been mapped to some specific locations including 2p13, 2q23, 4q12, 5q31, 7q33, and 15q26.[9,14,15]

However, it appears that somatic mutations may play a far more important role in the pathogenesis of congenital hemangioma (CH), which is the rarer variant of IH. Mutations in both GNAQ and GNA11 loci have been demonstrated recently in both variants of CH: the rapidly involuting type (RICH) and the noninvoluting type (NICH).[16]

The exact pathogenetic events leading to the development of hemangioma are unknown. It is hypothesized that vascular stem cells, the so-called hemangioma stem cells (HemSCs) that are normally present in the fetus, occasionally persist and become dysregulated leading to hemangioma formation, but it is not clear whether they originate from the placenta or the bone marrow.[17,18] A placental origin of IH has been proposed repeatedly over the years. Recent evidence is more in favor of a placental embolic origin during

early fetal life, in addition to a postnatal favorable environment that supports proliferation and differentiation of those embolized primitive cells.[19,20] Embolization usually occurs in the first trimester coinciding with the migration of neural crest cells, which leads to the integration of these cells along the neural crest migratory routes, thereby manifesting as segmental lesions. If embolization occurs later during fetal life, it usually results in discrete lesions which are the more frequently observed pattern in the periorbital region.[19,20] This placental origin of IH is supported by the expression of glucose transporter 1 (GLUT1) protein on the endothelium of hemangiomas and is also supported by the increased incidence of IH in infants born following amniocentesis and chorionic villus sampling.[19,20]

It is also not entirely clear whether the initial or proliferative phase of IH involves angiogenesis (formation of new blood vessels from existing ones through sprouting of endothelial cells) or vasculogenesis (de novo formation of vessels from *(Print pagebreak 484)* progenitor cells). The former theory is supported by the detection of angiogenic factors such as basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF-A) within the tumor. The vasculogenesis theory is supported by the presence of immature multipotent progenitor stem cells, which are capable of de novo blood vessel formation as well as adipogenesis.[1,21] It is not implausible that both mechanisms may play a role, with vasculogenesis as the initiating event, followed by angiogenesis, which amplifies the size of the lesion to become an irregular mass full of blood vessels.[21] The involution of IH is attributed to the gradual depletion of HemSCs.[17]

Recently, it has been shown that hemangioma patients have significantly increased serum levels of renin and angiotensinogen II. This discovery of a potential role for the renin-angiotensin system in the pathogenesis of IH provides a credible explanation for the programmed biologic behavior of IH and the accelerated involution that occurs with the use of β-blockers.[13,20] The insulin-like growth factor system and the TRAIL-osteoprotegerin antiapoptotic pathway are also possibly involved in the evolution of IH.[20]

Historically, vascular anomalies were classified according to the size of the lumen (capillary vs cavernous), or according to the nature of their fluid content (hemangiomas vs lymphangioma). This classification is no longer accepted and currently vascular anomalies are classified according to the proliferative potential of the vascular endothelium.[12] A distinction should thus be made between hemangiomas, which are true tumors that grow by endothelial cell hyperplasia or proliferation, are not present at birth, do not grow indefinitely, and have a regression phase, and vascular malformations, which occur as a result of a structural defect in vascular morphogenesis, are present at birth, grow in size with growth of the individual, do not possess a regression phase, and have a normal rate of endothelial turnover.[14,22] Because of their clinical diversity, the classification of hemangioma itself is difficult. While IH elsewhere in the body is usually classified morphologically into (1) localized, (2) segmental, (3) indeterminate, or (4) multifocal, the majority of periocular IHs are small and localized, and even if they are large or display a geographic pattern, they are not consistently associated with a particular segmental distribution.[10,12] Although periocular IH still can be classified zonally into the aforementioned groups, which may indeed be of useful prognostic value, larger periocular lesions may not follow a specific dermatomal distribution,[11] which may hinder a strict classification. From a clinical standpoint, it may be better to classify periocular lesions according to their depth into superficial, deep, or mixed lesions where the lesions acquire characteristics of both subtypes.[4,5,12]

Clinical Presentation

IHs represent the most common vascular tumors in infancy. It most frequently involves the head and neck region, followed by the trunk, and the extremities. IH is found in greater frequency in girls (3:1-5: 1 ratio), whites, premature infants, and twins, and more commonly develops when the mother is of higher maternal age.[1,2,14] Obtaining an accurate natural history as regard the age of onset, ethnicity, and rate of progression/regression is extremely important in patients with hemangiomas to differentiate IH from closely related lesions but less common ones like CHs where the lesion is fully developed at birth, does not show a proliferative phase, and may either rapidly involute by 12 to 18 months (RICH) or may never regress at all, but instead grows with the growth of the child (NICH).[2,9] An intermediate form exists where partial regression may be observed (partially involuting congenital hemangioma, PICH).[12]

The classic dictum that IHs are not present at birth may not entirely be accurate.[1] Not infrequently, there is a precursor lesion, usually a small area of pallor or a slightly purplish hue that gradually brightens and expands in size. In actual clinical practice, those lesions become more apparent in the first few weeks of life as a flat macular area of telangiectatic vessels that usually blanches on compression.[1,4,5] This is followed by a rapid proliferative phase for 6 to 12 months, in which the tumor grows exponentially. Subsequently, this is followed by a phase of gradual involution or spontaneous regression.[2,4]

In superficial lesions that involve the skin, the infant usually presents with a flat to slightly elevated bright red tumor with a smooth or irregular outer surface (Figure 73.1). The surface may resemble a strawberry, and hence the old name strawberry nevus. During the proliferative phase, lesions enlarge rapidly, often resulting in aesthetic and functional disability (Figure 73.2). Deep lesions may be located subcutaneously where the eyelid assumes a deep bluish hue or may be located deep within the orbit where it causes a mass effect in the eyelid without any discoloration (Figure 73.3).[4,5,12] Deeper orbital lesions may displace the globe, causing axial

or nonaxial proptosis, optic neuropathy, or bony deformities.[4,13] Mixed lesions may involve both the skin and the deeper tissues. Rapidly growing superficial lesions may cause deprivation amblyopia in as little as 1 week during the proliferative phase because of occlusion of the visual axis.[4] IH is considered a relative oculoplastic emergency in the first year of life as the prevalence of amblyopia may be as high as 63%.[4,23] Deeper lesions are also potentially amblyogenic due to anisometropia or strabismus.[4,23]

The clinical behavior of CH is rather different. Because RICH develops in utero, it can be detected prenatally as early as 12 weeks of gestation. In the newborn, it presents as a raised, grayish solitary tumor with fine telangiectasias and a pale halo. RICH rapidly regresses, leaving a patch of subcutaneous atrophy, and dilated veins. However, NICH presents as a plaque-like, well-circumscribed telangiectatic tumor with a purple-pink rather than a grayish hue, and usually remains unchanged throughout childhood. However, there are exceptions where partial involution occurs (PICH).[12,16]

The proliferative phase usually lasts about 1 year. Afterward, hemangiomas tend to involute. Previously it was taught that IHs involute roughly at a rate of 10% per year, and that 30% of tumors completely regress at the age of 3 years and 75% to 90% *(Print pagebreak 485)* by the age of 7 years, although some lesions may take more than 10 years to resolve.[13,23] More recent evidence suggests that involution of IH is usually complete by the age of 3.5 to 4 years.[24,25]

FIGURE 73.1 Early minimally elevated infantile hemangiomas on the eyelids and periorbital region.

Although solitary lesions are the most common form of presentation in the periocular region,[1,14] segmental or diffuse involvement of the face, which generally follows the embryonic fusion lines, may occasionally be observed.[11] Larger IH lesions of the face (>5 cm in diameter) are prone to pain, bleeding, or ulceration, the frequency of which triples with diffuse hemangiomas. They are more commonly associated with other congenital anomalies including the PHACE syndrome, which is characterized by posterior fossa abnormalities, hemangioma, arterial abnormalities, cardiac defects, and eye anomalies, or the closely related LUMBAR syndrome (lower body hemangioma, urogenital anomalies, myelopathy, bony deformities, anorectal malformations, and renal anomalies).[1,4,5,26] IH may also be associated with extensive visceral hemangiomatosis, which can trap platelets within their vascular channels, leading to thrombocytopenia and secondary coagulopathy, and which can prove fatal (Kasabach-Merritt syndrome).[5] The current consensus, however, is that Kasabach-Merritt syndrome is not typically associated with the classic IH and only occurs in the setting of more aggressive hemangiomas like kaposiform hemangioendothelioma and tufted angiomas.[13] Multifocal hemangiomas may be associated with other systemic complications according to the location of the lesion including high output heart failure, airway obstruction, postural inability to turn the head in neck lesions, or auditory canal occlusion.[11] RICH could also be associated with congestive cardiac failure and transient low-grade thrombocytopenia and may occasionally result in overwhelming complications from heart failure or hemorrhagic ulceration.[16]

Although the clinical diagnosis of IH is straightforward, the diagnostic workup should include radiology in doubtful cases. Doppler ultrasound will reveal a high-flow lesion with a typical wave characteristic of IH,[1] while computed *(Print pagebreak 486)* tomography usually shows a lobulated multispatial heterogeneous mass with intense enhancement after contrast administration. MRI is the preferred modality of choice for the initial evaluation of these tumors because of the lack of ionizing radiation when compared to CT, and because it yields better tissue characterization. IH is isointense on T1-W images and hyperintense on T2-W images, demonstrating avid contrast enhancement.[4]

FIGURE 73.2 Late proliferative phase hemangiomas causing significant functional limitation of the eyelids or severe aesthetic disability.

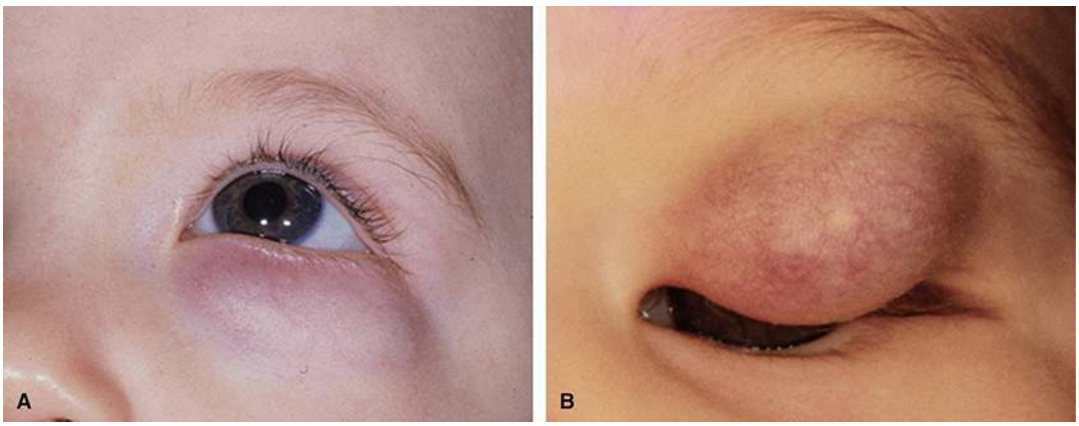

FIGURE 73.3 A and B, Deep subcutaneous infantile hemangiomas in the eyelid may extend into the anterior orbit.

(Print pagebreak 487)

Differential Diagnosis

When the hemangioma is superficial or involves the cutaneous surface, the diagnosis is usually effortless, and even in the setting of cutaneous capillary malformation (also called port-wine stain, PWS), establishing the diagnosis is not difficult. PWS, which develops as a result of a somatic mutation in the GNAQ gene, is present since birth as flat red macules that follow a typical trigeminal nerve distribution (V1, V2, or combined).[27] They grow proportionately with the growth of the child, progressively

acquiring a darker coloration. They may also become slightly thickened or raised (cobblestone appearance) as the individual reaches middle age.[27] PWS may occur in isolation or may be associated with Sturge-Weber syndrome (SWS) particularly if V1 is involved. SWS is a neurocutaneous disorder characterized by the presence of ipsilateral vascular malformations in the cerebral cortex.[27] Ipsilateral glaucoma should always be ruled out in patients with PWS regardless of the presence or absence of SWS. On the molecular level, IH is GLUT1 positive, while PWS is not.[4,27] Differentiating IH from RICH/NICH can be difficult if the history is not clear. However, in the rare event where a biopsy is needed, IH cells positively stain with GLUT1, while RICH and NICH are GLUT1 negative.[4,16]

Diagnostic problems arise when the superficial component of IH is missing, and differentiation from other space-occupying lesions, particularly vascular malformations or soft-tissue malignancies that involve the orbit or eyelids, is required.[4] When in doubt, the clinical characteristics, radiologic imaging including a CT angiography, MRI, computed tomography. or Doppler ultrasound, and possibly even tissue biopsy are used to confirm the diagnosis.[4]

Treatment

Several grading scales of IH have been developed to assess disease severity and guide the treatment protocol as well as follow-up.[13] The two most popular systems are the Hemangioma Severity Scale, which categorizes patients and gives a score based on the risk of complications, and the Hemangioma Activity Score (HAS), which grades IH according to the color profile.[13,28,29,30] The HAS score is a more valuable tool in assessing the response to medical therapy.[13,28,29,30]

Rarely, very small localized superficial IH may not require medical treatment. Management should include reassurance and close observation with photographic documentation, and the HAS scoring system to monitor the rate of growth particularly during the explosive early phase of the disease.[13]

The treatment of hemangiomas was revolutionized in 2008 with the accidental discovery of the beneficial effects of propranolol, a lipophilic nonselective β-blocker in the management of IH.[31] Because of its potency and its low-risk profile, propranolol rapidly became the first line of therapy in patients with IH, and FDA approval was obtained in 2014.[13,32] Propranolol works through several possible physiologic mechanisms, the most accepted being that it arrests the growth of IH by blocking the proangiogenic signaling of VEGF and bFGF, and also potentiates apoptosis.[13] Treatment is usually continued for 6 to 12 months although deeper lesions may require a longer duration.[13]

Propranolol is more effective in the proliferative phase where patients may achieve complete or near-complete resolution of the lesion after 3 to 6 months of treatment; however, it may still accelerate resolution in untreated older cases that are slow to involute.[13] The initial oral dose is in the range of 0.5-1 mg/kg/d, which is gradually increased over the first 2 weeks of treatment to ultimately reach 2 mg/kg/d.[13] Hospitalization usually is not required except in infants <5 weeks of age, or for patients with hypoglycemia, cardiovascular or respiratory diseases, or critically ill patients where parenteral therapy may be required.[33,34]

Propranolol is contraindicated in patients with PHACE syndrome who commonly suffer from aortic coarctation. All patients with PHACE syndrome should be prescreened with echocardiography or cardiac MRI.[13] Propranolol is also contraindicated in preterm infants and in patients with chronic hypotension, chronic sinus bradycardia, second- or third-degree heart block, heart failure, or history of airway disease.[13]

The most commonly encountered side effects are mild; however, severe intolerable side effects are encountered in 2.1% of patients.[35] Side effects include mild respiratory symptoms such as wheezing or respiratory hyperactivity (bronchospasm), hypoglycemia, mood and sleep disturbances, bradycardia, hypotension acrocyanosis, and diarrhea.[13] If mild side effects are encountered, reducing the dose of propranolol may suffice; however, if side effects are intolerable particularly sleep disturbances or respiratory problems, a shift to an alternative β-blocker with a more selective β1 effect and lesser β2 action like nadolol or atenolol may be required. Alternatively, another treatment modality may be chosen.[35,36,37,38]

While systemic therapy is required for vision-threatening cases,[13] small superficial lesions can be treated effectively with topical agents including topical timolol or propranolol. Topical agents may also be required as adjuvant therapy while patients are being tapered off systemic β-blockers to reduce the rate of regrowth or as a form of dual therapy in patients with severe disease.[13,39] Interestingly, topical agents may have some potential role in the management of deeper lesions within the orbit.[40,41]

Alternatives to β-blockers include oral, topical, or intralesional corticosteroids, topical imiquimod, interferon-α, intralesional injection of bleomycin, or angiotensin-converting enzyme inhibitors.[13,42] Currently, the role of systemic or intralesional corticosteroids is limited to patients with a contraindication to β-blockers or in patients who have failed systemic propranolol

therapy.[13,35] In the past, corticosteroids were highly effective in the management of IH, achieving more than 90% success, but the complication profile in the pediatric age group was not trivial.[4] Hypothetically, corticosteroids disrupt vasculogenesis by inhibition of VEGF expression.[13] Intralesional bleomycin may be contraindicated because of the need for multiple injections and because of the higher frequency of development of cutaneous problems including surface ulceration.[13,31]

Historically laser therapy had a more predominant role in the management of IH. Again, this role has been eclipsed by propranolol. Its use is currently limited to patients with residual *(Print pagebreak 488)* postinvolutional cosmetically disfiguring lesions.[13,43] Laser therapy is the only line of therapy for PWS because propranolol has no role in its management.[13,44] If laser therapy is indicated, a pulsed dye laser, argon laser, or CO_2 laser may be used.[13]

Surgical excision of IH is challenging, and its role is limited to patients with a failed response to propranolol or recurrence of the lesion after cessation of therapy. Eager parents who push for surgery should be notified that surgical interference may be fraught with complications including partial recurrence, bleeding, or rarely lid necrosis if excessive cautery is required. Surgery may also be indicated in some cases of CHs (RICH, NICH, PICH) because they do not respond to propranolol and may require surgical excision or embolization if they do not spontaneously involute.[45]

Prognosis

Although regression of IH may be dramatic, and some lesions may disappear without a trace even without treatment,[5] some patients may suffer residual sequelae. The skin in the involved areas could become variably pigmented or redundant from stretch, with residual telangiectasia or fibrofatty tissue.[1,13,24] Those residual lesions are more common with deep and mixed IH, in lesions which take a longer time to involute, and in untreated cases where significant or severe sequelae may persist in 50% to 69% of patients.[23,24,46]

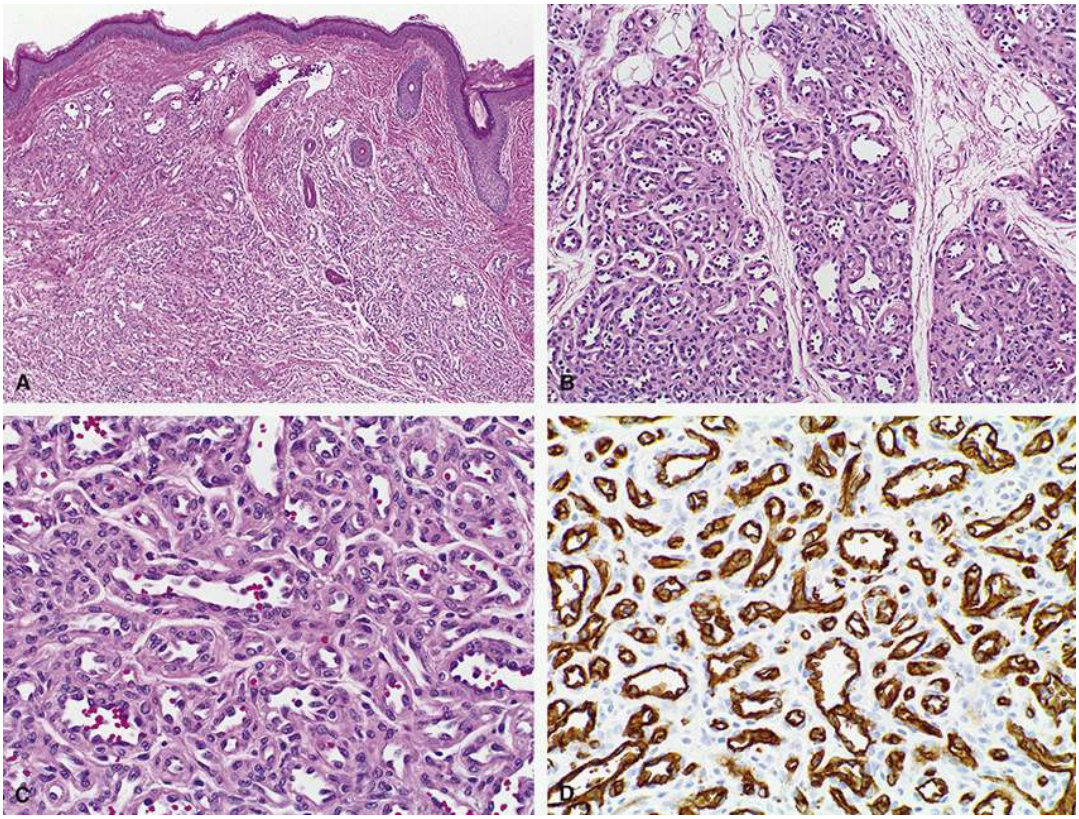

FIGURE 73.4 A, This infantile hemangioma of the glabella is a well-defined unencapsulated dermal mass of closely apposed capillaries. B, The capillaries form lobules separated by thin fibrous septa. C, The capillaries have small lumina and are lined by plump endothelial cells rimmed by plump pericytes. D, The endothelial cells highly express glucose transporter 1, while the pericytes are negative for this protein.

Rebound growth of IH is not uncommon after cessation of propranolol therapy. Large segmental hemangiomas, as well as deep lesions, may be more frequently associated with rebound growth.[47] Roughly 1% of IH are propranolol resistant. The lack of a demonstrated therapeutic response after 3 weeks of treatment should suggest alternative management options or that the initial diagnosis is wrong.[48]

Histopathology

The histological appearance of an IH depends on the phase during which it is examined.[25,49,50] During the early proliferative phase, IHs are well-defined unencapsulated dermal and/or subcutaneous masses of closely apposed capillaries with small lumina and lined by plump endothelial cells rimmed by plump pericytes (Figure 73.4).[25,49] The capillaries *(Print pagebreak 489)* form lobules separated by thin fibrous septa or normal intervening tissue.[25] Smooth muscle cells are absent.[25] Normally configured mitotic figures are usually abundant during the proliferative phase. During involution, the capillaries variably dilate and gradually disappear.[25,49] Mitotic figures decrease while mast cells and apoptotic increase during early involution.[25] The basement membrane of capillaries thickens and hyalinizes and contains apoptotic debris as involution progresses.[25,49] End-stage lesions have residual "ghost" vessels with thickened rinds of basement membrane and absent endothelial cells and pericytes embedded in loose fibrous or fibrofatty stroma.[25,49] The endothelial cells of IHs highly express GLUT1 during both the proliferative and involuting phases (Figure 73.4D).[25,50] Expression of GLUT1 distinguishes IHs from NICHs, pyogenic granulomas, tufted angiomas, kaposiform hemangioendotheliomas, and vascular malformations, all of which lack GLUT1 expression.[51,52,53]

CHAPTER 74

Intravascular Papillary Endothelial Hyperplasia

Key Points

- Intravascular papillary endothelial hyperplasia is a vascular lesion that usually arises in veins or arteries
- It is a reactive lesion representing an unusual form of organizing thrombus rather than a neoplastic process
- IPEH may occur as a primary lesion developing within the lumen of a distended vessel or associated with other vascular lesions or in a hematoma
- The pathogenesis is not understood, but may involve an autocrine loop of endothelial basic fibroblast growth factor secretion stimulating endothelial cell proliferation
- On the eyelid, lesions generally present as a bluish to reddish, painless, firm, mobile swelling, or nodule
- Treatment is surgical by opening the vessel and removing the mass, or by excision of the involved portion of the vessel
- The prognosis is usually excellent following surgical resection

Intravascular papillary endothelial hyperplasia (IPEH), also known as Masson tumor, is a vascular lesion of the skin and subcutaneous tissue that usually arises in veins or arteries situated either in the dermis or subcutis.[1,2] It consists of a reactive proliferation of endothelial cells occurring within an organizing thrombus.[3] The condition was first described in 1923 by Pierre Masson in a 68-year-old man with a painful, nonhealing subcutaneous lesion with endothelium-covered papillae and trabeculae that obstructed a vein. He proposed that this lesion was a peculiar angiosarcoma-like lesion arising as a primary process resulting from benign proliferation of endothelial cells with secondary thrombosis and fibrin deposition. He termed it hemangioendotheliome vegetant intravasculaire, believing it to be a true neoplasm.[4] Later, Clearkin and Enzinger recognized it as a reactive lesion representing an unusual form of organizing thrombus rather than a neoplastic process. They introduced the name IPEH.

IPEH occurs most commonly on the extremities and in the head and neck, and only rarely in the ocular adnexa and orbit.[5,6,7,8,9,10,11,12] When the eyelid is involved, 60% of lesions occur in the upper eyelid, 20% in the lower eyelid, and 20% in the medial or lateral canthal angles.

IPEH may occur as a primary lesion developing within the lumen of a distended vessel or associated with other lesions,[13] and they have been classified into several types. Type I represents the primary (pure) form, characterized by the presence of the lesion within a distended vessel. Type II, or secondary (mixed) form, shows an IPEH in a preexisting vascular lesion such as a hemangioma or pyogenic granuloma.[14,15,16] Type III is rare and indicates an extravascular location of the lesion in a hematoma often following recent trauma. These have been described in the adrenal and parotid glands, heart, intestine, kidney, liver, retroperitoneum, spine, maxillary sinus, and orbit.[16,17,18,19,20,21,22]

MRI is the preferred imaging technique for identifying IPEH. Lesions appear hypo- to isointense on T1-weighted imaging and hyperintense on T2-weighted imaging with homogenous enhancement following contrast administration.[23,24]

Etiology and Pathogenesis

The precise etiology and physiopathology of IPEH are incompletely understood. It is considered to be a reactive process, and not a true neoplasm, characterized by exuberant endothelial proliferation, mostly within the lumen of blood vessels.[25] It was proposed that this reactive process could be related to endothelial trauma or inflammation and subsequent thrombus formation.[3,14,15] However, in a review of 314 cases of IPEH from the literature, Pins et al[26] found that only 4% were related to known trauma.

Levere et al[27] studied five pooled cases of IPEH by Northern blot and immunoblot and showed a 5- to 10-fold increase in basic fibroblast growth factor transcripts and a 10- to 20-fold increase in immunoreactive basic fibroblast growth factor protein compared

to non-IPEH organizing thrombi and cavernous hemangiomas. The results suggested that the pathogenesis of IPEH might involve an autocrine loop of endothelial basic fibroblast growth factor secretion stimulating endothelial cell proliferation.

Clinical Presentation

IPEH is usually seen in middle-aged adults and presents as a bluish or reddish mass within the dermis or subcutaneous tissues. In most cases, it is confined to the intraluminal space of either an artery or vein and the walls of the vessel form the "capsule" of the mass. Patients generally report that the lesion has grown slowly over months to several years.[2] In the eyelid, as the lesion enlarges, it can compress adjacent soft tissues, resulting in ptosis.[28] It may occur deep in the orbit where it can involve the ophthalmic artery and other orbital vessels, and larger lesions can be associated with motility disturbance or visual loss.[8,29]

(Print pagebreak 492)

The overall gender distribution shows no specific predilection with a M:F ratio of about 1:1.3.[2,13,30] However, for periorbital lesions, males predominate in a ratio of 2:1. IPEH can occur at any age from early childhood to the 9th decade, with most cases in the 3rd to 5th decades. The extremities are involved in 52% of cases, the head and neck in 27%, the trunk in 13%, and the periorbital region in 7%.

Eyelid and eyebrow lesions generally present as a bluish to reddish, painless, firm, mobile swelling, or nodule (Figure 74.1). Zakka et al[31] described an eyelid IPEH with three stages of evolution. The oldest event was represented by a dystrophically calcified focus (phlebolith), formed on an ancient thrombus with a fibrous wall or pseudocapsule. There was adjacent fresh hemorrhage that displayed an internal network of CD34-positive proliferating endothelial cells that had permeated the thrombus but had not yet assumed a clear-cut papillary architecture. At another level, recanalization of an antecedent thrombus was signified by a labyrinth of vascular channels with collagenized septa that were covered by endothelial cells.[31]

While the symptoms and course of IPEH are usually benign, Weber and Babel[32] reported a case of orbital IPEH that infiltrated the temporal fossa by eroding the lateral orbital wall. Aggarwal et al[33] reported a case that presented with supraorbital nerve anesthesia from an IPEH abutting the supraorbital nerve at the supraorbital notch, and Fasina et al[8] described a case with severe visual loss from a large orbital IPEH.

Differential Diagnosis

The differential diagnosis of IPEH includes some more common benign and malignant vascular tumors. In most cases, the diagnosis must be based on histologic examination. IPEH can be distinguished from intravascular pyogenic granuloma, which displays a characteristic lobular growth pattern.[1] Kaposi sarcoma is a diffusely infiltrating spindle cell tumor that appears violaceous to red clinically and is histologically unrelated to any well-formed preexistent vascular structure.[34] A phlebolith usually has a fibrous capsule, which is a remnant of a preexistent vascular wall, and subepidermal calcified nodule features acanthotic epidermis covering spherical calcified deposits in the dermis.[35] Osteoma cutis exhibits lamellar bone, lacunae, Haversian canals, and osteoblasts. Other lesions in the differential include pleomorphic adenoma, mucocele,[13] hemangioma, thrombosed vein, traumatic fibroma, and nevus.[14]

The most important lesion in the differential diagnosis of IPEH is angiosarcoma from which it must be distinguished. The differentiation between these two lesions has caused some confusion in the literature.[3,18] In 1975, Salyer and Salyer examined the histology of 275 arterial thromboemboli and 140 venous thrombi and compared them to *(Print pagebreak 493)* 12 angiosarcomas. They postulated that in IPEH endothelial cells enter the mass of the thrombus material, which may become fragmented from intravascular pressure, and that additional thrombus material may be deposited focally due to endothelial trauma. The combination of these phenomena plus an ingrowing network of anastomosing vascular channels results in the apparent papillary structures within the vascular lumen.[3] This process is different from angiosarcoma characterized by mitoses and invasion into the perivascular space.

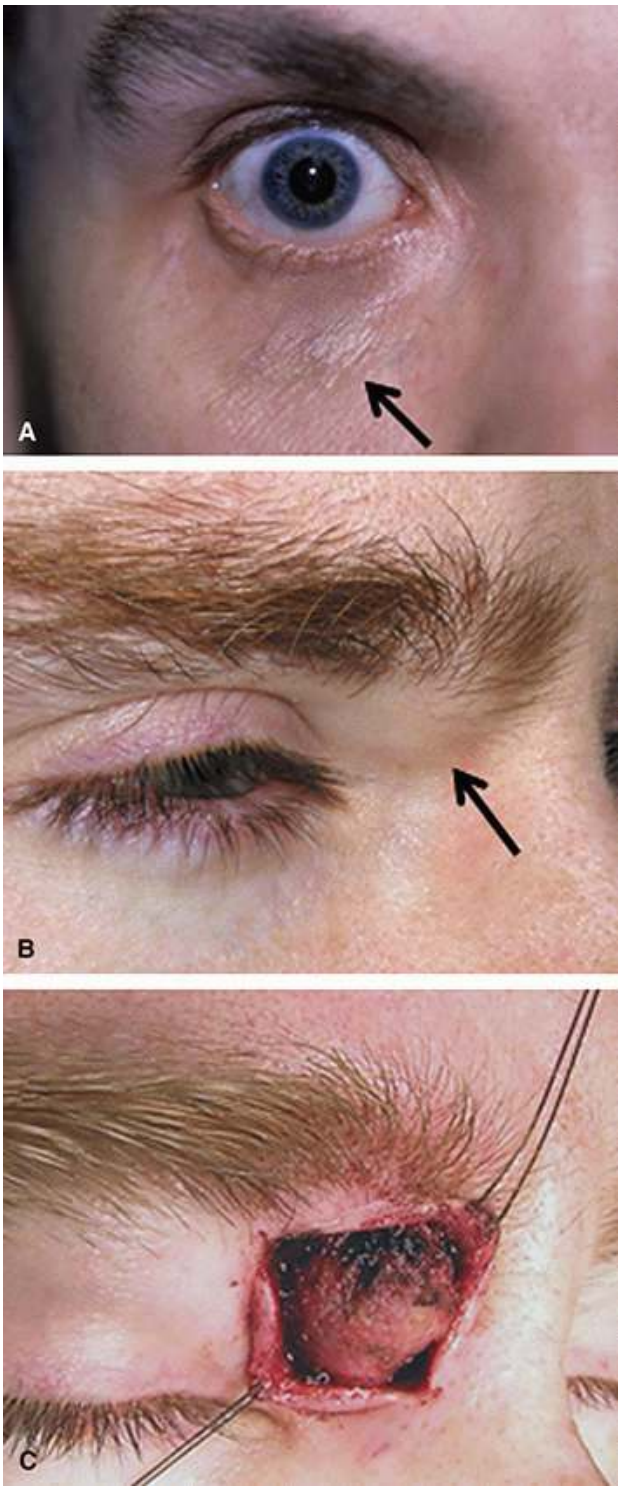

FIGURE 74.1 Intravascular papillary endothelial hyperplasia (IPEH). A, Vascular lesion in the medial lower eyelid (arrow). B, Medial brow and upper eyelid IPEH (arrow). C, Surgical excision of the lesion in Figure B. (B and C, Courtesy of Dr. Tamara Fountain.)

Treatment

Biopsy of IPEH is often required for diagnosis. For relatively superficial subcutaneous lesions, management is surgical by opening the vessel and removing the mass, or by excision of the involved portion of the vessel. For lesions in areas that are not readily accessible surgically or where surgery could result in functional compromise, like the deep orbit or intracranial compartment, radiosurgery has been reported to be effective.[29,36] Radiotherapy may also be successful for rare cases of

recurrence following excision.[37,38]

Prognosis

The prognosis of IPEH typically runs a benign course and is usually excellent following surgical resection,[38] except in cases where the lesion results in vascular compromise.[39]

Histopathology

IPEH arises within a dilated blood vessel of the dermis or soft tissue, and the histological appearance of orbital and periocular lesions[5,6,11,31,40] is similar to that elsewhere in the body.[2,13] It is composed of numerous, small, eosinophilic papillae formed of collagenous tissue and fibrin covered by a layer of endothelial cells that may be multilayered, plump, or flattened (Figure 74.2). The endothelial cells lack cytological atypia and mitotic activity. Thrombus is often adjacent to the lesion and is often in varying stages of organization.

The principal histological differential diagnosis is angiosarcoma. The lack of tissue necrosis, confinement within the vascular lumen without infiltration of the vessel wall, and the association with thrombus are histological features distinguishing IPEH from angiosarcoma.[13,31]

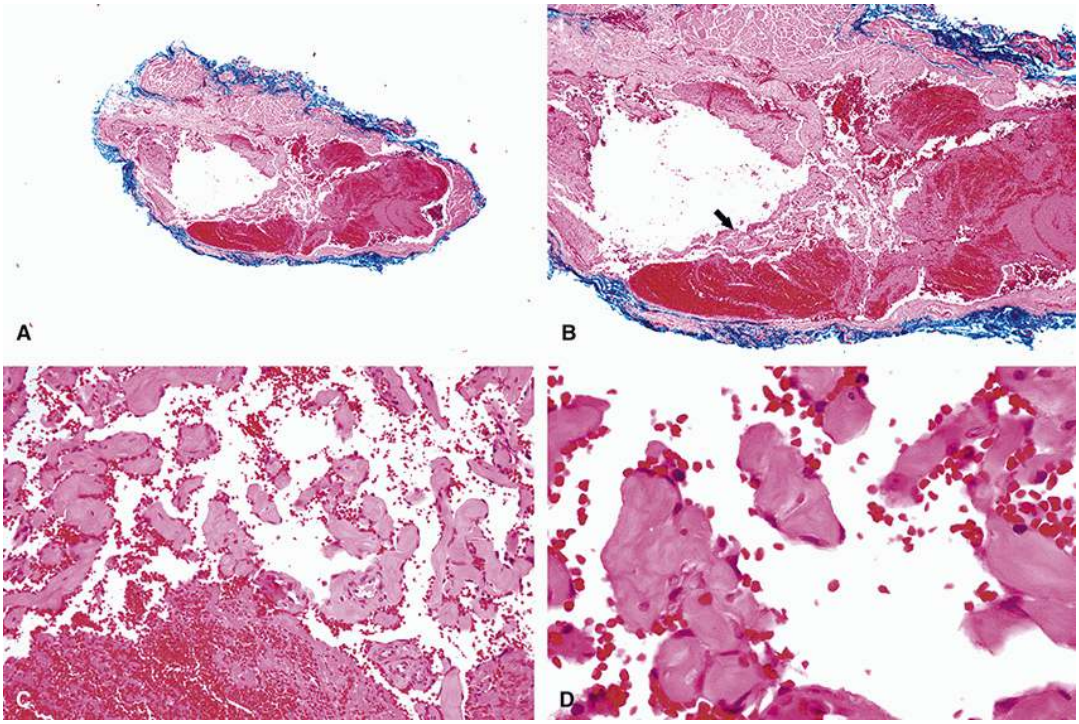

FIGURE 74.2 A, This example of intravascular papillary endothelial hyperplasia arose within a partially thrombosed varix of the right lower eyelid. B, The IPEH is present overlying thrombus (arrow). C, Small, eosinophilic papillae covered by a layer of endothelial cells overlie thrombus. D, The endothelial cells in this lesion are flat, but they may be plump or multilayered in other cases.

CHAPTER 75

Inverted Follicular Keratosis

Key Points

- Inverted follicular keratosis (IFK) is a rare benign epithelial tumor
- It originates from the infundibular portion of the hair follicle
- Ninety percent of IFK cases occur on the head and neck with a strong male predominance
- They usually present as a solitary lesion, seen most often in adults at a mean age of 50 years
- They usually present as asymptomatic, firm, pink-to-white scaly papules, and occasionally can be associated with a cutaneous horn
- IFKs are easily confused with other keratinizing cutaneous lesions such as viral warts, seborrheic keratoses, keratoacanthoma, adnexal tumors, and malignant cutaneous tumors
- Surgical excision has been the treatment of choice for IFK, with a low recurrence rate
- The prognosis for IFK is excellent following surgery

Inverted follicular keratosis (IFK) is a rare benign tumor that usually presents as a nonpigmented verrucous papule seen most often in middle-aged or elderly individuals.[1,2] In 1954, Helwig[3] described this tumor as an inverted cup-shaped crypt at the summit of an epithelial mass, which he named IFK. He felt that the apical crypt might be analogous to the opening of a pilosebaceous apparatus, which accounts for his use of the term “follicular” in the name. Several years later, Lund[4] used the term basosquamous cell epidermal tumor (basosquamous cell acanthoma) as a synonym for this tumor,[5] but that term is rarely used.

IFK is an epithelial neoplasm originating from the infundibular portion of the hair follicle.[2,6,7] It manifests as an exo-endophytic tumor with large lobules or fingerlike projections of tumor cells that extend into the dermis.[2,8] Several distinct histopathological variants exist, including a papillomatous wartlike pattern (exophytic), a keratoacanthoma-like pattern (exo-endophytic), and a solid nodular form (endophytic).

About 90% of IFK cases occur on the head and neck. Most previous larger series showed a male predominance ranging from 58% to 100%,[2,5,8,9,10,11,12] but in a small series of 11 periocular IFKs,[13] 64% were female.

Clinically, IFK is often misdiagnosed as a more common keratotic lesion. Some studies have estimated that fewer than 2% of IFK lesions are correctly diagnosed before surgical removal and histopathologic examination.[14,15] The clinical diagnosis is most often as a viral wart, actinic keratosis, keratoacanthoma, or a variety of malignancies such as basal cell carcinoma, squamous cell carcinoma, and adnexal tumors.[8,11]

IFK usually presents as a small solitary lesion, seen most often in adults at a mean age of 50 years,[8] and is rarely seen in children or adults in the second and third decades.[5,11,12,13,14,15,16,17] They are most often found on the face, particularly on the cheek, upper lip, chin, forehead, eyebrow, and nose. Occurrence on the trunk is uncommon, and involvement of the extremities is rare.[11] Lesions may have a history of slow growth over 2 to 6 months, but occasionally they may have been present for many years.[18] Most of the lesions are small, ranging from 3 to 8 mm in diameter. They rarely involve the eyelids, with a predilection for the eyelid margins.[19,20,21] In general, IFK appears as an asymptomatic, firm, pink-to-white scaly papule and occasionally can be associated with a cutaneous horn.[5,11,21]

Dermoscopy has been useful in the clinical diagnosis of IFK.[9,22] Llambrich et al[9] described the dermatoscopic features of 12 IFK and reported a distinct white structureless area in or near the center of the lesion present in all cases, and white scales were found in 75%. Vascular structures were also present in all cases, showing a monomorphic pattern in 58% and a polymorphic pattern in 42%. The most common vascular structure was hairpin vessels surrounded by a whitish halo, which was found in 83%. Keratin was

observed in 67% of lesions, mostly in the central area.

Vascular patterns, in general, have been considered important in the differential diagnosis of many nonpigmented skin tumors.[23] Hairpin vessels surrounded by a whitish halo are a common dermoscopic vascular pattern,[9,24] indicating epithelial differentiation,[25] that can be seen in benign and malignant keratinizing lesions including squamous cell carcinoma, verruca vulgaris, poroma, and thick melanoma.[23,26] In contrast to the arrangement of hairpin vessels in the keratoacanthoma type of squamous cell carcinoma,[26] those of IFK often show a central white or yellowish amorphous area.[24]

Etiology and Pathophysiology

The pathogenesis of IFK is not exactly known. Helwig[3] believed it arose from the pilosebaceous apparatus, and Boniuk and Zimmerman[5] suggested a possible viral etiology. Other authors believed IFK to be a variant of a viral wart[27] or irritated seborrheic keratosis.[28] Whether or not IFK is related to verruca vulgaris or seborrheic keratosis has been questioned.[8,27,29] Several studies failed to detect human *(Print pagebreak 496)* papillomavirus in the majority of IFK lesions, differentiating it from verruca vulgaris.[1,2]

It is now believed that IFK is derived from the infundibulum of the hair follicle above the sebaceous duct opening.[1,2,6,13,30] Mehregan and Butler[31] first coined the term “tumor of the follicular infundibulum” because the tumor cells contained glycogen like the outer root sheath. Schirren and Maciejewski[32] reported the rare occurrence of ductal structures resembling sebaceous ducts, hair germ papillae, and follicular papillae in several tumors of the follicular infundibulum.

Clinical Presentation

In 1953, Boniuk and Zimmerman[5] summarized data for 65 lesions from 64 patients with eyelid IFK from the Armed Forces and Veterans Administration. Of these, 57 (89%) were men and 7 were women, likely reflecting the bias of patients largely from the military. The age of the patients ranged from 17 to 74 years, with a mean of 45 years, and 95% were solitary lesions. The clinical presentation varied but most appeared as a painless, asymptomatic, skin-colored, brownish, gray, or pink lump or swelling (Figure 75.1), while others were elevated, nodular, papillary, or papillomatous (Figure 75.2). They may have a verrucous scaly appearance and some can be heavily pigmented, clinically mimicking a melanoma (Figure 75.3).[22] In five cases, the lesion presented as a cutaneous horn. The upper and lower eyelids were equally involved and accounted for more than three-fourths of the tumors. Lesions were generally small, with most 5 mm or less in diameter. But in several cases, they exceeded 10 mm. Of the 65 lesions, 40% occurred on the upper eyelid, 38% on the lower eyelid, 7.7% at the medial canthus, 1.6% at the lateral canthus, and 6.3% on the eyebrow.

FIGURE 75.1 A and B, Inverted follicular keratosis as a mild swelling on the mucocutaneous eyelid margin.

In five other smaller series of head and neck IFK with a total of 47 patients, the median age was 57.7 years with a range of 26 to 91 years, and males accounted for 68%.[9,10,11,24] In the 11 cases summarized by Díez-Montero et al,[13] IFK occurred on the upper eyelid in 36.4%, and the lower eyelid lid in 27.3%. In contrast to the report by Boniuk and Zimmerman, the medial canthus was involved in 36.4% of cases, equal to the upper eyelid.

One case of IFK has been reported on the conjunctiva.[33] This was in a 21-year-old man. The lesion was slow growing over 2 months. On examination, it was hard, yellowish in color, 5 mm in diameter, free from the underlying sclera, and adjacent to the corneal limbus.

Differential Diagnosis

The clinical appearance of IFK is easily confused with keratinizing and other cutaneous lesions. Initial clinical diagnoses include actinic keratosis, seborrheic keratosis, verruca vulgaris, papilloma, cutaneous horn, fibroma, molluscum contagiosum, and intradermal nevus. It is also frequently confused with keratoacanthoma and malignant cutaneous tumors.[9,22,24] The diagnosis is usually not made clinically, but only after histopathologic examination.[22] Seborrheic keratosis usually contains horny invaginations, many of which are unrelated to hair follicles, and melanin pigmentation is often more prominent. Keratoacanthoma can be distinguished easily on histopathology by its ballooned pale-staining squamous epithelium and the infiltrative pattern of the deep edge.[11]

Malignant tumors such as squamous cell and basal cell carcinoma are perhaps the most important lesions to be considered in the differential diagnosis since a misdiagnosis can lead to unnecessary radical surgery. Both are frequently in *(Print pagebreak 497)* the initial clinical diagnosis of IFK. Squamous carcinoma often lacks the lobular blunt-edged architecture of IFK and frequently shows a transition to abnormal epidermis.[11] Also, abnormal mitoses are not found in IFK.

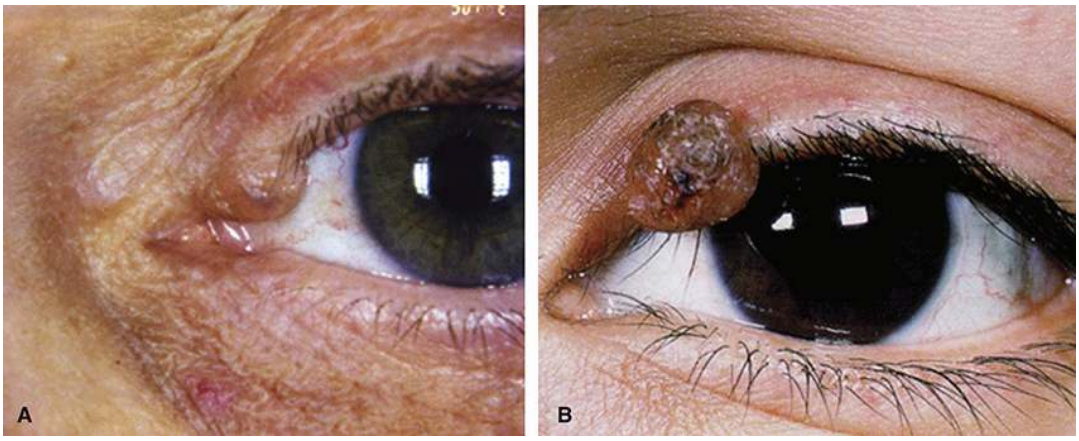

FIGURE 75.2 A and B, Nodular inverted follicular keratosis.

Treatment

Surgical excision has been the treatment of choice for IFK, with low recurrence rates of 0% to 9%.[5,10,13,34] Imiquimod is an immunomodulatory drug that modulates and upregulates the immune system and thus has both antitumoral and antiviral activity. It is most frequently used in the treatment of actinic keratosis, genital warts, and superficial basal cell carcinoma through its induction of cytokines from antigen presenting cells including toll-like receptor 7/8.[35] It also inhibits vascular tumor development by causing a decrease in tumor cell proliferation, an increase in apoptosis, and a decrease in matrix metalloproteinase 1 and 9 activity.[36] Karadag et al[37] reported a case of IFK successfully treated with topical 5% imiquimod cream resulting in near-complete tumor regression after 2 months of treatment.

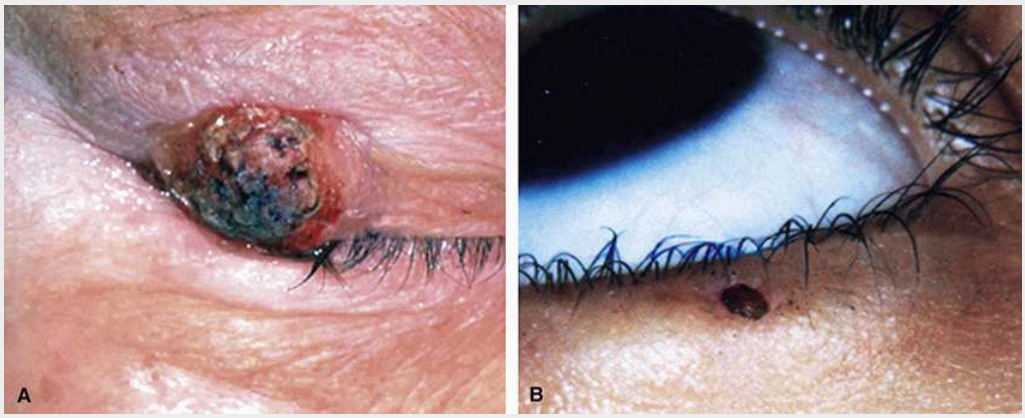

FIGURE 75.3 A, Large inverted follicular keratosis (IFK) with a rugose scaly surface. B, Small pigmented IFK. (Courtesy of Dr. Gregg Gayre.)

Prognosis

The prognosis for IFK is excellent. No tumor-related deaths have been reported and recurrences after surgery are uncommon. Schweitzer and Yanoff[20] reported two cases of eyelid IFK that recurred within weeks of primary excision. They recommended careful excision of the primary lesion, attempting to remove all of the lesion initially. Excisional *(Print pagebreak 498)* biopsy of any secondary lesion was recommended before contemplating more drastic surgery, with a careful review of the original specimen to determine if the initial diagnosis was IFK rather than a malignant tumor.

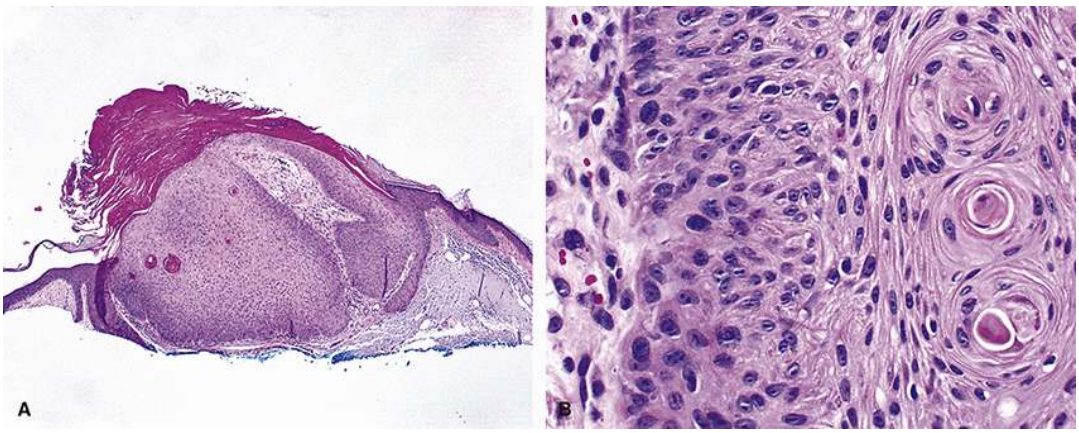

FIGURE 75.4 A, This nodular inverted follicular keratosis has a thick layer of hyperkeratosis and parakeratosis overlying a tumor composed of a large and small lobule and a fingerlike projection into the actinically damaged dermis. The tumor cells around the periphery of the lobules are basaloid, resulting in the darker blue staining. B, Squamous eddies with concentric layers of flattened squamous cells in a whorled pattern are usually most frequent at the junction of the basaloid cells and squamous cells.

Histopathology

Inverted follicular keratoses are predominantly endophytic lesions composed of lobules or broad, blunt-tipped, fingerlike projections of neoplastic epithelial cells into the dermis (Figures 75.4 and 75.5).[5,8,12,38,39,40,41] The outer portion of the lobules and fingerlike projections are composed of basaloid cells that may exhibit palisading, while the central areas are composed of larger squamous cells. Inverted follicular keratoses characteristically have squamous eddies with concentric layers of flattened squamous cells in a whorled pattern (Figure 75.4B).[5,38] The squamous eddies may have central keratinization and form small keratinous cysts,[38] and they tend to be most frequent at the junction of the basaloid and squamous cells.[5] Clefts may be present between squamous eddies.[12] Larger tumor masses may have funnel-shaped parakeratotic plugs in the center of invaginating tumor masses.[38] There is a variable degree of hyperkeratosis and parakeratosis overlying most tumors.[5] The tumor and dermis are sharply *(Print pagebreak 499)* demarcated,[12] and the dermis may exhibit increased vascularity, mild fibrosis, and mild nonspecific inflammation.[38]

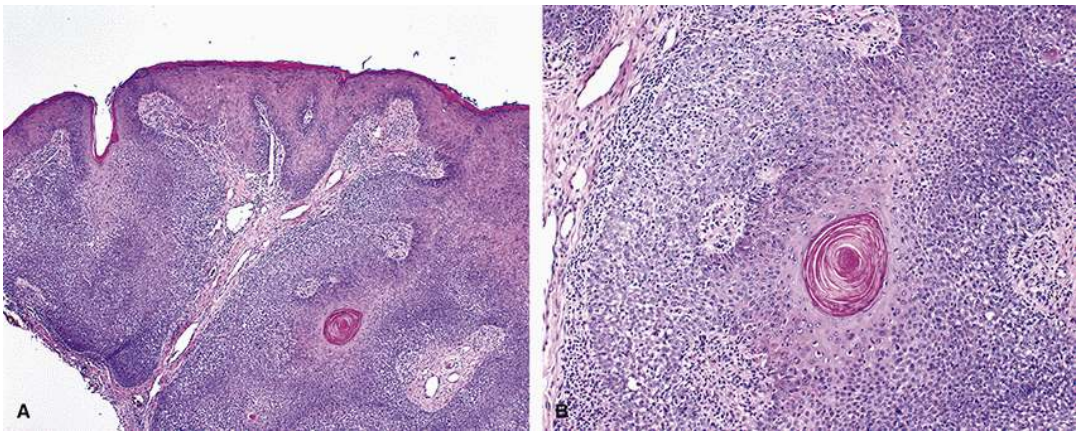

FIGURE 75.5 A, This nodular inverted follicular keratosis has lobules and broad interdigitating cords of tumor cells within the dermis. The basaloid layer around the periphery of the lobules and cords is prominent. B, The basaloid layer has a cuff of mononuclear inflammatory cells, and scattered lymphocytes infiltrate the basaloid layer. A small

keratinous cyst is in the squamous portion of the tumor.

While inverted follicular keratoses most often have a nodular pattern, they may also have a papillomatous or wartlike appearance, resemble a keratoacanthoma with surrounding epidermis forming a marginal buttress, or be cystic.[5,8] Lack of cellular anaplasia differentiates an IFK from squamous cell carcinoma or keratoacanthoma, while the presence of squamous eddies in an IFK distinguishes it from a verruca vulgaris.[38]

CHAPTER 76

Keratoacanthoma

Key Points

- Keratoacanthoma is a common tumor
- It is seen most frequently in fair-skinned individuals with a predilection for sun-damaged skin
- Keratoacanthoma can be solitary or multiple
- Solitary KA presents as a rapidly growing nodule with a central keratotic crater
- After a stable phase lasting several months, they often undergo spontaneous regression
- Multiple KAs are rare and can be sporadic or familial
- The pathophysiology of KA and its relation to squamous cell carcinoma is unknown, but they have been thought either to be separate entities, or related, lying on two ends of the same disease spectrum
- Surgical excision with histologic control of margins is considered the gold standard for the management of KA

Keratoacanthoma (KA) is a common tumor, originally described by Hutchinson in 1889.[1] It is seen most frequently in fair-skinned individuals and has a predilection for sun-damaged skin.[2] KA has been reported to show a seasonal presentation with a peak incidence noted in the summer and early autumn months.[3] The annual incidence of cutaneous KA varies depending on the geographic location. In Hawaii, the annual incidence was estimated to be 104 cases per 100,000 population,[4] and in northern Australia, the incidence was 150 cases per 100,000 population.[5]

KA is seen most frequently in middle-aged individuals.[6] The peak age at presentation is between 45 and 69 years old.[7] In a series of 108 patients with KA, lesions were seen in patients from teens to old age, with 80% older than 40 years and a mean age of 56 years. Males are affected more commonly than females, in a ratio of 2:1.[8] These tumors can occur on any part of the body but show a predilection for the face.[9] Periocular involvement is uncommon, and in one review of 592 cases of KA, more than 70% were located on the face, and 5.6% involved periorbital skin.[10]

The two major types of KA are solitary and multiple KA. Solitary KA is the most common type, and this group is further subdivided into several subtypes.[11] Typical solitary KAs present as a rapidly growing nodule with a shiny epidermis and a central keratotic crater. They generally are small, ranging in size from a few mm to 2 cm, with a multilocular keratin-filled central crater where dermal papillae undergo necrosis.[12] After a stable phase lasting several months, these lesions generally undergo complete regression. Giant KA rapidly grows to sizes larger than 3 cm. They are seen mostly in males (74%), with a predilection for the head, predominantly on the eyelids and nose. They show a downward vertical growth pattern, invading the dermis with the destruction of underlying tissue, and persist for long periods before undergoing variable degrees of regression.[13,14] Subungual KA is a rare solitary variant appearing under nails. It usually occurs in Caucasian men with a predilection for the first three fingers of the hand.[15] It grows rapidly over several weeks and shows an aggressive behavior with destruction of the underlying bone of the terminal phalanx and rarely undergoes spontaneous regression. Mucosal KA is another rare variant seen mostly in the oral cavity and occasionally on the conjunctiva or vulva. Lesions grow rapidly over 2 to 8 weeks, and like some other variants, they show little tendency to regress. KA centrifugum marginatum is another variant reported to occur after trauma and is characterized by progressive peripheral extension with raised rolled-out margins showing multiple comedonal orifices. They are seen more frequently on the dorsum of hands and legs, can attain a size of up to 20 cm, and do not show a tendency for spontaneous regression.[16,17]

Multiple KAs are rare and can be sporadic or familial.[2] They have been described in the literature as several types. Multiple familial KAs of Ferguson-Smith type, also known as multiple self-healing squamous epithelioma, are a rare autosomal dominant genodermatosis characterized by the development of recurrent KAs and well-differentiated squamous cell carcinomas (SCCs).[18] Slow-growing lesions appear in continuous waves on the face and limbs at any age from childhood to old age. Like common KAs,

they do tend to undergo spontaneous regression over several months. Generalized eruptive KA of Grzybowski is an extremely rare variant of KA affecting the skin and mucous membranes on both sun-exposed and sun-protected sites. It occurs in older individuals in the fifth to seventh decades of life. Hundreds to thousands of tiny 1 to 2 mm dome-shaped KA lesions without a central crater appear with an eruptive onset.[2,19] Multiple KAs of Witten and Zak type are assumed to have a familial predisposition. Lesions have a predilection for sun-exposed areas and arise as 1 to 30 papules that can remain small or increase to a very large size. These lesions undergo regression over several months.[20]

Three clinical stages are recognized in the natural history of solitary KA.[21] An initial proliferative stage is characterized *(Print pagebreak 501)* by rapid growth over 1 to 2 months. This is followed by a mature stage appearing as a nodule, often with a central keratotic crater. After several months to years depending on the size, a spontaneous involutional phase is seen resulting in a hypopigmented scar.[2,22] The spontaneous regression can be partial or complete.

In a retrospective histopathologic study of 50 patients with KA, Lawrence and Reed[21] found carcinoma-like foci (invasive cords of atypical epithelium) in the majority of specimens, most of which occurred in stable-stage lesions. They speculated that stage I lesions break into the reticular dermis and incite an immune response. Typical, possibly neoplastic clones of keratinocytes are held in check by the body's immune response in stage II. Stage III lesions are equivalent to a senescent phase of a cell-mediated immune response with an associated desmoplastic reaction.[21] In some instances, alteration in the immune response may allow the emergence of neoplastic clones with the possible development of SCC.

There is no consensus as to whether KA is a benign or malignant neoplasm.[23] KA progressing to SCC with metastatic spread is rare,[24,25,26,27] and KA-like SCCs have been described in numerous publications.[6,12] Perineural invasion of facial KA is uncommon, seen in only 1% to 4% of excised specimens.[28] This can lead to tumor extension into facial mimetic muscles, tumor recurrence, and metastasis to regional lymph nodes.[29]

Etiology and Pathogenesis

Debate concerning the pathogenesis of KA has persisted for more than 60 years, and it is not clear whether these tumors always regress or whether, under certain circumstances, they can progress to invasive SCC.[30] One thought is that KA and SCC are separate entities, KA being a benign lesion undergoing rapid initial growth followed by spontaneous regression and SCC being a malignant invasive tumor with metastatic potential.[31] Another thought is that KA and SCC are distinct but related entities on two ends of the same disease spectrum.[32,33,34]

While the pathogenesis of KA is unknown, several features of this tumor are suggestive of possible etiologies. These include its apparent derivation from hair follicles, its association with ultraviolet (UV) radiation exposure, the proposed linkage with occupational chemicals such as tars and mechanical oils, association with human papillomaviruses (HPVs), genetic abnormalities in the Ferguson-Smith type of multiple KA, the association of KA with syndromes such as the Muir-Torre syndrome and familial incontinentia pigmenti, and the expression of tumor suppressor genes, oncogene expressions, and mutations, and telomeric alterations in some KAs.[30,35,36,37,38] The epithelium of the hair follicle has been proposed as the origin of some KAs,[39] although this does not explain the occurrence of KA on mucosal surfaces. It has been proposed that KAs arising in mucous membranes represent a variant of pseudoepitheliomatous hyperplasia.[21]

Cabibi et al[40] studied 43 lesions of KA and SCC and reported differences in GLUT1 antibody expression that distinguished typical KA from SCC and also highlighted an intermediate group of atypical KA, supporting the hypothesis of a progression along the spectrum from KA to SCC. The atypical KA showed focal areas with some features of KA that overlapped with those of SCC, consisting of a higher degree of cytologic atypia, a higher nuclear/cytoplasmic ratio, several mitoses, and focal aspects of irregular infiltration at the deep boundary.[40] When these features were limited to less than 30% of the tumor, it was defined as an atypical KA. The authors suggested that KA may regress as the result of functioning immunity, but when local immunity was deficient, some KAs might develop into SCCs.

The predilection of KA for sun-exposed areas suggests UV radiation might be an important etiological factor, similar to SCC.[3,4,5,6,41] This is supported by the association of KA with other UV-induced tumors such as xeroderma pigmentosum.[6] Papillomavirus-related DNA has been found in some KAs,[42] but the relationship is inconsistent, and no conclusive etiology has yet been established.[43] Occupational exposure to pitch, tar, coal, or machine oil was reported to occur in 20.3% of 108 patients with KA compared with only 2.7% in 147 controls without KA, suggesting a possible chemical-induced KA etiology.[8] KA has also been reported as a complication of damaged skin previously treated with CO_2 laser, radiotherapy, and PUVA photochemotherapy.[44,45,46]

Some gene alterations have been found in KA.[47,48] Expression of Bcl-2 protooncogene was found in some KA, but to a much less degree than in SCC. Sleater et al[49] suggested that KA could be an SCC that is deficient in Bcl-2 expression. Transforming growth factor beta receptor 1 also has been described in KA lesions associated with multiple familial KAs of Ferguson-Smith type,[50] and

mismatch repair genes were found in KA seen with the Muir-Torre syndrome.[51]

KA is known to have a relationship with some systemic syndromes. Muir-Torre syndrome is an autosomal dominant genodermatosis combining malignancies, most notably colon cancer, with sebaceous neoplasms.[52] The syndrome is caused by germline mutations of hMSH2 and hMLH1 genes, involved in the mismatch repair system, and KA are seen in Muir-Torre syndrome as solitary or multiple lesions. KA occurring with this syndrome is explained by the common pilosebaceous gland origin of sebaceous neoplasms and KA.[6] KAs have also been observed in patients with xeroderma pigmentosum, a rare autosomal recessive genodermatosis that results from mutations in nucleotide excision repair. Patients demonstrate severe photosensitivity, skin pigmentary changes, malignant tumor development, and sometimes progressive neurologic degeneration,[53,54] resulting in the development of cutaneous melanoma, basal cell carcinoma, SCC, and KA in early childhood. Other rare associations include florid cutaneous papillomatosis[55] and nevus sebaceous of Jadassohn.[56,57]

Clinical Characteristics

KAs are frequently seen in older individuals with light skin and a history of chronic sun exposure.[58] Common areas of involvement include the lips, cheeks, nose, eyelids, and the *(Print pagebreak 502)* back of the hands. Males are affected slightly more frequently than females.[7,59] During the initial proliferative phase, the tumor grows rapidly as a firm papule. The border is skin colored or erythematous, occasionally with fine telangiectatic vessels (Figure 76.1).[6] In the mature phase, it becomes dome shaped with a central keratinous crater (Figure 76.2). During the involutional phase, the lesion becomes flattened with less of a crater, more hyperkeratotic, with granulation tissue at the base (Figure 76.3), ultimately resulting in an atrophic scar.[41,60]

Of 66 cases of periorbital KA from the literature with some data, 55% were males.[61] The mean age at presentation was 53.3 years with a range of 19 to 96 years. The mean duration from tumor appearance to clinical diagnosis in most cases was about 8 weeks, with a range of 1 to 20 weeks. Rare cases had a duration of 2 to 20 years.[61,62] The tumor was located in the lower lid in 63% of cases, the upper lid in 20%, and the medial or lateral canthus in 13% and 6%, respectively. The lesion ranged in size from 2 mm to 8 cm, with a mean of 1.7 cm. In one case, a very large lower eyelid KA extended into the anterior orbit.[24]

FIGURE 76.1 Early-stage keratoacanthoma on the eyelid margin with an incipient central crater.

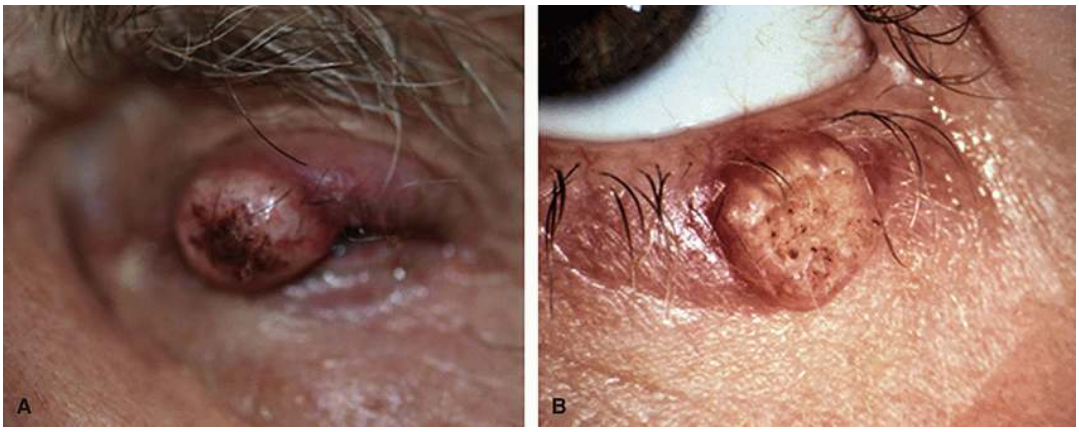

FIGURE 76.2 A and B, Mature phase domed keratoacanthoma with a central keratinous crater. A, (Courtesy of Dr. Suzanne Freitag). B, (Courtesy of Dr. Alan McNab).

Conjunctival KAs are rare. The first case was reported by Freeman et al in 1961, and since then, fewer than 20 additional cases have been described.[27,63,64,65,66] Conjunctival KAs are seen in younger patients than seen with cutaneous KA, with a mean of 42.1 years and range of 17 to 83 years. They appear as elevated, dome-shaped, white hyperkeratotic nodules almost always at the corneal limbus. They are usually associated with conjunctival injection and can bleed spontaneously.[63] Because ocular surface lesions are rare and are usually excised early, the natural course of conjunctival KAs is not clear.

Differential Diagnosis

The differential diagnosis of KA includes any rapidly growing mass on the skin or conjunctiva. For cutaneous KA, the most important tumor in the differential is SCC. In one study of 1949 biopsies with histologic characteristics of KA (crateriform architecture, epithelial lip, sharp demarcation), 1547 specimens (79.3%) were classified as "classic" SCC with KA-like features, based on histopathologic features and in situ hybridization studies.[9] Another 389 cases (19.9%) were diagnosed as HPV papilloma with KA-like features, and 15 cases (0.8%) were reported as "verrucous seborrheic keratosis (VSK) with KA-like features." Tas et al[67] reported a case of parotid carcinoma misdiagnosed as KA.

Several other neoplasms with crateriform architecture should be distinguished from KA. These include crateriform Bowen disease that shows an exoendophytic silhouette with a central keratotic horn, crateriform seborrheic keratosis which is an exoendophytic lesion, often with finger-like *(Print pagebreak 503)* exophytic projections, and crateriform verruca characterized by an epithelial liplike structure at the periphery, with a central keratinous plug resembling KA.[68]

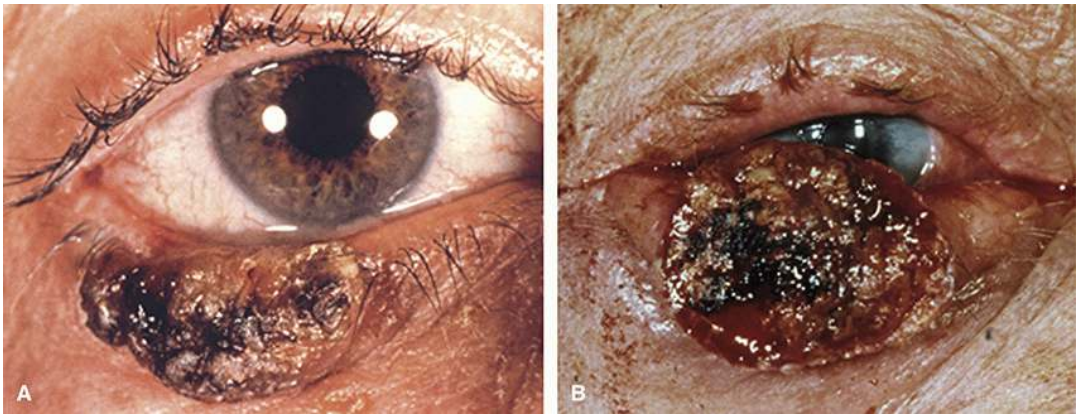

FIGURE 76.3 A and B, Late-stage hyperkeratotic keratoacanthomas with surface necrosis.

Conjunctival KA typically presents as a white, hyperkeratotic lesion, often seen in the interpalpebral bulbar conjunctiva adjacent to the limbus. They grow rapidly over a short period.[66] Simulating conjunctival lesions include pyogenic granuloma and malignant tumors such as ocular surface squamous neoplasia and amelanotic melanoma.[69] Pyogenic granulomas present as red, elevated masses, often associated with or following ocular surface surgery. Conjunctival melanomas clinically appear as elevated, amelanotic, or pigmented lesions with prominent feeder vessels.[70]

Treatment

Surgical excision with histologic control of margins is considered the gold standard for the management of KA, except when they are present in anatomic locations that could compromise function. Tumor eradication is generally excellent with few complications.[13,62,71] Surgery is preferred by many clinicians because of the uncertain behavior of some lesions. The importance of complete excision and histologic examination of KA was demonstrated by the study of Leibovitch et al,[41] who found 2/12 (16.7%) of lesions clinically diagnosed as KA eventually proved to be invasive SCC on histopathology. Because of this risk, it has been suggested that the role of more conservative therapies should be limited to patients unable to undergo surgery.[41] Even so, the recurrence rate following surgical excision of cutaneous KA has been reported at 0% to 8% during follow-up periods of up to 11 years.[6,61,62] Curettage has also been used for small solitary KA, sometimes together with electrodesiccation. Recurrence following this approach has been reported at 3.6%.[5,6,72,73] Mohs micrographic surgery is another potential option, especially in locations like the eyelids where maximum preservation of tissue is critical for function. It has been reported in several isolated case reports.[6,74]

5-Fluorouracil was advocated either as an intralesional injection of a 5% solution directly into the base of the KA every other day or as a topical cream or ointment up to five times daily.[75] This approach resulted in a 60% to 80% decrease in the size of the lesions after an average of 3 weeks.[76] Intralesional corticosteroids,[77] bleomycin,[78] methotrexate,[71,79] and interferon alpha[80] have all been used in isolated reports with up to 100% clearance of lesions. Topical imiquimod as a 5% cream every other day for 4 to 12 weeks resulted in regression of solitary facial keratoacanthomas.[81]

Radiotherapy has been used as primary therapy for KA or after tumor recurrence, resulting in tumor regression over several months with good to excellent cosmetic results,[82,83,84] but recurrences have been reported.[85] Radiotherapy has also been used for more aggressive lesions with perineural invasion with good results. Argon laser ablation can be employed for small early KAs in locations that are difficult to treat with other modalities. Sixty-five percent of patients achieved excellent results with re-epithelialization at 2 to 3 weeks and no recurrences after 2 years. However, 35% healed with mild scarring.[86] Cryosurgery with liquid nitrogen was reported to be of value as primary treatment for small KAs, and as adjunctive therapy following curettage or surgical excision.[87]

For multiple KAs such as generalized eruptive KA of Grzybowski where other treatment modalities fail, systemic chemotherapy with cyclophosphamide at 100 mg/d for 1 to 3 months can result in clearance of thousands of cutaneous and oral KAs without scarring.[88,89,90]

Conjunctival KAs are most often managed with surgical excision and double freeze cryotherapy to the corneal and conjunctival margins and the scleral bed. This can be supplemented with adjuvant topical chemotherapeutic agents, such as interferon alfa-2b 1 million IU/mL or cycles of 5-fluorouracil 1% for 2 months postoperatively.[91,92]

Prognosis

Savage et al[23] reviewed 445 cases of KA from 113 reports published between 1954 and 2013, with follow-up data from 1 week to 288 months. Of these 445 cases, spontaneous regression was reported in 52 (11.6%) patients who had no *(Print pagebreak 504)* treatment, and in 393 (88.3%) patients following medical or surgical treatment. In 46 (10.3%) cases, perineural or perivascular invasion was identified. Local recurrence was seen in 18 (4%) cases, all with previous treatment. There were no cases of metastatic disease. Regardless of the treatment option, the prognosis is generally good, and recurrences are generally less than 10%.

Histopathology

The histopathological features of cutaneous KAs vary by clinical stage.[6,61,68,93,94,95] The early or proliferative stage has a few keratin-filled invaginations of the epidermis or infundibulocystic structures that have not merged to form a large keratotic horn characteristic of the well-developed stage of KA development.[94] The invaginations have epithelial cells with prominent keratohyaline granules and laminated keratinization.[6,94] In the deeper aspect of the invaginations, the epithelial cells have pale pink cytoplasm with a glassy appearance.[94] There is poor differentiation of the deep border from the stroma,[94] and nuclear atypia is scant.[68] At this stage, KAs have an immunophenotype characteristic mainly of follicular infundibular differentiation.[94,95]

The well-developed or fully developed stage of cutaneous KA formation is usually seen in skin biopsies,[94] including the eyelid.[61] Well-developed KAs are exoendophytic lesions with a proliferation of well-differentiated, keratinizing squamous epithelium forming lobules at the sides and bottom of the lesion, with a central keratin-filled crater that enlarges as the lesion matures (Figures

76.4 and 76.5). A key diagnostic feature is a lip of epidermis (collarette) overlapping the central crater (Figure 76.4).[6,68] Squamous cell keratinization results in eosinophilic glassy cytoplasm (Figure 76.5).[6,68] The lesion's lower border usually remains superficial to the eccrine sweat glands.[6] The adjacent dermis contains a mixture of lymphocytes, macrophages, plasma cells, neutrophils, and varying numbers of eosinophils.[6,61,93] Well-developed KAs have a follicular isthmus immunophenotype.[94,95]

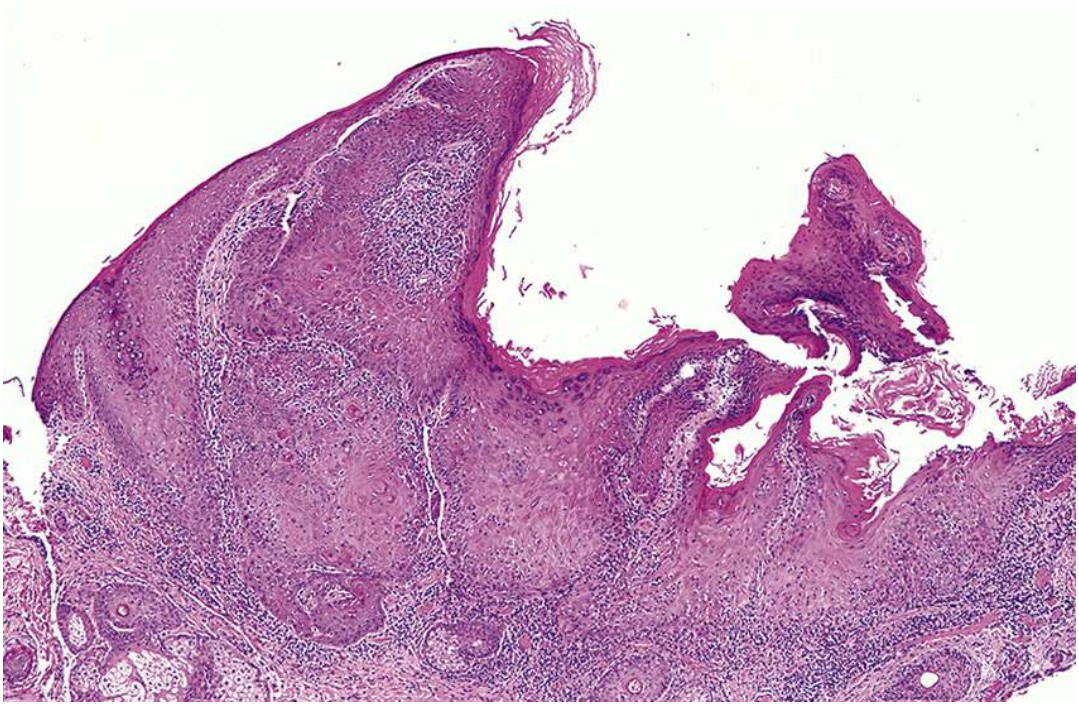

FIGURE 76.4 This right upper eyelid keratoacanthoma arose over several months and appeared clinically to be a cutaneous horn. The lesion has features characteristic of a fully developed exoendophytic lesion with a proliferation of well-differentiated, keratinizing squamous epithelium forming lobules at the sides and bottom of the lesion, a central keratin-filled crater, and a lip of epidermis (collarette) overlapping the central crater. The dermis has a moderately intense infiltrate of lymphocytes, plasma cells, and macrophages.

Regressing- or involutional-stage KAs become flattened and less crateriform, most cells are keratinized, and shrunken *(Print pagebreak 505)* apoptotic cells with brightly eosinophilic cytoplasm may be adjacent to the large tumor cells and within the stroma.[6,68,96] The dermis may have multinucleated foreign body giant cells as a response to keratin.[6] Granulation tissue and fibrosis are at the base of regressing KAs.[6,96] Lesional cells lose immunohistochemical features of follicular differentiation and assume epidermal characteristics at this KA stage.[94]

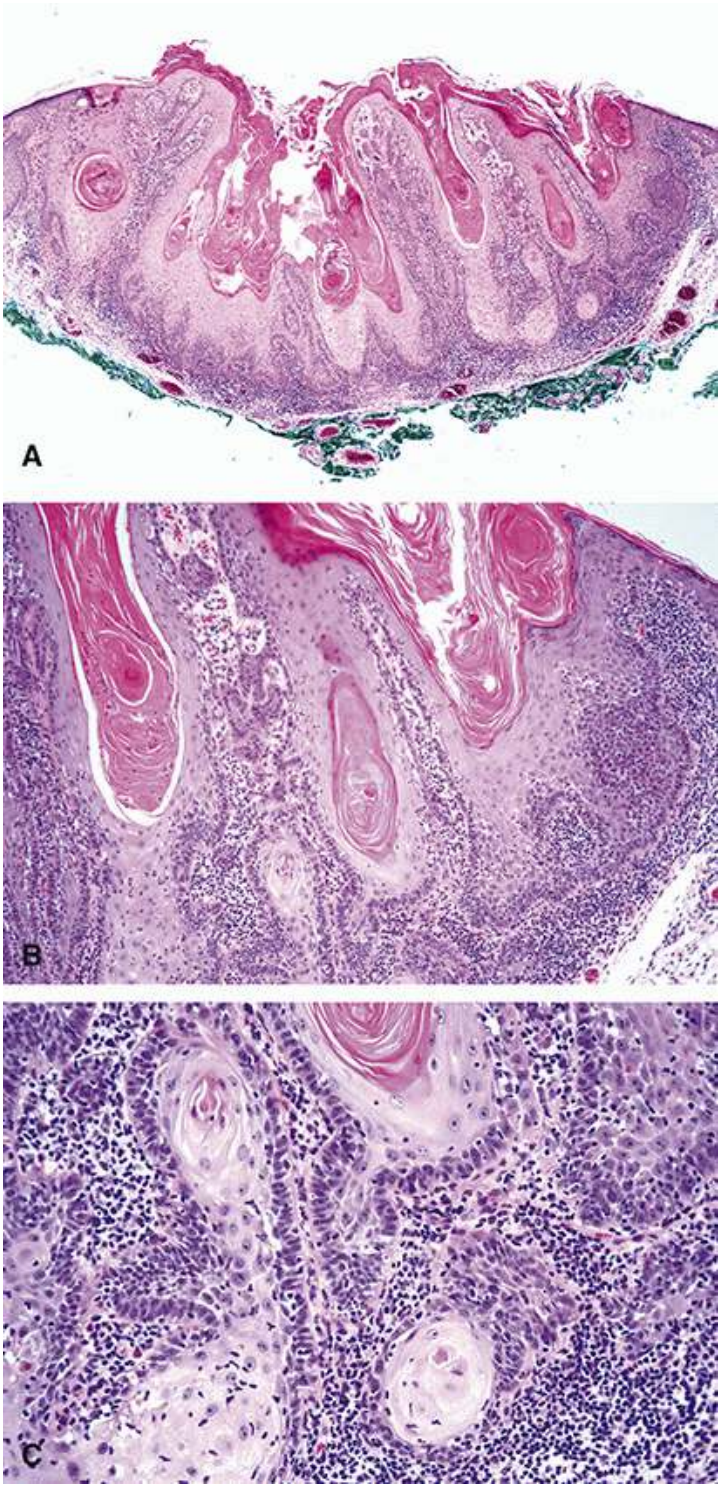

FIGURE 76.5
A, This medial right upper eyelid lesion appeared over 1 month. There is a lobular proliferation of well-differentiated squamous epithelium with keratin filling the central crater. B, The lobules are predominantly composed of epithelial cells with lightly eosinophilic (pale pink) glassy cytoplasm surrounding laminated keratinization. C, The periphery of lobules had basophilic cells, and the borders were minimally infiltrative. The dermis has a dense infiltrate of mononuclear leukocytes without fibrosis.

KAs must be differentiated from infundibular SCCs, crateriform Bowen disease, crateriform seborrheic keratoses, and crateriform verruca.[68,97] The principal differential diagnosis is SCC, with which it may be histologically indistinguishable.[2,93] The overlap in histological appearance is why many dermatopathologists classify these lesions as "SCC, KA type" or "probable KA; SCC cannot be ruled out."[2] Conjunctival and caruncular KAs have an appearance similar to their cutaneous counterpart.[98]

CHAPTER 78

Keratinous Cyst, Intratarsal

Key Points

- Intratarsal keratinous cysts arise from the meibomian glands of the tarsal plates
- They do not arise from the dermis, and therefore are distinct from epidermoid cysts of the eyelid
- 80% are located in the upper eyelids without a history of trauma, inflammation, previous eyelid surgery, or preexisting lesions
- The etiology of these cysts is unclear, but blockage of meibomian ducts appears to be responsible for their formation
- They present as a yellow-white to skin-colored, smooth, well-circumscribed, noninflammatory lesion that can appear as a prominent bulge beneath the eyelid skin over the tarsus, or may only be detectable when the eyelid is everted
- Treatment includes complete excision of the entire cyst, exposure of the capsule, amputation from the tarsus, and generous cautery at the base wall to prevent a recurrence
- With inadequate excision or drainage, the recurrence rate is high, but with complete excision the prognosis is excellent

Intratarsal keratinous cysts (IKC) are a recently described entity that arises from the meibomian glands of the tarsal plates.[1,2] After chalazion and sebaceous carcinoma, IKC is the third most common cause of primary tarsal swelling.[1] This lesion has also been referred to in the literature as a tarsal keratinous cyst, intratarsal inclusion cyst, intratarsal epidermal inclusion cyst, meibomian gland ductal cyst, epidermal cyst, and epidermoid cyst.[1,3,4,5,6,7,8] However, these lesions arise within the meibomian glands of the tarsal plates, not from the dermis, and therefore are distinct from epidermoid cysts of the eyelid.

The term “intratarsal keratinous cyst” was introduced by Jakobiec et al[1] based on six cases and a review of cases previously described in the literature as intratarsal inclusion cyst.[3] All of these cases were characterized by progressive growth of a mostly palpable cystic lesion on the eyelid fixed to the tarsus. Larger series were subsequently described by Kim et al[9] who added 11 cases, and Zhang et al[10] who reported 15 new cases lacking external signs on the eyelid skin. Among all of these cases, the incidence was equal between men and women, and only 7% of patients were younger than 20 years of age. To date, only 59 cases have been described, although, among 35 cases of all eyelid cysts, Suimon et al[11] diagnosed IKC in 14%, so that the incidence may be higher than appears in the literature.

About 80% of IKCs are located in the upper eyelids, and typically there is no history of trauma, inflammation, previous eyelid surgery, or preexisting lesions. The mean age at presentation has been reported to be 45 to 68 years,[1,9,10,11] and there is no gender predilection.

Patients usually present with an eyelid lump that may have been present for several months to up to 5 years. Initial diagnosis is frequently missed, usually made as a more common lesion such as chalazion. Patients most commonly present with complaints of a foreign body sensation, but pain and epiphora are rare symptoms reported in only about 20% of cases.[10]

Etiology and Pathogenesis

The etiology of IKC and other eyelid cysts is not clear, but previously they were considered to result as a complication of previous eyelid surgery.[12,13] However, attachment of the cysts to the tarsus as well as the histopathology and immunohistochemistry suggests that these lesions originate from the meibomian glands or their ducts. Meibomian gland ducts are lined with keratinizing stratified squamous epithelium without a granular layer and with an innermost cuticle layer,[14,15] similar to the lining of IKC. Also, both IKC and meibomian ducts stain positive for epithelial membrane antigen (EMA) on immunohistochemistry. Blockage of these ducts appears to be responsible for the formation of IKCs.[10] IKC is distinct from a chalazion, which is a chronic granulomatous inflammatory lesion of the meibomian gland or gland of Zeiz resulting from lipid breakdown products leaking into surrounding

tissues.

Clinical Presentation

The main symptoms of IKC include foreign body sensation, irritation, tenderness, or photophobia, mostly from the nodular elevation beneath the conjunctiva. Some lesions are very prominent as a bulge beneath the eyelid skin and are easily visible and palpable externally (Figure 78.1). Others point posteriorly and are only detectable when the eyelid is everted (Figure 78.2).[10] With the eyelid everted, lesions appear as a yellow-white, smooth, well-circumscribed, noninflammatory nodule ranging from 1 to 10 mm in diameter on the palpebral conjunctival surface.[10] Lesions with an anterior extension may have a slight blue color beneath the skin, probably from the Tyndall effect.[9] Clinically, lesions appear as a firm subcutaneous nodule mostly on the upper eyelid. The lesion is fixed to the tarsus and the skin is freely mobile over it, normal in color, and without inflammatory signs. Lesions are usually isolated, although multiple IKCs have *(Print pagebreak 517) (Print pagebreak 518)* been known to occur.[2] Transconjunctival leakage of the keratinous cyst contents may occasionally occur and cause irritation.[2]

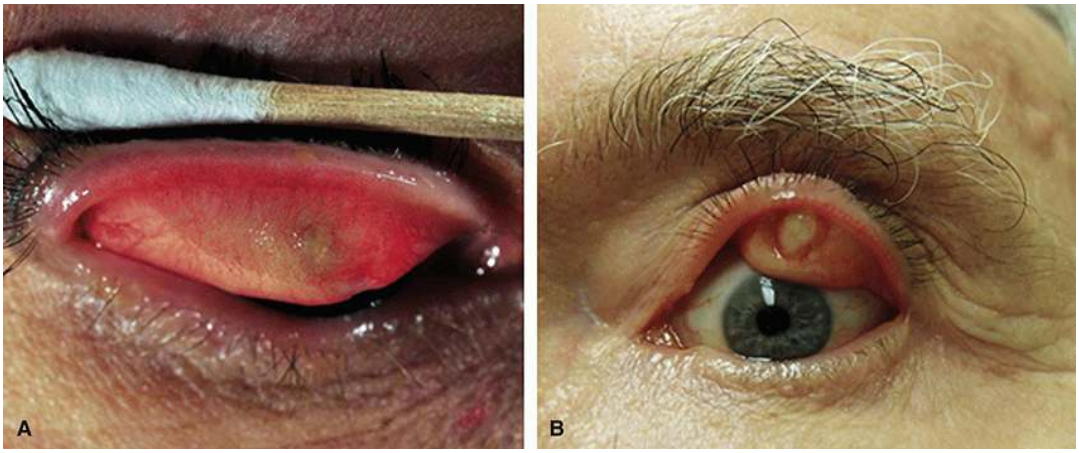

FIGURE 78.2 A and B, Posterior intratarsal keratinous cysts pointing on the conjunctival surface. A (Courtesy of Dr.

Reza Vagefi). B (Courtesy of Dr. Robert Kersten).

Differential Diagnosis

The main differential diagnoses of IKC include epidermoid and epidermal inclusion cysts, steatocystoma, chalazia, and meibomian gland carcinomas. Epidermoid cysts are situated in the dermis and are freely moveable over the tarsus, unlike the fixed position of IKC. Steatocystoma occurs in younger individuals, usually less than 30 years old, the cyst is lined with nonkeratinizing squamous epithelium, and the cyst contents consist of yellow sebum with scattered hair shafts.[16,17] Chalazia are typically fluctuant inflammatory lesions.

Treatment

Treatment of IKCs must include complete excision of the entire cyst, exposure of the capsule, amputation from the tarsus, and generous cautery at the base wall to prevent a recurrence.[18] This requires a more aggressive approach than that used for epidermoid cysts or chalazia. The recurrence rate is significant following more limited procedures such as incision and drainage (I&D), or curettage as is commonly performed for chalazia. A full-thickness pentagonal eyelid wedge resection or transconjunctival tarsectomy including all of the cyst walls is usually recommended.[1,5,6] At surgery, the cyst wall is thick and well-developed and fused to the tarsus, making more limited dissections difficult. If the cyst is opened, a milky to viscid fluid is released.[1]

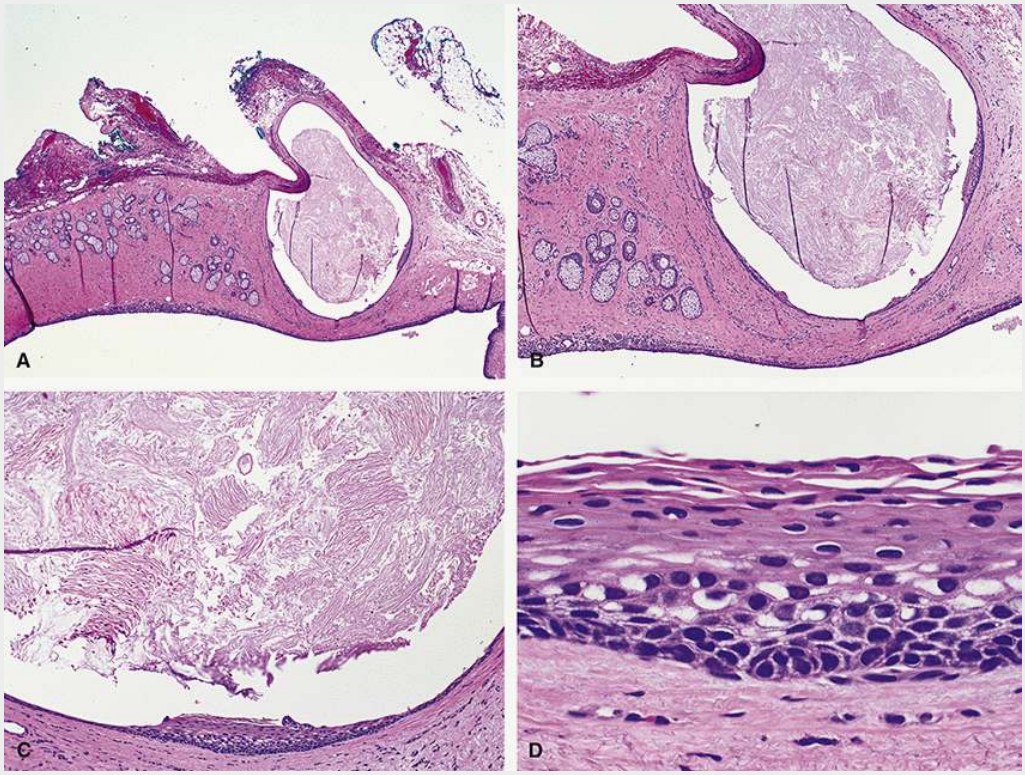

FIGURE 78.3 A and B, Intratarsal keratinous cyst located within the dense collagenous tissue of the tarsus. C and D, The cyst is lined by stratified squamous epithelium with an inner layer that may be undulating or corrugated and lacks keratohyalin granules, goblet cells, or sebaceous cells. The lumen contains loose, eosinophilic keratin (C).

Prognosis

With inadequate excision or drainage, the recurrence rate is high. Following complete excision, by wedge resection or anterior or posterior tarsectomy, the prognosis is excellent, with no recurrences reported.

Histopathology

IKCs are located within or attached to the tarsus (Figure 78.3).[1] They are lined by stratified squamous epithelium with an inner layer that may be undulating or corrugated.[1,6,8,19,20] The *(Print pagebreak 519)* lining lacks keratohyalin granules, goblet cells, or sebaceous cells.[1] The lumen contains loose, eosinophilic keratin (Figure 78.3C), though we recently had a case with the typical epithelial lining but only minimal luminal contents (Figure 78.4). The epithelial lining and keratin contents express cytokeratin 17 and carcinoembryonic antigen, while those of epidermoid cysts do not.[1,20] Immunohistochemical stains are not needed for diagnosis if the cyst is located within the tarsus and has an appropriate histological appearance.

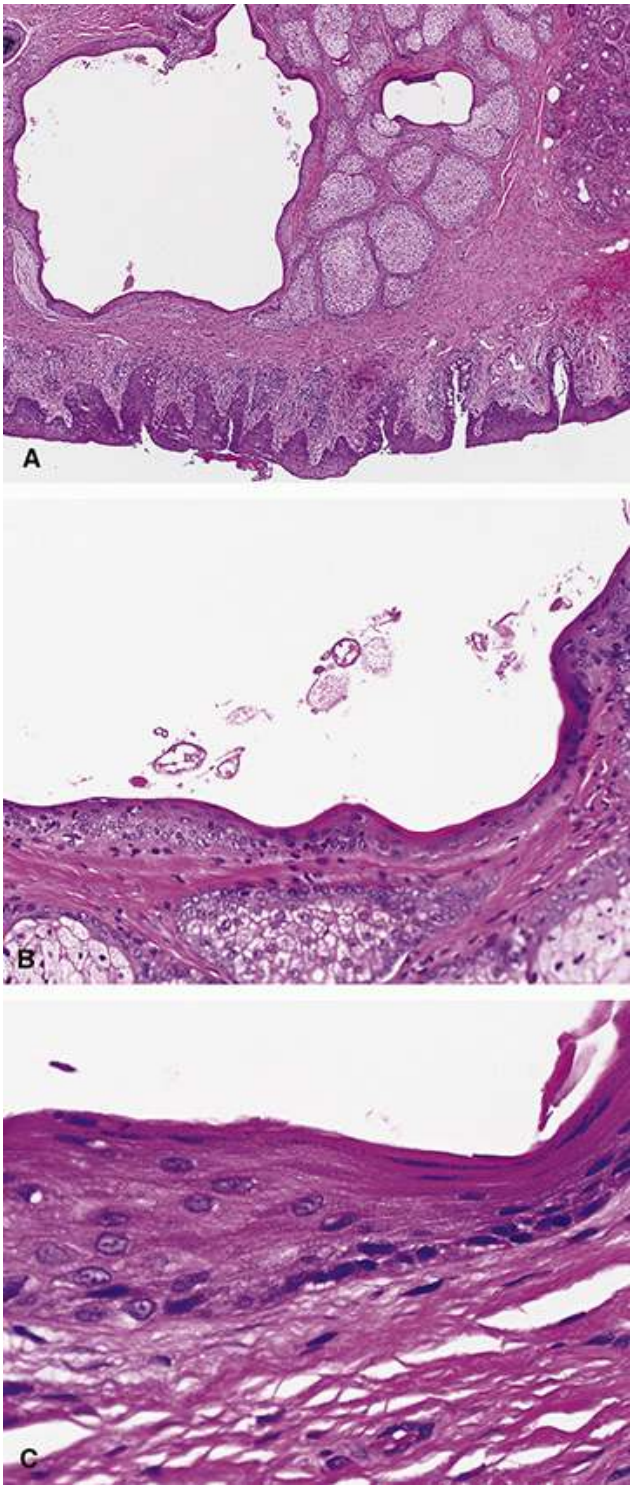

FIGURE 78.4 This intratarsal (A) cyst has the typical epithelial lining (B and C) of an intratarsal keratinous cyst but only minimal luminal contents (B). It is not possible to determine if the minimal luminal content is due to this being an early cyst lacking time for the keratin to accumulate or if the contents drained before or during surgery.

CHAPTER 79

Leiomyoma

Key Points

- Leiomyoma is a benign soft-tissue neoplasm arising from smooth muscle
- Cutaneous leiomyomas are divided into three subtypes: piloleiomyomas originate from the attachment points of the arrector pili muscle; angioleiomyomas originate from vascular smooth muscles of the tunica media of small-to medium-sized arteries and veins; and dartoic leiomyomas arise from the smooth muscles of genital skin and areola
- The pathogenesis of leiomyomas is unknown
- Genetic mutations have not been associated with sporadic solitary piloleiomyomas, but multiple cutaneous leiomyomas possess a heterozygous germline mutation in fumarate hydratase
- In angioleiomyomas, 35% exhibit DNA copy number changes involving one or two chromosomes
- Piloleiomyomas on the eyelid appear as painful, red, bluish-black or yellow, slow-growing, smooth, firm, rubbery papules or nodules
- Angioleiomyomas are slow-growing, asymptomatic, solitary skin-colored, well-defined, firm, vascularized, deep dermal or subcutaneous nodules
- The gold standard for treatment is surgical excision for small, localized tumors
- Morbidity associated with untreated lesions is primarily from pain, but following surgical excision the prognosis is excellent

Leiomyoma is a benign soft-tissue neoplasm arising from smooth muscle that was first described by Virchow in 1854 as "tuberculum dolorosum."[1] These lesions are found most commonly in the uterine myometrium in 95% of cases, followed by the skin in 3%, and the gastrointestinal tract in 1.5%. Less than 1% are seen in the head and neck region.[2] These tumors are typically asymptomatic, slow-growing lesions, most often seen in the 4th and 5th decades of life with a slight predilection for females.

Cutaneous leiomyoma has been divided into three subtypes according to the site of origin.[2,3] Pilar leiomyomas or piloleiomyomas originate from the attachment points of the arrector pili muscle, proximal to the hair follicle and distal to multiple attachment points within the papillary and reticular dermis and basement membrane zone.[4] Angioleiomyomas originate from vascular smooth muscles of the tunica media of small- to medium-sized arteries and veins. Dartoic or genital leiomyomas arise from the smooth muscles of genital skin and areola.[1] The angioleiomyoma and dartoic subtypes usually present as solitary lesions, whereas pilar leiomyomas can manifest as solitary or multiple cutaneous tumors.

Superficial leiomyoma can occur at any age from infancy to old age, with most patients in middle age[5,6,7] and a peak incidence between 40 and 60 years.[8] Various studies have shown male or female predilection, but overall the sexes are equally affected. There is no racial predilection for leiomyoma, except in oral angioleiomyomas, for which the white-to-black ratio has been reported to be 3:1.[9]

Leiomyoma can appear in any body location where smooth muscle is present. In the head and neck region, about 23% of tumors involve the lips, tongue oral cavity, buccal mucosa, soft palate, larynx, esophagus, trachea, nasal cavity, salivary glands, paranasal sinuses, thyroid gland, intraosseous sites in the maxilla, and mandible, and orbit. Other rare sites include the ear, cheek, neck, forehead, and scalp.[10,11]

Piloleiomyomas usually present as a papule or nodule on the face, trunk, or extremities, either solitary or as multiple nodules that may be in a clustered, linear, dermatomal, or scattered distribution. Nodules range in size from 2 to 20 mm and vary in color from skin color, to pink, red, or brownish. Solitary piloleiomyomas are more common on the lower extremity, whereas multiple

piloleiomyomas more often occur on the trunk or the extensor surface of the extremities.[2] Pain is a common presenting symptom, which may occur spontaneously or initiated by pressure or low temperature.[12]

In 1973, Reed et al reported the association of multiple cutaneous leiomyomas with leiomyomas of the uterus, a condition known as Reed syndrome.[13] The condition is also referred to as multiple cutaneous and uterine leiomyomatosis (MCUL) and also can occur with renal cell carcinoma.[14,15,16] When MCUL is associated with renal cancer, it is referred to as hereditary leiomyomatosis and renal cell cancer. The inheritance pattern is thought to be autosomal dominant with incomplete penetrance,[17] so that not all women in a family are similarly affected; some may only have cutaneous tumors, others only uterine tumors, and some may have both cutaneous and uterine leiomyomas.[18,19] When this condition occurs as a genetic syndrome, the piloleiomyomas tend to occur earlier in life, with an average age of onset at 25 years and a range of 10 to 50 years.[2]

(Print pagebreak 521)

Angioleiomyoma, also known as vascular leiomyoma, most commonly involves the lower extremities and head and neck region.[10] Orbital and eyelid involvement is extremely rare.[20,21,22,23] They usually present in females in the 5th to 7th decades as a firm, painful, solitary subcutaneous nodule and are more common in women than in men, with a ratio of about 2:1.[24,25,26,27] Angioleiomyomas have been further subclassified based on histopathology as capillary (or solid), which is the most common type; venous; and cavernous types.[28]

Genital leiomyomas typically develop on the genitals, including the scrotum, penis, and vulva, and also on the nipple-areolar region. The lesions usually present as an asymptomatic, solitary nodule.

Etiology and Pathogenesis

The pathogenesis of leiomyomas remains unknown. Genetic mutations have not been associated with sporadic solitary piloleiomyomas. Contrary to sporadic solitary leiomyoma, approximately 89% of patients with multiple cutaneous leiomyomas possess a heterozygous germline mutation in fumarate hydratase (FH),[29] an enzyme in the Krebs cycle that functions in the conversion of fumarate to malate.[2] In 85% to 90% of female patients with FH mutations, both cutaneous and uterine leiomyomas may be present. The FH mutation is also associated with renal cell carcinoma, seen in approximately 15% of these patients.[2] The pathophysiology of heterozygous FH deficiency and the production of leiomyomas is not known, but it has been suggested that FH may function as a tumor suppressor.[30,31,32] In dominantly inherited, multiple cutaneous piloleiomyomas associated with uterine leiomyomas, evidence has been reported for linkage to chromosome 1q42.3-q43.[33]

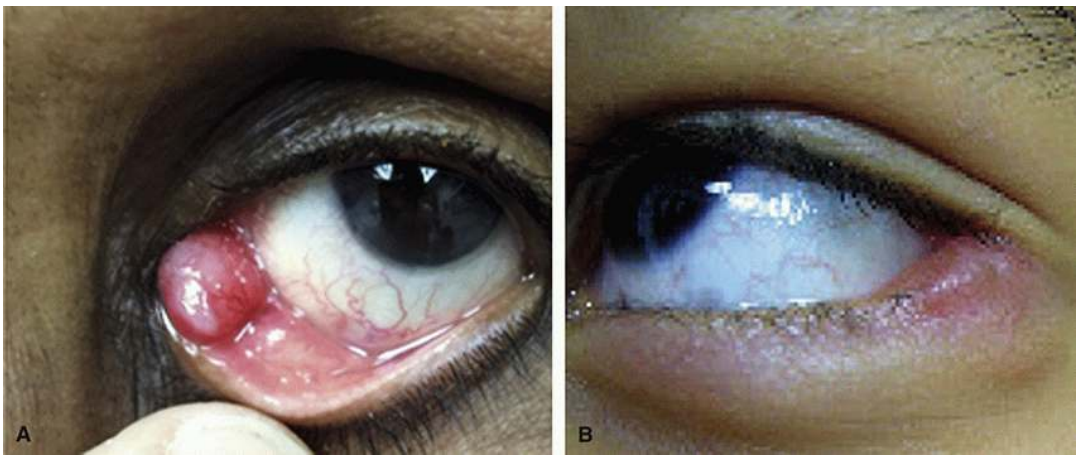

FIGURE 79.1 A, Leiomyoma on the conjunctival surface at the medial lower eyelid. B, Piloleiomyoma nodular mass of the right upper eyelid in a 13-day old infant. (A, Courtesy of Dr. Roman Shinder. B, Reprinted with permission from Alam S, Banerjee P, Subramanian K. A rare case of congenital piloleiomyoma of the eyelid. *Orbit*. 2020 Aug 26, Online ahead of print.)

In a series of 23 cases of angioleiomyoma, 35% exhibited DNA copy number changes involving one or two chromosomes, with the most common recurrent loss found at chromosome 22q11.2.[34] Genital leiomyoma has been associated with several chromosomal anomalies including clonal translocation between chromosomes 7 and 8 (7;8)(p13;q11.2)[35] and pericentric inversion involving chromosome 12 (12) (p12q13-14).[36]

The pathogenesis of pain associated with leiomyomas is not known. Various theories have proposed that pain could result from local pressure on cutaneous nerves, or that specific infiltrating cells play a role, or that muscle contraction be contributory.[26]

Clinical Characteristics

Individual piloleiomyomas on the eyelid appear as slow-growing, smooth, firm, rubbery papules or nodules.[37] They can be skin-colored, red, reddish-brown, bluish-black, or yellow and can even be hypopigmented in color and are usually less than 2 cm in diameter (Figure 79.1). The skin may be irregularly thickened and when located on the eyelid margin can be associated with madarosis, tearing, and mattering.[38] Since these lesions develop in the superficial dermis, they are fixed in the skin, but not adherent to deeper structures.[26] Ninety percent of piloleiomyomas are painful, described as burning, pinching, or stabbing, exacerbated by tactile pressure, or even emotion.[26,39,40,41] Multiple cutaneous leiomyomas occur on the face, trunk, or extremities and may be bilateral. The distribution pattern can be grouped, dermatomal, and linear.[42]

Angioleiomyomas are usually slow-growing, asymptomatic, solitary skin-colored, well-defined, firm, vascularized, deep dermal or subcutaneous nodules on the lower *(Print pagebreak 522)* extremities, but occur less commonly on the trunk and head.[26,27,43,44,45,46,47] In the head and neck region, they can occur on the oral or nasal mucosa, or the skin of the face, lip, or eyelid.[48] Other rare locations include the larynx, salivary glands, and retropharyngeal space.[49,50,51,52]

Differential Diagnosis

The appearance of solitary cutaneous leiomyoma is nonspecific so that the differential diagnosis is extensive and includes a large variety of dermal lesions and connective tissue tumors that clinically can be similar.[3] These include chalazion, dermal nevus, lipoma, neurofibroma, dermatofibroma, glomus tumor, eccrine tumors, fibrosed epidermoid inclusion cyst, and trichoepithelioma, among others. Most of these can be distinguished from leiomyoma on histopathology.[2]

The most important lesion in the differential diagnosis of leiomyoma is leiomyosarcoma. Like leiomyoma, these malignant tumors arise from similar smooth muscle tissues. Leiomyosarcomas have been associated with a history of various types of insults such as trauma, burns, inoculation sites, tick bites, radiation, and lupus vulgaris.[26] The majority occur on the hair-bearing surfaces of the extremities, particularly the lower extremities, but occasionally they can be seen on the head and neck.[53,54,55] Contrary to benign leiomyomas, they may be poorly demarcated and occasionally bleed.

Treatment

If left untreated, cutaneous leiomyomas continue to grow slowly and new lesions may appear over many years.[39] Specific treatment depends on the number of lesions, the anatomical location, and the symptoms. The gold standard for treatment is surgical excision for small, localized tumors.[26]

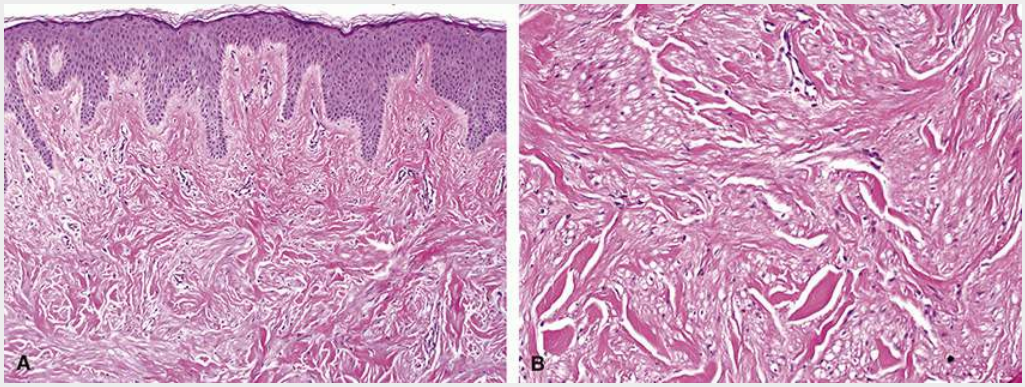

FIGURE 79.2 A, This piloleiomyoma has acanthotic epidermis separated from intersecting bundles of palely eosinophilic smooth muscle cells with entrapped brightly eosinophilic collagen bundles. A thin layer of normal dermis (grenz zone) separates the epidermis from the dermal tumor. B, The well-differentiated neoplastic smooth muscle cells have palely eosinophilic cytoplasm, perinuclear vacuoles, and fibrillary cytoplasm. The intersecting smooth muscle bundles have entrapped brightly eosinophilic collagen bundles.

Nonsurgical ablative treatments have occasionally been used with variable results. Cryotherapy has been applied to the resection bed in several cases of tracheobronchial leiomyoma.[56,57] In a case of multiple piloleiomyomas in Reed syndrome, liquid nitrogen cryotherapy resulted in a marked improvement in the pain and size of the skin lesions.[58] Laser ablation has been advocated for some deep mucosal lesions, and for larger cutaneous lesions where surgical excision might be

cosmetically unacceptable.[59,60,61]

Contraction of the smooth muscle in leiomyoma combined with the presence of the increased number of nerve elements has been proposed as mechanisms for the pain associated with these lesions.[12,26,62] Smooth muscle is primarily under the control of the autonomic nervous system, and increased cytoplasmic calcium concentration is the primary stimulus for the contraction of smooth muscle.[63,64] Therefore, smooth muscle relaxing agents, such as receptor inhibitors or calcium channel blockers, have been used to reduce the pain of leiomyomas.[62,65,66] Injection of botulinum toxin into the lesion has shown mixed results for symptomatic relief.[63]

Prognosis

The morbidity associated with untreated cutaneous leiomyoma is primarily from pain, either spontaneous or evoked by cold and or touch. Multiple piloleiomyomas also can be cosmetically disfiguring. Following surgical excision of solitary lesions, the prognosis is excellent and recurrences are rare.[10]

Histopathology

Piloleiomyomas are poorly demarcated, nonencapsulated, dermal nodules of intersecting fascicles of smooth muscle with entrapped collagen bundles (Figure 79.2).[67,68] *(Print pagebreak 523) (Print pagebreak 524)* The tumor cells are well-differentiated spindle cells with elongated, blunt-ended nuclei, perinuclear vacuoles, and eosinophilic fibrillary cytoplasm.[67,68] Neoplastic cells with enlarged, hyperchromatic nuclei are encountered occasionally.[67,68] There may be rare mitoses.[67] Tumor cells have fuchsinophilic cytoplasm using Masson trichrome stain,[68] and their smooth muscle nature may be confirmed using immunohistochemical staining using antibodies to desmin, smooth muscle actin, and caldesmon.[67] The epidermis over the tumor may be hyperplastic, and a thin band of normal dermis (grenz zone) usually separates the epidermis from the neoplasm.[68]

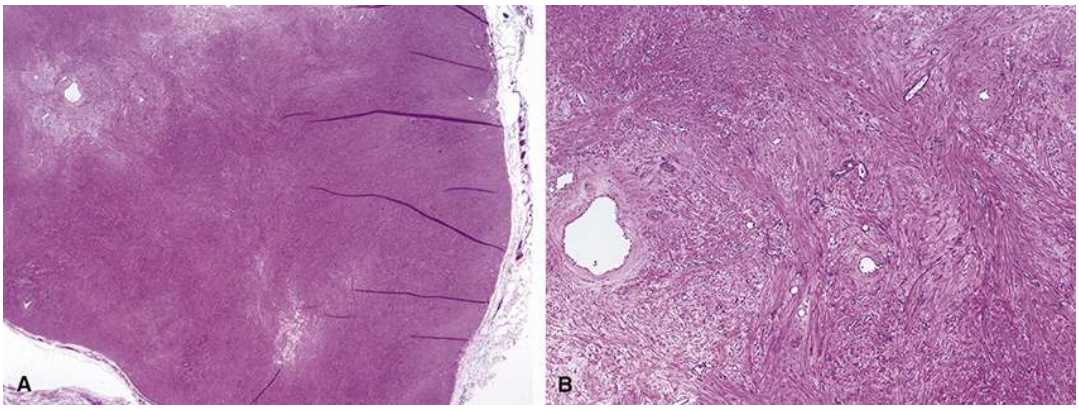

FIGURE 79.3 A, This angioleiomyoma has the typical sharp circumscription of these neoplasms. B, Cytologically bland smooth muscle cells form fascicles arrayed around blood vessels.

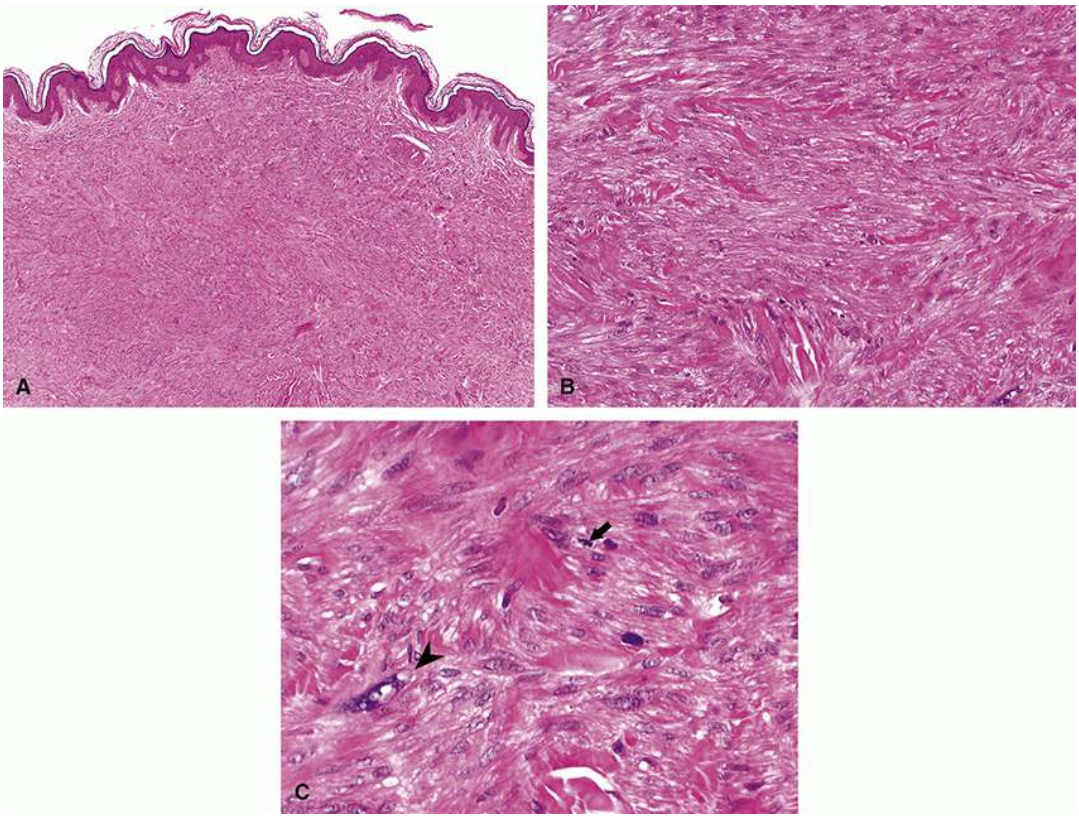

FIGURE 79.4 A, This dermal atypical smooth muscle tumor is separated from the epidermis by a thin layer of normal dermis. B, Brightly eosinophilic collagen bundles are entrapped by fascicles of well-differentiated smooth muscle cells with more lightly eosinophilic cytoplasm. C, Tumor cells have elongated nuclei with blunt ends. Atypical smooth muscle neoplasms differ from piloleiomyomas by nuclear atypia (arrowhead) and more frequent mitotic figures (arrow).

Angioleiomyomas are sharply circumscribed dermal or subcutaneous nodules of cytologically bland smooth muscle cells arranged in fascicles arrayed around blood vessels (Figure 79.3).[68,69] Mitotic figures are infrequent.[69] The neoplastic cells express smooth muscle actin, muscle-specific actin, desmin, calponin, and sometimes caldesmon.[68,69]

Atypical smooth muscle tumors, often termed “cutaneous leiomyosarcomas,” are dermal tumors usually composed of well-differentiated smooth muscle cells forming fascicles (Figure 79.4).[70,71] The tumors typically infiltrate the surrounding dermis and may extend into the subcutaneous fat.[71] Atypical smooth muscle tumors are differentiated from piloleiomyomas by greater cellularity, nuclear enlargement and hyperchromatism, and increased mitotic activity.[71] Smooth muscle actin, desmin, and caldesmon are typically expressed by tumor cells.[67,70] There may be scattered cells immunoreactive to cocktails of antibodies reactive to low- and high-molecular-weight cytokeratins.

CHAPTER 80

Lipoblastoma and Lipoblastomatosis

Key Points

- Lipoblastoma and lipoblastomatosis are rare, benign, soft-tissue tumors of embryonal fat occurring primarily in children
- Lipoblastoma refers to a circumscribed encapsulated form, and lipoblastomatosis refers to a more diffuse, infiltrative form of the tumor
- This tumor is believed to arise from altered embryogenesis of human white fat resulting in the uncontrolled proliferation of lipoblasts well into the postnatal period
- Various types of cytogenetic aberrations including translocations, insertions, and derivatives are found in lipoblastoma
- It presents clinically as a painless, soft, lobulated, yellowish, white, or tan palpable mass that may be associated with swelling and erythema simulating cellulitis
- Complete surgical excision is the recommended treatment
- Recurrences have been reported in up to 46% of cases, mostly related to incomplete excision, especially in lipoblastomatosis

Lipoblastoma and lipoblastomatosis are rare, benign, soft-tissue tumors of embryonal fat occurring primarily in children younger than 3 years. They arise from the continued proliferation of lipoblasts in white fat after birth.[1,43]

Jaffe first used the term “lipoblastoma” in 1926 for lipomatous tumors containing immature fat cells, which did not metastasize.[2] In 1958, Vellios et al[3] applied the term “lipoblastomatosis” to these tumors. They noted the presence of adipocytes in various stages of differentiation and compared these with the temporal stages of embryonic white fat development based on morphologic criteria. They suggested that these tumors represent an arrest in the development of fat maturation primarily in areas of the body where postnatal fat maturation occurs, such as the axilla, mediastinum, and retroperitoneum. In 1977, Gibbs et al[4] applied the term “lipoblastomatosis” to all benign lipoblastic adipose tumors and used the term “lipoblastoma” for tumors of brown fat, otherwise known as hibernomas. More precise morphologic criteria for diagnosis were established in 1973 when Chung and Enzinger[5] distinguished two distinct forms of this same entity. They designated the term “lipoblastomatosis” for a more diffuse, infiltrative form of the tumor and reserved the term “lipoblastoma” for the more circumscribed encapsulated form. Aside from this difference, these two forms of the tumor have identical cell morphology histologically. In 2000, O'Donnell et al[6] argued that because lipoblastoma does not metastasize, the term *blastoma* was confusing. They proposed replacing it with the term “infantile lipoma.” However, the terminology proposed by Chung and Enzinger is still the most commonly used nomenclature.

Of the 410 cases of lipoblastoma and lipoblastomatosis reported in the literature to date, approximately 68% were encapsulated and represented lipoblastoma, and 32% showed a more diffuse growth pattern, more consistent with lipoblastomatosis.[7] Tumors occurred most frequently on the trunk and extremities (80%) and much less commonly on the head and neck (17%). Of the latter group, most were seen in the neck, with only 5% occurring on the face and head.

Lipoblastoma is a well-circumscribed encapsulated lesion.[7,8] It has been reported in patients from birth to 60 years of age, but the mean age at presentation is 3.2 years.[7] Nearly 80% of patients are younger than 3 years, and 94% are younger than 10 years. Only 2% are older than 20 years at presentation. Although some earlier reports suggested a strong male predominance of as high as 4:1,10 larger reviews have shown only a slight male predominance of 1.5:1.[7] The most common sites of involvement are on the extremities and trunk,[7,10,11,12] and less frequently in the abdomen, retroperitoneum, mediastinum, axilla, groin, inguinoscrotal, labia, vulva, and gluteal region. Occurrence on the head and neck is relatively uncommon.[7,10,11,13,14,15,16]

To date, only three cases of lipoblastoma have been described in the eyelid. Enghardt and Warren[17] reported a congenital lipoblastoma in a 13-month-old female patient with a mass in the eyelid anterior to the orbital septum. Adams et al[18] presented a

case of a 16-month-old male patient with a lipoblastoma in the eyelid and anterior lateral orbit associated with eyelid edema and strabismus. Singh et al[19] presented a rare case of a large congenital lipoblastoma of the scalp that extended into the brow and eyelid. Three additional cases involved the orbit. Seider et al[20] described a newborn infant with a congenital lipoblastoma involving the nasal cavity and orbit. Hwang et al[21] reported a 3-month-old infant with an orbital lipoblastoma since birth, 2 cm in size, and causing 4 diopters of astigmatism. A previous case of orbital lipoblastoma was described by Bernolet and Jaeger in 1949.[22] One case of lipoblastomatosis has been described extending from the eyelid into the anterior orbit.[7]

Diagnostic imaging of lipoblastoma and lipoblastomatosis can be helpful in clinical diagnosis. Ultrasound may demonstrate a diffuse to well-defined mass with weak heterogeneous *(Print pagebreak 527)* echogenicity.[23] High internal echoes represent cellular and septate areas, and low echoes represent myxoid and fatty areas. On radiologic imaging, the appearance depends on the amount of myxoid stroma and fibrous septa among the fat. On CT, lipoblastoma appear as a well-defined or diffuse, heterogeneous, hypodense mass. Areas of low attenuation represent fat,[24,25,26] and enhancement can be seen in areas of rich capillary network and in the interlobular septa.[27] MRI is the modality of choice to define the extent of the mass and the possibility of local invasion. T1-weighted images demonstrate a heterogeneous mass that is isointense to slightly hypointense to subcutaneous fat. T2-weighted images reveal a heterogeneous lesion with areas of high signal intensity.[28,29,30] Lesions become markedly hypointense with fat suppression.

Malignant transformation has not been documented in lipoblastoma or lipoblastomatosis. Recurrent tumors may transform into more mature lipomatous tumors, such as a lipoma.[9,31,32]

Etiology and Pathogenesis

Lipoblastoma is believed to arise from altered embryogenesis of human white fat.[32] This results in the uncontrolled proliferation of lipoblasts well into the postnatal period. Various types of cytogenetic aberrations including translocations and insertions have been found in lipoblastoma. Sandberg et al[33] were the first to demonstrate a translocation with a break point at chromosome locus 8q12 in a lipoblastoma and this has been confirmed in several subsequent reports.[34,35,36,37,38,39] Batanian et al[35] described a recurrent common chromosomal break point in a number of rearrangements at 8q11.2-8q12, and the critical region of chromosome 8q11.2 seen in lipoblastomas may contain an important gene that plays a role in the pathophysiologic pathway of the tumor.[35]

It has been proposed that the developmental gene pleomorphic adenoma gene 1 (*PLAG1*) at 8q12 may be the putative target oncogene responsible for lipoblastoma development.[40,41] Approximately 70% of lipoblastomas have a rearrangement of the *PLAG1* gene located in 8q12.1, possibly resulting in transcriptional upregulation of this oncogene through a promoter swapping event, while 18% of lipoblastomas present polysomy for chromosome 8 with or without a *PLAG1* rearrangement.[42,43,44]

Coffin et al[45] reported the presence of central nervous system disorders such as seizures, autism, and developmental delay, congenital anomalies, Sturge-Weber syndrome, or a family history of lipomas in 17% of 59 patients with lipoblastoma. They suggested that these observations raise the question of whether predisposing genetic or other constitutional factors contribute to the development of lipoblastoma or whether this tumor is indicative of a syndrome.

Clinical Characteristics

The most common clinical manifestation of lipoblastoma/lipoblastomatosis is a painless, soft, lobulated, yellowish, white, or tan palpable mass.[7,8], It may be associated with swelling and erythema simulating cellulitis.[7] Most lesions are 5 cm or less in size, but larger tumors have been reported. When symptoms do occur, they tend to be associated with a mass effect in the area of tumor growth.[38] In the eyelid, this can manifest as upper eyelid ptosis (Figure 80.1).[7] Growth may be slow or rapid but generally is slowly progressive. Most tumors occur superficially, but occasionally they can appear as deep lesions that cause organ dysfunction, such as respiratory insufficiency when the lesion is located in the neck,[24,46,47,48,49,50,51] or even hemiparesis.[52] In rare instances, these tumors may rupture, resulting in a significant inflammatory reaction.[47]

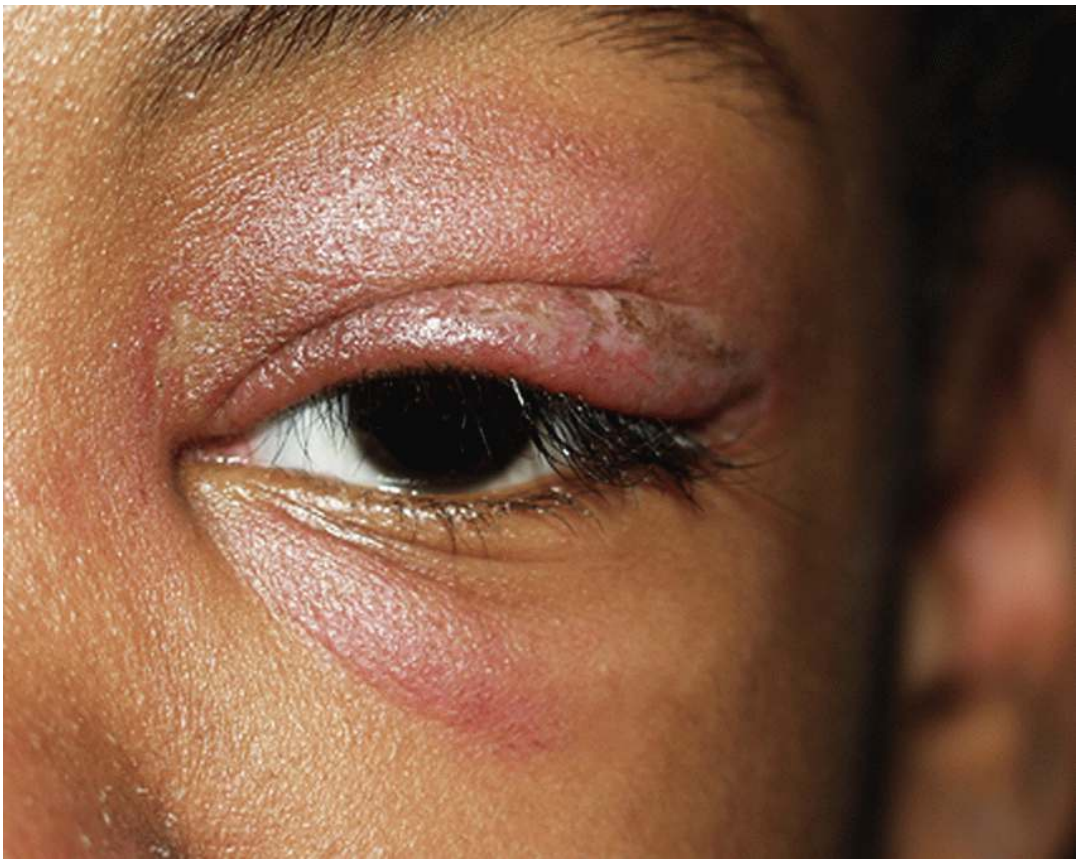

FIGURE 80.1 Lipoblastomatosis of the left upper and lower eyelids with erythema, crusting, and mechanical ptosis.

Differential Diagnosis

The differential diagnosis for lipoblastoma includes other adipose-derived mesenchymal tumors. These include lipoma, fibrolipoma, hibernoma, liposarcoma, and fibroliposarcoma, as well as a dermoid cyst, teratoma, and fibrosarcoma. Most teratomas and dermoid cysts contain calcifications or cystic areas in addition to soft-tissue and fatty elements. Hibernomas are mostly seen in the 3rd to 4th decade of life, frequently with prominent branching and serpentine vascular structures. Malignant myxoid liposarcomas are most similar histologically, but they are extremely rare in patients younger than 10 years[14,53,54] and occur most often during the third to sixth decades of life.[55] Myxoid liposarcomas also show a more hypocellular spindle cell proliferation having a predominantly myxoid appearance with atypical bizarre lipoblasts, nuclear cellular atypia, necrosis, and mitoses.[56,57]

Treatment

While both lipoblastoma and lipoblastomatosis are considered benign, complete surgical excision is the recommended treatment. In most reports, recurrence rates have been seen in up 28% of cases,[5,58,59,60] but Coffin et *(Print pagebreak 528)* al[45] reported recurrence in 46% of 30 patients with lipoblastoma. Most recurrences are related to incompletely excised tumors or in those where complete excision is not possible for functional reasons. Lipoblastomatosis has a higher recurrence rate because of its infiltrative nature and the greater difficulty in achieving complete excision. Given the relatively high recurrence rate in incompletely resected tumors, close follow-up is recommended for at least 2 to 5 years.[1,59,61]

Prognosis

After complete surgical resection, most cases of lipoblastoma and lipoblastomatosis do well. Several cases of lipoblastoma have been reported to undergo spontaneous regression,[62,63] but this is a very rare event. A case of maturation of a lipoblastoma to mature fat has also been reported.[64] Following incomplete excision, recurrence has been reported in from 0% to 46% of cases and may occur after several years, so close follow-up is necessary.[59,65]

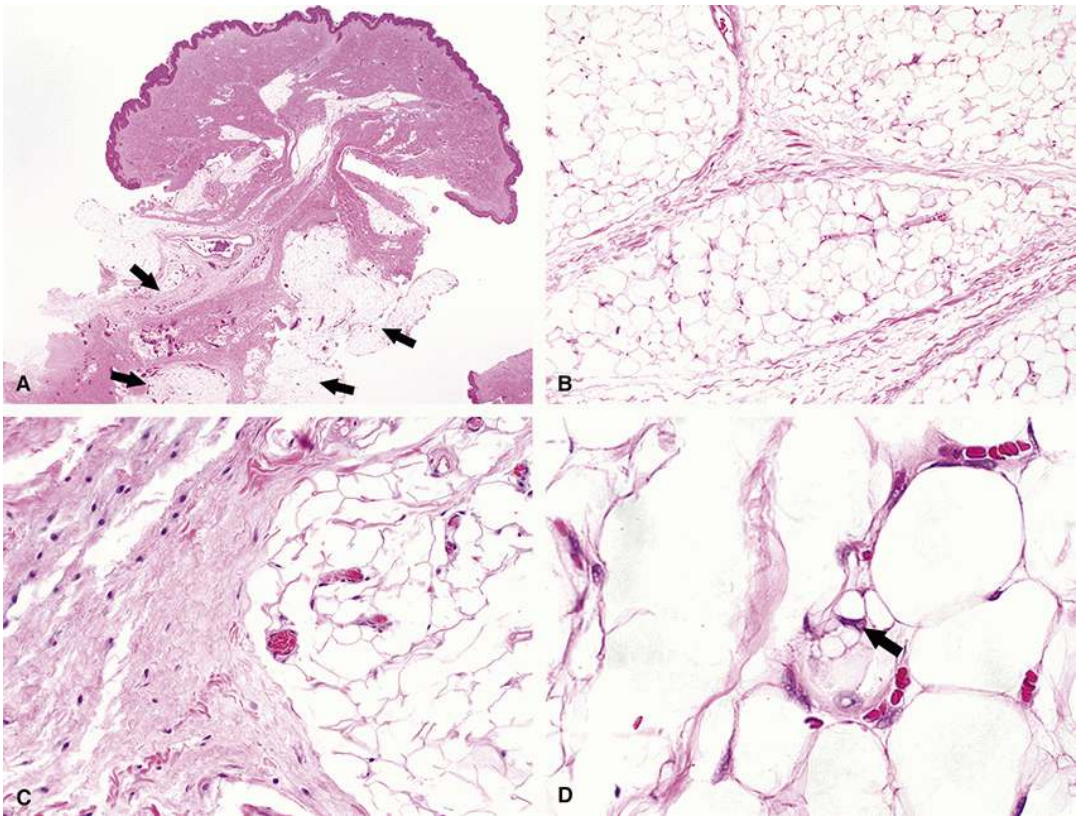

FIGURE 80.2 A, A well-differentiated lipoblastoma in the subcutis (arrows). B, Fibrovascular septa separate the adipocytes into lobules. C, The tumor cells have a variable appearance ranging from primitive stellate or spindled mesenchymal cells (preadipocytes) to mature adipocytes. D, The number of lipoblasts (arrow) is variable, and they may be rare in mature lipoblastomas.

Histopathology

Cutaneous lipoblastomas are usually circumscribed tumors composed of lobules of adipocytes separated by fibrovascular septa (Figure 80.2A and B).[8,66,67,68] The fat cells feature a spectrum of differentiation ranging from primitive stellate or spindled mesenchymal cells (preadipocytes) to mature adipocytes (Figure 80.2C).[66,67] The proportion of cells in different maturation stages varies from one case to another and between lobules. Primitive areas typically appear myxoid. The adipocyte lobules have a fine vascular network (Figure 80.2B and C). Tumors composed of mature fat cells resemble fibrolipoma but are distinguished by rare lipoblasts (Figure 80.2D).[66] Lipoblasts have indented or scalloped nuclei and mono- or multivacuolated cytoplasm and must be distinguished from mimics such as adipocytes with intranuclear vacuoles (lockern cells) and lipoblast-like cells resulting from starvation, malnutrition, or trauma.[69] The lipoblasts in lipoblastoma do not exhibit cytological atypia or mitotic figures, distinguishing them from those in liposarcoma.[68] *(Print pagebreak 529)* Primitive mesenchymal cells may express desmin,[8,67] CD34 is expressed by adipocytes and vascular endothelial cells,[8] and adipocytes are immunoreactive using antibodies to S100 protein[66] and CD56.[66] Cutaneous lipoblastomatosis differs from lipoblastoma by infiltrating the dermis and underlying muscle.[67]

CHAPTER 81

Lipoid Proteinosis

Key Points

- Lipoid proteinosis is a rare autosomal recessive dermatosis that presents with dermatological, ophthalmological, otolaryngological, and neurological manifestations
- It is a multisystem disease due to multiple mutations in the *ECM1* gene
- A hoarse cry is usually the first clinical sign, usually present at birth
- Enlargement of the tongue with a thickened frenulum manifests as restricted tongue movements
- Moniliform blepharosis is considered a pathognomonic feature presenting as small yellow-white beaded papules on the eyelid margins
- There is no cure for lipoid proteinosis
- Medical treatment for skin lesions includes acitretin, dimethyl sulfoxide, steroids, D-penicillamine, and intralesional heparin
- Prognosis for life is good, but there is usually significant effect on quality of life

Lipoid proteinosis (LP), also known as Urbach-Wiethe disease and hyalinosis cutis et mucosae, is a rare autosomal recessive dermatosis that usually presents with dermatological, ophthalmological, otolaryngological, and neurological manifestations. It was first described by Siebenmann in 1908[1] and later established as a distinct clinical and histologic entity by Urbach and Wiethe in 1929.[2,3] It is characterized by generalized infiltration of amorphous hyaline material in the skin, vocal cords, mucosa, and multiple internal organs.[3,4,5]

The clinical diagnosis is based on the triad of early-onset hoarse voice, typical skin lesions, and beaded papules on the eyelids. Various laboratory tests can help confirm the diagnosis. The skin tissue strongly stains with PAS because of the presence of hyaline. Immunohistochemical staining for antibodies against the EMC1 protein is reduced in LP.[4] Staining with anti-type III, anti-type IV, or anti-type VII collagen antibodies reveal bright, thick bands at the dermal-epidermal junction. More than half of the patients also show bilateral symmetrical damage in the amygdaloid region of the brain on a CT scan.[6,7]

Etiology and Pathophysiology

LP is a multisystem disease due to multiple mutations in the *ECM1* gene on chromosome 1 at 1q21.2 encoding extracellular matrix protein 1 (ECM1), present in the epidermis. This is a secretory glycoprotein expressed in the dermis and other tissues.[4,8,9,10] More than 50 mutations in the *ECM1* gene have been documented including missense, nonsense, frameshift, or splice site mutations with the majority occurring in exons 6 and 7.[4,10,11,12,13] Hamada et al[14] reported that patients with mutations in exon 7 of the *ECM1* gene tend to have a milder phenotype as compared with patients having mutations in other parts of the gene.

The ECM1 protein functions in epidermal differentiation, binding of dermal collagen and proteoglycans, and regulation of angiogenesis.[15] Reduced expression of this protein results in aberrant deposition of eosinophilic hyaline-like material in the skin and viscera, leading to the clinical features of this disease.[16,17]

Clinical Presentation

The clinical manifestations of LP involve respiratory, cutaneous, and neurologic tissues, but any organ can be involved. A hoarse cry is usually the first clinical sign, typically present at birth or shortly thereafter due to infiltration of the laryngeal mucosa.[18,19,20,

[21] Enlargement of the tongue with a thickened frenulum manifests as restricted tongue movements and is another reliable clinical sign of LP. In addition, there are yellow-white submucous infiltrates on other mucosal surfaces such as the pharynx, soft palate, and esophagus. Dental anomalies and dental caries also may be seen.[16,20] Skin lesions are a later finding appearing as blisters and erosions in early childhood and progressing to more distinct yellow waxy and warty papules and nodules, hyperkeratosis, facial and extremity spontaneous or trauma-induced acneiform or pocklike scars, and alopecia.[22,23]

Ocular manifestations can involve any part of the eye and ocular adnexa.[24] Moniliform blepharosis is considered a pathognomonic feature of LP and presents as small yellow-white beaded papules on the eyelid margins and skin (Figure 81.1).[25] Other less common ophthalmic findings include hyaline deposits on the iris, cornea, and the trabecular meshwork. Chorioretinitis, conjunctival nodules, uveitis, cataract, and lens subluxation are other possible findings.[26,27,28,29] Focal degeneration of the macula and drusen formation in Bruch membrane is seen in about 30% to 50% of patients.[29] The lacrimal gland can be infiltrated with hyaline material resulting in dry eyes.[24] Open-angle glaucoma and retinitis pigmentosa have also been reported.[29] Infiltration of meibomian glands and glands of Zeiss and Moll is seen, often associated with madarosis, trichiasis, and sometimes *(Print pagebreak 532)* distichiasis.[16,24] Cystic punctal lesions and nasolacrimal duct obstructions are other rare complications of LP.[28,30,31,32,33] Neurological manifestations usually present as migraines, seizures, mental retardation, anxiety, depression, and panic attacks,[7] associated with intracranial calcifications within the amygdala or the temporal lobes.[34]

Differential Diagnosis

The diagnosis of LP is generally straightforward with the presence of the typical findings of hoarseness and moniliform blepharosis. The diagnosis is confirmed by histopathology, which shows deposition of periodic acid-Schiff-positive hyaline material at the dermal-epidermal junction, along blood vessels, and along the adnexal epithelium.[16] The differential diagnoses include erythropoietic protoporphyria, lichenmyxedematosus, amyloidosis, hyalinosis, and blepharitis.

Treatment

There is no cure for LP. Many treatments have been used, but none have resulted in sustained benefit.[16] Medical treatment for the skin lesions has been reported with oral acitretin at an initial dose of 0.5 mg/kg/d.[18,35] After 6 months of treatment with oral acitretin, symptoms were partly improved and there was an improvement in voice hoarseness, but no effect on the skin lesions was reported. Complications included dry mouth and lips and scaly skin. Recurrence occurred after the discontinuation of treatment. Oral dimethyl sulfoxide, steroids, D-penicillamine, and intralesional heparin have also been used with inconsistent results.[36]

CO_2 laser ablation of the eyelid and vocal cord lesions were reported to help in some patients,[37,38] but the results were not corroborated in a large case series.[39] Cutaneous lesions have also been treated with dermabrasion and chemical peeling.[36,38]

Prognosis

Patients with LP have a normal life span but some manifestations, such as laryngeal involvement, can lead to airway compromise necessitating a tracheostomy.[28] The disfiguring cutaneous lesions and the permanent hoarseness often lead to significant impairment in quality of life.

Histopathology

LP manifests histologically as hyaline eosinophilic material accumulating in the dermal connective tissue, in the basement membrane around sebaceous glands, and surrounding dermal blood vessels, eccrine sweat glands, apocrine glands, and nerves (Figure 81.2).[40,41,42,43,44,45,46] The hyaline deposits stain positively using periodic acid-Schiff reagent and resist diastase digestion.[45] Deposits are green-yellow with van Gieson stain,[40] dark red (fuchsinophilic) with Mallory trichrome stain,[40] and red using Fat Red [40] and Oil Red O stains.[45] Congo red stain for amyloid is negative, while Alcian blue and Hale colloidal iron stains for glycosaminoglycans are variably positive.[45,47] Collagen type IV and laminin are detected immunohistochemically in early but not well-developed lesions.[47]

The earliest histological manifestation of LP in the skin is wall thickening of upper dermal capillaries due to deposition of hyaline material beneath the basement membrane.[45] Concentric, laminated rings of the hyaline material develop around the vessels (Figure 81.2A and C) culminating in adjacent vessels' fusion.[45] Early lesions also have lamellae of hyaline material along hair follicles, nerves (Figure 81.2B), and sweat glands (Figure 81.2B).[47]

Well-developed cutaneous LP lesions have masses of amorphous eosinophilic material in the upper and mid *(Print pagebreak 533)* dermis.[47] The deposits initially push aside the normal dermal connective tissue, but the connective tissue is incorporated within the deposits in the late stages.[45] Sebaceous glands are unaffected by their basement membrane thickening, while eccrine sweat glands become atrophic and eventually completely hyalinized.[45] Apocrine glands have surrounding hyaline lamellae, but they do not become atrophic.[45] The epidermis usually has hyperkeratosis and pigmentary incontinence in the basal layer.[46]

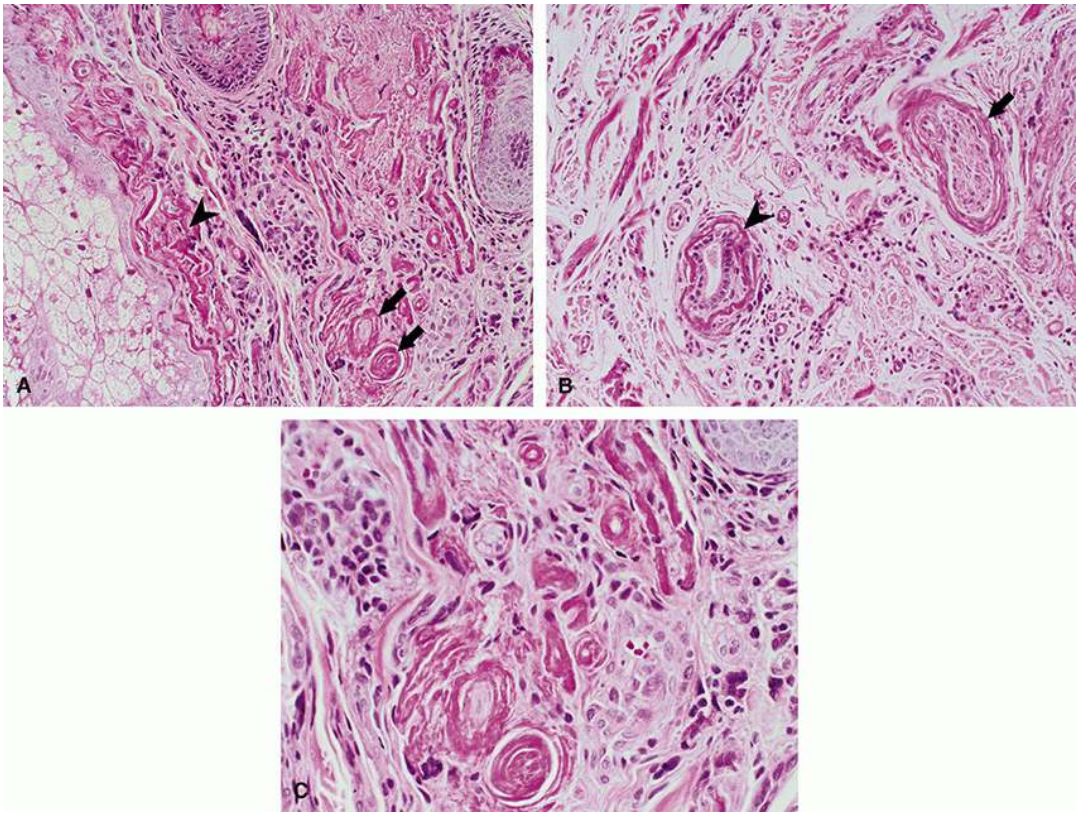

FIGURE 81.2 A, This lipoid proteinosis example shows lamellae of hyaline eosinophilic material adjacent to a hair follicle seabceous gland (arrowhead) and concentrically surrounding dermal capillaries (arrows). B, Hyaline eosinophilic deposits surround an eccrine sweat gland (arrowhead) and nerve (arrow). C, Hyaline eosinophilic material encompasses all of the dermal capillaries, several of which have occluded lumens.

CHAPTER 82

Lipoma

Key Points

- Lipomas are the most common benign soft-tissue mesenchymal tumors
- They are classified into subtypes depending on the types of tissues, including simple, spindle cell lipoma, hibernoma, pleomorphic lipoma, angiolipoma, chondroid lipoma, myolipoma, myxolipoma, myelolipoma, fibrolipoma, intramuscular lipoma, and osteolipoma
- Simple lipoma is the most common form, composed of mature adipocytes
- Spindle cell lipomas are rare, characterized by an admixture of adipocytes and small uniform spindle cells
- The etiology is not well established, but theories include chronic intermittent compression, an origin from lipoblastic embryonic cell nests, fatty degeneration, hormonal causes, infection and infarction, metaplasia of muscle cells, and chronic irritation
- Genetic aberrations have been associated with many types of adipocytic tumors including chromosomal aberrations involving 12q13˜q15
- Lipomas present as a slow-growing, painless, soft, fluctuant, lobulated, well-circumscribed, mobile subcutaneous mass with freely mobile overlying skin
- The usual treatment of lipoma is complete surgical excision
- The prognosis for benign lipomas is excellent and recurrence following surgical excision is uncommon

Lipomas are the most common benign soft-tissue mesenchymal tumors.[1] They are slow-growing, benign adipose lesions that form soft, lobulated masses enclosed by a thin, fibrous capsule. They have a prevalence rate of about 2.1 per 1000 population[2] and occur mostly in the fifth and sixth decades of life.[3] Lipomas are uncommon in children. Males are affected more frequently than females in a ratio of about 2.5 to 3:1.[4] Although lipomas may develop in any organ throughout the body, only 13% occur in the head and neck area.[5] Within the head and neck region, the most common location is the cheek, followed by the tongue, buccal mucosa, lip, and neck. Occurrence on the eyelid is relatively rare.

Lipomas are classified histopathologically into several distinct subtypes depending on the admixture of other types of tissues. These include simple lipoma, spindle cell lipoma, hibernoma, pleomorphic lipoma, angiolipoma, chondroid lipoma, myolipoma, myxolipoma, myelolipoma, fibrolipoma, intramuscular lipoma, and osteolipoma.[1] Among eyelid lipomas, the most common types are simple lipoma and spindle cell lipoma, but other described forms include fibrolipoma, intramuscular lipoma, and osteolipoma.

Simple lipoma is the most common form, accounting for 80% of head and neck lipomas.[4] They are composed of mature adipocytes and usually occur just under the skin, but occasionally may be deeper. Most are less than 5 cm in size. The most common locations include the upper back, shoulders, and abdomen, and in a review of 338 simple lipomas, 17% occurred in the head and neck.[4] The male to female ratio is about 2.5:1. Occurrence in the eyelid is very rare and only two cases of simple lipoma have been reported in this location.[6,7]

Spindle cell lipomas are rare tumors that were first described by Enzinger and Harvey in 1991,[8] characterized by an admixture of adipocytes and small uniform spindle cells. They are benign, painless, slowly growing subcutaneous tumors that occur most often on the upper back, shoulders, and posterior neck with a predilection for middle-aged men.[9] Rare cases have been reported in the orbit,[10,11,12,13] and one case was reported in the eyelid.[14]

Myolipoma of soft tissue was first described in 1991 by Meis and Enzinger[15] as a rare benign neoplasm characterized by the admixture of mature adipocytes and well-differentiated smooth muscle cells. They are seen predominantly in middle-aged to older

females in a male to female ratio of 16:1.[16] The most frequently affected sites are the retroperitoneum (47%), pelvis (15%), abdominal wall (12%), and intra-abdominal sites (9%). One case was reported in the eyelid.[17]

Fibrolipoma is an extremely rare subtype of lipoma found most commonly in males. They are characterized by the presence of adipose tissue and abundant amounts of fibrous tissues[18,19,20,21,22] and present clinically as a well-circumscribed, firm to soft, asymptomatic, slowly growing subcutaneous mass.[18,23] Transformation to liposarcoma has been reported in several cases of fibrolipoma.[23] One case was described in the eyelid.[24]

Angiolipoma consists of an admixture of mature fat and numerous small blood vessels and usually affects adolescent males.[25] This variant accounts for 6% to 17% of all lipomas, but is rare in the head and neck. Only two cases have been described involving the eyelids and two in the orbit.[26]

(Print pagebreak 536)

Osteolipoma is a very rare variant of lipoma.[27] It is a type of lipoma that undergoes osseous metaplasia to become an ossifying lipoma or osteolipoma. Only a few cases affecting the head and neck are reported in the literature.[28] One case was described involving the upper eyelid as a nodular swelling that gradually increased in size over 5 years.[29] It presented as a 2 cm, firm, freely mobile, painless mass with a smooth surface that was initially diagnosed clinically as a dermoid cyst.

An intramuscular lipoma is a subgroup of lipoma usually seen in large muscles of the extremities and which diffusely invades skeletal muscles. They have also been referred to as infiltrating lipoma.[30] It is a rare variant that accounts for about 1.8% of all lipomas[31] and is very rarely reported in the small muscles of the head and neck.[32] Charles and Palu[33] reported a case of an unencapsulated intramuscular lipoma within the lower eyelid orbicularis oculi muscle consisting of mature adipocytes traversed with sheets of striated muscle fibers. A second case was described involving the upper eyelid orbicularis muscle by Buller et al.[34] Shiraki et al[35] reported a case of intramuscular lipoma in the medial rectus muscle of the orbit. The recurrence rate of intramuscular lipoma after treatment is higher than for most other types reported to be 3% to 62.5%,[36,37] most likely due to incomplete resection of the involved muscle.

A pleomorphic lipoma is characterized by the presence of spindle cells and bizarre hyperchromatic giant cells. It occurs most often in the neck and upper body of middle-aged to elderly males, but also has been reported in the orbit,[38,39,40,41] and the bulbar conjunctiva.[38,39,41] Although it is distinguishable from other variants of lipoma by floret-like cells as a specific histological feature, there is some debate as to the relationships of this tumor.[39] Ebrahimi et al[42] evaluated 146 cases of normal orbital and prolapsed orbital fat and found these cells in 16% and 43% of specimens, respectively. They concluded that floret-like cells may be present in orbital and prolapsed orbital fat as a degenerative process and that what has been called “orbital pleomorphic lipoma” may only be age-related orbital fat.

Nasopalpebral lipoma-coloboma syndrome is an extremely uncommon autosomal dominant craniofacial disorder characterized by upper eyelid and nasopalpebral lipomas, colobomas of upper and lower eyelids, telecanthus, a broad nasal bridge, broad forehead, widow's peak, flaring of medial eyebrows, telecanthus, and maxillary hypoplasia. Other features can include aplasia of the lacrimal puncta with epiphora, aberrant eyelashes, conjunctival hyperemia, opacities of the cornea and lens, and divergent strabismus. This syndrome was originally described as a familial disorder, but several sporadic cases have been described.[43,44,45,46] The condition is usually bilateral, but rarely it can be unilateral.

Excepting the nasopalpebral lipoma-coloboma syndrome, only 12 cases of lipoma have been reported in the eyelid.[3,6,7,14,17,24,29,33,34,47,48,49] Of these 12 cases, four were simple lipomas, two were intramuscular, two were a spindle lipoma, two were a fibrolipoma, one was a myofibroma, and one was an osteolipoma. The case by Thyparampil et al[48] was found on surgery to be a soft, yellow lesion surrounding the orbital septum with significant adhesions to the underlying conjunctiva and the levator aponeurosis laterally, so technically it can be considered to be a combined eyelid and anterior orbital lipoma.

Etiology and Pathogenesis

The etiology of lipomas and their variants is not well established. Some theories include chronic intermittent compression, an origin from lipoblastic embryonic cell nests, fatty degeneration, hormonal causes, infection and infarction, metaplasia of muscle cells, and chronic irritation.[21,25] Some studies reported that trauma may be a risk factor by causing injuring to the fibrous septa and connections between the skin and deep fascia, allowing the adipose tissue to proliferate rapidly.[50]

An association with genetic aberrations has been described for many types of adipocytic tumors. Chromosomal aberrations have been observed in the majority of lipomas, 50% to 65% of which involve chromosomal region 12q13˜q15.[51,52,53,54,55,56] The target gene for rearrangements involving 12q13-15 is *HMGA2*, which encodes a protein belonging to a family which is important for the regulation of chromatin structure and gene expression.[54,57,58] Genes derived from the fusion of the *HMGA2* with other

partners play a probable role in the development of benign mesenchymal tumors.[54] *HMGA2/LPP* (Lipoma Preferred Partner) is the most frequent gene aberration seen in lipomas.[57,58,59] However, it is not specific for lipoma suggesting that gene fusion as such may not be decisive for tumor cell differentiation, but may activate the regulatory pathway leading to the development of benign tumors.[54,60]

In simple lipomas, deletions of 13q are also reported in around 15% of cases. Spindle cell/pleomorphic lipomas show heterozygous deletions in 13q14,[61] a locus that contains the *RB1* gene and can lead to loss of RB1 protein expression.[62] Also, spindle cell/pleomorphic lipomas also show deletions in chromosome 16.[61]

Clinical Characteristics

Lipomas usually present as a slow-growing, painless, soft, fluctuant, lobulated, well-circumscribed, mobile subcutaneous mass with freely mobile overlying skin (Figure 82.1). They are mostly solitary lesions but rarely may be multiple. About 80% of lipomas are less than 5 cm in size,[4] but occasionally can present as a giant lipoma, between 10 and 40 cm diameter (Figure 82.2A).[63,64] On the eyelid, reported lipomas range from 1 to 2.5 cm in size. Females are affected slightly more frequently than males (55%), and the lesion usually has been present for 1 to 5 years, but in one case was present for 50 years.[17] Of the reported eyelid lipomas, the upper eyelid was involved in 78% of *(Print pagebreak 537)* cases, and the left side in 67%. Most patients were in the sixth to seventh decades of life with a mean age of 63.1 and a range of 47 to 82 years. Rarely, an eyelid lipoma can cause functional impairment such as ptosis.[7]

Differential Diagnosis

For subcutaneous lipomas, the differential diagnosis most often includes a sebaceous cyst or abscess. Both lipoma and sebaceous cyst are rounded and fluctuant, but the sebaceous cyst originates in the dermis and is situated in the skin at the dermal-epidermal junction. They can be differentiated from lipomas by the presence of a central punctum and surrounding induration and the fact that lipoma is subcutaneous with freely mobile overlying skin. An abscess is usually associated with overlying cutaneous induration and erythema, which are not seen with lipomas.

Lipoma should also be distinguished from prolapsed orbital fat, nodular fascitis, erythema nodosum, nodular subcutaneous fat necrosis, sarcoidosis, rheumatic nodules, hematomas and infections, schwannoma, and other subcutaneous tumors and metastatic tumors. In addition, giant intramuscular lipomas should be differentiated from liposarcomas, metastatic carcinomas, and malignant

histiocytomas.[3,65,66]

The differential diagnosis of nasopalpebral lipoma coloboma syndrome includes other syndromes associated with eyelid colobomas such as Goldenhar syndrome, Treacher Collins syndrome, frontonasal dysplasia, and Delleman syndrome. These syndromes differ from nasopalpebral lipoma coloboma syndrome by various features such as preauricular tags, vertebral anomalies, epibulbar dermoid, and eyelid coloboma in Goldenhar syndrome; antimongoloid slant, lateral lower eyelids colobomas, microphthalmos, cataract, and nasolacrimal duct atresia in Treacher Collins syndrome; orbital hypertelorism, bifid nose, and median facial cleft in frontonasal dysplasia; and orbital cysts, agenesis of the corpus callosum, and lip defects in Delleman syndrome.[43]

MRI is very useful for the diagnosis of lipomas and in distinguishing them from other lesions. High signal intensity is seen on T1-weighted images and a relatively low signal on T2-weighted images similar to orbital fat. A fat-suppressed MRI is particularly beneficial for diagnosis. On CT images, lipomas appear as a nonenhancing hypodense mass.[23]

Treatment

The usual treatment of lipoma is complete surgical excision (Figure 82.2B). Removal is most often indicated for esthetic concerns or functional compromise of adjacent structures from focal compression. The tumor can usually be excised completely within its capsule. Since lipomas may be lobulated, it is essential to dissect and remove all lobules. When fatty tumors cause symptoms or grow large, a biopsy may be required for histopathologic examination to rule out more dangerous lesions such as liposarcoma. Following excision, the local recurrence rate is less than 5%.[3,67,68]

Nonsurgical techniques have included intralesional injection of triamcinolone acetonide that results in local *(Print pagebreak 538)* fat atrophy, and this is best utilized on smaller lesions.[69] Liposuction has been used in selected patients with lipomas,[70,71] but should be avoided in lesions with an atypical evolution or suspicious clinical presentation that might suggest a more ominous diagnosis such as liposarcoma.[72]

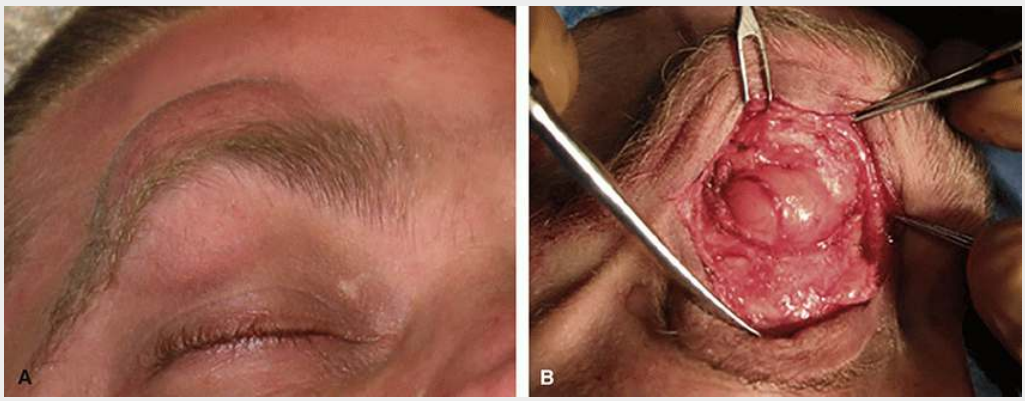

FIGURE 82.2 A, Massive lipoma involving the right upper eyelid and brow. B, Surgical excision of the lipoma in A through an upper eyelid crease incision.

Prognosis

The prognosis for benign lipomas is excellent. Recurrence following surgical excision is uncommon but may develop if the excision is incomplete.

Histopathology

Conventional cutaneous lipomas are sharply circumscribed, thinly encapsulated masses formed by sheets of mature adipocytes with thin, incomplete fibrous septa containing blood vessels (Figure 82.3).[73,74] The adipocytes have uniform nuclei without atypia and may be slightly larger than the adipocytes in adjacent subcutaneous tissue.[73] Dermal lipomas have scattered groups of mature adipocytes between collagen bundles and are less circumscribed than conventional lipomas (Figure 82.4).[75] The histological features of other lipoma variants are described in detail elsewhere.[73,74,75]

CHAPTER 83

Lupus Erythematosus

Key Points

- Lupus erythematosus (LE) is a multisystem, chronic autoimmune disease with a wide spectrum of presenting symptoms
- Cutaneous manifestations appear in 72% to 85% of patients with SLE, and in 23% to 28% it can be the presenting sign of the disease
- Acute cutaneous LE is characterized by a butterfly rash over both cheeks, seen in 87% of patients
- Discoid LE is a chronic condition that presents as well-demarcated, scaly, erythematous macules or papules that gradually develop into indurated discoid plaques
- LE is caused by dysfunction in the immune system, involving loss of self-tolerance through the production of autoantibodies
- Sunlight can precipitate cutaneous disease de novo or it can aggravate existing lesions
- Eyelid lesions often begin as erythematous scaly maculae or papules that gradually grow peripherally into larger discoid plaques and may be associated with blepharitis and madarosis
- Management involves avoidance of UV exposure and topical steroids, tacrolimus, antimalarial drugs, or immunosuppressant agents
- The prognosis for cutaneous LE depends on the specific clinical variant and on the presence and severity of any associated systemic manifestations
- 5% to 10% of patients with CLE will evolve to SLE over 5 years

Lupus erythematosus (LE) is a multisystem, chronic autoimmune disease with a wide spectrum of presenting symptoms ranging from mild manifestations in localized cutaneous LE (CLE) to severe, life-threatening systemic LE (SLE) with involvement of internal organs.[1] In Europe, the prevalence of SLE is estimated to be 39.2 cases per 100,000 individuals, and the annual incidence rate is 1 to 3.8 per 100,000 individuals.[2,3] Cutaneous manifestations appear in 72% to 85% of patients with SLE, and in 23% to 28% it can be the presenting sign of the disease.[4] Moreover, isolated CLE, while rare, is still several times more common than SLE and can occur in the absence of systemic disease.[5]

CLE may present in various forms and it must be determined if it is isolated or a manifestation of SLE. The association with SLE varies depending upon the specific phenotype of CLE. The association has been reported at 100% in acute cutaneous lupus erythematosus (ACLE),[6] to 50% in subacute cutaneous lupus erythematosus (SCLE),[7] to only 5% for localized discoid lupus erythematosus (DLE).

In 1982, the American College of Rheumatology (ACR) developed a widely used classification of criteria for the diagnosis of SLE.[8] The ACR classification included 11 clinical and laboratory criteria, including four cutaneous features (malar rash, discoid lesions, mucosal ulcers, and photosensitivity). However, skin features seen in CLE occur with a broader spectrum of clinical presentations beyond those listed in the ACR criteria for SLE.[9] In 2012, the Systemic Lupus Collaborating Clinics (SLICC) revised the ACR criteria to comprise 17 clinical and immunological criteria, including some minor revisions of the cutaneous criteria, omitting photosensitivity, and adding nonscarring alopecia.[10]

Criteria for the diagnosis of the subtypes of CLE are still largely based on the classification system proposed by Gilliam in 1981.[11] CLE was divided into LE-specific lesions and LE-nonspecific lesions.[12] LE-nonspecific lesions included findings that are not usually characteristic of SLE and may be present in other diseases. These include Raynaud's phenomenon, periungual telangiectasias, livedo reticularis, and leukocytoclastic vasculitis.[12,13] The phenotypes included under the umbrella of LE-specific

lesions encompass several subtypes defined by clinical features, the average duration of the cutaneous lesions, histologic findings, as well as laboratory abnormalities. These subtypes include acute, subacute, and chronic CLE.[11] Chronic CLE included several subgroups: DLE, LE profundus (LEP), and chilblain LE (CHLE). In more recent years, new subtypes of CLE have been added, including LE tumidus (LET),[14,15] although there is still no agreement whether this form should be considered as a subtype of CCLE or should be differentiated as a separate category of CLE.[16,17]

Acute Cutaneous Lupus Erythematosus

ACLE is characterized by a transient malar, or "butterfly" rash, over both cheeks, induced by sun exposure, seen in 87% of patients, and sometimes associated with fine surface scales and/or edema.[1] A discoid rash can be seen in 20%, and oral ulcers in 33%. The condition may be associated with diffuse hair thinning.[6] ACLE typically presents in the third decade of life[12] and is frequently associated with active SLE.[18,19] It can be associated with arthritis, renal disorders, or neurologic involvement in 20% to 60% of cases.

(Print pagebreak 542)

Subacute Cutaneous Lupus Erythematosus

SCLE occurs primarily in young to middle-aged women.[17] It presents clinically with a photosensitive malar rash in 30% to 40% of cases, which can either be annular or papulosquamous or occasionally with features of both.[12,20] The annular type is characterized by scaly annular erythematous plaques, which tend to coalesce.[17] Lesions occur in sun-exposed areas of the throat, upper back, and the extensor surfaces of arms, generally with sparing of the face and scalp. About 50% of cases meet the criteria for SLE,[21] but most of these patients usually have only mild systemic symptoms, and renal or neurologic involvement is seen in 4% to 20% of these patients.[1]

Chronic Cutaneous Lupus Erythematosus

Chronic cutaneous LE (CCLE) includes four subtypes that include DLE, LEP, CHLE, and LET. They differ by relatively minor clinical and histopathologic features. Unlike ACLE and SCLE, CCLE only rarely shows systemic involvement.[22]

Discoid lupus erythematosus (DLE) - Discoid lesions are the most common photosensitive rashes seen in CCLE, occurring in 90% of patients.[1] They occur more frequently in females in their fourth and fifth decades of life.[17] Localized DLE typically involves the head and neck, whereas generalized DLE occurs both above and below the neck. DLE lesions present as well-demarcated, scaly, erythematous macules or papules that gradually develop into an indurated discoid plaque.[12,23] Hair follicles become involved resulting in scarring alopecia. Rarely, squamous cell carcinoma can occur within a DLE lesion.[24]

Lupus erythematosus profundus (LEP) - LEP, also known as lupus erythematosus panniculitis, presents as a painful firm, tender, subcutaneous nodules in areas of increased fat deposition, such as the upper arms and legs, face, and breasts. They run a chronic course with episodes of remission and exacerbation, finally healing as depressed, atrophic plaques.[19,24] Occasionally, systemic or other forms of cutaneous LE may occur concurrently with LEP. Several cases have been associated with dermatomyositis.[25]

Chilblain lupus (CHLE) - Chilblain lupus is a rare form of CCLE that presents as painful, pruritic, infiltrative, violaceous erosions or ulcerations on skin areas exposed to cold, including the fingers, toes, nose, and ears. Involvement of the face is uncommon. Lesions tend to improve during warmer months. Two-thirds of patients may also have hypergammaglobulinaemia. Most cases are sporadic, but there have been familial cases inherited in an autosomal dominant manner.[26] About 20% of these patients will eventually develop features of SLE.[27]

Lupus erythematosus tumidus (LET) - Lupus tumidus is another subtype of chronic CCLE. It occurs mostly in men and is characterized by photosensitive, elevated, erythematous, and edematous lesions on the face and neck.[28] It is considered to be the most benign form of CLE, rarely associated with SLE. Skin lesions have an annular or semiannular appearance without scales, ulceration, or crust formation. Lesions heal without scarring or postinflammatory pigmentary changes.[29] Drugs are considered to be minor risk factors for LET, reported to be associated with infliximab, adalimumab, etanercept, thiazide diuretics, and bortezomib.[29]

Etiology and Pathophysiology

Lupus erythematosus is caused by dysfunction in the adaptive and innate immune system, involving a loss of self-tolerance through the production of autoantibodies.[30] Skin lesions in CLE can be induced by both UVB (290-320 nm) and UVA (320-400 nm) radiation.[31,32,33] Sunlight can precipitate cutaneous disease de novo or it can aggravate existing lesions. Also, phototherapy (UVB)

and tanning beds (UVA) have been reported to either induce or exacerbate SLE.

UV light has multiple effects on living tissue and molecular targets include DNA, RNA, proteins, and lipids. It can induce the binding of antibodies to selected nuclear antigens associated with LE and photosensitivity.[31] UV radiation can also induce apoptosis in keratinocytes by a variety of mechanisms including ligand-independent activation of membrane death receptors, sensitization of keratinocytes to TNF-induced apoptosis, DNA damage, or through the mitochondrial pathway.[31] Apoptotic cells accumulate in the epidermis of patients with cutaneous LE after UV irradiation,[34,35] It has been proposed that the biochemical processes of apoptosis can generate novel antigens that can be targeted by autoantibodies.[36,37] Proteins phosphorylated during apoptosis become targets for autoantibody production in patients with SLE, and these might be important in the initiation of autoimmune responses.[31]

This model of the pathogenesis of CLE originally proposed by Norris[38] presupposes an abnormal susceptibility to UV light resulting in altered cytokine expression and induction of increased keratinocyte apoptosis, the presence of antibodies with appropriate specificities targeting keratinocyte components, and the presence of activated lymphocytes specific for autoantigens.[31] Since this model was proposed, new data have been presented supporting this concept and uncovering genetic abnormalities in apoptosis induction or apoptotic cell clearance, as well as various cytokines linked to CLE. Details are beyond the scope of this chapter and are well discussed elsewhere.[39,40,41,42,43]

Erythema is a normal response to UV light and is mediated by a wide range of vasoactive mediators, neuropeptides, and cytokines released from keratinocytes, mast cells, endothelial cells, and fibroblasts.[31] UV light can induce significant and persistent erythema in patients with CLE. UV light can also induce cutaneous inflammation through the release of inflammatory mediators, cytokines, and chemokines that attract inflammatory cells to the skin.[44]

Cigarette smoking may have phototoxic effects[45] and is an important environmental trigger for CLE, linked with increased disease activity and a poor response to antimalarial therapy.[46,47] In a series of 405 patients with CLE and SLE, 45.9% were smokers, and in LET the rate was 83%, *(Print pagebreak 543)* both significantly greater than the 33.2% of smokers in the matched general population.[48]

Twin studies in SLE have shown a much higher disease concordance in monozygotic twins (24%-57%) than in dizygotic twins, indicating there is a genetic predisposition to the disease.[49,50,51,52,53] In a study of 183 CLE patients, Kunz et al[54] identified polymorphisms in genes responsible for antigen presentation, regulation of apoptosis, RNA processing, and interferon response (*HLA-DQA1, MICA, MICB, MSH5, TRIM39,* and *RPP21*). There are likely genetic predispositions and environmental triggers that underlie the development of SLE and CLE. While no single gene or single environmental factor is associated in most individuals, genetic studies have shown a relationship between smoking and several genes, including *TNFRSF1B, NAT2,* and *CYP1A1/GSTM1,* with an increased risk of SLE in the presence of both factors.[55,56]

Clinical Presentation

Eyelid lesions often begin as erythematous scaly maculae or papules (Figure 83.1).[57] They gradually grow peripherally into larger discoid plaques that heal, leaving an atrophic scar and pigmentary changes.[58] With SLE and some variants of CLE, ocular presentation can begin with localized eyelid erythema and edema.[59,60,61,62,63,64,65,66] In a meta-analysis of 41 articles with 111 patients having CLE affecting the eyes, Arrico et al[57] evaluated the ocular complications associated with cutaneous lupus. The most common phenotype was DLE. Facial lesions were seen in 93% of these patients with the most frequent lesions on the eyelid, forehead, philtrum, malar region, nose, and cheek, and 65% had ophthalmic complications. Of the latter, 53.5% were unilateral and 46.5% bilateral. Among those patients with ophthalmic complications, the main site of involvement was the eyelid, seen in 88.7% presenting as plaques, erythematous papules or maculae, or eyelid edema. Blepharitis was seen in 53.5%, almost cases in the lower eyelid. Madarosis was relatively common, occurring in 28.2%, and areas of skin depigmentation or hyperpigmentation, and skin ulceration were rarely reported (Figure 83.2). Corneal involvement was uncommonly seen in 5.6% of cases as punctate keratopathy or stromal keratitis.

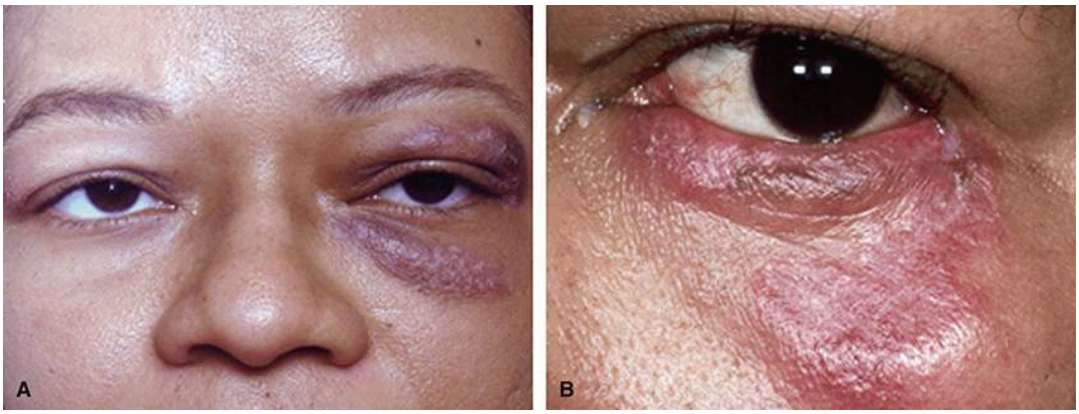

FIGURE 83.1 A and B, Eyelid lupus erythematosus manifesting as erythema and edema. A, (Courtesy of Dr. Robert Goldberg). B, (Courtesy of Dr. Charles Soparkar).

In a series of 25 cases of SLE presenting with periorbital erythema and edema, 68% were female.[67] The average age was 46.7 years with a range of 19 to 77. The upper eyelid was involved in 72% of patients and the lower eyelid in 24.0%. One patient (4%) presented with skin lesions involving both the upper and lower eyelids. The duration of symptoms before presentation ranged from 2 weeks to 4 years with a mean of 58.8 weeks. Three-fourths of the patients were initially misdiagnosed as contact dermatitis, eczema, dermatomyositis, lymphoproliferative disorder, cellulitis, chalazion, or angioedema.

Differential Diagnosis

Unilateral periorbital erythema and edema seen with CLE can be confused clinically with contact dermatitis, eczema, lymphoproliferative disorders, or a chalazion. However, CLE is typically exacerbated by sun exposure and runs a more protracted course. Most of these masquerading lesions can be differentiated on histopathology. Dermatomyositis or angioedema should be included in the differential diagnosis when the CLE is bilateral. Dermatomyositis is an inflammatory muscle disease associated with a violaceous facial rash and progressive muscle weakness. Angioedema is usually a very acute reaction with onset over minutes to hours and is often associated with hives. It usually affects the face, oral mucosa, tongue, and hands, and patients may show other hypersensitivity reactions such as dyspnea. In a large series of 716 patients with SLE, the initial clinical diagnoses were SLE (41%), rheumatoid arthritis (17%), myositis (8%), chronic cutaneous lupus (7%), undifferentiated connective tissue *(Print pagebreak 544)* disease (6%), vasculitis (5%), primary antiphospholipid antibody syndrome (5%), scleroderma (4%), and fibromyalgia, Sjögren syndrome, rosacea, psoriasis, sarcoidosis, and juvenile idiopathic arthritis, all 4% or less.[10]

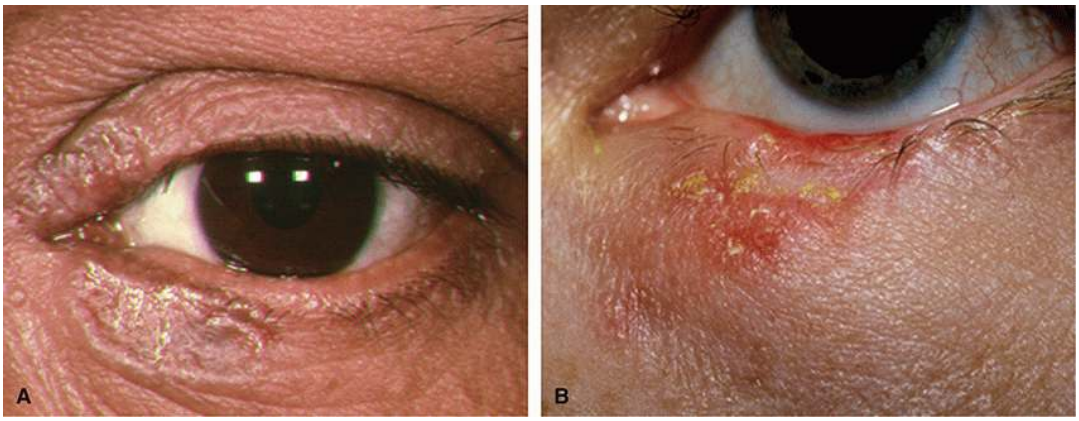

FIGURE 83.2 Advanced systemic lupus erythematosus (SLE) of the eyelids. A, Scaly plaque on the lower eyelid. B, Central lower eyelid SLE with depigmentation, madarosis, and ulceration. A, (Courtesy of Dr. Charles Soparakar). B, (Courtesy of Dr. Gordon Klintworth).

The malar rash can be confused with acne rosacea and seborrheic dermatitis; however, the former is associated with the formation of papules and pustules, and the latter typically occurs within the nasolabial folds.[68] Generalized ACLE may resemble dermatomyositis since both diseases can involve the dorsum of the hands. However, dermatomyositis affects the distal interphalangeal, proximal interphalangeal, and metacarpophalangeal joints, whereas these sites are not involved in ACLE.[68] Other conditions that should be included in the differential diagnosis include atopic dermatitis, contact dermatitis, granuloma annulare, tinea corporis, pemphigus erythematosus, drug-induced photosensitivity, photocontact dermatitis, and drug eruptions.

Treatment

The treatment of CLE is initially aimed at prevention of the disease or slowing the progression of skin lesions. Topical sunscreens are recommended, as well as UV-blocking films on windows.[69] Patients should avoid sunbathing, extended outdoor work, and recreational activities. Klein et al[70] analyzed UV radiation from indoor fluorescent light bulbs and its risk of exacerbating photosensitive diseases, especially with repeated daily exposure. They concluded that bulbs with the lowest UV irradiance should be used to minimize the cumulative dose. Even so, shielding of bulbs or indirect lighting is preferred. In CLE patients who avoid sun exposure, vitamin D deficiency can be a problem, so that levels should be monitored and oral supplementation given as indicated.[71]

Once the cutaneous disease has appeared, the treatment of CLE lesions should begin with topical therapy. Higher dose topical steroids, such as fluocinonide 0.05%, were shown to be more efficacious in improving or eliminating lesions compared to low-dose hydrocortisone 1% cream.[72] However, topical steroids can be complicated by significant side effects such as atrophy, telangiectasia, and dermatitis. On the face and eyelids, low potency steroids, such as hydrocortisone 1% or fluocinolone acetonide 0.01%, are preferred.[12] Scalp lesions are more appropriately treated with steroid foams or solutions, and refractory lesions anywhere may require intralesional injections of triamcinolone.[73]

Calcineurin inhibitors, such as tacrolimus, have been introduced as a topical treatment for various subtypes of CLE.[74] A randomized clinical trial of 30 patients with various types of CLE showed that topical application of tacrolimus 0.1% ointment twice daily may provide at least temporary benefit for acute edematous, nonhyperkeratotic lesions, but the benefit did not persist for more than 2 to 3 months.[75] However, other studies have shown conflicting results.[76]

Pulsed-dye laser therapy has been reported to show some efficacy in the treatment of CLE, with significant improvement in lesions and high levels of patient satisfaction.[77,78,79] However, side effects can include local pain, purpura, and pigmentary changes.

Systemic therapy is indicated for patients with widespread disease or in cases refractory to topical treatments. The oral antimalarial drugs, hydroxychloroquine, chloroquine, and quinacrine, have been considered first-line therapy for all subtypes of CLE, with response rates of 50% to 82%.[80] Hydroxychloroquine sulfate at a dose of up to 6.5 mg/kg/d is considered the drug of choice because of its lower complication profile.[12] Reported side effects include xerosis, exanthematous urticaria, hyperpigmentation, ocular toxicity, gastrointestinal upset, myopathy, cardiomyopathy, dizziness, headache, insomnia, and psychosis.

(Print pagebreak 545)

For patients refractory to antimalarials, immunosuppressant agents are another option.[81] Methotrexate at doses of 7.5 to 25 mg orally or subcutaneously once a week has been reported to yield improvement in 98% of cases, but 16% developed severe side effects including gastrointestinal toxicity, bone marrow suppression, nephrotoxicity, and hepatotoxicity.[71] Mycophenolate mofetil and mycophenolate sodium also are effective in treating SCLE.[82]

Oral retinoids, such as acitretin and isotretinoin, offer another alternative therapy. They have been used for mixed CLE subtypes and acitretin was shown to be effective in 50% of patients with CLE.[73] Complications of retinoids include hyperlipidemia and hepatotoxicity.

Rituximab is a chimeric monoclonal antibody that targets CD20 and has been reported to be efficacious for refractory cases of SCLE.[83] Two doses of IV 1000 mg given 2 weeks apart are accompanied by intravenous cyclophosphamide or methylprednisolone, but response rates are variable, reported between 35% and 76%.[84,85,86]

Overall, all treatment responses tend to be mostly unsatisfactory with the resolution of lesions seen in only about one-third of cases.[67] About 25% of patients with CLE may go on to develop SLE.

Prognosis

The prognosis of SLE depends on the severity of the disease and the extent of visceral involvement. Most fatalities result from active renal or central nervous system involvement, or various infections.[87] Nevertheless, with oral corticosteroids and immunosuppressive drugs, the 10-year survival rate is 80% or better.[88,89,90] For CLE the prognosis depends on the specific clinical variant and on the presence and severity of any associated extracutaneous manifestations.[87] Risk factors such as genetic

predisposition, race, sex, age at disease onset, and triggering factors such as ultraviolet light exposure likely influence the clinical course and ultimate prognosis of CLE.[87] The overall prognosis is generally more favorable than that of SLE.[87] However, over time 5% to 10% of patients with DLE will experience a transition to SLE, although in most cases the transition will take 5 years or longer.[91,92,93,94,95] Other studies have shown that when mild signs of systemic manifestations are present in patients with CLE, such as proteinuria and arthralgia, 14% to 27% of patients with DLE and 67% to 70% of patients with SCLE will have extracutaneous involvement.[21,96,97,98,99,100] In rare cases, severe life-threatening complications from renal or neurologic involvement will be seen.[92]

Histopathology

The cutaneous histopathology of lupus erythematosus has been studied extensively over the past 65 years,[101,102,103,104,105,106] and Crowson and Magro have provided a thorough summary of lupus erythematosus cutaneous histopathology.[107] A summary of the histopathological features of the most common subtypes of lupus is as follows:

1. *Systemic lupus erythematosus* [107]: Macular eruptions of SLE have subtle histological changes, including cell-poor vacuolar interface dermatitis, absent or slight epidermal atrophy, absent or patchy parakeratosis, normal basement membrane zone thickness, and prominent papillary dermal edema and mucin accumulation. Mucin accumulation is a particularly useful finding that helps to differentiate lupus erythematosus from other forms of cell-poor interface dermatitis such as morbilliform drug reactions, acute graft vs host disease, acute erythema multiforme, vitiligo, and viral exanthemata. Other common cutaneous histological findings in SLE are erythrocyte extravasation, telangiectasia, and focal basement membrane zone duplication around blood vessels and at the dermal-epidermal junction.

2. *Subacute cutaneous lupus erythematosus* [102,107]: SCLE biopsies exhibit interface dermatitis with prominent suprabasilar exocytosis of lymphocytes (migration of lymphocytes into the suprabasal epidermis), dyskeratosis extending into the upper spinous (prickle cell) layer, prominent epidermal atrophy, and a mild to moderate infiltrate of mononuclear leukocytes confined to the superficial dermis. Follicular plugging and basement membrane zone thickening are minimal or absent. The interface dermatitis has a mixture of cell-poor foci of vacuolopathy with small vacuoles within, above, and below the basal lamina alternating with band-like (lichenoid) dermatitis zones. SCLE is thus a form of lichenoid connective tissue disease syndrome that includes SCLE, anti-Ro-associated SLE, and mixed connective tissue disease; these require differentiation using serological tests.

3. *Discoid lupus erythematosus* [103,107,108]: Active lesions of DLE are manifest histologically by a lymphocyte-rich interface dermatitis involving the epidermis and hair follicles with lymphocyte extension into the basal layer of adnexal and interfollicular epidermal keratinocytes, basal layer epithelial destruction with homogenous eosinophilic, round bodies termed hyalin, colloid, or Civatte bodies in the basal cell layer and upper papillary dermis, pigment incontinence, dyskeratotic cells in the epidermis, marked hyperkeratosis with keratotic follicular plugging, variable epidermal acanthosis and atrophy, basement membrane zone thickening that often appears as a broad eosinophilic homogeneous band of basement membrane material in sections stained with hematoxylin and eosin, a moderate to marked superficial and deep perivascular and peri-appendageal lymphocytic infiltrate, and dermal mucin accumulation. Healing lesions of DLE have hyperkeratosis, generally atrophic epidermis with loss of rete ridges, prominent basal vacuolar degeneration, markedly thickened epidermal basement membrane, decreased to absent dermal lymphocytic infiltrate, dermal fibrosis, abundant dermal mucin, and marked follicular plugging. All lupus erythematosus eyelid biopsies that we have examined exhibited histological features of DLE (Figure 83.3).[109]

(Print pagebreak 546)

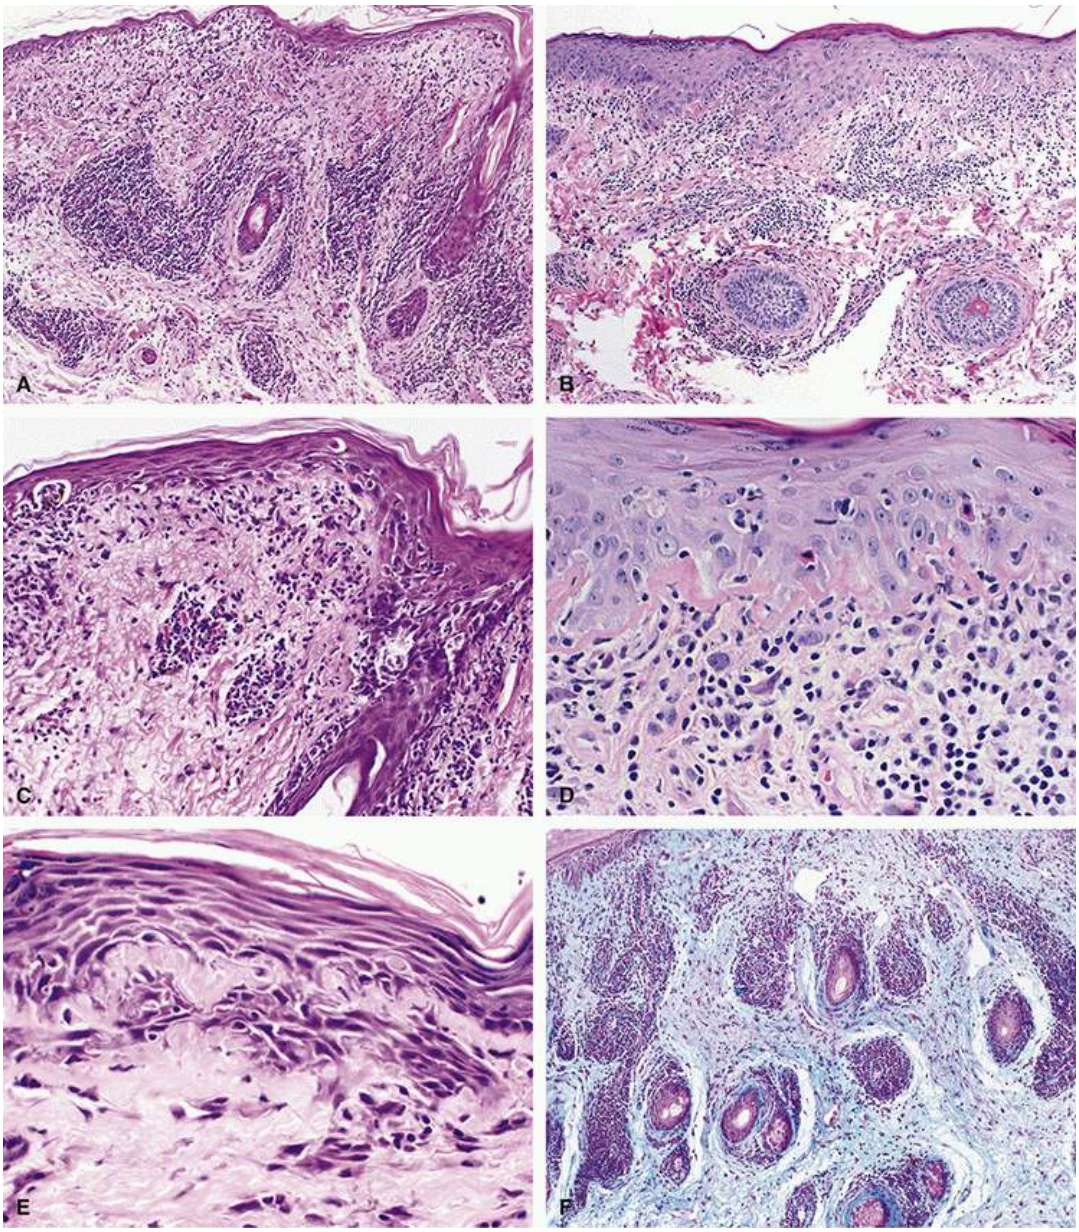

FIGURE 83.3 These eyelid biopsies were all diagnosed as discoid lupus erythematosus (DLE) based on correlating the histopathological and clinical findings. A, Interface dermatitis with superficial and deep perivascular and periadnexal chronic inflammation. The epidermis is atrophic, and the hair follicle on the right has keratotic plugging. B, The epidermis has parakeratosis and acanthosis, and there is superficial perivascular and periadnexal chronic inflammation. C, Interface dermatitis extends down the hair follicle with keratinocyte cell death. D, The epidermis is infiltrated with lymphocytes, and there are two cells undergoing apoptosis with brightly eosinophilic cytoplasm in the basal epidermis. The epidermal basement membrane is eosinophilic, markedly thickened, and undulating. Lymphocytes and macrophages infiltrate the papillary dermis. E, Pseudoepitheliomatous (pseudocarcinomatous) epidermal hyperplasia. The angulated nuclei, thickened basement membrane, and Civatte bodies are clues to DLE diagnosis and are not features expected in squamous cell carcinoma, which this lesion mimicked clinically. F, Alcian blue stain highlights prominent derma mucin accumulation. Alcian blue stains normal skin only faintly, if at all.

CHAPTER 84

Lymphatic Malformation

Key Points

- Lymphatic malformations (LM) are benign developmental vascular channels lined by endothelial cells and composed of anomalous, usually dilated, lymphatic channels and spaces
- The pathogenesis of LM is incompletely understood but developmental malformations take place due to a genetic hit to the vascular endothelial cells very early during embryogenesis
- LM are usually present at birth, grow in size with the growth of the individual until adulthood, and do not possess a regression or involutional phase
- They usually present with eyelid swelling or blepharoptosis, and occasionally pain, proptosis, diplopia, or strabismus when the orbit is also involved
- They often appear as a crop of small superficial cutaneous vesicle-like lesions or cyst-like excrescences which may become hyperkeratotic or verrucous and can be hemorrhagic especially following manipulation
- Patients may experience an abrupt onset of enlargement and pain due to sudden intralesional hemorrhage
- For small, minimally symptomatic lesions, conservative measures are appropriate
- For more extensive and symptomatic or amblyogenic lesions, percutaneous sclerotherapy is now the treatment of choice
- The prognosis varies from completely innocuous lesions to those with very high morbidity

Lymphatic malformations (LM) are benign tumor-like developmental vascular channels that are lined by endothelial cells and are composed of anomalous, usually dilated, lymphatic channels and spaces. LM commonly involve the orbit together with the eyelids and conjunctiva, but isolated eyelid involvement is rare.[1,2,3,4,5,6,7,8,9]

LM are not true tumors, and the previous name for LM (lymphangioma) is incorrect because the suffix *angioma* implies a proliferative and an involutional phase which does not occur with LM.[1,2,3,4,5,6,7,8,9] Unfortunately as late as 2018, the term "lymphangioma" is still occasionally used in the ophthalmic literature.[10] Other synonyms for LM which were frequently used in the past include cystic hygroma and lymphangioma circumscriptum.[11,12]

Etiology and Pathogenesis

The pathogenesis of LM is incompletely understood due to the lack of proper understanding of lymphatic development.[7] Very early during embryogenesis, there is no visibly discernible difference between the arterial or venous endothelium and arteries and veins, either in the orbit or elsewhere in the body, and they remain virtually indistinguishable until the dynamics of venous flow starts by the end of the fourth week.[13] Around this time, endothelial specification into either an arterial or venous fate (arteriovenous specification) is observed, as evidenced by the expression of distinct arterial and venous markers in separate endothelial populations.[1,14] After the arteriovenous specification is already established, a third endothelial cell type appears later, which is the lymphatic endothelial cell (LEC). There are two competing theories about the embryonic origins of lymphatic vessels and lymphatic development, and these two theories have been debated for over a century.[14,15] The centrifugal or venous theory maintains that primary lymph sacs bud off from primitive veins from a subset of venous endothelial cells that downregulate genes concerned with venous development and upregulate lymphatic ones.[14,16] This theory maintains that the lymphatic vessels grow out centrifugally from these sacs by endothelial budding and lymphangiogenesis.[16] In contrast, the centripetal (nonvenous) model maintains that lymphatic vessels and sacs arise from the mesenchyme parallel to the venous circulation which transforms into LEC. These LECs later develop a primitive lymphatic network and subsequently make secondary connections with the venous system.[15,16]

Recently, attempts have been made to reconcile both theories, and a dual venous and nonvenous origin of lymphatic vessels has been suggested.[15] The discovery that the *Prox1* gene, one of the most important genes that is involved in lymphatic development, is specifically expressed in a subpopulation of venous endothelial cells supports the centrifugal theory.[15] In contrast, some recent experimental animal studies have demonstrated that while the deep lymphatic vessels are indeed of venous origin, the superficial lymphatic vessels are derived from nonvenous dermatomes.[15]

Developmental vascular malformations take place due to a genetic hit to the vascular endothelial cells very early during embryogenesis. This genetic hit usually occurs before endothelial specification into an arterial or venous fate.[1,9,14] Because all vascular components including the lymphatic ones are born from the very same primitive capillary plexus, *(Print pagebreak 551)* conceptually every single tumor or malformation listed in the International Society for the Study of Vascular Anomalies (ISSVA) classification may occur in the orbit as pure (venous, lymphatic, etc.) malformation or in combination (venolymphatic, etc.).[1,14] It must be stressed that because of the plasticity of the progenitor vascular elements destined to form arterial, venous, or lymphatic vessels, it should come as no surprise that lymphatic vascular malformations may occur in the orbit, a location where the very existence of normal lymphatics is questionable in the first place. This plasticity also helps to explain why the most typical form of LM is a mixed lymphovenous type.[1,9]

Despite this apparent embryological complexity, one of the two major molecular pathways is deregulated in vascular anomalies, the RAS/MAPK pathway and the PI3K/AKT/mTOR.[17] LM appear to occur due to abnormalities in the PIK3CA catalytic subunit, which is a part of a family of intracellular transducer enzymes called the PI3K (phosphoinositide 3-kinase), which are generally involved in the activation of the mTOR pathway.[7,17,18] The mTOR pathway is a master regulator of cellular growth and development, and its dysregulation results in a variety of diseases besides LM, including cancers, diabetes, obesity, neurological diseases, and genetic disorders.[18] Most cases of LM are sporadic in onset due to somatic or *de novo* germline mutations, although dominant, recessive, and paradominant (two-hit model) inheritance have been reported.[17]

Because LM is a vascular malformation that occurs as a result of a structural defect in vascular morphogenesis, they are usually present at birth, grow in size commensurately with the growth of the individual until the patient reaches adulthood, do not possess a regression or an involutional phase, and have a normal rate of endothelial turnover.[19,20,21,22] LM may enlarge with upper respiratory tract infections due to the proliferation of lymphoid aggregates within the tumor.[2,23,24] Other predisposing factors that may cause upregulation in the lymphatic system and cause LM to enlarge include infection, hormonal changes, trauma, or even surgical intervention such as needle aspiration for biopsy or therapeutic purposes which can “ignite” an explosive LM growth.[9,21] Regardless of the predisposing factor, the sudden expansion of the anomalous lymphatic channels can lead to disruptions in the normal capillary network that feeds the malformation, with subsequent bleeding into the dead-end lymphatic channels, which may, in turn, become hemorrhagic cysts.[21]

Clinical Presentation

LM have no sex predilection and the exact prevalence is unknown, although some studies estimate an overall incidence throughout the body to be one in every 2000 to 5000 live births.[12,25,26,27] Seventy-five percent of LM occur in the head and neck.[12] Within the orbit, it constitutes 4% of all orbital tumors and around 25% of all vascular masses.[8] Although LM are generally present at birth, it may not become clinically apparent until late in the first or second decades of life, typically following an upper respiratory tract infection or trauma, when bleeding into a previously undetected subclinical LM prompts an ophthalmic evaluation.[2,28]

Patients with periorbital LM usually present with eyelid swelling or blepharoptosis. Ptosis which may be observed in up to half of the patients with periorbital LM is usually mechanical.[27,28] Other less common presentations include pain, proptosis, diplopia, or strabismus which may be more related to orbital LM.[28] LM are generally classified into macrocystic (>2 cm^2), microcystic (<2 cm^2), or mixed lesions, although some authors prefer to bring the cutoff figure for orbital lesions to 1 cm rather than 2.[1] Regardless of the correct cutoff value, from a clinical standpoint, a microcyst should be defined as a cyst which cannot be safely accessed with a needle.[27] Of note is that macrocystic LM (previously called cystic hygroma) are more common in the posterior orbit and are often observed with orbital imaging displaying fluid levels, while microcystic LM (previously called lymphangioma circumscriptum) are more common in the anterior orbit, eyelids, and the conjunctiva.[21,22]

Periorbital LM are rarely pure LM and are more commonly mixed-type malformations that contain venous channels and less commonly arterial or capillary channels.[21] Based on the predominance of one vascular element, they are sometimes classified as venous-dominant or lymphatic-dominant.[22] It should also be pointed out that isolated eyelid LM are exceptionally uncommon, as eyelid lesions are either anterior extensions of orbital LM or eyelid extensions of facial LM.[2]

Eyelid involvement (either with or without orbital/conjunctival involvement) may present with one of the two different forms. They may present as small superficial cutaneous vesicle-like lesions or cyst-like excrescences which may become hyperkeratotic or verrucous and can be hemorrhagic especially following manipulation.[2] Fluid levels may be seen within some of the cysts which are typically observed near the eyelid margin. Alternatively, eyelid LM may occur deep to the epidermis as a dark blue solid lesion,

which may be soft to firm, fluctuant, and may infiltrate eyelid tissue causing a diffuse or localized thickening of the eyelid (Figure 84.1), and in extreme cases may lead to elephantiasis of the eyelid.[2,21,22] Both forms of presentation may be observed together.[22] LM by definition do not enlarge with the Valsalva maneuver.[21,22] With a mass in the upper eyelid, significant ptosis can result in obstructing vision (Figure 84.2).

Patients with orbital LM may present with an abrupt onset of proptosis due to sudden hemorrhage within the dead-end lymphatic channels (Figure 84.3), but a detailed description of concomitant orbital involvement is beyond the scope of this text. Conjunctival involvement which is not infrequently associated with eyelid LM may present with solitary, diffuse, or multiloculated cyst-like lesions on the bulbar and palpebral conjunctiva which may contain clear fluid (lymph) (Figure 84.4). Similar to eyelid LM, conjunctival LM usually present as a superficial component of a deeper or diffuse orbital LM. These conjunctival lesions may be present at *(Print pagebreak 552)* birth and may remain asymptomatic (nonhemorrhagic) or may spontaneously bleed.

FIGURE 84.1 Deep lymphatic malformations lesion in eyelids and orbit.

FIGURE 84.2 Eyelid lymphatic malformations with upper eyelid ptosis.

Rarely, patients with LM malformations can present with intense eyelid and orbital inflammatory changes which may be indistinguishable from orbital cellulitis.[5] This rare form of presentation is usually due to a secondary bacterial infection, but an acute aseptic inflammatory episode is also occasionally observed.[5,29]

The diagnostic workup for patients with suspected LM should include ultrasonography, color Doppler sonography, contrast-enhanced magnetic resonance imaging (MRI), dynamic MRI imaging with DWI-ADC (diffusion-weighted imaging-apparent diffusion coefficient) series, and TRICKS (time-resolved imaging of contrast kinetics) sequences.[1,9] Biopsy is rarely required to diagnose an eyelid LM, as they most commonly show typical clinical and radiologic findings, but if any uncertainty exists, a biopsy may be required.[6,8]

Differential Diagnosis

The list of simulating lesions includes infantile hemangioma, venous malformation, rhabdomyosarcoma, fibrosarcoma, or eyelid lymphoma.[2,28,30] Rhabdomyosarcoma, in particular, may occasionally present a diagnostic challenge. Both entities occur in the same age group, both typically present with a rapid or explosive onset of proptosis, and both may have conjunctival involvement. Although radiology will usually clinch the diagnosis, rhabdomyosarcoma may occasionally show cavitation on MRI which may be difficult to differentiate from the fluid levels of macrocystic LM, and a biopsy may be required to establish the correct diagnosis.[31,

LM may be clinically similar to a venous malformation, but the majority of LM lesions in the orbit are mixed venous/lymphatic lesions, and differentiation may be exceptionally difficult.[9] Intense inflammatory signs are not common in *(Print pagebreak 553)* LM, but if an LM presents with a hot orbit, the condition may be confused with orbital cellulitis or idiopathic orbital inflammation.[5]

FIGURE 84.3 Infiltrative lymphatic malformations involving the eyelids, conjunctiva, and orbit with massive proptosis. (Courtesy of Dr. Michael Hawes.)

FIGURE 84.4 Lymphatic malformations of the conjunctiva.

Treatment

Currently, there is no gold standard for treatment, and therapy should be standardized according to the presentation which varies from one patient to the other. Watchful observation of focal, cosmetically nondisfiguring, minimally symptomatic, or functionally insignificant (nonamblyogenic) lesions is an acceptable first line of management.[21,24,33] Conservative measures include limitation of strenuous physical activity and bedrest, cold compresses, monitoring of visual functions (visual acuity and pupillary light reaction), and the use of systemic steroids. Corticosteroids are recommended for symptomatic relief and to prevent loss of vision, but they do not always work.[23,34,35] Patching of the *(Print pagebreak 554)* contralateral normal eye may be tried to fend off amblyopia, and a temporary tarsorrhaphy may be indicated if the cornea is threatened. If periorbital lesions are complicated by a secondary bacterial infection, intravenous antibiotics may be required.[28]

Patients with isolated superficial cystic lesions are usually minimally symptomatic; although occasional bouts of hemorrhage may be observed, they typically resolve spontaneously. However, if hemorrhage persists, or if they are cosmetically disfiguring, simple excision of these small, superficial cystic lesions has been somewhat successful and is usually bloodless,[22] but it may occasionally be a frustrating experience because the margins are hard to define, and large confluent cysts which are not infrequently observed as crops covering a large area of the anterior surface of the eyelid may have to be excised en bloc, therefore complete excision may require a skin graft.[22]

For more extensive subepidermal lesions, most authors agree that surgery is the definitive form of therapy to effect a complete cure in potentially amblyogenic lesions.[26,28] However, because of the vascular and infiltrative nature of LM, these lesions may bleed significantly during surgery, and the surgeon may face tremendous difficulty in obtaining a clear cleavage between the mass and the normal tissue planes which is almost impossible particularly in microcystic LM.[1,3,9,21,22] Therefore, although complete surgical excision of anterior orbital/eyelid lesions may be tried, it may be hazardous because of the possibility of iatrogenic damage to adjacent eyelid structures,[1,3,9] and in the event of incomplete excision or subtotal debulking, it may be associated with frequent recurrences.[6] Therefore, some authors believe that surgery should be reserved for patients with vision-threatening lesions alone, a rare situation in isolated eyelid LM. If debulking is undertaken, ptosis usually improves following surgery, but if levator resection surgery is required to address the ptosis it should be deferred to a second stage 6 months later, and any residual LM from the previous first stage surgery may be further excised,[27] but it should be stressed again that because of the aforementioned risks, surgery based on cosmetic indications alone is discouraged.[1]

Within the orbit several options are available for management of LM, embolization followed by surgical excision, or sclerotherapy alone. Simple evacuation of the hemorrhagic macrocysts compressing the optic nerve may be tried but this will probably result in slow transudative reformation of the cyst and recurrences.[22,36] Surgical resection of macrocystic LM in the posterior orbit may be performed alone or as an adjunct to sclerotherapy where the cysts are partially evacuated followed by embolization of the cysts with one of the traditional sclerosants like *n*-butyl cyanoacrylate. The solidified lesion is subsequently debulked or excised in the same session.[22,27,28] An alternative approach in facial LM is to debulk the lesion as a first-line measure and reserve the intratumorous injections of sclerosant agents for future recurrences.[27]

Because of the obvious challenges of surgical ablation outlined earlier, percutaneous sclerotherapy alone is suggested as an alternative to surgery in the treatment of macrocystic superficial periocular LM.[3,6] The modality is, in fact, a well-established option in superficial vascular lesions elsewhere in the body; however, sclerotherapy for microcystic LM which is more common in the eyelid has a less favorable outcome possibly because there are no obvious cysts to target with the sclerosant, and the sclerosant agent may extravasate and cause serious consequences as it may damage normal adjacent eyelid tissue.[9] However, in selected cases, sclerosants may be tried, and the recommended sclerosing agents include sodium tetradecyl sulfate (STS), bleomycin, doxycycline, ethanol (not recommended in the periorbital region), pingyangmycin, and OK-432 (Picibanil), which is a killed strain of group A *Streptococcus pyogenes*.[3,6,9,37,38,39] Intravenous injection of STS, a synthetic surfactant, causes an intimal inflammation and subsequent thrombus formation which usually occludes the injected vein, followed by fibrous tissue deposition.[3] Bleomycin is an antineoplastic antibiotic that was isolated from the fungus *Streptomyces verticillus*, and besides its use in the management of vascular malformations, it is used as a chemotherapeutic agent in squamous cell carcinoma, lymphoma, and testicular carcinoma.[6] The proposed mechanisms of action of bleomycin involve apoptosis of rapidly dividing endothelial cells, inhibition of DNA synthesis, followed by involution of the lesion by fibrosis.[6]

Lesions involving the eyelids or anterior orbit are clinically visible on the surface and are usually prominent; therefore, the injections if indicated can be carried out under direct visualization without ultrasonographic or digital subtraction angiography guidance. Injections are carried out with general anesthesia for children or local anesthesia for adults. A 21, 23, or 25 gauge needle or a scalp vein set is used, and partial or complete aspiration of the lesion is performed first.[3,6] With the needle in the same position, intralesional injection of the sclerosing agent like bleomycin (0.5 IU/kg body weight, arbitrarily around 20% of

the aspirate) or STS (0.1 mL STS 1%) follows.[3,6] Because these injections may not always result in complete lesion obliteration, and because the effects may not be permanent, injections may be repeated every 4 to 6 weeks until the desired effect is achieved.[3,6,39]

Commonly encountered complications are mild and include pain at the site of injection, red itchy skin (hives), temporary skin hyperpigmentation, lid edema, ecchymosis, erythema, transient increase in proptosis, and rarely eyelid necrosis due to drug extravasation. Anaphylactic shock and catastrophic vascular embolic events are extremely rare but should be promptly diagnosed and treated if encountered.[3,6] It is important to understand that partial lesion aspiration is not solely intended to clear up space for the injection of the sclerosing agent, but it is also a safeguard precautionary measure to make sure the needle is not misplaced intraarterially.[3,6] Although some authors claim a good long-term outcome with transcutaneous and/or transconjunctival non-image guided sclerotherapy in patients with orbital/adnexal lymphatic malformations,[39] a recent cross-sectional cohort study which focused on orbital venolymphatic malformations demonstrated that sclerotherapy alone may only provide initial temporary improvement, however, in the *(Print pagebreak 555)* medium to long term, recurrence were universal.[40] In contrast, embolization with excision appears to provide more definitive management with far fewer recurrences.[40]

Of note is that the vascular channels of LM are not amenable to endovascular approaches; however, other possible forms of therapy for superficial lesions include oral medications, radiofrequency, or carbon dioxide laser (CO_2) resurfacing/ablation.[26,40,41,42] Because of its inhibitory effects on the mTOR pathway, rapamycin (sirolimus), a macrolide drug that was initially discovered as an antifungal metabolite produced by *Streptomyces hygroscopicus*, was later found to possess immunosuppressive and antiproliferative properties, as well as life span extension properties.[7,18] Sirolimus was shown to be effective in venous as well as LM both within the orbit and in extraorbital locations throughout the body.[7,17,18] Because of the low risk-benefit profile of the drug and the infrequent side effects, rapamycin may be a safer alternative for the treatment of microcystic orbital LM than surgical excision or sclerotherapy where they may not be particularly useful.[7] Of note is that the recommended dose range, as well as the duration (6-53 months) of drug therapy, is not yet standardized.[7] Phosphodiesterase type 5 inhibitors like sildenafil (Viagra, Pfizer) or tadalafil (Cialis, Lilly) have also shown some promise in the management of systemic LM.[21]

Prognosis

The clinical course of LM varies from completely innocuous lesions to lesions with very high morbidity which may cause progressive anatomic distortions and serious functional problems.[28,33] Amblyopia is common and is attributed both to ptosis (occlusive amblyopia) and strabismus (strabismic amblyopia).[28] Relapses are common, and recurrent hemorrhages may cause a disfiguring cosmesis which may be very difficult to treat.[24] Visual loss may be profound and is also multifactorial (amblyopia, corneal complications, and/or optic nerve compression). True regression, which may be seen with infantile hemangioma, does not occur with LM.[2] Relentless bleeding with severe associated pain which may require exenteration for palliation is unusual and is a sequel of orbital rather than eyelid disease.[24]

It should be noted that because of the rarity of LM, the condition does not lend itself to large, randomized controlled trials, and evidence-based information is lacking.[26,43] Furthermore, the literature is plagued with inconsistent reporting and all the information that can be retrieved is obtained either from small case series or even single case reports, some of which do not take into account the size/extent/depth of the lesion or the histopathologic subtype as a variable affecting the prognosis or clinical therapeutic outcome.[26] More robust clinical studies are needed to compare the results of different treatment modalities side by side.[26]

The consensus that the treatment of macrocystic LM is more successful than the treatment of microcystic LM may not hold true in the orbit where both forms of presentation whether in the posterior or anterior orbit are intermixed with vital structures.[38] Patients should be notified that except in very rare situations, complete surgical resection is not possible,[24,28] and sclerotherapy usually requires more than one session until the lesion resolves. Patients should also be informed that regardless of the treatment option chosen, success is variable, recurrence is the rule, and a complete cure is an exception.[26]

Histopathology

Superficial LM may arise in the superficial dermis (previously termed “lymphangioma circumscriptum”) or deep dermis, often with extension into the superficial subcutis (previously termed “lymphangioma cavernosum”).[44,45] The lymphatic channels in both are thin-walled and empty or contain lightly eosinophilic, homogenous fluid (lymph) with few or no erythrocytes unless there has been spontaneous hemorrhage into the lesion. In contrast to hemangiomas, the endothelial cells lining the lymphangioma vascular channels are widely spaced, the channels in fixed specimens often have irregular shapes with acute bends, and they usually lack a

muscular layer.[45] Immunohistochemical stains using antibodies to podoplanin (D2-40), lymphatic vessel endothelial hyaluronan receptor 1 (LYVE1), or prospero homeobox protein 1 (PROX1) highlight LECs and may be employed to confirm the diagnosis of an LM.[44]

Superficial LMs, formerly termed "lymphangioma circumscriptum," feature enlarged lymph vessels immediately beneath the epidermis, causing it to become elevated with a vesicle-like appearance.[45,46,47] Lymphatics protruding into the acanthotic epidermis may simulate intraepidermal vesicles.[45] A few lymphocytes may be found in the stroma around the lymphatics.[45] In some cases, a superficial LM (lymphangioma circumscriptum) arises over a macrocystic LM (previously called cystic hygroma).[48] In these cases, the superficial lymphatics are horizontally oriented, while deeper lymphatics are vertically oriented, have thicker walls, and communicate with a subcutaneous lymphatic cistern.[48]

Lymphangioma cavernosum has a variable histological appearance.[45] Simple cases have lymphatics that appear to push apart the stroma (Figure 84.5), while complex lesions have connective tissue around the lymphatics that varies from loose stroma to compact stroma to fibrosis.[45] The stroma frequently contains a few lymphocytes, and larger lesions may have aggregates of lymphocytes.[45]

Eyelid cutaneous LMs are poorly demarcated lesions with wide variation in the amount of stroma accompanying the lymphatics.[49] Some eyelid LMs have back-to-back lymphatics with minimal stroma, and others have lymphatics widely spaced in the stroma.[49] The channels in a given lesion vary from small caliber to cavernous spaces[49,50]; Jones noted that the smaller caliber lymphatics tended to be more superficially located.[49] Stromal lymphocytes vary from scattered to lymphoid follicles.[49] An adventitial coat of the lymphatic spaces is inconspicuous in most eyelid LMs, but there may be focal investment by smooth muscle cells.[50] Hemorrhage into eyelid LMs is common.[50]

Conjunctival LM may be an extension of a deeper process,[51] or they may rarely be isolated lesions.[49,52] Conjunctival LMs usually have closely packed, dilated lymphatics with scant stroma (Figure 84.6).[49] Stromal lymphocytes may be sparse[49] or form lymphoid follicles.[52]

CHAPTER 85

Lymphedema

Key Points

- Lymphedema is a chronic disease characterized by localized eyelid swelling caused by an impairment of lymphatic drainage, resulting in the excessive retention of protein-rich lymphatic fluid in the interstitial compartment
- Primary lymphedema is due to aplasia or hypoplasia of the lymphatic vessels but has not been reported in the eyelid
- Secondary periocular lymphedema is associated with chronic inflammatory conditions, surgical or nonsurgical trauma, infections, neoplastic processes, and miscellaneous causes such as hypothyroidism, amyloidosis, nephrotic syndrome, alcoholism, continuous positive airway pressure nasal masks, or malar festoons
- Clinically, the edema is initially pitting and pendulous, but later becomes doughy, firm, and nonpitting
- Treatment options are palliative at best depending on the associated systemic disorders and include tetracycline antibiotics, isotretinoin, or oral steroids
- Surgical debulking is another option
- Chronic eyelid lymphedema, regardless of the etiology, is a progressive disease with serious physical and psychosocial implications that may be challenging to diagnose and is notoriously difficult to eradicate

Lymphedema is a chronic progressive disease characterized by a localized form of eyelid swelling that is caused by an impairment of lymphatic drainage, which results in the excessive retention of protein-rich lymphatic fluid in the interstitial compartment.[1,2,3,4,5] The term “elephantiasis” is synonymous with the term “lymphedema.”[3]

Etiology and Pathogenesis

Although lymphedema is not uncommon, our understanding of its basic underlying pathogenetic mechanisms is still limited. A brief overview of the lymphatic eyelid anatomy may shed some light on its etiology.[4] Eyelid lymphatics lie superficial and deep to the orbicularis muscle forming superficial and deep systems that drain to the parotid and submaxillary nodes.[2,6] The deep vessels traverse through the suborbicularis oculi fat and drain the conjunctiva and tarsus directly into the parotid (preauricular) lymph nodes. On the other hand, the superficial system which runs anterior to the orbicularis muscle drains the skin of the eyelids and orbicularis muscle.[6] Medially, this superficial system collects lymphatic drainage from the medial aspects of both eyelids and drains into the submandibular lymph nodes, while the lateral aspect of both eyelids is drained by a separate system that flows into the parotid (preauricular) lymph nodes.[6,7]

If these channels are blocked, lymph stasis ensues which causes an accumulation of tissue protein and fluid, resulting in edema.[2] Accumulation of lymph increases oncotic pressure which draws even more fluid into the interstitium, which in turn may cause inflammation, further compromising support for lymphatic vessels. As the eyelid edema progresses, fibrotic changes ensue, and the already dysfunctional lymphatic channels are even more impaired by fibrosis of the surrounding tissues.[8,9] This vicious cycle causes the initially soft eyelid subcutaneous tissue to become thickened, fibrotic, and solid.[8]

Lymphedema is subdivided into primary and secondary types. Primary or hereditary lymphedema due to aplasia or hypoplasia of the lymphatic vessels has not been reported in the eyelid; therefore eyelid lymphedema is usually a localized form of secondary lymphedema. The list of periocular conditions associated with lymphedema includes (1) chronic inflammatory conditions like rosacea, Melkersson-Rosenthal syndrome (MRS), or oculofacial granulomatosis; (2) trauma either surgical or nonsurgical; (3) infections like erysipelas; (4) conditions including giant cell angiofibroma or neurofibroma; and (5) miscellaneous causes, including hypothyroidism, amyloidosis, nephrotic syndrome, alcoholism, continuous positive airway pressure nasal masks, malar festoons, or it may be idiopathic.[8,10,11,12,13,14,15,16,17,18,19,20,21,22,23]

Concomitant injury to both the deep and superficial lymphatic drainage systems explains the increase in the rate of persistent chemosis/eyelid edema that has become more prevalent as cosmetic procedures that combine traditional transcutaneous blepharoplasty with trans-eyelid midface suspension have become more common.[6] Historically, placement of surgical incisions over the inferior orbital margin to access the anterior orbit not only resulted in an unsightly scar but these incisions caused significant lymphedema as well.[17] Another procedure that can be associated with considerable lymphedema is myectomy for essential blepharospasm.[18] Eyelid lymphedema does not occur only from trauma or surgery involving the periocular region, and several cases have been reported following modified radical neck dissection for head and neck cancer metastases.[2,8]

Rosacea is a chronic inflammatory skin condition affecting approximately 10% of adults and is characterized by *(Print pagebreak 560)* facial erythema, papules, pustules, telangiectasia, sebaceous gland hyperplasia, and meibomian gland dysfunction.[13,14,15] In the absence of a history of a surgical or a nonsurgical traumatic insult, rosacea is by far the most common underlying etiologic condition associated with lymphedema and is observed in roughly 50% of patients. While ophthalmologists are familiar with the classic ocular manifestations of rosacea, such as conjunctivitis or blepharitis, rosacea is often overlooked as a common cause of eyelid lymphedema.[24]

MRS is a rare locally infiltrative granulomatous disease of obscure etiology, which is characterized by a triad of idiopathic eyelid or lip edema, facial palsy, and fissured tongue. However, the classic triad is encountered in one-third of patients only,[11,12,25] and patients can present solely with eyelid lymphedema (Figure 85.1). The disease has a worldwide distribution, with no racial predilection, but is diagnosed more often in females.[25]

Orofacial granulomatosis (OFG) is an uncommon non-necrotizing granulomatous disorder of the orofacial tissues. The term is a catch-all term that was coined in 1985[25] to encompass several entities that share two common features: orofacial swelling and the histologic evidence of noncaseating granulomas.[26] This condition has a multifactorial etiology and uncertain pathogenesis, but an underlying genetic or immunologic (delayed hypersensitivity) mechanism that favors a granulomatous inflammatory response is possible.[25,26,27,28,29] Although the term is nonspecific, establishing the diagnosis of OFG is still important because it should prompt the clinician to thoroughly search for the underlying disease, including granulomatous cheilitis, Miescher cheilitis, Crohn disease, or MRS.[26] Unfortunately, the diagnosis remains elusive in a significant proportion of patients,[26] and in these individuals, the term “OFG” can be used alone, a situation which is not quite dissimilar to the use of the term “idiopathic orbital inflammation” in orbital disease.

An often overlooked clinical condition that is at least partially attributable to lymph stasis is malar mounds, the other contributory or comorbid mechanism being anatomical laxity of dermal attachments. Both factors (laxity and lymph stasis) contribute to the characteristic clinical appearance of festoons.[16]

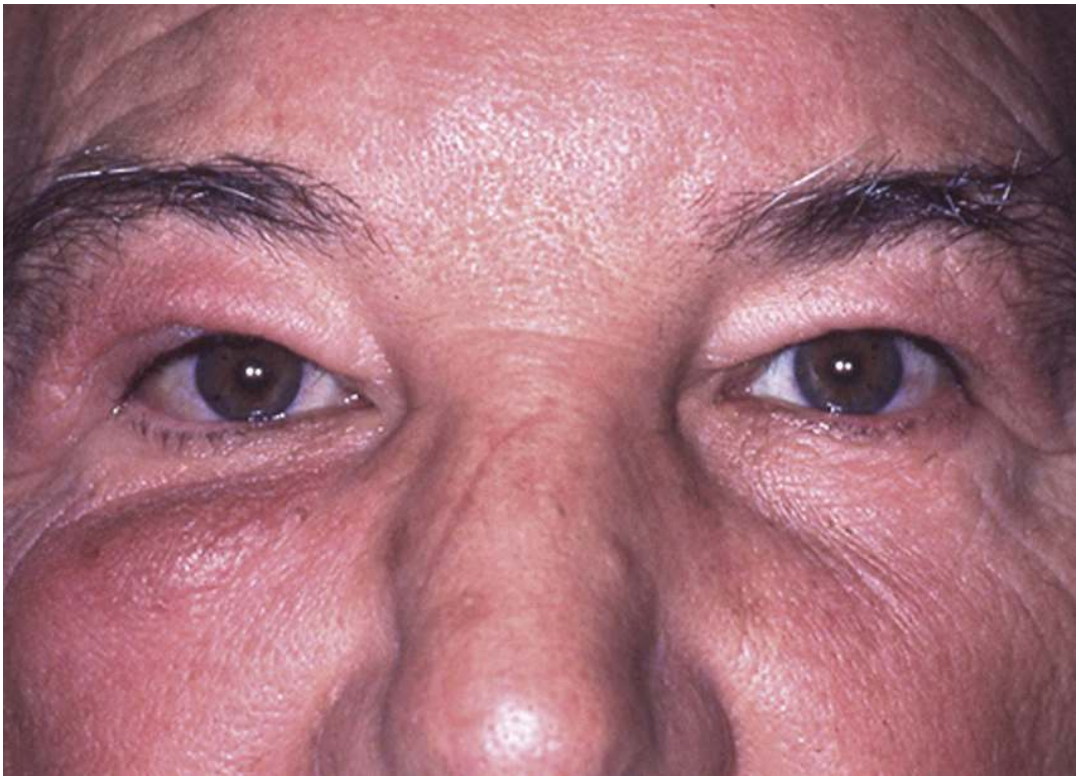

FIGURE 85.1 Lymphedema associated with Melkerson-Rosenthal syndrome.

Comorbid factors that may increase the risk of developing lymphedema include genetic factors, obesity, radiation, and infections.[1,2,3,4] Interestingly, genetic factors do not only play a role in primary lymphedema but may be implicated in cases of secondary lymphedema.[4] An increased rate of mutations in the HGF/MET pathways which regulate lymphangiogenesis, as well as mutations in the CJC2 protein which regulates lymphatic flow, have been observed in patients with secondary lymphedema.[30,31] Obesity has repeatedly been shown to impair lymphatic function and patients with a higher body mass index have a higher incidence of lymphedema, but this may be reversible after weight loss.[4] Radiation per se is associated with an increased risk of lymphedema but is an important comorbid risk factor if performed following surgery.[4] Infections can also cause significant destruction of the lymphatic system.

Clinical Presentation

The prevalence of lymphedema is unknown because lymphedema is not a reportable disease.[20] Pain is usually absent, but patients are concerned about the nature of the edema and the associated cosmetic disfigurement which is bothersome because chronic lymphedema may cause a significant change in orbital and facial contour.[5] On physical examination, the eyelid tissue initially shows a variable degree of mild edema, which later progresses to severe or profound lymphedema (Figure 85.2). If the upper eyelid is involved, the visual axis may partially or completely be occluded, but the levator function is difficult to assess amidst the edema.[2]

The edema is initially pitting and pendulous, but as fibrosis and chronic inflammation progress, lymphedema becomes doughy, then later becomes firm and nonpitting or woody, and the overlying skin becomes thickened and hyperpigmented.[8,10] Rosacea patients often present with solid persistent facial edema coupled with erythema which is referred to in the literature as rosacea lymphedema or Morbihan disease.[3,5] These patients typically suffer from edema involving the upper two-thirds of the face not circumscribed to the eyelids but may involve the forehead, glabella, nose, and cheeks (Figure 85.2).[5] Patients with OFG, including patients with MRS, may also present with severe nontender upper and lower eyelid edema and induration which may be associated with mechanical ptosis and obscuration of the visual axis.[29]

Eyelid lymphedema can be associated with conjunctival chemosis if the deep lymphatic plexus is also involved, a situation that is commonly observed in patients with trauma or surgery. Other than conjunctival chemosis, the rest of the ocular examination is typically normal in lymphedema patients. Systemically, the association of lymphedema with a fissured tongue (lingua plicata) or facial nerve paralysis may point to the diagnosis of MRS, but monosymptomatic or *(Print pagebreak 561)* oligosymptomatic variants of the disease are the rule rather than the exception.[11,12,25,26,27,28] Of note is that lingua plicata may be a normal variant in the population and is not diagnostic of MRS. Other subcategories of OFG are commonly associated with upper or lower lip edema rather than eyelid edema,[25,26,27,28] but a recent study has demonstrated that eyelid lymphedema may also be a common associated finding.[29]

FIGURE 85.2 The spectrum of manifestations of lymphedema involving the eyelids.

Differential Diagnosis

The generic use of the term "lymphedema" has been applied to any patient with eyelid edema, but lymphedema is a specific condition, and it is important to avoid the liberal use of the term in every patient with a swollen eyelid since this might lead to serious clinical errors.[1,32] An analogy can be made with the erroneous use of the term "hemangioma" in every patient with an orbital vascular lesion.[32] The list of disease conditions mimicking lymphedema is extensive and is summarized elsewhere in the literature.[11,12] Detailed history taking is pivotal in establishing the diagnosis of lymphedema as most patients are not aware of a causal association except in cases related to trauma or surgery. However, even after an exhaustive diagnostic workup, the diagnosis may still be elusive.[3] The diagnostic workup should include all the diseases causing chronic eyelid edema, categorized into inflammatory, infectious, neoplastic, or miscellaneous causes. The more important causes to consider include thyroid orbitopathy, idiopathic orbital inflammation, blepharochalasis, sarcoidosis, floppy eyelid syndrome, and angioedema.[3,11,12,33,34] There is a significant clinical, histopathological, and even immunohistochemical overlap between lymphedema and giant cell angiofibroma which is a curious neoplasm suspected of being a variant of solitary fibrous tumor.[20,23,35] This overlap is so substantial that some authors suggest that giant cell angiofibroma and lymphedema represent variations of the same process.[23]

It should not be difficult clinically to differentiate lymphedema from angioedema, which is an abrupt inflammatory allergic reaction of the subcutaneous tissue and the reticular dermis.[36] Unlike lymphedema, the onset of angioedema typically is more rapid, usually over a few hours, and is associated with a history of intake of a known allergen through ingestion, inhalation, or via parenteral administration, at least in patients with nonhypersensitivity angioedema (Chapter 48).[37] In addition to acute onset, the edema in angioedema is usually nonpitting, asymmetric, and has a tendency not to involve gravitationally dependent areas.[34]

(Print pagebreak 562)

Treatment

Because the underlying pathophysiologic and cellular mechanisms that cause lymphatic dysfunction remain poorly understood, the available treatment options for lymphedema are palliative at best.[4] In patients with Morbihan disease, oral preparations include the use of tetracycline-based antibiotics for prolonged periods (200 mg daily for 4-6 months); however, the response is usually partial.[5] The underlying mechanisms behind the efficacy of tetracyclines in rosacea include downregulation of proinflammatory cytokines, inhibition of neutrophil chemotaxis, and inhibition of matrix metalloproteinases.[1,2,3] Alternatively, oral isotretinoin may be prescribed in rosacea lymphedema (40 mg daily for 6 months), but the results are underwhelming.[5] Oral steroids also have been tried in patients with eyelid lymphedema, but the response is partial and the disease tends to recur after cessation of steroids.[5] A steroid/antibiotic combination oral therapy may provide a better treatment response than either treatment alone, although it may be associated with more sinister side effects.[5]

OFG and its subentities including MRS are difficult to treat, and there is no gold standard of treatment at this time.[27,29] The list of therapeutic options is long and is mostly based on case reports. These include corticosteroids (local, intralesional, and systemic), antibiotics (metronidazole, minocycline, or doxycycline), antileprosy therapy (dapsone, clofazimine), and immunosuppressive therapy (azathioprine, infliximab, adalimumab, or etoposide).[27,28,29]

As a general rule, the aforementioned systemic medications either in oral or even parenteral form do not usually work because they fail to be delivered locally in ample concentration, as the chronic perivascular inflammation and the abundance of interstitial fluid that accompanies lymphedema limit their reach.[3] Therefore, local injections theoretically may have a potential role in management.[3] Some patients may show a partial response to intralesional injection of steroids, either alone or in combination with surgical debulking.[3] Injection techniques vary, but a general rule is to inject a 50:50 mixture of triamcinolone and dexamethasone locally into the eyelid tissue. A total volume of 1.5 to 2 mL is distributed evenly in three divided doses and injected in three different regions of the eyelid.[3] Injections may be repeated after 6 months if recurrence occurs.[3]

Patients with festoons and malar edema may benefit from the intralesional injection of tetracyclines including doxycycline.[38] Theoretically, the therapeutic benefit is twofold. In addition to the profound immunomodulatory potential of tetracyclines, their sclerosing potential, whereby they induce collagen and fibrin deposition and create dense adhesions and fibrosis, also is significant.[16,38] It is not entirely implausible that the periocular injection of tetracycline/doxycycline may be beneficial in patients with Morbihan disease as well, and at least with regards to rosacea, although this has not been reported previously and remains hypothetical at best.

More recently, promising results were observed with the topical application of anti-T cell immunosuppressive drugs such as tacrolimus in lymphedema patients both in experimental and clinical studies. This was shown to be highly effective in treating established lymphedema, with a dramatic improvement in lymphatic function in treated animals.[39,40,41] Topical tacrolimus has not been used for eyelid lymphedema, and the dramatic response mentioned earlier was observed in lymphedema elsewhere in the body, as well as in lip edema in patients with OFG.[39,40,41] There are, however, a few case reports where tacrolimus was used with variable success in other types of eyelid edema like psoriatic eyelid edema, and eyelid edema associated with dermatomyositis.[42,43] It is quite possible, though unproven, that topical tacrolimus may have a therapeutic role in eyelid lymphedema as well.

Surgical excision of the lymphedematous tissue may be the most beneficial option particularly in patients with a significant functional and cosmetic impairment.[1,2] Through a standard blepharoplasty incision, debulking of the lymphedematous subcutaneous tissue along with the thickened pretarsal and preseptal orbicularis muscle is undertaken. This should be coupled with fixation of the lateral canthal tendon if the lymphedema involves the lower eyelid or levator tightening if the upper eyelid is involved. Frost sutures may also be used to fix the eyelid in position.[8] A slightly more involved approach consists of a pinch excision of the skin and subcutaneous tissue akin to the pinch technique used in upper eyelid blepharoplasty. The pinched skin is marked, and the base is gently clamped with artery forceps and excised. This is followed by the debulking of subcutaneous tissue.[33] Combining surgical debulking with the control of the inflammatory component using anti-inflammatory medications (steroids or tetracyclines) may be the most logical approach.[3] This dual therapy may be particularly relevant in rosacea lymphedema, but then again residual disease almost always persists.[3]

Prognosis

Chronic eyelid lymphedema, regardless of the etiology, is a progressive disease with serious physical and psychosocial implications that may be challenging to diagnose and notoriously difficult to eradicate.[2,3,4,44] The inflammatory signs in patients with Morbihan disease, the archetypal example of chronic lymphedema, may respond to medical therapy but with the persistence of lymphedema,[3] and even if surgical debulking is undertaken, patients could still have a residual degree of edema.[1,2,3] In short, lymphedema has no definitive cure.[45]

Histopathology

Localized lymphedema features dilated lymphatics and dermal edema manifest as pallor of the connective tissue with increased spacing between collagen bundles (Figure 85.3).[3,20] Dermal inflammation is a constant feature and was minimal *(Print pagebreak 563)* in 50%, moderate in 12%, and marked in 38% of biopsies in the study of 23 cases of localized lymphedema by Lu et al.[20] The inflammatory infiltrate was superficial perivascular in 38% of cases, deep perivascular in 20%, superficial and deep perivascular in 42%, or follicular/perifollicular in 29%.[20] The inflammatory infiltrate may be lymphocytic with focal histiocytes[3] or predominantly plasma cells.[20] Lu et al observed lymphoid follicles in 25% of biopsies, granulomas in 12%, and neutrophils in 12% of the cases.[20] Fibroplasia with an increase in fine, widely spaced, dermal collagen bundles was present in all 24 lymphedema cases examined by Lu et al, and there were dense dermal scars in two-thirds of the biopsies.[20] All biopsies had fragmentation, clumping, and/or loss of mature elastic fibers in the reticular dermis.[20] Sebaceous hyperplasia with a peri-infundibular infiltrate of lymphocytes, histiocytes, plasma cells, and mast cells is a histological finding in extreme eyelid lymphedema associated with rosacea.[3]

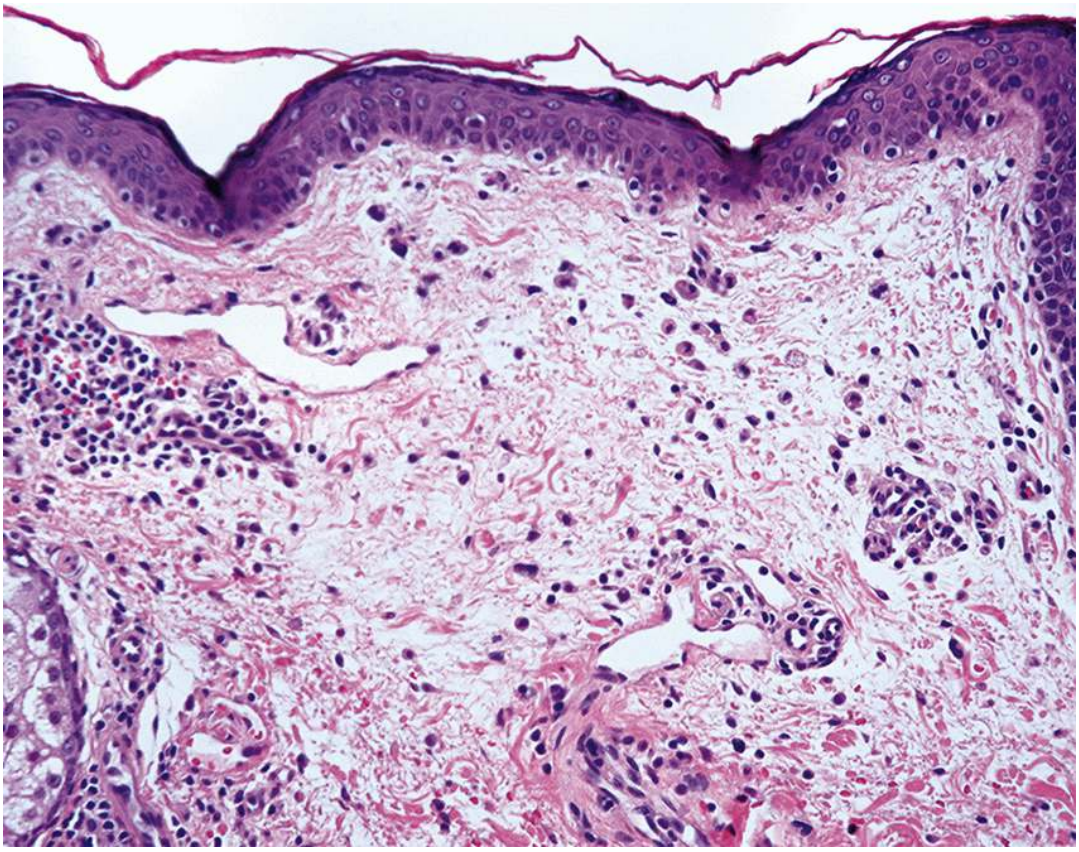

FIGURE 85.3 This right upper eyelid biopsy is from a man in his late 40s with edema for 4 months. There is lymphangiectasia, dermal edema with increased spacing between collagen bundles, and perivascular inflammatory infiltrates of lymphocytes, macrophages, and mast cells.

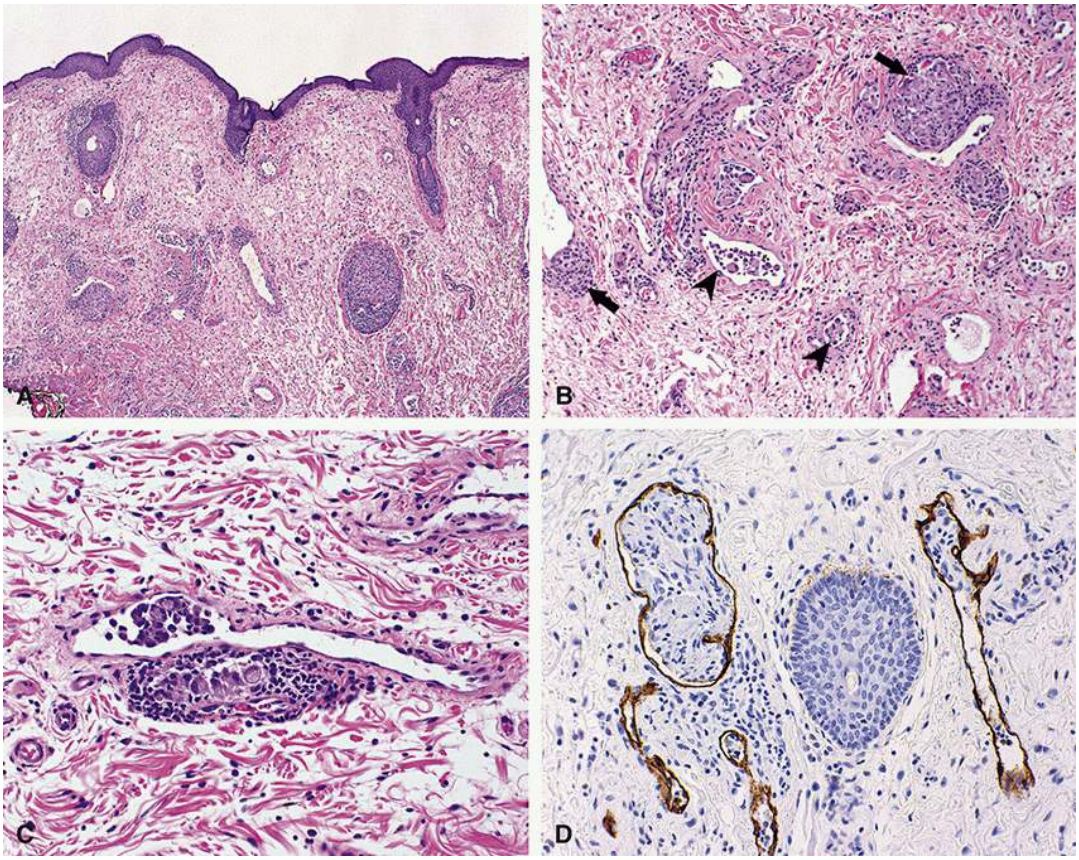

FIGURE 85.4 This woman in her middle 60s with orofacial granulomatosis had unilateral swelling of the right upper eyelid for 1.5 years. A, Lymphangiectasia and dermal edema, manifest as pallor, are prominent at low magnification. B, Perilymphatic noncaseating granulomas (arrows) and intralymphatic histiocytes (arrowheads) were frequent in this

case, but they are sparse in some cases. C, High magnification photomicrograph showing a perilymphatic noncaseating granuloma and a cluster of histiocytes and multinucleated giant cells within the lymphatic lumen. D, An immunohistochemical stain using D2-40 antibodies to podoplanin highlights the lymphatic endothelial cells. Histiocytes are in all of the lymphatics, with the large lymphatic on the left distended by histiocytes.

OFG (Figure 85.4)[29,46,47] and MRS[48,49] are characterized by dermal edema, lymphangiectasia, perivascular lymphohistiocytic inflammation, perilymphatic noncaseating *(Print pagebreak 564)* granulomas, and sometimes intralymphatic histiocytes or granulomas. Eyelid biopsies typically have perilymphatic and/or intralymphatic granulomas.[29,48,49] In our experience with 12 eyelid biopsies diagnosed with OFG, there were perilymphatic noncaseating granulomas with or without intralymphatic histiocytes or granulomas in all cases. In a few cases, granulomas were sparse, and multiple sections were needed to identify them. Immunohistochemical staining using antibodies (D2-40) to podoplanin helped confirm the intralymphatic histiocytes or granulomas (Figure 85.4D). In contrast to our results in the eyelid, Marcoval and Penin, in a study of 22 patients with OFG causing lip swelling, identified perilymphatic granulomas in 12 lip biopsies, intralymphatic granulomas in 2 biopsies, and intralymphatic histiocytes in 2 biopsies.[46] OFG may resemble cutaneous sarcoidosis or cutaneous lesions of Crohn disease, and OFG may be the initial presentation of Crohn disease in some patients.[50] The perilymphatic and/or intralymphatic distribution of granulomas, together with prominent clinical and histological edema, help to distinguish OFG from sarcoidosis, in our experience.

CHAPTER 86

Melanocytic Nevus

Key Points

- Melanocytic nevus refers to common moles on the skin and is composed of nests of altered melanocytes
- Cutaneous melanocytic lesions are designated by the histopathologic location of melanocyte cells relative to the dermis-epidermis junction
- Junctional nevi have nests of nevus cells only at the junction
- Intradermal nevi are the most common type in adults and are confined to the dermis
- Compound nevi contain nevus cells at the junction and in the dermis
- Congenital melanocytic nevi have been associated with mutations in proteins of the MAPK signal transduction pathway, particularly NRAS and BRAF
- Congenital melanocytic nevi appear at birth or within the first 6 months of life and as small, flat, smooth to irregular, lightly pigmented lesions
- Divided nevi span across the palpebral fissure and lie on adjacent portions of the upper and lower eyelids
- Acquired nevi develop later in life and sunlight exposure is a risk factor for their development
- Management includes surveillance for changes in size, texture, shape, or color suggestive of malignant transformation
- Surgical removal is indicated for cosmetic concerns, or for changes in size, color, or progressive elevation
- The prognosis is generally good and the risk of malignant transformation is about 14% during a lifetime

The term “nevus” is used to describe a variety of benign neoplasms or hamartomas composed of melanocytes.[1] Melanocytic nevus refers to common moles on the skin. Melanocytes are derived from the neural crest, and during embryogenesis, they migrate to selected ectodermal sites in the skin, meninges, eyes, inner ear, vaginal epithelium, bones, and heart. In the skin, melanocytes normally are located evenly distributed in the basal layer of the epidermis. In melanocytic nevi, nests of altered melanocytes are distributed in the epidermis and/or the dermis. Cutaneous melanocytic lesions are broadly designated by the histopathologic location of melanocyte cells relative to the dermis-epidermis junction. Junctional nevi have nests of nevus cells only at the junction. Dermal nevi have nests of nevus cells only in the dermis, and compound nevi contain nevus cells at the junction and in the dermis.[2]

Junctional nevi clinically present as flat, well-circumscribed brown to black macules anywhere on the body. They appear during childhood or early adolescence.[3] Intradermal nevi are the most common type of melanocytic nevi and are mostly found in adults.[3] They show essentially no junctional activity and are confined to the dermis where they are arranged in nests and cords.[4] They may show a depigmented halo around the pigmented lesion.[3,4] The depigmented halo shows an absence of melanin pigment and melanocytes with inflammatory cells.[3] Compound nevi occur more commonly in children and adolescents.[3] Clinically, they appear as a pigmented papule or plaque.[4]

Melanocytic nevi can be congenital, present at birth or shortly thereafter, or they may be acquired. The acquired type usually begins in childhood in the basal epithelium where it presents as a junctional nevus and gradually migrates into the dermis in young adults where it becomes a compound nevus. Later in life, they tend to reside entirely in the dermis as a dermal nevus.[5] The average young adult has about 15 cutaneous nevi and the eyelid is occasionally affected.[3] The most common types of melanocytic nevi that can affect the eyelids are congenital, acquired, blue nevus, and Spitz nevus.

A congenital melanocytic nevus (CMN) may be defined as a lesion present at birth or within the first 6 months of life. It can be seen

on the skin anywhere on the body and is seen in about 1% to 2% of newborn infants.[4,6,7] Most are less than 10 mm in diameter, but occasionally they may be large.[4] Giant CMN is very rare, occurring in 1/20,000 to 1/500,000 newborns.[8] They are an important entity to recognize because potentially they can be associated with complications, such as developmental anomalies, neurocutaneous melanocytosis, melanoma, and psychosocial impairment.[9] The most recent consensus classification of CMN is based on several factors including the predicted adult size, the number of satellite lesions, the anatomic location, color heterogeneity, surface rugosity, presence of hypertrichosis, and presence of dermal or subcutaneous nodules.[10]

On the eyelid, lesions can vary in size, and the intensity of pigmentation can diminish during the first year.[11] Congenital melanocytic nevi occurring on the eyelid are uncommon.[12] They may be small and isolated only to the eyelid, or they can be large, extending to the adjacent periorbital or facial skin.[13,14,15] Large or heavy nevi on the upper eyelid can be associated with mechanical ptosis. On the lower lid, exophytic growth of the nevus may produce a warty excrescence that can cause secondary entropion.[12] Growth of eyelashes associated with CMN can be disorderly resulting in corneal abrasion.

(Print pagebreak 567)

For small-sized CMN, the risk of malignant transformation to melanoma is very rare,[16] estimated to be less than 1%, and it tends to begin at puberty.[8,17] But large and giant melanocytic nevi carry a greater risk during the first 5 years,[18] estimated to be 4.6% over 30 years.[9,19,20,21] But regardless of size, rapid growth, color change, nodular elevation, pain, or bleeding are worrisome and should prompt immediate evaluation.

Divided congenital nevus of the eyelids, also known as a kissing nevus, split ocular nevus, or panda nevus, was first described in 1919 by Fuchs.[22] This is a congenital compound nevus that affects portions of both the upper and lower eyelids. These nevi extend to the eyelid margins so that when the eyelid closes the two nevi touch, or “kiss.”[13] Kissing nevi arise during melanocyte migration from the neuroectoderm to the epidermis during the 12th to 14th-week stages of gestation. The nevus forms on the eyelids during the period of eyelid fusion.[23,24,25,26] During this period, the nevus is a single lesion overlying the zone of future eyelid separation that begins in the 20th to 24th week of gestation,[27,28] dividing the nevus into segments that lie on adjacent portions of the upper and lower eyelids.

Acquired melanocytic nevi (AMN) develop later in childhood, adolescence, or in adults most commonly in the 30 to 40 year age range. The major environmental risk factor for their development is exposure to sunlight.[29,30,31,32,33] Other risk factors include fair skin color, red hair, blue eyes, a tendency to freckle, and a propensity to sunburn.[33,34]

The risk of malignant transformation of AMN has been estimated to be 1 per 2000,[35,36,37] but the molecular events responsible for the progression from AMN to melanoma remain unclear. An increased risk for melanoma occurs in patients with more than 50 melanocytic nevi and those with clinically atypical nevi. Additional risk factors include a family history of melanoma, a history of excessive UV light exposure, and lightly pigmented skin with a tendency to burn.[38,39] In children with acquired nevi, the lifetime risk of transformation from benign nevus to melanoma is only approximately 1 in 10,000, with more than 50% of melanomas occurring de novo, on previously normal skin.[40,41] Children with a history of chemotherapy or other immunosuppressive medications, such as for organ transplantation, are also at increased risk of both irregular moles and melanoma.[42,43]

Melanocytic lesions of the conjunctiva include nevus, melanosis, intermediate melanocytic proliferations, and malignant melanoma,[44,45,46] of which the circumscribed nevus is the most common. They generally become clinically apparent in the first or second decades of life where 58% of cases are seen in pediatric and adolescent patients. Three-fourths of conjunctival nevi are of the compound type, with 24% subepithelial, 3% junctional, and 1% blue nevus.[45] Conjunctival nevi present as dwell-defined, variably pigmented, slightly elevated lesions that may become more pigmented over time.[45,46] They most commonly are located on the bulbar conjunctiva (60%-83%), followed by the caruncle (12%-29%), and the palpebral conjunctiva (1%-2%), and less than 1% may involve the cornea.[44,45,46] Less than 1% may transform into malignant melanoma.[45]

The common blue nevus is composed of melanocytes in the mid- and upper dermis. It is most common in children and young adults but can occur at any age.[3,47] They present most often as small, solitary, pigmented papules, plaques, or nodules with a dark-bluish or blue-black coloration.[48,49,50] The bluish color is caused by the Tyndall effect resulting from the scattering of the short-wavelength component of visible light by melanin particles. Blue nevi occur on any part of the body, including on the eyelid and conjunctiva.[51,52,53,54,55,56,57,58]

The cellular blue nevus is a variant of blue nevus composed of melanocytes with islands of neural crest-derived epithelioid and spindle cells that fail to complete their normal migration to the epithelium.[59,60] The most typical sites of occurrence are the dorsal aspects of extremities, scalp, and buttocks. Other locations include male and female genital tract, breast, subungual mucosa, eyelids, orbit, and conjunctiva.[61,62,63,64] It is seen in all age groups, but are most common in adults younger than 40 years.[65]

Spitz nevus, also known as spindle cell nevus, epithelioid cell nevus, and benign juvenile melanoma, is rare and diagnosed in only 0.5% to 1.0% of excised nevi in children.[3] Spitz nevi occur on the trunk, extremities, the lower face, and have rarely been described

in the eyelid,[66,67,68] or the conjunctiva.[69,70] It usually appears as a dome-shaped, hairless, small pink to lightly pigmented papule or nodule less than 1 cm in size.[4,66] These lesions may appear suddenly and undergo rapid growth, hemorrhage, and change of color or may cause pruritus.[71] They are more common in children, but can also be seen in adults. Spitz nevi are rare in black patients and more common in females, especially in patients older than 15 years.[72] Nonpigmented lesions predominate in the head and neck and pigmented ones in the lower extremities.[66]

The pigmented spindle cell nevus of Reed may be a morphologic variant of Spitz lesion with histologic features concerning for melanoma.[73,74,75] It is usually a small, rapidly growing, well-circumscribed, darkly pigmented lesion and has only rarely been reported on the eyelid[76] and conjunctiva.[77]

Etiology and Pathogenesis

Melanocytic nevi are benign clonal proliferations of cells that express a melanocytic phenotype.[78] They are a heterogeneous group of neoplasms with varying clinical and molecular features,[79] and they share associated mutations with melanomas. Congenital melanocytic nevi (OMIM #137500, 1p13) have been associated with mutations in proteins of the mitogen-activated protein kinase (MAPK) signal transduction pathway, particularly NRAS and BRAF, and a relationship between nevus size and the corresponding genetic mutation has been described.[79,80,81,82] Smaller congenital nevi more frequently have a BRAF mutation, but NRAS mutations are more frequently seen in medium and large nevi.[79,83,84,85,86] AMN and blue nevi also harbor oncogenic mutations in BRAF and NRAS, but Spitz nevi (OMIM #137550, 11p15) have been *(Print pagebreak 568)* linked to HRAS and BAP1 alterations and kinase fusions.[79] Most of the gene alterations associated with melanocytic nevi have also been described in the development of melanoma, but contrary to melanomas, nevi undergo senescence where the initial growth phase is followed by loss of proliferative activity and stabilization of size.[79] Therefore, at least some melanocytic nevi are likely benign clonal tumors that temporarily undergo proliferation through BRAF signaling followed by growth arrest.[87]

Not only do acquired nevi and melanomas share a common genetic basis, but they also share common environmental risk factors such as fair skin and a tendency to sunburn.[37,88] Also, 20% to 30% of melanomas arise from preexisting melanocytic nevi, emphasizing the genetic basis underlying both.[89]

Clinical Characteristics

Congenital melanocytic nevi appear at birth or within the first 6 months of life. They are generally small, initially flat with smooth to irregular borders, and can be pink, lightly pigmented or more darkly pigmented in shades of tan, brown, or black (Figures 86.1 and 86.2). They usually are not associated with telangiectasia, madarosis, or ulceration, which helps to distinguish them from some common simulating lesions. Most CMN are solitary, but they may be multiple or even confluent.[10] They may show heterogeneous pigmentation and sometimes develop coarse dark hair and become more elevated and rugose over time (Figure 86.3).[90,91] Rarely they can be flat and diffuse (Figure 86.3D). Occasionally, proliferative nodules may develop within the nevus.[92] Small satellite lesions can be present at birth or develop later in infancy or childhood. Occasionally, CMN may regress spontaneously,[93] sometimes preceded by the development of a local depigmented halo surrounding the lesion.[94]

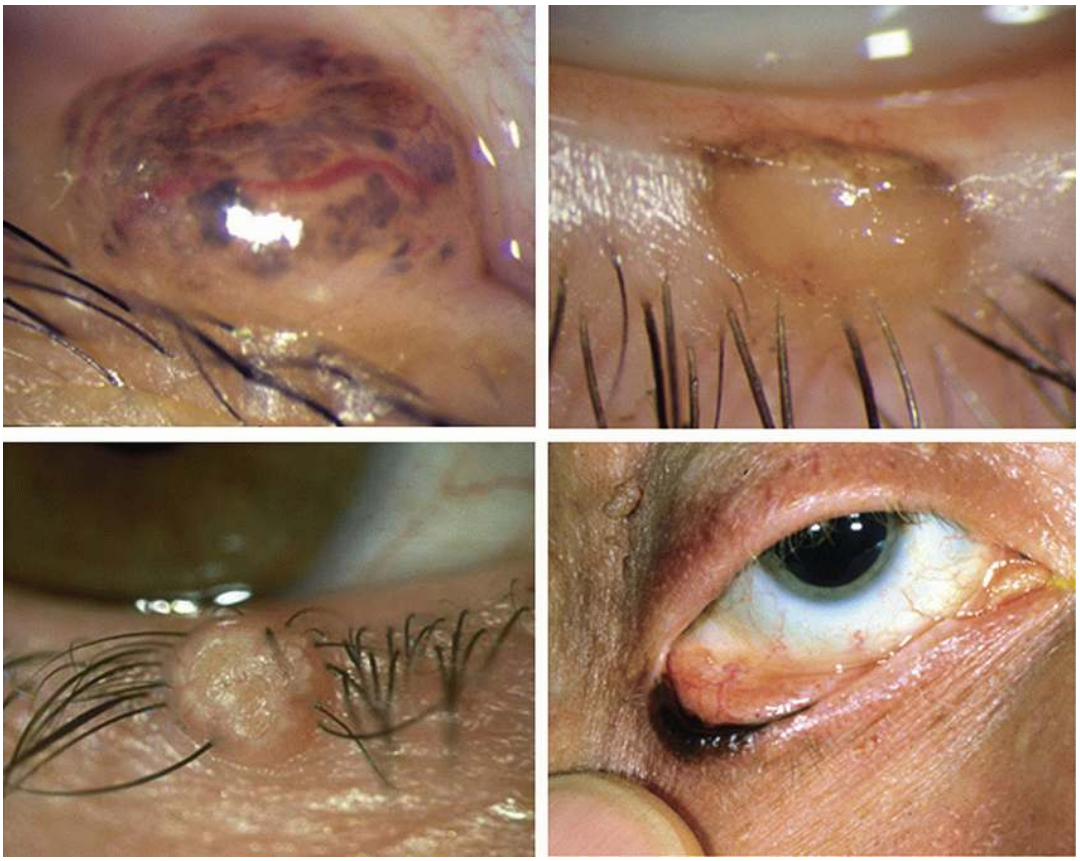

FIGURE 86.1 Marginal nevi along the cutaneous/conjunctival border.

Divided nevi span across the palpebral fissure and lie on adjacent portions of the upper and lower eyelids (Figure 86.4). They vary in size and may be small, located on the middle thirds of the eyelid margins, or they can be large, extending across the canthal angles onto the forehead, nose, or cheek.[95,96] Occasionally the bulbar conjunctiva may also be involved.[97]

(Print pagebreak 569)

FIGURE 86.2 A and B, Compound melanocytic nevi. C and D, Intradermal melanocytic nevi.

AMN usually appear during childhood, adolescence, or early adulthood, initially appearing as flat, smooth, light to dark brown macules, and less commonly black or flesh-colored lesions. They may be elevated in about 25% of cases and may be papillomatous or have a course rugose surface in 20% of lesions.[98] Most lesions begin as junctional nevi but later develop into compound nevi with a more nodular appearance. Lesions are often multiple, with about 39% located on the head and neck, and 39% on the trunk.[98] Most patients with acquired nevi have a Fitzpatrick skin type of III or IV.

Sun exposure represents an important environmental factor influencing the number and location of nevi that develop during childhood.[99] White children living in tropical climates tend to develop a greater number of nevi at an earlier age than those living in temperate locations.[40]

Cutaneous blue nevi present as a flat to slightly elevated, smooth macule or papule, with a gray, blue, or bluish-black color (Figure 86.5).[55,100] The blue appearance is due to the Tyndall effect, but the specific color is affected by the thickness and the depth of the lesion.[101] They frequently appear during the first and second decades of life, most commonly on the extremities, buttocks, scalp, and the eyelid margin.[52] Cellular blue nevi on the conjunctiva appear as black lesions with diffuse margins and may be unifocal or multifocal.[57,61,102,103]

Differential Diagnosis

The most important lesion in the differential diagnosis of melanocytic nevus is malignant melanoma. However, these are usually more often asymmetric, irregular in outline, with heterogeneous pigmentation, and may be associated with focal erythema, atrophy, or ulceration. Pigmented basal cell carcinomas tend to arise in older individuals, more often on the lower rather than the upper eyelid. They often have central ulceration with upraised telangiectatic margins. Pigmented apocrine hidrocystomas are usually restricted to the eyelid skin at or near the margins or the caruncle, have a smooth surface, and are compressible. Pigmented seborrheic keratosis (melanoacanthoma), actinic keratosis, and squamous papilloma can also be confused with melanocytic nevi. *(Print pagebreak 570)* Mucinous neuroendocrine carcinoma is another bluish-appearing lesion on the eyelid margin that can be confused with a blue nevus. Postinflammatory hyperpigmentation occurs after an inflammatory event, acne, or cosmetic surgery and is seen more commonly in patients with darker skin types. Other conditions in the differential diagnosis include iatrogenic pigmentation caused by drugs such as minocycline and tattoos.

Treatment

The management of small- and medium-sized CMN depends upon factors such as location, size, and aesthetic concerns.[104] Surveillance for changes in size, texture, shape, or color suggestive of malignant transformation is most important after puberty since the risk of melanoma in small nevi is extremely low before adolescence.[40] Sun protection should also be stressed in all patients with melanocytic nevi.

(Print pagebreak 571)

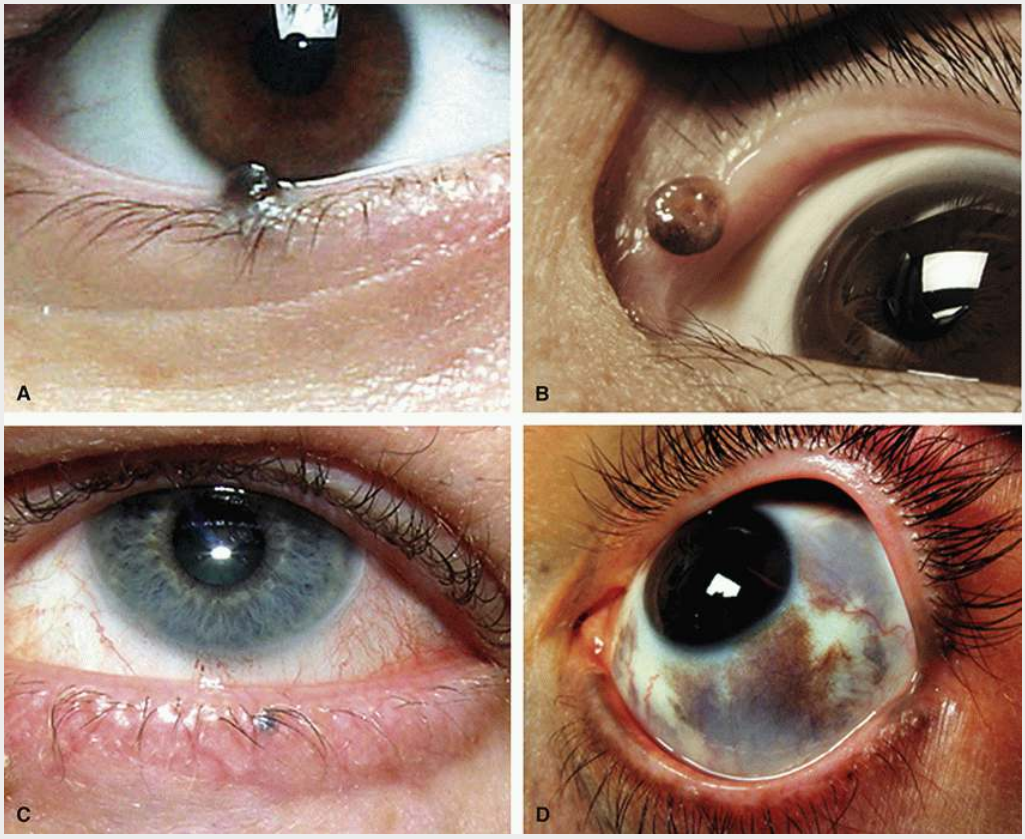

FIGURE 86.5 A-D, Congenital blue nevus of the eyelids. C and D, (Courtesy of Dr. Robert Goldberg).

Removal of melanocytic nevi at any age is indicated primarily for cosmetic concerns, and less frequently for worrisome changes in size, color, or progressive elevation. Depending upon size and location, the most common techniques have been surgery, laser therapy, and dermabrasion. Even though the goal of surgery is mostly for aesthetic improvement, some nevus tissue may have to be left behind to minimize any functional compromise to the eyelid margin. Small lesions can be excised with anterior lamellar skin resection with primary closure. Nevi involving up to one-fourth of the upper or lower eyelid margin can be excised with full-thickness wedge resection and primary layered repair. Larger eyelid resections, particularly in younger patients where there is no significant tissue laxity, may require more complex reconstruction techniques, including lid-sharing procedures. Nevi extending onto the forehead, temple, and cheek may require local flaps and skin grafts. It is important to understand, however, that more than half of cutaneous melanomas seen in these patients arise from previously normal skin and not from the transformation of benign nevi so that prophylactic excision of a nevus does not necessarily prevent a melanoma.

The Q-switched Nd:YAG laser is the laser of choice for the treatment of dermal and junctional pigmented lesions, especially in dark skin.[105] This laser targets melanosomes in melanocytes with an ultrashort pulse width and adjustable spot size.[106] The Q-switched Nd:YAG laser at a wavelength of 1064 nm is ideal for dermal lesions because of its deeper penetration and poor absorption by epidermal melanin.[105,107] Laser treatment of large nevi in the periorbital area has been suggested for the shallower, peripheral portions of the lesion to reduce it to a smaller size for surgical excision.[108]

Dermabrasion has been described as a treatment for a divided nevus that is limited to the superficial dermis.[109,110] Limited reports have shown that dermabrasion can result in an appreciable and stable reduction of hyperpigmentation, although many patients may still require reconstructive surgery to improve the aesthetic result.[111] However, when the deeper dermis or

subcutaneous tissue is involved, recurrence can be seen as quickly as 4 weeks after treatment.[13,112]

(Print pagebreak 572)

Prognosis

The prognosis for patients with melanocytic nevi of the eyelids is generally good and acceptable aesthetic results are often attainable. Lesions on the upper eyelid may cause mechanical ptosis with obstruction of the visual axis resulting in amblyopia in young children.[113,114] There is a risk of malignant transformation to malignant melanoma, particularly for large nevi with an average risk of 14% during a lifetime.

Histopathology

The histopathological features of melanocytic nevi of the eyelid skin and periocular region are similar to those occurring elsewhere on the body,[115] except for nevi at special sites that have site-related atypia (occurring on acral sites, genitalia, ears, scalp, breast, flexural skin, legs, back, and shoulder).[116,117] Melanocytic nevi are composed of nevus cells (nevomelanocytes), which are melanocytes[78] that have lost their long dendritic processes and are characteristically arranged in nests.[115,118,119] Epidermal nevus cells (type A melanocytes) are large and polygonal with eosinophilic cytoplasm, a variable amount of melanin, and sometimes form nests or clusters.[120] Upper dermis nevus cells (type A melanocytes) are large polygonal or oval cells with eosinophilic cytoplasm, a variable amount of melanin, and usually form nests or clusters surrounded by a reticulin network.[120] Cytoplasmic invagination into the nucleus often creates nuclear pseudoinclusions in dermal melanocytes,[121] but true inclusions are rare.[118] Nevus cells in the mid dermis (type B cells) are smaller than those in the upper dermis, melanin is rare, and the nevus cells may resemble lymphocytes.[120] Deep dermal nevus cells in the deep dermis tend to be smaller than those of the upper dermis, round or spindle-shaped, and only rarely contain melanin.[120] The fusiform nevus cells in the deep dermis (type C cells) may resemble fibroblasts or Schwann cells.[120] Goovaerts and Buyssens showed that the diameter and area of the nevus cell nucleus progressively decreased with the depth of localization of the cells, but there was no difference in size between cells in the epidermis and upper dermis or between cells in the middle and deep dermis.[120]

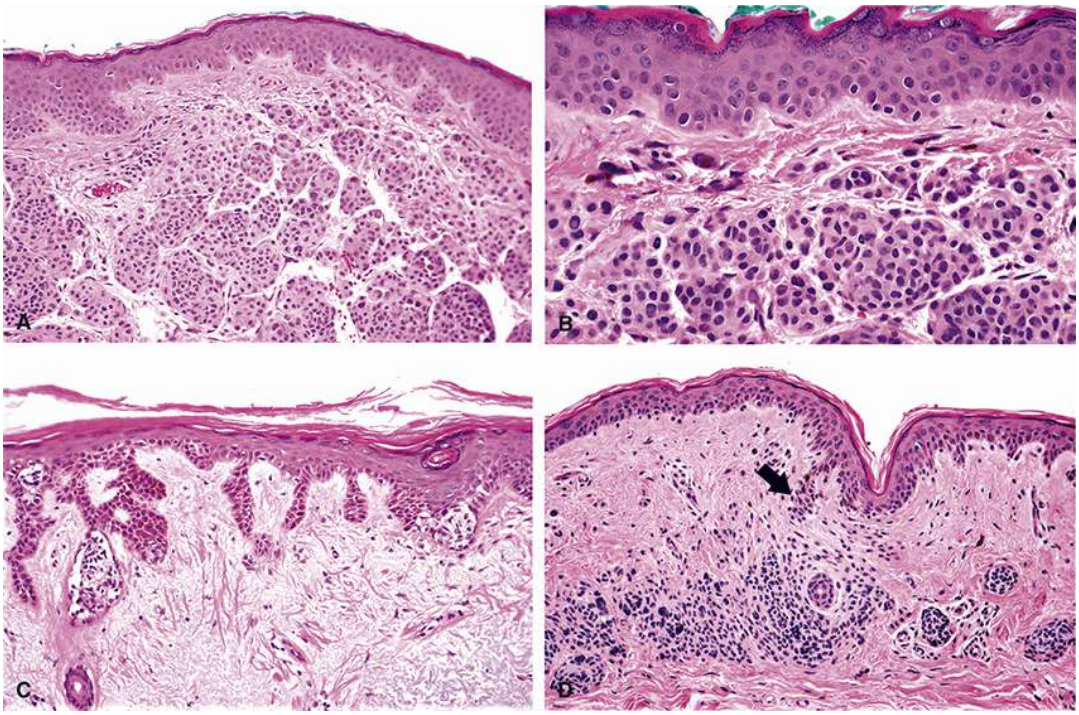

FIGURE 86.6 Common melanocytic (nevocellular) nevi are classified according to the location of nevus cells. A and B, Intradermal nevi are the most frequent nevus in the eyelid and feature nests and cords of nevus cells in the dermis separated from the overlying epidermis by an intact zone of dermal collagen. C, Junctional nevi have discrete nests of nevus cells at the junction of the epidermis and dermis, usually on the rete ridges, which often exhibit some elongation. Junctional nevi are very uncommon in the eyelid skin. D, Compound nevi have junctional (arrow) and intradermal nests of nevus cells.

The vast majority of cutaneous nevi of the eyelid are common melanocytic (nevocellular) nevi.[115,119,122] Intradermal nevi are the

most frequent nevus in the eyelid[115,119] and feature nests and cords of nevus cells in the dermis separated from the overlying epidermis by an intact zone of dermal collagen (Figure 86.6A and B).[115,118,119] Junctional nevi have discrete *(Print pagebreak 573)* nests of nevus cells at the dermoepidermal junction, usually on the rete ridges, which often exhibit some elongation (Figure 86.6C).[118] Compound nevi have both junctional and intradermal nests of nevus cells (Figure 86.6D). Junctional nevi of the eyelid skin are uncommon; only 4 of 839 eyelid melanocytic nevi (0.2%) in the study by Deprez and Uffer were junctional.[122] If a junctional nevus is present in initial sections, deeper sections often reveal compound nevi.[115,119] On the eyelid, compound and intradermal nevi may be keratotic[123] with a seborrheic keratosis-like appearance to their epidermis. Dysplastic nevi[124] of the eyelid are exceptionally uncommon in our experience, possibly due to nevi being removed early for cosmetic reasons. Dysplastic nevi accounted for only 4 of the 839 nevi (0.5%) in the study of Deprez and Uffer.[122]

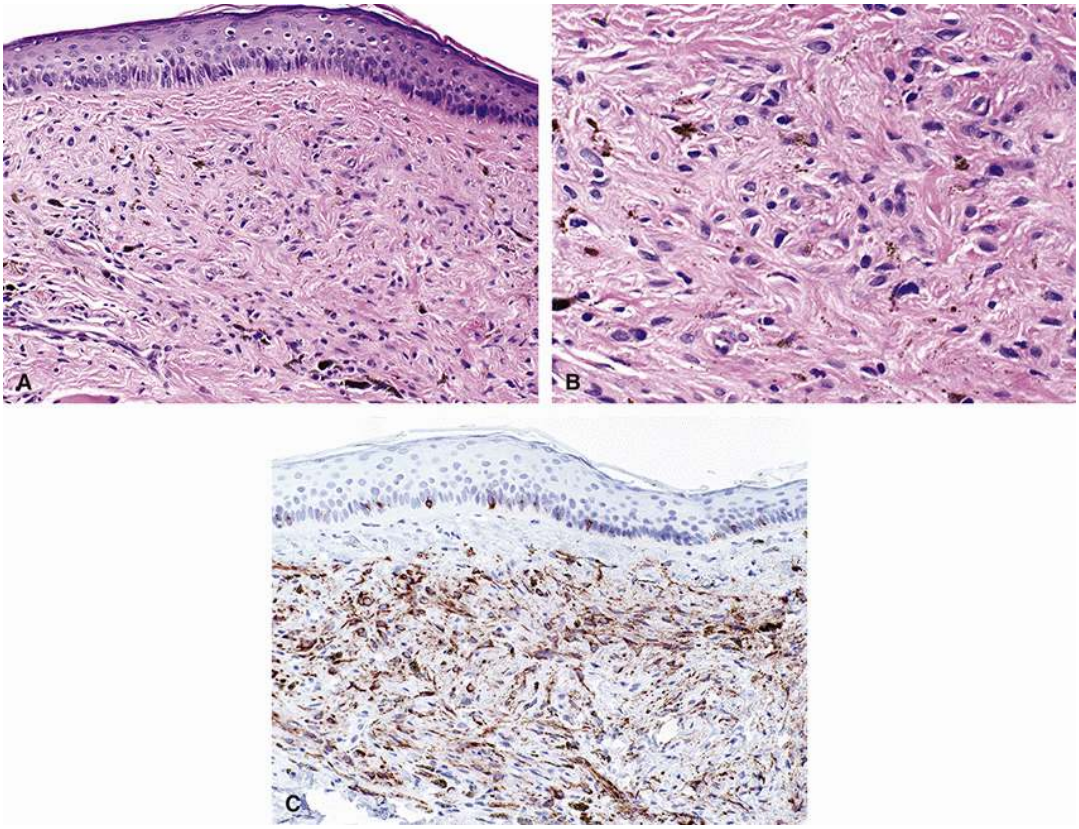

FIGURE 86.7 This common blue nevus was in the right lower eyelid of a man in his early 30s. A, The blue nevus has only scattered heavily melanin-laden spindle cells. There is a zone of normal dermis separating the blue nevus from the overlying epidermis. B, The melanin-laden spindle cells are intermixed with nonpigmented or minimally pigmented oval to spindle melanocytes. There is no cytological atypia or mitotic figures. C, An immunohistochemical stain using antibodies to MART-1 (Melan-A) highlights the spindle melanocytes comprising the common blue nevus. The presence of melanin-containing dermal melanocytes interspersed with the nonpigmented cells aids in differentiating lightly pigmented blue nevi from other spindle cell tumors such as dermatofibroma. Immunohistochemical stains using antibodies to melanocytic markers, such as MART-1, may be helpful to confirm the identity of lightly pigmented blue nevi.

Blue nevi are second in frequency to common melanocytic nevi in the eyelid skin, but they are uncommon, accounting for only 1.2%[115] to 1.5%[122] of eyelid skin nevi. The diagnostic cells in blue nevi are variably pigmented spindle-shaped dendritic melanocytes.[50,63,125] The cells are spindle-shaped, bipolar, dendritic cells thickest at their center and gradually tapering at both ends to a fine point; some have branching or dendritic processes.[126] The dendritic processes are seen best by staining with silver nitrate (Fontana-Masson stain).[126] Common blue nevi are usually in the lower two-thirds of the dermis, with a zone of normal dermis separating the blue nevus from the overlying epidermis.[126] The dendritic melanocytes are typically intermixed with elongated, oval to spindle melanocytes that resemble intermediate (type B) or deep (type C) dermal melanocytes of common (nevocellular) nevi.[50] Dendritic melanocytes are often only a minor component of a blue nevus (Figure 86.7).[50] Blue nevi lack significant cytological atypia or mitotic *(Print pagebreak 574)* figures.[50] Melanophages are present in varying numbers and are distinguished from the blue nevus cells by the absence of fine wavy bipolar dendritic processes.[126] Cellular blue nevus is a biphasic variant of blue nevus with varying proportions of classic (common) blue nevus and sharply demarcated cellular areas of spindled to oval melanocytes with clear, pale, or lightly pigmented cytoplasm.[50,63,125] The cellular areas are most often at the lesion base and extend into the deep reticular dermis and subcutaneous tissue, though sometimes the cellular areas are surrounded by classic blue nevus or form the bulk of the nevus.[50,125] Mitotic figures are usually absent or infrequent (<1 mitosis/mm^2).[127] The melanocytes in

all variants of blue nevus are usually positive for expression of HMB-45, SOX10, and Melan-A (MART-1; Figure 86.7C) but may be negative for S100 protein.[127,128] Eyelid cellular blue nevi are rare and may be confused histologically with melanoma.[56] Features that help to differentiate cellular blue nevus from melanoma are a low mitotic rate, absence of necrosis, a low Ki-67 proliferation index, and mostly uniform HMB-45 immunoreactivity.[56]

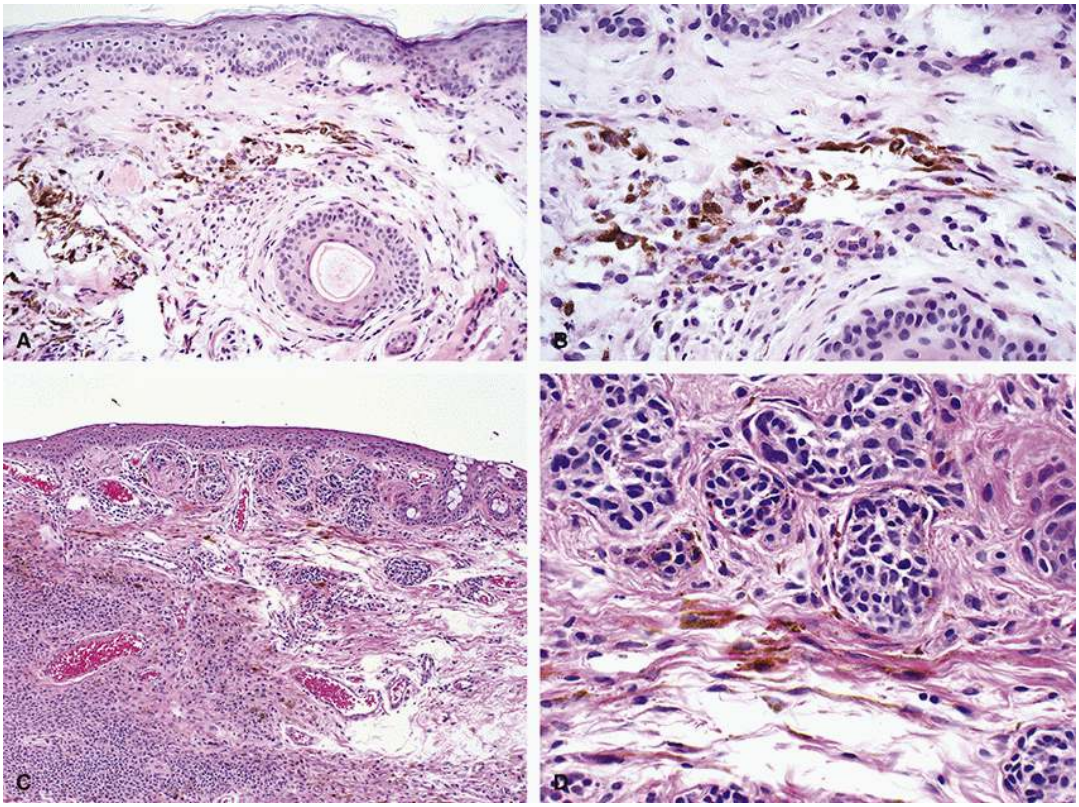

FIGURE 86.8 A and B, This combined nevus was in the central left lower eyelid of a man in his early 70s. The melanin-laden spindle blue nevus cells and nests of round to oval nevocellular nevus cells are easiest to discern at high magnification (B). C and D, This combined nevus arose in the right caruncle and plica semilunaris of a woman in her late 20s. The melanin-laden spindle melanocytes tended to be around the periphery of the round to oval nevocellular nevus cell nests.

Combined nevi feature two (or occasionally three) cytologically distinct populations of melanocytes in the same lesion[129,130,131] and may occur in the eyelid skin[122] or conjunctiva[45,55,132] (Figure 86.8). The two populations of nevus cells may be side by side or intermingled.[131] The most frequent combination is common nevus cells and spindle or dendritic blue nevus cells.[129,131] Pulitzer and coworkers found spindle cells to be more frequent than dendritic cells,[129] but Massi and LeBoit state "the dendritic cells of a 'common' blue nevus are far more often seen in combined nevi than are spindled blue nevus cells."[131] Other combined nevi are combinations of common nevus and Spitz nevus, common nevus and deep penetrating nevus, Spitz nevus and blue nevus, and common nevus and melanocytoma,[131] but we have not encountered any of these combined nevus types in our clinical practices.

(Print pagebreak 575)

Congenital nevi are mostly compound or intradermal but have varying histological appearances.[133,134,135,136,137,138,139] Mark and colleagues were the first to report differences between congenital (n = 60) and acquired (n = 60) melanocytic nevi in 1973.[133] They concluded that congenital nevi have three diagnostic features distinguishing them from acquired nevi: (1) Nevus cells were in the lower two-thirds of the reticular dermis in 59/60 cases and the fibrous septa and adipose tissue of the subcutis in 35/60 of the congenital nevi. Acquired nevi involved the lower two-thirds of the reticular dermis and subcutis in only 2 of 60 cases. (2) The most distinctive feature of congenital nevi was the permeation of nevus cells between collagen bundles of the lower reticular dermis as single cells or in a single file (Figure 86.9), while this was "virtually absent" in acquired nevi. In congenital nevi involving the fibrous septa and subcutaneous fat, the nevus cells occurred singly as single cells or in a single file. (3) In the lower two-thirds of the reticular dermis in congenital nevi, nevus cells involved arrector pili in 42/60 cases (Figure 86.9C), nerves in 28/60, sebaceous glands in 21/60, eccrine ducts in 14/60 (Figure 86.9C), hair follicles in 10/60, blood vessels in 8/60, and lymphatics in 4/60 cases. None of the acquired nevi had nevus cell involvement of appendages, nerves, or blood vessels in the lower two-thirds of the reticular dermis.[133] Subsequent studies confirmed the observations of Mark and coworkers but noted that some congenital nevi, especially those that are small,[134,136] are indistinguishable from acquired nevi.[135,140] For example, Everett reported *(Print pagebreak 576)* that all 9 congenital nevi <1.5 cm in diameter had nevus cells only in the papillary and upper reticular dermis, 9 of

21 nevi between 1.5 and 10 cm had nevus cells confined to the papillary and upper reticular dermis, but only one of 9 congenital nevi >10 cm in diameter exhibited that pattern.[136] Barnhill and Fleischli reported slight cytological atypia in 14.9%, slight to moderate atypia in 8%, moderate atypia in 4.6%, and severe atypia in 2.3% of 87 congenital nevi removed from infants 12 months of age or younger.[137] Simons and colleagues observed cytological atypia in 70% of 197 congenital nevi, with most having mild atypia.[139] Architectural disorder and pagetoid spread of nevus cells were present in 67% and 62% of congenital nevi, respectively.[139] Only 2/197 nevi had mitotic figures.[139] Atypia did not correlate significantly with nevus size in either study.[137,139] All 130 subjects with outcome data in the study by Simons and coworkers were alive and without a diagnosis of melanoma after a mean follow-up of 8.4 years (range 7 months to 21.3 years).[139] Congenital melanocytic nevi may also display proliferative nodules that are usually <5 mm in diameter.[141] The proliferative nodules are cohesive cellular aggregates in the dermis with higher cellularity and larger cells than the associated nevus.[141] The cells in the proliferative nodule blend with the adjacent nevus cells without an abrupt interface.[141] Proliferative nodules have little or no inflammation and lack necrosis unless ulcerated.[141] Proliferative nodules were present in 5% of the 197 congenital nevi studied by Simons et al, and none of the subjects developed a melanoma.[139] Other studies have noted proliferative nodules in 2.9% to 19% of giant congenital melanomas.[142] Proliferative nodules may exhibit atypia,[92] potentially causing difficulty differentiating them from melanoma.[142,143] Histological features that distinguish atypical from routine proliferative nodules are sharp demarcation, expansile growth that does not invade adjacent adnexal structures, effacement of the epidermis with loss of rete ridges, variable pleomorphism, and the presence of mitoses.[92] Both the Ki-67 proliferation index and phosphohistone H3 labeling index are significantly higher in atypical vs routine proliferative nodules, but these indexes are not significantly different between atypical proliferative nodules and dermal melanoma.[92] In lesions with numerous mitosis, histological features that help to distinguish an atypical proliferative nodule from a dermal melanoma are a destructive growth pattern with obliteration of local structures, ulceration, necrosis, uniform high-grade nuclear atypia, and the presence of atypical mitoses.[144,145] Reduced immunohistochemical expression of H3K27me3, a regulator of chromatin remodeling-controlled transcription, favors the diagnosis of nodular melanoma in congenital melanocytic nevi.[146,147] Despite the atypical features, there are no reported examples of metastatic disease arising from an atypical proliferative nodule.[92]

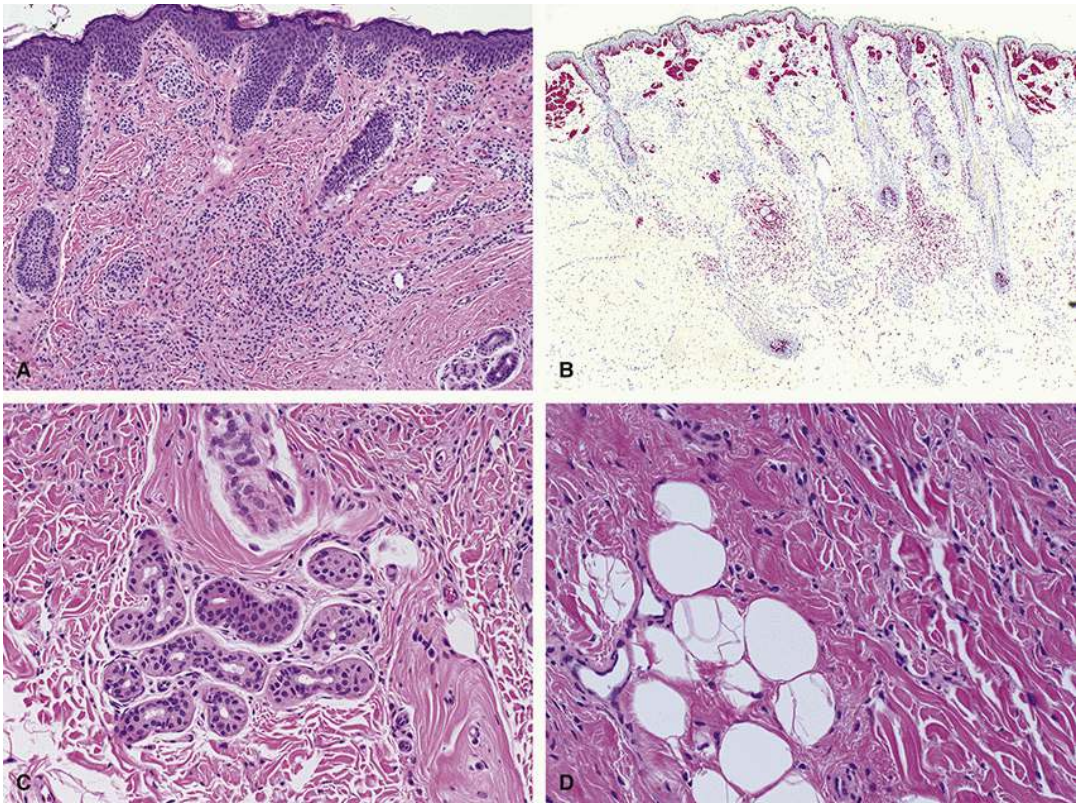

FIGURE 86.9 This congenital compound nevus from the right lower eyelid of a 3-year-old girl also involved the upper cheek. It was visible at birth and grew slowly larger and darker over the next 3 years. A, The compound nevus has small nests of nevus cells at the epidermal-dermal junction, in the papillary and superficial reticular dermis, and in the deep reticular dermis. In the deeper aspect of the lesion, the nevus cells percolate between collagen bundles as individual cells or in a single file. B, A section stained using antibodies to MART-1 shows the nevus cells extending into the deep reticular dermis. The superficially located nevus cells are nested, while those in the deep dermis form single files or occur individually. C, Nevus cells form single files between collagen bundles, insinuate into an eccrine lobule, and infiltrate an arrector pili muscle. D, Nevus cells form single files between collagen bundles in the deep reticular dermis.

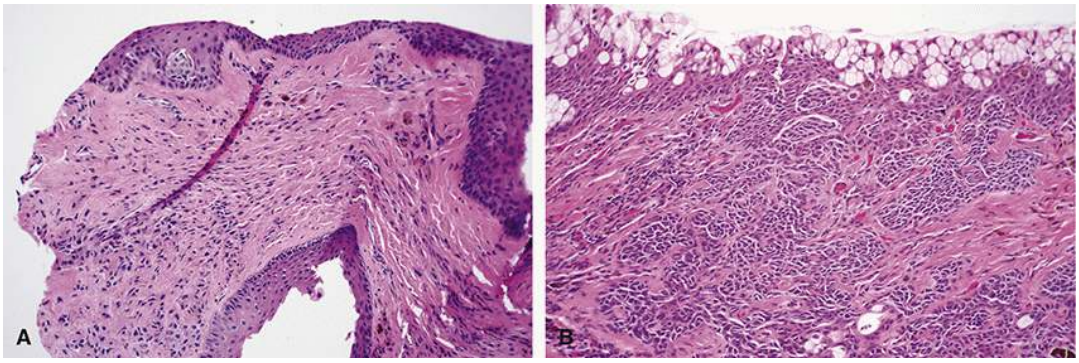

FIGURE 86.10 A, This compound combined conjunctival nevus is composed of a mixture of nevocellular nevus cells and spindle blue nevus cells. The nevus was present around the punctum of the right upper eyelid for 35 years before being biopsied due to a change in color over 8 months. The tissue was sectioned parallel to the epithelial surface resulting in epithelium on both sides of the substantia propria. B, This compound nevus involved the medial right lower eyelid conjunctiva in a child who had other nevi in the right caruncle and the right lower eyelid skin. The numerous goblet cells in the conjunctival epithelium result from the biopsy being from the medial lower eyelid.[150]

Conjunctival nevi rarely involve the eyelid.[45,148,149] Shields and coworkers noted only three nevi of the tarsal conjunctiva in 410 consecutive patients with conjunctival nevi (0.7%),[45] while Kim and colleagues identified four tarsal nevi in a pathology database of 116 cases of conjunctival nevi (3.4%).[149] In our practices, we identified four nevi involving the tarsal conjunctiva in a database of 297 conjunctival nevi examined pathologically (1.3%): two nevi (one compound nevus and one combined nevocellular and blue nevus (Figure 86.10A) arose adjacent to the lacrimal punctum on the eyelid margin; a subepithelial nevus arose on the margin of the right lower eyelid and involved both the skin and conjunctiva; and one compound nevus involved the medial right lower eyelid conjunctiva (Figure 86.10B).

CHAPTER 87

Milia

Key Points

- Milia are small, benign, superficial keratinous cysts that resemble miniature infundibular cysts on histopathology
- Congenital milia are common in newborns and present with a few or numerous lesions on the face, scalp, upper aspect of the trunk, and upper extremities, and tend to resolve spontaneously within weeks to several months
- Benign primary milia develop spontaneously and tend to be more persistent than congenital lesions, without spontaneous resolution
- Multiple eruptive milia occur spontaneously in very large numbers over weeks to months
- The etiology of milia remains controversial; some authors argue that they are retention cysts, and others argue that they represent a simple keratinizing type of benign tumor
- On the eyelids, milia appear as multiple unilateral or bilateral 0.5 to 2 mm, or sometimes larger white to yellowish, firm, asymptomatic papules or cysts on the upper or lower eyelids
- Conservative treatments include topical or systemic retinoids and oral minocycline
- For deeper dermal milia, electrodesiccation, dermabrasion, CO_2 laser ablation, and cryosurgery may be effective
- The prognosis is very good with most treatment options resulting in a reduction in lesion number with improvement in esthetic appearance

Milia are small, benign, superficial keratinous cysts that resemble miniature infundibular cysts on histopathology.[1] Hubler et al[2] followed the Epstein and Kligman[3] classification in dividing milia into primary spontaneous milia and secondary milia associated with various skin conditions or trauma, but they also proposed the additional term “milia en plaque” (MEP) for unusual cutaneous lesions consisting of multiple milia on an erythematous edematous base. Primary milia have been further classified into several different forms based on demographic and clinical characters. These are congenital, benign primary of children and adults, en plaque, and multiple eruptive milia.

Congenital milia are common in newborns. In various studies of cutaneous lesions in newborn infants with patient databases of 420 to 5387 infants, the incidence of milia was found to be between 7.5% and 36%.[4,5,6,7,8,9,10,11] Congenital milia present with a few or numerous lesions and most occur on the face, scalp, upper aspect of the trunk, and upper extremities. There are no significant racial or gender differences. Lesions tend to resolve spontaneously within weeks to several months.

Benign primary milia of children and adults develop spontaneously. Unlike congenital primary milia, they occur most often on the cheeks, eyelids, forehead, and genitalia, and lesions tend to be more persistent than congenital lesions, without spontaneous resolution.[1]

MEP is a relatively rare variant characterized by erythematous plaques containing numerous milia.[2,12,13,14,15,16] Lesions are generally unilateral, may be indurated, and are usually located on the head and neck, the periorbital region, the nasal bridge, or the trunk. MEP is more common in middle-aged adults with a female predominance.[1] It can be associated with pseudoxanthoma elasticum,[17] discoid lupus erythematosus,[18] lichen planus,[19] trauma, and renal transplantation,[20] but also arises in healthy individuals. Dogra et al[20] suggested that cyclosporine immunosuppression may predispose patients to MEP.

Multiple eruptive milia occur spontaneously in very large numbers.[21,22,23,24,25] Cases have been reported in patients from teens to old age, occurring most often on the head, upper trunk, and upper extremities. Lesions continuously erupt over weeks to months. Ratnavel et al[26] described a variant of eruptive milia restricted to the eyelids in a family over three generations.

Milia can be associated with several genodermatoses, rare inherited disorders with skin manifestations.[1] Bazex-Dupre-Christol syndrome (BDCS) is an X-linked dominant disorder consisting of congenital hypotrichosis, follicular atrophoderma, and basal cell carcinoma, and milia are seen in 75% of cases.[27] Rombo syndrome resembles BDCS with atrophoderma vermiculatum of the face, multiple milia, telangiectases, acral erythema, and a propensity to develop basal cell carcinomas.[28] Atrichia with papular lesions is an autosomal recessive disorder,[29] characterized by alopecia and widespread milia, especially on the cheek, scalp, elbows, and knees.[30] They tend to appear during the first decade of life and lesions may increase in number with age or partially regress.[31] Hereditary vitamin D-dependent rickets type IIA is an inherited disorder in which 50% of patients have milia on the face, scalp, and upper trunk, appearing in childhood. Basal cell nevus syndrome (Gorlin syndrome) is an autosomal dominant disorder characterized by numerous basal cell carcinomas, odontogenic keratocysts, rib abnormalities, abnormal facies, spina bifida occulta, calcified falx cerebri, comedones, palmoplantar pitting, chalazion, and cleft palate or lip. Milia occur in about 30% of patients,[32,33] mostly located in the periorbital region or on the forehead.

(Print pagebreak 581)

Secondary milia represent a localized form of milia that may be associated with systemic disease, medication, or trauma. Diseases reported with secondary milia include bullous pemphigoid, herpes zoster,[34] contact dermatitis,[35] bullous lupus erythematosus,[36] lichen sclerosus,[37] Stevens-Johnson syndrome,[38] bullous erysipelas,[39] bullous amyloidosis,[40] lichen planus,[41] leprosy,[42] pseudoxanthoma elasticum,[17] lupus erythematosus,[43] phototoxic reactions,[44] and allergic contact dermatitis.[45]

Several medications have been associated with secondary milia. These include sorafenib for the treatment of unresectable hepatocellular carcinoma,[46] benoxaprofen,[47] topical steroids,[48] 5-fluorouracil,[49] cyclosporine,[20] and penicillamine.[50]

Superficial trauma is a common cause of secondary milia in children. Other traumatic injuries causing secondary milia include dermabrasion,[51] radiotherapy,[52] chemical peels,[53] skin grafts,[54] and ablative laser therapy.[55]

Milia have been reported to occur within tattoo pigments.[56] They can occur weeks to months following placement of the tattoo but have also even been reported within long-standing tattoos. There is usually no accompanying history of other trauma. Lesions typically manifest as asymptomatic small, yellowish to white papules but can also be pruritic. The pathogenesis of tattoo-related milia remains unknown.[57]

Etiology and Pathogenesis

The etiology of milia is not clear. Primary milia are situated within the undifferentiated sebaceous collar that surrounds vellus hair follicles.[3] They are thought to be derived from the lowest portion of the infundibulum of vellus hairs at about the level of the sebaceous duct.[58] Secondary milia may develop from any epithelial structure, such as a hair follicle, sweat duct, sebaceous duct, or epidermis.[37,59,60,61,62,63,64] Sweat duct milia represent the majority of all secondary milia and have been widely believed to be retention cysts of eccrine origin following an injury to the skin.[65,66,67] However, the etiology of milia remains controversial, and some authors have argued that milia are not retention cysts, but rather represent a simple keratinizing type of benign tumor.[3] Honda et al[58] examined milia specimens and found them to consist of an epithelial cyst filled with a lamellated keratinous mass. In some specimens, the cyst opened to the skin surface (incomplete milia), but in others, the cyst was not connected with the overlying epidermis (complete milia). In both incomplete and complete milia, the cyst wall was composed of three or four layers of epithelial cells. An eccrine duct penetrated into the cyst wall at the center of its base, forming a circular path within the wall, and opening into the inner cavity. This circular path of the eccrine duct within the cyst wall suggests an acrosyringeal (that part of the eccrine duct that spirals through surface epidermis) origin of milia. The authors proposed that an incomplete milium is the result of a fusion between cells derived from an eccrine duct and those derived from the surrounding epidermis, while the formation of a complete milium does not involve this fusion.[58]

FIGURE 87.1 Milia involving the upper and lower eyelids.

Clinical Characteristics

On the eyelids, milia appear as multiple tiny, 0.5 to 2 mm, white to yellowish, firm, asymptomatic papules or cysts (Figure 87.1).[12,13,14,15,26,68,69,70,71,72,73] They may be unilateral or bilateral and can involve the upper, lower, or both eyelids. The appearance of lesions is gradual over months to years. There is usually no history of trauma, or skin manipulation such as surgery or dermabrasion, or of drug use. Affected patients generally are in their teens to middle age, and there is a slight predominance of females.

Differential Diagnosis

The differential diagnosis for milia includes multiple trichoepitheliomas, fibrofolliculomas, eccrine hidrocystomas, and syringomas. Trichoepithelioma is inherited in an autosomal dominant manner and presents as multiple translucent *(Print pagebreak 582)* yellow or pink nodules on the cheeks, eyelids, and nasolabial folds.[74] Multiple fibrofolliculomas may also be autosomal dominantly inherited and usually appear as yellow or flesh-colored papules on the face, forehead, or neck.[75] Both are distinguished from milia by histopathology.

Eccrine hidrocystomas can be solitary or multiple. They typically are dome-shaped, have a clear amber or bluish color, and range from 1 to 6 mm in diameter.[76,77] They are not located on the eyelid margins but can be seen on the pretarsal and preseptal eyelid skin and may increase in size during warm summer months.[78] Syringomas typically appear as soft to firm, skin-colored, yellowish, or translucent, dome-shaped papules 1 to 3 mm in diameter.[79,80] Lesions can occur at any age, but the age distribution shows a bimodal peak in the third and fifth decades.[81] Lesions most commonly occur on the face, eyelids, armpits, abdomen, chest, extremities, and genitalia.

Treatment

Conservative treatment options for milia include topical or systemic retinoids,[82] or oral minocycline but all options show variable success with a high incidence of local recurrence after discontinuation of therapy. Superficial milia tend to respond better to these conservative measures and to manual expression. Periocular superficial milia have also been reported to respond to manual expression either alone or in combination with oral minocycline 100 mg/d for 2 to 3 months.[12,16,73] However, manual expression is rarely effective for milia located in the mid-to-deep dermis.

For milia located in deeper dermal layers, invasive methods such as electrodesiccation, dermabrasion, CO_2 laser ablation, and cryosurgery have been described to be effective in the literature.[71,83,84] However, all of these options are associated with an unpredictable risk of mechanical or thermal injury, pigmentary changes, and scarring to the eyelid margins and other structures such as the lacrimal puncta.[85,86] The erbium:YAG laser offers an alternative tissue ablative option with less thermal damage to surrounding tissue and can reduce the risk of scarring compared to CO_2 laser.[68,87] Photodynamic therapy with 20% topical aminolevulinic acid has resulted in partial remission of MEP.[13] Radiosurgical destruction of small superficial cysts has been successful and causes less collateral tissue damage than electrodesiccation.[88,89] While this can reduce the number of milia and improve the esthetic appearance, it does not result in complete remission.

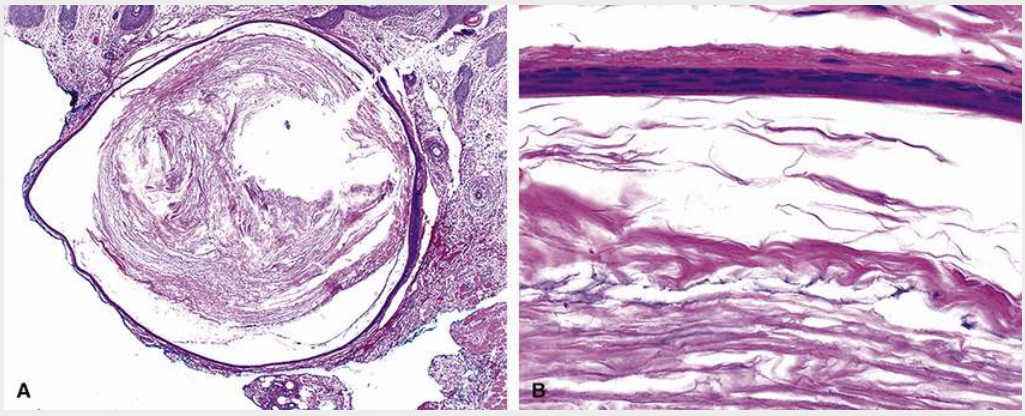

FIGURE 87.2 A, This eyelid milium was an incidental finding in an excision of a right lower eyelid seborrheic keratosis. The milium resembles a miniature epidermoid cyst in the superficial dermis. B, The epithelial lining is

thin and resembles that of an epidermoid cyst with keratinized, stratified squamous epithelium and prominent keratohyaline granules in the cells nearer the cyst lumen. Laminated keratin fills the cyst lumen.

Inconsistent response has been reported with topical tretinoin.[2,90] Oral etretinate 50 mg/d for 3 months followed by 10 mg every other day for 11 months was reported to decrease the number of milia but did not result in complete remission.[82]

Prognosis

In general, the prognosis for milia is very good with most treatment options resulting in a reduction in lesion number with improvement in esthetic appearance and a relatively low recurrence rate. Complete resolution is often not possible with more conservative modalities, but more aggressive therapies carry a risk of scarring or pigmentary changes.

Histopathology

Milia are miniature epidermoid cysts present in the superficial dermis, usually measuring 1 to 3 mm in diameter.[91] As with epidermoid cysts, the lining is keratinized, stratified squamous epithelium, and keratohyaline granules are often prominent in the cells nearer the cyst lumen.[92] Laminated keratin fills the cyst lumen (Figure 87.2).

CHAPTER 88

Molluscum Contagiosum

Key Points

- Molluscum contagiosum (MC) is a benign viral infection found more commonly in warm, moist climates
- It is transmitted from one host to another by direct contact with infected skin or through fomites on clothing or towels
- MC is caused by a large double-stranded DNA virus, a member of Poxvirus
- Eyelid lesions typically present as asymptomatic, single or multiple, firm, dome-shaped, pink, or flesh-colored papules with a central area of umbilication that range in size from 2 to 6 mm, although lesions as large as 1.5 cm have been described
- MC lesions are usually self-limited and will resolve over 6 to 9 months if left untreated in immunocompetent hosts
- Treatment with topical preparations have been advocated, including retinoids, salicylic acid-lactic acid, and imiquimod
- No single intervention is completely effective, but most patients can achieve resolution of a high proportion of lesions

Molluscum contagiosum (MC) is a benign viral infection characterized by flesh-colored, dome-shaped papules on the skin or mucous membranes. It was first described in 1811 by Thomas Bateman.[1] In 1841, Henderson[2] and Paterson[3] in separate papers described intracytoplasmic inclusion bodies, referred to as molluscum bodies or now often referred to as Henderson-Paterson bodies, that distinguish these lesions histologically.

MC infection is very common, often cited to occur in between 2% and 8% of the population.[4] However, more recent studies based on serology testing suggest a much higher infection rate in Australian and European healthy populations ranging from 14.8% to 30.3%.[5]

The virus is found more commonly in warm, moist climates worldwide[6] and is transmitted between individuals by close physical contact.[7] It most often affects children, immunosuppressed individuals, and sexually active adults.[6,8] In immunosuppressed individuals, the disease is typically more extensive.[6] Rarely, vertical transmission can result in congenital MC.[9,10]

MC is transmitted from one host to another by direct contact with infected skin or through fomites on clothing or towels,[11] and it can even be transmitted from contact sports.[12] The average incubation time is between 2 and 7 weeks but can be as long as 6 months.[13] Individual lesions are mostly 2 to 5 mm in diameter with a central umbilication, and papules usually occur in clusters. Swimming has been associated with a higher risk of developing MC.[14] Among children, the risk of MC among swimmers is nearly twice that of nonswimmers,[15] and the risk for children who swim frequently is about twice as high as the risk for those who use swimming pools infrequently.[16]

Several studies in Europe and the United States have reported an association between atopic dermatitis and MC ranging from 18.2% to 43%.[17,18,19] However, a prospective observational pediatric study in Brazil found no relationship between MC and the development of atopic dermatitis.[20]

The eyelid is the most commonly involved ophthalmic site,[21] but conjunctival lesions also have been described,[22,23,24] and a case of intraocular MC was reported following a corneoscleral laceration.[25] Eyelid lesions are often associated with chronic conjunctivitis or keratitis.[26,27]

Etiology and Pathogenesis

MC is a contagious viral skin infection caused by the MC virus. This is a large double-stranded DNA virus, a member of the Poxvirus family.[28] There are four subtypes of the molluscum contagiosum virus (MCV-1, MCV-2, MCV-3, and MCV-4), based on

genetic polymorphisms, but their clinical manifestations are all similar.[29] MCV-1 is the most common genotype seen in 75% to 96% of cases.[11,30,31] The MCV is distinct from other poxviruses and is specialized to infect human skin, both because of its growth habit and its ability to evade local immune defenses.[31] The virus propagates in differentiating cells of the human epidermis but does not cross the basement membrane, thus avoiding immune surveillance that would otherwise cause a systemic immune response. Free virus cores have been found in all layers of the epidermis, and the molluscum bodies contain large numbers of maturing virions. These are intracellular collagen-lipid-rich saclike structures that are thought to deter immunological recognition by the host.[32]

Clinical Characteristics

In children, the most commonly affected sites are the trunk, extremities, genitals, and face.[33,34] Involvement of the oral mucosa is also seen but is rare.[35] In adults, lesions are more often located on the lower abdomen, thighs, genitals, and perianal area,[36] reflecting the common mode of acquisition *(Print pagebreak 586)* through sexual contact.[37] Less common sites include the areola, eyelids, and fingers. MC rarely involves the mucosa of the lips,[38] buccal mucosa,[39] and conjunctiva.[40] In immunosuppressed patients, lesions may be more extensive, larger, and more refractory to treatment.[41,42,43]

Eyelid MC typically presents as asymptomatic, firm, dome-shaped, pink, or flesh-colored papules (Figure 88.1). They may be single or multiple (Figure 88.2), occur on the upper or lower eyelid or both, and range in size from 2 to 6 mm, although lesions as large as 1.5 cm in diameter have been described (Figure 88.3).[44] When multiple, the number of individual lesions on any individual is generally fewer than 20 in immunocompetent hosts, but occasionally can be more than 100.[45] MC papules contain a white, waxy curd-like core and a central area of umbilication is a distinguishing feature. But, in some lesions, the umbilication may not be visible. Occasionally, lesions can be pruritic, tender to touch, or even painful. A case of MC papule has been associated with a cutaneous horn.[46] Several cases of eyelid MC with secondary infection, abscess, and cellulitis have been reported.[47,48,49] Rarely, MCV lesions occur on the conjunctiva.[23,50,51] MC infects patients at all ages from early childhood to old age, but 65% of cases are aged 40 years or younger, with a mean age of about 30 years.[52] Females represent slightly more than half of the reported cases. In immunocompromised hosts, lesions may be very numerous, very large, and confluent.

FIGURE 88.1 A-D, Solitary, dome-shaped, umbilicated molluscum lesions of the eyelid. (B, Courtesy of Dr. Mohammad Javed Ali; D, Courtesy of Dr. Alan McNab.)

Recently, Rosner and Zloto[53] proposed a classification of periocular MC based on six different presentations. These are (1) umbilicated nodular; (2) big/giant; (3) conglomerated; (4) erythematous; (5) inflamed; and (6) pedunculated. The umbilicated nodular type is the most common,[21] seen in nearly 66% of cases.[53] This type may be singular or multiple, present at any age, and

appear as white, pink, or flesh-colored, dome-shaped nodules with a central umbilication. The upper eyelid is more commonly involved, and lesions are usually unilateral, but occasionally can be bilateral. The inflamed type of MC lesion is reddish, tender, erythematous, and umbilicated with an inflammatory reaction.[47] Big MC are lesions between 5 and 10 mm in diameter, and giant MC are larger than 10 mm.[44] They are more common in children 1 to *(Print pagebreak 587)* 5 years of age and in immunocompromised adults. Lesions are white, pink, or flesh-colored, dome-shaped nodules with no central umbilication.[53,54] The erythematous presentation of MC appears with extensive erythema and surrounding scaling.[53,55] The conglomerated type is not umbilicated so that the diagnosis is more difficult. Lesions are well-demarcated, white, sessile, and papillomatous aggregates of multiple microscopic MC nodules. The pedunculated type of MC is rare and protrudes like squamous papilloma.[25,52]

Differential Diagnosis

MC usually can be identified as a small nodule with a unique central umbilication. However, some lesions may not have a well-defined umbilication, and others, especially larger ones, can have varied presentations that make initial diagnosis more difficult, so that pathologic examination may be necessary for a diagnosis.[13,56] The major lesions in the differential diagnosis of MC lesions must include benign adnexal tumors such as verruca vulgaris, syringoma, condyloma accuminata, papilloma, epithelioma, juvenile xanthogranuloma, epidermal inclusion cyst, papular granuloma annulare, keratoacanthoma, and lichen planus; infectious lesions

such as varicella, herpes simplex, cutaneous cryptococcosis, and coccidiomycosis; and some malignant tumors such as basal cell carcinoma.

Treatment

MC lesions are usually self-limited and will resolve over 6 to 9 months if left untreated in immunocompetent hosts so that observation is appropriate in most cases.[57] In immunocompromised hosts, however, lesions may persist for several years. When patients desire removal, there are several options available that can speed resolution. Many publications have suggested the efficacy of various treatment modalities for MC, but most reports have been small with methodological shortcomings so that there is little clear evidence for or against the most commonly used treatment options for MC.[57]

A number of topical preparations have been advocated for the treatment of MC that can be used by patients at home. A preparation of povidone-iodine (PVP-I)/dimethyl sulfoxide gel comprising 2% PVP-I in a dimethyl sulfoxide vehicle preparation was reported to achieve complete resolution in 8 (67%) of 12 patients and partial resolution in the rest.[58] Hydrogen peroxide has antimicrobial properties possibly associated with its oxidizing ability. Topical preparations of 5% to 10% have been effective in the treatment of MC lesions.[59,60] In a study of 21 immunocompetent children who were treated with hydrogen peroxide 1.8% cream applied twice daily for 21 days, 3/21 children showed complete remission of lesions, and in 18/21 children, there was a 37.8% reduction in the number of lesions.[61]

(Print pagebreak 588)

Retinoids act by their ability to control abnormal growth and differentiation of keratinocytes.[62] Several randomized controlled trials comparing topical tretinoin cream 0.05% with hydrogen peroxide[63,64] suggested that both agents reduced the number of MC lesions after 4 weeks of treatment, although the rate of resolution was slower with tretinoin.[65]

Topical salicylic acid-lactic acid 16.7% combination solution was reported to be equally effective as 10% hydrogen peroxide with 83% complete remission of MC lesions over 6 weeks, although 35% also acquired new lesions during this period.[66] A solution of 5% podophyllotoxin cream has also been used for MC, showing a 92% rate or lesion resolution in as little as 3 days with no recurrence after 9 months.[67] But its use is contraindicated during pregnancy.

Oral cimetidine is a histamine 2 receptor antagonist that stimulates delayed-type hypersensitivity. Significant clearance of lesions has been reported in patients treated with a 2-month course,[68,69] and successful treatment has been seen in cases of severe MC infections.[70]

Imiquimod is a toll-like receptor 7 agonist capable of immune modification. It acts by stimulating an immune response via cytokines such as interferon-alpha, interferon-gamma, interleukin-12, interleukin-8, and tumor necrosis factor.[71] Topical imiquimod 5% cream has been reported to be effective for MC.[72,73] In a study of imiquimod 5% cream three to five times per week for 12 weeks for MC on the head and neck, extremities, trunk, and genitals in immunocompetent children aged 2 to 12 years old, 91.8% showed complete clearance in 6 to 12 weeks. Results were slower than with cryotherapy, but eventually equally effective with less pain and better cosmetic acceptance.[74,75] More invasive treatments include some degree of mechanical ablation of MC lesions.

Curettage involves removal of the epithelial surface of the papule with a needle and scraping away the viral core.[76,77] Side effects include pain, bleeding, and occasionally infection. But the recurrence rate can be as high as 66% over 4 to 8 weeks.[78] Cryotherapy is equally effective as imiquimod or hydrogen peroxide in clearing MC les ions,[74,79,80] but it is usually associated with pain, bleeding, dyspigmentation, and blistering at the freeze site. Pulsed dye laser has been used to effectively and safely treat MC.[81,82,83] Complications include pain, erythema, pigmentary changes, and occasionally atrophic scarring and ulceration.

Immunocompromised patients often have lesions that are resistant to standard therapies,[84] although in HIV-positive patients lesions may resolve after highly active antiretroviral therapy.[85,86] For resistant lesions, combined treatment involving several different modalities may be beneficial.[87,88] In immunocompromised patients with severe infections recalcitrant to standard treatment, it may be necessary to discontinue immunosuppressive therapy.[89,90] Cidofovir, an antiviral nucleoside analog of deoxycytidine monophosphate, has been reported to be effective for giant MC lesions in immunocompromised patients.[91,92,93]

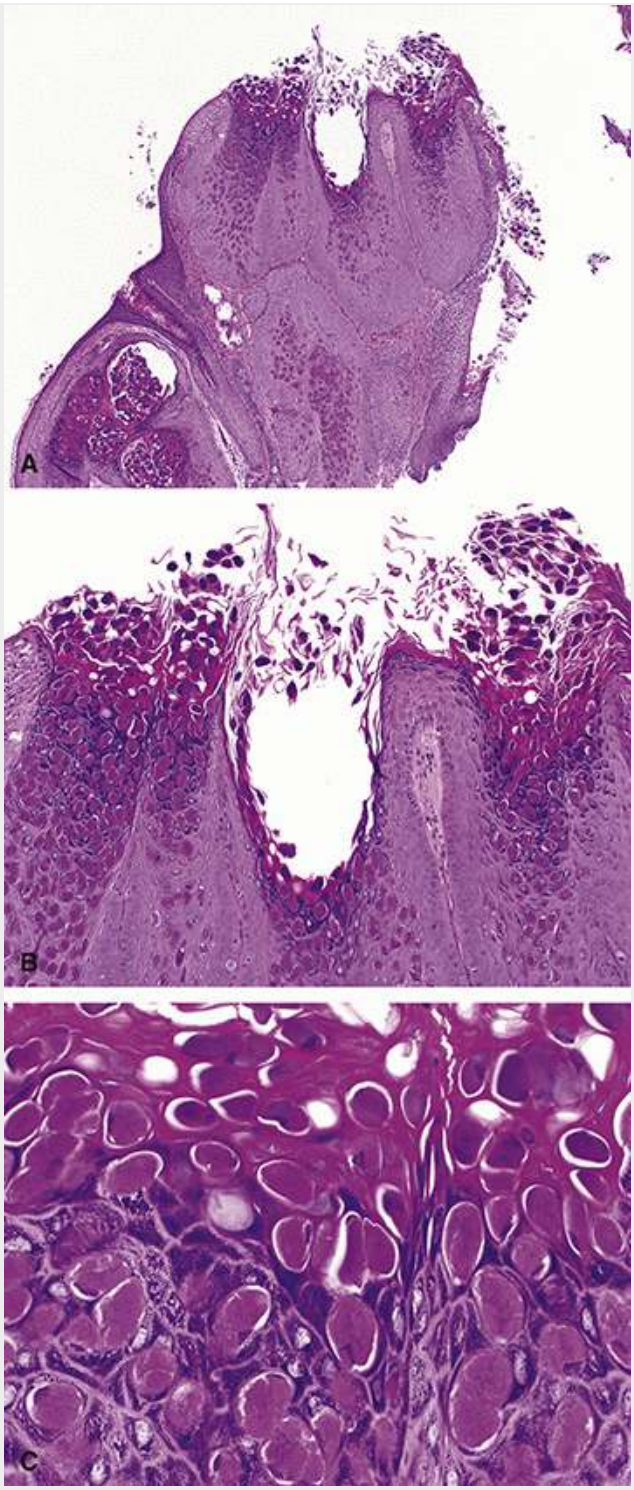

FIGURE 88.4 A, This eyelid molluscum contagiosum shows the characteristic lobules of hyperplastic squamous cells expanding into the underlying dermis with fine septa of dermis between lobules. Keratinized debris and viral inclusion bodies are being discharged onto the skin surface through a dilated ostium. B, Close-up of the ostium showing the keratin debris and molluscum bodies being discharged. Molluscum bodies are eosinophilic but may become basophilic near the skin surface, as seen in this case. C, Molluscum bodies may occupy almost the entire cell with compression of the nucleus toward the periphery of the cell.

(Print pagebreak 589)

Prognosis

MC is a benign lesion that generally is self-limiting. The average duration of a single lesion is about 2 months,[94] but because the virus spreads by autoinoculation following scratching or trauma, the infection may persist for 8 to 12 months or even longer.[95]

Topical therapies can be effective in eradicating lesions, but their action is usually slow. Mechanical ablative treatments give more rapid results but can cause pain, hyperpigmentation or hypopigmentation, and scarring. While no single intervention is completely effective or acceptable to all patients, most can achieve complete clearance of the lesions, although recurrences may occasionally be observed after complete lesion eradication.

Histopathology

Cutaneous lesions of MC have lobules of hyperplastic squamous cells that expand into the underlying dermis (Figure 88.4A).[2,3,96,97,98,99,100] Fine septa of dermis separate the lobules. Keratinized debris and viral inclusion bodies are discharged from the lobules into dilated ostia leading to the skin surface (Figure 88.4A and B).[2,3,96,97,98,99,100] Infected cells are recognizable by cytoplasmic molluscum bodies that begin to form in keratinocytes just above the cells at the margin of the lobule (termed "the basal layer").[99] Molluscum bodies progressively enlarge toward the center of the lobule or ostium, where they may occupy almost the entire cell (Figure 88.4C).[3] Inclusion bodies are eosinophilic but may become basophilic near the skin surface (Figure 88.4B).[98] Whether the primary site of cutaneous infection is the epidermis or hair follicles has been debated for over a century,[96,97] and infection may likely begin at either site either directly[96] or by follicular neogenesis.[101] The stroma surrounding the infected lobules is edematous or myxoid in about one-half of the cases[102] and may rarely be inflamed.[103]

Shedding of viral particles into the conjunctiva from a molluscum lesion on the eyelid margin may result in follicular conjunctivitis,[104] manifest histologically as lymphoid follicles in the substantia propria of the conjunctiva. In conjunctival lesions, the epithelium is thickened, and molluscum bodies lie within the epithelial cells.[104,105]

CHAPTER 89

Mucormycosis

Key Points

- Mucormycosis is a rapidly progressive angioinvasive infection in immunocompromised patients
- It is caused by saprophytic fungi of many genera related to Phycomycetes (Zygomycetes) of the order Mucorales
- Mucormycosis may affect the pulmonary, rhinocerebral, gastrointestinal, cutaneous, or the central nervous systems
- Primary cutaneous mucormycosis is the least common form, often secondary to direct skin trauma most frequently on the face and extremities
- The gold standard for treatment is aggressive surgical debridement of infected necrotic tissues with adjunctive intravenous antifungal therapy and management of predisposing factors
- The prognosis for patients with rhino-orbito-cerebral mucormycosis, in general, is poor

Mucormycosis is an angioinvasive infection that causes a rapidly progressive invasive disease in immunocompromised patients, particularly those with poorly controlled diabetes, hematologic malignancy, posttransplant status, and iron overload states.[1] It is caused by saprophytic fungi of many genera related to Phycomycetes (Zygomycetes) of the order Mucorales,[2] which are ubiquitous in the environment. The first cases of pulmonary mycosis caused by mucor were presented by Cohnheim in 1865[3] and mucormycosis was later described by Paltauf in 1885[4] based on the findings of focal mucor lesions in the brain, lungs, pharynx, and ileum of a 52-year-old patient.

Although most cases of mucormycosis are seen in patients with unregulated diabetes mellitus, the number of these cases has been decreasing. Over the past several decades, there has been an increase in mucormycosis among immunocompromised patients, particularly among transplant patients.[5,6,7,8] Studies have indicated that 1% to 3% of bone marrow transplant patients present with mucormycosis.[6,8,9] The incidence of mucormycosis in adult leukemia patients was reported at around 2%.[10] Leukemia patients who have developed neutropenia are particularly susceptible to mucormycosis.

The annual incidence of mucormycosis in the general population is estimated to be 1.7 cases for every 1 million individuals in the United States or approximately 500 affected individuals per year.[11] Nosari et al[12] felt that this is likely to be an underestimate because a large number of cases remain undiagnosed due to the low rate of antemortem diagnosis (23%-50%) and the decline in autopsies over the years to less than 5% today.[13,14,15,16]

Mucormycosis has been classified according to the anatomic sites of involvement. These include rhino, maxillary, orbital, central nervous system, cutaneous, pulmonary, disseminated, and miscellaneous,[17] and the site depends on whether the fungal spores are inhaled, ingested, or inoculated.[18] The most common sites for involvement are the paranasal sinuses (39%), lungs (24%), skin (19%), brain (9%), and gastrointestinal tract (7%).[19]

Mucormycosis in children is associated with prematurity, low birth weight, immunodeficient states, febrile neutropenia, corticosteroid or broad-spectrum antibiotic treatment, malnutrition, and local skin trauma.[20,21] Pediatric cases of cutaneous mucormycosis have been associated with wooden tongue depressors, cotton stockinettes, and adhesive bandages.[18] The patterns of distribution in pediatric patients are cutaneous (27%), gastrointestinal (21%), rhinocerebral (18%), and pulmonary (16%).[22]

Primary cutaneous mucormycosis is the least common form. Inoculation is often secondary to direct skin trauma[23,24] or from adhesive skin bandages or intravenous catheter insertion.[18,23,24,25,26] It can present as superficial or gangrenous infections.[27] The superficial form is characterized by a slow onset of erythematous cellulitis with vesicles or pustules. The gangrenous form is usually more aggressive. Angioinvasion by the fungal hyphae produces thrombi that occlude the arteries leading to progressive ulceration, eschar formation, ischemia, and tissue necrosis.[18,23] The infection can extend to involve deeper structures such as tendons, muscles, or bone, and 19% can spread to other organs by hematogenous dissemination.[27]

Etiology and Pathogenesis

The causative organisms of mucormycosis are of the class Phycomycetes, subclass Zygomycetes. The most commonly seen genera are from the Mucoraceae family,[18,23,25,28] but an increasing number of infections from the Cunninghamellaceae family are also being reported.[29,30,31] The most commonly identified organisms are *Rhizopus* species in 44% of cases and *Mucor* species in 15%.[22] These fungi are ubiquitous saprophytes commonly found in soil, decomposing vegetation, and in healthy human respiratory and digestive tracts.

Mucormycosis typically presents as rhino-orbital or rhinocerebral disease but also occurs as a disease involving *(Print pagebreak 593)* the lungs, skin, and gastrointestinal tract.[32] Environmental fungal spores are inhaled and enter the sinuses where the fibrous mycelium and thin-walled aseptate or hyposeptate hyphae grow rapidly within the host tissues. Increased availability of soluble iron in the host is believed to play a role in promoting Mucorales growth, especially in patients receiving deferoxamine iron chelation therapy.[33,34,35] The infection progresses to soft tissues causing facial swelling, numbness, and pain. It may extend to the orbits and brain, causing vision loss and cerebral abscesses. Hematologic dissemination with seeding of visceral organs can follow.[36] As the hyphae grow, they invade the blood vessels leading to thrombosis and tissue necrosis.[37]

For optimal growth in humans, Mucorales fungi require the host to have decreased levels of neutrophils.[38] In healthy individuals, neutrophils are a key defense against the fungi in the host tissue and phagocytize these pathogens, but in neutropenic individuals, the pathogens proliferate leading to infection.

Once the infection is initiated, mucormycosis has an affinity for arterial blood vessels,[39] where they adhere to the arterial wall and grow along the internal elastic lamina causing thrombosis, ischemia, and necrosis of the surrounding tissues.

During the COVID-19 pandemic, coronavirus disease-associated mucormycosis (CAM) has become a growing threat globally, especially in tropical regions. The emergence of CAM cases has been attributed to environmental, host, and iatrogenic factors.[40] In COVID-19 patients, virus-induced endothelial dysfunction, hyperglycemia, and immune dysfunction following corticosteroid use is believed to increase the risk of acquiring mucormycosis by the interaction of Mucorales spores with damaged epithelial cells, followed by endothelial invasion.[40] Corticosteroid treatment, frequently required by COVID-19 patients, further reduces or abolishes the innate immune functions of phagocytic cells contributing to the pathogenesis of CAM.[40]

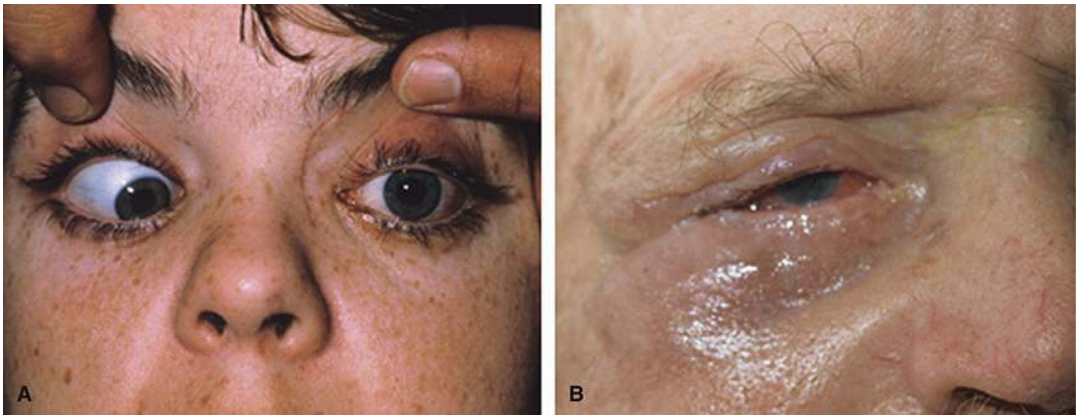

FIGURE 89.1 A, Sinus and orbital mucormycosis with proptosis and ophthalmoplegia. B, Orbital-cutaneous mucormycosis with progressive facial and eyelid induration, edema, and cellulitis.

Clinical Characteristics

Mucormycosis commonly presents in five forms: it may affect the pulmonary, rhinocerebral, gastrointestinal, cutaneous, or central nervous systems.[37] Systemic dissemination, where infection affects two or more noncontiguous organ systems, may also occur due to the highly invasive nature of this fungus.[37] Of the five forms, pulmonary and rhinocerebral are the most common. Cases of rhinocerebral mucormycosis present with facial pain, periorbital cellulitis, proptosis, ophthalmoplegia (Figure 89.1A), visual deficiencies, black necrotic lesions, discharge from the nasal and palatal mucosa, and fever.[41,42,43] CNS mucormycosis is not common by itself but is usually a result of dissemination of the fungal infection from pulmonary or rhinocerebral sources.[44]

Cutaneous involvement by mucormycosis is most often seen on the face and extremities. Patients present with fever and rapidly progressive facial and eyelid induration, edema, and cellulitis (Figure 89.1B), with ulceration, purulent discharge, occasionally bleeding, and necrosis (Figure 89.1B and 89.2).[20,27,45,46,47,48,49,50] There may be a history of trauma, burn, insect bite,

uncontrolled diabetes, or hematologic malignancy. Chronic infections may sometimes persist for months or years.[51]

In a series of 115 cases of cutaneous mucormycosis in Mexico, 18/115 cases (16%) were considered primary cutaneous infections, and 97/115 cases (84%) as secondary cases. Primary cutaneous cases are caused by implantation of the Mucorales due to disruption of the cutaneous barrier, and most cases are associated with adhesive bands or trauma. Secondary cases result as a part of the disease process, and most are associated with rhinocerebral mucormycosis and diabetes.[52]

(Print pagebreak 594)

FIGURE 89.2 Cutaneous mucomycosis with necrosis of the lateral nose and eyelid in a patient with lymphocytic leukemia. (Reprinted with permission from Bonifaz A, Tirado-Sánchez A, Hernández-Medel ML, et al. Mucormycosis with cutaneous involvement. A retrospective study of 115 cases at a tertiary care hospital in Mexico. *Autralas J Dermatol*. 2021;62:162-167, Figure 2C.)

Differential Diagnosis

The differential diagnoses of mucormycosis are varied due to the different clinical presentations and organ systems that can be involved. The most commonly employed technique for differentiating between mucormycosis and other diseases is a

histopathological study.[53] However, Mucorales may be difficult to distinguish from other filamentous fungi.[54] There are many similarities in the clinical presentations of aspergillosis and mucormycosis.[38] The drugs usually used for the treatment of aspergillosis are generally ineffective for the treatment of mucormycosis so that it is important to confirm the diagnosis as early as possible in the course of the disease. Rhino-orbital and rhinocerebral mucormycosis can be confused with more routine cases of sinusitis. Cutaneous mucormycosis has also been misidentified as cutaneous malignancy or an infected sebaceous cyst.

Treatment

Mucormycosis can be a fatal infection and early diagnosis and treatment are critical for the successful eradication of the infection and patient survival. The gold standard of treatment is aggressive surgical debridement of infected necrotic tissues with adjunctive intravenous antifungal therapy and management of predisposing factors.[32] Medical antifungal therapy alone is generally ineffective because extensive tissue invasion and necrosis limit drug penetration into infected areas.[23,24] Liposomal amphotericin B (L-AmB) has better tissue penetration than amphotericin B, has less hepatotoxicity, and is considered a first-line treatment.[19] Intravenous liposomal amphotericin B is preferred also because of its ability to penetrate the central nervous system.[32,55] The latest guidelines of the European Confederation of Medical Mycology/European Society of Clinical Microbiology and Infectious Diseases and the European Conference on Infections in Leukemia recommend the use of L-AmB with a daily dosage of at least 5 mg/kg/d for mucormycosis,[56,57] and dosages of 10 mg/kg/d are strongly supported for cerebral infections.[57] The duration of antifungal treatment is still a matter of debate but should be determined on an individual basis and adjusted based on the underlying condition. Some authors propose a treatment for at least 3 weeks.[58] The total duration of antifungal drug treatment in mucormycosis varies, but at least 12 weeks is recommended.[59]

Salvage therapies with drugs like posaconazole and isavuconazole have shown promising results when combined with L-AmB even without surgical debridement,[5,60,61,62,63,64,65] but are not considered first-line medical therapy.[66,67,68]

Hyperbaric oxygen therapy has a fungistatic effect and helps the revascularization of ischemic tissue. In selected cases, it can be combined with antifungal agents.[69] Several studies reported improved survival rates using hyperbaric oxygen as an adjuvant therapy to amphotericin B and surgical debridement.[70,71]

Retrobulbar injection of amphotericin B has been reported as a minimally invasive, globe-sparing intervention for orbital aspergillosis[72,73,74,75] and has been reported as a successful treatment in combination with systemic antifungals and endoscopic sinus debridement.[76]

Prognosis

The prognosis for patients with rhino-orbito-cerebral mucormycosis, in general, is poor. In a retrospective study of 63 patients (79 eyes) with biopsy-proven disease, the presence of a frozen globe, nasal mucosal involvement, and shorter duration of antifungal therapy were significantly associated with lower patient survival.[77] Exenteration did not significantly change survival. Globe survival was seen in 43% and vision survival was observed in 25.3%, in whom younger age was significantly associated with a worse vision survival.

Improved survival of patients with mucormycosis is related to earlier diagnosis and institution of early and aggressive multidisciplinary treatment.[78,79,80] Even with treatment, mucormycosis has a high rate of morbidity and mortality.[81,82] The survival rate has improved with combination therapy, but the overall mortality rate remains high, especially in immunocompromised patients and in young *(Print pagebreak 595)* children.[22] Delayed diagnosis of more than 5 days is associated with an increased risk of mortality.[83]

The all-cause mortality rates for mucormycosis range from 40% to 80% depending on underlying conditions and sites of infection.[78,84,85,86,87] The highest survival rates are reported in patients with a healthy immune status and without comorbidities. The poorest prognosis is reported in patients with hematologic malignancies, bone marrow transplant recipients, and patients with severe burns.[84,87] Patients with disseminated disease and CNS involvement can be associated with mortality rates greater than 80%.[84]

Localized sinus or cutaneous infections usually carry a more favorable prognosis since earlier diagnosis is likely and intervention can be instituted more quickly.

In a review of 113 articles published between 1943 and 2004, it was shown that mucormycosis patients older than 46 years, with frontal sinus involvement, and with fever were less likely to survive compared with those without these conditions,[88] and patients treated with amphotericin B were more likely to survive. While patients with fever undergoing orbital exenteration were more likely

to survive compared with nonexenterated patients, no standard of care was found among surveyed orbital surgeons with regard to exenteration for cases of orbital mucormycosis.[88]

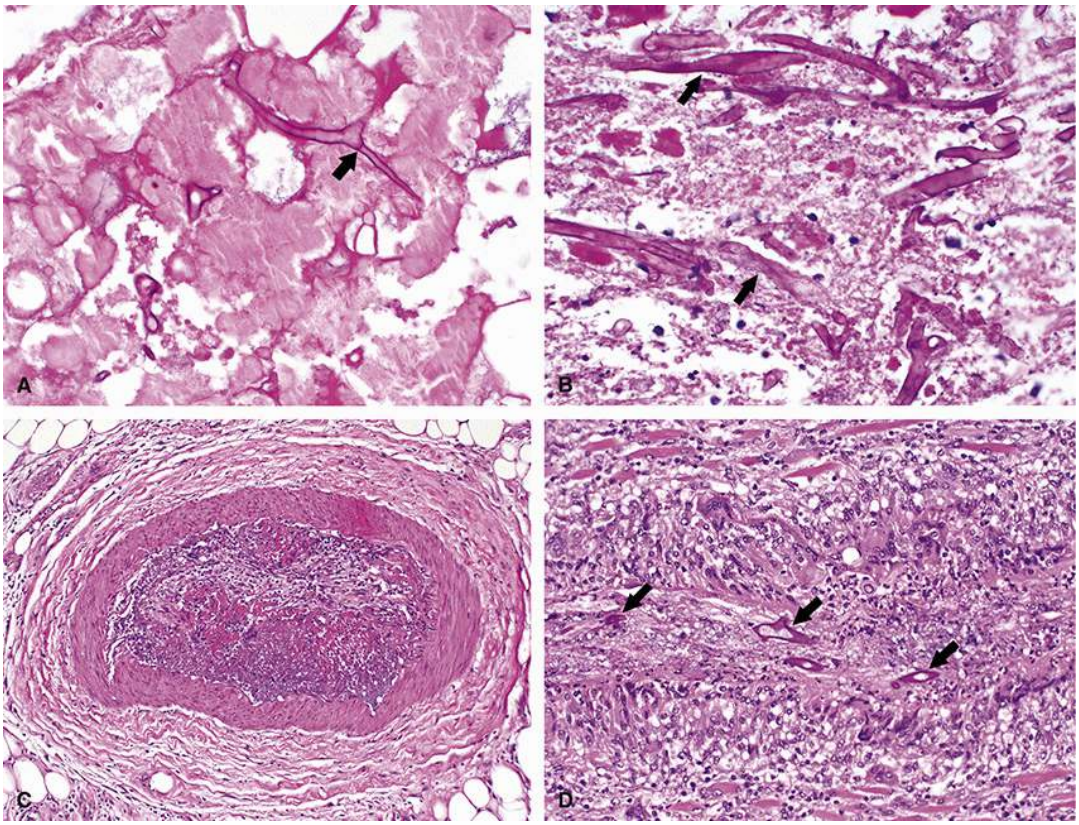

FIGURE 89.3 A, The hyphae of mucormycosis are basophilic in sections stained with hematoxylin and eosin. The hyphae are broad (5-20 µm), thin walled, irregularly contoured, pleomorphic, and typically branch from 45° to 90°. The hyphae are pauciseptate (arrow) and are in infarcted adipose tissue in this patient with cerebro-rhino-orbital mucormycosis. B, The hyphae are often twisted (arrows), folded, and collapsed due to their thin walls. Many hyphae have absent cytoplasm and appear clear. C, Vascular invasion and thrombosis are ubiquitous with mucormycosis. D, Mucormycosis may stimulate a granulomatous reaction, as seen in this case with basophilic fungal hyphae (arrows) enveloped in a granuloma.

Histopathology

The hyphae of mucormycosis are usually apparent in sections stained with hematoxylin and eosin in which they are basophilic (Figure 89.3). The hyphae are broad (5-20 µm), thin walled, irregularly contoured, pleomorphic, and typically branch from 45° to 90°.[54,89] The hyphae are pauciseptate *(Print pagebreak 596)* (not nonseptate, as often described), but septa are only rarely seen in tissue sections and may be simulated by folds in the hyphae (Figure 89.3A).[54,89] The hyphae are often twisted, folded, and collapsed due to their thin walls (Figure 89.3B).[89] Many hyphae have absent cytoplasm and appear clear.[89] Vascular invasion and thrombosis are ubiquitous with mucormycosis (Figure 89.3C),[54,90] but their presence may require a careful search of multiple sections. Arterial thrombosis results in ischemic (coagulative) necrosis, and infarcted adipose tissue may have birefringent crystals of fatty acid calcium salts.[91,92] Perineural invasion is also a common histological feature in mucormycosis, occurring in 90% of cases in the study by Frater and Procop.[54] Tissue infection may result in a neutrophilic response, a mixed neutrophilic and granulomatous response (Figure 89.3D), or less commonly a pure granulomatous response or no inflammation.[54,90]

CHAPTER 90

Myasthenia Gravis

Key Points

- Myasthenia gravis (MG) is an acquired neurological autoimmune disease characterized by skeletal muscle fatigability and weakness
- 75% to 80% of patients have IgG1 and IgG3 antibodies directed against the acetylcholine receptor and 1% to 10% of patients have antibodies directed against muscle-specific tyrosine kinase
- 40% to 50% of myasthenia patients initially present with purely ocular symptoms, but 50% to 80% of those develop generalized myasthenia within 2 years
- Ocular MG (OMG) usually presents with variable pupil-sparing ptosis and extraocular muscle weakness that worsens with sustained muscle use and improves with rest or sleep
- Patients may complain of difficulty chewing solid food, dysphagia, or dysarthria
- Treatment requires long-term acetylcholinesterase inhibitors, immunosuppressants, or a drug combination of both which should be individualized according to the response to therapy
- If ptosis surgery is indicated, silicone slings are the preferred suspensory material, and the open sky approach is preferred over the closed Fox method
- MG may be visually disabling and cosmetically disturbing, but the quality of life and life expectancy have improved with modern therapy

Myasthenia gravis (MG) is an acquired neurological autoimmune disease hallmarked by skeletal muscle fatigability and weakness which is caused by impaired synaptic transmission across the neuromuscular junction. It is one of the five main causes of neurogenic blepharoptosis.[1,2,3,4,5,6,7,8,9,10,11,12]
The other causes include oculomotor nerve palsy, Horner syndrome, Marcus-Gunn Jaw wink, and ptosis induced by botulinum toxin injections which are discussed separately in Chapters 12, 36, and 38.

Etiology and Pathogenesis

Under normal conditions, the process of neuromuscular transmission is initiated by an action potential that depolarizes the terminal membrane of the motor nerve axon. This opens the voltage-dependent calcium channels, increasing calcium permeability which elicits the release of acetylcholine (ACh) and agrin molecules from the nerve terminal into the synaptic cleft.[5,12] ACh diffuses across the synapse, binds to receptors on the striated muscle, and depolarizes the postsynaptic membrane, thus producing muscle contraction.[12] The postsynaptic skeletal muscle fiber membrane (the sarcolemma) is a convoluted structure with a high density of acetylcholine receptors (AChR) at the crests of the folds and acetylcholine molecules within the clefts. To ensure successful neuromuscular transmission, normally there is a vast excess (safety margin) of released acetylcholine molecules and available postsynaptic receptors. Ultimately, the acetylcholine molecules that are released are rapidly eliminated from the synaptic cleft by the acetylcholinesterase enzyme.[12] As we shall see later, the released agrin is involved in the normal process of AChR clustering, an integral step of neuromuscular junction transmission.[5,12] Any disruption of the aforementioned delicate processes predisposes to failure of neuromuscular transmission, ultimately causing muscle weakness.[12]

MG is an autoimmune disorder caused by antibodies targeting the neuromuscular junction. These antibodies bind to the postsynaptic muscle end plate, attack, and destroy the postsynaptic molecules, consequently impairing signal transduction which ultimately results in muscle weakness and fatigability.[5] Although MG is considered the archetypal example of an autoimmune disease involving the neuromuscular junction,[4,5,6,7,8,9] it is an etiologically as well as an immunologically heterogeneous disease.

Different autoantibody patterns, as well as the diverse clinical manifestations, may help identify the disease subgroups which include (1) early-onset MG, (2) late-onset MG, (3) muscle-specific kinase MG (MuSK$^+$ MG), (4) low-density lipoprotein receptor-related protein 4 MG (LRP4 MG), (5) seronegative MG, (6) thymoma MG, and (7) OMG.[5] In MG patients, three major antibody types predominate including (1) antibodies directed against the acetylcholine receptors (AChR), (2) antibodies directed against MuSK, and rarely (3) LRP4 antibodies, but other antibodies may be observed as well.[5]

The two major antibodies (AChR and MuSK) probably represent two distinct immunopathologic mechanisms as they are mutually exclusive and rarely manifest simultaneously in the same individual. Also, the clinical picture, the ocular findings, and thymic pathology are different.[5,9,10] On the other hand, the clinical picture in patients with AChR and LRP4 antibody positivity may overlap, particularly regarding their ocular symptoms.[5]

(Print pagebreak 599)

In the great majority of MG patients, antibodies directed against acetylcholine receptors are the ones responsible for the characteristic muscle fatigability, and they can be detected with routine assays or more-sensitive cell-based assays in up to 75% to 80% of patients.[5] Anti-AChR antibodies are usually IgG1 and IgG3 antibodies which are directed against the α-subunits (more pathogenic) or the β-subunits of the acetylcholine receptor and cause disease morbidity through three distinct mechanisms.[5] The predominant antigenic mechanism is that they activate the complement cascade (C1), which in turn binds to the extracellular domains of the ACh receptors at the neuromuscular junction. This results in the formation of membrane attack complexes on the sarcolemmal cell membranes, which destroys the typical folds in the sarcolemma, thereby indirectly impairing signal transduction.[5] Another less frequent mechanism for blocking the signaling pathway also exists, as AChR antibodies are bivalent and are capable of direct antigenic modulation which may result in AChR conformational changes and additional damage to the AChR function.[5] The third and least common mechanism is that anti-AChR antibodies may directly target the acetylcholine ligand-binding site of the receptor itself without complement activation, also potentially blocking the signaling pathway.[5] Although total AChR antibody concentration does not appear to correlate with symptom severity, fluctuations in AChR antibody levels in an individual patient have been reported to correlate with the severity of muscle weakness.[5]

A small minority of MG patients (1%-10%) have monovalent antibodies to muscle-specific tyrosine kinase (MuSK) and not to the acetylcholine receptors (MUSK$^+$ MG).[5] MuSK is a protein that is concentrated in the neuromuscular junctions of skeletal muscles where it colocalizes with the densely packed acetylcholine receptors. It is responsible for AChR clustering, a key event in neuromuscular transmission,[11] so that MuSK plays a critical role in establishing and maintaining neuromuscular synapses.[4,5] However, this interaction also requires the presence of the low-density lipoprotein receptor-related protein 4 (LRP4) and the motoneuron-secreted heparan sulfate proteoglycan agrin to co-stimulate MuSK.[4,5,11] MuSK is, therefore, one of the components of the agrin-mediated AChR clustering signaling cascade (*agrin-LRP4- MuSK* signaling).[4,11]

Autoantibodies that are directed against MuSK are predominantly of the IgG4 subclass; therefore, MuSK$^+$ MG belongs to the relatively new class of autoimmune diseases which are hallmarked by the predominance of IgG4 autoantibodies. In contrast to AChR antibodies that bind to complement and crosslink their antigenic target, MuSK antibodies are directly pathogenic.[5] They act by reducing the postsynaptic density of AChRs and impairing their alignment.[5] Of note is that the association with MuSK positivity and ocular symptoms (MuSK-OMG) is extremely rare.[5,9,10] To the best of our knowledge, only nine cases of MuSK-OMG have been described in the literature so far.[10] In addition, thymus pathology is also different, as the thymus is frequently involved in AChR MG, whereas in MUSK$^+$ MG, it is not.[8,12]

A small proportion of MG patients who do not have either AChR or MuSK antibodies may possess antibodies directed against another component of the agrin-LRP4-MuSK signaling cascade, LRP4, which is a receptor for agrin that relays the signal to MuSK to initiate AChR clustering.[5] It should be noted the prevalence of ocular symptoms and signs is similar among MG patients with either anti-AChR or anti-LRP4 antibodies, although LRP4$^+$ patients usually present with milder disease and thymomas are rare.[5]

Patients who have no detectable antibodies against any of these three antigens are referred to as seronegative MG, although some of these patients may have antibodies against other cytoplasmic muscle proteins (agrin, titin, Kv1.4, ryanodine receptor antibodies, collagen Q, or contractin antibodies). However, the exact role played by these antibodies in MG pathogenesis or any relevance to diagnosis, treatment, or prognosis remains to be proven.[5]

The primary autoimmune form mentioned earlier is not the only underlying cause of MG. Thymic pathology, acute infections, and several medications may trigger or exacerbate myasthenia probably through presynaptic or even postsynaptic inhibition of acetylcholine release.[13] Pathological thymic changes, including thymic hyperplasia (follicular or diffuse thymitis) earlier in the course of the disease, and thymomas, as well as an atrophic thymus gland (late in the disease), are seen in 80% of seropositive myasthenia patients.[14] Systemic infections (viruses, bacteria, and even fungi) may also trigger a myasthenic crisis.[15,16] The list of drugs inducing MG is extensive,[12] but drugs that are relevant to the current discussion are antibiotics including fluoroquinolones (ciprofloxacin and levofloxacin), macrolide antibiotics (telithromycin and azithromycin), and aminoglycosides (amikacin and gentamycin).[13,17,18,19,20] Therefore, if a patient develops an acute exacerbation of MG due to a systemic infection, the very

antibiotics used to treat the infection may exacerbate the symptoms even more.[13]

Clinical Presentation

The incidence of generalized MG is 5.3 per million person-years, and the estimated prevalence is 77.7 cases per million of the population.[9] MG affects all age groups, genders, and ethnicities; however, it has a bimodal age distribution, being more prevalent both in young females (less than 30 years of age) and older males (more than 50).[7,21] The exact incidence and prevalence of OMG is largely unknown, and a recent metanalysis of population-based epidemiological MG studies did not list a single study singularly concerned with OMG.[9] But in general, OMG is considered rarer than generalized disease,[22] shows a predilection for men, and appears to be more prevalent in Asian populations.[6,23]

MG patients are substratified not just according to their seropositivity toward antibody markers, but also according to thymic pathology, as well as the clinical presentation. Although each patient should be stratified into one group, some patients with ocular myasthenia may progress to *(Print pagebreak 600)* systemic MG during their disease, thus necessitating a diagnostic revision.[5] AChR MG patients are classified into either early-onset MG (onset <50 years) or late-onset MG (onset >50). This stratification does not have any prognostic significance except regarding thymic pathology as thymectomy in early-onset MG may have a clear clinical benefit, while in late-onset MG the benefit is doubtful.[5] The vast majority of $MuSK^+$ MG patients are females with profound muscle weakness that may even progress to muscle atrophy. Although respiratory muscle weakness is severe, ocular muscles are usually spared, and therefore this type is rarely seen in everyday ophthalmology practice.[5] In contrast, LRP4 MG is a milder form of AChR MG and thymomas are not reported.[5] Seronegative MG constitutes about 10% of patients with generalized MG and is a heterogeneous disease. It includes patients with very low concentrations of antibodies, patients with antibodies against antigens that have not been defined yet, and possibly patients with nonautoimmune myasthenic mechanisms, although repeated testing can sometimes lead to a diagnostic revision.[5] Around 30% of patients with thymoma develop MG, and another 15% have asymptomatic anti-AChR antibodies. Overall, thymoma-associated MG represents about 10% of all MG patients, but this type is not typically associated with any other antibodies except AChR.[5]

About 40% to 50% of MG patients initially present with purely ocular symptoms, with a history of chronic remitting, but generally progressive painless weakness or fatigability of the extraocular muscles manifesting with double vision and ptosis. Over the course of the disease, the symptoms may alternate between both the eyes, and an acute onset may rarely be encountered.[7,23,24] Overall, ocular muscles are involved in 90% of patients with generalized myasthenia.[12] On the other hand, 50% to 80% of ocular myasthenics ultimately develop generalized disease, which usually occurs within the first 2 years from onset; however, the use of immunosuppressants may reverse this trend.[8,12,25]

On examination, OMG is hallmarked by the presence of pupil-sparing ptosis (Figure 90.1) and extraocular muscle weakness (Figure 90.2), which is typically characterized by being variable, increasing with sustained muscle use even for brief periods, and improving with rest or sleep.[23] Ptosis may be unilateral or bilateral and is usually asymmetrical.[26] When ptosis is unilateral or markedly asymmetrical, two phenomena may be observed, and both are attributable to the Hering law of equal innervation.[12,27] The first is apparent or "pseudoretraction" of the contralateral normal upper eyelid,[23,27] and the second phenomenon is "enhanced ptosis." After manually elevating the more ptotic eyelid, ptosis may appear to be increased or "enhanced" in the contralateral less ptotic eyelid.[12,28] A more characteristic, albeit rarer and more difficult to elicit phenomenon is the Cogan lid twitch sign, which is characterized by a brief episode of lid retraction after a vertical upwards saccade from a downgaze position.[23] Clinicians should also be aware that MG may cause orbicularis muscle weakness.[23,29] When OMG patients are instructed to close their eyelids and keep them closed, a few seconds later the palpebral fissure widens and the cornea is exposed because of orbicularis fatigue.[29] This sign has been dubbed the "eyelid peek" or "peek-a-boo sign" because the patient appears to peep or peek at the examiner.[12,29] Orbicularis muscle weakness may also manifest with "afternoon ectropion" and "nocturnal lagophthalmos."[29,30]

FIGURE 90.1 Myasthenia gravis presenting with asymmetric blepharoptosis of the right eyelid. (Courtesy of Dr. Kyle Godfrey.)

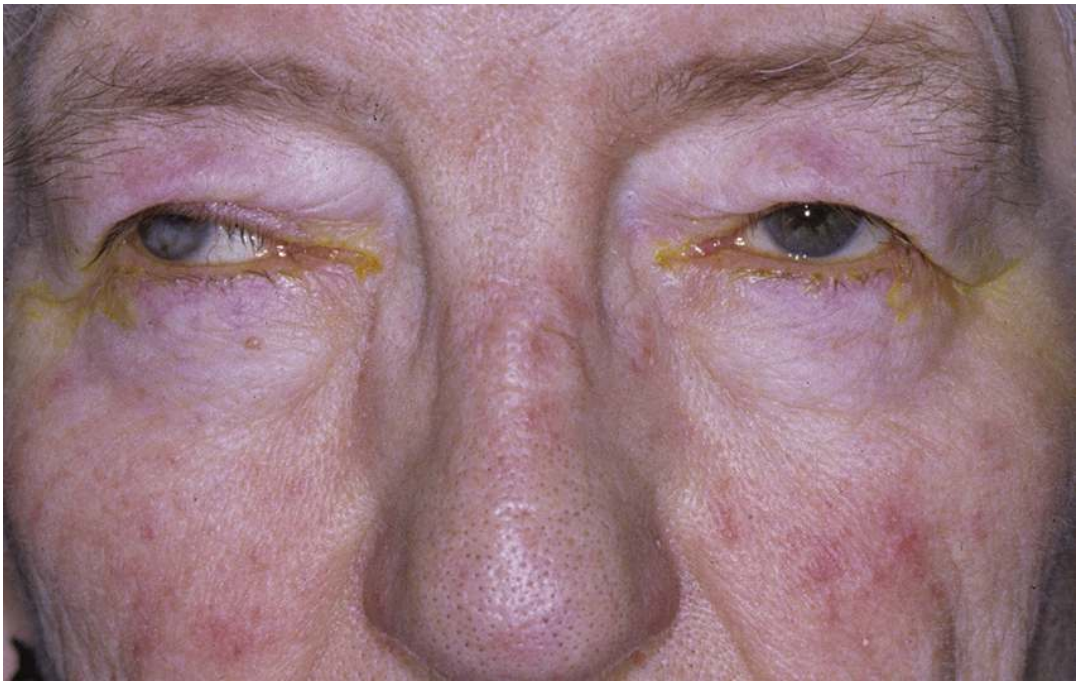

FIGURE 90.2 A patient with myasthenia gravis showing asymmetric blepharoptosis and pupil-sparing adduction weakness on the right side.

Several office-based tests can be performed in the clinic to help establish the diagnosis of OMG including the ice test, the sleep test, the eyelid fatigability test, and the rest test.[12] Local cooling of the eyelids is a rapid, safe, and inexpensive test for OMG with a high degree of specificity and sensitivity. Cooling is believed to reduce the activity of the acetylcholinesterase enzyme, indirectly increasing the amount of available ACh at the neuromuscular junction. The ice test is performed by having the patient apply ice compresses over a closed eyelid for 2 to 5 minutes, and the patient is photographed before and after the application of ice to provide accurate documentation of the test outcome (Figure 90.3). An upper eyelid elevation of ≥2 mm is considered suggestive of MG, but the effect usually lasts less than 1 minute.[12] In the eyelid fatigability test, the patient is asked to look upward for *(Print pagebreak 601)* 2 to 5 minutes. The sustained muscle fatigue results in exacerbation of the eyelid ptosis in patients with OMG (Figure 90.4). The sleep test is performed by letting the patient sleep alone in a dark quiet room for 30 minutes. Again, measurements are taken, and the patient is photographed before and after sleeping, but the results are also very transient lasting no more than a minute or 2.

The rest test is essentially a mini-sleep test where the patient is asked to gently close the eyelids for 2 to 5 minutes which is reportedly sufficient in a sizable proportion of patients to document a diagnostic improvement. It should be noted that in a busy clinical setting, the sleep test is less practical than the other tests, and it appears that the ice test is more sensitive than the rest test.[12]

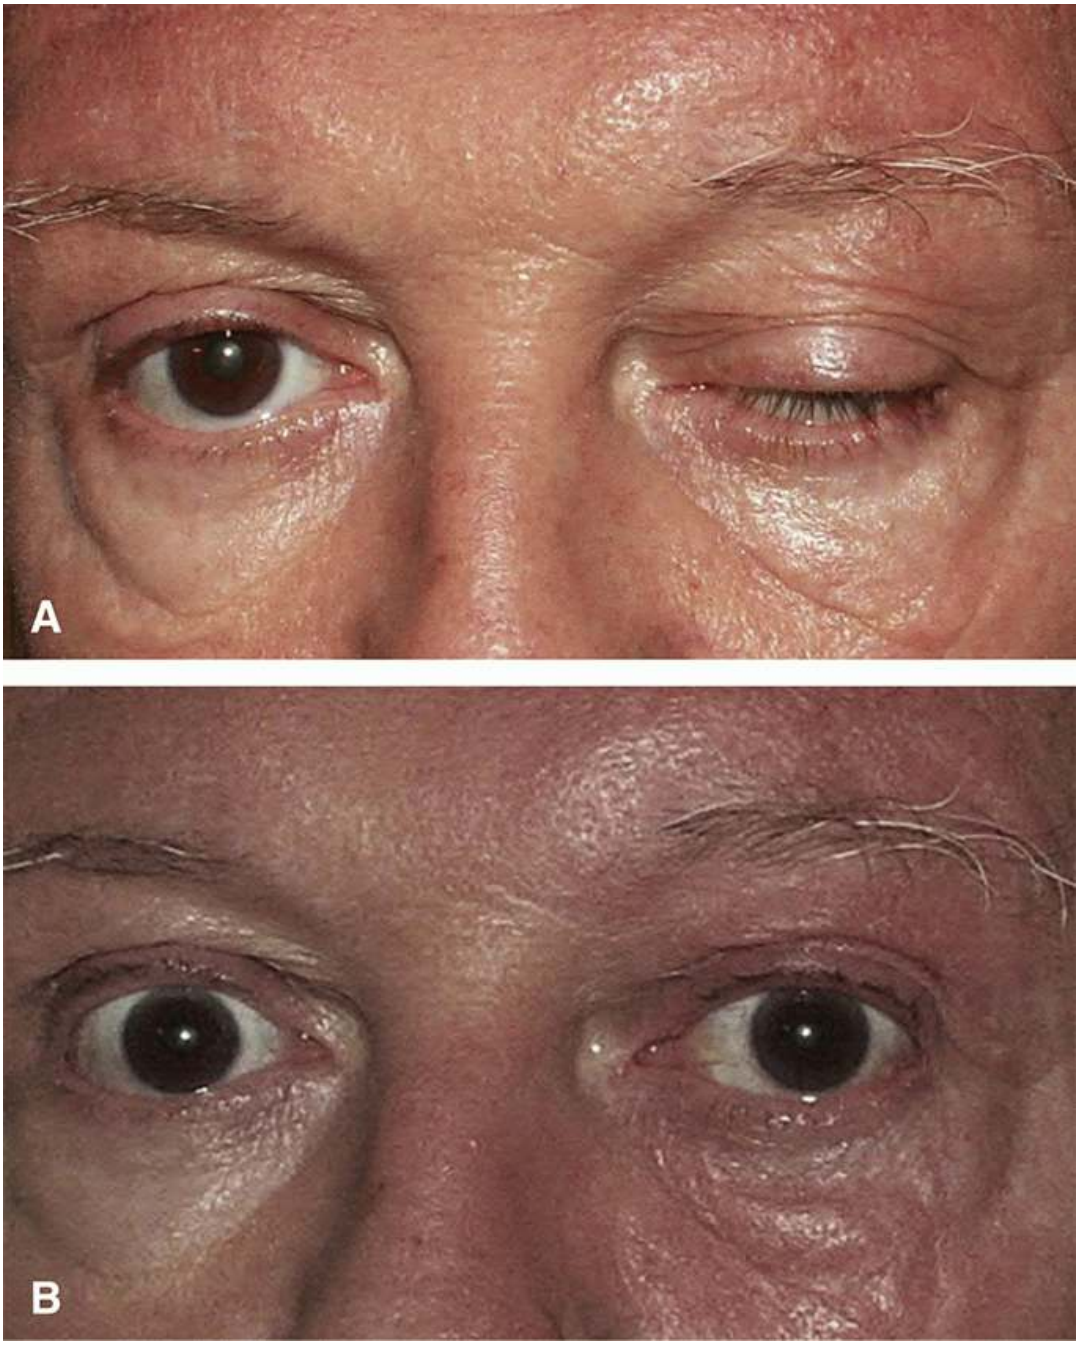

FIGURE 90.3 The ice test. A, Left eyelid ptosis before the ice is applied. B, Immediately after the ice pack is applied to the left eyelid for 5 minutes, the patient is asked to open the eyelids. The rest test should provide similar results.

Extraocular muscle involvement is also a common symptom in OMG and is found in as many as 90% of patients, usually associated with ptosis.[12] It can mimic any pupil-sparing ocular motility disorder, ranging from a single extraocular muscle paresis to complete external ophthalmoplegia, but OMG patients may also present with full ocular motility.[12]

Systemically, patients may complain of difficulty in chewing solid food, dysphagia, or dysarthria, as well as difficulty whistling, using straws, or inflating balloons. MG patients may exhibit a nasal tone of voice which becomes increasingly apparent if history taking is prolonged. Patients with generalized MG may also demonstrate a depressed or expressionless facial appearance, and the characteristic myasthenic snarl may also be observed on an attempted smile.[26] Air readily escapes through the lips, and liquid may escape through the nose during attempted swallowing with nasal regurgitation. Patients with limb weakness may complain of *(Print pagebreak 602)* difficulty climbing the stairs or performing overhead tasks with their arms.[26]

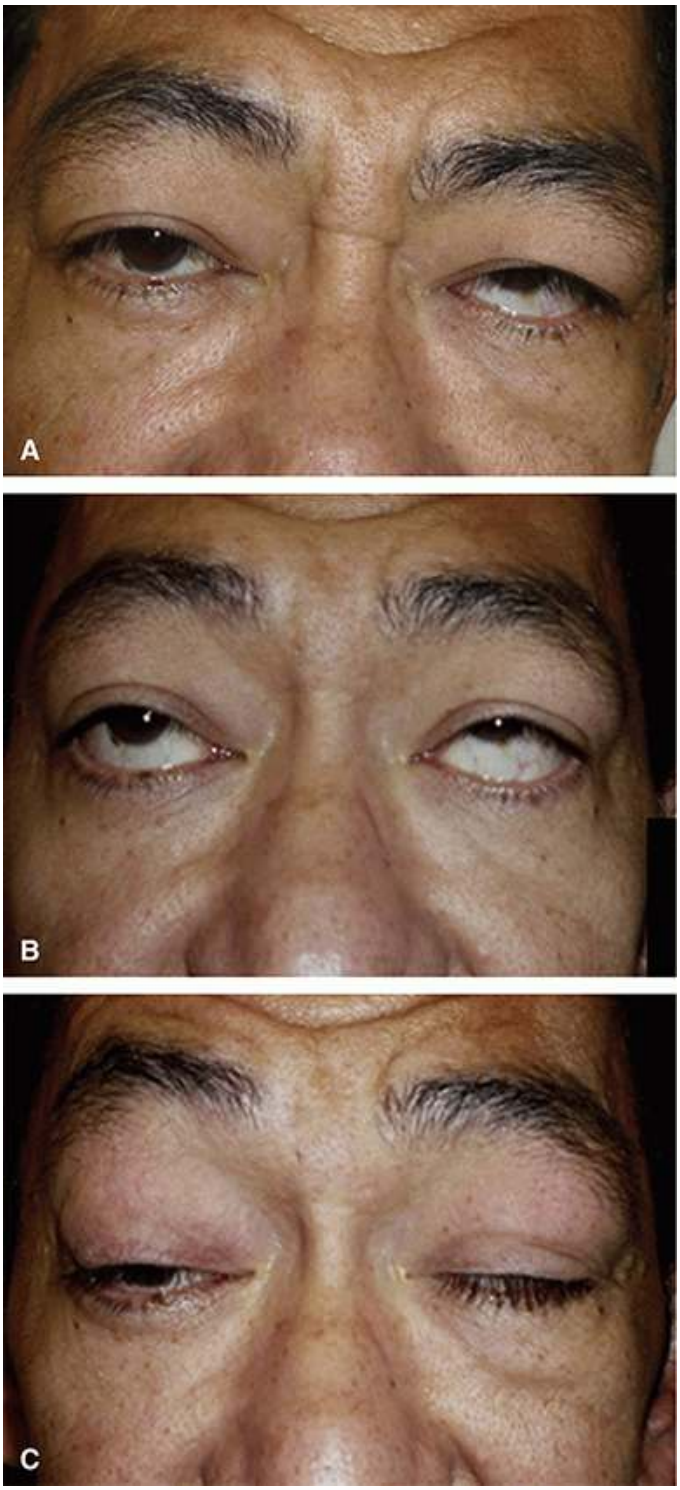

FIGURE 90.4 The eyelid fatigability test. A, Before the start of levator muscle contraction. B, Sustained upgaze for 2 to 5 minutes. C, Immediately following the test, the ptosis is increased. (Courtesy of Dr. Robert Kersten.)

The diagnosis of MG and in particular OMG is primarily a clinical one, and OMG should be suspected in any patient presenting with painless, pupil-sparing ptosis with ophthalmoparesis even if the results of antibody testing and nerve stimulation are negative. Nevertheless, this statement should not undermine the fact that diagnostic tests are still of utmost importance to support the diagnosis of generalized myasthenia and to a lesser extent OMG. These tests can be categorized into clinical, laboratory, electrophysiologic, pharmacologic, and radiologic tests.[31] The typical workup of suspected MG/OMG usually includes anti-AChR antibody testing, anti-LRP4 antibody testing, anti-MuSK antibody testing, single-fiber electromyography, and CT or MRI of the mediastinum, but MuSK antibodies are virtually nonexistent in OMG and therefore the test should not be ordered if ocular signs are the sole presenting findings of the disease.[5,21] One important clinical point that should not be overlooked is that 10% of MG patients will have a thymoma on chest radiology and 70% will have thymic hyperplasia. Those relatively high figures are not observed in healthy patients, which argues for a central role of the thymus gland in the pathogenesis of the disease.[32] Therefore, a negative antibody workup does not rule out MG/OMG if the clinical signs are highly suggestive.[12]

Differential Diagnosis

Ptosis due to OMG should be differentiated from other types of acquired ptosis like aponeurotic, myopathic, or neurogenic ptosis; however, because of the concomitant involvement of the extraocular muscles, the list of other simulating conditions is not short.[3] The diagnosis of OMG is rarely in doubt when the patient presents with the proper history and characteristic clinical findings. However, excluding MG may occasionally be challenging because some myasthenia patients may not present with the typical muscle use-dependent fatiguability and may test negative for AChR antibodies. Signs that should raise suspicion against a diagnosis of MG/OMG include the lack of variability or fatigability, the presence of pupillary abnormalities, diminution of vision, and the presence of pain or strictly persistent unilateral signs and symptoms.[12]

The most common type of ptosis that may be confused with OMG in clinical practice is aponeurotic ptosis. Although aponeurotic dehiscence immediately springs to mind when an adult presents with acquired ptosis, clinicians should always be on high alert for OMG particularly if the variability of symptoms is marked or if there is a history of diplopia. A normal levator excursion would suggest an aponeurotic etiology, while a diminished levator function (<10 mm) in an adult should direct the clinician to a myopathic or a neurogenic etiology.

The types of myopathic ptosis that may be confused with OMG include oculopharyngeal muscular dystrophy (OPMD), myotonic dystrophy (MD), and mitochondrial myopathies like the chronic progressive external ophthalmoplegia. The orbicularis muscle is exceptionally weak in MD, much more than in patients with mitochondrial myopathy, whereas in OPMD it may be normal.[33] The presence of meibomian gland dysfunction could suggest MD,[33] while a relative sparing of the extraocular muscles and a good Bell phenomenon may point to OPMD. Cogan lid twitch and the eyelid peek sign may help clinch the diagnosis,[29] but they are not 100% pathognomonic of MG and have been documented in other conditions.[12,34] The coexistence of poor eyelid closure and ptosis with ophthalmoparesis is strongly suggestive of OMG because the facial nerve and the third cranial nerve have separate courses,[12] but this combination has been observed in several types of myopathic ptosis as well (see Chapter 11).[33] Systemic features may not be of much help either, because some symptoms such as dysphagia and dysarthria may also be shared with OMG and myopathic ptosis.[12,23]

Other causes of neurogenic ptosis should be excluded as well. Patients with oculomotor nerve palsy usually present with a specific pattern of ophthalmoplegia in the form of sudden onset of diplopia with one eye turned down and out, with partial or more commonly complete ptosis. The presence or absence of pain, as well as pupillary abnormalities, may help clinch the diagnosis, but these findings vary according to the etiology of the nerve palsy. Angiographic imaging studies, as well as standard radiology (CT/MRI), are often required for diagnosis.[35] Patients with Horner syndrome typically present with minimal ptosis (1-2 mm) and therefore are not usually confused with OMG. Ptosis following botulinum toxin injections may also pose a diagnostic dilemma particularly if the patient denies or the physician fails to inquire specifically about a recent episode of injection. Acute onset of ptosis with diminution of levator function in an otherwise healthy middle-aged female should always raise suspicion.

OMG may simulate virtually any pupil-sparing eye movement disorder like internuclear ophthalmoplegia and the one-and-a-half syndrome because of its predilection to affect the medial rectus muscle particularly early in the course of the disease.[23] But because of the variable patterns of ocular motility disturbances encountered in OMG, it may also mimic trochlear, abducens, or even oculomotor nerve dysfunction.[12] On the other hand, many intracranial sinister etiologies may masquerade as MG (pseudomyasthenia).[27,34]

Although OMG patients may present with lid retraction due to Hering law, thyroid eye disease should be ruled out in any known MG patient who presents with unilateral or bilateral retraction, because both conditions may coexist in 4% to 10% of patients.[12] Similarly, the presence of proptosis should not exclude a diagnosis of MG.

It is also important to differentiate MG from paraneoplastic disease (Lambert-Eaton myasthenic syndrome [LEMS]) which is a distinct autoimmune disease of neuromuscular junction transmission caused by paraneoplastic antibodies directed against the presynaptic voltage-gated calcium *(Print pagebreak 603)* channels (VGCCs).[36] An aggressive search for an underlying malignancy is central to the management of LEMS as it is associated with a small lung cell cancer in approximately 40% to 50% of patients but other malignancies may be observed as well.[36,37] The initial presentation may be similar to MG/OMG with variable ptosis and diplopia which are not as rare as was previously thought.[12,36] Systemically, LEMS may suffer more proximal muscle weakness/fatigability, hyporeflexia, and an important differentiating point is that LEMS may rarely manifest with autonomic dysfunction symptoms like pupillary abnormalities.[12,36] Antibodies to VGCCs may also clinch the diagnosis as they are positive in 75% to 100% of patients with LEMS and only 5% with MG, while the reverse is true if anti-AChR ABs are tested.[37] Other neurologic disorders that should also be differentiated from MG include neuromyotonia, the Miller Fisher variant of Guillain-Barré syndrome, and genetic and toxic myasthenic syndromes.[5]

Treatment

Acetylcholinesterase inhibitors remain the mainstay treatment modality in MG. However, any long-term treatment plan should include immunosuppression, which is required in generalized MG.[38] Glucocorticoids, azathioprine, cyclosporine A, mycophenolate mofetil, cyclophosphamide, methotrexate, and tacrolimus have all been tried as single agents or in combination.[38] In OMG, treatment with acetylcholinesterase inhibitors may be sufficient in milder cases, but the indications for use of immunomodulating agents are less clear-cut.[38,39] A recent randomized, double-blind, placebo-controlled trial (the EPITOME study) showed a beneficial effect of an initial low dose of prednisone with gradual escalation when OMG is resistant to acetylcholinesterase inhibitors.[22] Immunosuppressants do not only ameliorate the symptoms of the disease but may also reduce the rate of progression of OMG to generalized MG.[12] In severe or drug-resistant cases, co-treatment with intravenous immunoglobulins or plasmapheresis may be considered.[38] More recently, rituximab[40] and a newer monoclonal antibody eculizumab (Soliris) have shown some promise in cases refractory to conventional treatment.[41]

Any thymic enlargement detected on CT scan or MRI should be removed. Some authorities recommend routine transsternal/endoscopic thymectomy even in nonthymoma patients, particularly children and adults up to the 5th decade, provided it is performed during the first year into the disease in the hope of achieving a medication-free remission.[26,32,42] A recent randomized clinical trial (the MGTX trial) conducted over 3 years has demonstrated clinically significant improvement in nonthymomatous MG patients and a more favorable outcome than prednisolone.[32] A 5-year follow-up study confirmed a possible beneficial effect of thymic resection in nonthymoma patients;[43] however, patients with $MUSK^+$ MG and patients with late-onset MG may not benefit from the procedure.[5,8]

Nonsurgical management of ptosis in OMG may involve taping the ptotic eyelid up or the use of ptosis crutches, but these measures may exacerbate corneal dryness, as well as corneal exposure,[12] and the crutches may cause chronic ocular pain. Ptosis surgery in OMG is considered high risk due to a combination of perioperative considerations, poor ocular motility, poor Bell phenomenon, and the reduced orbicularis muscle strength which may further impair eyelid closure mechanisms following surgery.[44] Perioperative considerations in the surgical management of OMG include the choice of anesthetics and the choice of postoperative antibiotics.[7] Although general anesthesia no longer poses an untenable risk to myasthenic patients, local anesthesia may be preferred, as resistance to neuromuscular blocking agents may result in a higher likelihood of prolonged postoperative recovery.[7] Postoperatively, the choice of antibiotics used is another critical issue. As we mentioned earlier, fluoroquinolones, aminoglycosides, and macrolide antibiotics should be used with caution.

MG patients with esthetic concerns pushing for full correction should be counseled that the main goal of surgery is to clear the pupillary axis while minimizing the risk of corneal exposure. When a frontalis suspension procedure is considered, silicone slings are the preferred sling material because of their elastic nature and their potential for easy reversibility if corneal exposure is observed postoperatively. The open technique is generally favored over the closed Fox method for brow suspension.[44,45,46,47] Surgical management of ptosis in OMG and other causes of neurogenic ptosis is discussed in further detail in Chapter 12.

Prognosis

Before the widespread use of immunosuppressants in the management of MG, the disease-specific mortality rate was as high as 30%; however, with the use of immunomodulators along with advances in mechanical ventilation and intensive care, the overall mortality rate has dropped to less than 5%,[26] but despite the improved management, MG patients may remain dependent on long-term immunosuppressants and acetylcholinesterase inhibitors, which may be required for life, and some patients with severe disease may still develop a permanent disabling weakness.[15,26,42] Luckily, patients with mild to moderate disease who constitute the majority of MG patients can still lead essentially normal lives as the daily life functions may only be modestly impaired or may not even be affected at all, and some may enter a phase of complete stable remission without a reduction in life expectancy.[15,42,48] Thymoma patients pose a different problem as the prognosis is related to the histological staging of the tumor.[42,49]

Histopathology

Europa, Nel, and Heckmann recently reviewed skeletal muscle histopathology in MG patients.[50] Nonocular skeletal muscles exhibit neurogenic atrophy, with groups of skeletal muscle fibers being atrophic and angulated.[50] Prolonged disease *(Print pagebreak 604)* duration may cause atrophy with fatty replacement of skeletal muscle.[50] Extraocular muscles in MG patients have severe fatty change and mitochondrial stress alterations, though similar findings occur in extraocular muscles from strabismus patients.[50] Europa and coworkers postulate that “extraocular muscles may be more susceptible than limb muscles to poor contractility as a

consequence of myasthenia, resulting in a cascade of atrophy signaling pathways and altered mitochondrial homeostasis which contribute to the tipping point in developing treatment-resistant myasthenic ophthalmoplegia."[50] Our experience is limited to examining one inferior oblique muscle from a patient with MG for 1 year. No histological abnormality was identified in this muscle removed as part of enucleation for fungal endophthalmitis.

CHAPTER 91

Necrotizing Fasciitis

Key Points

- Necrotizing fasciitis is an uncommon soft-tissue infection characterized by extensive suppurative fasciitis, vascular thrombosis, and cutaneous gangrene
- The infection progresses rapidly over hours to several days, spreading along superficial and deep fascial tissue planes to involve subcutaneous tissue and fascia, with secondary necrosis of the overlying skin
- Patients often suffer from diabetes mellitus, alcoholism, collagen vascular disease, or conditions requiring immunosuppression
- Type I necrotizing fasciitis usually occurs after trauma or surgery caused by polymicrobial anaerobic and facultative bacteria
- Type II necrotizing fasciitis is a monomicrobial infection usually with virulent subtypes of *Streptococcus pyogenes*
- Patients are usually febrile and present with extensive, rapidly progressive eyelid swelling, and erythema, pain, crepitus, a foul-smelling watery wound discharge, and areas of necrosis
- Treatment includes broad-spectrum antibiotics, surgical debridement, fluid resuscitation, and cardiorespiratory supportive care when necessary to maintain vital organ function
- Systemic complications are frequent and the prognosis generally is poor with a mortality rate up to 50%

The first description of necrotizing fasciitis (NF) is generally attributed to Fournier in 1883,[1] although a very similar gangrene-like infectious process was previously described by Ambrose Paré in 1575.[2] However,

the term, NF, was only introduced by Wilson in 1952.[3] NF is an uncommon soft-tissue infection characterized by extensive suppurative fasciitis, vascular thrombosis, and cutaneous gangrene.[4,5] The infection progresses rapidly over hours to several days, spreading along superficial and deep fascial tissue planes to involve subcutaneous tissue and fascia, with secondary necrosis of the overlying skin.[5,6] The most common causative organism is group A β-hemolytic *Streptococcus*, but other gram-positive, gram-negative, and anaerobic bacteria, and even fungi, can also be involved.[7,8] NF commonly occurs on the extremities, abdomen, and perineum, and less commonly in the head and neck.

NF only occasionally involves the eyelids, with about 150 cases reported.[7,9,10,11,12] Patients often suffer from diabetes mellitus, alcoholism, collagen vascular disease, or conditions requiring immunosuppression,[13,14,15] although in many cases, there are no obvious predisposing risk factors for infection. Periorbital NF has been reported after trauma,[16,17] after surgery including dacryocystorhinostomy,[18] and blepharoplasty,[19] and following an insect bite.[9]

Eyelid NF can be caused by aerobic, anaerobic, or polymicrobial infections, although the vast majority of bacterial isolates are group A β-hemolytic streptococci or *Staphylococcus aureus*.[10,20,21] In a report of 67 cases of NF at a Philippine University Medical Center, *Escherichia coli* was the most common isolate seen in 44% of patients.[22] A case of NF caused by *Apophysomyces* belonging to the order *Mucorales* was reported in a burn patient.[23]

Etiology and Pathogenesis

Necrotizing soft-tissue infections are potentially lethal infections that require early recognition and aggressive management.[24,25,26] These infections most frequently involve the abdomen, perineum, and lower extremities, but can occur in any part of the body. Surgery and trauma are the most common predisposing factors, but it rarely has been reported following diverse etiologies such as spinal anesthesia,[27] measles vaccine,[28] as a complication of infectious mononucleosis,[29] following dental procedures,[30] and

associated with insect bites.[31] Immunocompromised individuals, especially those with diabetes, are more likely to develop necrotizing infections. However, in many cases, there is no identifiable preceding event.

All necrotizing infections are best viewed as a spectrum of clinical conditions with similar pathophysiological features and common treatment approaches.[26,32,33] NF has been classified according to the types of microbial organisms involved. Type I NF usually occurs after trauma or surgery.[3,34] Initially, the subcutaneous fat and fascia are primarily involved, and later may extend into the muscle. But most commonly, widespread necrosis is present in the subcutaneous fat and fascia, with relative sparing of muscle. Polymicrobial anaerobic and facultative bacteria are involved in tissue destruction, and gas may or may not be present. The clinical pace of the disease is usually slower than that seen with type II NF.[8] Patients usually have a predisposing risk factor, such as diabetes mellitus.

Type II NF is a monomicrobial infection usually with virulent subtypes of *Streptococcus pyogenes*.[5,35,36] It presents clinically in a similar fashion to type I NF, but the presence of gas in tissues is unusual.[8] Varicella infection and the use *(Print pagebreak 607)* of nonsteroidal anti-inflammatory drugs may be additional predisposing risk factors besides trauma or surgery.[5,37,38,39] This form of NF is also more frequently associated with streptococcal toxic shock syndrome.[40]

FIGURE 91.1 Necrotizing fasciitis involving the eyelids. A, Upper and lower eyelid edema, erythema, and early devitalization of eyelid skin. B, Bilateral skin necrosis and crusting. C, Bilateral involvement with necrosis of the left eyelids. D, Severe necrosis of upper and lower eyelids with extensive loss of tissue. (A, Courtesy of Dr. Charles Soparkar; B, Courtesy of Dr. Grant Gilliland; C, Courtesy of Dr. James Gigantelli; D, Courtesy of Dr. John Holds.)

Clinical Characteristics

In the eyelids, NF is often identified earlier than elsewhere in the body because of the thin skin and the orbicularis oculi muscle that lies superficial to the fascial layers allowing the infection to become more easily recognized.[9] Of the reported eyelid cases, nearly half are bilateral, and deep orbital involvement by spread of the infection along the orbital fibrous septae and blood vessels can result in arterial thrombosis with diffuse ophthalmoplegia, central artery occlusion, papilledema, and blindness.[9,41]

Patients with periorbital NF are usually febrile and present with extensive eyelid swelling and erythema rapidly progressive over several days.[11] Other clinical features include pain, crepitus, a foul-smelling watery wound discharge, violaceous discoloration, serosanguinous skin blisters, and areas of necrosis (Figure 91.1).[8] In early cases, the skin wound may appear only mildly infected, unlike deeper fascial layers, and this may contribute to devastating diagnostic delay. Soft-tissue gas is a classic sign but is not always present.[42] The past medical history may include immunosuppression, diabetes, hyperglycemia, acidosis, and severe dehydration. Even with early recognition and timely appropriate treatment, some cases may progress rapidly to septic shock and

death.[24,25,34,42]

Differential Diagnosis

The differential diagnosis of periorbital NF includes any infectious or inflammatory processes in the periorbital region such as preseptal and orbital cellulitis.[6] Dacryocystitis, erysipelas, and *herpes zoster* are also included.

(Print pagebreak 608)

NF should also be differentiated from other causes of necrotizing soft-tissue infections such as clostridial myonecrosis (gas gangrene), which is a life-threatening infection that affects the skeletal muscle and is most commonly caused by *Clostridium perfringens* or to a lesser extent *Clostridium septicum*.[42,43] Although both entities fall under the rubric of necrotizing soft-tissue infections and may indeed look identical clinically, the presence of an extremely pungent foul-smelling discharge, as well as the presence of air or gas in tissues in radiological studies, is more suggestive of clostridial myonecrosis, which may have up to a 100% mortality without prompt and repeated debridement.[43] Clostridial myonecrosis is occasionally referred to in the literature as type III NF, but it is rarely encountered in the periocular region (Figure 91.2).

Treatment

Prompt diagnosis and aggressive treatment of periorbital and orbital NF are critical for the preservation of vision and life.[9,10,44] Appropriate treatment includes broad-spectrum antibiotics, surgical debridement, fluid resuscitation, and cardiorespiratory supportive care when necessary to maintain vital organ function.[15,45,46,47,48,49] Empiric antibiotic treatment should be broad to cover both polymicrobial (mixed aerobic and anaerobic microbes) and monomicrobial (group A streptococci and community-acquired methicillin-resistant *S. aureus*) organisms. These can include vancomycin or linezolid plus piperacillin-tazobactam, or carbapenem, and ceftriaxone and metronidazole.[50] For documented group A streptococcal NF, penicillin plus clindamycin is recommended.[51,52]

Complete subcutaneous debridement of affected tissue and removal of all necrotic skin are critical. The extent of debridement is determined by the surgical findings, retaining maximal amounts of viable skin and orbicularis oculi muscle to prevent disfiguring facial deformities. Tissue debridement should be repeated until the local infectious process is under control.[53] Hyperbaric oxygen therapy has been advocated, but it has an uncertain role. Whereas some studies have suggested a survival benefit,[42,46,54,55] others have not shown any benefit.[56,57]

Although most cases will require a combination of intensive parenteral antimicrobial therapy and prompt surgical debridement, mild cases may respond to medical therapy alone.[58] Intravenous pooled immunoglobulin and heparinization may also have beneficial roles by neutralizing superantigen activity and aiding antibiotic perfusion.[4]

Prognosis

Because NF progresses rapidly and systemic complications are frequent, the prognosis generally is poor. Despite aggressive therapy, the mortality rate has been reported to be up to 50%.[24,26,35,45,52,53,56,59,60] When the eyelids are involved, NF has a more favorable prognosis, reported in from 10%[10] to 18%,[13] probably owing to the eyelid's more extensive vascular supply and the typically earlier recognition and treatment of infection. Mortality in these cases is often secondary to inadequate treatment or delayed debridement resulting in *(Print pagebreak 609)* systemic sepsis and shock with multiorgan failure. Visual loss in patients with periorbital or orbital involvement can be seen in 13% to 30% of cases.[10]

FIGURE 91.2 Clostridial myonecrosis (gas gangrene). A, Clinically, clostridial myonecrosis looks remarkably similar to necrotizing fasciitis. B, On closer examination, gas bubbles can be seen coming out of necrotic eyelid tissue. C, Noncontrast CT scan of the orbit shows the presence of an extensive amount of air along fascial planes and muscles of the periorbital region.

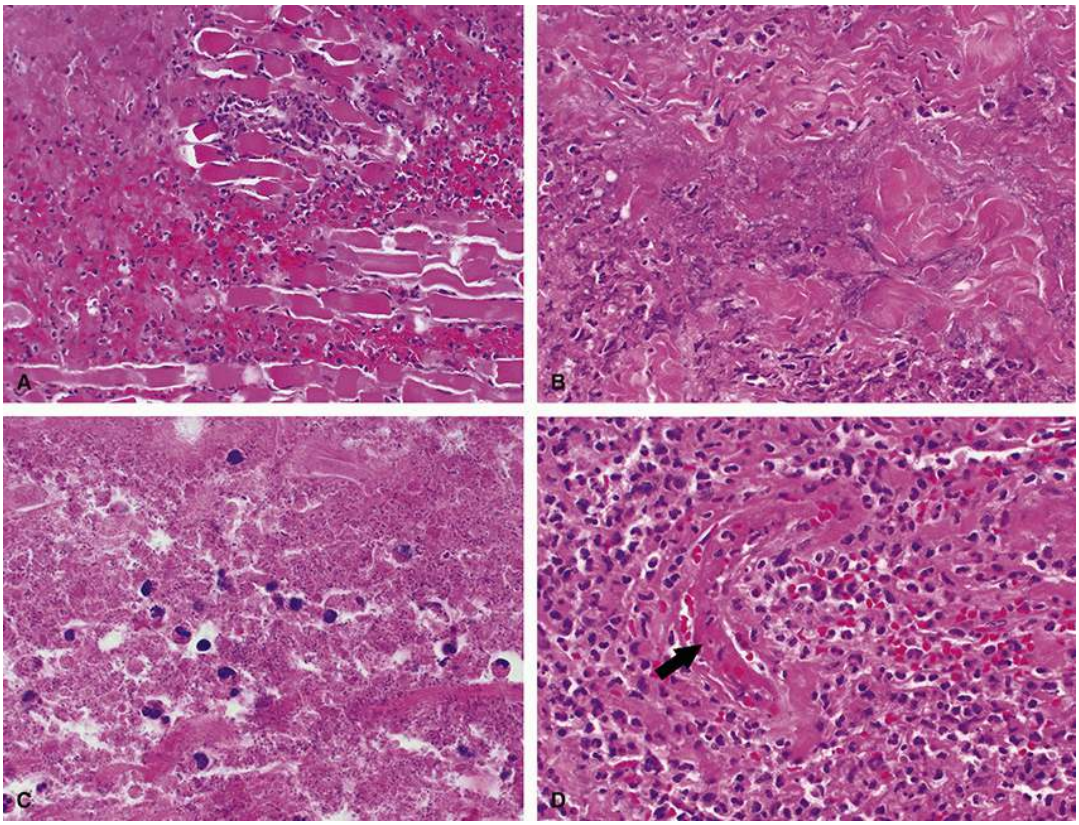

FIGURE 91.3 A 12-month-old boy developed necrotizing fasciitis of the left lower eyelid after blunt trauma.[36] Skeletal muscle (A) and fascial connective tissue (B) were infiltrated by neutrophils and macrophages, accompanied by extensive necrosis. C, Areas with numerous bacterial cocci caused a stippled appearance in the hematoxylin- and eosin-stained sections D, Rare vessels (arrow) contained fibrin thrombi.

Histopathology

The histopathology of NF varies depending on the disease's duration.[61,62,63,64] Stamenkovic and Lew[63] used these criteria for diagnosing NF: "(1) necrosis of superficial fascia, (2) polymorphonuclear infiltration of the deep dermis and fascia, (3) fibrinous thrombi of arteries and veins passing through the fascia, (4) angiitis with fibrinoid necrosis of arterial and venous walls, (5) the presence of microorganisms within the destroyed fascia and dermis in a tissue specimen with Gram stain, and (6) an absence of muscle involvement." Early in the course of NF, thrombi are more frequent[61] and inflammatory cells may be sparse.[62] Features of clinically established streptococcal NF include subepidermal blisters, eccrine gland necrosis, and myonecrosis with neutrophilic inflammation (Figure 91.3).[62]

CHAPTER 92

Neurofibroma, Solitary

Key Points

- Neurofibromas are tumors that arise from nonmyelinated Schwann cells and perineural fibroblasts
- Isolated neurofibromas are benign, slowly growing, unencapsulated neoplasms that usually arise from cutaneous nerves, with the occasional involvement of deep organs or bone nerves
- As many as 90% of solitary lesions occur sporadically, but 10% are associated with neurofibromatosis type 1 or 2
- The pathophysiology of both sporadic and syndromic cases of neurofibroma is similar and results from a deletion in the NF1 gene
- Solitary lesions on the eyelid present as circumscribed, oval, smooth, firm, immobile, subcutaneous nodules ranging in size from 4 to 15 mm
- Small, asymptomatic eyelid tumors can be followed conservatively, but for lesions that show significant growth, are painful, or cause ptosis or visual symptoms, surgical resection is indicated
- The prognosis for eyelid lesions is excellent following adequate surgical resection

Benign peripheral nerve sheath tumors are divided into three broad categories: neuroma, neurofibroma, and schwannoma.[1,2] Neurofibromas are tumors that arise from nonmyelinated axons, Schwann cells, fibroblasts, and perineural cells. Most neurofibromas are sporadic lesions, but multiple neurofibromas, plexiform neurofibromas, and large neurofibromas are almost always associated with neurofibromatosis type 1 (NF-1).[3]

Three distinct forms of neurofibroma are described: plexiform, diffuse, and solitary subtypes. Plexiform neurofibroma is mostly associated with NF-1 and is the most common benign peripheral nerve tumor occurring in the eyelid, where it typically tracks along peripheral branches of the trigeminal nerve. It can attain massive sizes and cause significant functional and cosmetic compromise (Chapter 93). Diffuse neurofibromas are uncommon, poorly defined, infiltrative cutaneous, subcutaneous, or soft-tissue tumors, seen most often in the head and neck of children and young adults. They extend between tissue planes, along connective tissue septa, and surround adjacent normal structures, encasing vascular and neural structures.[4,5] Unlike the plexiform subtype, only about 10% of diffuse lesions are associated with neurofibromatosis.

Isolated neurofibromas are benign, slowly growing, unencapsulated neoplasms that usually arise from cutaneous nerves, with the occasional involvement of deep organs, bones, or nerves. They can be seen in patients with NF-1 where they tend to be multiple and are seen more commonly in deep locations. However, in most cases, isolated neurofibromas occur in patients who do not have NF-1, and in such cases, they are termed solitary neurofibroma.

The solitary neurofibroma is usually a well-circumscribed tumor that forms an ovoid or fusiform cutaneous or subcutaneous mass.[6,7] As many as 90% of solitary lesions occur sporadically, while 10% are associated with NF-1 or NF-2.[3,6] In the head and neck region, solitary neurofibromas most often involve the trigeminal (fifth) and facial (seventh) cranial nerves. The most frequently affected sites include the tongue, buccal mucosa, and lips,[8,9,10,11] and deep lesions typically present as a facial mass.

Solitary neurofibroma of the eyelid is rare. Woog et al[12] mentioned 65 cases of orbital and periorbital neurofibroma but without specific details. Of these cases, 40% were associated with NF-1, and 55% involved the eyelid. It was not clear how many of the eyelid cases were nonsyndromic or how many were plexiform vs solitary lesions.

To date, only 15 cases of solitary neurofibromatosis involving the eyelids have been described with sufficient clinical detail.[13,14,15,16,17,18,19,20,21,22] Of these cases, 79% were female. The ages ranged from 38 to 81 years with a mean of 63.3 years. Lesions presented on the upper eyelid in 57% of the cases and the lower eyelid in 43%.

Neurofibroma involving the conjunctiva has also been described, of which 75% are solitary and 25% are syndromic.[23,24,25,26,27,28,29,30,31,32,33,34,35,36] Conjunctival tumors occur equally among males and females, and the age at presentation is somewhat younger than for eyelid lesions, ranging from 22 to 78 years with a mean of 51 years.

Malignant transformation of a neurofibroma to malignant peripheral nerve sheath tumor is seen occasionally with plexiform neurofibromas but is exceptionally rare in solitary neurofibroma not associated with neurofibromatosis, although it can be seen with recurrent lesions.[37]

Etiology and Pathogenesis

The pathophysiology of both sporadic and syndromic cases of neurofibroma is similar and results from a deletion in the NF1 gene. In syndromic cases, the neurofibroma results from a germline mutation in the NF1 gene *(Print pagebreak 613)* on chromosome 17q11.2, which encodes the tumor suppressor protein neurofibromin.[38,39] This genetic defect results in overexpression of the p21 *RAS* proto-oncogene, a cellular protein that plays a role in mitogenic signaling pathways. Heterozygous loss results in Schwann cell and fibroblast proliferation that forms neurofibromas. In sporadic cases, only the lesional cells and their somatic progeny carry the mutation.

FIGURE 92.1 A and B, Solitary neurofibroma of the eyelids.

Several studies have shown a loss of heterozygosity at the NF1 locus in dermal and plexiform neurofibromas,[40,41,42,43] or inactivation of both copies of the *NF1* gene in the *NF1* gene in some isolated neurofibromas.[43,44,45,46] Although some authors have suggested that sporadic neurofibromas may arise through a different genetic mechanism,[47,48] Storlazzi et al[49] showed that biallelic somatic inactivation of the *NF1* gene through chromosomal translocation can lead to the cellular proliferation of Schwann cells associated with neurofibroma. Other chromosome studies of neurofibromas have reported clonally abnormal karyotypes, such as monosomy 22, hyperdiploid tumors, and complex translocations that may play a role in tumor growth.[50,51,52,53,54,55] Marocchio et al[56] considered that solitary neurofibroma may be a hyperplastic hamartomata rather than a neoplastic tumor.

Solitary neurofibroma can also rarely arise in patients with germline changes in the *NF1* gene but with no clinical evidence of neurofibromatosis.[57] One case has been reported of a solitary neurofibroma that was thought to be related to local trauma 3 months earlier.[57]

Clinical Characteristics

Most neurofibromas involving the eyelid are solitary lesions and present as a circumscribed, oval, smooth, firm, immobile, subcutaneous nodule. Lesions are usually small, ranging in size from 4 to 15 mm in diameter with normal overlying skin (Figure 92.1). While generally painless, they may sometimes be tender or even painful. Lesions are slow growing over months to as long as 5 years.[21] In patients with NF-1, cutaneous neurofibromas tend to be multiple[58,59,60,61,62] and appear as discrete, subcutaneous nodules that can involve the eyelids and adjacent periorbital skin (Figure 92.2).

On the conjunctiva, a solitary neurofibroma appears as a smooth, white, reddish, or yellow-gray; sessile, pedunculated, or dome-shaped mass located in the conjunctival stroma (Figure 92.3).[63] It may be firm to gelatinous and associated with corneal pain, photophobia, or dellen formation.[20,24,32]

Differential Diagnosis

The differential diagnosis of eyelid neurofibroma includes a wide variety of clinically similar lesions. Most frequently, it has been mistaken for a chalazion.[15,16,17,20] In the case by Shibata et al[20] the tumor occupied the full thickness of the *(Print pagebreak 614)* tarsal plate, was surrounded by normal acini of the meibomian glands, and apparently developed from a small nerve coursing through the tarsal plate.

FIGURE 92.2 Neurofibromas in the setting of neurofibromatosis type 1. Hundreds of small lesions on the face, forehead, and eyelids.

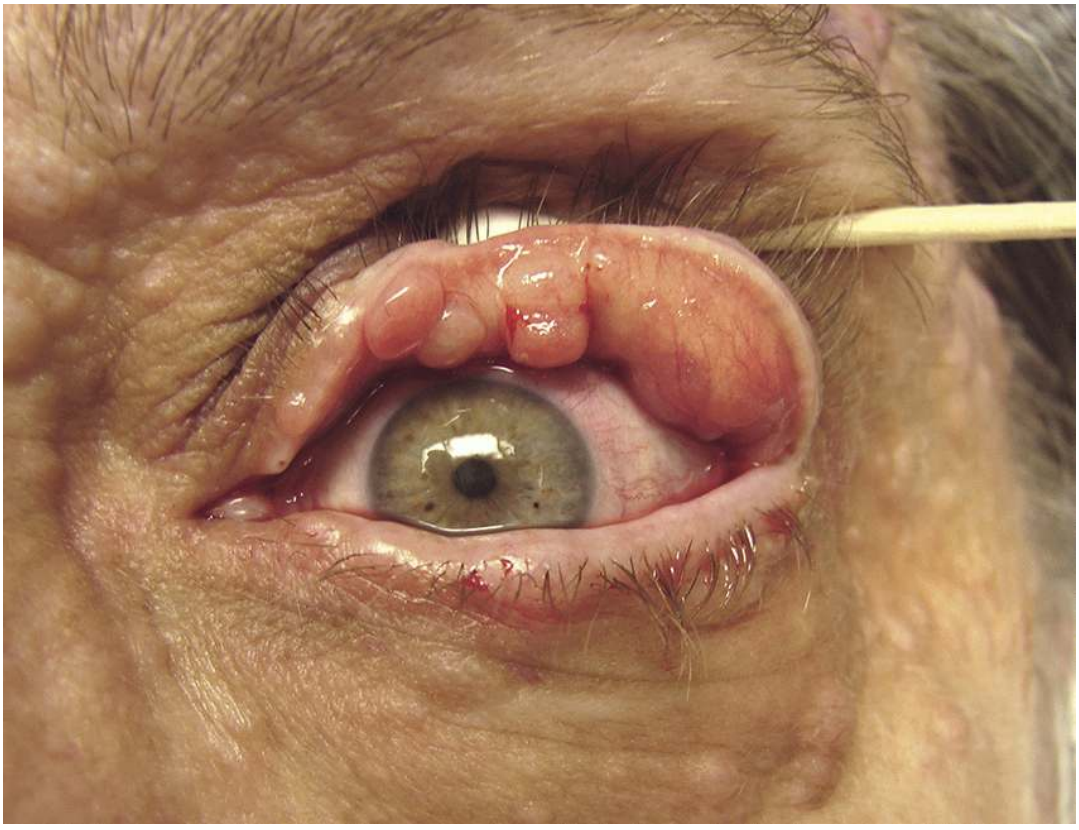

FIGURE 92.3 Nodular neurofibromas on the eyelid skin and conjunctival surfaces.

Other conditions simulating neurofibroma on the eyelid include amelanotic or poorly pigmented nevomelanocytic nevus, apocrine hidrocystoma, early basal cell carcinoma, benign apocrine gland tumor, dermal leiomyoma, and molluscum contagiosum. Hidrocystomas are often white to yellow in color, and early basal cell carcinomas frequently have central ulceration with elevated pearly borders. Molluscum contagiosum is usually characterized by a prominent central umbilication. Nevi and molluscum contagiosum generally occur in children.

Rare lesions that might be considered in the differential diagnosis also include malignant peripheral nerve sheath tumor, schwannoma, perineurioma, dermatofibroma, dermatofibrosarcoma protuberans, superficial leiomyoma, ganglioneuroma, and desmoplastic melanoma. Most can be differentiated from solitary neurofibroma by their association or lack thereof with NF-1, by immunohistochemistry, and by their genetic profile.

Treatment

Because the malignant potential of solitary cutaneous neurofibromas is minimal, small, asymptomatic eyelid tumors often can be followed conservatively. For lesions that show significant growth, are painful, or are large enough to cause ptosis or visual symptoms, surgical resection is indicated. Unlike diffuse or plexiform neurofibromas on the eyelids, solitary lesions can often be resected via a skin crease incision with the preservation of overlying skin. The tumor cannot easily be separated from the involved nerve so that complete excision usually requires sacrificing the nerve. Tumor recurrence following surgical excision is rare[17,20,29] and is usually related to incomplete resection.

There are currently no widely accepted alternative therapies for a solitary neurofibroma.[64] Diode and CO_2 laser therapy have been used successfully for oral, laryngeal, and multiple cutaneous tumors, including the eyelids. However, laser therapy is only useful in removing superficial neurofibromas and has been reported to cause hypertrophic, depigmented scars.[65,66] Electrodessication and scoop diathermy were reported to achieve good results in treating several hundred lesions in a single setting with minimal complications in patients with recurrent cutaneous neurofibromas,[67,68] but these techniques have not been repeated.

Prognosis

The prognosis for patients with a solitary neurofibroma of the eyelid is excellent following adequate surgical resection. Recurrence can be seen with incomplete resection. Several cases of recurrence were previously misdiagnosed as a chalazion and treated with incision and curettage.[15,17]

Malignant transformation of neurofibroma associated with NF-1 is unusual and less common in solitary tumors than in plexiform neurofibroma. Transformation of solitary neurofibroma, without association to NF-1, is extremely rare.[37] Malignant peripheral nerve sheath tumors are insensitive to radiotherapy and chemotherapy and carry a poor prognosis, with a 5-year disease-specific survival rate of 32% to 50%, worse for head and neck tumors.[69,70,71,72,73,74]

Histopathology

We have examined only a few solitary eyelid neurofibromas over the past 30 years (Figure 92.4). They may resemble isolated neurofibromas in patients with NF-1 (Figure 92.5) and are indistinguishable from solitary cutaneous neurofibromas at other body sites. Classic solitary (sporadic) cutaneous neurofibromas are nonencapsulated, poorly to well-circumscribed dermal tumors that often extend into the subcutis.[75] The tumors are palely eosinophilic (Figures 92.4 and 92.5),[76] with a band of normal dermis separating the tumor from the overlying epidermis (Figures 92.4 and 92.5B).[77,78] Solitary neurofibromas are composed of spindle-shaped cells with scant palely eosinophilic cytoplasm, indistinct cytoplasmic borders, and oval or S-shaped nuclei (Figures 92.4C, D and 92.5C, D) set in fibrillar, collagenous, and sometimes myxoid stroma[75,78,79] containing mast cells (Figure 92.5D).[75,80] The tumor cells may form delicate, loosely arranged fascicles that are only one-or two cell thick.[75] Tumor cells surround but do not destroy hair follicles and dermal glands (Figure 92.5B).[75,76,77] A variable number of axons,[75] demonstrable using Bodian silver stain or immunohistochemistry, are present and may assist in distinguishing cutaneous neurofibromas from schwannomas that consist almost solely of Schwann cells.[77] Multinucleated floret-type giant cells are present in about one-fourth of neurofibromas.[78] Immunohistochemical stains are not usually needed for diagnosis; if performed, tumor cells express S100 protein while the admixed fibroblasts express CD34.[76,78] *(Print pagebreak 615)* Immunostaining for CD34 has a “fingerprint” pattern that is useful for

differentiating cutaneous neurofibroma from desmoplastic melanoma.[81]

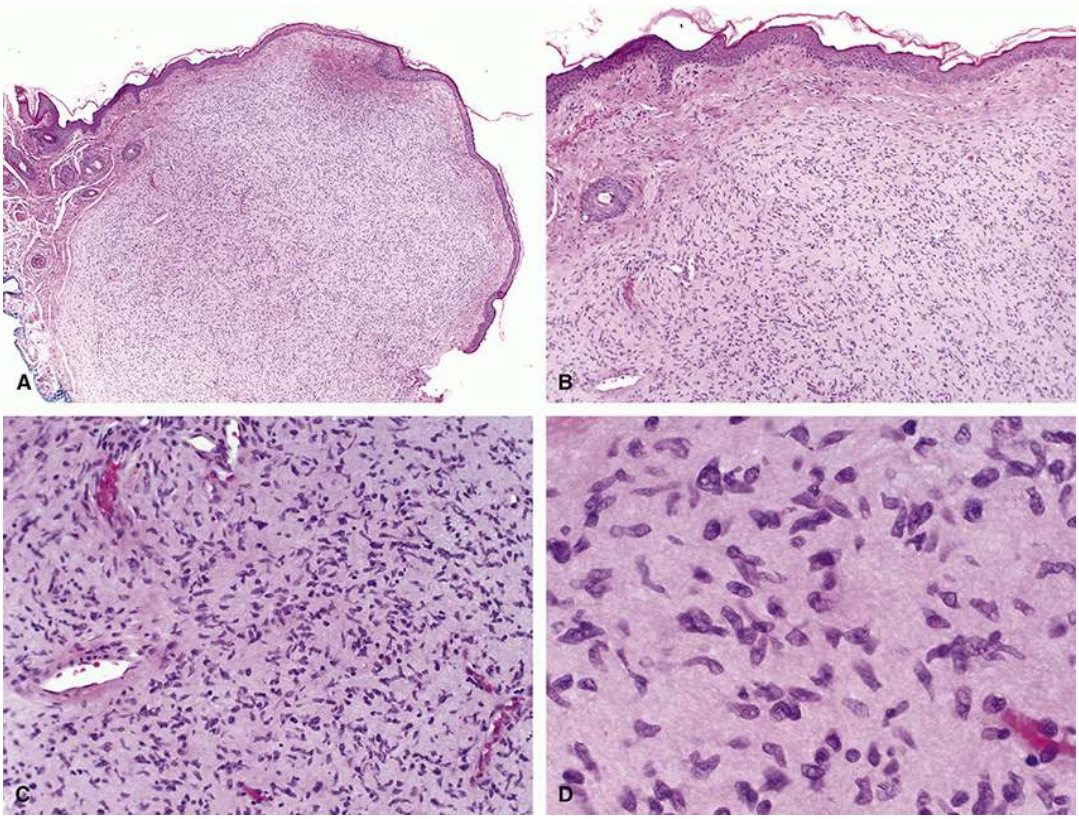

FIGURE 92.4 A, This solitary (sporadic) neurofibroma arose in the medial right upper eyelid of a woman in her early 60s without a history or clinical manifestations of neurofibromatosis type 1. The dermal tumor is nonencapsulated, well circumscribed, and more palely eosinophilic than the surrounding dermis. B, A band of the normal dermis (grenz zone) separates the tumor from the overlying epidermis. C, This solitary neurofibroma is composed of spindle-shaped cells with scant palely eosinophilic cytoplasm and indistinct cytoplasmic borders. D, The tumor cells have oval and curved nuclei.

A lesion that may be confused with eyelid neurofibroma is a solitary circumscribed neuroma, formerly termed palisaded encapsulated neuroma.[78,82] These tumors have a predilection for the face[78,82,83] and may involve the eyelid.[18,83,84,85] Solitary circumscribed neuromas are well-circumscribed dermal nodules with a delicate, often incomplete, epithelial membrane antigen-positive fibrous capsule surrounding broad fascicles of S100 protein-positive Schwann cells and numerous neurofilament protein-positive axons.[77,82,85] Artifactual clefts often separate the tumor cell fascicles.[82,85] Tumor cells may focally align in a “vaguely”[85] parallel arrangement, but classic palisading or Verocay body formation is uncommon.[82,85]

(Print pagebreak 616)

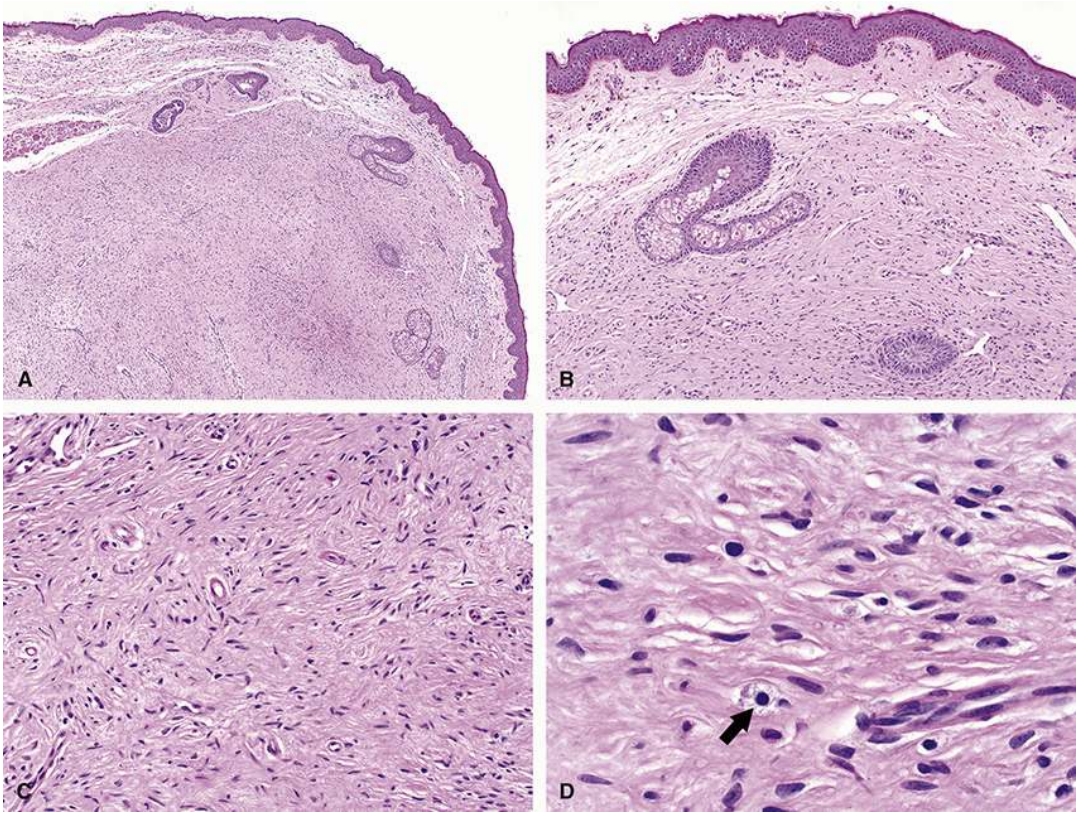

FIGURE 92.5 A, This isolated neurofibroma developed in the right upper eyelid of a woman in her early 50s with a history of neurofibromatosis type 1. The tumor is indistinguishable from a sporadic solitary neurofibroma. The lightly eosinophilic neurofibroma was centered between the orbicularis oculi muscle and the tarsal plate. B, A band of normal dermis separates the tumor from the overlying epidermis. Tumor surrounds hair follicles and sebaceous glands without altering their structure. C, The tumor is composed of spindle cells in a vascularized fibrillary stroma. D, The tumor cells have oval and occasionally wavy nuclei. A mast cell is present among the tumor cells (arrow).

CHAPTER 93

Neurofibroma, Plexiform

Key Points

- Neurofibromatosis type 1 is an inherited multisystem neurocutaneous disorder
- The disease results from mutations in the *NF1* gene that results in the loss of neurofibromin function and overall increase in active Ras leading to unchecked cellular proliferation and possibly cancers
- Plexiform neurofibroma (PN) is the most common benign peripheral nerve tumor
- Eyelid tumors typically occur along the peripheral branches of the trigeminal nerve and can assume a massive size with significant visual compromise
- PN may have extensive infiltration of the levator muscle and its aponeurosis with impairment of levator function
- Surgery may be indicated for cosmesis and for prevention of amblyopia in children from visual obstruction
- Because of the infiltrative nature of the tumor and the lack of a circumscribed capsule, complete surgical debulking is impossible
- Repeated sessions of surgical debulking are usually required as the tumor gradually continues to grow. Eyelid functional disturbances are almost inevitable

Neurofibromatosis type 1 (NF1) is an inherited multisystem neurocutaneous disorder with considerable clinical variability that has been extensively studied in the literature by almost all medical disciplines, yet proper management still eludes practitioners. Plexiform neurofibroma (PN) is one of the many striking features of NF1 involving the periorbital region, and it has assumed a variety of names in the literature, including orbital, orbitopalpebral, orbitofacial, or orbitotemporal neurofibromatosis, and more recently, the more complex yet all-encompassing name, orbital-periorbital plexiform neurofibroma.[1,2]

Etiology and Pathogenesis

NF1 is inherited in an autosomal dominant fashion with full penetrance and variable expression.[3,4] The gene responsible for NF1 is an unusually long tumor suppressor gene spanning a length of over 280 Kb of genomic DNA on the long arm of chromosome 17 (17q11.2).[1,2,3,4] Because of this unusual length, almost 1500 mutations have been identified in the gene so far,[4] with approximately half of these mutations being de novo.[3,4] The *NF1* gene codes for a protein called neurofibromin, which during embryonic and fetal life is involved in the differentiation of neural crest-derived cells. Neurofibromin has significant homology to GTPase-activating proteins, which in turn are negative regulators of the RAS-MAPK signal transduction pathway. Ras proteins are signaling molecules involved in physiologic control of cellular proliferation, as well as several pathological processes such as cancer. When the *NF1* gene mutates, this results in the loss of neurofibromin function, which in turn reduces GTPase activity within the cell, and therefore results in an overall increase in active Ras proteins leading to unchecked cellular proliferation and possibly cancers. Therefore, NF1 is a cancer predisposition syndrome, and NF1 individuals are at a greater risk than the general population for developing malignancies.[5,6] Because NF1 was the first syndrome to be associated with a germline mutation in the RAS pathway, NF1 is considered by some researchers as belonging to a large genetic family called the RASopathies, which are a well-studied group of medical genetic syndromes caused by germline mutations in genes that encode the components or regulators of the RAS-MAPK pathway.[4,5,6]

Clinical Presentation

NF1 is one of the most frequently seen neurocutaneous syndromes with a reported incidence between 1/2300-1/3500 live births.[7,8] The clinical presentation which usually involves the skin and the nervous system is remarkably variable with some patients having

very few manifestations, whereas others are seriously affected.[1,2,9,10]

PN is the most common benign peripheral nerve tumor occurring in the eyelid and typically tracks along the peripheral branches of the trigeminal nerve.[1,2] They can assume massive sizes, which may cause significant visual compromise, as well as placing a substantial psychological burden on the patient. PN, which usually occurs as part of the typical constellation of signs and symptoms of NF1, may affect up to 20% of NF1 patients.[11,12] Contrary to some textbooks that emphasize that PN is practically diagnostic of NF1, PN is no longer considered pathognomonic of the disease.[13] This is because a variant of NF1 may affect the periorbital region in an isolated segmental manner without the other National Institutes of Health (NIH) stigmata of the disease.[13,14] exclusively affects the orbital region.[13] This so-called orbitotemporal variant or segmental NF is reportedly more common in females, and an *NF1* gene mutation may be absent.[13,15,16,17] *(Print pagebreak 620)* To settle the argument whether this is a segmental form of NF1 or an entirely separate entity[13,17] requires that tumor tissue from the periorbital region in this subset of patients be directly investigated for this mutation.[13]

For reasons that are not yet clear, PN is usually a unilateral disease,[18] but bilateral cases have been reported.[9,12] PN in the periorbital region typically assumes a more aggressive course than neurofibromas elsewhere in the body, for reasons that are yet known, this aggressive behavior does seem to level off as the patient matures.[12,18] Upper eyelid involvement is usually full thickness extending to the conjunctiva in more than one-half of the patients.[9] The tarsus and the levator aponeurosis are also significantly involved (Figure 93.1).[19] Ptosis initially occurs due to the mechanical "weight" of the plexiform eyelid lesion even in the presence of good levator muscle function. However, as the neurofibroma enlarges, extensive infiltration of the levator and its aponeurosis may result in distortion of the muscle and disinsertion of its aponeurosis, with impairment of levator function.[19] Initially, the temporal part of the upper eyelid is more infiltrated, resulting in a typical early S-shaped deformity (Figure 93.2).[1,9,18] As the disease progresses, the entire eyelid becomes infiltrated, and the temporal region beyond the eyelid becomes extensively involved with occasional involvement of the entire lateral face. Exclusive involvement of the lower eyelid is extremely rare (Figure 93.3), although combined involvement of the upper and lower eyelids is not uncommon (Figure 93.4).[9] Lateral and medial canthal malpositions are commonly associated with PN with a reported incidence between 50%-60%,[9,18] although predictably lateral canthal involvement always precedes medial canthal malposition.[20] Although NF1 often causes vision loss secondary to optic pathway gliomas, it should be noted that decreased visual acuity in NF1 is multifactorial, and PN of the eyelid and orbit can independently cause significant visual morbidity secondary to deprivational amblyopia.[2] A recent study showed that more than three-fourths of patients with unilateral PN have a visual acuity less than 20/60.[12]

Differential Diagnosis

Except for very early cases in which the upper eyelid may assume an S-shaped contour or lateral ptosis, where PN may be confused with lacrimal gland enlargement or simple congenital ptosis, the condition on the eyelid is relatively easy to diagnose. However, in other parts of the body, PN has been confused with rare lesions such as plexiform spindle cell lipoma, plexiform schwannoma, hemangioma, sarcoma, and plexiform fibrohistiocytic tumor.[20,21,22,23,24,25]

Treatment

Although the literature is replete with various innovative techniques for the surgical management of PN, there are no universal agreements or formal recommendations for clinical care of children or adults with eyelid and orbital PN. Management decisions are particularly problematic when there is significant bony involvement with disfiguring alteration in the globe position. In an attempt to standardize management, Marchac and Britto proposed a classification system based on the severity of ptosis, canthal position, and eye-globe relation,[26] but in our opinion as well as others, the treatment approach should be tailored to each patient, with an open visual axis as the main goal of surgery, followed by improving the cosmetic appearance.[9]

FIGURE 93.4 A and B, Combined involvement of both upper and lower eyelids with plexiform neurofibroma.

(B, Courtesy of Dr. Charles Soparkar.)

Although some authors recommend delaying surgery[27] because of the high recurrence rate if the child is operated upon very early, it should be borne in mind that surgery should be performed promptly and without delay in younger children regardless of age if occlusion of the visual axis is progressing rapidly.[28] However, rushing to surgery to debulk the eyelid in all patients presenting with rapidly advancing PN and defective vision may not be the most prudent approach before excluding other causes of visual compromise. These include optic nerve glioma or globe enlargement, which is not uncommonly observed in NF1 patients with or without glaucoma[28,29] and may cause concurrent refractive amblyopia.[12]

Because of the infiltrative nature of the tumor and the lack of a circumscribed capsule, complete surgical debulking is impossible.[9] Additionally, surgery may be complicated with extensive hemorrhage,[9] and in our experience, it may also be associated with prolonged postoperative edema. Hemorrhage is particularly bothersome when debulking the temporal region beyond the eyelid. Eyelid remodeling in the form of partial-thickness debulking of the upper eyelid through an extended blepharoplasty incision, combined with en bloc vertical resection of the lateral palpebral area, or full-thickness pentagonal wedge in the lateral part of the eyelid is performed. The contralateral normal eyelid serves as a model or template for determining the extent of debulking, but the extent of eyelid tissue resection also depends on the quality of the Bell phenomenon.[26] Debulking is usually followed in the same session with lateral canthal tendon tightening or reconstruction, and aponeurotic advancement.[9,26] Some authors warn against extensive full-thickness eyelid resection in the upper temporal quadrant to avoid damaging the lacrimal gland and its ductules,[27] although, in our experience, the lacrimal gland is usually extensively infiltrated and difficult to define.

Meticulous control of bleeding is required throughout the procedure. However, as the medial part of the eyelid is approached, cautery should be used with caution. It should be borne in mind that after debulking, what remains of upper eyelid tissue is technically a composite axial flap hinged medially, and based on the medial palpebral artery only. Another precaution to safeguard against vascular compromise is that although generous debulking of eyelid tissue may be required especially in older individuals where definitive surgery is important, the emphasis is placed on minimizing tissue excision near the eyelid margin. Despite being heavily infiltrated by neurofibromatous tissue, the levator aponeurosis is usually not difficult to identify and it is relatively easy to reattach it to the tarsus. The lateral canthal tendon should be tightened before reattaching the levator aponeurosis. When there is a cosmetically disfiguring downward and/or forward displacement of the entire orbit due to bony factors or herniation of the temporal lobe of the brain into the orbit, maxillofacial and/or neurosurgical repair is required to achieve bony symmetry of the midface before embarking on soft-tissue reconstruction.[9,26]

Prognosis

These tumors typically are diffuse and infiltrative into eyelid tissues so that complete surgical removal is usually impossible. Repeated sessions of surgical debulking are usually required as the tumor gradually continues to grow. Eyelid functional disturbances are almost inevitable. The most severe outcome is malignant transformation to malignant peripheral nerve *(Print pagebreak 623)* tumor that rarely can arise within the eyelid, and in other areas, and may show a high mortality rate of over 70%.

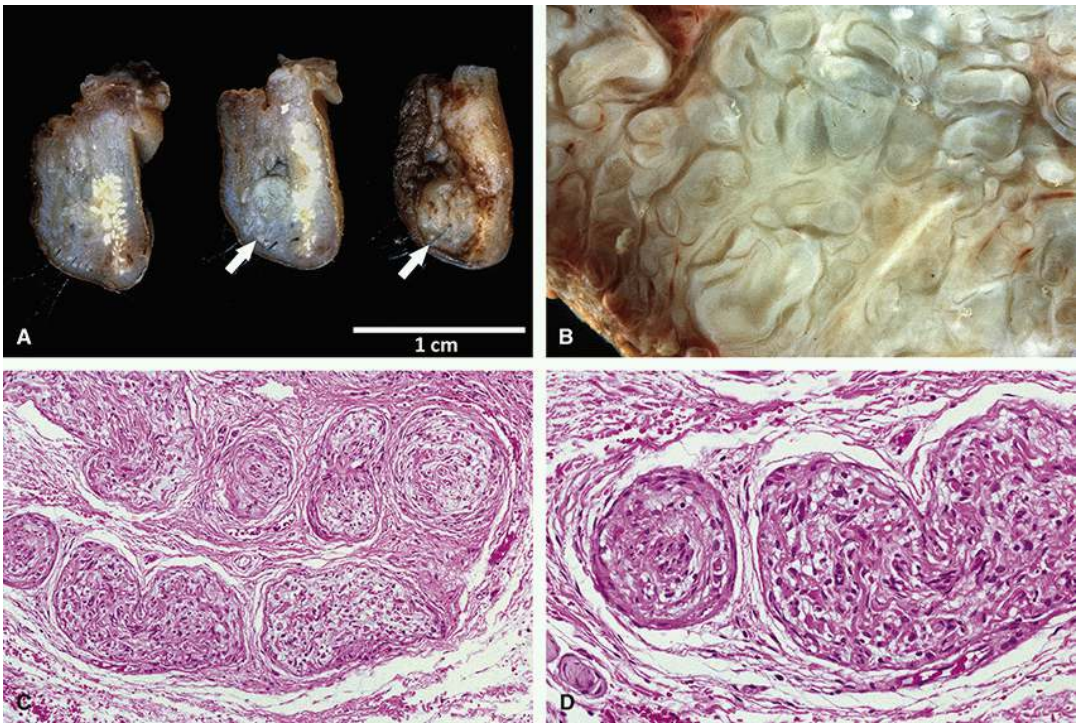

FIGURE 93.5 A, This child with neurofibromatosis type 1 had a plexiform neurofibroma in the right upper eyelid dermis forming a nodule near the eyelid margin (arrows). B, A close-up view shows large segments of enlarged convoluted peripheral nerve fascicles that correspond to a "bag of worms" texture on palpation. C, The dermis has expanded nerve fascicles, each surrounded by a thickened perineurium. The expanded fascicles have a patchy pale appearance due to glycosaminoglycan accumulation in the endoneurium. Dense fibrous tissue is between the nerve fascicles and appears as an extension of the thickened perineurium. D, Expanded fascicles contain wavy nerve fibers, spindle-shaped Schwann cells, fibroblasts, mast cells, small blood vessels, and glycosaminoglycan-rich endoneurium.

Histopathology

PNs are the most common subtype of ocular adnexal peripheral nerve sheath tumors.[30] PNs feature large segments of enlarged convoluted peripheral nerve fascicles that may be grossly discernible (Figure 93.5A and B) and correspond to a "bag of worms" texture on palpation.[31,32] Other cases appear as large multinodular masses.[32,33] Microscopically, the dermis and/or subcutis[34,35] have a tortuous mass of expanded nerve branches, each surrounded by a thickened perineurium (Figure 93.5C and D).[35,36] The expanded fascicles contain nerve fibers (axons) that are often centrally situated, spindle-shaped Schwann cells, fibroblasts, mast cells, blood vessels, and mucin (glycosaminoglycan)-rich endoneurium.[31,32,34,36,37,38] The Schwann cells immunohistochemically express S100 protein, the nerves stain using antibodies to neurofilament protein, and epithelial membrane antigen antibodies highlight perineurial cells.[31,35] The endoneurium often has a pale myxoid appearance (Figure 93.6A and B) due to Alcian blue-positive glycosaminoglycan accumulation, sometimes with the formation of mucin pools.[36,37,38] Collagen may accumulate in the endoneurium, often in longstanding PNs, making them firm.[32] Dense fibrous tissue is between the nerve fascicles and may appear as an extension of the thickened perineurium.[36] Approximately 5% of periocular neurofibromas are a mixture of diffuse and plexiform subtypes (Figure 93.6).[30] PNs usually have a distinctive histological appearance, but other lesions such as plexiform schwannoma, plexiform granular cell tumor, and plexiform nevi should be considered in the differential diagnosis.[35]

(Print pagebreak 624)

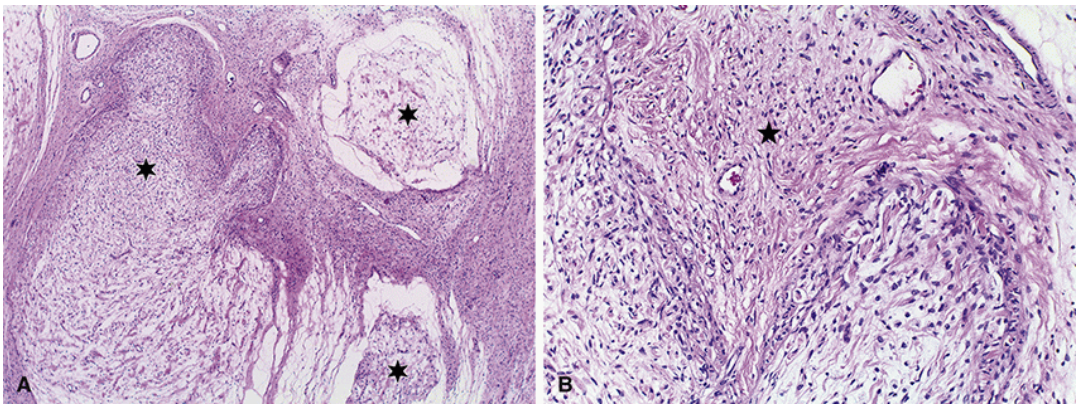

FIGURE 93.6 This teenager with neurofibromatosis type 1 had a plexiform and diffuse neurofibroma involving the right orbit and entire upper eyelid. A, The tumor's plexiform component (★) is very pale due to marked endoneurial accumulation of glycosaminoglycans. B, The diffuse component of the tumor (★), composed of spindle-shaped cells with eosinophilic cytoplasm and indistinct cell borders, surrounds the plexiform fascicle.

CHAPTER 94

Neurothekeoma

Key Points

- Neurothekeoma includes several lesions previously reported as nerve sheath myxoma or cellular neurothekeoma
- While some studies have questioned the relationship between these two entities, other authors have supported the idea that these lesions are variants of the same entity
- Immunohistochemical and ultrastructural data indicate that nerve sheath myxomas exhibit true nerve sheath differentiation, whereas such evidence is lacking for cellular neurothekeomas
- Several studies have demonstrated distinct genetic mutations in these two entities
- On the eyelids, 60% of neurothekeomas present on the upper eyelids as small, slow-growing, painless, pink to flesh-colored nodules that may be mobile and cystlike or firm and immobile
- The treatment of choice for neurothekeoma is surgical excision
- The prognosis following surgical excision is generally good with a recurrence rate of about 15% associated with incomplete excision

Several types of lesions have been included under the broad term of "neurothekeoma" (NTK), most commonly nerve sheath myxoma (NSM) and cellular neurothekeoma (CNTK). Over the years, the classification of these tumors has been in a constant state of flux.[1] NSM and CNTK have been classified as benign primary neurogenic tumors arising from peripheral nerves.[2] NSM was first described as a distinct pathologic entity by Harkin and Reed in 1969 and designated as a benign myxomatous cutaneous tumor believed to be of peripheral nerve sheath origin.[3] Gallager and Helwig[4] later reported a series of cutaneous tumors that bore the same histologic features as the previously described NSM, but which they named NTK. Over subsequent years, the terms "NSM" and "NTK" frequently have been used interchangeably in the literature. In 1986, Rosati et al[5] described a cellular variant of NSM, termed "CNTK." However, other studies have questioned the relationship between CNTK and NSM. Some authors supported the idea that these lesions are variants of the same entity.[6,7] Others, however, felt that they are unrelated.[8,9,10] In 2008, Weiss and Goldblum[11] proposed the term "classic NTK" for NSM to distinguish it from CNTK based on immunoreactivity to S-100. While it is generally accepted that a classic NTK is a true benign nerve sheath tumor, the etiology of CNTK remains unknown.[8,10]

It has been thought by some authors that cellular and myxoid NTK represent two ends of a spectrum of the same neoplasm.[6,12,13,14,15] According to this view, cellular NTK is considered a neoplasm with immature or poorly developed nerve sheath differentiation, whereas the myxoid type shows well-developed nerve sheath differentiation.[3,4,6,8,13,14,15,16] Others have questioned this concept, suggesting that cellular NTK should be classified as a fibrohistiocytic tumor and myxoid NTK as a tumor with nerve sheath differentiation.[10,16,17,18]

NTKs occur most commonly in the head and neck, especially the nose and scalp. Less frequently, they are seen on the cheeks, chin, eyelids, lower extremities, and trunk.[10,19] They are seen most commonly in young individuals, ranging in age from 1 to 85 years, with a mean of 21 to 25 years.[9,10,20] The male-to-female ratio is approximately 1:2.[9,10]

NTKs involving the eyelid are often referred to as NTK palpebrae and are very uncommon with less than a dozen cases reported. Slightly more than half of the eyelid cases have been classified as NSMs or classic NTKs,[1,21,22,23,24,25,26,27] and the rest as CNTKs.[28,29,30] Where location was specified, about two-thirds of these lesions occurred in the upper eyelid. The duration of symptoms before presentation ranged from 6 weeks to 8 years.

Etiology and Pathogenesis

Based on light microscopic similarities, CNTKs and NSMs previously were considered to be related to cutaneous neoplasms of

peripheral nerve sheath origin. However, immunohistochemical and ultrastructural data indicate that NSMs exhibit true nerve sheath differentiation, whereas such evidence is lacking for CNTK. Although CNTK lack a specific immunohistochemical profile, evidence related to antigen expression and histopathologic patterns suggest that they may be categorized as fibrohistiocytic tumors.[8,10,12,16,17,18]

In a study of 10 spinal NSMs, 80% showed loss of chromosome 22q, typically encountered in peripheral nerve tumors, and 2 demonstrated mutations of the *NF2* gene.[31] This may indicate the involvement of other tumor suppressor genes on 22q in NSMs. In another study on 25 CNTK, 8 mixed NTK, and 1 NSM, SOX-10 and S-100 were found to be absent in CNTK but present in NSM.[32]

(Print pagebreak 627)

The cell of origin of CNTK is not known, but ultrastructural and immunohistochemical studies suggest a possible origin from Schwann cells of the perineurium or from fibroblasts.[17] CNTK has a less prominent myxoid component, lacks immunoreactivity to most neuronal markers, and is characterized by large size, extension into subcutaneous fat and muscle, infiltrating borders, vascular invasion, high mitotic rate, and cytologic pleomorphism.

Clinical Presentation

In general, NTKs present as slow-growing, painless, nodular lesions measuring 0.5 to 4 cm in size, with a duration of symptoms from 3 months to 12 years.[20] Among 57 cases of NSM, 86% percent occurred in the extremities, with the most common locations being the hand/fingers (n = 22), knee/pretibial region (n = 10), and ankle/foot (n = 7). Only seven cases (12.3%) involved the trunk or head and neck region.[10]

FIGURE 94.1 A-D, Neurothekeoma of the eyelids and conjunctiva. (C, Reprinted with permission from Gray ME, Palileo CM, Sheridan RM. Cellular neurothekeoma of the eyelid in a 6-year-old boy. *JAAPOS*. 2016;20:374-376; D, Courtesy of Drs. Daniel Lefebvre and Michael Migliori.)

Of the lesions described on the eyelids, the mean age at presentation was 35.9 years with a range of 4 to 76 years. The male-to-female ratio was 1:5. The size at presentation was 4 to 10 mm, with a mean of 7.5 mm, and 60% were located on the upper eyelid. Lesions were generally slow growing and the duration of symptoms ranged from 6 weeks to 10 years, with 60% being 12 months or less. Clinically, lesions appear as small, pink to flesh-colored, painless nodules that may be mobile and cystlike or firm and immobile (Figure 94.1).[1,21,22,23,24,25,26,27,28,29,30]

Differential Diagnosis

The differential diagnosis of NTK includes epidermal inclusion cyst, intradermal nevi, lipoma, pilomatrixoma, fibroma, and dermatofibroma. For eyelid lesions, the initial clinical diagnosis most frequently is chalazion or epidermal inclusion cyst. Epidermal inclusion cysts are usually isolated asymptomatic, freely moveable cystic intradermal or subcutaneous *(Print pagebreak 628)* nodules. Chalazia are red, often tender, inflammatory lesions typically involving the meibomian glands along the eyelid margins. Dermatofibroma are asymtomatic, nontender cutaneous, dome-shaped nodules that may have central dimpling. Lipomas are painless, soft, fluctuant mobile subcutaneous masses with freely moveable overlying skin.

Treatment

The treatment of choice for NTK is surgical excision. Recurrence has been reported in about 15% of cases so that wide margins[9,10] and frozen-section control of margins are recommended.[19] Patients with tumor recurrence have been reported to be younger, be female, have facial lesions, and harbor tumors with a myxoid pathology pattern.[10]

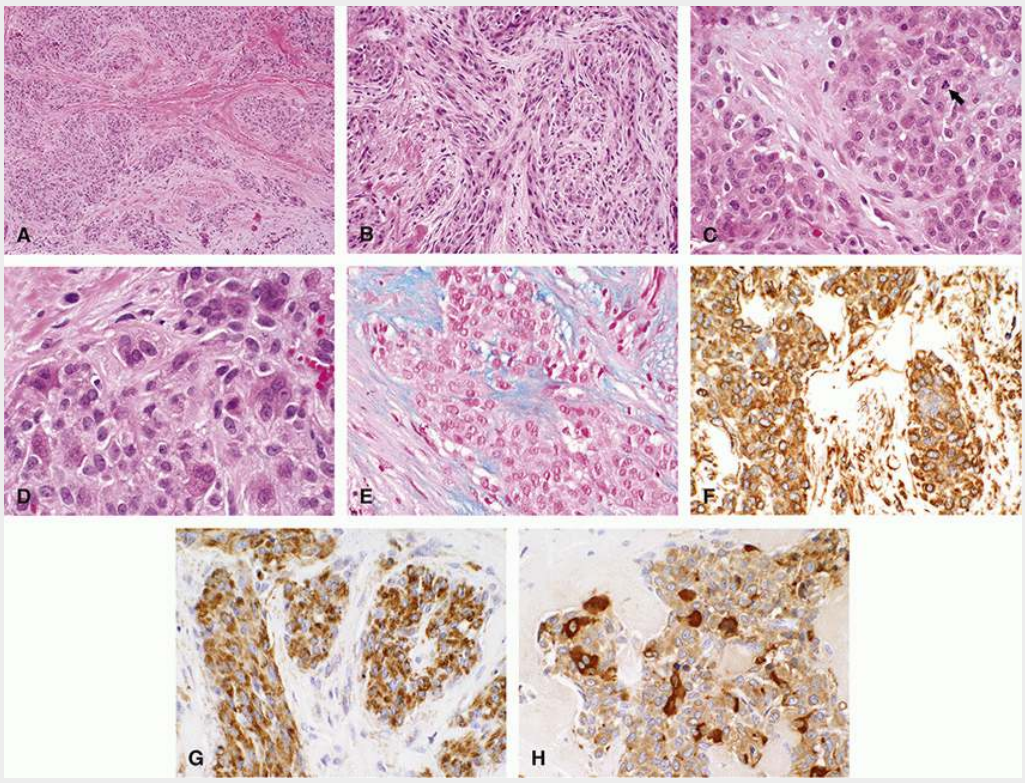

FIGURE 94.2
This cellular neurothekeoma (CNTK) presented as a 5.5 mm tumor of the left upper eyelid in a 4-year-old girl. A, Tumor cells form variably sized and shaped nodules within the dermis with sclerotic areas of brightly eosinophilic collagen. B, Tumor cells are spindle shaped or epithelioid with lightly eosinophilic cytoplasm and mostly indistinct cell borders. C, The matrix between cells and between nodules stains palely indicative of myxoid change (glycosaminoglycan accumulation). An atypical tripolar mitotic figure is present (arrow) but is not indicative of malignancy in CNTKs.[10] D, Some areas of the tumor feature large multinucleated cells. E, Myxoid matrix in and between tumor nodules is highlighted blue using Alcian blue stain. F, Tumor cells and stromal fibroblasts between nodules are uniformly immunoreactive using antibodies to vimentin. G, All of the tumor cells stain intensely using antibodies to NKI/C3 (CD63). H, The tumor cells express CD68, with the most intense staining being in the large multinucleated cells.

Prognosis

The prognosis following surgical excision is generally good. Recurrence is associated with incomplete excision.[9] In a series of 34 cases of NSM managed by simple surgical excision, where almost all instances showed tumor extending to the resection margin,

47% experienced local recurrence over a follow-up period of 8 months to 28 years (median, 14 years 3 months).

Histopathology

The histological features of periocular CNTKs are similar to those occurring elsewhere on the body.[1,33] CNTKs are multinodular, nonencapsulated, poorly marginated tumors of the dermis that often extend into the subcutaneous tissue (Figures 94.2 and 94.3).[4,10] Tumor nodules vary in size and *(Print pagebreak 629)* shape, but they are most often round or ovoid.[4] The nodules are separated from the epidermis by a layer of normal dermis,[9] and they are separated from each other by variable amounts of dermal collagen that may be sclerotic (hyalinized).[4,10,34] The amount of myxoid matrix in the tumor nodules ranges from <10% of the area to >50%, leading Fetsch and coworkers to classify the tumors as cellular (<10% myxoid matrix; 35% of NTKs), mixed (>10 and ≤50% myxoid matrix; 38% of NTKs), or myxoid (>50% myxoid matrix; 27% of NTKs).[10] NTKs usually have both spindled and epithelioid tumor cells, though Hornick and Fletcher found 21% of 133 cellular NTKs with only spindle cells and 16% with only epithelioid cells.[9] Tumor cells have abundant lightly eosinophilic cytoplasm, indistinct cytoplasmic cell borders, ovoid nuclei, and fine chromatin.[9] Tumor cells may be organized randomly or form whorls.[10] Cytological atypia was minimal (35%), mild (61%), focally moderate (12%), generalized moderate (11%), or focally marked (1%) in the 178 NTKs examined by Fetsch and colleagues.[10] The average mitotic rate was 3 per 10 high-power fields (range 0-22) in Hornick and Fletcher's study[9] and 2.0/mm^2 in Stratton and Billing's report of 37 NTKs.[34] Fetsch and coworkers also noted wide variability in the mitotic rate ranging from no apparent mitoses in 15% of cellular NTKs to >20 mitoses in 25 wide-field high-power fields in 3% of tumors.[10] Fetsch et al identified multinucleated osteoclast-like giant cells in 39% of NTKs.[10] Atypical histological features, including cellular pleomorphism, high mitotic rate, entrapped skeletal muscle, and infiltration of the subcutis, do not seem to have any clinical significance if the tumor is resected completely (Figure 94.3).[9] NTKs may also exhibit perineural[9,34] and vascular[9] invasion in a small minority of cases, but these features do not signify malignancy.

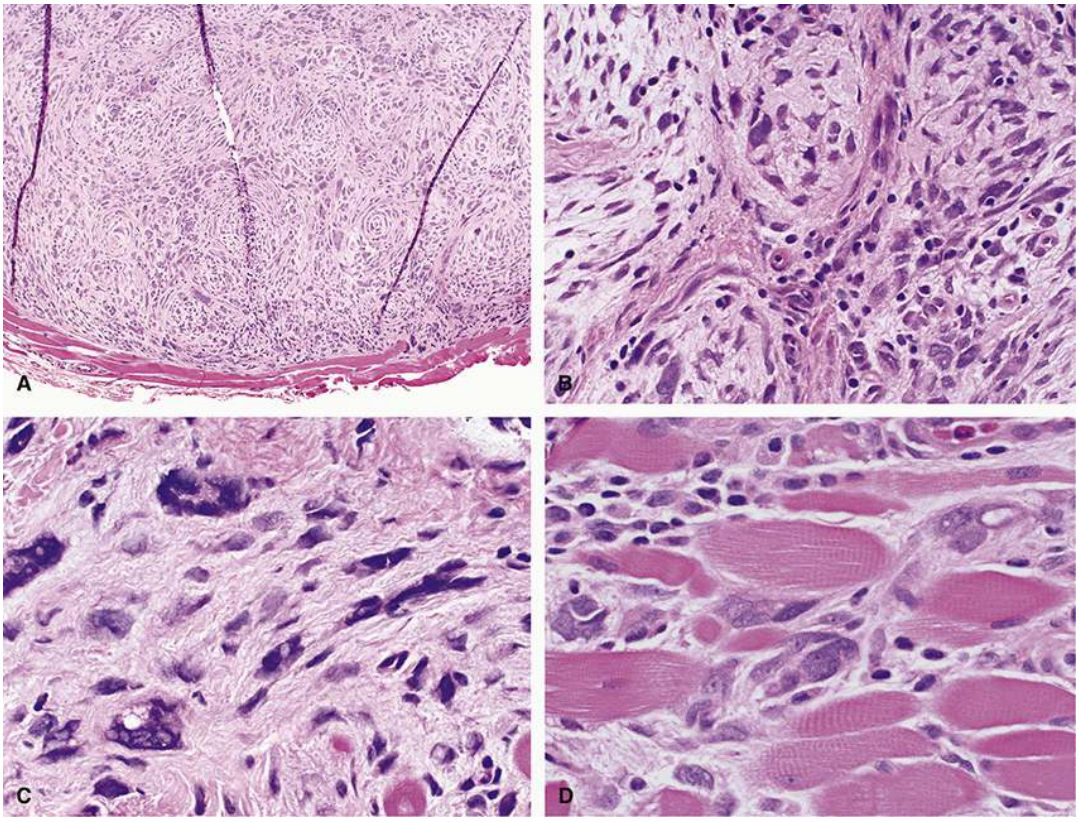

FIGURE 94.3 This cellular neurothekeoma (CNTK) was a 6 mm nodule in the medial left upper eyelid of a 13-year-old girl. A, The tumor features coalescent nodules, many with a whorled configuration. Numerous large multinucleated tumor cells are seen even at this low magnification. Orbicularis oculi muscle is at the bottom of the picture. The bright vertical streaks are sectioning artifacts. B, The islands of spindle-shaped and epithelioid cells have pale myxoid stroma, and thin dermal collagen bands separate them. C, Marked nuclear pleomorphism, such as seen in this photomicrograph, does not indicate malignancy in CNTKs. D, Tumor cells infiltrate between orbicularis oculi muscle fibers, but this does not signify malignancy in CNTKs.

Immunohistochemistry helps confirm the diagnosis of NTK, especially in tumors with pleomorphism or a high *(Print pagebreak 630)* mitotic rate. The most extensive immunohistochemical studies were by Fetsch and colleagues: 100% of 39 tumors expressed vimentin (Figure 94.2F), 100% of 47 tumors expressed NKI/C3 (CD63), 100% of 41 tumors were CD10 positive, 83% of 52 cases

expressed microphthalmia transcription factor, 80% of 10 cases were CD99 positive, 80% of 10 cases expressed collagen IV, 66% of 35 cases expressed neuron-specific enolase (NSE), 60% of 50 tumors were positive for PGP9.5, 59% of cases were CD68 positive (Figure 94.2H), and 38% of 56 cases expressed smooth muscle actin.[10] None of the tumors examined in the Fetsch study expressed S100 protein (n = 119), glial fibrillary acidic protein (GFAP; n = 12), melanoma antigen recognized by T cells 1 (MART-1, Melan A; n = 11), tyrosinase (n = 4), neurofilament protein (n = 27), CD34 (n = 29), desmin (n = 31), CD163 (n = 25), CD117 (n = 11), MAC387 (n = 10), lysozyme (n = 5), polyclonal carcinoembryonic antigen (n = 6), or factor VIII-related antigen (n = 5).[10] Hornick and Fletcher reported that 100% of tumors were positive for NKI/C3 (CD63; n = 130), 89% expressed NSE (n = 123), 57% had at least focal staining for smooth muscle actin (n = 127), one tumor (0.9%) expressed GFAP, and no tumor expressed S100 protein.[9] The absence of expression of S100 protein in NTKs distinguishes them from NSMs, which are consistently positive for that protein.[8]

CHAPTER 95

Nevus Flammeus

Key Points

- Nevus flammeus or port-wine stain (PWS) is a congenital, low-flow vascular malformation of the skin that represents a progressive ectasia of the superficial cutaneous vascular plexus
- It does not involute, but gradually enlarges in size and can darken due to progressive vascular ectasia
- It can occur as an isolated cutaneous birthmark or it can be associated with structural abnormalities such as Sturge-Weber syndrome
- The pathogenesis of nevus flammeus is unknown, but hypotheses include vascular denervation and genetic mutations
- Whole-genome sequencing of DNA from patients with nevus flammeus suggests a somatic activating mutation in *GNAQ* as a possible underlying cause
- The lesion presents as a painless, well-demarcated flat pink macule that thickens and darkens over time
- They are unilateral and appear to involve the distributions of one or more divisions of the trigeminal nerve
- The current treatment of choice for PWS is pulsed dye laser
- Improvement and lightening of lesions and decrease in size are likely after laser therapy, but complete clearance is achieved in fewer than 10% of cases

Nevus flammeus, also known as port-wine stain (PWS), is a congenital, low-flow vascular malformation of the skin that represents a progressive ectasia of the superficial cutaneous vascular plexus.[1,2] According to the most recent iteration of the International Society for the Study of Vascular Anomalies (ISSVA) classification for vascular anomalies (May 2018), the term “PWS” is retained, while the term “nevus flammeus” is discarded, and the disease is listed as one of the subtypes of capillary malformations. The prevalence of PWS is estimated to be 3 to 5 per 1000 live births.[3,4,5,6] The inheritance pattern is generally sporadic, and males and females are equally affected.[7]

Approximately 90% of PWSs are located on the face, and much less frequently on the neck, trunk, and extremities.[8,9] Most facial PWSs are unilateral and are approximately located in the distribution of the trigeminal nerve dermatomes.[10] Pyogenic granulomas and eczematous dermatitis can develop within PWS.[11,12] Larger and more advanced lesions can cause functional limitations of speech or vision.[13,14] In addition to facial skin, PWS can involve the mucosa of the oral cavity, tongue, larynx, and nose, as well as soft tissues of the neck and even the parotid gland. These can cause gingival bleeding, epistaxis, and upper airway obstruction.[13,15]

Unlike infantile hemangiomas, PWS does not involute, but lesions gradually enlarge in size as the body grows, and can darken due to progressive vascular ectasia. With age, approximately two-thirds of patients develop soft-tissue or bony hypertrophy and vascular nodules.[1,16,17,18]

PWSs can occur as isolated cutaneous birthmarks or they can be associated with structural abnormalities involving the choroidal vessels in the eye and leptomeningeal vessels in the brain (Sturge-Weber syndrome [SWS]).[19,20] In one study of 274 patients with PWS localized to the face, 8% also had eye and/or central nervous system (CNS) involvement.

SWS is a neurocutaneous disorder that was described by Sturge in 1879[20] as a triad of facial, scalp, and trunk capillary malformation (PWS), focal seizures, and intraocular vascular malformation with glaucoma. The incidence is unknown but is estimated to be 1 in 20,000 to 50,000 live births.[21] SWS usually manifests with facial PWS, and rarely with PWS on the trunk or extremities. The risk of developing glaucoma is up to 50%, almost always ipsilateral to the facial PWS.[21] SWS occurs sporadically with equal frequency in males and females. Although some early studies on the relationship between facial PWS and the risk of SWS implicated PWS in the ophthalmic division of the trigeminal nerve, bilateral distribution, and involvement of the upper

eyelids,[22,23] more recent studies suggest that extensive PWS within a V1 distribution (and to a lessee extent V2 and V3) of the trigeminal nerve is a strong predictor for an underlying neurological and/or ocular disorders (SWS).[24]

Acquired PWSs are rare skin lesions that are morphologically and histopathologically identical to congenital PWSs[25] and can be associated with telangiectasia and local heat from increased blood flow within the affected skin.[26] They can be associated with trauma, chronic actinic exposure, oral contraception, cluster headache, acoustic neuroma, and medications such as isotretinoin, simvastatin, and metformin.[25,27,28,29] One case was reported to develop after repeated episodes of sunburn.[30] In a review of 59 patients with acquired PWS, trauma was found to be a causative factor in 17 (29%) cases.[31] It has been proposed that injury may result in loss of a previously effective sympathetic regulation of the cutaneous blood flow, leading to development of the lesions,[31] or that traumatic injury of the skin induces perivascular atrophy leading to vessel dilation or that impaired reparative processes in vessels result in dilated vessel walls.[32]

(Print pagebreak 632)

Etiology and Pathogenesis

The pathogenesis of PWS and SWS is unknown, but there are at least two major competing hypotheses: the neural (nerve degeneration) theory, and the vascular (genetic mutation theory).[33] However, recent confirmatory evidence favors the genetic mutation theory. A deficiency of nerve innervation in PWS led to speculation that this could be a cause of these abnormal hypervascular skin lesions.[23,34,35] Smoller and Rosen[36] reported that S-100-positive nerve fibers were found in only 17% of PWS blood vessels, while 89% of normal dermal vasculature had S-100-positive nerve fibers. Rydh et al[34] showed that defective nerve innervations were found only in pathologically dilated PWS vessels, but not in other normal skin structures. Selim et al[35] found that there is a significant decrease in nerve density in all PWS sites compared to normal skin. The absence of nerve innervation to blood vessels may cause a decrease in the basal tone of the vessels and/or a loss of neuronal trophic factors, which contribute to the development of PWS.[33]

However, whole-genome sequencing of DNA from patients with PWS and SWS has suggested a somatic activating mutation in GNAQ as a possible underlying cause. A nonsynonymous single-nucleotide GNAQ variant (c.548G→A, p.Arg183Gln) was identified in 88% of 26 patients with SWS (OMIM #185300, 9q21) and from 92% of 13 patients with apparently nonsyndromic PWSs (OMIM #16300, 9q21).[37,38,39] This is a somatic activating mutation in the GNAQ gene, which increases cell proliferation and inhibits apoptosis due to increased downstream signaling through the RAS effector pathways. The cell of origin affected by the mutation is not known, but it may be that the mutation occurs earlier during embryonic development in SWS than in isolated PWS, thus affecting a more primitive progenitor with wider potential effects.[40] These mutations may lead to dysregulation of vascular MAPK and/or PI3K signaling pathways during embryonic development causing the pathogenesis and progression of PWS/SWS.[33] Interestingly, the GNAQ mutation is found significantly more frequently in lesions located on the forehead, eyebrow, and upper eyelid than in those located in other facial regions, and PWS in these regions are more likely to be associated with SWS.

Waelchli et al[40] examined 192 children with PWS and divided the face into several areas on each side that were involved with PWS, including the forehead, upper eyelid, lower eyelid, maxillary area, mandibular area, ear, and chin, and correlated these with clinical complications such as seizures and glaucoma and abnormal head magnetic resonance imaging findings. They considered the adult arterial supply and venous drainage, and the embryological origin of the face and its vasculature. Based on their results, they proposed that the distribution of facial PWS appears to follow the embryological vasculature of the developing face rather than the trigeminal nerve distribution.

Dutkiewicz et al[41] evaluated the distribution patterns of facial lesions in children with PWS and those with SWS. They identified six phenotypes: linear, frontotemporal, cheek and canthus, combined linear and cheek, hemifacial, and median. These phenotypes support the idea that PWS lesions may not strictly correspond to dermatomes of trigeminal innervation.

Clinical Characteristics

PWSs are capillary malformations that occur in up to 0.5% of newborns. They initially present as painless, well-demarcated flat pink macules and patches that may be mistaken for a superficial bruise (Figure 95.1).[42] Over time, these lesions thicken and darken, with some developing significant nodularity (Figure 95.2).

The majority of PWS lesions are unilateral and superficially appear to involve the distributions of one or more of the divisions of the trigeminal nerve (ophthalmic [V1], maxillary [V2], mandibular [V3]). In a study of 310 patients with PWS, 32% involved the dermatome innervated by V2 (Figure 95.1), 41% in the distribution of both V1 and V2, 5% in the distribution of V2 and V3, and 10% in all three.[23] In another study of 192 PWS patients, 14.6% involved V1 alone, 32% V2 alone, and 5.3% V3 alone, while 41% involved V1 and V2, 5% V2 and V3, and 10% all three dermatomes.[40] When all three dermatomes were involved with PWS, there

was a significantly higher likelihood of ophthalmic or CNS complications.[23]

There are a number of other ophthalmic complications that can be associated with PWS. Glaucoma is seen in about 18% of cases, more common with bilateral lesions and in those cases involving both the upper and lower eyelids.[43] In PWS patients with glaucoma, 91.3% have involvement of V1, and they are more likely to have multiple trigeminal dermatome involvement (88.3%).[10] Other ophthalmic complications include the so-called episcleral hemangioma (35%), and the so-called choroidal hemangioma (23%), and iris *(Print pagebreak 633)* heterochromia (6%). Face and eyelid involvement can cause significant negative effects on quality of life, lead to psychological disabilities, and result in adaptation problems toward the social environment, especially in children.[44]

FIGURE 95.1 A child with numerous unilateral patchy port-wine stains primarily in the distribution of the maxillary division of the trigeminal nerve.

FIGURE 95.2 An older individual with a well-defined nevus flammeus of the medial lower eyelid. (Courtesy of Dr. Alan McNab.)

PWSs do not involute over time, but often continue to evolve into adulthood. With increased age, there is progressive vascular ectasia, and the color changes from pink to purple.[1] While PWS lesions first appear as macular lesions, by the fifth decade of life, 65% may become hypertrophied or nodular.[45] In these cases, there is an increased risk of pyogenic granulomas and spontaneous bleeding or hemorrhaging following minor trauma. Intralesional basal cell carcinoma,[45,46,47] squamous cell carcinoma,[48] and melanoma[49] have been described rarely in these hypertrophic and nodular lesions, some of which had been previously treated, but others untreated. While some cases of malignant association may have been related to previous treatment, its occurrence in untreated lesions suggests a chance occurrence for others.[1]

Certain facial PWS distribution phenotypes are associated with a greater potential for having SWS with neurological and ocular associations.[40] These high-risk phenotypes include the hemifacial, forehead, and median PWS types and involve skin-derived embryologically from the frontonasal placode, which shares common progenitor cells with the brain.[40,41,50]

Seizures occur in 75% to 100% of children with PWS and SWS,[51,52,53] so that early recognition and treatment of seizures is crucial to prevent neurodevelopmental complications.

Differential Diagnosis

The differential diagnosis of PWS includes infantile hemangiomas, but these usually involute later in childhood,[54] in contrast to PWS which behaves in a similar manner to other vascular malformations and grows with the growth of the individual. Early inflammatory morphea can present with erythematous or violaceous patches or plaques similar to PWS, but this lesion usually develops later in childhood.[55,56,57] Localized scleroderma has also been confused with PWS, presenting as an erythematous or purplish patch. But they are often also hypo- or hyperpigmented and can be associated with alopecia and bone atrophy.[56,58]

Treatment

The current treatment of choice for PWS is pulsed dye laser (PDL),[59] where selective photothermolysis is used to destroy subsurface but relatively superficial targets without injuring adjacent normal tissue. The PDL wavelength of 595 nm is preferentially absorbed by hemoglobin in blood vessels where it is converted into heat, leading to necrosis of the blood vessel walls. Skin cooling technology can be used to prevent light absorption and injury to nearby melanin,[60] and thus to help reduce dyspigmentation.[61] To target blood vessels situated deeper in the skin, other laser wavelengths have been used, including alexandrite 755 nm, diode 800 to 940 nm, and Nd:YAG 1064 nm.[7,62]

In a study of 73 children with PWS treated with PDL, 87% showed 50% or greater skin lightening after one to three treatments, but only three had complete clearance.[63] In another study of 102 PWS patients treated with PDL, 15.3% showed >90% lesional lightening, 65.3% showed 50% to 90% lightening, 17.8% showed 11% to 49% lightening, and 1.7% showed <10% lightening. However, 50% of these patients experienced recurrence 1 to 4 years after treatment.[64]

Clinical trials have investigated the use of topical agents as an adjunct to PDL. These have included timolol, imiquimod, and rapamycin.[65] Topical timolol combined with PDL did not show any improvement in efficacy compared with PDL alone,[66] but imiquimod did show enhanced lightening of PWS compared with controls.[67,68] Several trials of topical rapamycin combined with PDL have shown variable and inconclusive results.[69,70,71,72]

Surgical treatment has been advocated for patients with large PWS lesions that fail to respond adequately to laser therapy. Various techniques have included full-thickness skin graft, local skin flap, free flap transfer, and prefabricated expanded flap transfer.[73,74,75]

Prognosis

Although treatment options for PWS are varied and include lasers, cosmetic tattooing, electrotherapy, cryosurgery, dermabrasion, and skin grafting, none of these alternatives is completely satisfactory and none can provide consistent, satisfactory responses or cures.[76] Improvement with lightening of the lesion and decrease in size after PDL treatment are well documented, but complete clearance is achieved in fewer than 10% of cases, and roughly 20% of lesions show no response.[77] Recurrent darkening of treated lesions occurs secondary to revascularization of the capillary bed. Between 16% and 50% of patients report redarkening of their PWS as early as 5 years after PDL treatment.[64,78] Also, response to treatment differs not only between affected individuals but *(Print pagebreak 634)* also within the same lesion due to the heterogeneous nature of PWS.

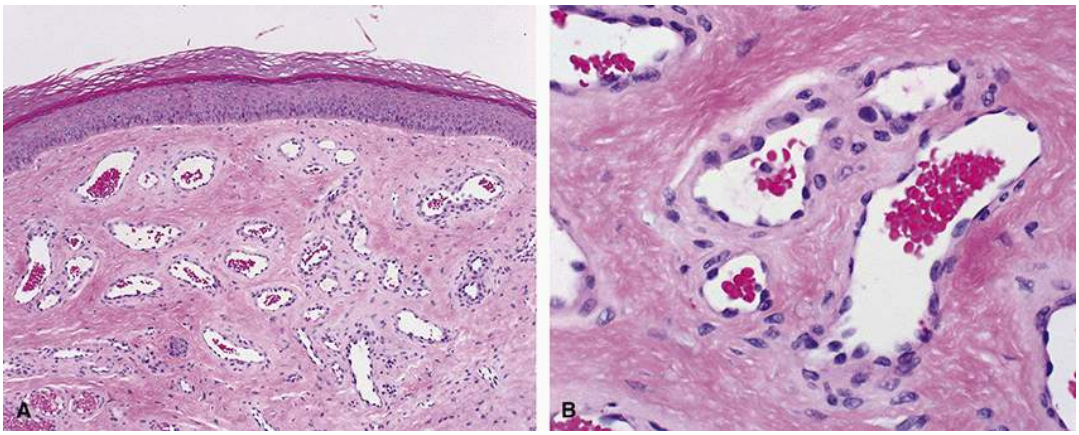

FIGURE 95.3 A, Port-wine stain with numerous capillaries of varying caliber within the dermis. B, Higher magnification of the varying caliber capillaries lined by endothelial cells and lacking a muscle layer.

One study involving 83 patients aged between 2 weeks and 17 years compared treatment outcomes based on patient age alone. They found that when treatment was initiated before the age of 1 year, 32% of cases achieved lesion clearance compared with only 18% in older patients.[79] Nguyen et al[80] also reported that patients less than 1 year of age at the time of PDL treatment showed an average of 63% decrease in size compared with a 48% decrease in children aged 1 to 6 years. A better response rate was also shown for smaller lesions less than 20 cm in size compared with those greater than 40 cm in size.[80]

A decrease in the size of lesions treated with PDL was also shown to be correlated with anatomical location. Central forehead PWS showed 100% clearance after five treatments, whereas those on the peripheral face achieved 58% clearance and those in the central face showed a clearance rate of 48%.[80] Renfro and Geronemus[9] reported that central facial lesions were more resistant to PDL treatment as evaluated by percent lightening than forehead and lateral facial lesions.

Histopathology

PWS is characterized histologically by ectatic capillaries and venules of varying caliber within the dermis (Figure 95.3).[44,81,82,83] The most common site is the superficial reticular dermis, but vessels may occasionally extend into the superficial subcutaneous tissue.[83] Narrow and intermediate caliber vessels predominate before 20 years of age, while vessels of intermediate and wide caliber

prevail after age 20 years.[81] The area of dermis occupied by vessels also increases with age,[82] due to progressive vascular ectasia.[44]

CHAPTER 96

Nevus Sebaceous of Jadassohn

Key Points

- Nevus sebaceous of Jadassohn (NSJ) is a congenital hamartoma of the pilosebaceous follicular unit
- The pathogenesis of NSJ is unknown, but a developmental arrest during the seventh or eighth month of gestation leading to a disturbance of cell migration and differentiation due to toxic or infectious agents has been suggested
- Another possible etiology proposed that a defect of fusion and separation of tissue during early embryogenesis may result in the ocular malformations associated with nevus of Jadassohn
- NSJ is initially characterized in early childhood by papillomatous hyperplasia and immature hair follicles, followed by hormonally driven rapid growth at puberty, and the development of benign and malignant epithelial neoplasms seen in 10% to 20% of cases in adulthood
- Surgical excision is the treatment of choice
- The prognosis of nevus sebaceous depends on whether it is benign or malignant, and with only benign neoplasms, the prognosis is excellent
- For lesions associated with malignant tumors, most are basal cell carcinomas, which carry a good prognosis

In 1968, Solomon et al[1] coined the term “epithelial nevus syndrome” as a single entity containing a group of disorders characterized by the coexistence of epidermal nevi and extracutaneous anomalies. More recently, it has become obvious that the original concept of that term was erroneous and contained several different entities that could be distinguished by the type of associated epidermal nevus and by the criterion of heritability in some of them.[2,3] Genetic mosaicism in this group of diseases results in different syndromes, all of which include epidermal nevi.[3] Each syndrome presents a different phenotype with a spectrum of abnormalities. These can vary from isolated epidermal nevus with no other manifestations to epidermal nevi with multiple organ involvement.[2] The best known epidermal nevus syndromes include Proteus syndrome, CHILD syndrome, nevus comedonicus syndrome, pigmented hairy cell nevus syndrome, and nevus sebaceous syndrome.[4]

Nevus sebaceous of Jadassohn (NSJ) is one of the nine well-defined groups of epidermal nevus syndrome[5] and was comprehensively described in 1957 by Schimmelpenning.[6] This phenotype is the best known of the epidermal nevus syndromes and is still referred to as epidermal nevus syndrome by some authors.[7,8] The terminology of this birth defect is further confused with other names applied to it in the medical literature, such as Schimmelpenning syndrome, Feuerstein-Mims syndrome, Schimmelpenning-Feuerstein-Mims syndrome, Solomon syndrome, Jadassohn nevus phacomatosis, Jadassohn-Schimmelpenning-Feuerstein-Mims syndrome, organoid nevus phacomatosis, organoid nevus syndrome, sebaceous nevus syndrome, linear sebaceous nevus syndrome, and Jadassohn sebaceous nevus syndrome.[5]

NSJ represents a congenital hamartoma of the pilosebaceous follicular unit. The clinical features were mentioned in 1895 by the dermatologist Josef Jadassohn,[9] who referred to this condition as “organoid nevus” to describe the combination of sebaceous gland changes with nevi. Later, the term “NSJ” was established for lesions of the facial skin characterized by sebaceous gland enlargement. The condition affects approximately 0.3% of newborns. The incidence is equal between males and females and it affects all races and ethnicities. Overall, nevus sebaceous appears as a solitary lesion right after birth, or it may appear sometime before puberty. However, the classic features may not fully develop until after puberty.[10] Clinical features include an epidermal nevus of the sebaceous type on the head and neck area, with ocular and neurological abnormalities.[11,12] Ocular findings can include epibulbar choristomas, corneal pannus, colobomas of the eyelid, iris, retina, choroid, or optic nerve, macrooptic discs, and optic nerve hypoplasia.[13,14,15,16,17,18,19] The major neurological features are mental retardation, seizures, hemiparesis, quadriparesis, hypotonia, reflex abnormalities, gait disorders, diencephalic syndrome, and microcephaly.[20,21,22] Structural abnormalities seen on neuroimaging include hemimegalencephaly, gyral malformations, enlarged ventricles, intracerebral calcification, intracranial vascular abnormalities, porencephalic cysts, and, rarely, intracranial tumors including astrocytoma, pineal germinoma, choroid

plexus papilloma, and lipoma of the corpus callosum.[20,23] Previous estimates of neurologic abnormalities were approximately 15%,[12] but in a larger study of 196 patients with sebaceous nevi, the incidence was less than 7%.[24]

A variety of tumors can arise within NSJ. In an evaluation of 21 reviews involving 4823 cases of nevus sebaceous, benign tumors developed in 16% of cases (range 0%-51%) and malignant tumors developed in 8% of cases (range 0%-22%).[25] Benign tumors included pilar, sebaceous, apocrine, and eccrine neoplasms, such as trichoblastoma and *(Print pagebreak 638)* tricholemmoma, sebaceous adenoma, tubular apocrine adenoma, syringocystadenoma papilliferum, syringoma, and nevocellular nevus.[26] Cutaneous horn arising from an NSJ has also been described.[27]

Malignant tumors often begin with the sudden appearance of discrete, large, often ulcerating nodules.[28,29] They may include basal cell, squamous cell, and sebaceous carcinoma; apocrine carcinoma; adnexal carcinoma; and eccrine porocarcinoma.[26,30] The vast majority of the malignant lesions reported have been basal cell carcinoma (BCC). Earlier published studies reported a higher incidence of both benign and malignant tumors compared with later studies published after 1990. Cribier et al[31] published a retrospective study of 596 nevus sebaceous cases and reported a 0.8% incidence of BCC, with more than 90% of the other tumors being trichoblastomas.[31] They described a common histologic change consistent with benign epidermal hyperplasia and suggested that many previously reported cases of BCC arising in this condition were really benign trichoblastomas. Of the true malignant neoplasms associated with NSJ, BCC is by far the most common, followed by squamous cell carcinoma. Occasionally, more than one malignant lesion can occur in the same NSJ lesion. Although most of these tumors develop during adulthood, malignancies have been reported in children younger than 18 years.[32,33,34,35,36,37,38]

While NSJ is not usually considered to be an inherited disorder, West et al[39] reported three cases localized to the scalp in a mother and two daughters, supporting an underlying genetic association with an autosomal dominant transmission.

Etiology and Pathogenesis

The pathogenesis of NSJ is unknown, but a developmental arrest during the seventh or eighth month of gestation leading to a disturbance of cell migration and differentiation due to toxic or infectious agents has been suggested.[15] Kruse et al[14] reported a case with corneal pannus that could be explained by such a disturbance of differentiation of corneal epithelial stem cells at the limbus. Another possible etiology proposed that a defect of fusion and separation of tissue during the early weeks of pregnancy may result in NSJ associated with ocular malformations[13] and may also be consistent with colobomas of the optic disc with deep cupping and abnormal blood vessels described by Shields et al,[16] as well as the macrooptic discs described by Kruse et al.[14] Other studies have pointed to a possible link with the human papillomavirus[40] or mutations in the patched gene (PTCH).[41]

Although nevus sebaceous is not an inherited skin lesion, it carries postzygotic somatic mutations of the RAS protein family. One study reported 95% of NSJ with *HRAS* mutations and 5% with KRAS mutations. These RAS mutations have also been described in the secondary tumors associated with NSJ, such as trichoblastomas.[10,42,43]

Clinical Presentation

The natural history of NSJ is traditionally divided into three stages.[44] The first is an early infantile stage, characterized by papillomatous hyperplasia and immature hair follicles. The second stage involves expansion at puberty, characterized by rapid growth of the nevus. This is hormonally driven, related to the development of sebaceous glands and maturation of apocrine glands, transforming the lesion from a smooth to a verrucous plaque. The third stage is seen in adults with the development of benign and malignant epithelial neoplasms seen in 10% to 20% of cases.

The symptoms and severity of nevus sebaceous syndrome vary greatly. In childhood, they may be inconspicuous and unrecognized. However, in most cases, NSJ presents as an asymptomatic cutaneous sebaceous nevus lesion. The scalp, neck, and face are most often affected, with the arms, legs, and trunk involved less frequently. Sebaceous nevi are usually hairless, salmon, or yellowish-colored smooth patches in childhood (Figure 96.1), becoming more pronounced and thickened during puberty, and may even appear warty (Figure 96.2).[44] When located on the scalp, they are usually associated with alopecia. Neurological abnormalities can include seizures, developmental delay, intellectual impairment, hemimegalencephaly, malformation of certain brain vessels, agenesis of the corpus callosum, agyria, microgyria, and pachygyria.[20,21,22,23,24]

Ophthalmic manifestations are common and include complex limbal choristomas,[17,18,19] peripapillary yellowish dermal lesions,[17] limitations of extraocular movement,[18,45,46,47] eyelid coloboma,[17,44] and absence of the superior rectus muscle.[48]

(Print pagebreak 639)

FIGURE 96.2 Warty nevus sebaceous of Jadassohn of the upper eyelid. (Courtesy of Dr. Alan McNab.)

Affected individuals may also have skeletal malformations including abnormal curvature of the spine, dislocation of the hip, limb bone hypoplasia, osteopenia, and multiple insufficiency fractures.[49] Craniofacial skeletal findings can include frontal bossing, asymmetry of cranial facial and orbital bones, sphenoid bone malformation, and premature closure of the sphenofrontal suture.[50] Additional skeletal malformations may include bone cysts, underdevelopment of the pelvis, and incomplete formation of certain bony structures including the ankle, foot, and vertebrae.

Differential Diagnosis

The differential diagnosis of nevus sebaceous depends on the stage of development. In early infancy, the differential diagnosis may include aplasia cutis congenita or mastocytoma. In later stages of development, the differential includes congenital and epidermal nevi, seborrheic keratosis, verruca, early juvenile xanthogranulomas, and other epidermal nevi such as phacomatosis pigmentokeratotica, nevus comedonicus syndrome, and Proteus syndrome. Nevus psiloliparus is a distinct scalp lesion also associated with alopecia and fatty tissue and should be distinguished from NSJ.

Treatment

The specific treatment of NSJ depends upon symptoms, the extent of the disorder, patient age, health, and personal preferences of the patient and clinician. Treatment may require the coordinated efforts of a team of specialists. Pediatricians, pediatric neurologists, dermatologists, orthopedists, orthopedic surgeons, ophthalmologists, and other healthcare professionals may need to collaborate on the treatment options.

The two main reasons to treat NSJ include the development of malignancy and cosmetic improvement. Once a malignant lesion arises within NSJ, the entire nevus should be removed. However, in children with no evidence of malignancy, recommendations regarding prophylactic excision to decrease the risk of future malignant growths have been controversial. Although earlier studies showed high rates of BCC that led to recommendations for early prophylactic excision, during the past several decades, larger studies showed very low rates of BCC arising in these lesions, in the range of 1% or less. As a result, the current opinion is that uncomplicated NSJ lesions can be observed with close follow-up. Despite the low risk of malignant development, surgical removal is appropriate for cosmetic improvement given that these lesions are common on the face and scalp and can cause alopecia.[25]

Once the decision for treatment is made, surgical excision is the treatment of choice. Shave removal is usually unsuccessful because it leaves deep dermal tissue and residual nevus behind.[51,52,53] A full-thickness dermal and epidermal surgical excision should be the goal. For associated ocular lesions such as epibulbar choristomas, surgical excision combined with amniotic membrane transplantation when necessary is an acceptable treatment yielding a good cosmetic outcome.[54]

Ablative laser therapy has shown good aesthetic benefit and treatment response for cutaneous nevi,[55,56] but the long-term efficacy for nevus sebaceous has been questioned.[57] Photodynamic therapy has also been reported to yield moderate to marked improvement in lesions with no significant side effects.[58]

Whether the brain should be imaged in all children with large sebaceous nevi is a controversial issue.[59] Some authors argue that neuroimaging is appropriate only if clinical signs of central nervous system involvement are found or in patients with large nevi involving the centrofacial area.[24]

Prognosis

The prognosis of nevus sebaceous depends on whether it is benign or malignant at the time of diagnosis. In cases with only nevi or benign neoplasms, the prognosis is excellent. For lesions associated with malignant tumors, most are BCCs, which carry a good prognosis following complete surgical excision. The rarer squamous cell carcinomas and melanomas can be associated with local recurrence, regional lymph node involvement, distant metastasis, and mortality.[60,61]

Histopathology

NSJ's histological appearance depends on the patient's age at the time of biopsy, as documented in a study of 150 patients by Mehregan and Pinkus.[44] Mehregan and Pinkus categorized the histological appearance according to patient's age: 0 to 6 years (n = 19 cases), 7 to 12 years (n = 28 cases), 13 to 18 years (n = 35 cases), and 18 years and older (n = 68 cases). One hundred nine patients had their nevus since birth, 33 had their nevus for "many years," and the duration of the nevus was unknown in 8 cases.[44] One hundred seven of the nevi were from the scalp, 35 from the face (2 from *(Print pagebreak 640)* the eyelids), and the remainder from the arm (n = 3), chest (n = 2), back (n = 1), or site unknown (n = 2).[44] Mehregan and Pinkus's histological findings are summarized here according to skin structure and age groups[44]:

1. Epidermis: The epidermis was hyperplastic in 84% of patients from 0 to 6 years, 93% from 7 to 12 years, 97% between 13 and 18 years, and 94% in ages 18 years and older. The hyperplastic epidermis was papillomatous, but it was milder in early lesions and more prominent in older nevi (Figures 96.3 and 96.4). The hyperplasia was due to an increased number of prickle cells with a thickened stratum spinosum and was accompanied by hypergranulosis and hyperkeratosis. Approximately 6% of nevi had an appearance of seborrheic keratosis with basaloid cell hyperplasia. Pedunculated nodules of hyperplastic epidermis projected from the surface in 7% of cases.

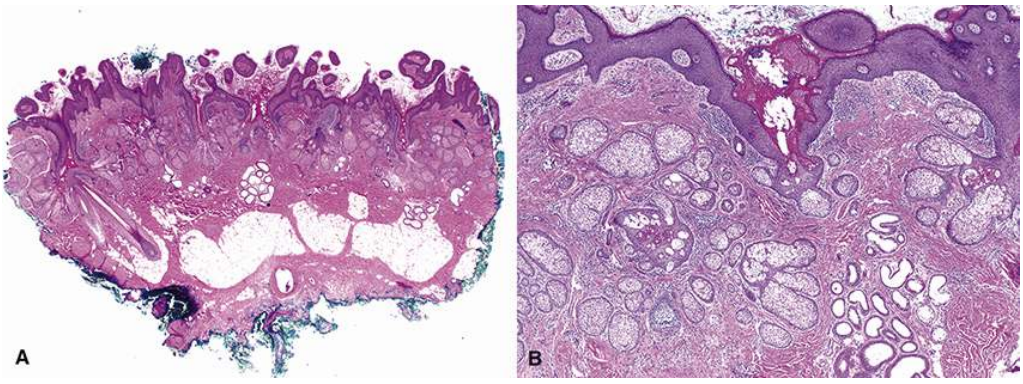

FIGURE 96.3 This nevus sebaceous of Jadassohn (NSJ) of the left occipital scalp was excised at age 12 years after a new papule developed. A, Papillary epidermal hyperplasia with hyperkeratosis, sebaceous gland hyperplasia, and apocrine gland hyperplasia is prominent at scanning magnification. B, Epidermal acanthosis and hyperkeratosis, hyperplasia of sebaceous and apocrine glands, and dermal fibrosis are common features of NSJ after 11 years. The hair follicle is maldeveloped with an absent hair shaft.

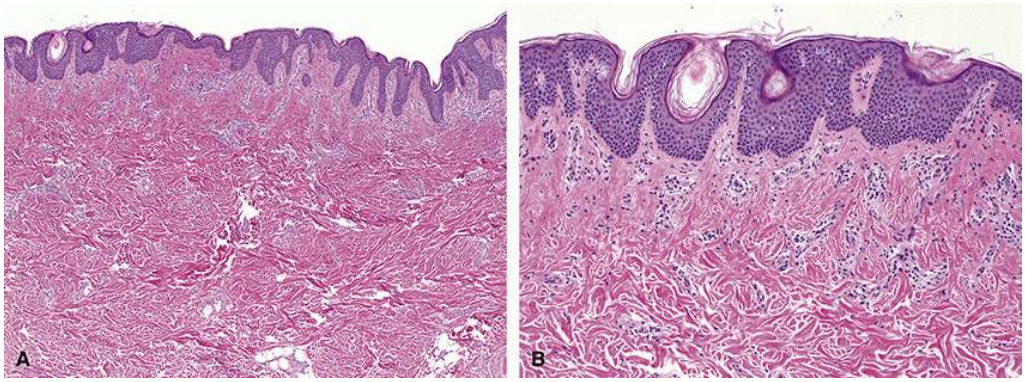

FIGURE 96.4 This scalp nevus sebaceous of Jadassohn was noted at birth and excised at 10 years of age due to increasing size and itchiness. A, The epidermis is acanthotic, and pilosebaceous units and apocrine glands are absent. B, The acanthosis is due to thickened stratum spinosum, and the papillary dermis is fibrotic.

2. Hair follicles: Hair follicles were abnormal in all nevi from patients between 0 and 6 years (Figure 96.5), 93% between 7 and 12 years (Figure 96.3), 91% between 13 and 18 years, and 88% in patients 18 years or older. Early lesions manifest clinically as an area of alopecia had abnormally developed hair follicles with cords of undifferentiated cells resembling embryonic follicles (Figure 96.5B). There were papillae and matrix-like epithelial arrangements surrounded by connective tissue in some areas and occasional keratinization or formation of small hair shafts. The older lesions had many normal-appearing hair follicles with hair shafts along with scattered buds of undifferentiated basaloid cells surrounded by fibrous connective tissue connected to the lower border of the epidermis or pilosebaceous structures. Hair follicles were absent in 8%, 9%, 12% in *(Print pagebreak 641)* age groups 7 to 12 years, 13 to 18 years, and 18 years and older (Figure 96.4).

3. Sebaceous glands: Between 0 and 6 years, 95% of cases had numerous small undeveloped lobules of sebaceous glands connecting to incompletely formed hair follicles (Figure 96.5C). Between 7 and 12 years, there were small sebaceous glands in 39%, small and large glands in 25%, large sebaceous glands in 25% (Figure 96.3), and absent glands in 11% of cases (Figure 96.4). The number of small immature sebaceous glands decreased, and large, well-developed glands increased in the older age groups. Between 13 and 18 years, there were small sebaceous glands in 9%, small and large glands in 20%, large in 57%, and absent glands in 14% of cases. For cases 18 years or older, there were small sebaceous glands in 3%, small and large in 6%, large in 79%, and absent glands in 12%. In older lesions, the sebaceous glands sometimes had excessive size and formed "massed arrangements."[45]

4. Apocrine glands: Apocrine glands were absent in 89% of cases between 0 and 6 years, 50% between 7 and 12 years, 31% between 13 and 18 years, and 40% from age 18 years or older. The apocrine glands, when present, had active secretion.

5. Dermis: The dermis was abnormal in 87% of cases, with the most common abnormalities being increased thickness, increased vascularity, and proliferation of fibrous connective tissue. The changes were most marked in the papillary and anterior reticular dermis and at the periphery of pilosebaceous units. Twenty-eight percent of cases had a moderate to heavy infiltrate of lymphocytes, plasma cells, and "some eosinophils." Melanophages were present "occasionally," 5% of cases had a foreign body granulomatous reaction to degenerating pilosebaceous structures, and 2% had small areas of dermal calcification.

6. Secondary tumors: Tumors increased in frequency in older lesions. Tumors developed in 5% of cases between 0 and 6 years, 4% between 7 and 12 years, 9% between 13 and 18 years, and 41% of patients 18 years or older. Mehregan and Pinkus identified 52 tumors in 33 cases, with BCC being the most common (40% of the tumors), followed by syringocystadenoma papilliferum (15%) and solid hidradenoma (12%).

Mehregan and Pinkus summarized the life history of NSJ as underdevelopment of hairs and sebaceous glands in the early stage; massive development of sebaceous glands, papillomatous epidermal hyperplasia, and maturation of apocrine glands during a second phase usually beginning at puberty; and development of secondary benign and malignant tumors in the lesions in the third stage.

Morioka confirmed age-related changes in the histological appearance of NSJ in a study of 86 cases.[62] Sebaceous glands were absent in 6% of lesions, normal in 26%, slightly proliferated in 38%, and markedly proliferated in 30%.[62] Morioka identified sebaceous gland proliferation in lesions *(Print pagebreak 642)* of any age, but most of the cases of marked proliferation were in subjects aged 11 years or older.[62] Apocrine glands were absent in 72% of lesions, normal in 8%, slightly proliferated in 10% (Figure 96.4B), and markedly proliferated in 10%. Apocrine gland proliferation was most common in the subjects aged 11 years or older, similar to the finding for sebaceous glands.[62]

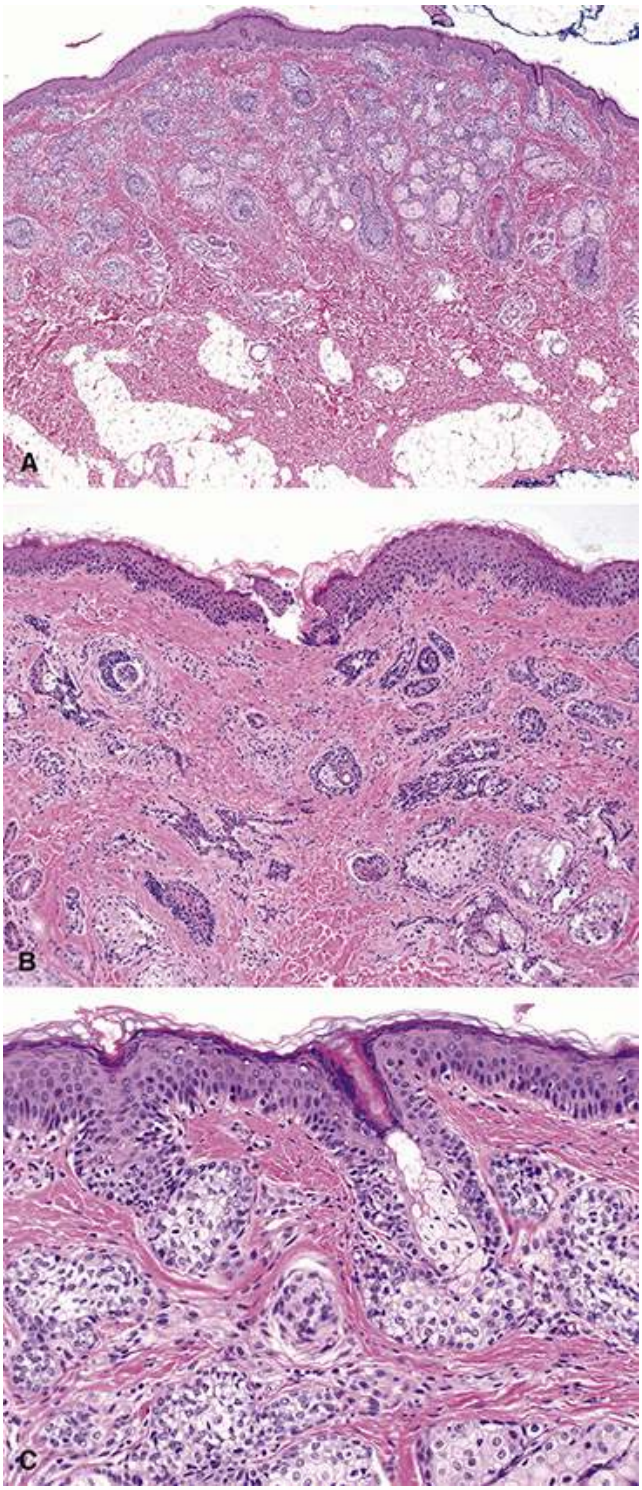

FIGURE 96.5 This nevus sebaceous of Jadassohn of the right medial canthus was noted at birth and excised at the age of 1 year. A, There are an increased number of sebaceous glands and no normal hair follicles at scanning magnification. B, The superficial dermis has many abnormally developed hair follicles with cords of undifferentiated cells and rudimentary follicles. C, Small lobules of sebaceous glands connect to incompletely formed hair follicles.

CHAPTER 97

Nodular Fasciitis

Key Points

- Nodular fasciitis is a rare benign reactive lesion characterized by a proliferation of fibroblasts and myofibroblasts that involve subcutaneous tissue, skeletal muscles, and fascia
- It is classified according to the plane of tissue that is primarily involved, including subcutaneous, dermal, intramuscular, and fascial types
- The etiology of NF remains unknown but a traumatic etiology has been proposed
- Gene rearrangements suggest that nodular fasciitis may be an unusual phenomenon of transient or self-resolving neoplasia
- The clinical presentation is usually a skin-colored to light brown firm, smooth, mobile subcutaneous nodule that grows rapidly and measures 1 to 2 cm in diameter
- Surgical excision is recommended as the treatment of choice to exclude malignancy, and lesions can be cured with a conservative surgical resection
- The prognosis is usually good, and recurrence is exceptionally rare

Nodular fasciitis (NF) is a rare benign reactive lesion of unknown etiology characterized by a proliferation of fibroblasts and myofibroblasts[1,2] that involves subcutaneous tissue, skeletal muscles, and fascia.[3,4] It was first described by Konwaler and Weiss[5] in 1955 as "subcutaneous pseudosarconiatous fibromatosis (fasciitis)." In that report, the authors reported eight cases of a rapidly growing nodule that histologically resembled fibrosarcoma.

NF can appear in any part of the body, but the most common sites of involvement are the upper extremity, followed by the chest and back. Approximately 7% to 20% of cases occur in the head and neck region,[6,7,8,9,10,11,12,13] and these cases are more often seen in younger children.[6,14,15,16] In the facial region most lesions are located in the skin, parotid gland, and subcutaneous tissues of the mandible and zygoma.[7] The eyelid is rarely involved,[17,18,19,20,21,22,23,24,25,26,27] but several cases of orbital involvement have been described.[22,28,29]

There is no clear gender predilection, with reports varying from male and female equivalence, male predominance, to female predominance.[7,11,30,31] NF is often initially misdiagnosed as a sarcoma because of its rapid growth and its histologic appearance and has been referred to as pseudosarcomatous fasciitis.[8,14,32]

Nodular fasciitis can be classified according to the plane of tissue that is primarily involved. These include subcutaneous, intramuscular, and fascial types.[7] A fourth variant, the dermal NF, is more commonly found in the head and neck region.[2] Among 16 cases of facial NF, all lesions involved subcutaneous tissues, but 7 (43.8%) also involved the muscle layers and 10 (62.5%) had dermal involvement.[33]

Lesions are usually attached to the fascia from which they arise and extend into the subcutaneous fat. Occasionally they arise from the fibrous septa of the subcutaneous fat and only secondarily extend to the fascia.[7] In 1966, based on 17 personal and 314 cases from the literature, Mehregan[34] defined the clinical appearance, epidemiology, and histologic findings of NF as a freely mobile, subcutaneous nodule, sparing the dermis, with an aggressive appearing, fibroblast-like histologic picture. Lesions typically grow rapidly, with a duration of <1 month in 57% of cases and >3 months in only 15%. Tenderness or pain was reported in 55% of cases.

Etiology and Pathogenesis

The etiology of NF remains unknown but a traumatic etiology has been proposed.[34] In a study of 50 patients with NF, 5 (10%)

recalled antecedent trauma.[16] In another study of 16 patients with facial NF, 9/16 (77%) had a history of trauma or stimulation before development of the lesion.[33] However, most other studies show only a small number of patients who report even a vague history of trauma.[5,11,12,31,32,34,35,36,37] Because some cases of nodular fasciitis appear to arise after minor trauma and then spontaneously resolve, it has not been clear whether these lesions arise as a reactive process or as a true neoplasm.[38] Erickson-Johnson et al[39] reported that 92% of NF tumors contain a gene rearrangement involving *USP6* on 17p13, with the most common fusion partner being *MYH9* on 22q12. This leads to overexpression of *USP6* under *MYH9* promoter and appears to drive *(Print pagebreak 645)* tumorigenesis.[40] These results suggest that nodular fasciitis may be an unusual phenomenon of transient or self-resolving neoplasia.[39]

Clinical Characteristics

The clinical presentation of nodular fasciitis is usually a firm, smooth, mobile subcutaneous nodule that grows rapidly over weeks to several months (Figure 97.1). Lesions are skin colored to light brown and measure 1 to 2 cm in diameter, but they can be up to 4 cm.[41] When involving the upper eyelid, larger lesions can cause mechanical ptosis.[1,17] In rare cases, NF can be immobile due to infiltration into the dermis and underlying muscle.[19]

Lesions may be painless and asymptomatic, but 55% are tender or even painful.[34,36] One case was reported to have a cystic appearance that could be transilluminated.[19] While most periorbital lesions involve the eyelid skin, rare cases have been described located beneath the episcleral conjunctiva (Figure 97.2).[24,27] Periorbital NF lesions tend to be smaller than those in other parts of the body, possibly due to the less abundant subcutaneous fat and fascia.[42]

Differential Diagnosis

The clinical features of NF are not pathognomonic and can lead to diagnostic confusion. The differential diagnosis includes solitary fibrous tumor, dermatofibroma, fibrous histiocytoma, fibroma, fibrolipoma, lipoma, neurofibroma, neuroma, neurilemmoma, dermoid and epidermoid cyst, leiomyoblastoma, fibrosarcoma, and sarcoma.[1,25,26,34]

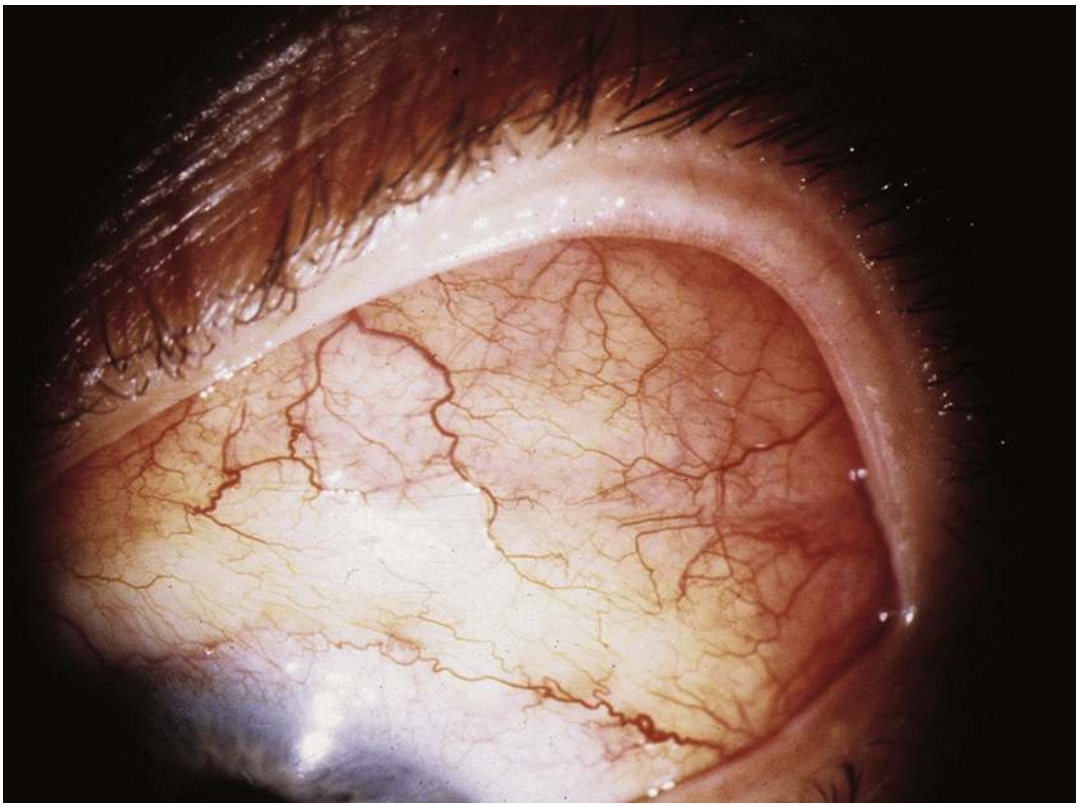

FIGURE 97.2 Nodular fasciitis beneath the superior episcleral conjunctiva.

Treatment

Because NF is frequently mistaken for sarcoma both clinically and histopathologically, surgical excision is usually recommended as the treatment of choice to exclude malignancy.[43] Nodular fasciitis usually can be cured completely with a conservative surgical resection.[8] Local recurrence is uncommon, generally reported at 8% or less.[16,44] Of 18 cases of recurrence noted by Bernstein and Lattes,[35] on re-excision all were reclassified histologically as inflammatory fibrous histiocytoma. It has even been proposed that any recurrence of supposed NF should lead to a reconsideration of the diagnosis.[45] However, in a series of nine cases of histologically confirmed facial NF treated surgically, seven (77%) recurred,[33] likely due to incomplete resection with more conservative surgery to minimize scarring. Therefore, for lesions occurring on the face, nonsurgical treatment and regular follow-up has been proposed as an alternative approach.[33]

For nonsurgical treatment, intralesional injection with triamcinolone has been proposed, assuming that NF is a benign reactive or inflammatory condition of mesenchymal fibroblasts.[46] Intralesional steroid injection has been reported to result in significant improvement[33] or even complete resolution of NF lesions in 1 to 3 days,[19,46] but data are limited.

NF on the face is frequently of the intradermal type. Facial muscles are located superficially beneath the skin so that NF lesions can extend beyond the fascia and subcutaneous tissue to invade the skin.[47] Such superficial, intradermal types of NF are more easily managed by laser treatment. CO_2 laser therapy can decrease the size of the lesion through tissue contraction using a pinhole method.[33,48] This technique may especially be effective for lesions on the face that may be of greater aesthetic concern.

Spontaneous regression has been reported after incomplete excision,[15,33] so that in such cases it may be appropriate to follow the patient closely and wait for regression before considering further surgery.

(Print pagebreak 646)

Prognosis

The prognosis of NF is usually good. Following surgical excision, most cases can be cured and recurrence is exceptionally rare.[2,26,28]

Histopathology

NF is far more common in the subcutis than the dermis.[49,50,51] Subcutaneous lesions may be well circumscribed but unencapsulated,[51] or they may have "a central body of more solid cellular growth sending outward in all directions numerous processes within the connective tissue septa of the surrounding fat lobules" creating the appearance of an infiltrating tumor.[34] The lesions are composed of variably sized spindle cells without a consistent or distinguishing pattern.[35] The spindle cells may have a vague storiform pattern, form interconnecting fascicles (Figure 97.3A and B), be randomly oriented, appear similar to granulation tissue with proliferating fibroblasts associated with fine capillaries, or lie within a myxoid matrix that may have small cystic spaces.[34,35,52] Lesional cells may be plump, oval, stellate, or fusiform[34] with pale eosinophilic cytoplasm.[42] Nuclei may be plump,[34] oval,[34] vesicular,[34] or stellate[52] with one or more prominent[34] or small, round, and basophilic[52] nucleoli. Scattered multinucleated giant cells are in 10%[51] to 50%[35] of cases (Figure 97.3C). Mitoses are usually easily noted, although the number varies widely from one area of the lesion to another.[35] Bernstein and Lattes counted mitotic figures in 20 high-power fields (HPF) and noted an average of one mitotic figure/HPF in 8% of cases, one mitotic figure in 2 to 5 HPF in 49%, and one mitotic figure in >5 HPF in 41% of cases.[35] Atypical mitotic figures are absent[42,52] or rare[35] in NF. The stroma usually has areas of extravasated erythrocytes (Figure 97.3B)[5,34,35,42,52] and scattered acute and chronic inflammatory cells.[52] Rare lesions may have plasma cells or lymphoid tissue with germinal centers.[35] Mehregan observed occasional areas of granulomatous inflammation near the junction of NF and the adjacent fat tissue.[34] Stromal capillaries may exhibit endothelial cell proliferation or be dilated and engorged with erythrocytes.[34] Collagen within NF may be almost absent[34] or heavily hyalinized with a keloidal appearance.[42,51] Foci of osteoid were identified in 3/116 (2.6%) and foci of osteoid and cartilage in 4/116 (3.4%) of the cases studied by Bernstein and Lattes.[35]

Immunohistochemical studies of subcutaneous NF have yielded somewhat variable results. Montgomery and Meis, in a study of 53 lesions, reported immunoreactivity for muscle-specific actin (MSA) in 100% of cases, smooth-muscle actin (SMA) in 98% (Figure 97.3E), CD68 (KP1) in 98%, vimentin in 94%, and no reactivity to keratins, S-100 protein, or desmin in any case.[52] SMA immunoreactivity was diffuse and, in many cases, was weak compared with vascular smooth muscle.[52] CD68 (KP1) stained a minority of the spindle cells and all of the giant cells (Figure 97.3F).[52] "KP1 reactive cells were clearly lesional rather than part of the inflammatory background; they were indistinguishable from nonreactive spindle cells in the H&E-stained sections".[52] Weinreb and coworkers identified SMA immunoreactivity in 100% (24/24) cases; the staining was diffuse and strong staining in 19/24 (79%) and focal in 5/24 (21%) of cases.[42] "The lesional fibroblastic/myofibroblastic cells were negative for S-100 (0/22), desmin (0/19), CD34 (0/19), CD68 (0/15), and factor XIIIa (0/15)."[42] Lu and colleagues reported diffuse expression of SMA; positive staining for calponin, MSA, and CD10; expression of CD68 by "intralesional histiocytes and small multinucleated giant cells"; and no staining using antibodies to desmin, h-caldesmon, β-catenin, AE1/AE3, CD34, and S-100 protein.[51] Fluorescent in situ hybridization analysis using a break-apart probe to detect *USP6* gene rearrangement has a sensitivity of 74%[53] to 86%[54] and a specificity of 100%[53,54] for diagnosing NF.

Cutaneous NF involves the dermis with extension into the superficial subcutis in about 40% of cases (Figure 97.3).[40,47,55] In a review of 24 cases of dermal NF by de Feraudy and Fletcher, 23 cases were well circumscribed but unencapsulated, one had ill-defined margins, and the epidermis was ulcerated in 11/24 (46%).[47] Lesional cells were uniform plump spindle cells, cytologically bland without significant atypia or pleomorphism, and arranged in short intersecting fascicles (Figure 97.3A and B) within a focally microcystic myxoid stroma with extravasated erythrocytes (Figure 97.3B) and scattered lymphocytes.[47] There were one to six mitoses per 10 HPF.[47] All cases were diffusely positive for SMA, but tested cases were negative for expression of desmin, caldesmon, CD68, CD34, AE1/AE3, CAM52, pan-cytokeratin, S100 protein, MART-1 (melanin A), microphthalmia-associated transcription factor, and HMB-45.[47]

Intravascular fasciitis (IF) is a rare variant of nodular fasciitis[56,57,58,59] that may involve the periocular skin (Figure 97.4).[60] It may involve small veins or arteries, usually with a predominant extravascular component.[56,59] IF may appear to be NF with a multinodular growth pattern, with vascular involvement becoming apparent only using elastic and muscle stains.[59] Most cases affect the intima, media, and adventitia.[56] The histological appearance is similar to NF, although prominent myxoid stroma is uncommon.[56,58] The spindle cells are immunoreactive using antibodies to vimentin, smooth muscle actin, and muscle-specific actin, and they lack expression of desmin, cytokeratins, S100 protein, CD31, and CD34.[57,58,61]

(Print pagebreak 647)

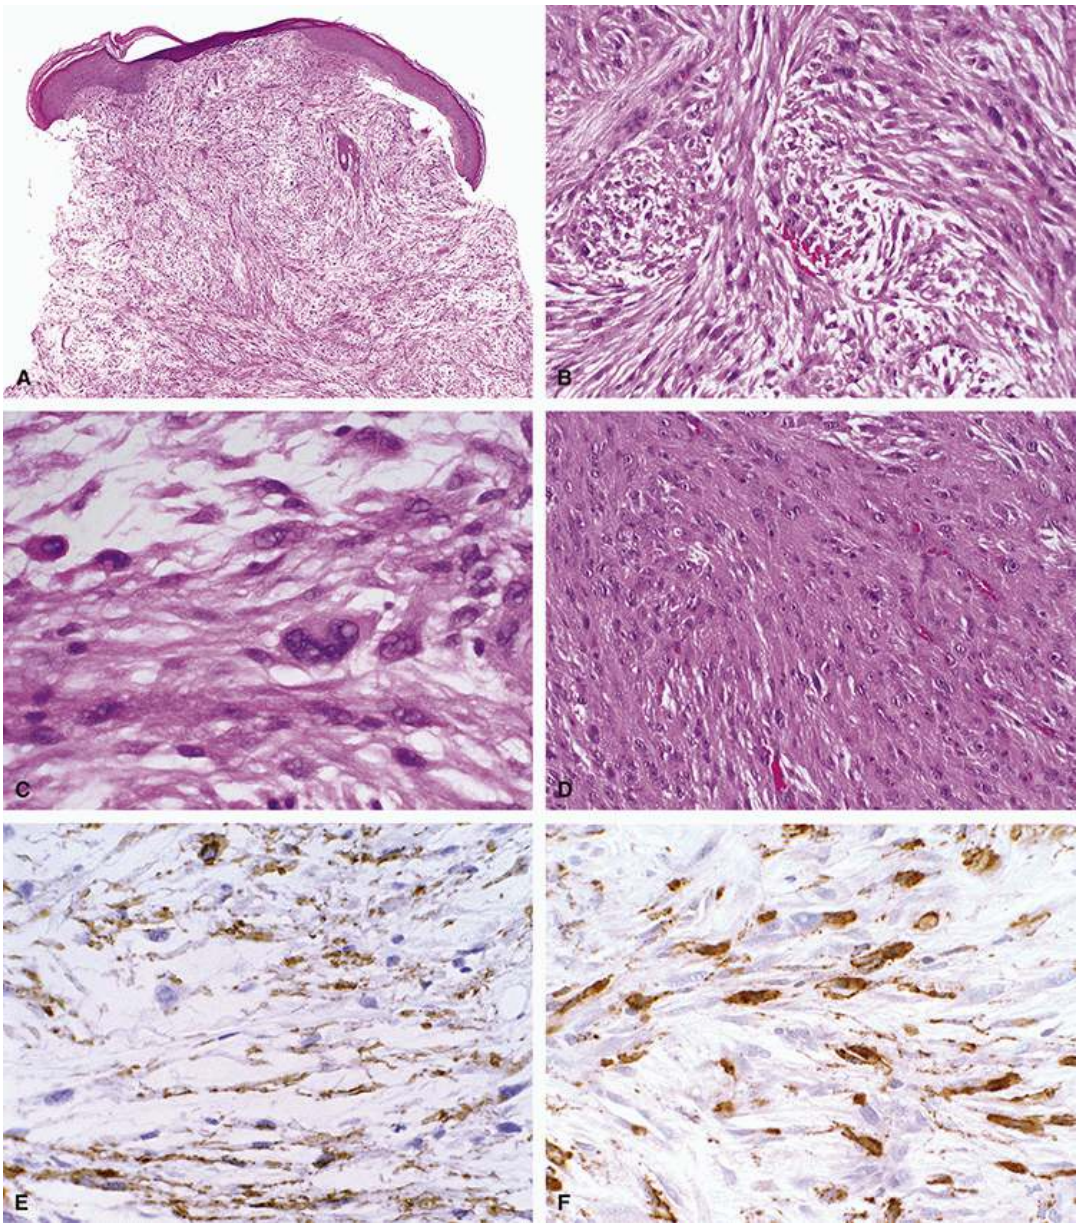

FIGURE 97.3 This NF arose at the right lateral canthus in a woman in her late 20s. The NF was painless, nontender, and erythematous and grew continuously over 7 months to 1.5 cm in diameter. A, The NF extends from the papillary dermis through the reticular dermis. In this area, the NF has a fascicular pattern, with many of the fascicles having a loose appearance. The epidermis has an artifactual fold. B, The fascicular appearance is prominent in this area, and there is a focus of extravasated erythrocytes in the stroma. C, There were scattered multinucleated giant cells throughout the tumor. D, Some areas of the NF had a more compact appearance with sheets of spindle cells and intervening capillaries. E, Immunohistochemical staining with antibodies to smooth muscle actin is positive in >95% of cases of NF. F, Immunohistochemical expression of CD68, a marker of macrophages (histiocytes), was present in this case of NF, but the proportion of cases expressing CD68 has varied widely in published series of NF.

(Print pagebreak 648)

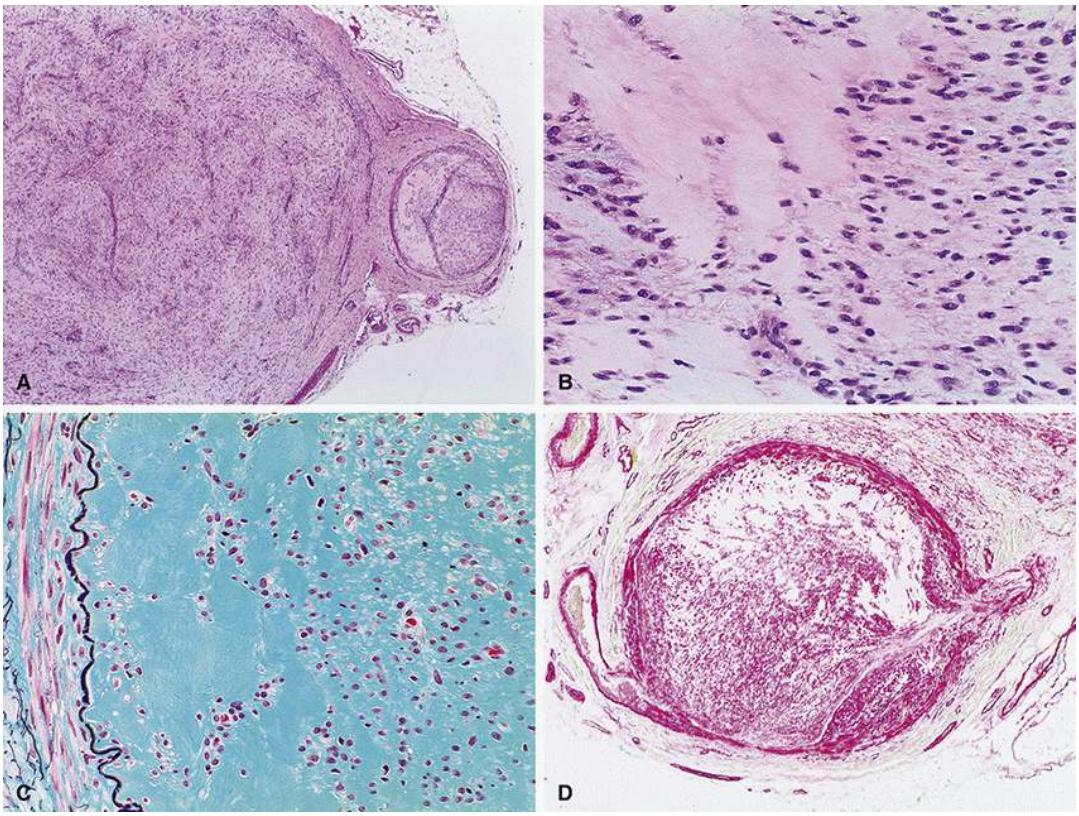

FIGURE 97.4 A septuagenarian woman developed a round, firm, mobile mass of her right upper eyelid that increased to a diameter of 5 to 6 mm over 6 months. A, Excisional biopsy disclosed a bilobed mass with intravascular fasciitis (IF) of a small artery on the right, and a larger adjacent extravascular nodule of fasciitis. B, The IF had cells with oval nuclei and indistinct cell borders embedded in a predominantly myxoid stroma. C, Movat pentachrome stain highlights the arterial smooth muscle light red, the internal elastic lamina black, and the myxoid IF stroma blue. D, Immunohistochemical staining with antibodies to smooth muscle actin showed intense staining of the arterial wall smooth muscle and slightly less intense staining of the IF cells.

CHAPTER 98

Ocular Cicatricial Pemphigoid

Key Points

- Mucous membrane pemphigoid describes a heterogeneous group of autoimmune disorders characterized by chronic inflammatory, mucous membrane blistering involving the ocular, oral, genital, nasopharyngeal, esophageal, or laryngeal regions and the skin
- It is characterized by the presence of linear deposits of C3, IgG, IgA, or IgM along epithelial basement membranes, and more than 10 target antigens have been identified
- Ocular and palpebral findings are attributable to subepithelial fibrosis
- It manifests initially with unilateral or bilateral chronic conjunctivitis, tearing, and redness, followed by progressive obliteration of the conjunctival fornix and ultimately complete bilateral occlusion of the fornices or ankyloblepharon with lagophthalmos
- Aggressive immunosuppression is required to suppress inflammation, promote healing, and prevent further cicatrization
- The treatment for trichiasis is destruction of the cilia follicles responsible for the aberrant eyelash growth with electrolysis, cryotherapy, or laser
- The success rates for the surgical correction of the cicatricial entropion and trichiasis generally are very good, but management of systemic disease shows only partial success, and recurrence rates are high

Mucous membrane pemphigoid describes a heterogeneous group of autoimmune disorders bearing several names in the literature, which are characterized by chronic inflammatory, mucous membrane-dominated, subepithelial blistering at the body orifices involving the ocular, oral, genital, nasopharyngeal, esophageal, or laryngeal regions and the skin (Figure 98.1). Blindness or life-threatening complications may occur.[1,2,3,4,5,6,7,8,9] Occasionally, the clinical manifestations may primarily involve the eyes, and in such patients, the term “ocular cicatricial pemphigoid” (OCP) is often used.[4,5]

Etiology and Pathogenesis

Mucous membrane pemphigoid is characterized by the presence of linear deposits of C3, IgG, IgA, or IgM along the epithelial basement membranes. More than 10 target antigens have been identified in mucous membrane pemphigoid, and these are all components of the epithelial basement membrane.[3] Autoantibodies against these basement membrane components include Bullous pemphigoid antigen 1 and 2, Laminin 5 and 6, and type VII collagen. These probably play a role in the pathogenesis of this group of diseases,[3] and in the case of OCP, in particular, one antigen, the β4 subunit of α6β4 integrin, has been identified as the target conjunctival basement membrane autoantigen.[4] When the circulating autoantibodies bind to antigens within the basement membrane, they activate the complement cascade with complement deposition at the level of the lamina lucida with release of inflammatory cytokines and hydrolytic enzymes.[4]

Conventional histopathologic examination is not usually conclusive in OCP, but there are some suggestive findings including the predominance of T cells, neutrophils, and histiocytes; a decrease in goblet cell density; and a mild capillary proliferation.[4,5] The predominance of T cells has led some authors to hypothesize a model for the pathogenesis of OCP. This model postulates a shift away from T suppressor cells to T helper cells that allow the B cells, which are normally prevented by T suppressor cells from releasing autoantibodies against basement membrane components, to escape this surveillance mechanism and promote the activation or release of rogue clones of B lymphocytes, which synthesize these autoantibodies.[4] It must be underscored that the gold standard for diagnosis of OCP is with the use of immunofluorescence and not conventional histology.[4] Although the demonstration of linear deposits of IgA, IgG, IgM, or C3 along epithelial basement membranes is one of the essential criteria for the diagnosis of mucous membrane pemphigoid,[3] the situation with OCP is more complicated,[3,4,7] and the range of positive biopsies vary from 20% to

67% only. Therefore, although a positive biopsy establishes the diagnosis, a negative one does not exclude OCP.[3,4,7,9] It should be noted that demonstration of linear IgG alone is nonspecific as it can be demonstrated in any inflammatory eye condition.[4] Certain precautions, however, may improve the diagnostic yield: (1) the biopsy specimen should be obtained from conjunctival tissue immediately adjacent to the inflamed tissue and not from the inflamed tissue itself, let alone scarred tissue; (2) if there is multiorgan involvement, a nonocular site should be chosen; (3) fresh tissue should be immediately submitted for immunofluorescence; and (4) the routine use of immunoperoxidase staining in addition to immunofluorescence significantly increases the diagnostic yield.[3,4,7]

(Print pagebreak 651)

FIGURE 98.1 A and B, Oral mucous membrane involvement with cicatricial pemphigoid. A, (Courtesy of Dr. Charles Soparkar.)

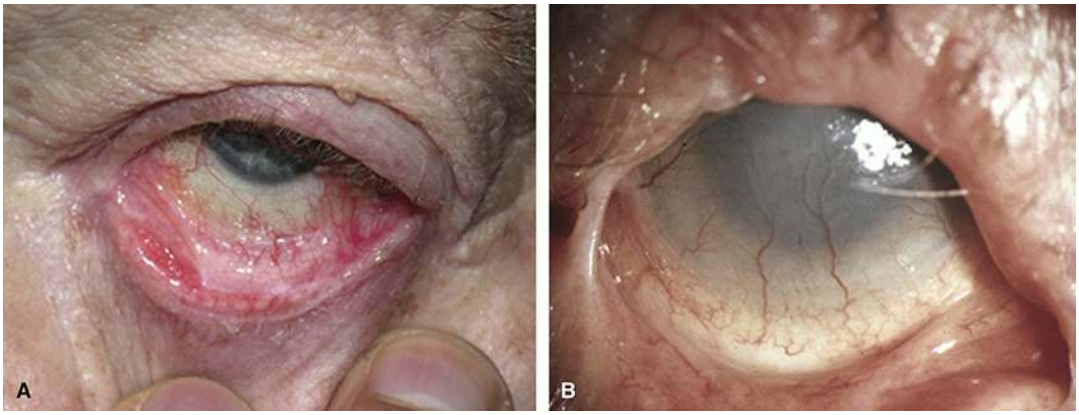

FIGURE 98.2 A and B, Early OCP with conjunctivitis, fornix shortening, and symblepharon formation.

Clinical Presentation

The age of onset of OCP peaks during the 7th and 8th decades, but this may be partially attributable to a delay in presentation rather than just a delay in onset.[5,9] The ocular, as well as the palpebral findings of OCP, are all attributable to subepithelial fibrosis,[4,7] which usually manifests initially with unilateral or less commonly bilateral chronic conjunctivitis, and nonspecific symptoms of tearing, redness, and foreign body sensation. This is followed by progressive shortening of the conjunctival fornix and symblepharon formation, which usually starts in the lower followed by the upper eyelid (Figure 98.2). Progressive fibrosis results in deformed eyelids with loss of normal architecture, ankyloblepharon with lagophthalmos, keratinization of the mucocutaneous junction, trichiasis, distichiasis, or frank cicatricial entropion (Figure 98.3). The process is progressive and ultimately results in complete bilateral occlusion of the fornices (Figure 98.4). An important clinical finding that is rarely discussed in the literature is that the palpebral, as well as the conjunctival, findings usually start medially. Trichiasis and distichiasis are not uncommon medially and may extend to the lacrimal portion of the eyelids, which is normally devoid of lashes. Ankyloblepharon also starts medially with effacement of the plica semilunaris before advancing laterally as the disease progresses. Additional ocular findings include punctal and canalicular fibrosis, which typically precede occlusion of the ducts of the main and accessory lacrimal glands. Thus, patients with OCP initially present with tearing followed years later by symptoms of severe dry eyes that may also be exacerbated by progressive destruction of the goblet cells.[7] It is always important to rule out OCP in all patients presenting with tearing and punctal/canalicular fibrosis before rushing to lacrimal surgery that could exacerbate *(Print pagebreak 652)* dry eyes in the future. This vicious cycle of entropion, trichiasis, dry eyes, and lagophthalmos eventually leads to corneal scarring and even corneal

perforation.[7] The clinical manifestations of OCP might not always conform to a strict classification scheme, so it is necessary to keep a broad categorization in mind to serve as a framework for therapeutic decision making. Several classification schemes have been proposed over the years, but the most accepted staging system is the Foster staging system, which classifies ocular/periocular changes in OCP into four stages: Stage I findings include conjunctivitis with discharge and conjunctival subepithelial fibrosis, stage II is characterized by inferior fornix foreshortening, stage III is defined by the appearance of a symblepharon, and stage 4 is an end-stage disease with marked ocular surface keratinization and ankyloblepharon (Figure 98.2B).[5,8] Foster stages II and III are further classified into four subcategories (a-d) according to the degree of fornix shortening.[10]

FIGURE 98.3 OCP with (A) entropion and trichiasis and (B) ankyloblepharon.

FIGURE 98.4 Late-stage OCP with (A) corneal opacification and symblepharon and (B) complete obliteration of upper and lower fornices.

It is important to underscore the fact that OCP is still a systemic disease with frequent involvement of extraocular sites, like the oral mucosa (desquamatous gingivitis in 65% of patients), the skin (small vesiculobullous lesions in the extremities and/or the inguinal region, or flat erythematous plaques on the face or scalp in 4% to 15%), esophagus *(Print pagebreak 653)* (strictures and aspiration on swallowing, 26%), and larynx (intermittent hoarseness and dysphonia).[4,5] Less frequently involved sites include the vagina, urethra, and anus.[5] Conversely, 70% of patients with mucous membrane pemphigoid have ocular involvement (ocular MMP).[7]

Differential Diagnosis

Differentiating OCP from trachomatous entropion trichiasis (TT) may be challenging in areas endemic with trachoma, and even in nonendemic areas because of emigration. Although symblepharon and effacement of the plica may be encountered in OCP as well as TT,[11] symblephara or fornix shortening are earlier findings in OCP (Foster stages II or III),[5,8,10] while it is a very delayed manifestation of severe TT.[11] Although ankyloblepharon is a delayed feature of both OCP (Foster stage 4)[5,8] and TT, when encountered in patients with trachoma it is of a much milder variety. Another differentiating clinical point is that, although TT preferentially involves the upper eyelids, OCP does not show a peculiar affinity to involve either the upper or the lower eyelids. A positive conjunctival biopsy may also settle the diagnosis in favor of OCP, although a negative biopsy does not rule out the ongoing autoimmune process.

Several other peculiar conditions may be confused with OCP. Stevens Johnson syndrome (SJS), ocular rosacea, atopic keratoconjunctivitis, paraneoplastic pemphigus, and scleroderma however these conditions lack the characteristic progression of cicatrizationn that is so characteristic of OCP.[10,12] Several topical medications like pilocarpine, epinephrine, timolol, latanaoprost, and rarely systemic medications (eg, practolol [now withdrawn], Dupilumab, & penicillamine) can induce a pseudopemphighoid-like picture, which may be virtually indistinguishable from OCP both clinically or even with immunofluorescence.[4,10,12] A notable exception occurs in cases of unilateral application of the offending topical medication, where the disease is confined to the eye receiving the medication while the untreated eye remains normal.[10] In cases of bilateral use of topical medications, a subtle differentiating point is that the fibrotic changes are concentrated in the inferior fornix and medial canthi, areas that are more prone to damage because they come in maximal contact with the medication as it is cleared from the eye.[12] This process usually quiesces after discontinuation of the medication. The term pseudopemphigoid is loosely applied in the literature as an umbrella term for several conditions like SJS that simulate OCP, and recently, some authors have started to use the more specific term drug-induced cicatrizing conjunctivitis (DICC).[12]

Treatment

OCP is a systemic autoimmune disorder with evidence of immune activation. Topical medications will not suppress OCP activity effectively, and aggressive immunosuppression is required to suppress inflammation, promote healing, and prevent cicatrization regardless of whether surgery is contemplated in the near future or not.[10] Because most patients with OCP are diagnosed when they are already Foster stage III or even IV,[5] and because OCP is usually a disease of the elderly, and most importantly because of the cumulative toxicity of long-term immunosuppressants,[4,10] systemic immunotherapy is only offered to patients with active progressive disease, and not to patients with burnout end-stage disease where the prognosis is notoriously poor.[10] All patients with OCP should accurately be staged before initiating therapy, and this should include a formal assessment by an internist to rule out systemic disease.[10] Patients also need to be informed of the potential risks involved with each drug and to be reminded that immunosuppressive therapy can only arrest the disease process but will not reverse it.[10] A detailed review of systemic immunomodulating options are beyond the scope of this chapter, but the list of drugs includes high-dose oral corticosteroids, diaminodiphenylsulfone (Dapsone), mycophenolate mofetil (CellCept), methotrexate, cyclophosphamide (Cytoxan), Rituximab, or intravenous immunoglobulins.[4,10]

The optimal treatment for trichiasis manifesting in patients with OCP without frank entropion is the destruction of the cilia follicles responsible for the aberrant eyelash growth, with electrolysis, cryotherapy, or Argon laser.[10] This is essential in patients with OCP to prevent damage to the ocular surface epithelium. It could also help eliminate confusion about the exact cause of ocular redness, whether it is of a mechanical nature from the eyelashes or due to immunologic activation in OCP.[10]

The consensus is that rotational eyelid surgery to correct cicatricial entropion trichiasis is a key component in management to prevent potentially blinding corneal scarring.[3,6] Patients with active OCP requiring entropion surgery represent a special challenge, and surgery should be deferred if possible until disease activity is controlled.[5,8,13] However, if surgery is inevitable, it should be performed under an umbrella of profound immunosuppression.[10] A detailed discussion of the recommended procedures for cicatricial entropion in OCP is discussed in detail in Chapter 19, but tarsal sparing procedures, like anterior lamellar recession or reposition with or without a gray line split, may be the preferred approach in the majority of patients with OCP, since neither tissue resection nor a conjunctival incision is required.[13] In addition, techniques that involve a tarsotomy usually require a conjunctival incision. Conjunctival surgery should be avoided in OCP if possible, since this may trigger conjunctival inflammation or aggravate tarsal cicatrization, eventually resulting in surgical failure and disease activation. The management of symblepharon is usually challenging and should be undertaken only after proper systemic control of disease activity. Amniotic membrane transplantation, preferably coupled with intraoperative application of mitomycin C, may help achieve successful fornix reconstruction in patients with cicatrizing conjunctival diseases like OCP.[14,15]

(Print pagebreak 654)

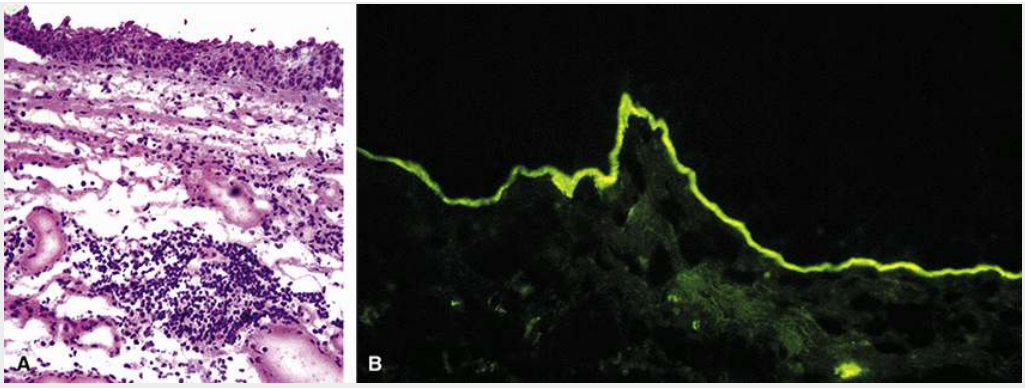

FIGURE 98.5 A, This conjunctival biopsy frozen section has normal epithelium, a mild diffuse infiltrate of lymphocytes and macrophages in the substantia propria, and focal perivascular accentuation of the mononuclear inflammation. B, The same biopsy had a continuous linear band of IgA deposited along the basement membrane zone.

Prognosis

Untreated OCP may eventually lead to chronic inflammation and conjunctival scarring, and possible blinding keratopathy. Ophthalmologists not comfortable with prescribing and monitoring the available immunomodulatory and biologic therapies should seek collaboration with appropriate specialists.

The success rates for the surgical correction of the cicatricial entropion and trichiasis seen in this disease generally are very good and parallel those for Steven-Johnson syndrome (see Chapter 117). For the systemic disease, data show only partial success and recurrence rates are high. Dapsone and methotrexate have been the first line of treatment in mild-to-moderate OCP, but adverse effects such as skin rash, malaise, vomiting and diarrhea, anemia, hepatotoxicity, and leukocytopenia have led to high rates of discontinuation of 30% to 100% in several trials.[16,17,18,19]

Mycophenolate mofetil has a lower rate of discontinuation, and the rate of inflammation control is reported at 58% to 70%.[20,21] Topical medications have not been found to reliably and consistently halt progression or induce remission of OCP, but they may assist in the treatment of conjunctival scarring.

Histopathology

Routine light microscopy of conjunctival biopsies usually reveals squamous metaplasia of the epithelium with loss of goblet cells,[5,22,23,24] although the number of residual goblet cells varies widely.[5] There is hyperproliferation of conjunctival epithelial cells,[24] with keratinization and parakeratosis in 25% and 75% of biopsies, respectively.[22] Subepithelial bullae are seldom observed in conjunctival biopsies.[4,25] The substantia propria is infiltrated by plasma cells, lymphocytes, and macrophages, along with fewer mast cells and occasional eosinophils and neutrophils.[5,22] The chronic inflammatory infiltrate may be diffuse or have a perivascular predominance (Figure 98.5A).[5] Patients with acute manifestations of OCP present clinically as diffuse conjunctival hyperemia with chemosis or a localized conjunctival mound with ulceration and intense hyperemia.[26] Biopsy of acute OCP shows a heavy infiltrate of neutrophils in the epithelium and substantia propria, along with the typical chronic inflammatory infiltrate.[26] Substantia propria scarring may be absent or present,[22,27] and there may be mild ectasia or proliferation of substantia propria capillaries.[4]

Light microscopic features are nonspecific; histological diagnosis rests on demonstrating by direct immunofluorescence the continuous linear deposition of immunoglobulin and often of complement component C3 along the basement membrane zone (BMZ).[4,5] IgA (Figure 98.5B) and IgG are the most frequent immunoglobulins deposited along the BMZ, although IgM, IgD, and IgE may also be detected, and there is often more than one immunoglobulin deposited.[5] The rate of positive biopsies varies widely in the literature from about 20% to 70%,[4] and a negative biopsy does not exclude the diagnosis of OCP.[7]

CHAPTER 99

Oculodermal Melanocytosis

Key Points

- Oculodermal melanocytosis is a benign congenital anomalous pigmentation of deep facial skin and ocular tissues
- It is a dermal melanocytic hamartoma that presents with unilateral or bilateral, brown or blue discoloration on facial skin areas that are innervated by the ophthalmic and maxillary divisions of the trigeminal nerve
- It is 10 to 25 times more common among Asians than in Caucasian and black individuals
- The pathogenesis is not known but is considered to be a dermal hamartoma that represents a failure of migration of melanocytes from the neural crest to the dermal-epidermal junction and subsequent arrest within the dermis
- Lesions usually present as poorly defined separate or contiguous areas of pigmentation on the facial skin and nasal and oral mucosa, but in some patients only ocular involvement may be present
- In addition to eyelid skin, the sclera, conjunctiva, cornea, and lens can be involved as well as orbital tissues and bone
- Malignant degeneration is rare, but most cases occur in Caucasian patients
- Treatment includes surgical excision with skin grafting, cryosurgery, and dermabrasion, but Q-switched laser therapy has become the treatment of choice
- Laser therapy has significantly improved the prognosis with 80% to 90% of patients attaining a satisfactory cosmetic outcome
- Malignant change is seen in 4% to 5% of patients

Oculodermal melanocytosis (ODM), or nevus of Ota, is a benign congenital anomalous pigmentation of deep facial skin and ocular tissues. It was first described by Hulke in 1861[1] in a patient with unilateral pigmentation of the face and sclera. That case was complicated by the presence of an ipsilateral choroidal malignant melanoma. In 1939, Ota[2,3] described additional patients in Japan, defining the syndrome as a clinical entity. Since that time over 1000 cases have been described.

ODM is a dermal melanocytic hamartoma that presents with unilateral or bilateral, brown or blue discoloration on facial skin areas that are innervated by the ophthalmic and maxillary divisions of the trigeminal nerve.[4] Approximately 50% to 55% of cases involve both the ophthalmic and maxillary divisions, 25% the maxillary division alone, and 20% the ophthalmic division alone.[5] The occurrence of pigmentation in the distribution of the mandibular division of the trigeminal nerve is very rarely observed, with only one case described involving the buccal mucosa[6] and another case involving the oral mucosa and the jaw.[7] Several other cases of blue nevus have been described involving the buccal mucosa or oral floor,[8,9,10] and some authors have grouped ODM and blue nevus together as variants of dermal dendritic melanocytic proliferations.[11,12]

The incidence of oculodermal melanocytosis is difficult to assess since many mild cases go unrecognized or unreported. Yoshida[5] reported 110 cases among 27,082 consecutive clinic patients in Japan, an incidence of 4 per 1000 population (0.4%). Tanino[13] found 26 cases among 2300 dermatologic patients in Japan, for an incidence of 11 per 1000 (1.1%). Among a series of 8680 subjects in Shanghai, Wang et al[14] found acquired bilateral nevus-of-Ota-like macules in 2.5%. The only comparable figures for the United States are four affected patients among approximately 25,000 (0.016%) seen in the ophthalmology clinic at Philadelphia General Hospital.[15] Gonder et al[16] examined 13,150 white and black patients in an ophthalmology clinic and found an ODM incidence of 0.038% (2/5251) among white patients and 0.014% (1/6915) among black patients. Thus, oculodermal melanocytosis is at least 10 to 25 times more common among Asians than in Caucasian and black individuals.[4,17]

In 1939, Tanino[18] observed several patients with oculodermal melanocytosis and divided them into four types according to the extent of skin involvement, and these were further divided into seven subtypes based on their location.[17,19,20] These types were Ia,

eyelids, periorbital and temporal areas; Ib, zygomatic area, nasolabial fold, and the lower eyelid; Ic, forehead area; Id, nostril area; II, upper and lower eyelids, zygomatic area, cheek, temple area; III, scalp, forehead, eyebrow, and nose; and IV, bilateral.

However, other authors found that Tanino's classification failed to accurately include all affected patients. Huang et al[21] reported that 19.7% of their 1079 patients with oculodermal melanocytosis were not accommodated by the Tanino classification, and Nam et al[22] found an even higher rate at 35.8%. The Peking Union Medical College Hospital (PUMCH) classification is a newer system developed by a Chinese group in 2013 based on five large categories and 15 subdivisions according to the extent of involvement in the distribution of the trigeminal nerve branches.[21] These are I, pigmentation involving one branch of the trigeminal nerve; *(Print pagebreak 657)* II, pigmentation involving two branches of the trigeminal nerve; III, pigmentation involving all three branches of the trigeminal nerve; IV, bilateral type; and V, melanocytosis accompanied by other cutaneous complications. In 2017, Nam et al[22] introduced a three-point severity scale based on the proportion of the melanocytosis on the half-face as follows: mild, ≤one-third of the half-face; moderate, >one-third to ≤two-thirds; and severe, >two-thirds.

Several families have been reported in which some close relatives were affected with ODM. Hidano et al[23] found a father and son in one family and two sisters in another with the syndrome. Yoshida[5] reported a mother, her son, and his cousin, all similarly affected. Two families were noted by Watanabe,[24] one involving a mother and daughter, and in the other, two sisters. In the Hidano et al series of 240 patients,[23] 15 of 208 for which family histories were obtained, were related to each other, usually as first cousins. However, they could not recognize any definite pattern of hereditary, nor was there any consistent history of consanguinity. Goyal et al[25] reported a case of a brother and sister with bilateral familial nevus of Ota. Previous reports of familial cases suggest that inheritance may be autosomal recessive or autosomal dominant, with variable expressivity; however, definite hereditary patterns have not been established.[26,27,28,29]

Etiology and Pathogenesis

The pathogenesis of ODM is not known. It is usually considered to be a dermal hamartoma that represents a failure of migration of melanocytes from the neural crest to the dermal-epidermal junction and subsequent arrest within the dermis.[4] Melanocytic cells are not normally found in deep dermal layers of adult humans, and their presence in ODM suggests an embryonic anomaly. The etiology of melanoblasts is from neuroectoderm, either directly from neural crest precursors or from dermal Schwann cells.[30] In other anthropoid apes, such dermal melanocytes are normally seen in the adult,[30] and they can also be found beginning in the 11- to 12-week embryonic stage in humans.[31] Whether or not these dermal melanocytes gradually disappear or migrate up into the epidermis is not clear, but dermal melanocytes in adult humans are usually not present. They represent a developmental defect in which these cells persist abnormally and therefore represent an abnormal migration.[30,32] In this regard, it has been suggested that the pathogenesis of blue nevus, the Mongolian spot, and oculodermal melanocytosis are all related, if not identical.[30]

Because the incidence of ODM is so much greater in females, a hormonal relationship has been proposed for the development of pigment in previously nonpigmented cells.[33] Wang et al[14] reported that, among 196 females with ODM-like pigmentation, the prevalence of the disease increased after the age of 15 years and sharply declined after the age of 50 years, with nearly half of the cases observed within ages 45 to 55 years. Age, contraceptive use, and sun exposure were independently associated with the disorder. These findings suggested that sex hormone alteration and UV exposure may independently play important roles in the pathogenesis of ODM.

Histologically, ODM shows significant overlap with a blue nevus. Blue nevi show mutations in *GNAQ*, a GTPase acting downstream of G protein-coupled receptors.[34,35] This mutation has also been found in ODM, although at a lower frequency.[35] There is a clear relationship between ODM and uveal melanoma, and about 50% of uveal melanomas also harbor the *GNAQ* mutation, suggesting a link between these two conditions.[35] Although ODM is far more common in Asians, the risk of melanoma is mostly seen in white populations.[4] In Caucasian patients with ODM, the risk of developing uveal melanoma is approximately 20 times higher than seen in the general population. The development of cutaneous malignant melanoma in ODM is less frequent.

Clinical Presentation

ODM is characterized by dermal involvement of the face and ocular tissues, but in about one-third of patients, the eye is not involved.[36] In a series of 28 Chinese cases with ODM,[37] the most frequent areas involved were the eyelids (82%), forehead (79%), cheek (71%), and temporal regions (64%). In 96.4% of cases, more than three regions were involved, and ocular and nasal mucosal involvement was observed in 57%. Among Japanese with ODM, pigmentation of the eustachian tube and tympanic membrane may be seen in up to 55% of patients, the nasal mucosa in 24%, and the palate and pharynx in 18%.[23,38] Pigmentation may also occur in the underlying periosteum, bone, dura mater, cerebral cortex,[39] the maxillary sinus,[40] and the orbicularis and temporalis muscles. The condition is usually unilateral, and bilateral involvement is rare, seen in only approximately 5% to 13% of cases.[2,5,37,38]

Lesions of ODM usually present as areas of pigmentation on the facial skin and nasal and oral mucosa,[41] and in some patients only

ocular involvement may be present. The cutaneous lesions typically consist of macular, poorly defined, separate, or contiguous areas of hyperpigmentation that are not associated with increased vascularization or hair (Figure 99.1). There may be elevated nodules of denser pigmentation within it. Color varies from light brown to blue-black, to purple,[5] and may be so subtle as to be missed clinically.

ODM has been reported to occur in two peak age groups. In 48% to 61% of cases, it presents at birth or soon afterward in the perinatal period.[4,5,17,23] In a report on the occurrence of ODM in Korea, Lee et al[42] noted that 32% of the patients had lesions from birth, 18% from childhood, 25% from puberty, and 25% experienced onset in adulthood. It is not uncommon for such lesions to enlarge or darken under hormonal influences such as menstruation, pregnancy, or puberty.[5,23] ODM also occurs predominantly in females, which represent about 77% to 90% of all reported cases.[14,17,23,43]

(Print pagebreak 658)

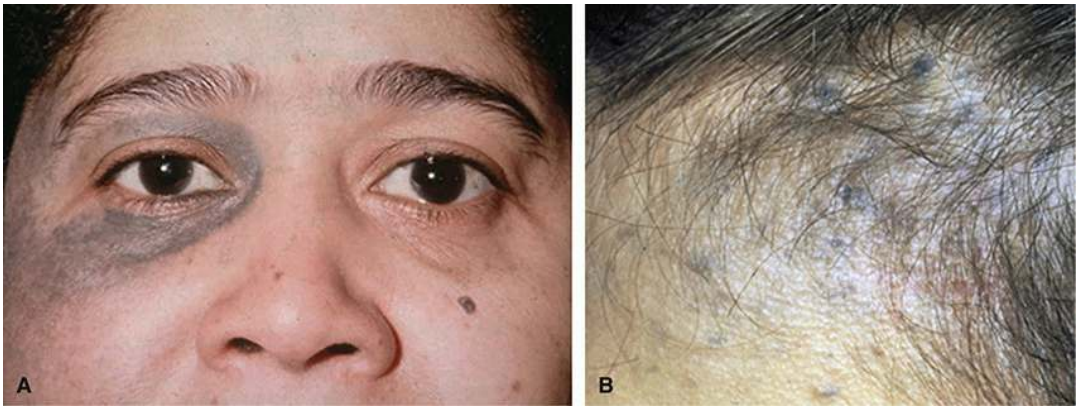

FIGURE 99.1 Cutaneous pigmentation in oculodermal melanocytosis. A, Pigmentation involving the periocular upper and lower eyelids. B, Scattered pigmentation on the forehead. This patient also had pigmentation of the choroid, orbital fat, orbital bones, and intracranial dura.

In the periocular region, ocular pigmentation is seen clinically in 49% to 65% of patients with this syndrome.[5,13,38] In addition to eyelid skin, the sclera is almost always involved with pigmentation,[15] typically appearing as discrete spots or diffuse blue-black pigmentation most commonly in the superior or temporal quadrants. The conjunctiva is involved in 40% of cases. Other ocular tissues that can be involved include the sclera, corneal epithelium, stroma or endothelium, and the anterior part of the lens (Figure 99.2).[36,44] The iris stroma shows pigmentation in about 50% of cases,[15] and in up to 18% the choroid is thickened and diffusely infiltrated with pigment cells.[15,45,46,47] These cells have been seen histologically to extend out of the globe along emissary veins.[47] The retina and optic nerve head are rarely involved, in 1% to 4% of cases.[48,49,50,51,52]

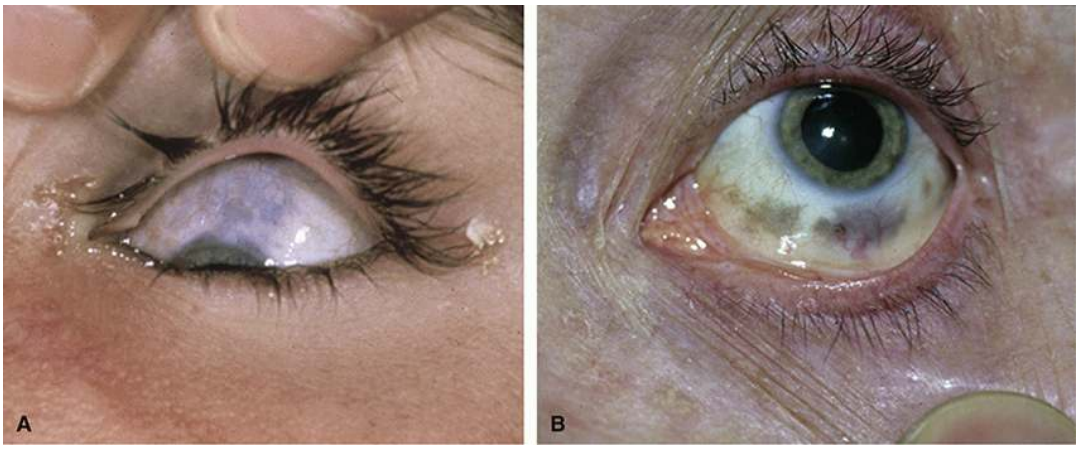

FIGURE 99.2 Ocular pigmentation with ODM. A, Conjunctiva. B, Sclera.

Melanocytes may also be seen in orbital fat, extraocular muscles, and in the orbital periosteum.[4,53,54,55,56] The actual incidence of orbital pigmentation is not known since these structures are not typically seen clinically. It becomes apparent only during orbital surgery if the ODM undergoes malignant transformation. Of the approximately 18 cases of orbital ODM described with abnormal pigmentation, 15 (83%) harbored a malenoma.

The most severe ocular complications associated with ODM are glaucoma and malignant melanoma.[44] The trabecular meshwork

and Schlemm canal are frequently involved, but frank secondary glaucoma has only occasionally been reported.[57,58,59,60,61] Increased intraocular pressure (IOP) may be seen with increased angle pigmentation and has been described with ODM in 10% to 15% of patients.[36] *(Print pagebreak 659)* However, frank glaucomatous change associated with ODM is very rare and most cases reported as glaucoma in ODM had pigmentation of the trabecular mesh but normal IOP and normal optic disk. Some authors have suggested that glaucoma, when it is seen, has not been demonstrated to be caused by ODM alone. Cronemberger et al[62] reported that there was no glaucoma in the eight eyes in which the gonioscopy revealed an intensively pigmented angle. Kitagawa et al[63] reported that ODM can cause abnormal thickening of the cornea causing a false elevation of measured IOP by tonometry.

A clear case of ODM-related glaucoma was reported by Magarasevic and Abazi[41] in a patient who developed progressive pigmentation of the trabecular mesh over several years, with increasing IOP, glaucomatous disk cupping, thinning of the nerve fiber layer, and a visual field defect. Several mechanisms for glaucoma in ODM have been proposed, including congenital glaucoma, acute angle-closure glaucoma, uveitis, and open-angle glaucoma. However, obstruction of aqueous outflow by accumulated melanocytes in an open angle is the most likely mechanism directly associated with the ODM.[60,64]

Malignant degeneration is a rare but potentially deadly complication of oculodermal melanocytosis. Dutton et al[4] recorded an incidence of 4.6% melanomas among 670 cases from the literature. Of the reported cases, only three (9.4%) occurred among Asian patients, even though this group accounted for 87% of oculodermal melanocytosis cases. Since then, approximately 86 additional cases of melanoma associated with ODM have been described, and of these, 78% were in white, 13% in black, and 9% in Asian patients. Adjusting for race, the incidence of malignancy is about 25% for whites, 1% for blacks, and 0.5% for Asians, confirming that melanoma associated with ODM is far more common in white patients and is very rare in Asian and black individuals.[4,33] Although ODM usually appears in early childhood or adolescence, cases associated with melanoma are typically in the fifth to seventh decades, with a mean age of 60 years, and men and women are equally represented.

The most common sites for malignant degeneration in ODM are the choroid (42%), orbit (18%), brain and meninges (12%), and skin (9%).[4] In several large series of choroidal melanoma, ODM was associated in 2.7% of 400 cases reported by Carreño et al[65] and in 3.0% of 7872 cases reported by Shields et al.[32] Unal et al[48] reported a case of ODM-associated melanoma of the optic nerve head and Font et al[59] described a case of melanoma involving the pigmented iris. Malignant melanoma of the brain and meningeal tissues has been noted in only a few patients,[66,67,68,69] one of which involved the pineal gland. Kojima et al[70] found a case of melanoma arising within the optic chiasm in a 37-year-old man in which melanocytosis was present in the meninges, cerebral cortex, and optic nerve.

Melanomas associated with ODM are typically of the spindle cell type, with very few having an epithelioid component.[71,72,73] Several cases of melanoma have occurred in patients with bilateral involvement.[46,66,71,74]

Differential Diagnosis

The differential diagnoses of ODM consists of a very wide variety of pigmented and vascular lesions. Such lesions include facial cafe-au-lait patches, speckled lentiginous spilus nevus, blue nevus and its variants, Mongolian spots, melanocytic nevi, congenital and acquired melanosis, dermal melanocytic hamartoma, melanoderma from B12 deficiency, and ceruloderma from chronic amiodarone usage.

Treatment

A variety of treatments have been introduced for ODM, including surgical excision with skin grafting, cryosurgery, and dermabrasion. However, in recent decades, laser technology, based on the concept of photothermolysis, has been advocated and is currently the treatment of choice.[75,76,77,78]

Q-switched lasers were introduced in 1992 and have resulted in better outcomes and less scarring than previous laser technologies.[79] The 694-nm Q-switched ruby laser (QSR) was the first applied to ODM but has largely been replaced by the 755-nm Q-switched alexandrite laser and the 1064-nm Q-switched Nd:YAG laser, which has dramatically increased the success rate and decreased the complication rate.[77] Most reports of ODM treatment with the Q-switched alexandrite and Nd:YAG lasers have shown high success rates of 71% to 97%, with low complication rates of 0% to 6.4%.[78,80,81] Permanent hypopigmentation is the most commonly reported complication of Q-switched lasers in the treatment of ODM.[82,83]

Prognosis

The pigmentation in ODM is mostly of cosmetic concern, and the use of Q-switched lasers has significantly improved the prognosis, and early treatment is associated with better results.[81] About 80% to 90% of patients can attain a satisfactory cosmetic outcome. Of greater concern is malignant change seen in 4% to 5% of patients with ODM, 93% of which are in Caucasians. Most of these involve the choroid, and patients with uveal melanoma in the setting of ODM vs no ODM show a higher rate of metastasis (48% vs 24%) and a greater mortality rate (19% vs 12%) at 10 years.[32]

Histopathology

Ito reported cutaneous histological findings from 24 patients with ODM.[5] Heavily pigmented melanocytes were most common in the upper reticular dermis, next in the middle dermis, and least often in the lower reticular dermis and subcutaneous adipose tissue (Figure 99.3). Melanocytes in the upper dermis were fusiform or stellate shaped, while cells lower in the dermis were predominantly long string- or fiber-like cells. The melanocytes' long axes were usually oriented parallel to the skin surface, but they were oriented vertically or obliquely around small blood vessels, sweat glands, sweat *(Print pagebreak 660)* ducts, sebaceous glands, and adipose tissue. The melanocytes were dispersed in the dermis, but some connected with each other through tapered cytoplasmic tips. Dermal melanocytes only occasionally formed small bundles similar to those in a blue nevus. Melanin granules in the dermal melanocytes were coarser than those in the overlying epidermis, and a large amount of cytoplasmic melanin often obscured nuclei. The epidermis was usually normal, although there were sometimes patches of hyper- and hypopigmentation limited to several epidermal ridges. Other authors have reported similar histological findings in ODM.[15,61,84,85]

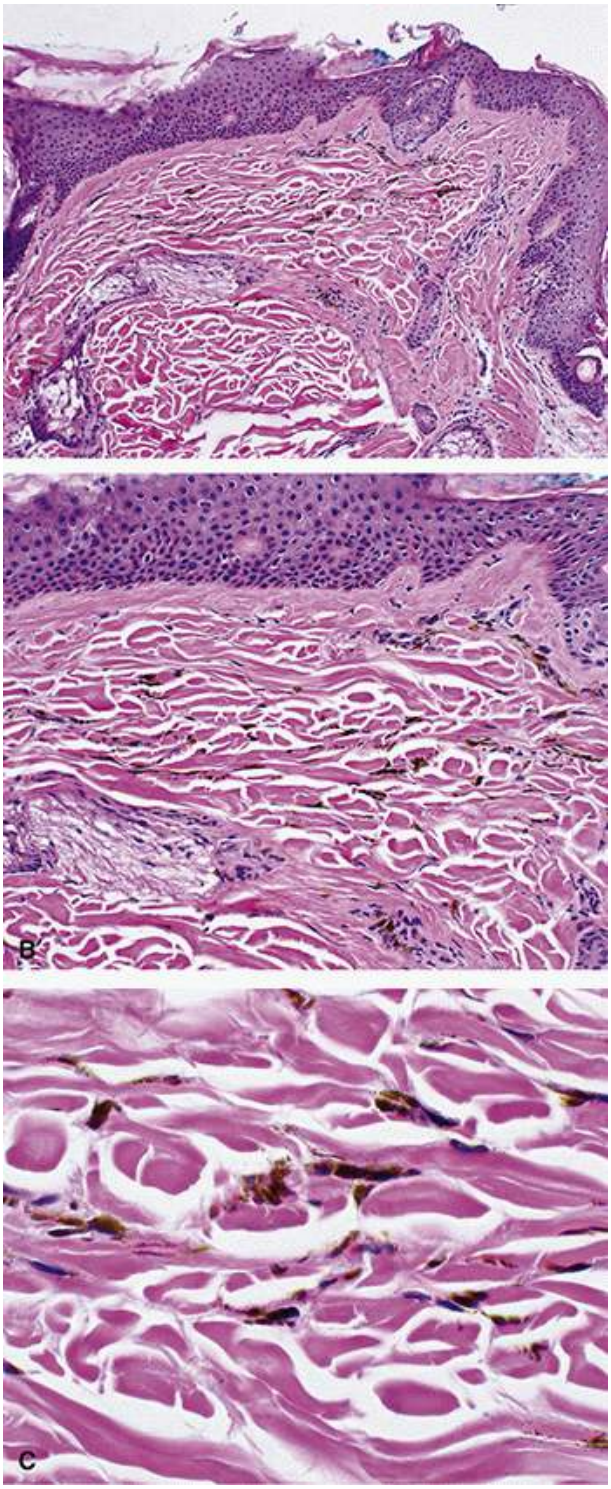

FIGURE 99.3 A, Heavily pigmented melanocytes are in the upper and mid-dermis in ODM. B, The melanocytes are spindle shaped and oriented parallel to the skin surface except around epidermal appendages. C, High magnification to show the characteristic abundant melanin within the spindle-shaped melanocytes. The dispersed melanocytes are separated by intervening collagen bundles. The dispersion of melanocytes distinguishes ODM from a blue nevus.

More recently, Hirayama and Suzuki correlated clinical appearance with histological findings in at least 3 biopsies from 40 patients with nevus of Ota.[86] They classified lesions into five histological subtypes: (1) superficial type (S) with melanocytes located in the superficial dermis, (2) deep type (De) having melanocytes in the deep dermis, (3) diffuse type (Di) with melanocytes dispersed throughout the dermis, (4) superficial dominant type (SD) with a diffuse distribution of melanocytes with a greater concentration of melanocytes in the superficial dermis, and (5) deep dominant (DD) type with a greater concentration of melanocytes in the deep dermis.[86] The ratio of the S, SD, Di, DD, and De types was approximately 3:2:3:1:1. Lesions that were brown clinically were the superficial or superficial dominant types, while bluer lesions were the diffuse, deep dominant, and deep histological types. The diffuse, deep dominant, and deep subtypes were more frequent on the eyelids, temple, and forehead, and the superficial and superficial dominant types were more common on the cheeks.

CHAPTER 100

Pemphigus Vulgaris

Key Points

- Pemphigus vulgaris (PV) is an autoimmune disease in which autoantibodies are directed against desmosomal adhesion molecules resulting in blistering in the suprabasal layers of the cutaneous epidermis and mucosa
- Triggers of the immune response include drugs, viral infections, contact allergens, physical agents, and foods
- The etiology remains unknown, but associations have been reported with major histocompatibility complex class II antigens
- Involved mucosal surfaces include oral, pharyngeal, esophageal, and nasal bullae
- Ocular PV presents with eyelid skin erythema, erosions and ulcerated blisters, as well as bilateral hyperemic conjunctivitis, often associated with pain, stinging, irritation, pruritus, photophobia, and epiphora
- Initial management includes identification and removal of specific triggers, followed by corticosteroid therapy to reduce the inflammatory reaction
- Where conjunctival cicatrization is evident, early debridement should be performed to minimize symblepharon formation
- PV can be associated with sepsis, fluid and electrolyte imbalances, impaired thermoregulation, and cardiac and renal failure, but with systemic, corticosteroid, and immunosuppressive therapies, the mortality rate has been reduced to approximately 10%

Pemphigus is a life-threatening autoimmune disease in which autoantibodies are directed against desmosomal adhesion molecules resulting in blistering in the suprabasal layers of the cutaneous epidermis and mucosa.[1,2,3,4] The disease is classified as pemphigus vulgaris or foliaceus depending upon the histologic layer of blistering, and as paraneoplastic pemphigus.

Paraneoplastic pemphigus, mostly presenting as pemphigus vulgaris (PV) with severe mucosal involvement,[5] is often associated with lymphoproliferative neoplasms and carcinomas of the colon, lung, breast, pancreas, prostate, uterus, liver, and kidney.[5,6,7,8,9,10] It may be related to an altered immunologic state and immunologic cross-reactivity between the tumor and the skin.[2,5] Paraneoplastic pemphigus is characterized by painful erosions and ulcerations affecting the mucous membranes of the oropharynx, tongue, lips, and conjunctiva.[6,11,12] Skin lesions vary in appearance from blisters to lichenoid-like[2] and are seen most often on the head, neck, upper trunk, and proximal extremities.

Induced or triggered pemphigus is a condition in which an exogenous factor induces the onset of the disease.[2] Triggers can include drugs, viral infections, contact allergens, physical agents, and foods.[13] Viral infections, especially herpes virus infections, have been linked to pemphigus, and herpes virus DNA has been detected in lesions of some patients with PV.[2,14] Dietary factors have been implicated as triggers for pemphigus in genetically predisposed individuals, including thiol-allyl compounds present in garlic, leeks, and onions; and polyphenolic compounds present in black pepper, red chili pepper, cherry, cranberry, blackberry, red wine, and tea.[2,13] Physical agents, such as thermal burns, ultraviolet radiation, and surgical procedures have also been shown to trigger pemphigus in genetically predisposed individuals.[13,15,16,17] Contact allergens such as pesticides of the organophosphate group can serve as potential triggers.[13] Drugs capable of inducing pemphigus include non-thiol angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory drugs, calcium channel blockers, and some vaccines and interferons.[2]

PV accounts for approximately 80% of all types of pemphigus and is the most common form. It occurs more frequently in individuals of Mediterranean and Jewish descent[3,18,19] and is seen most often in the fourth or fifth decades of life. Some reports have shown a slight predilection for females at about 66%,[20,21] whereas others have shown no gender predominance.[22] The incidence of PV varies from 1 to 16 new cases per million persons per year.[23,24]

PV is typically seen in previously normal skin as a blister caused by the separation of the superficial epidermal layers from its basal layer.[2] In nearly half of cases, the oral mucosa is initially involved, but later, lesions spread to involve the skin and other mucous membranes including the pharynx, esophagus, conjunctiva, urethra, cervix, and rectum.[19,22,25,26] Bacterial infection can be seen following the sloughing of the fragile blister walls.[27,28] The disease is characterized by repeated exacerbations, fluid and protein loss, and opportunistic infections,[2] and even with treatment, these can lead to death in 10% of cases.[3,13]

Ocular PV is uncommon but well-known.[4,19,29,30,31,32,33,34,35,36,37,38,39,40,41,42] It is reported to occur in approximately 7% to 26% of pemphigus cases,[19,22,43] but ocular findings are unpredictable and their presence does not correlate with the general severity *(Print pagebreak 664)* of the disease.[2,3,4,19] Ocular involvement involves the conjunctiva in most cases (88%), the eyelid skin or margin in 67% of cases,[22] and may be unilateral or bilateral. It usually presents as chronic blepharitis and conjunctivitis,[4,19,29,42,43] associated with conjunctival injection, foreign body sensation, photophobia, dry eye, and epiphora. Inflammation, blisters, and eyelid margin mucosal papillomas can be seen.[29,30,44,45] Conjunctival bullae can be seen, but are unusual.[46] PV can rarely present with a distinct conjunctival inflammatory mass without associated typical findings such as conjunctivitis, mucous discharge, blisters, or erosions.[47] Other rare findings include cicatricial contraction of the eyelid skin or conjunctiva,[2] cobblestone-like conjunctival papillae,[48] sicca keratoconjunctivitis, eyelid ectropion or entropion, and trichiasis.[2,3,42,49,50,51]

While eye involvement has been reported as an early manifestation of PV,[4,37] most patients develop the ocular lesions 1 to 3 years after the diagnosis of PV.[19,22]

Etiology and Pathogenesis

The etiology of pemphigus remains unknown. Multiple associations have been reported and the majority of genetic studies have shown an association between PV and major histocompatibility complex class II antigens such as HLA-DR4 or HLA-DQ1.[2,52,53,54,55] The HLA class II subtypes DRB1*0402 and DQB1*0503 have been recognized in more than 95% of patients with PV.[56] Even with these genetic findings, pemphigus has been reported in only one of two monozygotic twins and only two of three siblings with identical predisposing haplotype.[2] This suggests that environmental factors may also be required for initiation of the disease and for directing its clinical course.[13]

Patients with PV have IgG1 and IgG4 antibodies against mucocutaneous desmoglein 1 and/or the exclusive mucosal desmoglein 3.[57,58,59,60,61] Desmoglein 1 and 3 are transmembrane proteins that provide the desmosome of the epidermis with the function of cell adhesion.[13,62] As a result, the blisters seen in PV result from the loss of keratinocyte and conjunctival epithelial cell cohesion.[1,14]

FIGURE 100.1 Bilateral hyperemic conjunctivitis in a case of pemphigus vulgaris. (Courtesy of Dr. Mohsen Kashkouli.)

Pemphigus, especially PV, has been associated with other autoimmune diseases such as myasthenia gravis, systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, pernicious anemia, scleroderma, and thyroiditis,[5,13,63,64,65,66,67,68] and with other autoimmune blistering diseases including mucous membrane pemphigoid, herpetiform dermatitis, psoriasis vulgaris, and erythema multiforme.[5,68,69] The mechanisms and significance underlying these associations are unknown.

Clinical Characteristics

The diagnosis of PV is based on a combination of clinical presentation and detection of tissue-bound and/or circulating autoantibodies. The disease usually runs a chronic relapsing course. The most common clinical finding in ocular PV is bilateral hyperemic conjunctivitis observed in 87.5% of cases (Figure 100.1).[22] Conjunctival injection can be bilateral and seen on the

palpebral or bulbar conjunctiva. Subconjunctival hemorrhage and canaliculitis are seen only rarely. Additional symptoms are pain and stinging in 71.4%, irritation and pruritus in 47.6%, photophobia in 38.1%, and epiphora in 23.9% of cases.[22] Other involved mucosal surfaces include oral, pharyngeal, esophageal, and nasal bullae, often with scales, crusts, and ulcerations. The eyelid skin is involved in about 41% of patients with ocular PV and shows erythema and madarosis, with erosions and ulcerated blisters (Figure 100.2). Eyelid skin erosions are seen both on the upper or lower eyelids and in the medial canthus in about 21% of cases.[22]

Differential Diagnosis

The differential diagnosis of PV should include other autoimmune blistering diseases, such as mucous membrane pemphigoid, bullous pemphigoid, IgA-mediated bullous dermatoses, and epidermolysis bullosa, as well as impetigo, infectious, and *(Print pagebreak 665)* inflammatory diseases. For oral lesions, the differential should also include herpetic stomatitis, aphthous ulcers, lichen planus, paraneoplastic pemphigus, erythema multiforme, lupus erythematosus, and dermatitis herpetiformis.[2,5]

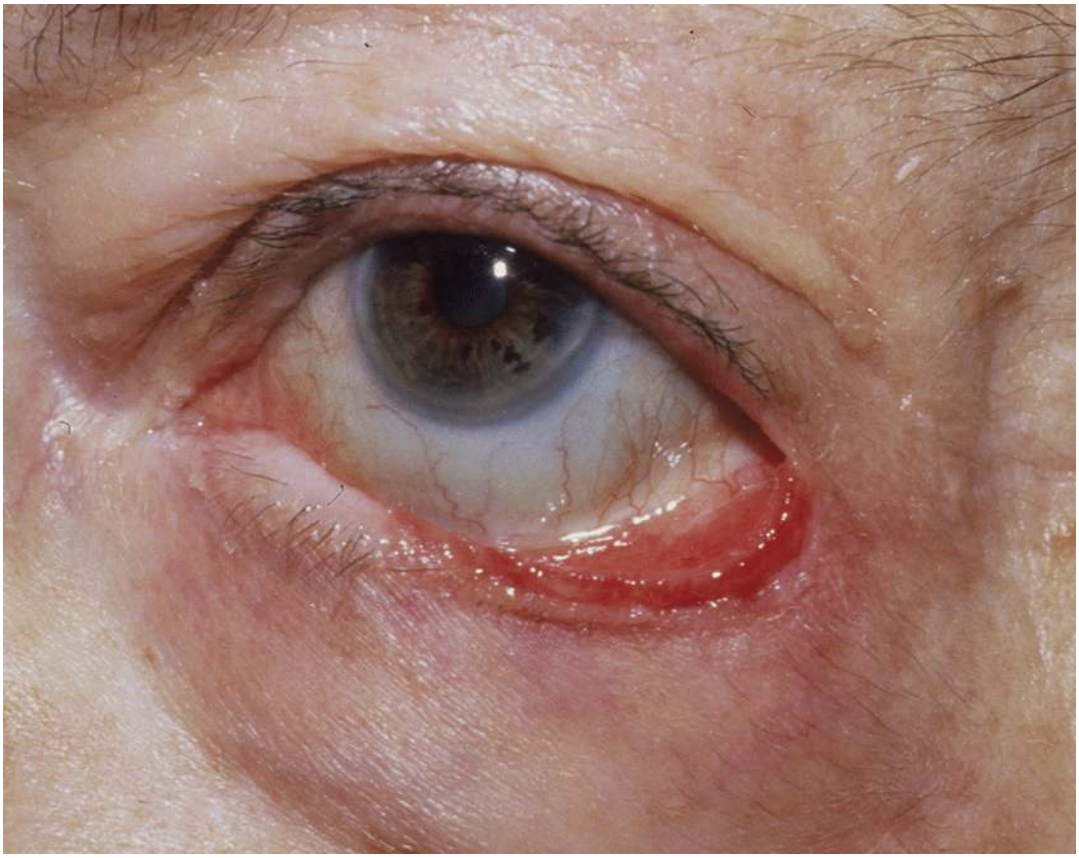

FIGURE 100.2 Pemphigus vulgaris with erosion of the eyelid margin and madarosis. (Courtesy of Dr. Gordon Klintworth.)

Treatment

In cases of PV initiated by specific triggers, identification and removal of the triggering agent is an important first step. Corticosteroid therapy is the first-line therapy for PV to reduce the inflammatory reaction,[3,11,13,19,29,70,71,72] supplemented with immunosuppressive agents, such as azathioprine and mycophenolate mofetil, for more refractory cases. Most patients respond well to these agents.[19] However, in a Danish study of 19 patients treated with prednisolone and azathioprine, the recurrence rate was 50% over a mean time of 15 weeks.[73] Intravenous immunoglobulins neutralize and slow down the production of circulating pemphigus antibodies. They are considered adjuvant therapy for pemphigus.

In cases where conjunctival cicatrization is evident, early debridement should be performed to minimize symblepharon formation.[74] A bandage contact lens may be necessary to limit corneal damage. Trichiasis and entropion are managed surgically.[3]

Biological agents such as rituximab may be helpful in cases where corticosteroids and immunosuppressive agents are not effective. In one study, rituximab plus a short course of prednisone resulted in a greater than threefold higher rate of complete

remission off prednisone therapy, and a greater than twofold decrease in the rate of moderate and severe relapse compared with standard-dose prednisone alone.[75]

For eyelid and conjunctival involvement with symptoms of severe dry eyes, artificial tears are used and punctual plugs may be helpful. Topical antibiotics can help prevent infections.[3] Conjunctival and mucosal lesions often resolve with systemic immunosuppressive therapy, but topical corticosteroids[36,76] and subconjunctival triamcinolone injection[36] can be used as adjunctive measures for eyelid erosions and conjunctival blisters. To minimize steroid use, success has been reported with topical cyclosporine.[46] Successful treatment with topical tacrolimus along with systemic immunosuppressive drugs has also been reported.[76]

Eyelid scrubs and warm compresses are used to improve eyelid margin hygiene,[3] and topical antibiotics may be included as a local treatment to prevent further bacterial infections.[77] In mild cases, topical corticosteroids plus oral tetracycline or minocycline in addition to conventional treatments may be beneficial.[13,70] In recent years, there has been a paradigm shift in the treatment of recalcitrant ocular surface diseases (OSD) including PV from the classic sequential, step-up topical therapy outlined above where synergistic therapies are sequentially added, to a combined approach where combinatorial topical therapy is given from the start.[71] This "triple play" therapy consists of (1) topical anti-inflammatory/immunosuppressive (steroid) eyedrops, (2) with immunomodulatory (pooled human immune globulin) eyedrops, and (3) tear substitute (serum) eyedrops. Preliminary results suggest this combined approach simultaneously targets several immunological pathways may be more efficacious than the standard approach.[71]

Any surgical procedure on the eyelid or conjunctiva during active disease can exacerbate the inflammatory process, so that whenever possible surgery should be deferred until the disease is inactive.[3,78,79] For trichiasis associated with PV, epilation of the eyelashes provides short-term relief. More permanent results are achieved with cryotherapy, laser ablation, or electrolysis (see Chapter 42). For eyelid malpositions including ectropion, entropion, and lagophthalmos, there are several different procedures available depending on the amount of skin and conjunctival scarring (see Chapters 16, 17, 18, 19 and 20).[80] Cicatricial lagophthalmos from symblephara and fornix shortening is managed surgically, often requiring autologous conjunctival transplantation, mucous membrane grafts, or amniotic membrane grafts.[81,82]

Ocular lubrication and antibiotic ointments should be used for corneal abrasions that may lead to infectious keratitis, ulceration, and even perforation. Where skin or conjunctival scarring results in significant lagophthalmos, a lateral tarsorrhaphy may be necessary to protect the corneal surface.

Prognosis

PV can be associated with multiple life-threatening complications such as sepsis, fluid and electrolyte imbalances, impaired thermoregulation, as well as cardiac and renal failure.[12] Without treatment, PV has a mortality rate ranging from 60% to 90%.[83] With adequate systemic treatment with corticosteroids and adjuvant immunosuppressive therapies, the mortality rate has been reduced to approximately 10%.[83] In a series of 24 patients with ocular PV, España et al[22] reported a complete clinical response to systemic treatment in 91.3% of cases, without complications on follow-up. In patients who do respond to systemic immunosuppression, blisters and erosions usually heal without significant seque *(Print pagebreak 666)* lae.[22,71,84] However, the use of high-dose corticosteroids and adjuvant steroid-sparing immunosuppressive agents do carry a risk of serious adverse events, especially infections.

Histopathology

The earliest histological change in PV, detectable before a clinical lesion appears, is intercellular edema in the lower stratum spinosum and stratum basale.[85] The basal cells become vertically elongated and narrowed, sometimes resulting in a spindle shape.[85] Clefts between the basal cells and the overlying prickle cells form next due to keratinocyte dissociation (acantholysis; Figure 100.3A).[85,86] Cleft formation results in basal cells returning to their normal shape.[85] The intercellular bridges between basal cells may rupture, leading to the lateral separation of cells and the appearance of a row of tombstones or a picket fence at the vesicle base.[86] As the cleft enlarges, individual epidermal cells lie individually or as small clumps in the clefts.[85,86] Fluid accumulation expands the clefts to form bullae whose base may be the single layer of basal cells or more than one layer of cells, especially near the middle of the bullae.[85,86] Bullae may rarely be in the mid epidermis.[85] At the periphery, bullae often taper into a suprabasal cleft, causing the edge to have an acute angle (Figure 100.3B). Approximately 50% of biopsies have bullae containing only acantholytic cells; 25% have acantholytic cells, neutrophils, and eosinophils; and 20% have acantholytic cells and neutrophils.[87] Acantholysis extends into hair follicles in one-third of biopsies, with hair follicles and sebaceous glands involved in about 15% of biopsies.[87] The bullae base may be gently undulating or have irregular upward growth of papillae lined by a single layer of epidermal cells.[85] As the bullae

age, the prickle and granular cells forming the roof degenerate until shedding as desiccated, thinned, and parakeratotic scale.[86] Epidermal regeneration begins in the bulla floor's central area, may begin before the roof ruptures or is shed, and may be uneven.[86]

Dermal inflammation is absent before bulla forming.[85] At the time of bulla formation, there is usually a mild to moderately intense inflammatory infiltrate around superficial dermal blood vessels, often containing numerous eosinophils[85] though there may be only lymphocytes or lymphocytes and neutrophils.[87] Older lesions with ruptured bullae and erosions may have more severe dermal inflammation, but eosinophils are usually few or absent.[85]

A diagnosis of PV relies on a typical light microscopic appearance and intercellular staining for immunoglobulin G (IgG) and/or C3 by direct immunofluorescence (DIF) using fluorescein-labeled antibodies.[88,89,90,91] Positive DIF staining for IgG creates a reticular pattern often termed “fishnet,” “net-like,” or “chicken-wire.” Other methods for confirming a PV diagnosis include indirect immunofluorescence staining using patient serum applied to monkey esophagus sections or an enzyme-linked immunosorbent assay (ELISA) to detect antibodies to desmoglein 3 and sometimes desmoglein 1.[90] Rare patients may have a negative DIF stain for immunoglobulins and C3 with positive indirect immunofluorescence staining for desmoglein 3.[87]

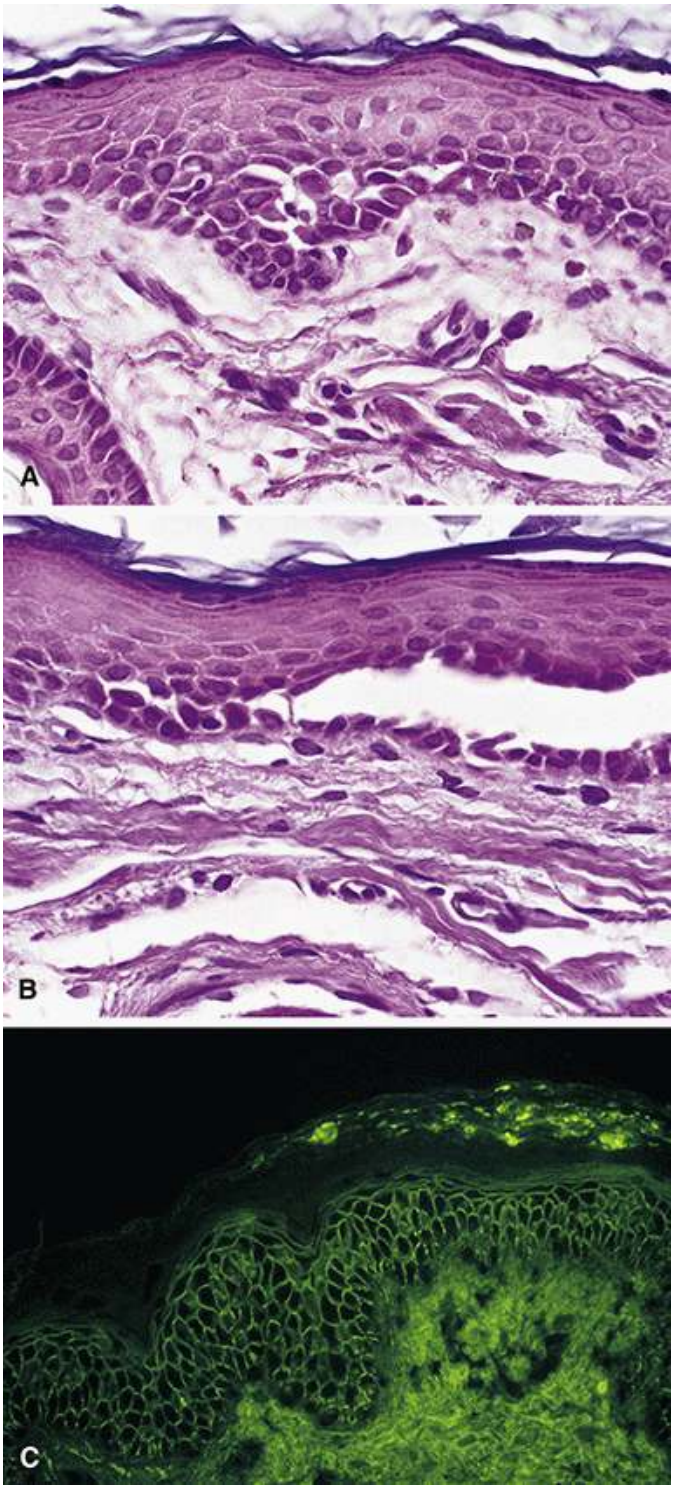

FIGURE 100.3 This biopsy from the left lower eyelid is from the patient shown in Figure 100.2. A, There is acantholysis with cleft formation between the basal cells and the overlying prickle cells. B, A suprabasal bulla with tapering at the periphery causing the edge to have an acute angle. C, Direct immunofluorescence demonstrating IgG in the intercellular regions of the epidermis.

The histological and DIF appearances of eyelid lesions in PV are similar to those in other body sites.[19] DIF staining of conjunctival biopsies has the typical intercellular staining pattern for IgG deposition.[19,30]

CHAPTER 101

Phakomatous Choristoma

Key Points

- Phakomatous choristoma is a very rare congenital lesion
- It is believed to arise early in the embryogenesis of the eye during the optic vesicle stage as tumor cells migrate toward the region of the embryonic choroidal fissure
- Elements that eventually form the phakomatous choristoma may have been left behind in the mesenchymal tissue
- Clinically, phakomatous choristoma presents as a smooth, firm, painless, generally immobile, palpable subcutaneous mass in the inferonasal eyelid
- Surgical excision is the initial treatment of choice to rule out alternative diagnoses
- The prognosis is excellent, and recurrences have not been reported

Phakomatous choristoma (PC), sometimes referred to as "Zimmerman tumor," is a very rare congenital lesion, first described by Zimmerman in 1971.[1] Since then fewer than 30 cases have been added to the literature.[2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25]

PC generally is present at birth, but in some cases, it may not become obvious until several weeks or months later.[14,15,16,21,25] Although published cases are few, some studies reported a male predominance of about 2:[1,14,25] whereas others report no apparent sex or ethnic predilection.[16,22] The tumor occurs equally on the left and right sides, and all reported cases have been unilateral. Although phakomatous choristoma is usually an isolated abnormality, association with other congenital ocular abnormalities has been reported, including hypoplasia of the optic nerve and coloboma.[20]

Etiology and Pathogenesis

When first described, Zimmerman postulated a lenticular anlage origin for PC based on the similarity of the microscopic appearance of the epithelial components to cataractous lenses, the presence of a thick basement membrane, and the absence of mucin and sebum secretions.[1] Since then, this histogenetic origin has been confirmed in several electron microscopic and immunohistochemical studies.[4,6,7,8,10,11] It is thought that PC arises early in the embryogenesis of the eye during the optic vesicle stage as tumor cells migrate toward the region of the embryonic choroidal fissure.[6]

Because this tumor occurs primarily in the lower eyelid, Peres et al[12] argued that PC must already have been present and growing at the time the eyelids are formed during embryogenesis. However, Seregaard[14] noted that the lens is formed through a depression of the lens pit from the surface ectoderm between the 5- and 9-mm embryonic stages and that the lens vesicle remains connected to the surface by a thin stalk. After the disappearance of this stalk, the lens vesicle closes and is surrounded by the lens capsule.[26] He argued that the elements that eventually form the phakomatous choristoma have to be left behind in the mesenchymal tissue before the 9-mm stage ends.[14] Since the buds that eventually become the eyelids do not arise until after the 10-mm stage,[27] and the bony walls of the orbit also develop after the 9-mm stage, deposition of the phakomatous elements that will form the tumor must occur before either the eyelid or orbit are anatomically defined. This supports the idea that these phakomatous elements are left behind in undifferentiated mesenchymal tissue that only later will give rise to the eyelids and orbit.

Several other hypotheses have been proposed for the origin of PC. These include aberrant migration of lenticular cells toward the embryonic choroidal fissure during the optic vesicle stage in early embryogenesis, invagination of surface ectoderm into the mesoderm of the eyelid, and proliferation of native ectodermal cells that are present in the subcutaneous tissue of the inferior medial eyelid.[4,6,8,10,15,16,23]

Clinical Characteristics

Clinically, phakomatous choristoma presents as a smooth, firm, painless, palpable subcutaneous mass in the inferonasal eyelid (Figure 101.1). It is generally immobile, but with free moveable normal-appearing overlying skin. The tumor usually ranges from 10 to 17 mm in diameter.[18] Lesions may remain unchanged in size, but slow enlargement may be seen in about 50% of cases.[14] The eye is usually normal, but larger lesions can be associated with an anisometropic refractive error.

Although most cases of PC are situated inferomedially in the lower eyelid, cases have been reported in the anterior medial orbit.[9,12,14,28] When located in the orbit the globe may be slightly laterally displaced.[22] Rarely, PC may involve the inferior rectus or inferior oblique muscles.[1,3] Adulkar et al[29] described a single case of PC occurring within the corneal stroma in a 6-month-old boy. Verb et al[22] reported a case of *(Print pagebreak 670)* PC in the medial lower eyelid presenting with a nasolacrimal duct obstruction from external compression of the NLD.

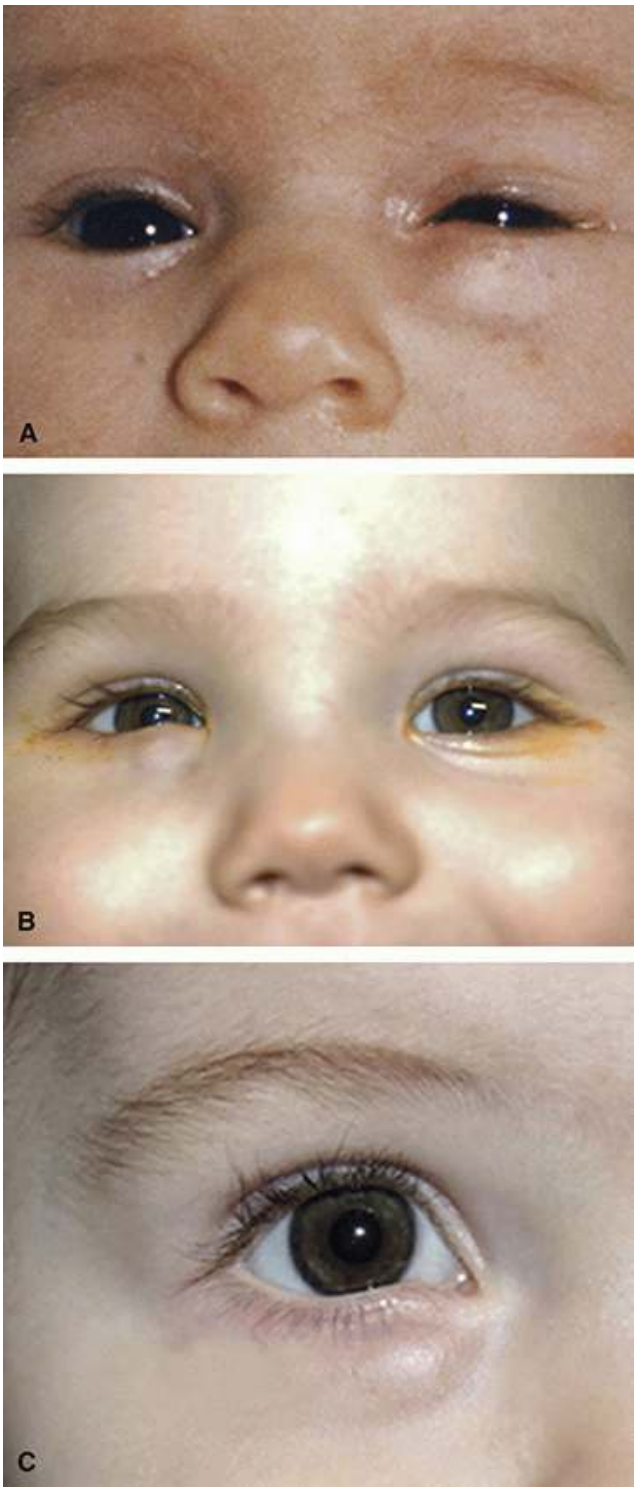

FIGURE 101.1 Phakomatous choristoma. (A, Courtesy of Dr. Stefan Seregaard. C, Reprinted with permission from Harris BF, Harris JP, Ducey PJ, et al. Phakomatous choristoma of the orbit with involvement of the inferior oblique muscle. *Ophthalmic Plast Reconstr Surg*. 2019;35:e9-e12.)

On computed tomography, PCs appear as well-circumscribed, discrete homogeneous mildly enhancing solid lesions without fat or calcification and not associated with any bony erosion.[9,11,12,13,14,22] On MRI, they have been reported to be well defined and mildly enhancing.[23,24]

Differential Diagnosis

Phakomatous choristoma is almost always clinically unsuspected and initially misdiagnosed. The most common clinical diagnosis is a dermoid cyst.[1,15,17,18,23] However, a dermoid cyst is situated superolaterally in 75% of cases, is often associated with bony erosion, is usually fluctuant, and on imaging frequently contains fat and a fluid level. Phakomatous choristoma, on the other hand, never has a fat content and is always located in an inferomedial location.

Other lesions in the differential diagnosis should include chalazion, dacryocele, dacryocystitis, infantile hemangioma, juvenile xanthogranuloma, lymphatic malformation, and ocular adnexal oncocytoma.[8,16,23] Dacryoceles generally present as a medial canthal mass below the medial canthal tendon, usually have a slight bluish discoloration,[22] and often resolve with probing and irrigation.[30] A chalazion occurs anywhere on the upper and lower eyelid, is usually fluctuant, and is often associated with blepharitis. Ocular adnexal oncocytoma is a benign tumor that occurs most commonly in the medial canthus of elderly patients, has a female predominance, and presents as a slowly growing red to tan mass.

The young age of patients with PC and the presence of a palpable mass often raise concern for malignant lesions, most importantly rhabdomyosarcoma. On MRI, malignant tumors often show heterogeneous signal intensities on T1-and T2-weighted images caused by areas of necrosis, which is not seen in PC. Also, rhabdomyosarcoma and associated cervical metastatic lymph nodes show variable heterogeneous enhancement.[31]

Treatment

Because PC is so rare and the diagnosis is not usually suspected on patient presentation, surgical excision is universally accepted as the initial treatment of choice to rule out alternative diagnoses like a dermoid cyst, dacryocele, and especially rhabdomyosarcoma and other malignancies. Complete surgical excision, preferably through a transconjunctival approach, is curative of this lesion,[3] and surgical excision is also warranted for the correction of any associated anisometropia and astigmatism. Following surgical excision, even if incomplete, no recurrence has ever been reported in the literature.[3]

Intraoperatively these lesions are often found to be adherent to adjacent structures such as the inferior tarsus, orbital septum, conjunctiva, and lateral lacrimal sac fascia,[2,16] making it more difficult to completely remove surgically.

Prognosis

In all available reported cases of phakomatous choristoma, treatment by surgical excision has been successful. There are no reports of recurrence even after incomplete surgical excision.

(Print pagebreak 671)

Histopathology

The histological features of phakomatous choristoma of the eyelid and orbit remain unchanged since the seminal description of this lesion by Lorenz E. Zimmerman in 1971.[1] Within dense collagenous tissue are nests and irregular islands of polygonal epithelial cells having lightly eosinophilic cytoplasm and round to oval nuclei without nucleoli (Figures 101.2 and 101.3). The nests and islands of epithelial cells are surrounded by basement membrane material that stains positively with periodic acid-Schiff reagent (PAS stain), and thick strands of PAS-positive material often accumulate between cells. Swollen epithelial cells may resemble "bladder cells" ("Wedl cells") occurring in cataractous crystalline lenses, and brightly eosinophilic material resembling cataractous lens fibers forms pools within the epithelial islands. Dystrophic calcification[1,14,19] and psammoma bodies[6] may be present.

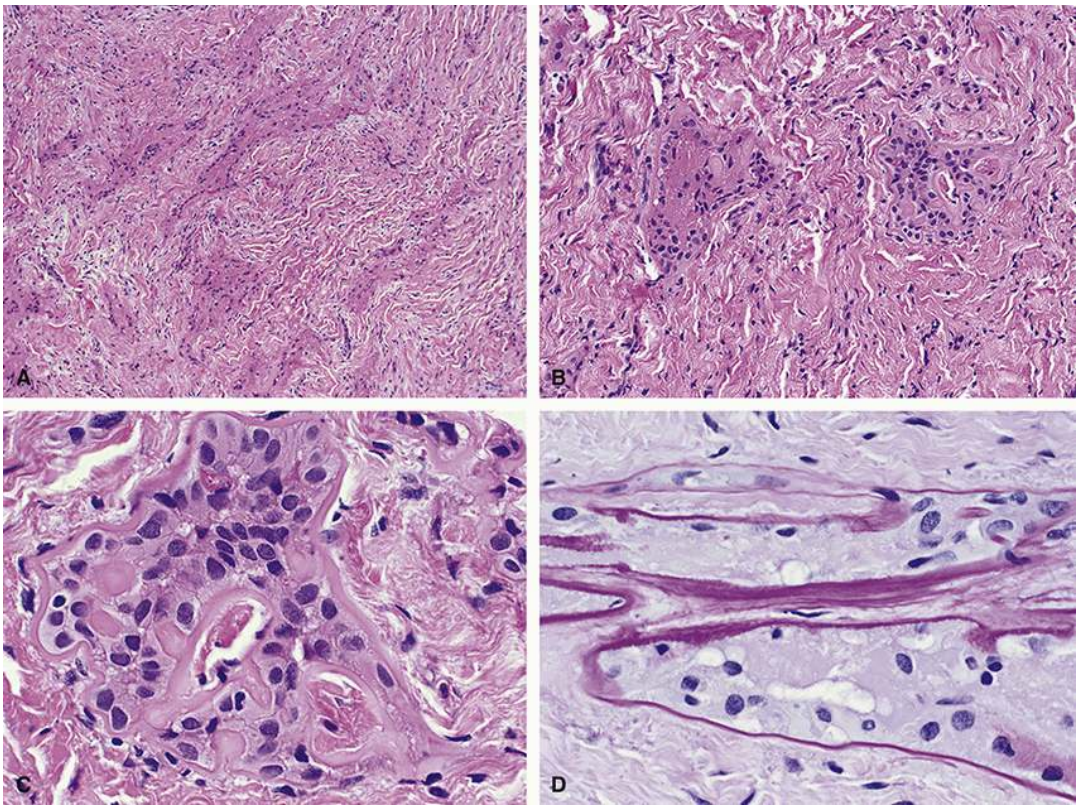

FIGURE 101.2 This phakomatous choristoma of the medial right lower eyelid of a baby boy was present from birth and excised at 3 months. A, Irregularly shaped islands of eosinophilic tumor cells are within dense collagenous tissue. B, The island of epithelial cells on the left surrounds a central zone of eosinophilic material, while the island on the right has entrapped basement membrane surrounding two small cysts. C, Higher magnification of the island on the right in (B) showing hyaline basement membrane surrounding two small cysts containing eosinophilic material with cells having pyknotic nuclei. D, Periodic acid-Schiff stain highlights a thick layer of basement membrane around the epithelial islands.

Immunohistochemical stains are not necessary for diagnosis due to the distinctive morphology by routine staining, and immunohistochemical studies have yielded variable results. Typically, the epithelial cells express S100 protein,[7,10,11,12,13,14,15,17,18] although staining may be focal and weak.[16] Epithelial cells are usually positive[10,11,12,13,14,15,16,17,18] but may rarely be negative[7] for immunoreactivity using antibodies to vimentin. Most studies have found no expression of cytokeratins by the epithelial cells, although one case had focal positivity using AE1/AE3 antibodies.[10] Neuron-specific enolase may[12,13,15] or may not[7] be expressed, while immunostaining for glial fibrillary acidic protein is either negative[13,21] or focally positive.[22] Immunoreactivity for crystallins supports a lenticular origin.[11,13]

(Print pagebreak 672)

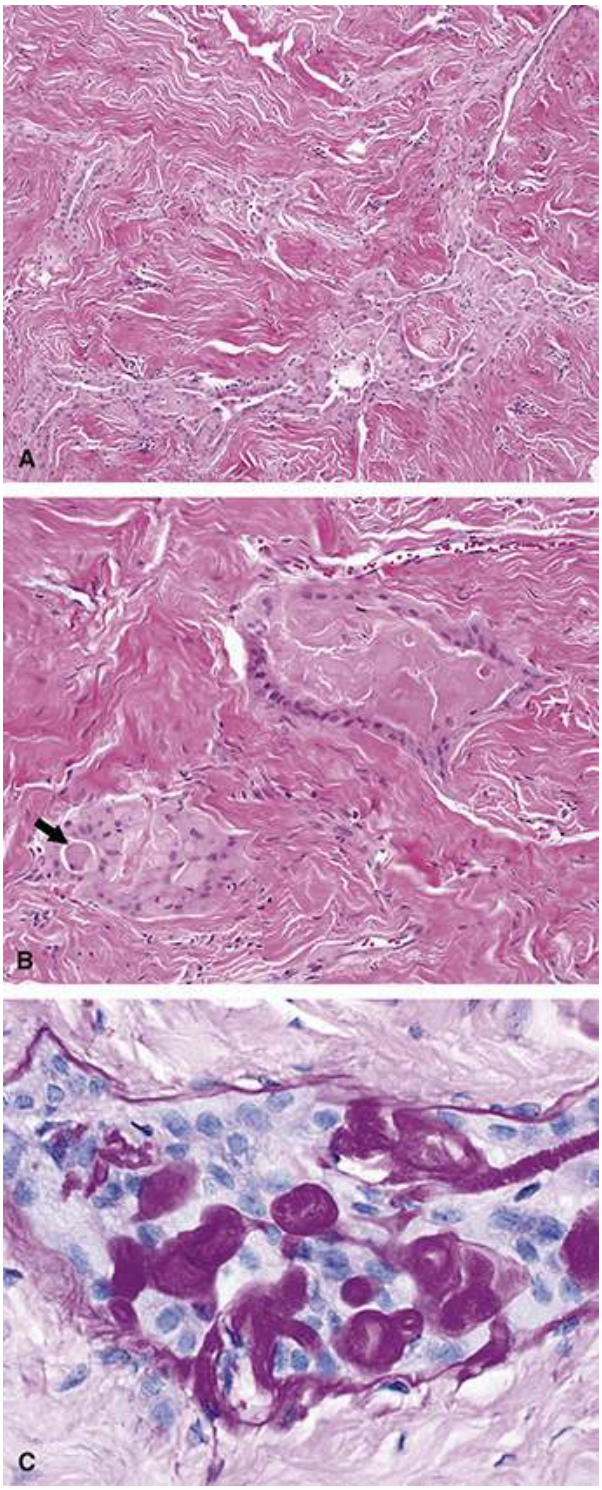

FIGURE 101.3 This phakomatous choristoma, present since birth, was removed from the preseptal medial right orbit at age 13 months due to anisometropia and eyelid deformity. A, Irregularly shaped, palely eosinophilic islands of epithelial cells are within dense, brightly eosinophilic collagenous tissue. B, Epithelial cells surround acellular eosinophilic material at the top right, while the island at the lower left has a bladder (Wedl) cell (arrow). C, Periodic acid-Schiff stain demonstrates thick ribbons of basement membrane among epithelial cells.

CHAPTER 102

Pilomatrixoma

Key Points

- Pilomatrixoma is a benign tumor of the hair follicle
- It occurs in any hair-bearing areas of the body, most often in the skin of the head and neck
- The pathogenesis remains unknown, but it has been suggested that pilomatrixoma may develop from sequestered epidermal elements into abnormal locations during embryonic development or that it may arise from ectodermal tissue from the hair matrix
- Clinically, periorbital pilomatrixomas present as slow-growing, solitary, asymptomatic, well-circumscribed, hard, mobile cutaneous masses
- The treatment of choice is complete surgical resection, and malignant transformation is very rare
- The prognosis is generally excellent following surgical resection, and recurrences are unusual

Pilomatrixoma, also known as pilomatricoma and calcifying epithelioma of Malherbe, is a benign tumor of the hair follicle. It was initially described by Malherbe and Chenantois in 1880 as a "calcified epithelioma," believed to derive from the sebaceous gland.[1] In 1949, Lever and Griesemer[2] suggested an origin from the hair matrix cells.

Pilomatrixoma can occur in any hair-bearing area of the body, although it occurs most often in the skin of the head and neck.[3,4] In the periorbital skin it arises from the matrix cells at the base of the eyelids and the eyebrows.[5] Although it can be seen in patients from infancy to old age, it is far more common in the first 2 decades of life. Sixty percent of cases arise before the age of 10 years,[6,7,8] and 75% occur in patients 20 years or younger.[9] Some studies have reported little or no gender difference,[10,11] but most have demonstrated a clear female predominance,[12,13,14,15] with a female to male ratio of 2:1 to 3:1.[9,16,17] The most common site of occurrence is the head and neck (51.8%), followed by lesions on the extremities (37.7%) and trunk (10.5%)[7,18] and other rare sites such as the middle ear.[19] Malignant transformation is rare but has been described, with metastasis to regional lymph nodes, the lung, brain, bones, and visceral organs.[9,20,21] Familial cases have also been observed,[18,20,22] sometimes in association with systemic syndromes. Lesions are typically single, and multiple pilomatrixomas are rare.[23,24,25] When multiple lesions are seen it should raise suspicion for related systemic disorders such as myotonic dystrophy,[26] Churg-Strauss syndrome,[27] Gardner syndrome,[28] trisomy 9,[29] Rubinstein-Taybi syndrome,[30] xeroderma pigmentosum,[31] and sarcoidosis.[32]

Periocular pilomatrixoma is uncommon, but many cases have been described.[1,5,30,33,34,35,36,37,38,39,40,41] In a series of 16 periocular cases, the mean age of patients at treatment was 17 years (range, 1-74 years),[16] and there was a clear female predominance.

Etiology and Pathogenesis

The exact pathogenesis of pilomatrixoma remains unknown. Some authors have suggested that pilomatrixoma may develop from sequestered epidermal elements into abnormal locations during embryonic development.[19,42] Lever and Griesemer[2] considered pilomatrixoma to be a hamartoma, and Dubreuilh and Cazenave[43] proposed pilomatrixomas arise from ectodermal tissue consistent with their origin from the hair matrix.

Several studies have demonstrated mutations in the Wnt signaling pathway and altered protooncogene expression in basophilic and shadow cells.[38,44] Other studies have demonstrated mutations in the *CTNNB1* gene (3q22), which encodes beta-catenin,[45] a downstream effector in the Wnt signaling pathway that affects multiple cellular processes, including cell differentiation into the hair follicle and cell proliferation.[44] Mutations of this gene result in an upregulation of intracytoplasmic and intranuclear beta-catenin leading to the development of neoplasms of hair matrix differentiation.[11,44] Associations between pilomatrixoma and several

genetic diseases, such as Gardner syndrome, Rubinstein-Taybi syndrome, Sotos syndrome, myotonic dystrophy, and Turner syndrome suggest abnormalities in other cell signaling pathways as well.[11,26,46]

Clinical Characteristics

Clinically, periorbital pilomatrixomas present as slow-growing, solitary, asymptomatic, well-circumscribed, hard, mobile cutaneous masses (Figure 102.1).[12,13,14,15,47] They can be multiple in up to 4% of cases.[18,25,48] The overlying skin may be normal or show a red to blue coloration,[7,16] and rarely, there may be areas of surface ulceration (Figure 102.2).[49,50,51] Lesions can range from 4 mm to 2.5 cm. Occasionally, lesions can show rapid growth after surgical trauma.[52] About 65% involve the eyebrow (Figure 102.3), 28% the upper eyelid, 5% the lower eyelid, *(Print pagebreak 675)* and 1.5% the medial canthus.[16] About one-third show some calcification, and 1% are ossified.[53,54]

FIGURE 102.1 A-D, Solitary pilomatrixoma of the eyelids. A, (Courtesy of Dr. Charles Soparkar.) B, (Courtesy of Dr. Alan McNab.) C, (Courtesy of Dr. Nahyoung Grace Lee). D, (Courtesy of Dr. Peter Rubin.)

FIGURE 102.2 Pilomatrixoma of the medial lower eyelid with crusting and areas of superficial ulceration.

Differential Diagnosis

The clinical characteristics of pilomatrixoma are nonspecific and are similar to many other cutaneous lesions so that the diagnosis is usually not suspected until the tissue is examined by histopathology.[15,55,56,57] The correct diagnosis of periorbital lesions is made clinically in only 12% to 23% of cases.[16,38] The differential diagnosis includes chalazion, dermoid cyst, epidermoid cyst, trichoepithelioma, basal cell carcinoma, keratoacanthoma, papilloma, and abscess.[36,38,58,59]

Treatment

The treatment of choice for pilomatrixoma is complete surgical resection.[8,9,20,24,56,57] Recurrences and malignant transformations following surgical excision have been described *(Print pagebreak 676)* but are very rare.[23,36,38,55,60] Incomplete resection is usually followed by local recurrence.[6,20,24] In a large review, among 1797 patients with pilomatrixoma who were followed for 1 month to 7 years after surgical resection, 27 (1.5%) had recurrence at the site of excision.[11]

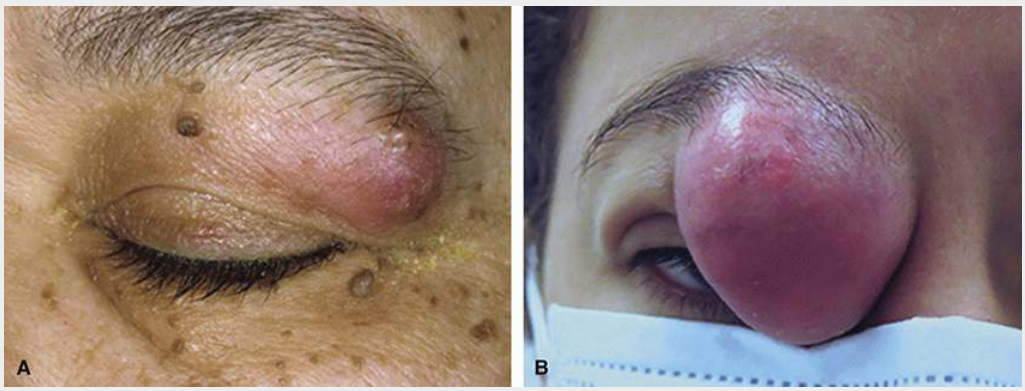

FIGURE 102.3 A and B, Pilomatrixoma of the lateral brow. B, (Courtesy of Dr. Robert Kersten.)

Prognosis

The prognosis for pilomatrixoma is generally excellent following surgical resection, and recurrences are unusual. Malignant transformation is very rare, seen more frequently in middle-aged to elderly males (76%).[12,61,62,63] The relationship between pilomatrix carcinoma and benign pilomatrixomas is incompletely understood,[61] but the histologic association between these two lesions raises the possibility the pilomatrix carcinoma arises from malignant degeneration of its benign counterpart.[61,64,65,66] In a review of 123 cases of pilomatrix carcinoma from the literature, the recurrence rate following excision was high (23%-83% depending on the extent of surgery). Metastasis occurred in 13% and the mortality rate was 7%.[61]

Histopathology

Pilomatrixoma histopathology is well described,[2,67,68,69,70] with the most thorough description being that of Forbis and Helwig.[48] Tumors are round or oval, well-circumscribed masses occurring in the dermis or dermis/subcutaneous tissue or confined to the subcutis.[48,71] Pilomatrixomas are partially or wholly surrounded by compressed collagenous connective tissue, creating the appearance of a capsule.[2,48,68] The tumors are composed of islands of basophilic cells and eosinophilic shadow (ghost) cells separated by connective tissue,[2,48,68] although basophilic cells are not identifiable in up to 45% of lesions.[48] Basophilic cells are small with hyperchromatic basophilic nuclei, a small nucleolus, scant palely eosinophilic cytoplasm, indistinct or inapparent cell borders, and moderate to abundant mitoses.[2,48] Eosinophilic shadow cells represent mummified basophilic cells and have pale pink cytoplasm, often a central unstained shadow where the nucleus was located, and distinct, although faint, cell borders.[2] Shadow cells contain melanin in 8% of pilomatrixomas.[48] Basophilic cells may form a band around masses of shadow cells or form variably sized and shaped clusters (Figure 102.4A and B).[2]

Forbis and Helwig described four fates for the basophilic cells. There may be an abrupt transition from basophilic cells to eosinophilic shadow cells, or there may be an intermediate zone of six to eight layers of transitional cells that develop progressively more eosinophilic cytoplasm while the nucleus becomes pyknotic and loses its basophilia (Figure 102.4C). The second fate is for the basophilic cells to form hyalinized shadow cells with translucent, glassy, eosinophilic material having unidentifiable cell boundaries. The third scenario is for basophilic cells to transition to squamoid cells with increased lightly eosinophilic or clear cytoplasm, occasional cells with keratohyalin granules, an enlarged nucleus with a prominent nucleolus, distinct cell boundaries, and rare intercellular bridges. Squamoid cells usually form small groups and may have associated keratin or parakeratin. The fourth fate for basophilic cells is to degenerate into amorphous debris "accompanied by hemorrhage, occasional shadow cells, and shreds of keratin."[48] A recent study showed that shadow cell differentiation from basophilic cells is a caspase-independent form of programmed cell death.[72]

Calcification is seen in from two-thirds[2] to 84%[48] of tumors. The calcification may appear as a dusting of basophilic particles or solid purple masses and tends to occur in the center of the shadow cell groups.[48] Ossification, most often at the periphery of calcified masses,[48] occurs in about 3%[13] to 21%[48] of tumors. Boniuk and Zimmerman observed ossification in 4 of 40 eyelid and eyebrow pilomatrixomas,[73] and it may occasionally be a striking feature of the tumor.[74] *(Print pagebreak 677)* Foreign-body giant cells occur in the stroma of 50%[13] to 100%[2] of tumors, usually along the edges of the shadow cell fields (Figure 102.4D).[2] The stroma between islands may feature hemosiderin in about 20% of cases.[48]

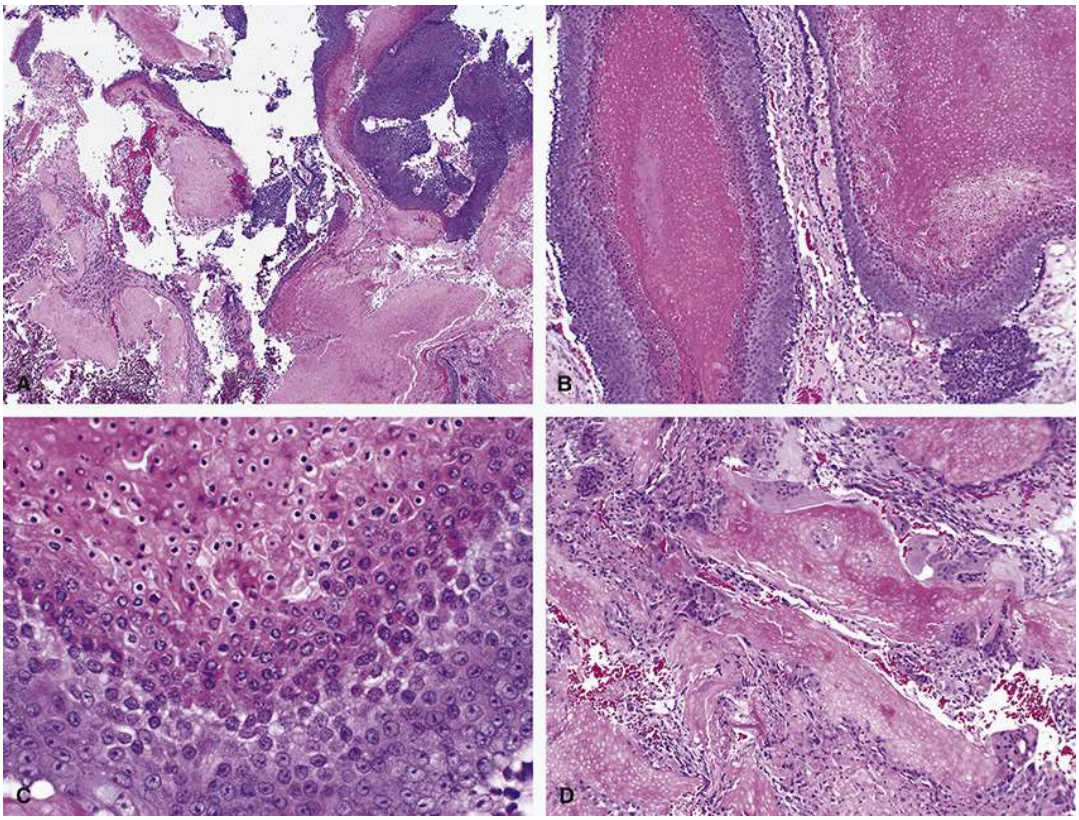

FIGURE 102.4 This pilomatrixoma developed in the left medial eyebrow of a middle-aged man. It arose over 3 months and was firm, mobile, and erythematous. The tumor fragmented during removal. A, At low magnification, the pilomatrixoma has a mixture of basophilic cells and eosinophilic shadow cells. B, Basophilic cells surround eosinophilic shadow cells. Both islands of tumor cells have an intermediate zone of transitional cells between the basophilic cells and the shadow cells. C, Transitional zone cells have progressively more eosinophilic cytoplasm and increasingly pyknotic nuclei as they move toward the center of the islands and become shadow cells. D, Pilomatrixomas often have foreign-body multinucleated giant cells, most often around the areas of shadow cells.

The variable histological appearance of pilomatrixomas led Kaddu and colleagues to postulate that pilomatrixomas evolve through four morphological stages.[70] They deem early lesions to be small cysts lined by squamoid and basaloid epithelium surrounding keratin filaments and shadow cells.[70] Large neoplasms with peripheral basophilic cells and central irregularly shaped zones of cornified masses containing shadow cells are considered fully developed lesions.[70] Early regressive lesions lack an epithelial lining but have peripheral basophilic cells foci and shadow cells surrounded by granulation tissue with multinucleated giant cells.[70] Late regressive pilomatrixomas are solid; lack basophilic and squamoid cells; have shadow cells with varying degrees of calcification, ossification, and giant cell reaction; and are embedded in thickened, hyalinized, and sclerotic collagen bundles.[70]

Pilomatrixomas in people >45 years of age resemble those in individuals <45 years of age, although atypical features may occur in patients >45 years of age.[69] Atypical features include a larger proportion of basophilic cells, with cells having cytological atypia manifest as increased variability in cell size, shape, and staining; increased mitoses with a few abnormal mitotic figures; variability in nuclear/cytoplasmic ratios; and hyperchromatic nuclei.[69] Malignant pilomatrixomas (pilomatrix carcinomas) are rare.[75,76,77] Malignant pilomatrixomas are often larger; have infiltrating borders with fascial or skeletal muscle invasion, basophilic cell predominance, nuclear pleomorphism, prominent eosinophilic nucleoli, high mitotic activity, abnormal mitotic figures, and areas of confluent necrosis; and may exhibit vascular, lymphatic, and perineural invasion.[76] Periocular pilomatrixomas resemble those at other body sites.[67,73,77]

CHAPTER 103

Pleomorphic Adenoma (Mixed Tumor)

Key Points

- Pleomorphic adenomas arise most often in the lacrimal or salivary glands, and less commonly from ectopic periorbital lacrimal gland tissue, sweat glands of Moll, or accessory lacrimal glands of Krause and Wolfring in the eyelids
- They are characterized by translocations or intrachromosomal rearrangements with breakpoints affecting 8q12 in 50% and 12q14-15 in 10% to 15%
- Lesions are very slow-growing, small, smooth, firm, nontender, nodular masses that may be associated with madarosis and telangiectasias
- Treatment is with complete local surgical resection and eyelid reconstruction when necessary
- The prognosis is excellent, and the reported eyelid cases showed no recurrence or malignant transformation

Mixed tumor of the skin was first described by Billroth in 1859,[1] and since then the terms “chondroid syringoma,” “benign mixed tumor,” and “pleomorphic adenoma” all have been used interchangeably for this lesion. In recent years the term “pleomorphic adenoma” has been preferred for salivary gland neoplasms,[2] while mixed tumor is preferred for skin tumors.[2] Pleomorphic adenoma (PA) most often arises in the lacrimal or salivary glands.[3,4,5] Less commonly it may arise from ectopic periorbital lacrimal gland tissue, sweat glands of Moll, or accessory lacrimal glands of Krause and Wolfring in the eyelids.[6,7,8,9,10,11,12,13,14]

At birth, there are between 20 and 40 accessory lacrimal glands of Krause in the upper conjunctival fornix and 6 to 8 laterally in the lower fornix.[15,16,17] Three to four accessory lacrimal glands of Wolfring are larger and are situated at the superior border of the tarsus in the upper eyelid.[15] Accessory lacrimal glands may also be encountered in the caruncle and in the plica semilunaris[18,19,20] Although ectopic lacrimal gland tissue has frequently been reported in the orbit, eye, and eyelid,[21,22,23,24,25,26,27,28] pleomorphic adenoma arising from ectopic lacrimal glands is rare,[29,30] and even less frequent is adenoid cystic carcinoma.[13,20]

Cutaneous malignant PA, usually termed “malignant chondroid syringoma”[31] or “malignant mixed tumor,” is very rare and usually develops on the torso or extremities, but about 25% may be located on the face and scalp.[32,33] It presents most frequently as a nonulcerated, slow-growing subcutaneous or intradermal nodule.[34,35,36,37,38,39,40] In contrast to benign cutaneous PA, malignant lesions tend to occur more frequently in women, with no age preference. They can develop de novo or less commonly from incompletely resected benign PA lesions. Malignant transformation has not been reported in pleomorphic adenomas arising in the eyelid. Nevertheless, because PA of the lacrimal and salivary glands carries a small but significant risk of malignant transformation if not completely excised, it is likely that this may also be seen eventually in tumors arising in ectopic or accessory lacrimal glands.

Etiology and Pathogenesis

Benign pleomorphic adenomas of the salivary glands are characterized by translocations or intrachromosomal rearrangements with breakpoints affecting 8q12 (in 50%) and 12q14-15 (in 10%-15%).[41,42] The translocations and rearrangements result in gene fusions involving the transcription factor genes *PLAG1* and *HMGA2*.[41,42,43,44] A subset of cutaneous mixed tumors feature *PLAG1* rearrangement with aberrant nuclear expression of PLAG1 protein,[45] while other tumors have *EWSR1* rearrangement.[46] Another study showed *PLAG1* expression by epithelial cells of cutaneous mixed tumors in the absence of fusion gene transcripts detectable using a reverse transcriptase-polymerase chain reaction method.[47] Oncogenic activation of the *PLAG1* gene on 8q12 is a crucial event in the formation of pleomorphic adenomas of the salivary glands[48] and some cutaneous mixed tumors.[47] Activation mainly results from recurrent chromosomal translocations that lead to promoter substitution between *PLAG1* and several other genes,[43,49] leading to an exchange of the regulatory control elements.[48] The replacement of the *PLAG1* promoter, inactive in adult salivary glands, by a strong promoter derived from the translocation partner, leads to ectopic expression of PLAG1 in the tumor cells and presumably results in deregulation of *PLAG1* target genes, causing salivary gland tumorigenesis.[50]

Clinical Characteristics

Fewer than 50 cases of pleomorphic adenoma arising in the eyelids have been reported. Most patients at presentation are 50 to 60 years old, with a range of 12 to 84 years, and there is a strong male predilection. The right and left sides are equally affected, and the lower eyelid is involved in 55% of the reported cases. Most lesions are very slow growing over 1 to 20 years before presentation. The vast majority of tumors *(Print pagebreak 681)* are small, with 96% being equal to or less than 1 cm in diameter. Clinical examination typically show a smooth, firm, nontender, nodular mass in 88% of cases (Figures 103.1 and 103.2), with rare lesions being ulcerative or cystic. Madarosis and surface telangiectasias is seen in about 25% of cases. The caruncle can be involved in 6% of affected patients.[9,10,12,18,31,51,52,53,54,55,56,57,58,59,60,61]

FIGURE 103.1 Pleomorphic adenoma of the medial canthus and side of the nose. (Courtesy of Dr. Alan McNab.)

Differential Diagnosis

There is no specific group of lesions that are more commonly confused with eyelid pleomorphic adenomas. The clinical differential diagnosis should include any nodular, slow-growing, periocular adnexal lesion, such as an epidermoid cyst, epidermal inclusion cyst, hidradenoma, pilomatrixoma, neurofibroma, acrospiroma, and nodular basal cell carcinoma, among others.[62]

Treatment

Pleomorphic adenoma of the eyelid is typically managed with complete local surgical resection with several millimeters of clear margin, and eyelid reconstruction as appropriate when necessary. PA is generally well circumscribed and shells out easily from the surrounding tissue.[63] However, because there is a potential low risk of malignant transformation, these patients should be monitored long term due to the possibility of local recurrence.[62,63,64,65,66,67]

Prognosis

With complete surgical excision, the prognosis for eyelid pleomorphic adenoma is excellent. Although the literature is sparse, none of the reported cases showed recurrence of tumor after follow-up intervals of 6 to 36 months.[20,68,69,70,71] Despite the lack of recurrence or malignant transformation in reported cases of eyelid PA, both have been reported for PA in other locations, so that postoperative monitoring is necessary.

Histopathology

Cutaneous mixed tumors exhibit epithelial, myoepithelial, and mesenchymal elements.[63,72,73,74,75,76,77,78,79] Hirsch and Helwig examined 188 cases of cutaneous mixed tumor.[63] The dermal tumors were circumscribed and multilobulated with fibrous septa between lobules.[63] Only two cases had a connection with the epidermis.[63] Cuboidal or polygonal epithelial cells with large uniform nuclei and abundant, homogeneous, eosinophilic cytoplasm lacked pleomorphism, cellular atypia, or "appreciable" mitotic activity.[63] Epithelial cells formed nests; tubuloalveolar structures with "gland-like elements lined with 2 or more (depending on the plane of sectioning) rows of cuboidal cells morphologically similar to those in nests of cuboidal cells"; ductal structures composed of one or two rows of cuboidal cells; and occasional keratinous cysts with the epithelial wall lined by flattened squamoid cells.[63] Tubuloalveolar and ductal structures connected by epithelial tracts formed lacelike networks.[63] A few scalp tumors had basophilic and shadow cells, similar to pilomatrixoma, together with the epithelial and matrix features of the more typical mixed tumors.[63] Homogeneous faintly basophilic chondroid matrix was most common, foamy myxoid areas were the next most common, and eosinophilic, homogenous, and hyaline matrix was the least common.[63]

At about the same time as Hirsch and Helwig's paper appeared in 1961, Headington classified seven mixed tumors into eccrine and apocrine types based on their histological features.[74] Eccrine mixed tumors were well-circumscribed and lobulated neoplasms located in the lower reticular dermis or at the junction of dermis and subcutis (the usual site of the coiled or secretory portion of eccrine glands).[74] They typically featured a homogeneous and monotonous pattern with numerous small gland-like spaces and individual cell nests evenly separated in a cartilaginous or chondroid matrix.[74] The individual glands had irregular outlines, and there were frequent small eccentric proliferations of cells creating the appearance of a "comma or eccentric handle."[74] Headington did not observe any large gland-like spaces lined by a double row of epithelium, characteristic of apocrine differentiation, in any of the four eccrine mixed tumors (Figure 103.3). The three apocrine mixed tumors were well circumscribed and lobulated, and they were also in the deep reticular dermis or at the junction of the dermis and subcutis. The tumors all had a variegated and haphazard tissue pattern similar to that of salivary gland mixed tumors.[74] "Broad sheets of squamous epithelial cells with and without intracellular bridges are interspersed in a connective tissue stroma showing varying *(Print pagebreak 682)* degrees of cartilaginous forms. Glandular spaces show marked variation in size and shape, and they may be lined by flattened cuboidal cells or by the characteristic double epithelial layer; this latter finding is considered to be the most important single diagnostic criterion. Areas of squamous and osseous metaplasia may be found. The haphazard distribution of epithelial and stromal components and the presence of typical apocrine epithelium are considered to be diagnostic."[74]

Since Headington's seminal publication, the classification of cutaneous mixed tumors into apocrine and eccrine subtypes is well established.[75,80,81] Hassab-El-Naby and coworkers examined 64 mixed tumors of the skin; none of the tumors involved the eyelids or eyebrows, and 52 (81%) were apocrine subtype.[75] A few of the apocrine tumors had follicular differentiation resembling a pilomatrixoma or sebaceous differentiation, and 25% of the tumors had an "overwhelming predominance of epithelial over stromal elements."[75] All of the eccrine mixed tumors had small glands and ductlike structures lined by a single layer of cuboidal cells with pale eosinophilic cytoplasm and round nuclei dispersed in stroma consisting mainly of chondroid or mucin.[75] Spindle-shaped and round cells similar to those forming the glands were also within the stroma.[75] Apocrine tumors showed immunohistochemical expression of S100 protein in aggregations of epithelial cells and polygonal cells arranged as solitary units, while tubules with decapitation secretion were negative for S100 protein. Carcinoembryonic antigen (CEA) and epithelial membrane antigen (EMA) were detected only in the inner layer of tubular structures and luminal secretory products. Muscle-specific actin occurred focally and weakly in some spindle-shaped stromal cells, especially in areas of fibroplasia. Gross cystic disease fluid protein-15 (GCDFP-15 [BRST-2]) was in tubules, aggregations of epithelial cells, and luminal secretions.[75] Eccrine mixed tumors had S100 protein expression in glands and ductlike structure and stromal polygonal cells; CEA in glands and ductlike structures with paraluminal accentuation; and no expression of actin, EMA, and GCDF-15 expression was seen.[75] Hassab-El-Naby et al. concluded that the immunohistochemical studies did not provide unequivocal evidence of either apocrine or eccrine differentiation.[75] A more recent study of 244 apocrine mixed tumors by Kazakov and colleagues identified 18 in the eyebrow and 9 in the eyelid.[80] The epithelial component of the 244 tumors exhibited a spectrum of metaplastic changes, including squamous, mucinous, oxyphilic, columnar, and hobnail metaplasia and clear cell change and cytoplasmic vacuolization. Myoepithelial cells had clear cell change, hyaline cells, plasmacytoid cells, spindling, and collagenous spherulosis, while the stroma had chondroid, osseous, and adipose metaplasia.[80] No eccrine mixed tumors were located in the eyebrow or eyelid in a more recent study of 50 eccrine tumors by Kazakov et al.[81]

FIGURE 103.2 Benign cutaneous apocrine mixed tumor of the lateral left lower eyelid of a man in his early 40s. It was a freely movable 1.5 × 0.9 cm tumor that had been slowly growing for about 5 years and was associated with episodic eyelid swelling.

Most malignant mixed tumors (Figure 103.4) likely arise de novo since remains of benign mixed tumors are uncommon.[77] The tumors are infiltrative, sometimes have ulceration of the overlying epidermis, and are composed of neoplastic epithelial cells within a myxoid stroma. The neoplastic epithelial cells have pleomorphic hyperchromatic nuclei and may form solid aggregates, cords, or ducts.[77] There may be atypical mitotic figures.[77] The myxoid stroma may be highlighted using alcian blue stain[74] but not with periodic acid-Schiff stain.[77,82] Immunohistochemical stains, although limited in number, have shown expression of S100 protein,[82,83] CAM5.2,[84] CK7,[84] and vimentin[82] by the epithelial cells. Tumor cells may[83] or may not[77] express CEA. One malignant mixed tumor of the eyebrow has been reported,[32] and we have seen one example arising in the eyelid (Figure 103.4). In the periocular region, cutaneous extension of tumor from a lacrimal gland primary must be excluded (Figure 103.4).[84]

(Print pagebreak 683)

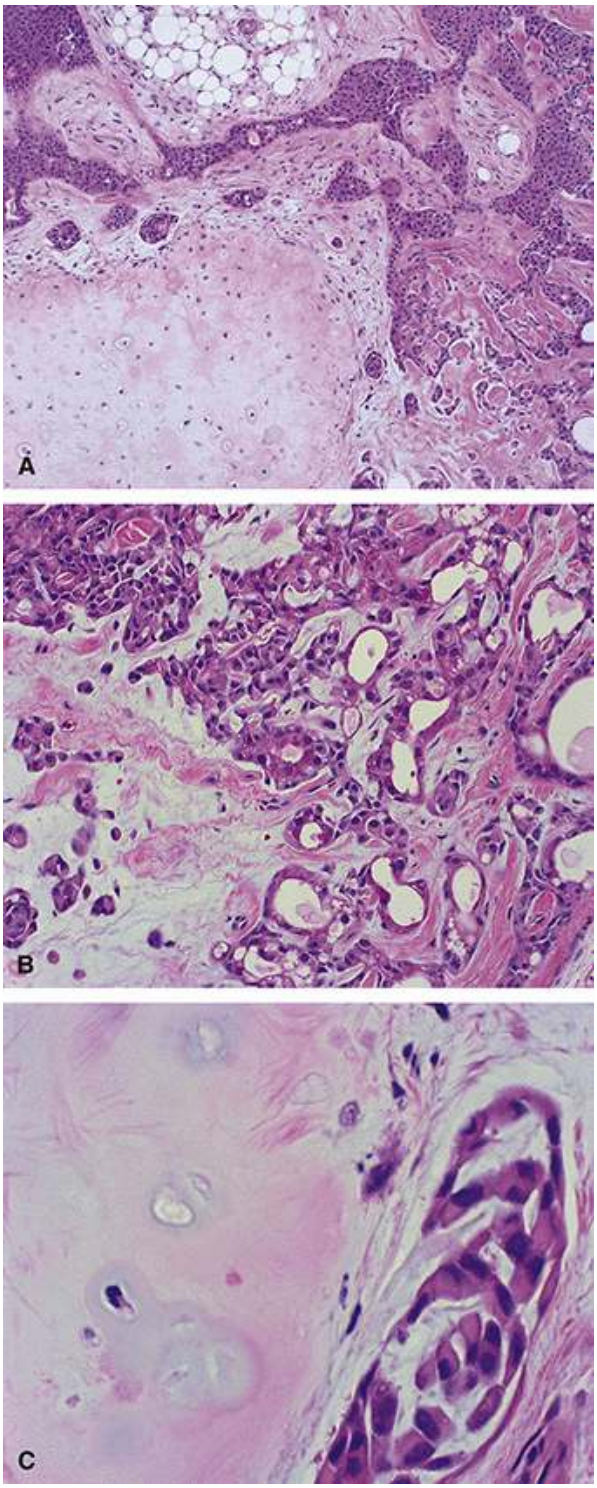

FIGURE 103.3 Benign cutaneous apocrine mixed tumor from the patient in Figure 103.2. A, Cords and tubules of epithelial cells are in a stroma having adipose (top) and chondroid (bottom) metaplasia. The stroma on the right is hyalinized and brightly eosinophilic. B, The epithelial cells formed solid cords, as well as ductlike structures. C, Chondroid metaplasia of the stroma was a prominent feature of this neoplasm.

(Print pagebreak 684)

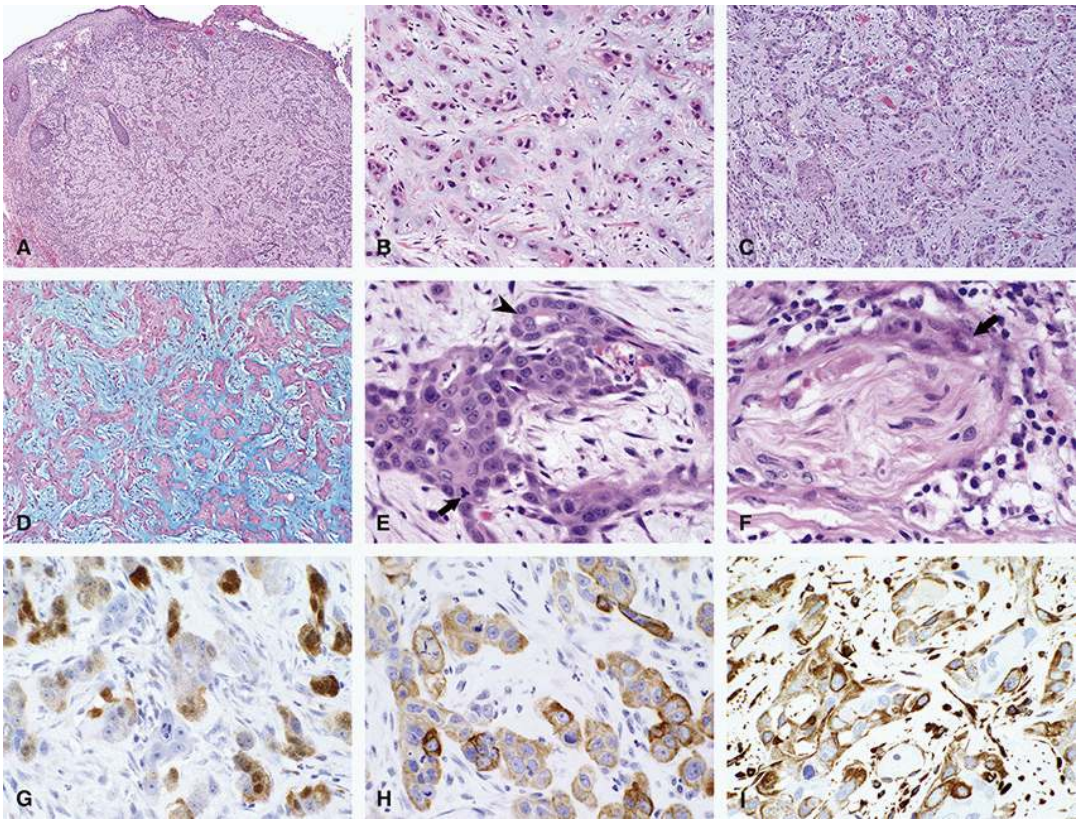

FIGURE 103.4 This malignant mixed tumor in a woman in her mid-70s involved most of the left lower eyelid and inferior anterior orbit and extended into the lateral left upper eyelid and superior anterior orbit. The tumor did not involve the lacrimal gland. A, The tumor is contiguous with the epidermis. Much of the epidermis is ulcerated, as seen on the right side of the photomicrograph. B, Nests of tumor cells were embedded in a faintly basophilic chondroid matrix focally. C, In most areas, the tumor cells formed cords, rudimentary tubules, and nests within a lightly basophilic, myxoid fibrous stroma. D, Alcian blue stain for glycosaminoglycans is strongly positive, confirming the stroma's myxoid nature. E, A rudimentary tubule is at the arrowhead. There were frequent mitoses; a tripolar mitotic figure is at the arrow. F, Perineural invasion (*arrow*) by tumor was common. G, Some tumor cells were immunoreactive using antibodies to S100 protein. The expression of S100 protein by the tumor cells varied widely from one area to another within the tumor. H, CAM5.2 antibodies, immunoreactive principally to cytokeratin 8 (Becton Dickinson Biosciences), highlighted some tumor cells. The normal epidermis lacked immunoreactivity. I, All of the tumor cells were immunoreactive using antibodies to vimentin, which also highlighted the stromal cells.

CHAPTER 104

Poliosis

Key Points

- Poliosis is a localized patch of hypopigmented hair caused by a reduction or absence of melanin in the affected hairs
- The pathogenesis is unknown, but this condition frequently occurs in the setting of several genetic syndromes such as piebaldism, tuberous sclerosis, and Waardenburg syndrome
- It can also be associated with nongenetic, autoimmune conditions such as Vogt-Koyanagi-Harada syndrome, congenital and acquired nevi, and sarcoidosis
- The clinical presentation of eyelash poliosis may vary from one or two white lashes to involvement of the entire eyelid margin
- There is no specific treatment for poliosis, and when the eyelashes and eyebrows are involved the condition can be socially disabling
- Treatment is directed toward cosmetic improvement such as with hair dyes
- Some cases of poliosis will resolve following management of the underlying inciting condition suggesting restoration of normal immune homeostasis

Poliosis, also known as poliosis circumscripta, is defined as a localized patch of hypopigmented hair caused by a reduction or absence of melanin in the affected hairs.[1] It may affect any region of the body including the eyelashes and eyebrows. On histopathology, poliosis demonstrates a decrease or absence of melanin or melanocytes in the hair bulbs of the affected hair follicles. The adjacent epidermal melanocytes are usually not affected unless there is associated vitiligo.[2] Poliosis can occur in the setting of several genetic syndromes, either as one of their characteristic clinical manifestations or as a rare manifestation.[3] It also has been described in association with a variety of acquired inflammatory, neoplastic, and medication-induced conditions.[1]

Etiology and Pathogenesis

Poliosis and Genetic Syndromes

The exact pathogenesis of poliosis in most cases is unknown or only speculative. Possible causes are extensive, and this condition frequently occurs in the setting of several genetic syndromes.[3] Although poliosis is not specific for any of these syndromes, it may be the initial presentation even before other more characteristic manifestations appear.[4]

Piebaldism is an autosomal dominant inherited disorder that most commonly develops secondary to a mutation in the c-kit proto-oncogene on chromosome 14q12 that affects melanoblast migration, proliferation, differentiation, and survival.[5,6] It is characterized clinically by the presence of congenital poliosis and leukoderma,[7] with a white forelock and poliosis of the eyebrows and eyelashes seen in 80% to 90% of cases.[1]

Tuberous sclerosis is an autosomal dominant disorder characterized by hamartoma development in various tissues, most frequently the brain, skin, heart, kidneys, and lungs.[8] It is caused by mutations in the *TSC1* (9q34) or *TSC2* (16p13) genes resulting in activation of the mechanistic target of rapamycin (mTOR) signaling pathway. More than half of cases present with seizures, and dermatologic manifestations may be seen initially in more than 90% of affected children.[4,9] Hypopigmented skin macules are identified in infancy or early childhood in 15% to 50% of patients.[4,9] Although poliosis is not one of the diagnostic criteria, it is often present as one of the earliest signs of the disease and may precede the appearance of other manifestations.[4]

Waardenburg syndrome type I is a rare autosomal dominant disorder of neural crest cell development associated with a

heterozygous pathogenic variant in *PAX3* (2q36). It is characterized by sensorineural deafness and pigmentary abnormalities, often associated with a white forelock and possible poliosis of eyebrows and eyelashes.[3,10] Other ophthalmic manifestations may include segmental heterochromia, or hypoplastic or brilliant blue irides, and segmental choroidal hypopigmentation.[11] Depigmentation in Waardenburg syndrome is caused by the absence of melanocytes from the affected areas in the skin, hair, eyes, or ears.[10,12]

Poliosis has also been reported rarely in patients with Rubinstein-Taybi syndrome,[13,14] Marfan syndrome,[15] and neurofibromatosis type 1.[16]

Poliosis and Acquired Conditions

Vogt-Koyanagi-Harada (VKH) syndrome is a rare, nongenetic, systemic T cell-mediated autoimmune inflammatory disorder. It is characterized by bilateral uveitis that is frequently associated with neurological, auditory, and integumentary manifestations. The etiology and pathogenesis are not completely understood, but it is believed that *(Print pagebreak 688)* the clinical manifestations are caused by an autoimmune response directed against melanin-associated antigens in the target organs, such as the eye, inner ear, meninges, and skin. Accumulating evidence suggests that predisposing genetic factors, including VKH disease-specific risk factors (HLA-DR4), general risk factors for immune dysfunction (increased Expression of IL-23 Receptor [IL-23R]), environmental triggers (eg, viruses), and recently COVID-19 vaccinations, are all involved in the development of VKH disease.[17,18] The clinical manifestations of VKH include vitiligo occurring in association with poliosis, uveitis, aseptic meningitis, tinnitus, dysacusis, and alopecia.[17,18,19,20,21,22] Vitiligo, poliosis, and alopecia usually develop in the late phase of the disease, although they can manifest earlier. Periocular hair involvement is common in this disorder and usually manifests as eyelash poliosis.

Alezzandrini syndrome is a very rare disease with only a few cases reported in the literature.[23,24] The etiology is unknown but several theories involving viral or autoimmune processes have been postulated. The disease is characterized by hearing abnormalities, unilateral tapetoretinal degeneration, ipsilateral facial vitiligo, and poliosis. It is suspected that an autoimmune process destroys melanocytes.[23,24]

Vitiligo is a chronic pigmentary disorder characterized by loss of epidermal melanocytes leading to depigmented skin macules.[25] The exact cause of the loss of functional melanocytes in affected skin is not fully understood, but it is believed that a triggering event leads to a stress response in the skin that initiates an autoimmune response against melanocytes in genetically predisposed individuals.[26] Genetic predisposition is supported by the fact that 25% of patients with vitiligo have a positive family history and more than 40 gene variants have been identified in genome-wide association studies.[27] The melanocyte destruction has been attributed to several mechanisms such as autoimmune, cytotoxic, neural, and viral causes.[25] Poliosis, especially of the eyebrows, can be associated with vitiligo in up to 48% of cases, especially in patients with segmental vitiligo.[2,28,29]

Alopecia areata is a disorder characterized by poliosis resulting from an immune response leading to hair-related melanocytes destruction.[30] Poliosis is seen in about 5% of these patients, and they tend to be older with a male predominance. The white hair is believed to result from dysregulation of signaling pathways and transcription factors in the microenvironment surrounding the hair follicles or by an imbalance in the management of oxidative stress.[31,32] Selective involvement affecting pigmented hairs leaves a salt-and-pepper appearance.

Blepharitis is a common chronic inflammatory disorder affecting the eyelid margin.[33] It may be associated with several conditions such as chalazion, conjunctivitis, keratitis, rosacea, and seborrheic dermatitis. Chronic blepharitis may manifest with lid margin hypertrophy, scars, trichiasis, madarosis, and poliosis.[33]

Poliosis also has been reported to occur with both congenital and acquired nevi.[34,35] In congenital nevi, poliosis arises as the fetal melanocytes proliferate in the perifollicular area secondary to the arrest of migration from the neural crest to the hair bulbs.[1] This results in a congenital nevus in the skin with nonpigmented hairs growing out of it.[35,36] In acquired nevi, poliosis may develop circumferentially around the nevus several months after its appearance.[37,38,39,40,41] Lymphohistiocytic infiltration around nevus nests suggests that an inflammatory or autoimmune cytotoxic T cell response against the melanocytic nevi may destroy adjacent normal epidermal and follicular melanocytes producing a halo reaction and poliosis.[38,39,40]

Eyelash poliosis has been described in patients with sarcoidosis.[42] The humoral response is believed to play a role in causing hair depigmentation.[43] It has been postulated that depigmentation is the result of an autoimmune mechanism where overactivity of CD3 and increased expression of cytokines IL-1b, IL-2, IL-6, and TNF-a leads to T helper cell differentiation and subsequent activation of T cytotoxic cells and B-cells, which produce circulating antibodies against melanocytes.[44,45]

Poliosis associated with malignant neoplasms has been reported with melanoma of the scalp,[43] conjunctiva,[46] and orbit.[47] The pathogenesis of poliosis in these cases is not known, but it has been suggested that it may be related to inflammatory destruction of melanocytes in the hair follicle, apoptosis of the follicular melanocytes, or a targeted autoimmune response.[48,49] The malignant cells may initiate an immune response that cross-reacts with the normal follicular melanocytes.[43,49]

A number of drug-induced cases of poliosis have been described.[50,51,52,53] Topical prostaglandin analogs alter melanocyte tyrosinase activity in some hair follicles, reducing melanogenesis and leading to poliosis.[54,55] The white lashes are typically interspersed among normally pigmented eyelashes. The pathogenesis is uncertain, but it has been suggested that cytotoxic T cell activation leads to melanocyte destruction.[56] Topical chloramphenicol sometimes used after eyelid surgery has been associated with anterior uveitis, poliosis, and periocular vitiligo, possibly as a T cell-mediated hypersensitivity reaction against melanin or melanocytes.[57] Acitretin, a metabolite of the aromatic retinoid etretinate, is utilized in the treatment of psoriasis and has been associated with poliosis with alopecia.[51]

There are several case reports of poliosis not associated with any underlying disease. One was a 5-year-old girl with congenital macular hyperpigmentation of the nose and eyelash poliosis. The authors proposed that this represented somatic mosaicism for genes affecting pigmentation.[58] In another case, spontaneous poliosis of the eyelashes in a 68-year-old male was described as a possible rare representation of idiopathic poliosis.[37]

Clinical Presentation

The clinical presentation of eyelash poliosis may vary from one or two white lashes to involvement of the entire eyelid margin (Figure 104.1). It may involve one eyelid or all four *(Print pagebreak 689)* lids depending upon the etiology. Poliosis is usually not seen with other ocular or eyelid abnormalities, except where it is associated with a nevus, vitiligo, or malignancy. The condition can evolve rapidly over days to weeks or slowly over months to years. In rare cases, eyelash poliosis can be associated with trichomegaly with curled and brittle lashes or with trichiasis (Figure 104.2). In most cases, a history of a systemic syndrome or acquired eyelid condition as discussed above can be uncovered. However, poliosis can be the initial manifestation of some genetic disorders so that depending on the presence of other signs, a thorough evaluation may be in order.

FIGURE 104.1 Poliosis associated with vitiligo. (Courtesy of Dr. Alan McNab.)

Differential Diagnosis

The differential diagnosis of poliosis includes several genetic disorders such as Griscelli syndrome, Chediak-Higashi syndrome, Hermansky-Pudlak syndrome, and oculocutaneous albinism.[1,3] However, the distribution of white hair in these syndromes is typically more diffuse than in poliosis. Another condition that can be confused with poliosis is white piedra, a mycotic infection caused by yeasts of the genus *Trichosporon* where individual hairs exhibit barely visible but palpable whitish to cream-colored,

easily detachable nodules 1 to 1.5 mm in size present over the shaft of hairs on the scalp, eyebrows, and eyelashes.[59,60,61,62]

Treatment

There is no specific treatment for poliosis. In most cases the condition is permanent, and when the eyelashes and eyebrows are involved the condition can be socially disabling. Treatment is directed toward cosmetic improvement such as with hair dyes.[63] In cases where poliosis is associated with segmental vitiligo, treatment with a 308-nm excimer laser has been reported to show 75% or more repigmentation of the white hairs.[64] A case of a halo nevus on the eyelid margin with localized poliosis of the eyelashes was treated with wedge resection of the involved region including the white eyelashes.[39]

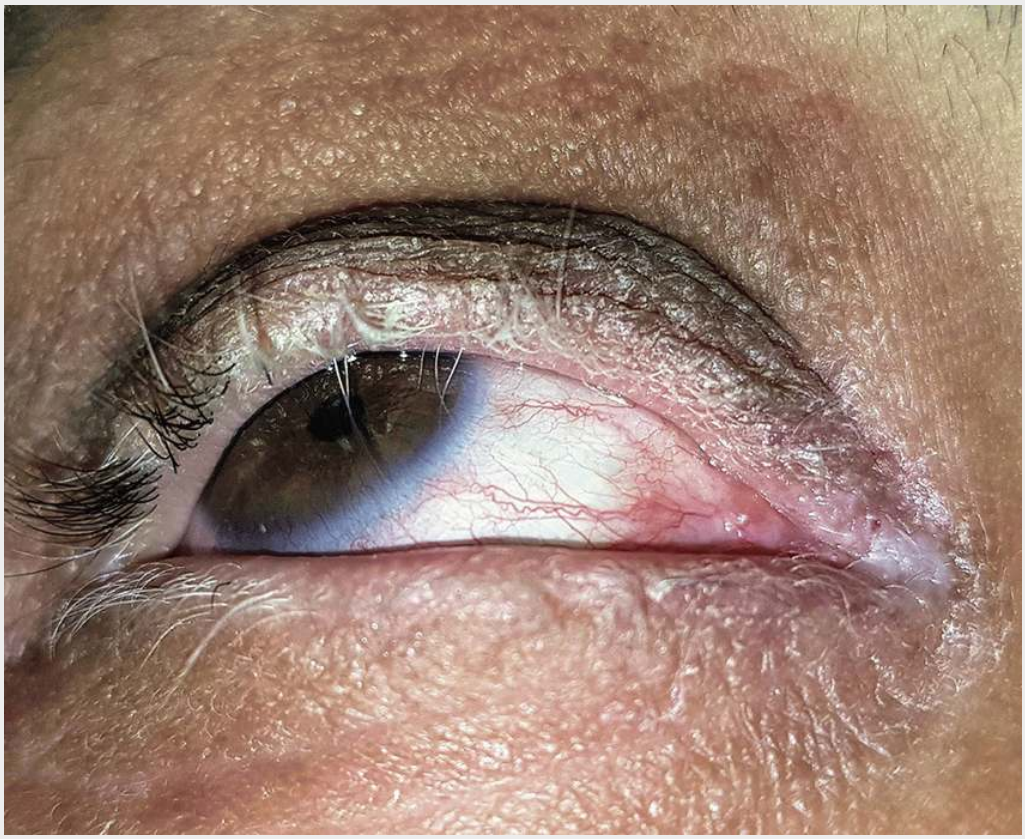

FIGURE 104.2 Poliosis associated with trichiasis. To the best of our knowledge, this association is hitherto unknown and could be accidental.

Prognosis

Some cases of poliosis will resolve following management of the underlying inciting condition. A child with intracranial ganglioglioma and brow poliosis showed resolution of the poliosis following tumor resection.[65] In a series of 22 patients with VKH disease treated with corticosteroids and cytotoxic agents, six (27%) showed reversal of the poliosis after treatment, suggesting restoration of normal immune homeostasis.[21] A case of poliosis and abnormal eyelash growth associated with cetuximab treatment for metastatic colorectal cancer was reported to resolve 1 month after cessation of drug therapy.[52]

Histopathology

There is no histopathologic description for poliosis.

CHAPTER 105

Pseudoepitheliomatous Hyperplasia

Key Points

- Secondary pseudoepitheliomatous hyperplasia (PEH) is a benign proliferative pseudoneoplastic response to trauma, wounds, burns, radiation therapy, cryotherapy, pharmaceutical agents, and cutaneous malignancies
- Primary PEH has no clinical or histopathological evidence for a definite etiology
- Keratinocyte proliferation is likely a secondary phenomenon due to cytokine expression by activated immune cells
- Clinically, it presents as a nodule or plaque of various sizes with a rugose surface, scaling, and occasionally crusting and ulceration evolving rapidly over several days to weeks
- Surgical excision is considered the most appropriate treatment to provide a definitive diagnosis and to rule out malignancy
- The prognosis is good following surgical resection

Pseudoepitheliomatous hyperplasia (PEH) is a benign proliferative pseudoneoplastic response to trauma, wounds, burns, radiation therapy, cryotherapy, pharmaceutical agents, and cutaneous malignancies.[1,2,3,4,5,6,7,8,9] It can simulate basal cell carcinoma clinically and squamous cell carcinoma (SCC) histopathologically, which often complicates the initial diagnosis and management.[4] One case of PEH was reported to be associated with a cutaneous horn.[10]

PEH can be secondary or idiopathic.[3,5] Secondary PEH is by far the most common form, associated with a known etiology such as infectious agents, insect bites, some drugs, or cutaneous malignancies. It also has been reported after Mohs micrographic surgery[11] and following diode laser therapy.[13] In primary PEH on the other hand, there is no clinical or histopathological evidence for a definite etiology.[14] These lesions have been described under various names such as verrugoma, molluscum sebaceum, and self-healing squamous cell epithelioma.[14]

Clinically, the most important associations of PEH are with malignant cutaneous tumors such as SCC, basal cell carcinoma, melanoma, cutaneous lymphoma, pulmonary adenocarcinoma, and metastatic breast cancer.[15,16,17,18,19,20,21] This makes initial biopsy or excision necessary to uncover the underlying pathology.

Besides its cutaneous manifestations, PEH can involve the conjunctival epithelium,[22,23,24,25] where it can be associated with vernal keratoconjunctivitis,[22,25] possibly resulting from chronic inflammation exacerbated by mechanical trauma to the limbal epithelium.[23] It also has been described as a complication of cultivated limbal epithelium transplantation.[23]

PEH is frequently associated with tattoo dye. The development of PEH in response to red tattoo pigment was first reported by Sulzberger in 1937.[26] In 1959, Goldberg[27] further defined this condition as multiple verrucous papules within an area of red ink. The verrucous growth pattern is often mistaken for SCC, which is important clinically since cases of SCC have also been reported arising in tattoos.[28,29,30,31,32] Although most reported tattoo-related PEH cases were associated with the use of either red or purple dye,[33,34,35,36] occasional cases also have been seen in black, green, and blue tattoos.[30,37] While PEH has not been described associated with blepharopigmentation, granulomatous reactions have been reported.[38,39,40]

The interval between tattooing and the onset of PEH varies from several days to several years. Upon transfer of the pigment into the dermis, pigment granules are ingested by skin phagocytes and a transient inflammatory period, characterized by a foreign body reaction and fibrous tissue formation, begins and lasts about 2 weeks.[41] Later, the pigment becomes encapsulated in dense layers of connective tissue located in the papillary dermis either within fibroblasts or between collagen bundles.[41]

Etiology and Pathogenesis

The tissue of origin for PEH has been a matter of controversy. Grunwald et al proposed that PEH is not a hyperplasia of the epidermal epithelium, but rather a hyperplasia of the adnexal epithelium of the follicular infundibula,[12,42] and Tuttle et al[17] reported 25 cases of infiltrative basal cell carcinoma associated with PEH with primarily a follicular differentiation pattern. In an experimental study of PEH occurring during the healing stages of cutaneous leishmanial ulcers in mice, Akilov et al[43] showed that the epidermal proliferation mostly involved epithelial structures of the hair follicle infundibula and that there was a continuity between the pseudoepitheliomatous epithelium and preexisting follicular infundibula and the proliferating epithelium. This suggests a follicular origin for PEH. Other authors argued that the hyperplastic epithelium is of eccrine origin, based on the observation that PEH is most commonly encountered on mucosal surfaces rich in salivary glands.[44,45]

The molecular mechanisms that underlie the etiopathogenesis of PEH are unknown.[44] These lesions appear to be an epithelial response to trauma or compression or might *(Print pagebreak 693)* result from aberrant expression of trophic epidermal growth factors.[43] Several cytokines and growth factors play a role in sustaining persistent dermal inflammation and epidermal proliferation, both of which are major characteristics of PEH. The regulation of leukocyte activation and recruitment plays a major role in the production and maintenance of PEH lesions, likely through the production of TNF-α and IFN-γ. Fibroblast stimulation by TNF-α may result in increased keratinocyte growth factor production, leading to abnormal keratinocyte hyperplasia.[43] Epidermal growth factor and transforming growth factor are also involved in epidermal proliferation, differentiation, and wound healing,[46] and it has been postulated that dysregulation of these factors may be important in the development of PEH.[47,48]

Keratinocyte proliferation is likely a secondary phenomenon due to cytokine expression by activated immune cells. The development of PEH may play a role in the normal healing process of ulcers and necrotic tissue through the process of transepidermal extrusion, where removal of damaged or necrotic tissue is enveloped within the proliferating epithelium.[49] PEH may be a means of removing superficial necrotic or other abnormal material and may be a physiological response to different forms of skin damage or disease where such foreign body material is present.[43] The presence of pathogenic bacteria in cutaneous wounds has been suggested to be a possible predisposing factor of PEH formation in some patients, and in a case of Mycobacterium ulcerans, Hayman et al[50] concluded that PEH represented a mechanism for active extrusion of necrotic material containing viable mycobacteria and should be seen as part of a protective physiological response to the infection.

The pathophysiology of PEH secondary to tattoos remains uncertain. It has been hypothesized that pigment granules act as foreign bodies causing early inflammation that could result in the development of PEH.[41] Alternatively, PEH has been regarded as an autoimmune reaction where epidermal hyperplasia results from lymphocyte-derived chemokines that promote keratinocyte proliferation.[41]

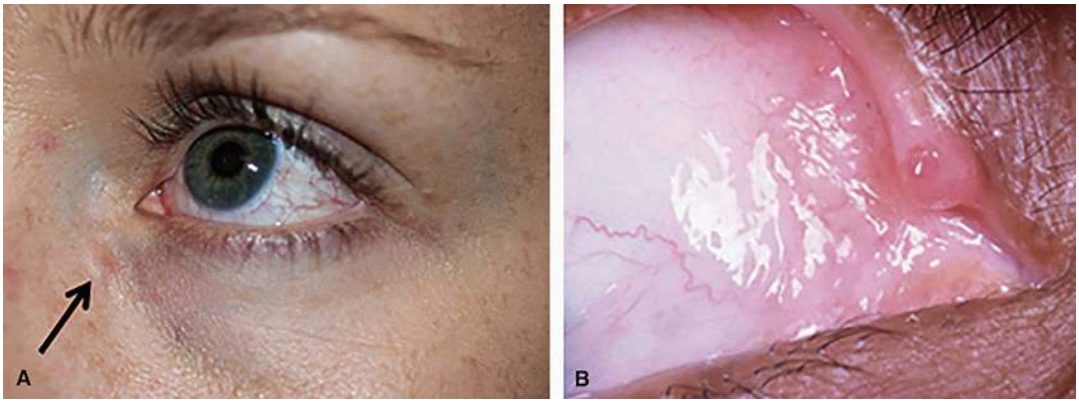

FIGURE 105.1 A, Subcutaneous nodule of pseudoepitheliomatous hyperplasia (PEH) in the medial lower eyelid. B, PEH around the superior punctum. (A, Courtesy of Dr. Suzanne Freitag. B, Reprinted with permission from Bothra N and Ali JM. Punctal pseudoepitheliomatous hyperplasia mimicking a mass lesion. *Orbit*. 2021;40(1):73-74.)

Clinical Characteristics

PEH of the head and neck can occur in patients of any age but are most prominent in the fifth and sixth decades. Clinically, they present as a nodule or plaque of various sizes with a rugose surface, scaling, and occasionally crusting and ulceration (Figure 105.1).[51] It often develops rapidly over several days to weeks. In burns, multiple dark red, soft to firm, fleshy granulomatous lesions tend to be confluent, associated with inflammation at the wound edges.[2]

On the conjunctiva, PEH presents as a white, hyperkeratotic, elevated proliferation of the conjunctival or corneal epithelium. It can be misidentified as ocular surface squamous neoplasia, especially when it arises at the corneal limbus.[24]

Differential Diagnosis

PEH can be confused with a variety of benign and malignant lesions. Squamous and basal cell carcinomas are the most frequent lesions that must be included in the differential diagnosis. When occurring on the conjunctiva, it can be confused with squamous neoplasia or nodular episcleritis.[52]

Treatment

There is no standard or optimal treatment for PEH. Because these lesions are often confused with cutaneous malignancies, surgical excision is usually considered the most appropriate treatment to provide a definitive diagnosis. Neither cryosurgery nor laser therapy has proven to be useful, and both have been associated with the development of PEH.[9,13,53] Photodynamic therapy is ineffective for the treatment of *(Print pagebreak 694)* PEH.[54] Some PEH lesions have been reported to gradually regress spontaneously over several months without treatment,[55] but given its similarity to malignant lesions in many cases, few lesions are observed conservatively.

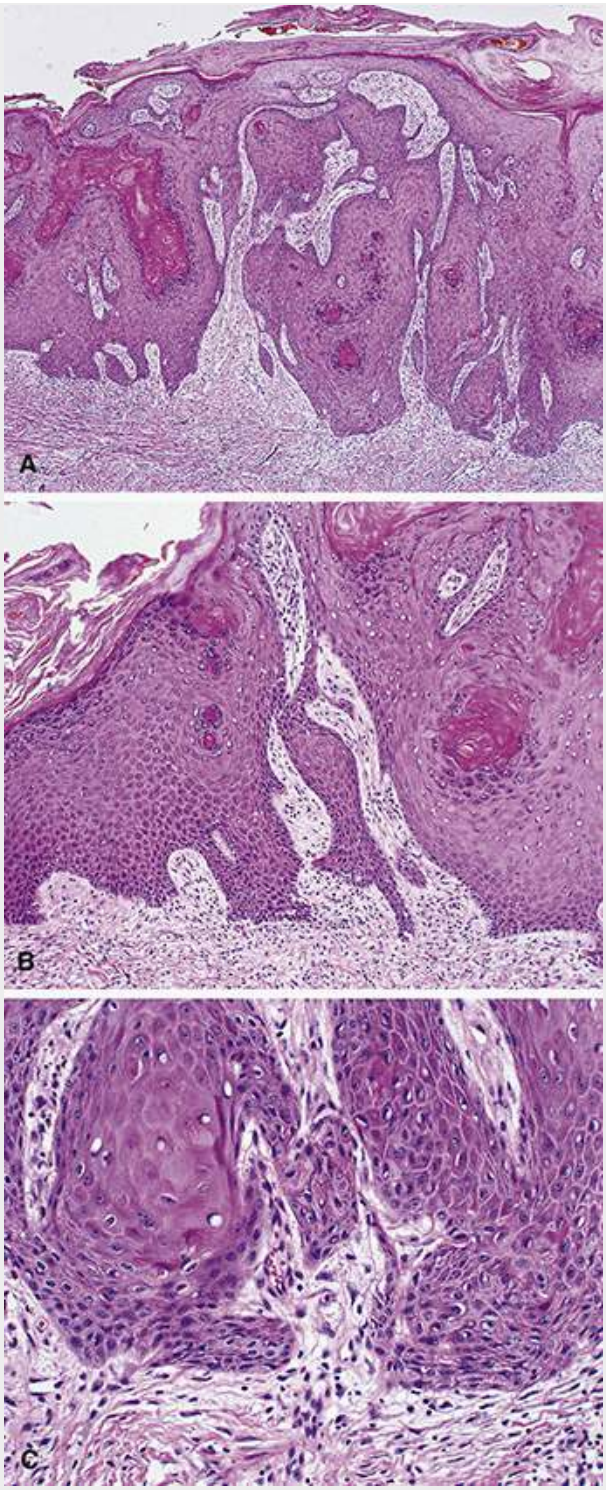

FIGURE 105.2 Cutaneous pseudoepitheliomatous hyperplasia at the site of newly formed scar from recent melanoma surgery. A, The epidermis has extensive irregular hyperplasia with anastomosing downward projections into the dermis with jagged borders and rounded or pointed bases. B, The epidermis has hyperkeratosis, and keratin pearls are in the anastomosing epidermal masses projecting into the dermis. C, There is minimal cytological atypia and foci of keratinization with brightly eosinophilic cytoplasm.

Prognosis

The prognosis for PEH is good following surgical resection for lesions associated with benign conditions such as wounds, burns, or tattoos. When PEH arises from infectious lesions or malignant tumors, the prognosis will depend upon the underlying pathology and its management.

Histopathology

Cutaneous PEH manifests as extensive irregular hyperplasia of the epidermis with downward projections of the epidermis into the dermis with jagged borders and often pointed bases (Figures 105.2 and 105.3).[51,56] The epidermis often has hypergranulosis and hyperkeratosis or parakeratosis.[51] The epidermal projections may anastomose,[56] and there may be keratinization and formation of "keratin pearls."[42,51] Hyperplastic epidermis may appear as discrete islands within the dermis.[42] PEH differs from SCC by having minimal cytological atypia, fewer mitoses, no abnormal mitotic figures, and no vascular, lymphatic, or perineural invasion.[42,51,56] Identification of an underlying pathological stimulus for PEH also helps to differentiate PEH from invasive SCC.[42]

Conjunctival PEH has thickened epithelium that may have parakeratosis or hyperkeratosis, extension of the hyperplastic epithelium into the substantia propria with jagged borders, and there may be keratin cysts and numerous *(Print pagebreak 695)* mitoses (Figure 105.4).[24,57,58] Lack of nuclear atypia differentiates conjunctival PEH from invasive SCC.[24] Extension of inflammatory cells into the hyperplastic epithelium may be seen with PEH but is rare in conjunctival SCC.[24]

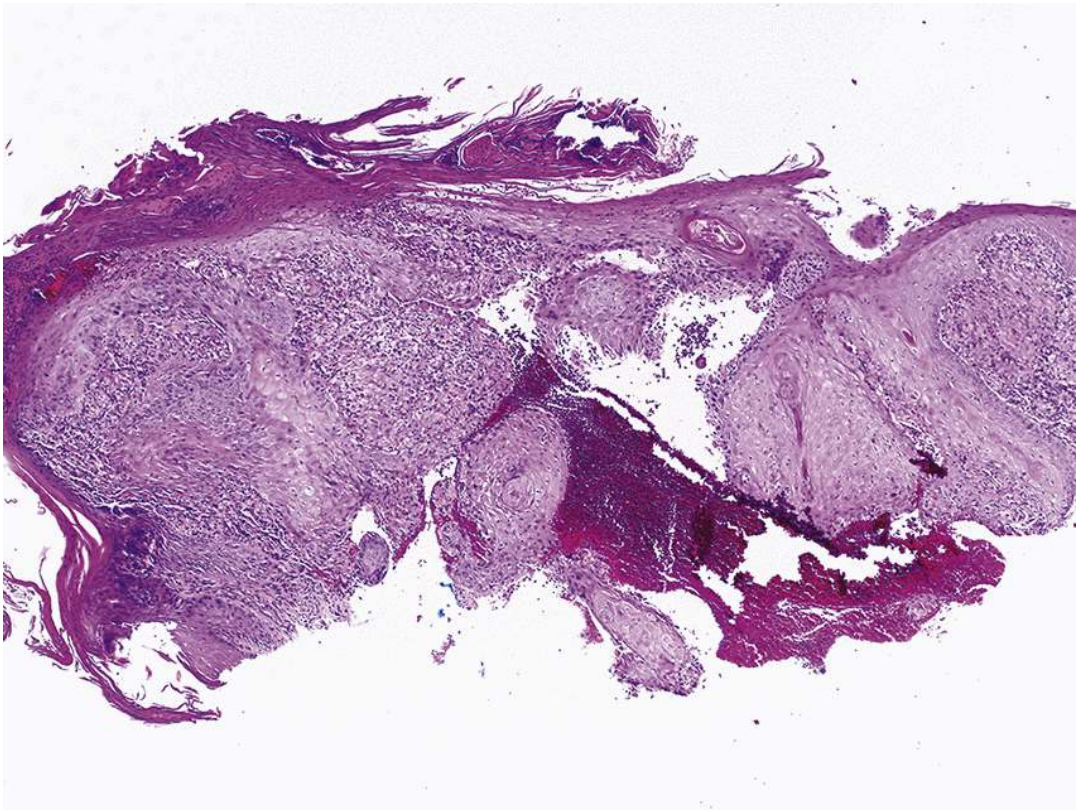

FIGURE 105.3 Pseudoepitheliomatous hyperplasia of the right upper eyelid in a man with ulcerative sarcoidosis. There is a thick layer of parakeratosis and pseudoepitheliomatous hyperplasia of the epidermis. The dermis has non-necrotizing granulomatous inflammation with a sparse lymphocytic infiltrate around discrete and coalescing granulomas. The focal hemorrhage at the base of the lesion is from the biopsy.

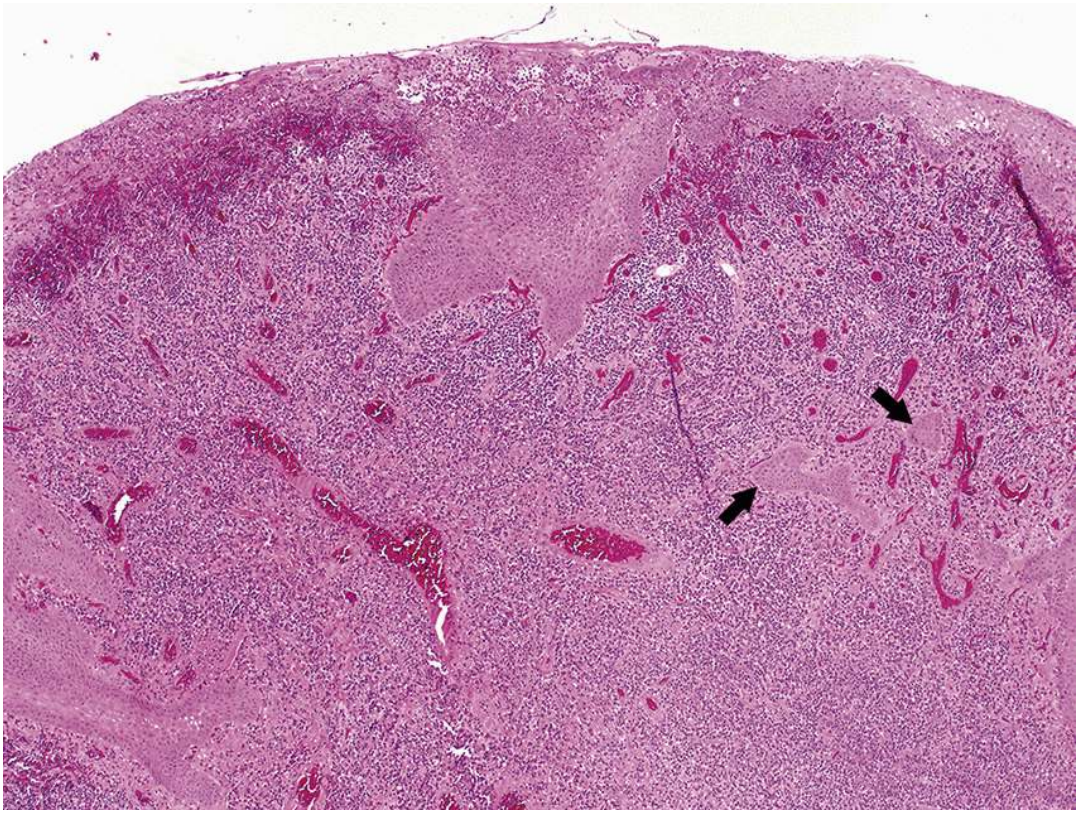

FIGURE 105.4 Pseudoepitheliomatous hyperplasia of the conjunctiva in a middle-aged man with herpes simplex virus conjunctivitis secondary to immunosuppression. There is an irregular thickening of the conjunctival epithelium with extension into markedly inflamed substantia propria. There are discrete, isolated nests of epithelium in the substantia propria (arrows).

CHAPTER 106

Punctal Stenosis and Agenesis

Key Points

- Punctal stenosis is a condition in which the proximal external openings of the nasolacrimal drainage system on the medial eyelid margins are narrower than normal
- Punctal agenesis refers to the congenital absence of the external punctum
- Punctal stenosis can be associated with aging, inflammatory syndromes, infectious agents, drugs, and local eyelid therapies such as surgery or laser treatment
- Etiologies vary but are often related to gradual fibrotic changes and progressive occlusion of the punctum
- Patients with punctal stenosis or agenesis most commonly complain of epiphora and in some cases lower lid ectropion
- Treatment of punctal stenosis is usually with punctal dilatation, minor surgical techniques such as punctoplasty, or the placement of perforated punctal plugs or silicone stents
- In patients with eyelid laxity or frank medial ectropion associated with punctal stenosis, lower eyelid horizontal tightening should also be performed
- The prognosis of punctal stenosis is usually excellent, and most patients can achieve a patent and normally draining proximal NLD system

Acquired punctal stenosis is a condition in which the proximal external openings of the nasolacrimal drainage system on the medial eyelid margins are narrower than normal. Stenosis of the puncta may also be accompanied by canalicular stenosis.[1] In contrast to stenosis, punctal agenesis refers to a complete congenital occlusion or absence of the external punctum.

The normal anatomy of the punctum varies greatly.[2] Common textbook measurements for normal punctal diameter generally range from 0.2 to 0.5 mm.[3,4,5,6] However, in formal studies, mean punctal diameters as measured visually, by infrared imaging, or by optical coherence tomography have varied from 0.1 to 0.9 mm.[2,7,8,9,10,11,12,13,14] As a result, the concept of what constitutes punctal stenosis is unclear and there does not appear to be any standard definition of a specific size. In the widely used Kashkouli grading system for punctal stenosis,[15] grade 2 is “less than normal size,” grade 3 is “normal regular size,” and grade 4 is “small slit <2 mm” without further definition. Caesar and McNab[16] defined punctal stenosis for their study as a diameter of less than 0.3 mm or the inability to intubate the punctum with a 26 G cannula (outer diameter 0.47 mm) without dilation.

The incidence of punctal stenosis has not yet been studied, but two reports have evaluated the prevalence of the disease. Of 682 patients seen in a hospital-based population, 54.3% had an element of punctal stenosis.[17] Another study showed a prevalence of 17.3% of punctal stenosis among 621 individuals in the general population in Spain.[18] In a study from Turkey on 278 patients 65 years and older, the prevalence of punctal stenosis was 63%, of which 48.9% also had chronic blepharitis, and other associated factors included the use of glaucoma medications and lower eyelid ectropion.[19] However, among 20,102 patients with lacrimal drainage disorders in India, only 3% were diagnosed with punctal stenosis,[20] and in a study from Canada of 150 patients with epiphora, 8% were diagnosed with proximal nasolacrimal duct (NLD) (punctal or canalicular) obstruction.

Patients with significant punctal stenosis requiring treatment predominantly have been older women at a mean age of about 65 years.[1,15,16,21,22,23] The most common clinical conditions associated with punctal stenosis include blepharitis, chronic conjunctivitis, meibomian gland dysfunction, and eyelid malpositions.[1,15,16,21,22,23,24] The preponderance of associations with inflammatory conditions and histopathology suggest a common mechanism of chronic inflammation resulting in fibrosis that progressively leads to narrowing of the punctum.[25] In several studies, chronic inflammation was found on histopathology of stenotic puncta in 80% to 100% of cases.[23,26,27]

Punctal stenosis has also been associated with a very large number of other conditions, although specific etiologic relationships are not always established. These include involutional changes such as aging; inflammatory syndromes such as ocular cicatricial pemphigoid and graft vs host disease; infectious agents such as *Chlamydia trachomatis*, herpes virus, and actinomyces; topical eye drops and systemic medications such as timolol, latanoprost, betaxolol, chloramphenicol, tobramycin, mitomycin C, 5-fluorouracil, and docetaxel; and local eyelid therapies such as photodynamic therapy.[15,28,29,30,31,32,33,34] An increased association was also reported with outdoor occupational activities, but not with tobacco and alcohol consumption, or with some systemic diseases such as rosacea, allergy, or diabetes.[18,30]

Punctal dysgenesis is a general term used for maldevelopment of the lacrimal punctum. It includes everything from incomplete punctal canalization to true punctal agenesis.[35] Familial association has been reported in 36% of cases and a syndromic association in 40%.[36]

(Print pagebreak 698)

Punctal agenesis was first documented in 1846 by Blanchet and is defined as an absence of the lacrimal punctum secondary to a defect in embryogenesis.[37] Although the epithelium of the lacrimal canaliculi makes contact with the conjunctiva in embryos at 9 to 10 weeks of gestation, the puncta remain occluded by a combination of conjunctival and canalicular epithelium until about 7 months of gestation.[38] Disruption at any point in this developmental process can lead to punctal dysgenesis.[39] One to or both puncta can be involved in one eye, but the condition can also be bilateral.[40] Epiphora is the most common presenting symptom, and a positive family history was reported in 26% of 50 patients with punctal agenesis.[40]

Incomplete punctal canalization refers to a form of punctal dysgenesis with external and internal punctal membranes.[41,42,43] In the external membrane variant, the membrane covers the external surface of the puncta simulating punctal agenesis. The internal membrane variety has a membrane just at the entrance into the punctum. Both varieties can be misdiagnosed as congenital nasolacrimal duct obstruction in pediatric patients or as punctal agenesis.[41,44] Clinical diagnosis is based on the presence of a translucent membrane with slight avascular dimpling at the site of the normal punctum.[41] Occasionally a balloon subtype can be seen with the external membrane variety where the translucent membrane is ballooned upward as a dome that merges with the tarsal conjunctiva.[42] The pathogenesis of punctal membranes is unknown but is believed to represent either failed dehiscence of the epithelium overlying the normally formed canaliculi or an incomplete canalization of the proximal-most part of the lacrimal drainage system.[42]

Etiology and Pathogenesis

Many factors have been implicated in the pathogenesis of acquired external punctal stenosis. Involutional changes associated with old age have been identified as factors causing punctal stenosis in several studies.[2,15,45] Eyelid inflammation, especially chronic blepharitis leading to gradual fibrotic changes and progressive occlusion of the punctum is also a major cause of punctal stenosis.[15,17] Dry eye syndrome has also been suggested as an etiological factor.[17] Eyelid infections such as trachoma, herpes simplex, chlamydia, actinomyces, and human papillomavirus may also be important factors.[16,28,29]

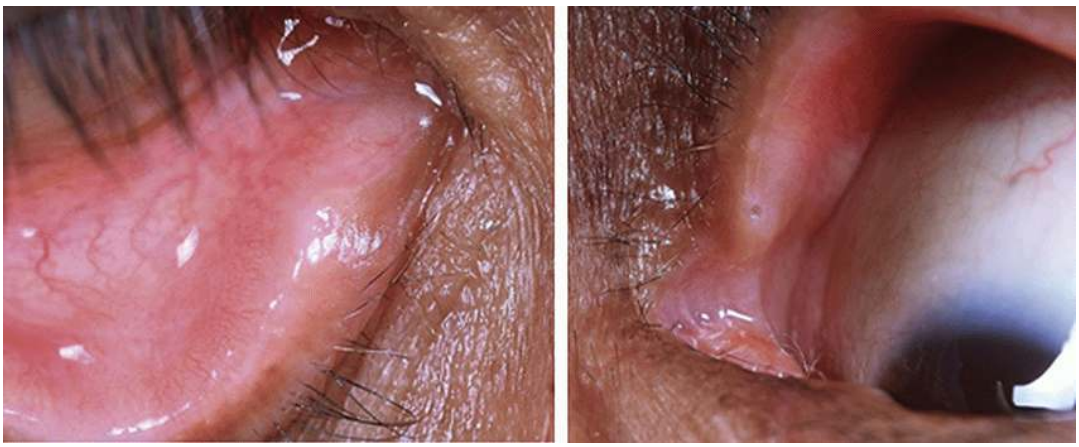

FIGURE 106.1 Lower eyelid punctal stenosis showing its small size. (Courtesy of Dr. Javed Mohammad Ali.)

Topical medications such as the antiglaucoma agents timolol, latanoprost, betaxolol, dipivefrin hydrochloride, echothiophate iodide, and pilocarpine have also been associated with punctal stenosis.[15,46] Other topical agents including prednisolone acetate, dexamethasone, phenylephrine hydrochloride, adrenaline, tobramycin, chloramphenicol, indomethacin, tropicamide, and naphazoline have also been suggested as causes of punctal stenosis.[46] Topical mitomycin C for ocular surface neoplasia has also been associated with punctal stenosis.[47,48,49] Systemic chemotherapeutic agents such as 5-fluorouracil, docetaxel, and paclitaxel

have also been associated with punctal stenosis and canalicular fibrosis.[22,32,50,51,52,53] Idoxuridine has also been thought to be a causative agent.[54]

Eyelid malpositions, particularly lower lid ectropion, can also cause punctal stenosis.[15,55,56,57,58,59] Very rare eyelid lesions including benign and malignant tumors near or around the puncta can also narrow the puncta.[56,57,58,59]

Clinical Characteristics

Patients with punctal stenosis most commonly complain of epiphora, but depending upon the degree of punctal narrowing and the association with other factors such as dry eyes, they may also be asymptomatic. While concurrent canalicular stenosis may also be present in some cases, for the most part, following dilatation and irrigation, the canalicular and lower nasolacrimal drainage systems are usually patent. The punctum is smaller than normal, usually smaller than 0.2 mm in diameter (Figure 106.1). Blepharitis is a common *(Print pagebreak 699)* associated finding, and lower eyelid malposition, such as generalized or medial ectropion, may also be noted.

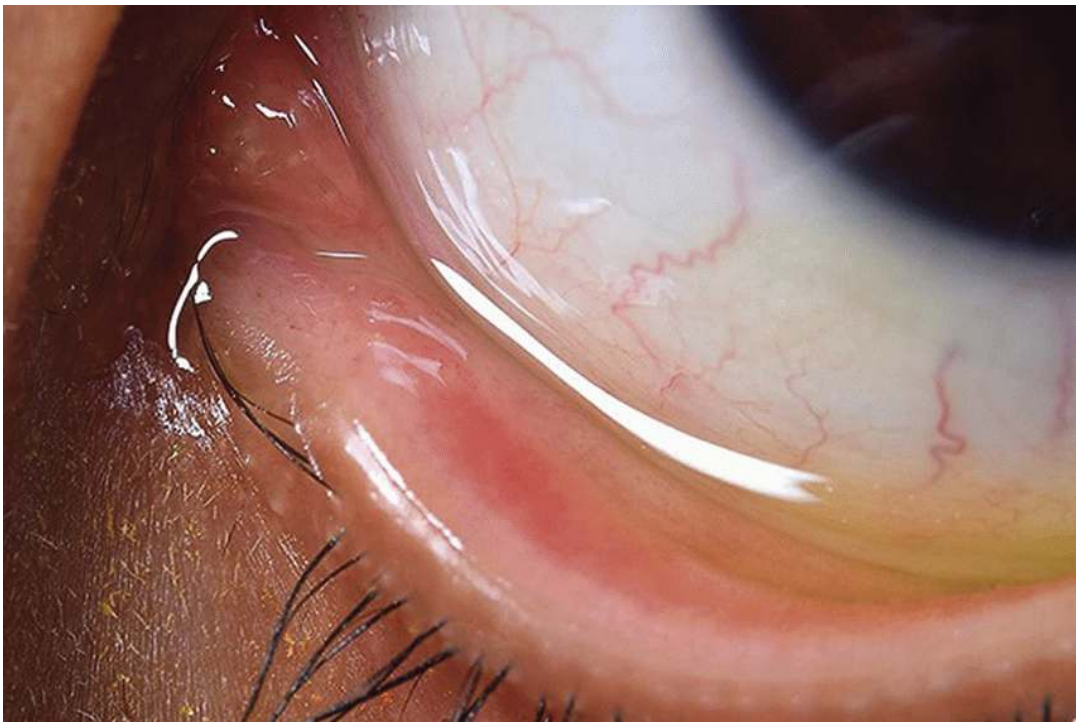

FIGURE 106.2 Punctal agenesis. (Courtesy of Dr. Javed Mohammad Ali.)

In patients with punctal dysgenesis or agenesis, the punctum is absent (Figure 106.2), epiphora is almost always, and there may be a positive family history.

Differential Diagnosis

The differential diagnosis of punctal stenosis includes a normal variant of punctal size. As previously discussed, normal puncta in asymptomatic patients may be as small as 0.1 mm, which by most evaluations might be considered “stenotic.” Benign peripunctal eyelid lesions, such as nevi, inclusion cysts, squamous papilloma, pyogenic granuloma, oncocytoma, and punctal keratinizing cyst, as well as a variety of malignant lesions can also partially or completely occlude the lacrimal punctum.[57,58,59,60,61,62,63,64]

Treatment

Several medical and surgical approaches are available for the management of punctal stenosis. In cases where punctal stenosis is associated with dry eyes or which are otherwise asymptomatic, no intervention is necessary. In patients where there is a history of topical ocular medications, cessation of the offending agent should be tried at first before proceeding with surgical intervention. Where bothersome epiphora is present, treatment may include minor surgical techniques such as punctoplasty, or the placement of reversible perforated punctal plugs or silicone stents. In patients with eyelid laxity or frank medial or

generalized ectropion associated with punctal stenosis, lower eyelid horizontal tightening should be performed with a lateral tarsal strip or alternative procedure along with any punctal procedure. Since chronic blepharitis or conjunctivitis are common associated findings, these should be managed appropriately before the correction of punctal anatomy.

Perforated punctal plugs are widely used for the management of punctal stenosis. It can be performed in an office setting where the punctum is dilated and the plug is placed in the external punctum. When left in place for several months, it may result in permanent dilation of the punctum with a reported success rate of 84.1%.[65]

Placement of a mini-Monoka silicone stent is appropriate for cases of punctal stenosis combined with canalicular stenosis. Instead of a punctoplasty, the system is dilated followed by stenting.[66] A success rate of 82% of 123 eyes with a limited follow-up of only 6 months was reported in one study.[67]

The one-snip punctoplasty was initially reported in 1853 by Bowman[68,69] using a full-length incision along the canaliculus. The technique was later modified by introducing a vertical snip along the ampulla.[70] Subsequent modifications have introduced 2, 3, and even 4 snips to accomplish enlargement of the punctum with resection of the posterior lip or ampulla wall. Success rates as high as 91% have been reported.[16,71]

In a small study of 44 eyes in 50 patients with inflammatory punctal stenosis treated with a topical antibiotic and steroid combination, evaluated with anterior segment OCT, and followed for 6 weeks, Awny et al[72] reported significant increase in punctal diameter from 228 μm to 373 μm and a significant reduction in the Munk score.

In patients with asymptomatic punctal agenesis with no epiphora or infection, observation alone is appropriate. If the underlying canalicular system is normal in cases of punctal dysgenesis, the canaliculus can be exteriorized to the conjunctival surface by membrane lysis using a punctal dilator.[73]

Prognosis

The prognosis of punctal stenosis is usually excellent, and most patients can achieve a patent and normally draining proximal NLD system following surgical punctoplasty or dilation with or without silicone stenting.

Histopathology

The normal human lacrimal punctum is funnel-shaped,[74] and nonkeratinizing stratified squamous epithelium covers its surface and inner lining.[75] The nonkeratinizing stratified squamous epithelium of the punctal surface merges with keratinizing stratified squamous epithelium of the eyelid and goblet cell-containing epithelium of the palpebral conjunctiva.[75] Dense fibrous connective tissue encircles the punctum[3,76] and contains elastic fibers[77] and the muscle of Riolan.[3]

Port and coworkers examined 30 three-snip punctoplasty specimens from 24 patients with punctal stenosis associated with one or more associated ocular conditions, including blepharitis, dry eye syndrome, or Meibomian gland dysfunction, or use of ocular medications associated with the development of punctal stenosis.[23] The authors observed chronic inflammation in 11 specimens (37%), fibrosis in 7 specimens (23%), chronic inflammation and fibrosis in 4 eyes (13%), squamous metaplasia in 3 eyes (10%), normal conjunctival mucosa in 3 eyes (10%), and *Actinomyces* species *(Print pagebreak 700)* in 2 specimens (7%).[23] In a subsequent report by Ali and colleagues, 20 punctoplasty specimens were examined by light microscopy and 6 by transmission electron microscopy.[26] The clinical characteristics of the patients were not provided.[26] "The universal histopathological and ultrastructural feature noted in the punctae was the presence of fibrosis involving the subepithelial areas of both canalicular and conjunctival epithelium."[26] Eighty percent (16/20) of the specimens exhibited chronic inflammation, and this was severe in 20%.[26] Two more recent studies examined the histopathological features of punch biopsy[25] and three-snip[78] punctoplasty specimens from patients with primary punctal stenosis. Jang et al identified subepithelial fibrosis in 83% and inflammation in 17% of the punch biopsy specimens,[25] while Eroglu et al identified fibrosis in 44%, inflammation in 23%, and fibrosis with inflammation in 26% of the three-snip punctoplasty specimens.[78] While it is tempting to conclude that fibrosis is the underlying histopathological correlate in many patients with acquired or primary punctal stenosis, it is crucial to note that none of the reports included control tissue from cadavers or orbital exenterations. Since dense fibrous tissue encircles the normal punctum, the significance of the fibrosis observed in the punctoplasty specimens requires clarification by additional studies.

CHAPTER 107

Pyogenic Granuloma

Key Points

- Pyogenic granuloma is a reactive benign vascular proliferation that can be seen on the skin or mucous membranes
- It can involve the conjunctiva and the eyelids as a sequel to incomplete surgical or traumatic wound healing
- The pathogenesis of PG is not well understood
- *BRAF* and *RAS* mutations have been demonstrated in some patients with PG believed to drive angiogenesis by enhancing the expression of several proangiogenic and proinflammatory molecules
- Lesions appear as small lumps that progressively increase in size, usually as a pedunculated mass with an underlying stalk of connective tissue and feeder blood vessels
- Topical steroids are usually prescribed as initial treatment but the addition of topical β-blockers can result in vasoconstriction within the lesion causing inhibition of vascular growth factors thus promoting apoptosis
- If medical measures fail, surgical excision followed by cauterization of the base of the lesion is recommended
- Following medical treatment or surgical excision, pyogenic granulomas usually heal with minimal scarring

Pyogenic granuloma (PG) is a commonly occurring acquired reactive tumor-like lesion or benign vascular proliferation that can be seen on the skin and mucous membranes throughout the body. PG frequently involves the conjunctiva and the eyelids and usually occurs as a sequel to incomplete surgical or traumatic wound healing.[1,2,3,4,5,6,7,8,9] Other less commonly used synonyms include granuloma pyogenicum, reactive tissue hyperplasia, acquired capillary hemangioma (pyogenic granuloma type), or lobular capillary hemangioma.[6,9,10,11] According to the latest iteration of the ISSVA (International Society for the Study of Vascular Anomalies) classification for vascular anomalies (May 2018), the term “PG” is still retained and is used interchangeably with the “term lobular capillary hemangioma.”

Etiology and Pathogenesis

The term “pyogenic granuloma” or “granuloma pyogenicum,” which is a relic of 19th century medicine, is a misnomer.[1,2,6,9,10] Because the inflammatory component is prominent, early pathologists erroneously implicated pyogenic bacteria. There is no bacterial infection or purulent inflammatory exudate involved, which belies the “pyogenic” prefix. Nor are epithelioid or giant cells observed, which negates that “granuloma” formation is involved in the histogenesis.[9,10]

The exact pathogenetic sequence of events underlying the development of PG on the eyelid is not well understood, but the quintessential event is an injury to the conjunctival epithelium,[6,7,9,10] particularly in the setting of a transverse conjunctival wound that transects the meibomian gland orifices, which may continue to express meibomian secretions for a few days hampering epithelial healing.[6,10] Alternatively, the presence of an exogenous agent like the sharp edge of a Jones Pyrex tube would also inhibit conjunctival healing and could result in the development of PG.[10] The older theory that a pyogenic granuloma is a reaction to foreign material is unlikely.[10,12,13]

Pyogenic granulomas may be classified as a primary (idiopathic) type or secondary to an insulting factor.[9] Primary lesions may appear de novo without any apparent cause[9]; however, this is an uncommon presentation. More commonly, pyogenic granulomas develop on top of preexisting chalazia even without a history of chalazion excision, due to minor trauma to the periocular region, or at the surgical site following chalazion excision. Other scenarios include the development of PG following transconjunctival surgical approaches to the orbital floor and transconjunctival blepharoplasty.[6,7,9,10] Other surgical procedures that may also be associated with the development of PG on the bulbar conjunctiva include strabismus surgery and scleral buckling, pterygium, or stent-related trauma with dacryocystorhinostomy surgery.[9,10,14,15,16]

Recently, *BRAF* and *RAS* mutations have been demonstrated in patients with secondary PG occurring on top of port wine stains.[17,18,19] *BRAF* and *RAS* drive angiogenesis by enhancing the expression of several proangiogenic and proinflammatory molecules.[17,18] Recent evidence also suggests that a viral etiology (herpesvirus type 1, Orf virus, and/or human papillomavirus type 2) may also be implicated.[19]

Clinical Presentation

Pyogenic granulomas can occur at any age or sex, but they have a predilection for male children and young adults.[18] A history of a prior insult such as surgery or trauma is usually elicited from the patient, and in cases where PG develops after chalazion excision, this may be interpreted by the patient as recurrence of the lesion. The patient should specifically be asked about a history of remote surgical procedures, particularly scleral buckling.[6,10]

(Print pagebreak 703)

Even when the patient denies any antecedent history, a ruptured chalazion, the presence of which may be unknown to the patient, can sometimes be felt as a palpable eyelid mass adjacent to the pyogenic granuloma upon clinical examination. Pyogenic granuloma is usually confined to the palpebral or bulbar conjunctiva. Rarely it may develop on the lid margin or the outer surface of the eyelid. It usually grows rapidly in the days to weeks after a conjunctival injury from surgery or trauma.[4] Typically, the new lesion starts as a small lump on the palpebral conjunctiva, progressively increasing in size, and may even protrude from the eyelids.[4] The shape of the lesion is variable from patient to patient.[9] It may rarely present as a sessile, broad-based lesion but more commonly presents as a pedunculated lesion with an underlying stalk of connective tissue and feeder blood vessels (Figure 107.1).[7] Lifting the tip of the granuloma off the surface of the conjunctiva usually demonstrates the peduncle.[9] Pyogenic granulomas are usually reddish and of friable consistency that may bleed on the slightest touch or even spontaneously because they receive florid blood supply from the conjunctive.[4,6,7,9]

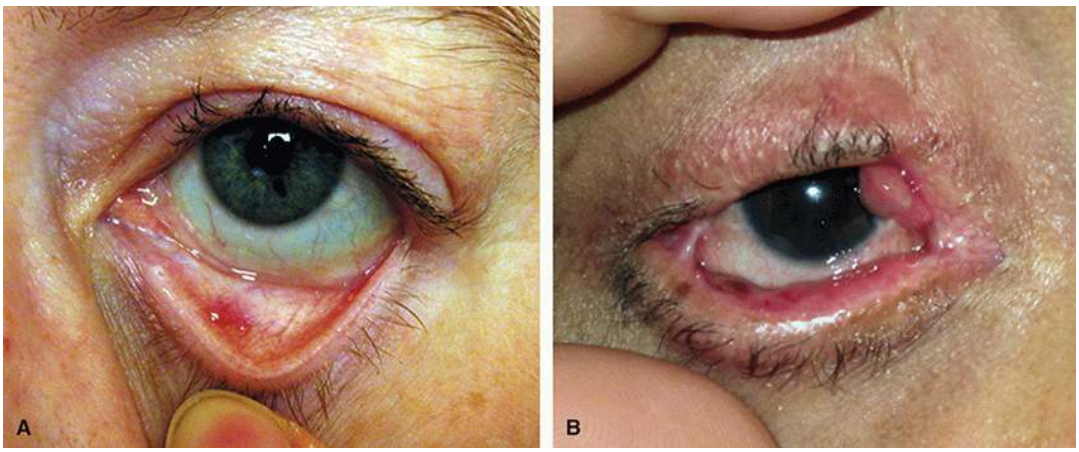

FIGURE 107.2 A, PG of the lower eyelid palpebral conjunctiva. B, Lateral upper eyelid PG from the conjunctiva associated with a traumatic defect. A, (Courtesy of Dr. Robert A. Goldberg.)

Pyogenic granulomas may also develop as an inflammatory outgrowth from the upper or lower punctum in patients with canaliculitis or after punctal plug insertion due to mechanical stress on the canalicular epithelium with attendant epithelial injury (Figure 107.2).[9,12,20] They can also be observed *(Print pagebreak 704)* in the medial canthal region following silicone intubation or after placement of a Jones Pyrex tube, or in an anophthalmic socket beneath an ocular prothesis (Figure 107.3).[12,21]

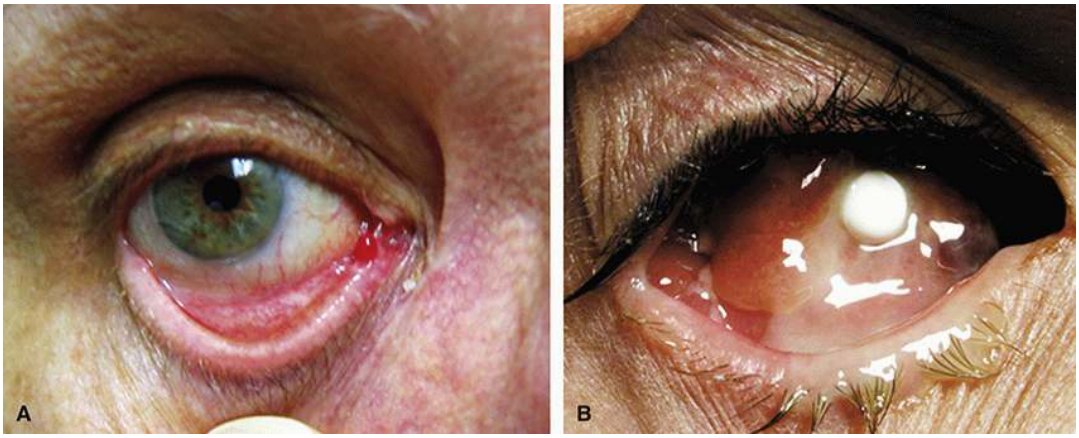

FIGURE 107.3 A, A small PG arising from the inferior punctum. B, An extensive PG in the medial canthal palpebral conjunctiva and the medial bulbar conjunctiva. B, (Courtesy of Dr. Robert A. Goldberg.)

Differential Diagnosis

Although the typical clinical picture combined with a history of chalazion excision or other conjunctival surgery or trauma easily establishes the diagnosis, pyogenic granuloma may be confused with several other entities. These include other vascular tumors of the eyelid or conjunctiva, particularly acquired or cherry angioma of the eyelid, which is considered by some authorities to be a variant of PG.[22] Other vascular tumors of the conjunctiva such as infantile hemangioma, lymphatic malformation, lymphangiectasia, Kaposi sarcoma, varix, cavernous venous malformation, racemose hemangioma, cherry angioma, glomangioma, and solitary fibrous tumor should be excluded as well.[8,18]

The differential diagnosis should also include conjunctival foreign body granulomas (teddy bear granuloma) caused by embedded synthetic fibers or eyelashes, a condition that is typically observed in the inferior fornix.[23,24,25] The color of those lesions is usually whitish yellow, which can help differentiate them from pyogenic granulomas. However, a bluish-black color can be encountered as well and may be difficult to discern from PG.[26]

Ointment granulomas, which may occur due to exposure of an open conjunctival wound to ophthalmic ointments containing petrolatum or paraffin, may also simulate a pyogenic granuloma.[27] Clinically, they present as unilateral or bilateral reddish or inflamed eyelid bumps following sutureless transconjunctival lower eyelid surgery.[27] If the diagnosis is in doubt, microscopic evaluation can help clinch the diagnosis because even in the setting of foreign body granulomas or ointment granulomas, the histopathological features are unique and distinct from a pyogenic granuloma.[23,24,25,26,27] Pyogenic granulomas may also mimic rare eyelid entities like amelanotic melanoma[18] or eyelid metastasis, which may occur with or without a detectable primary lesion.[28,29]

Treatment

Topical steroids have been routinely prescribed as initial monotherapy for the management of pyogenic granulomas. However, in recent years the options for the medical management of PG have been expanded with the addition of topical β-blockers.[30] Currently, recommended medical treatment consists of a twice-daily application of timolol 0.5% eyedrops, with or without the addition of topical steroid ointment for a minimum of 3 weeks.[3,5,11] The mechanism of action of timolol is probably similar to the role played by β-blockers in the management of infantile hemangiomas.[3,11] Vasoconstriction within the lesion causes inhibition of vascular growth factors thus promoting apoptosis.[11] Whether the addition of topical β-blockers reduces the need for surgery for a condition that was historically considered essentially surgical[10] requires further clarification in larger studies.[7,11] The role of topical timolol may clinically be more important in children with PG than in adults because it may be difficult to monitor the intraocular pressure in children receiving topical steroids alone. Moreover, if surgery is required, general anesthesia may be needed in children,[11] in contrast to adults where surgery can be performed with topical anesthetic eye drops alone.[6] *(Print pagebreak 705)* When the diagnosis of PG is in doubt, surgical excision for

histologic confirmation may be the preferred procedure of choice regardless of age.[30]

If medical measures fail, surgical excision followed by cauterization of the base of the lesion is recommended.[6,10] Because PG is essentially a vascular tumor, cautery is needed to control bleeding, but even if no cautery is used, intraoperative hemorrhage is seldom a problem and only minimal bleeding is encountered.[6] Also, cautery after surgery may reduce recurrences.[7,9] Low-dose plaque brachytherapy may also be indicated if multiple recurrences occur.[7,9] Intralesional injection of steroids at the time of surgery may also help reduce recurrences.[4]

Prognosis

Because the lesions are friable they can rarely fall off on their own.[6,10] Following medical treatment or surgical excision, pyogenic granulomas usually heal with minimal scarring; however, even after complete excision they may recur, and some patients may experience multiple recurrences especially if the initiating event is not attended to.[4,6,9,10]

Histopathology

Pyogenic granulomas may be encountered on the conjunctival surface or the epidermal surface of the eyelid, although conjunctival PGs are far more common. Conjunctival PGs represent a form of exuberant granulation tissue, usually resulting from trauma.[6,31,32,33,34,35] They feature proliferating capillaries, often with a prominent radial arrangement, extending from the base of the lesion toward the surface (Figure 107.4A). Endothelial cells are often plump and prominent.[31] The capillaries are within edematous stroma containing varying proportions of neutrophils, lymphocytes, plasma cells, and macrophages (Figure 107.4B and C).[6,31,35] The overlying epithelium may be attenuated or ulcerated.[6,31,35]

Early cutaneous pyogenic granulomas are identical histologically to granulation tissue, while mature lesions have a lobular pattern due to fibrous septa subdividing the capillary proliferation (Figure 107.5).[36] Many PGs feature an exophytic mass of proliferating capillaries in an edematous matrix superficially and a lobular pattern of proliferating capillaries in the deeper portion of the lesion.[37] Early lesions usually have eroded epidermis with a mixed inflammatory infiltrate in the edematous stroma.[36] Epidermis covers fully developed cutaneous PGs, a collarette of hyperplastic epidermis partially surrounds the base, stromal edema resolves, and inflammation is sparse.[36] Over time, there is increasing fibroplasia with diminishing capillaries until ultimate resolution into a fibroma.[36] Endothelial cells of cutaneous PGs do not express glucose transporter 1 (GLUT1).[38]

Intravenous PGs are the vascular analog of conjunctival and cutaneous PG.[39,40,41] There is a polypoid lobular *(Print pagebreak 706)* proliferation of capillaries embedded in a fibromyxoid stroma within the vessel lumen (Figure 107.6A and B).[39,40] Larger thin-walled veins, arterioles, and small arteries accompany the capillaries within the stroma.[39] A broad fibrovascular stalk connecting the lesion to the vein wall can usually be identified.[39,40] On other occasions, the lesion appears to be floating within the vessel lumen or it may completely occlude the lumen. Endothelial cells of the proliferating capillaries express CD31 (Figure 107.6C), CD34, factor VIII-related antigen, vimentin, and *Ulex europaeus* agglutinin-1 (UEA-1).[42,43] In addition to the endothelial cells, smooth muscle cells are carried from the vein wall into the fibrovascular stalk.[39] The fibromyxoid stroma of intravenous PGs contains scattered chronic inflammatory cells.[40]

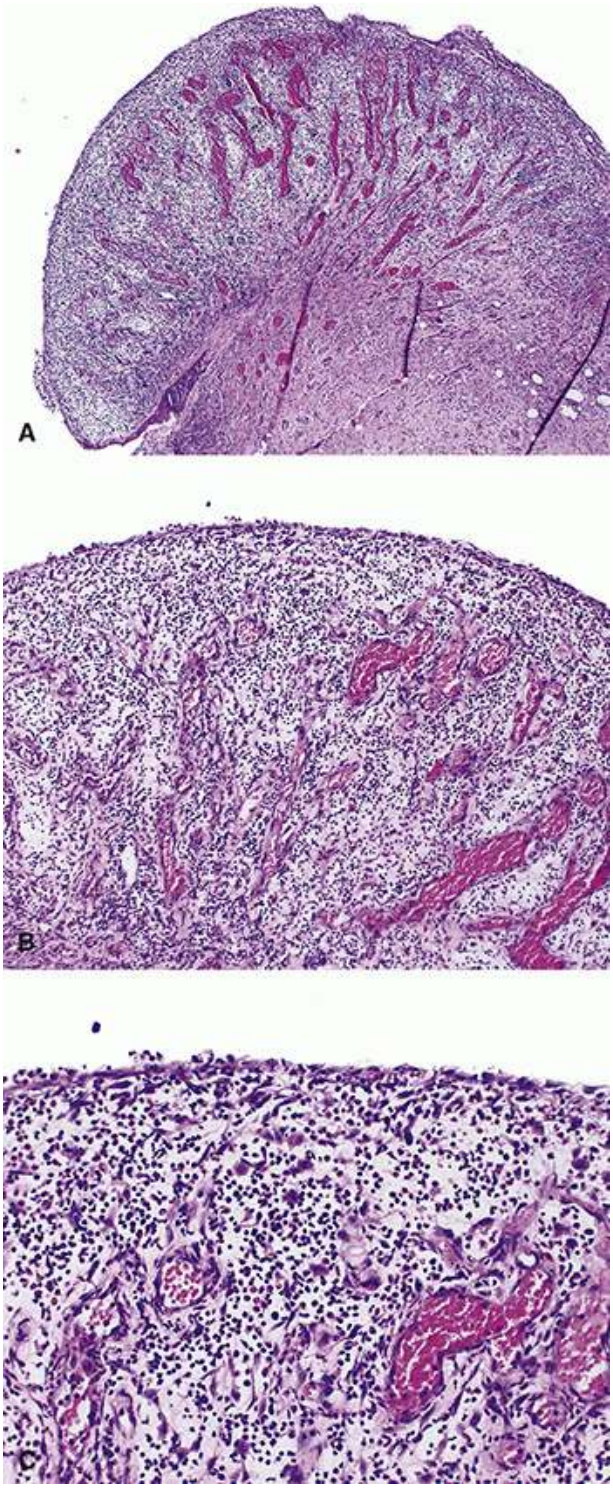

FIGURE 107.4 This conjunctival PG arose following surgery for a pterygium removal. A, At low magnification, proliferating capillaries within an edematous stroma radiate from a narrowed base toward the surface. The overlying epithelium is ulcerated, and there is focal hyperplastic epithelium creating a collarette at the lesion's base. B, Capillaries of varying caliber are within edematous stroma containing numerous leukocytes. C, The leukocytic infiltrate has a mixture of neutrophils, lymphocytes, plasma cells, and macrophages.

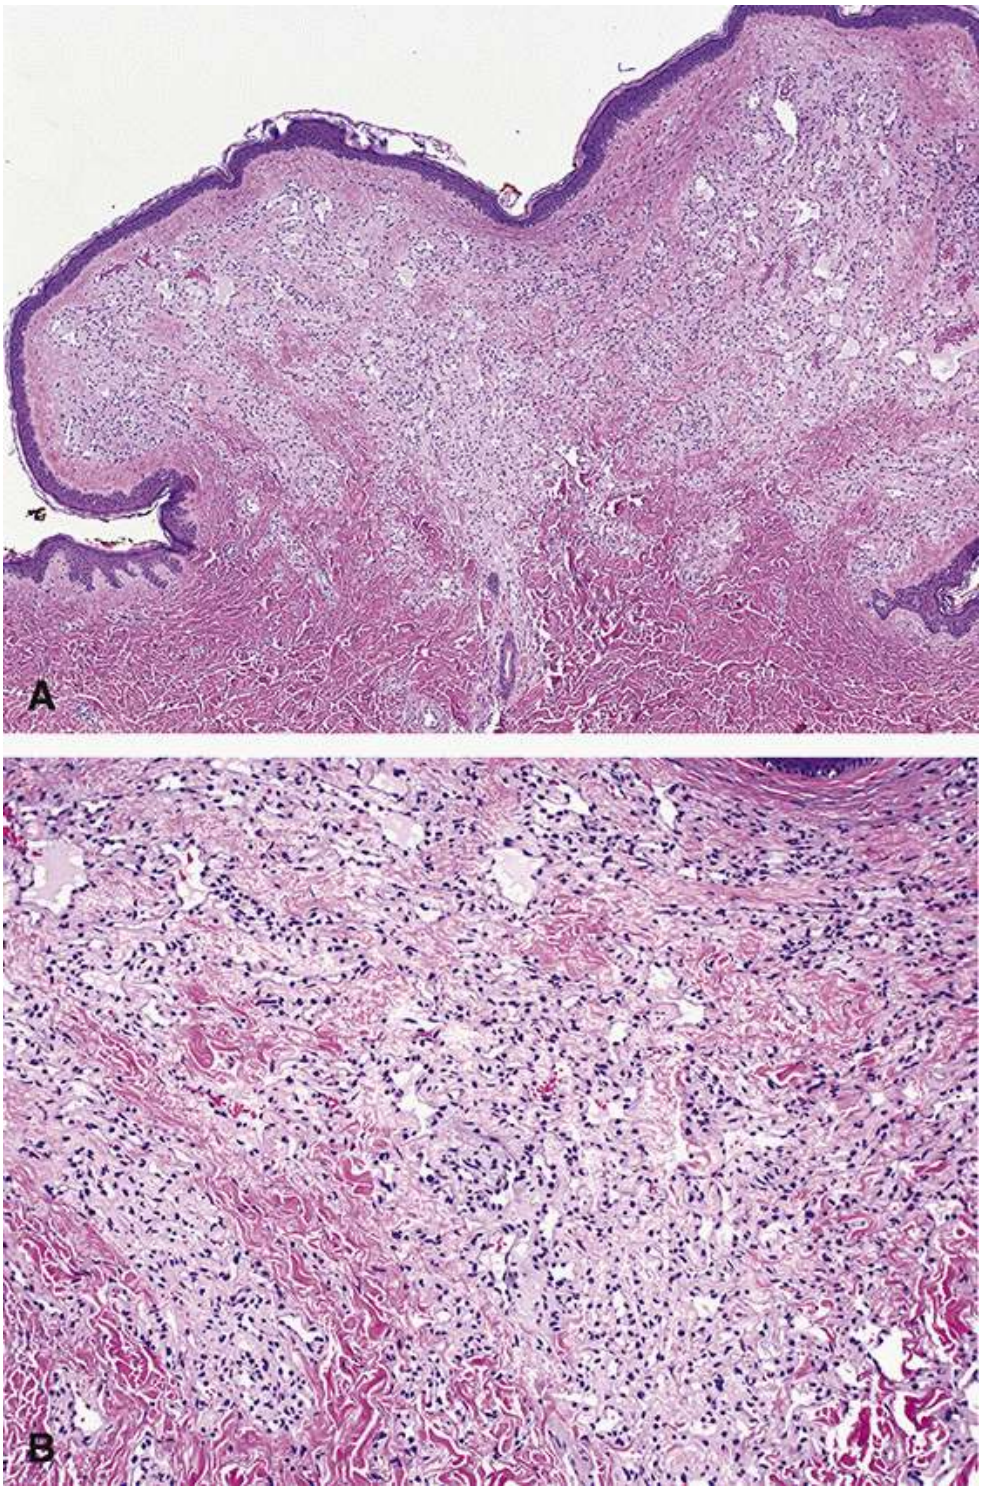

FIGURE 107.5 A, Epidermis covers this cutaneous PG, a collarette of hyperplastic epidermis surrounds the base, stromal edema is minimal, and inflammation is sparse. B, Lobules of capillaries are enmeshed in loose fibrous stroma and separated by dense fibrocollagenous septa.

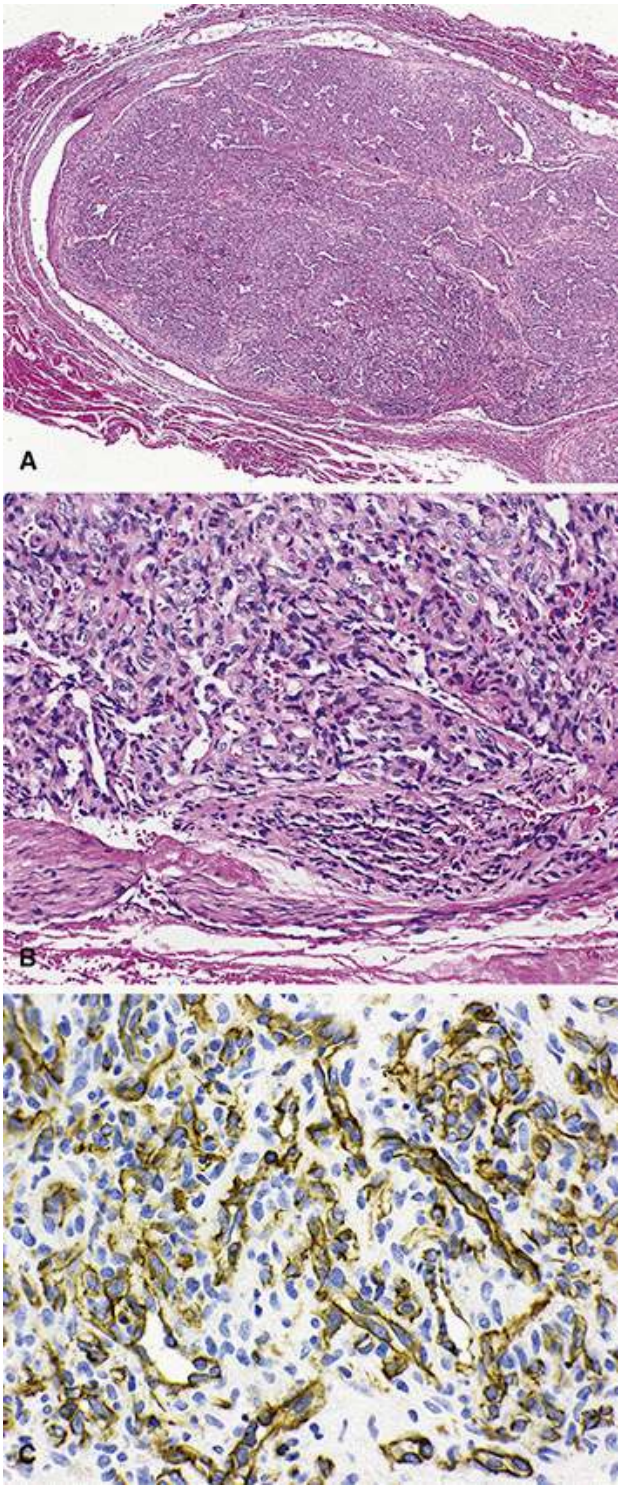

FIGURE 107.6 A, This intravenous PG arose in a vein at the left upper eyelid's lateral edge and was manifest clinically as a freely mobile subcutaneous mass. It was present clinically for 6 months before excision. B, The polypoid lesion is formed of lobules of capillaries enmeshed in fibromyxoid stroma with few chronic inflammatory cells. C, Immunohistochemical staining using antibodies to CD31 highlights the capillary endothelial cells.

CHAPTER 108

Rhabdomyoma

Key Points

- Rhabdomyoma is a rare benign mesenchymal tumor of soft tissue originating from skeletal muscle cells
- It is usually subdivided into two major subtypes, cardiac and extracardiac, based on their sites of location
- The extracardiac type is uncommon, usually affects the soft tissues of the head and neck, and most often derives from the musculature of the third and fourth branchial arches
- They frequently involve in the larynx, pharynx, floor of the mouth, and tongue, and very rarely the eyelid
- Rhabdomyoma has been considered to be a hamartoma of striated muscle, but it may also result from chronic irritative stimulation
- Tumors usually present as a unilateral or bilateral, solitary or multifocal, smooth, mobile, firm to rubbery subcutaneous or submucosal nodule
- Treatment is with complete surgical excision, but more recently, patients have been treated successfully with sirolimus and everolimus
- The prognosis is usually very good, and recurrence after surgery is very rare

Tumors showing skeletal muscle differentiation are classified as either benign rhabdomyomas or malignant rhabdomyosarcomas. Rhabdomyomas are rare benign mesenchymal tumors of soft tissue originating from skeletal muscle cells and account for about 2% of all skeletal muscle tumors.[1,2,3] Classification is based on histologic, topographic, clinical, and immunohistochemical criteria. They are usually subdivided into two major subtypes, cardiac and extracardiac, based on their location.[4,5]

The cardiac type is more common. It is seen mostly in children and is frequently associated with phacomatoses.[6] Cardiac rhabdomyomas are considered to be hamartomatous lesions derived from embryonal myoblasts. They exhibit a fetal pattern of atrial natriuretic peptide immune reactivity and are associated with tuberous sclerosis complex in up to 60% to 96% of cases.[7]

The extracardiac type of rhabdomyoma is extremely uncommon, usually affecting the soft tissues of the head and neck with a 2:1 to 3:1 male predominance.[6,8,9] The peak age of incidence is in the fifth to sixth decades, but they can be seen in patients ranging from childhood to old age. Tumors occur in diverse anatomical sites and have been divided into subtypes based on clinical and morphological criteria[1,2,10,11,12,13]: the adult and fetal subtypes. Unlike the cardiac type, extracardiac rhabdomyomas do not have an association with tuberous sclerosis.[10]

Adult rhabdomyomas most often derive from the musculature of the third and fourth branchial arches located in the head and neck.[14,15] They frequently involve the larynx,[16] pharynx,[6] floor of the mouth,[17] and tongue.[18] Other rare locations include the cheek,[19] lower lip,[20] the tunica vaginalis of the testis,[21] the sternocleidomastoid muscle,[1,22] and the muscular wall of the stomach, even though striated muscle is normally not present in this location.[23] Adult rhabdomyoma has also very rarely been reported in the skin.[24,25,26] Only two cases of adult rhabdomyoma have been described involving the eyelid,[27,28] and six orbital cases were described involving the rectus muscles.[29,30,31,32,33,34]

The fetal type of extracardiac rhabdomyoma is the least common variety. It is seen most often in the head and neck region of young male children, less than 3 years of age.[35,36] They are classified histologically into myxoid and cellular subtypes.[11,36] The myxoid type has been described in infants during the first year of life as subcutaneous lesions in the head and neck, particularly in the preauricular and postauricular regions, and in the vulvovaginal region of middle-aged women. The cellular type occurs most often in mucosal and soft tissues of the head and neck of children, adolescents, and occasionally older male adults.[36,37,38] This type has also been reported in the stomach, retroperitoneum, upper extremity, and anus.[11,39] Two cases of fetal rhabdomyoma were

described in the eyebrow.[40,41]

Etiology and Pathogenesis

Rhabdomyoma has been considered to be a hamartoma of striated muscle because most cases are seen in children, often associated with congenital conditions.[42,43] For fetal rhabdomyoma, the pathophysiology has also been considered as a developmental malformation,[44] or even a neoplasm.[25] In a case of parapharyngeal rhabdomyoma a translocation between chromosomes 15 and 17 and an abnormality on chromosome 10 was described, suggesting a neoplastic etiology.[45] In another case of an eyelid rhabdomyoma associated with an anophthalmic socket,[27] the tumor was associated with a prosthesis, perhaps suggesting a role for a chronic irritative stimulation in the development of the tumor.

(Print pagebreak 709)

FIGURE 108.1 Submucosal rhabdomyoma of the medial canthus.

Clinical Characteristics

The clinical presentation of rhabdomyoma varies depending upon the specific location. In most cases, it presents as a slow-growing lesion that may enlarge over months to years. Tumors usually present as a unilateral or bilateral smooth, mobile, firm to rubbery subcutaneous or submucosal nodule (Figure 108.1).[20,25,27] They are generally asymptomatic initially and for long periods but may become symptomatic if adjacent structures become compressed. Pain is unusual. Tumors are usually solitary but may be multifocal with up to 10 synchronous lesions.[46,47,48] When near the surface, the lesion may appear tan or brownish and can be focally ulcerated.[27]

Differential Diagnosis

The differential diagnosis of rhabdomyoma includes a wide variety of benign and malignant lesions. In published cases, initial diagnoses have included granular cell tumors, rhabdomyosarcoma, alveolar soft part sarcoma, hibernoma, oncocytoma, crystal storing histiocytosis, schwannoma, squamous cell carcinoma, and vascular malformations.

Treatment

Treatment of extracardiac rhabdomyoma is with complete surgical excision (Figure 108.2). Recurrences are rare and patients usually do well. The outlook for patients with cardiac rhabdomyoma has been considered to be poor, resulting in death within the first 5 years of life being usual.[49] Some authors have suggested that an aggressive surgical approach to this tumor is indicated.[50] More recently, patients have been treated successfully with sirolimus and everolimus resulting in significant tumor regression.[51,52] In a study of 7 children with 24 cardiac tumors followed for 2 to 15 years, 20 underwent complete and 3 partial spontaneous regression.[5]

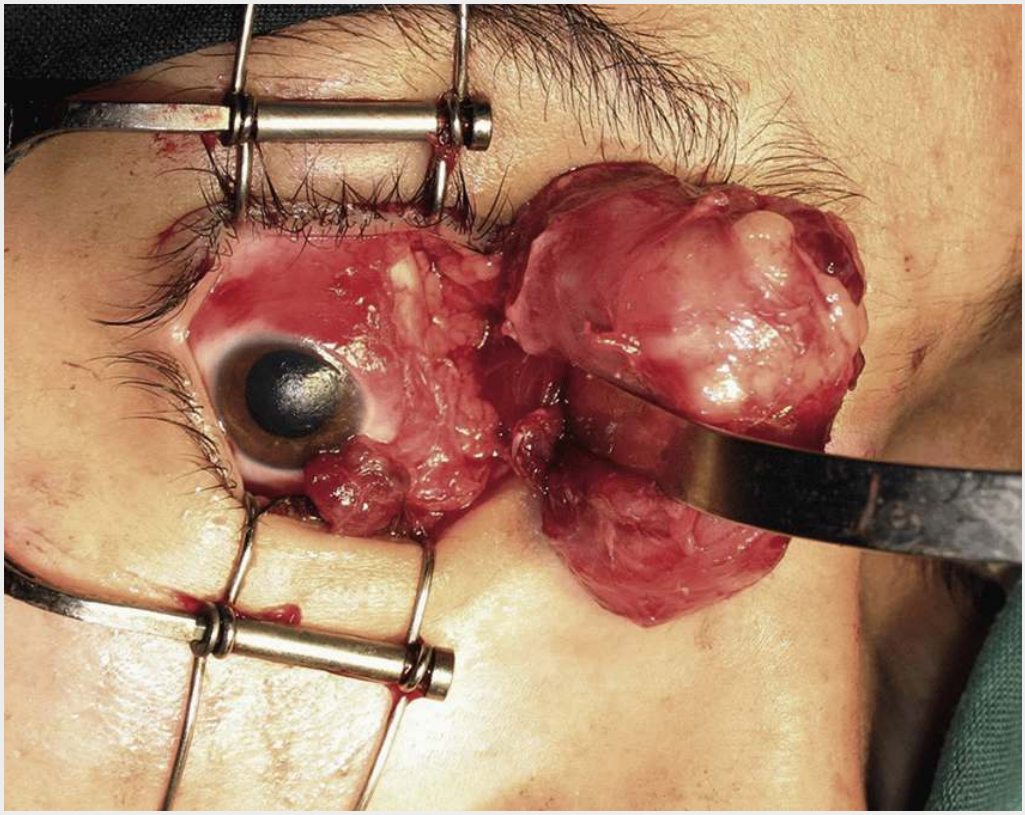

FIGURE 108.2 Surgical excision of the lesions in Figure 108.1.

Prognosis

The prognosis is usually very good, and recurrence after surgery is very rare, usually attributed to incomplete removal. No cases of malignant transformation have been reported.

Histopathology

Adult rhabdomyomas are composed of well-demarcated, unencapsulated lobules of large polygonal cells with scant intervening stroma (Figure 108.3).[10,15] Tumor cells have large amounts of eosinophilic granular cytoplasm or vacuolated cytoplasm, well-defined cytoplasmic borders, and small, round central or peripherally located nuclei with prominent nucleoli.[10,15,53] Cytoplasmic vacuoles may create a “spider web” appearance due to cytoplasmic strands between peripheral vacuoles.[10,15] Abundant cytoplasmic glycogen can be highlighted with periodic acid-Schiff stain.[10,15,53] Cytoplasmic cross-striations may be evident in hematoxylin and eosin-stained sections and accentuated using Masson trichrome or phosphotungstic acid hematoxylin stains.[15,54] The cytoplasm may also contain haphazardly arranged rod-like crystalline inclusions.[15,53] Mitoses are not seen,[10,15,53] but foci of inflammation and necrosis are identified in a minority of mucosal adult rhabdomyomas.[15] Tumor cells are immunoreactive using antibodies to muscle-specific actin, desmin, and myoglobin.[15,54] There may be focal immunoreactivity for vimentin, smooth muscle actin, S100 protein, and CD57 (Leu-7).[15]

Fetal rhabdomyomas are subdivided histologically into myxoid (classic) and intermediate (cellular) variants.[10,36] Myxoid fetal rhabdomyomas are well circumscribed but unencapsulated masses “composed of an admixture of haphazardly arranged, immature, slender skeletal muscle fibers with rare, delicate cytoplasmic cross-striations and undifferentiated round, oval to spindled, and serpentine cells in an abundant myxoid to fibromyxoid stroma.”[36] The skeletal muscle cells of myxoid fetal rhabdomyomas of the head and neck have small oval *(Print pagebreak 710)* nuclei, inconspicuous nucleoli, and scarce cross-striations.[35,36]

Undifferentiated mesenchymal cells vary from resembling small lymphocytes to large, spindle-shaped fusiform cells without myofibrils or cross-striations.[35] Mitoses are rare.[35]

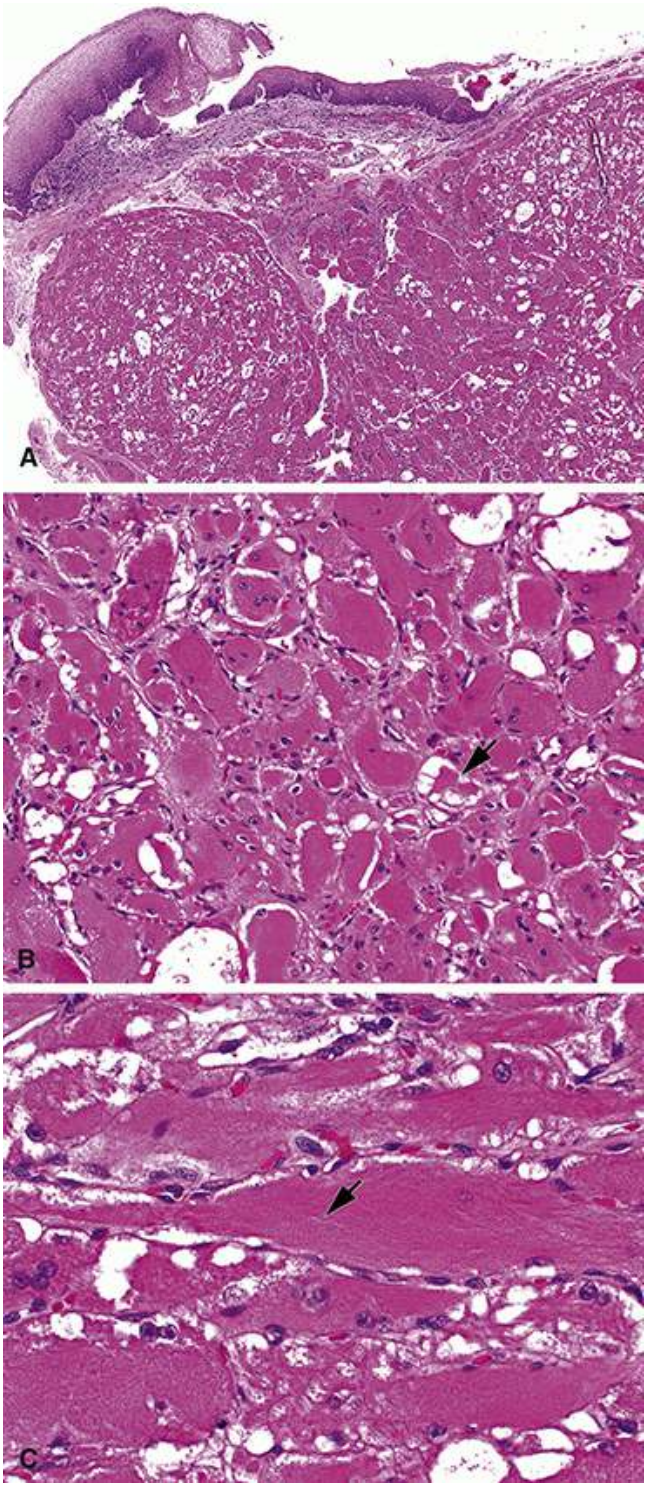

FIGURE 108.3 This adult rhabdomyoma developed in the base of the tongue of a man in his early 60s. A, Well-circumscribed lobules of tumor cells are in the submucosa. B, The tumor cells are large and round to polygonal and have eosinophilic and vacuolated cytoplasm. Round nuclei with distinct nucleoli are in the center or periphery of the cells. One cell has cytoplasmic strands between vacuoles creating a "spider web appearance" (*arrow*). There is scant stroma with blood vessels between tumor cells. C, The cells have variable vacuolation and focal cross-striations (*arrow*).

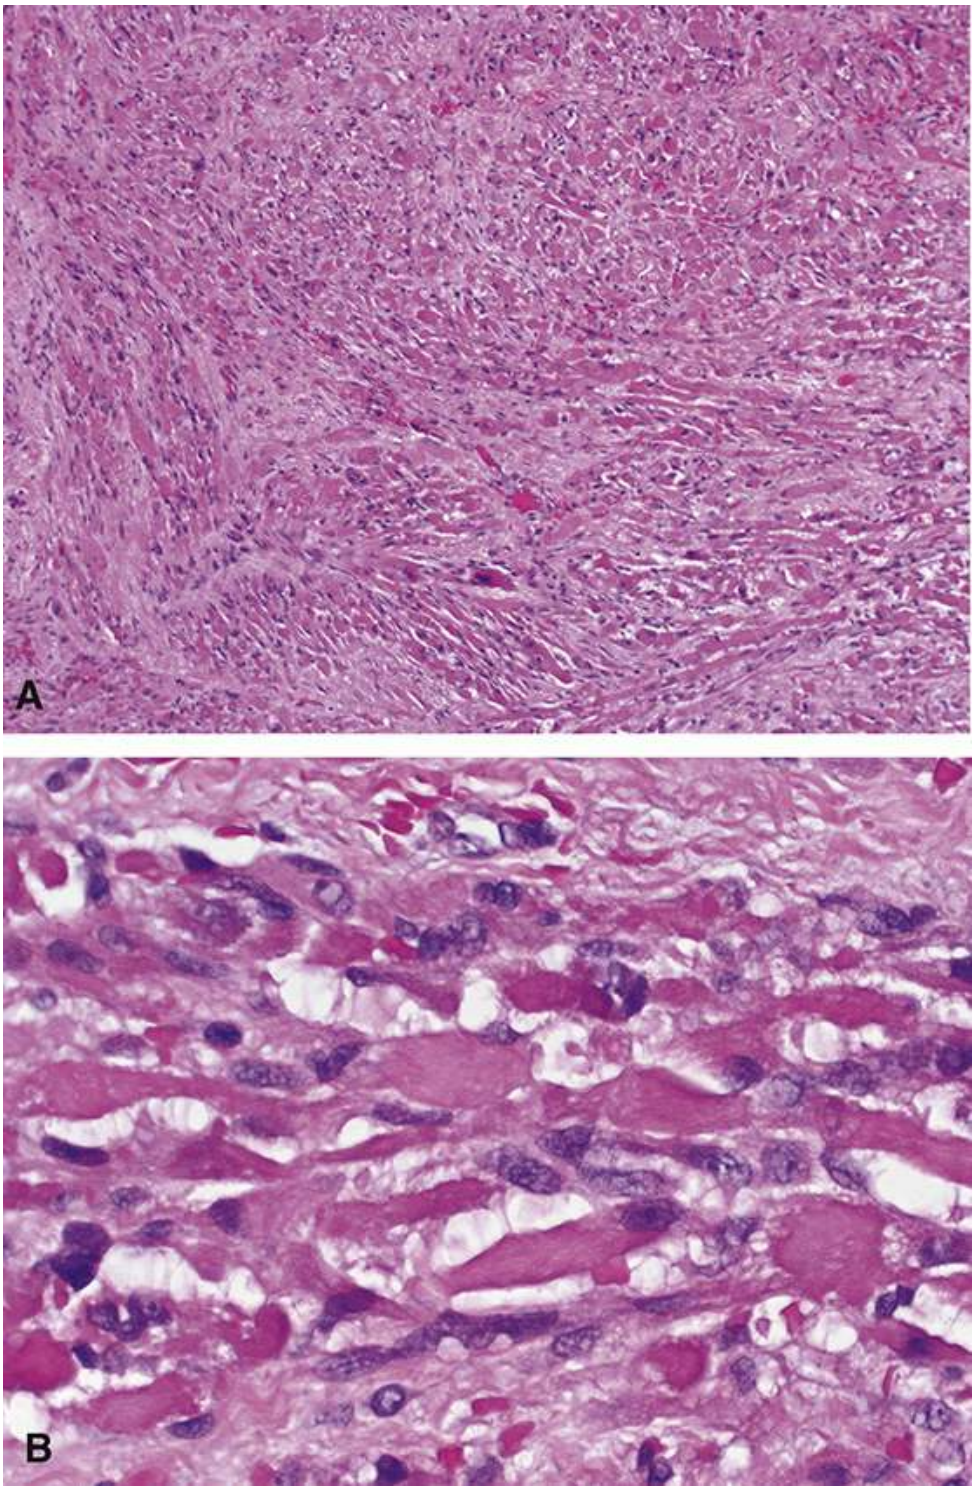

FIGURE 108.4 Intermediate fetal rhabdomyoma from the orbit of a 3-year-old boy. A, Eosinophilic tumor cells form fascicles with some sectioned longitudinally, others in cross-section. B, The tumor is a mixture of cells with scant cytoplasm and many strap cells with abundant eosinophilic cytoplasm and occasional cross-striations. There were no mitotic figures identified in the tumor.

Intermediate fetal rhabdomyomas exhibit a broad range of skeletal muscle differentiation, but most tumors have at least small foci of primitive mesenchymal cells and delicate rhabdomyoblasts.[36] Of the 16 intermediate fetal rhabdomyomas reported by Kapadia et al, 7 had differentiation ranging from primitive mesenchymal cells to large ganglion cell-like rhabdomyoblasts to strap cells having prominent cross-striations.[36] Ribbon-like rhabdomyoblasts may form sheaves or interlacing bundles.[36] Of the 16 intermediate fetal rhabdomyomas reported by Kapadia et al, 9 had maturation arrest with rhabdomyoblasts of slightly larger caliber than fetal-type muscle fibers and more abundant eosinophilic cytoplasm than in the myxoid variant of fetal rhabdomyoma (Figure 108.4).[36] Six of the cases with *(Print pagebreak 711)* maturation arrest had broad fascicles of cells that resembled a leiomyoma at low magnification.[36] Cross-striations are usually more apparent in intermediate fetal rhabdomyomas than in the myxoid variant.[36] Mitoses are uncommon, and atypical mitoses are not seen.[36] Tumor cells are immunoreactive using antibodies to muscle-specific

actin, desmin, and myoglobin, with focal or rare staining for vimentin, smooth muscle actin, S100 protein, glial fibrillary acidic protein, and CD57 (Leu-7).[36]

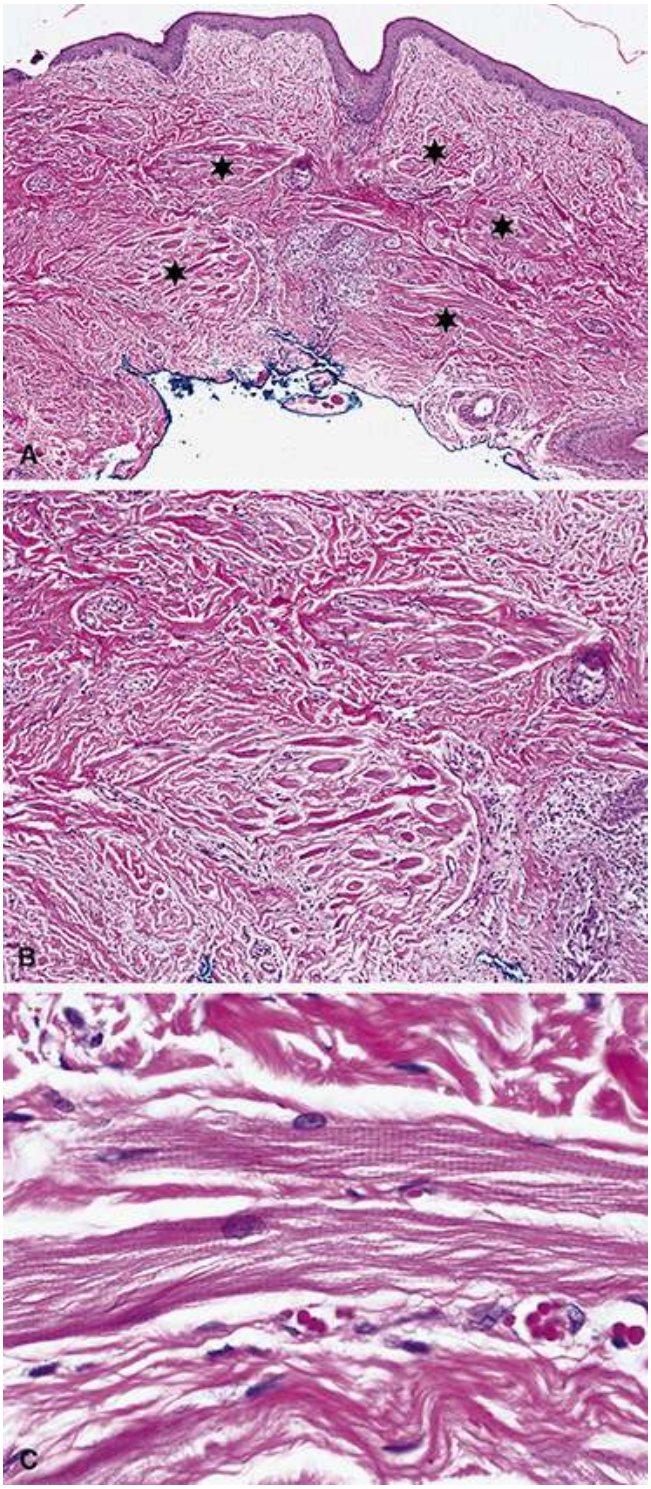

FIGURE 108.5 This skeletal muscle hamartoma (rhabdomyomatous mesenchymal hamartoma) was excised from the medial left lower eyelid of a 57-year-old woman.[57] A, Multiple striated muscle fiber bundles (★) are in the superficial to deep reticular dermis. B, Irregularly thickened collagen bundles are between and among the bundles of skeletal muscle fibers. C, Most of the myocytes have a splayed appearance with retained cross-striations.

A cutaneous lesion that may be confused with rhabdomyoma is rhabdomyomatous mesenchymal hamartoma, also termed "skeletal muscle hamartoma." These rare lesions feature single or small groups of mature skeletal muscle fibers in the dermis and subcutis, frequently in a collagenous stroma with mature adipose tissue and adnexal structures.[55] The cases reported in the adult eyelid have featured individual and bundles of disorganized well-differentiated skeletal muscle in the dermis (Figure 108.5).[56,57]

CHAPTER 109

Rosacea

Key Points

- Rosacea is a chronic skin disorder of diverse cutaneous manifestations associated with inflammation of the face
- It is characterized by episodes of flushing of the central face, sometimes associated with telangiectasia often brought on by alcohol, spicy foods, exercise, UV light exposure, cold or hot weather, or hot water
- Phymatous rosacea manifests as marked skin thickening and irregular nodularities that are most often seen on the nose and less frequently on the forehead, eyelids, and chin
- The etiology and pathophysiology of rosacea are not completely understood, but there is evidence to support a genetic predisposition
- Ocular rosacea usually presents with conjunctival hyperemia, epiphora, burning, itching, foreign body sensation, dry eyes, photophobia, blurred vision, conjunctival telangiectasia, eyelid blepharitis, and meibomian gland dysfunction
- A careful history should attempt to uncover any identifiable factors that trigger exacerbations of the symptoms
- Treatment includes warm compresses, eyelid scrubs, oral antibiotics, correction of collagen abnormalities, topical retinoids, and intense pulsed light therapy
- Ocular rosacea is not a curable disease, and patients typically suffer significant morbidity although symptoms can often be controlled

Rosacea is a chronic skin disorder of diverse cutaneous manifestations associated with inflammation of the face.[1] It occurs in about 10% of the population, most commonly in patients over 30 years of age and those with Fitzpatrick skin types I and II.[2] Women are affected with cutaneous rosacea more frequently than men,[3,4] but ocular rosacea affects both genders equally.[3] Rosacea most commonly affects middle-aged adults, with a peak incidence between the ages of 40 and 59 years,[3] but it may sometimes be seen in early childhood and old age.[5] Approximately 30% to 40% of patients with rosacea report a family member with the condition.[6]

The diagnosis of rosacea is based on the clinical findings, but these are generally nonspecific, making the diagnosis difficult in many cases.[7,8] In 2002, the National Rosacea Society Expert Committee on the Classification and Staging of Rosacea proposed four broad clinical subtypes of rosacea: erythematotelangiectatic, papulopustular, phymatous, and ocular.[9,10]

In erythematotelangiectatic rosacea, there are episodes of flushing of the central face, sometimes associated with telangiectasia. The redness also may involve the ears, scalp, neck, and chest, but the periocular skin is spared. Alcohol, spicy foods, exercise, cold or hot weather, and hot water may bring on these episodes.[9] Papulopustular rosacea generally presents with erythema and flushing of the central portion of the face combined with intermittent or persistent episodes of small papules and pustules. As with the erythematotelangiectatic subtype, the periocular skin is usually spared.[9] Phymatous rosacea is characterized by marked skin thickening and irregular nodularities that are most often seen on the nose (rhinophyma) and less frequently on the forehead, eyelids, and chin.[9] In ocular rosacea, ophthalmic manifestations usually occur along with the cutaneous findings, but in some cases, they may precede them by many years.[8,11] It is not clear if these different subtypes develop progressively or if they occur as discrete variants.[12,13]

Ocular rosacea usually presents with conjunctival hyperemia, epiphora, burning, itching, foreign body sensation, dry eyes, photophobia, blurred vision, conjunctival telangiectasia, eyelid blepharitis, and meibomian gland dysfunction.[8,14] The findings of ocular rosacea in children are generally similar to those seen in adults.[15] The skin findings are often absent in pediatric cases,[16,17] but when present, they follow the ocular manifestations in about 55% of cases.[18]

Etiology and Pathophysiology

The etiology and pathophysiology of rosacea are not completely understood, but there is evidence to support a genetic predisposition. This includes the increased prevalence of rosacea in some northern European populations and the association of rosacea with autoimmune disorders.[19] Gene array and polymerase chain reaction analyses indicate a defined gene profile for each of the different rosacea subtypes.[12,20] Proposed factors that may be contributory to the development of rosacea include abnormal vascular reactivity, dysregulation of the innate immune system, increased susceptibility of sensory nerves to temperature changes or spicy foods, ethanol, exercise, UV radiation, *Demodex* overgrowth on the face or small intestinal bacterial overgrowth, and pilosebaceous unit abnormalities.[4,13,21,22,23,24]

Rosacea shows great variation in clinical manifestations suggesting a possible wide range of pathophysiological mechanisms.[25] The major elements appear to be an augmentation of immune reaction and response, and neurovascular *(Print pagebreak 714)* dysregulation.[25,26] There is an upregulation of genes involved in vasoregulation and neurogenic inflammation in all subtypes of the disease.[27] The causes of transient flushing are poorly understood, but some evidence suggests it is associated with the release of antimicrobial peptides and proteases,[28] neuropeptides,[13] or transient receptor potential ion channels[29] in the induction of erythema and vasodilation. The inflammatory infiltrate present in all four subtypes is not well characterized, but in early-onset rosacea, a lymphomonocytic infiltrate consisting primarily of CD3+ T cells, with CD20+ B cells, mast cells, and dendritic cells has been described.[25,27,30]

FIGURE 109.1 Rosacea primarily involving the central face with little or no simultaneous eyelid involvement. A, Facial rosacea with telangiectasis and mild erythema of the eyelids. B, Diffuse facial rosacea. A, (Courtesy of Dr. Morris Hartstein.)

Environmental factors that are known to exacerbate the disease lead to the activation of proinflammatory products and innate immune responses.[20,21] Cathelicidin, which has both vasoactive and proinflammatory actions, is elevated in the skin of patients with rosacea and has been implicated in its pathogenesis.[21,28,31]

In patients with ocular rosacea, the inflammatory basis of the disease is supported by elevated concentrations of interleukin-1a and 1b, tumor necrosis factor-alpha, and a greater activity of metalloproteinase-9 and collagenase-2 in tear fluids.[32,33,34,35] Overexpression of toll-like receptor 2 on keratinocytes may explain enhanced inflammatory responses to environmental stimuli and may be a factor in the pathogenesis of rosacea.[36] The inflammatory markers ICAM 1 and HLA-DR have also been observed to be overexpressed in conjunctival epithelial cells.[37]

Clinical Presentation

The symptoms of rosacea show episodes of exacerbations and remissions, but over time the disease usually progresses. While certain trigger factors such as sun exposure, extreme temperatures, alcohol, spicy foods, exercise, and emotional stress can worsen the symptoms, others, like smoking, appear to significantly reduce the risk of developing rosacea.[3] Facial rosacea may present with little or no simultaneous eyelid involvement[7] (Figure 109.1) More often, facial lesions include acne, sebaceous thickening with edematous papules and pustules, and thickening of the nose as rhinophymia (Figure 109.2). The eyelid inflammatory reaction results in meibomian gland dysfunction, chronic scarring of the gland orifices, and eyelid margin telangiectasias. This leads to tear film instability, epiphora, photophobia, keratitis, and blurred vision.[38,39] Other common findings include blepharitis and collarettes around the eyelashes. Patients often experience recurrent hordeola and chalazia (Figure 109.3).[7,17] Dry eye is a major finding in up to two-thirds of patients with ocular rosacea,[37,40] and pinguecula, chronic cicatricial conjunctivitis, and fibrosis have also been reported.[41,42,43]

Corneal manifestations may be seen in up to 33% of patients.[38,44] These can include superficial punctate keratitis on the lower third of the cornea and peripheral neovascularization with subepithelial infiltrates and can proceed to stromal ulceration, and even corneal

perforation.[45,46] Iritis, episcleritis, and scleritis are other potential ocular findings,[7,47] and a case of spontaneous scleral perforation has been described.[48]

Differential Diagnosis

Systemic lupus erythematosus is a skin condition that can mimic rosacea. This is a chronic inflammatory disease that has protean clinical manifestations, which include malar erythema in approximately 50% of patients. The erythema may last for hours to days and often recurs, especially with sun exposure.[49,50] Dermatomyositis is an inflammatory myopathy characterized by varying degrees of muscle weakness and skin erythema, but some patients lack muscular involvement and initially present only with skin manifestations. Macular violaceous erythema occurs most frequently in the seborrheic area of the face[51] that might be *(Print pagebreak 715) (Print pagebreak 716)* confused with the erythema seen in rosacea. Polymorphous light eruption is a common idiopathic photodermatosis with a higher prevalence in fair-skinned individuals,[52] characterized by erythematous papules, papulovesicles, and plaques on exposed skin surfaces following sun exposure.[53] Seborrheic dermatitis is a chronic skin disease characterized by a relapsing erythematous rash with well-demarcated patches, papules, or plaques seen most often on sebum-rich areas such as the face and scalp. Acne vulgaris is characterized by noninflammatory comedones and inflammatory papules, pustules, and nodules. It typically affects areas of skin with a high density of sebaceous glands such as the face, upper chest, and back.[54] Other rare conditions that have been misdiagnosed as rosacea include carcinoid syndrome with flushing of the face, neck, and upper trunk[55] and cutaneous lymphoma that can present with violaceous papules, plaques, and nodules on the face.[56]

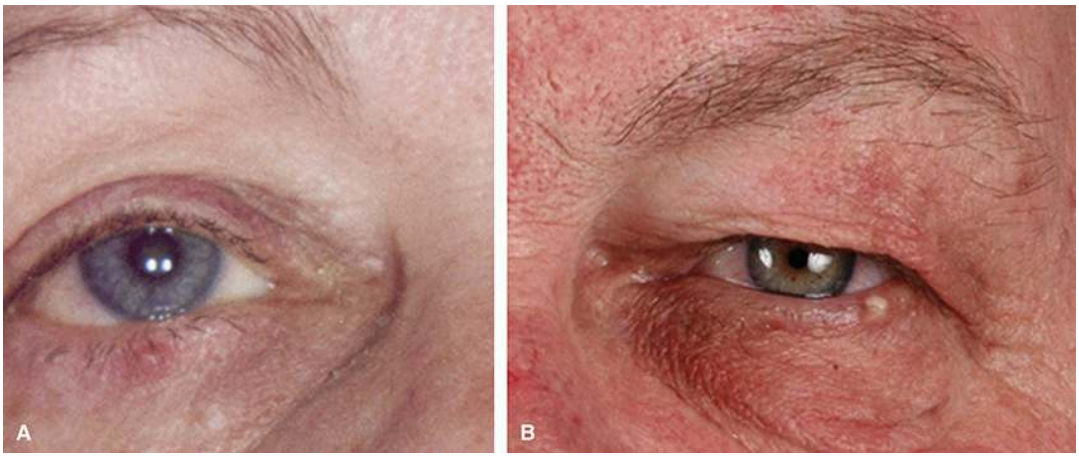

FIGURE 109.3 Eyelid rosacea with recurrent chalazia of the lower eyelids. B, (Courtesy of Dr. Peter Rubin.)

Treatment

Before the initiation of medical therapy, a careful history should attempt to uncover any identifiable factors that trigger exacerbations of the symptoms.[4,57] Identification of factors such as temperature extremes, wind, hot beverages, caffeine, exercise, spicy food, and emotional stress can help facilitate their avoidance or modulation.[58] A broad-spectrum sunscreen should be used for protection against UV light exposure. Some authors advocate the use of over-the-counter skin care products that contain a gentle cleanser designed to remove bacteria and other irritating residues, metronidazole topical gel for the treatment of inflammatory papules and pustules, and a hydrating agent to provide moisture and protect the skin barrier.[59]

More definitive initial approaches continue with conservative treatments to address the meibomian gland dysfunction and any ocular surface complications. Warm compresses, eyelid scrubs, and digital massage are used to express impacted oils and cellular debris from the meibomian glands.[60] Oral omega-3 fatty acids may help improve meibomian gland dysfunction, and artificial tears are used to improve corneal dryness.[61] Cyclosporine is an immunosuppressive agent that inhibits T cell functions, and topical cyclosporine is effective for the management of the ocular surface symptoms associated with ocular rosacea.[62]

Oral antibiotics have been used to help manage meibomian gland disease.[63] Although the mechanism by which antibiotics might influence meibomian gland function is not clear, it has been proposed that they may have an impact on matrix metalloproteinases, may effect changes in interleukins and nitric oxide, and correct collagen abnormalities.[34,35,64]

In addition to antibiotics, topical retinoids have been advocated as useful adjuncts for recalcitrant cases,[65] but recurrences are common. Retinoids inhibit comedone formation and make keratinocytes in sebaceous follicles less cohesive and easier to remove.[59]

Oxymetazoline cream is a vasoconstrictive alpha-adrenergic agonist used as a topical treatment for persistent facial erythema due to cutaneous vascular dilatation,[66] and in clinical trials, oxymetazoline resulted in a significant reduction of facial edema in patients with rosacea.[67,68]

Ivermectin has been used for some forms of rosacea because of its anti-inflammatory properties.[69] In several randomized, controlled studies, ivermectin 1% cream on the facial skin of patients with papulopustular rosacea was shown to be effective and well tolerated.[70,71] Gene expression levels for biomarkers including cathelicidin, interleukin-8, toll-like receptor-4, and human beta-defensin-3 were significantly downregulated following the use of topical ivermectin.[72]

Laser therapy for the treatment of rosacea has included the 595-nm pulsed dye laser and the dual-wavelength long-pulsed 775-nm alexandrite/1064-nm neodymium:yttrium-aluminum laser. These wavelengths are absorbed by hemoglobin, potentially eliminating cutaneous vascular lesions.[73,74] Studies have demonstrated the efficacy of laser therapy in treating telangiectasia [75] and in treating diffuse erythema in patients with rosacea.[76]

Intense pulsed light (IPL) therapy for rosacea is absorbed by telangiectatic vessels inducing coagulation and free radical vascular damage.[57] In several studies, IPL showed improvement in meibomian gland function and tear breakup time,[77,78] and others have shown improvement in erythema and telangiectasias.[79] A retrospective study demonstrated that doxycycline used in conjunction with laser or pulsed light therapy was efficacious in improving the signs and symptoms of rosacea.[80]

Surgical options are few for rosacea but may be appropriate in some cases. These include punctal occlusion for intractable dry eyes and ocular surface complications and incision and drainage of recurrent chalazia. For rhinophyma, mechanical dermabrasion, CO_2 laser resurfacing, or surgical shave procedures can provide a cosmetic improvement.

Prognosis

Ocular rosacea is not a curable disease, and patients typically suffer significant morbidity. Nevertheless, improved treatment options over the past several years have increased so that symptoms are more easily controlled. Identification and avoidance of trigger factors are important, as is routine everyday skincare. Recent investigations have expanded our options to include a variety of pharmaceutical agents, laser and IPL therapies. Strategies for the management of rosacea should be based on individual patient symptoms, as well as the psychological and psychosocial impact of the disease.[81,82]

(Print pagebreak 717)

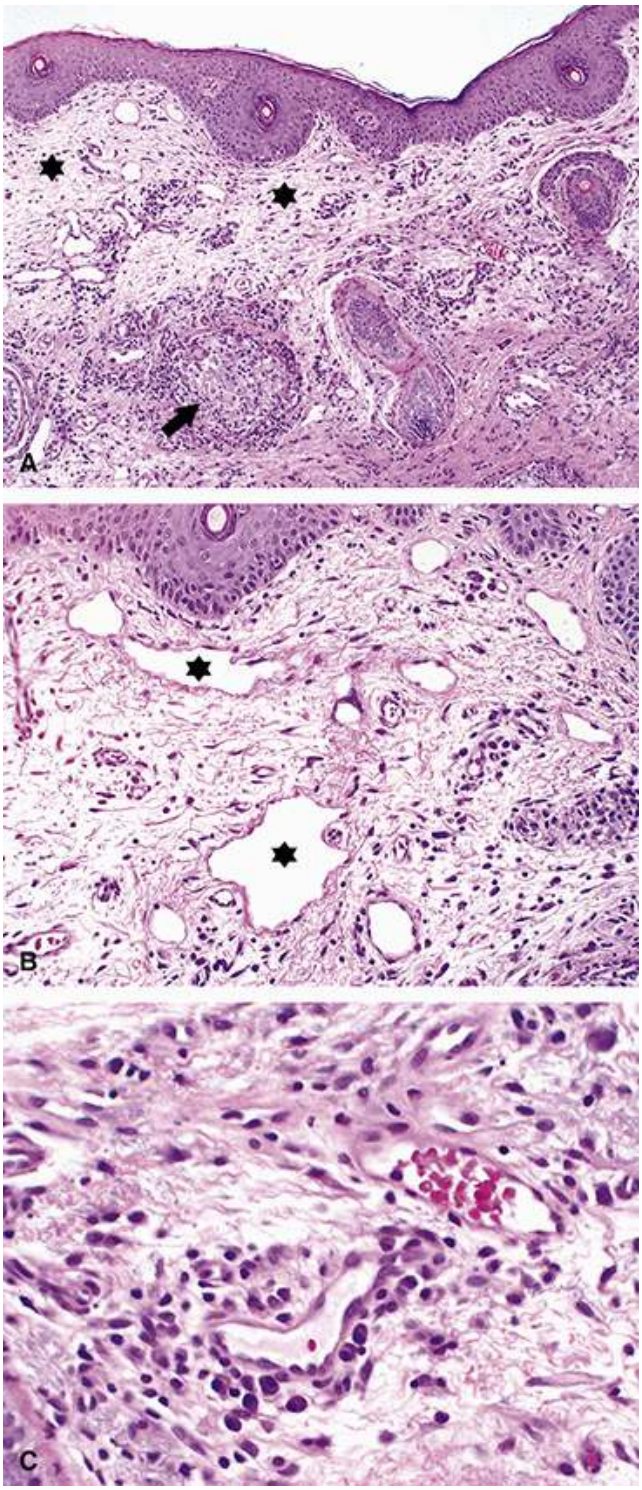

FIGURE 109.4 A man in his mid-70s with clinical rosacea had an incisional biopsy of an erythematous plaque of his right upper eyelid that was clinically suspicious for basal cell carcinoma. A, The papillary and superficial reticular dermis have telangiectatic vessels with marked edema of the papillary dermis (★). A granuloma is in the superficial reticular dermis (*arrow*). B, Markedly dilated vessels have irregular shapes, and some have a discontinuous endothelial cell lining (★). The papillary dermis is markedly edematous with separation of the collagen fibers and fibroblasts by clear edema fluid. C, Lymphohistiocytic infiltrate around a dermal blood vessel with swollen endothelial cells.

Histopathology

The histopathological findings in rosacea are variable and nonspecific.[83,84] The most common histological features are actinic (solar) elastosis,[83,84,85,86] telangiectasia (Figure 109.4A and B),[83,84,85,86] dermal edema (Figure 109.4A and B),[83,84,86] a loose lymphohistiocytic infiltrate around upper dermal blood vessels (Figure 109.4C)[83,84,86] and hair follicles,[84,86] acute folliculitis,[83,

[85] perifollicular granulomatous inflammation,[83] and *Demodex folliculorum* mites in hair follicles and sometimes in the dermis.[83,84,85,86] The actinic elastosis is usually moderate to severe,[84,85] characterized by curling, fragmentation, and aggregation of elastic fibers,[84] and more marked than in matched control specimens.[83] Vascular dilation is often prominent,[83,84] and the ectatic vessels are often irregularly shaped[84,87] with a discontinuous endothelial lining and swollen endothelial cells.[87] Perrigouard, Peltre, and Cribier found that two-thirds of the ectatic vessels with a diameter >30 µm were capillaries and venules and one-third were lymphatics.[87] None of the largest ectatic vessels were lymphatics.[87] Dermal lymphohistiocytic inflammation is usually more intense in papulopustular than erythematotelangiectatic rosacea.[83,86] A minority of rosacea biopsies have epidermal changes including parakeratosis,[83,84,86] hyperkeratosis,[83,86] acanthosis,[86] atrophy,[83] exocytosis of inflammatory cells,[86] and spongiosis.[84] Approximately 6% of biopsies have interface dermatitis.[86]

Granulomas may be found in erythematotelangiectatic[86] and papulopustular[83] rosacea and are an obligatory finding for diagnosing granulomatous rosacea (Figure 109.5).[85,88] Aroni et al identified granulomas in 48/73 (66%) of biopsies from patients with rosacea.[84] Biopsies with granulomatous inflammation had small palisaded granulomas with a concentric rim of histiocytes around degenerated collagen in 40/48 (83%) of cases, elastolytic granulomas in 20/48 (42%), and granulomas surrounding remnants of extrafollicular Demodex or destroyed follicles in 15/48 (31%) cases.[84] Sanchez and coworkers, in a study of 24 biopsies of granulomatous rosacea, classified the granulomatous inflammatory pattern as nodular (8 patients), perifollicular (3), diffuse (2), or combined perifollicular and nodular (13).[88] The different patterns of granulomatous inflammation were not specific for a particular clinical presentation; all were most common in people presenting with papules or erythematous plaques.[88] Helm and colleagues identified caseation necrosis in 11% of biopsies with granulomatous rosacea.[85]

Classic rhinophyma, clinically manifest as an enlarged nose with prominent pilosebaceous orifices and a preserved profile, has histological features of rosacea but with prominent sebaceous gland hyperplasia.[89] Severe rhinophyma, with a markedly distorted nose, has telangiectasia, dermal thickening, markedly diminished or absent pilosebaceous structures, and sclerotic collagen bundles with large amounts of mucin.[89,90]

(Print pagebreak 718)

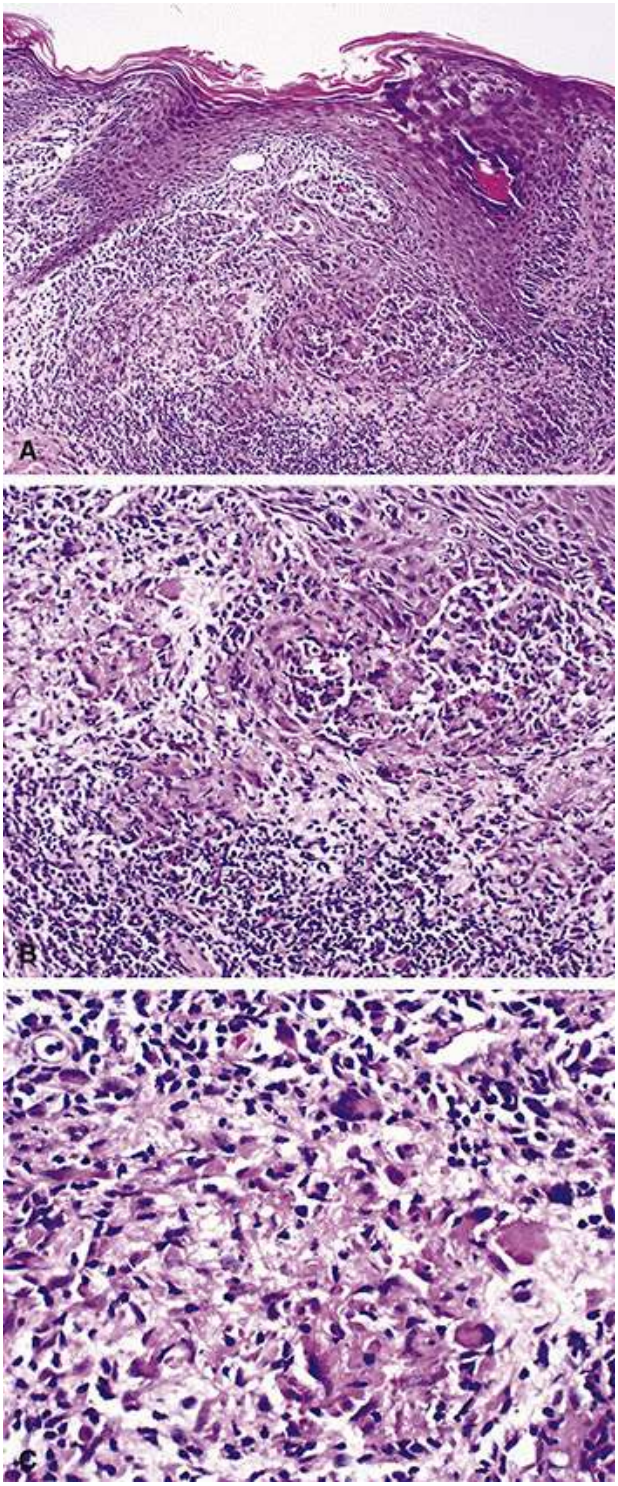

FIGURE 109.5 This man in his early 70s with chronic blepharitis had a biopsy of a hyperkeratotic area associated with madarosis. A, The epidermis is acanthotic with hyperkeratosis and parakeratosis. B, The dermis is diffusely infiltrated by lymphocytes and granulomas composed of loose aggregates of epithelioid cells with occasional multinucleated giant cells. The dermis between granulomas has a dense infiltrate of lymphocytes. C, The granulomas contain mostly epithelioid cells with a few giant cells. No fungi or acid-fast microorganisms were identified using histochemical stains. The histological findings in the biopsy are nonspecific, but the predilection for hair follicles favors granulomatous rosacea.

CHAPTER 110

Rosai-Dorfman Disease

Key Points

- Rosai-Dorfman disease (RDD) is a rare benign non-Langerhans cell condition characterized by a nonmalignant proliferation of histiocytes
- It most commonly is confined to cervical and other lymph nodes but can involve extranodal sites in 25% to 40% of cases
- The most common extranodal sites are the skin, orbit, eyelid, upper respiratory tract, salivary glands, central nervous system, bone, and testis
- Approximately 10% of patients exhibit skin lesions, and in 3% the disease is seen solely in the skin
- The etiology remains unknown, but proposals have included a disorder of immune regulation or a response to presumed infectious agents
- Most patients present with fever, fatigue, weight loss, night sweats, joint pain, and pharyngitis associated with painless, bilateral, massive cervical lymphadenopathy
- The most common ophthalmic presentation is with a painless soft eyelid thickening or a palpable mass, eyelid retraction, blepharoptosis, proptosis, uveitis, scleritis, decreased visual acuity, serous retinal detachments, and diplopia
- Symptomatic disease is treated with surgical excision, laser ablation, radiation therapy, intralesional steroids, or isotretinoin, but results are variable and inconsistent
- RDD often runs an indolent clinical course with spontaneous regression seen in about 41% of cases
- A 7% fatality rate has been reported from renal, CNS, or pulmonary complications

Rosai-Dorfman disease (RDD) is a benign non-Langerhans cell histiocytosis. It was first described in 1969 by Juan Rosai and Ronald Dorfman as a distinct histiocytic disorder in young black males presenting with chronic, bilateral, painless, massive cervical lymphadenopathy.[1] They termed the condition “sinus histiocytosis with massive lymphadenopathy,” which has since been referred to as Rosai-Dorfman disease. A subsequent report by these authors with a larger number of patients showed that there was no racial predilection for this disease.[2]

RDD is a rare disorder characterized by a nonmalignant proliferation of histiocytes.[3] The disease is typically located in lymph node sinuses but can also occur in extranodal sites.[1,2,4,5,6] Patients typically present with chronic, painless cervical lymphadenopathy seen in 90% of cases, combined with fever, leukocytosis, increased erythrocyte sedimentation rate, and hypergammaglobulinemia.[2] Other involved nodal groups include inguinal nodes in 26%, axillary nodes in 24%, and mediastinal lymph nodes in 15%.[2] The disease classically affects children and young adults at an average age of onset of 20 years, with a slight male predominance.

Although RDD most commonly is confined to the cervical and less commonly other lymph nodes, patients with RDD present with extranodal disease in 25% to 40% of cases. The most common extranodal sites are the skin, orbit, eyelid, upper respiratory tract, salivary glands, central nervous system, bone, and testis. The simultaneous involvement of multiple extranodal sites is not unusual. Foucar et al[2] reported extranodal involvement in the skin and soft tissue (16%), sinuses and nasal cavity (16%), bone (11%), salivary glands (7%), central nervous system (7%), oral cavity (4%), kidney/genitourinary tract (3%), and the lower respiratory tract (3%). In patients with extranodal involvement, lymphadenopathy may not develop until later in the course of the disease.[2]

Approximately 10% of patients with RDD exhibit skin lesions, and in 3% the disease is seen solely in the skin.[6,7] Cutaneous lesions may range from single papules to multiple nodules and plaques. They can be seen on any part of the body but are more common in the head and neck region. Skin lesions present as pink, red, purple, brown, or yellowish nodules, papules, or plaques that

can be sessile, polypoid, or exophytic and may be solitary or multiple.[8] In contrast to classic RDD, cutaneous RDD shows a slight female predominance, with an older age of onset in the fifth decade. These patients often lack lymphadenopathy as well as most of the systemic symptoms and laboratory abnormalities seen in classic RDD.[9]

The ophthalmic sites most commonly involved are the orbit and less frequently the eyelid.[2,10,11,12,13,14,15] Some ophthalmic cases may initially present without any evidence of lymphadenopathy,[16] and many also have other sites of extranodal involvement, such as the nasal cavity or paranasal sinuses.[2,10] In a series of 113 patients with RDD, Foucar et al[10] reported that 13 (11.5%) had ophthalmic manifestations, with the orbital soft tissue as the most frequent ophthalmic site of involvement. Orbital manifestations typically present as a nontender, rubbery mass often located in the lacrimal gland and eyelid.[17] Other clinical findings include conjunctival injection, blepharoptosis, epiphora, proptosis, blurred *(Print pagebreak 722)* vision, and diplopia.[18] Rare findings can include an epibulbar mass,[19] uveitis,[10,20,21] elevated intraocular pressure,[22] and endophthalmitis.[23]

Eyelid involvement is uncommon and usually is associated with orbital lesions.[2,8,13,17,18,24,25,26,27,28] The eyelids usually show a nontender thickening, often with massive swelling, erythema, and sometimes pitting edema. Eyelid masses usually measure 1 to 3 cm in size. Patients range in age from teens to old age, with more than half in the third to fifth decades. Males are affected more commonly than females.

Etiology and Pathogenesis

The etiology of RDD remains unknown. Middel et al proposed that this disease is a disorder of immune regulation or response to presumed infectious agents that has its major manifestation as the proliferation of sinusoidal histiocytes in lymph nodes.[29] They suggested that macrophage colony-stimulating factor (M-CSF) stimulation of monocytes/macrophages leads to immune suppressive macrophages as an important mechanism for the pathogenesis of sinus histiocytosis resulting in massive lymphadenopathy. Several viral and bacterial organisms have been suggested, including varicella zoster virus, cytomegalovirus, Epstein-Barr virus, human herpesvirus 6, Salmonella, Brucella, and Klebsiella species,[2,26,30,31,32,33,34] but to date, no specific infectious agent has been identified.[35] Other proposed etiologic mechanisms include autoimmune dysfunction or an aberrant reactive response to an unspecified antigen.[26] It has also been proposed that defective Fas/FasL signaling leading to altered apoptosis may be a mechanism leading to uncontrolled histiocytic proliferation.[30]

Clinical Characteristics

Most patients with RDD present with fever, fatigue, weight loss, night sweats, joint pain, and pharyngitis associated with painless, bilateral, massive cervical lymphadenopathy. Laboratory studies show an elevated erythrocyte sedimentation rate and hypergammaglobulinemia with a reversal of the albumin-globulin ratio.[2,30] Other findings can include leukocytosis with neutrophilia, a mild normochromic normocytic or hypochromic microcytic anemia, a positive rheumatoid factor and/or antinuclear antibody, and a polyclonal elevation of IgG.[2,30,34]

RDD usually affects children and young adults with an average age at onset of approximately 20 years, with a slight male predominance of 58%.[2] Although most cases are acquired, congenital cases have been reported.

Extranodal RDD has a predilection for the head and neck but intracranial lesions are uncommon.[36] The most common ophthalmic sites of involvement are the orbit or eyelid, seen in approximately 8% to 11% of cases.[2,10] In some patients, orbital involvement may be the presenting manifestation of the disease, and approximately 20% of ophthalmic cases have no initial evidence of lymphadenopathy,[2,16] and most may be associated with other extranodal sites of involvement.[2,10]

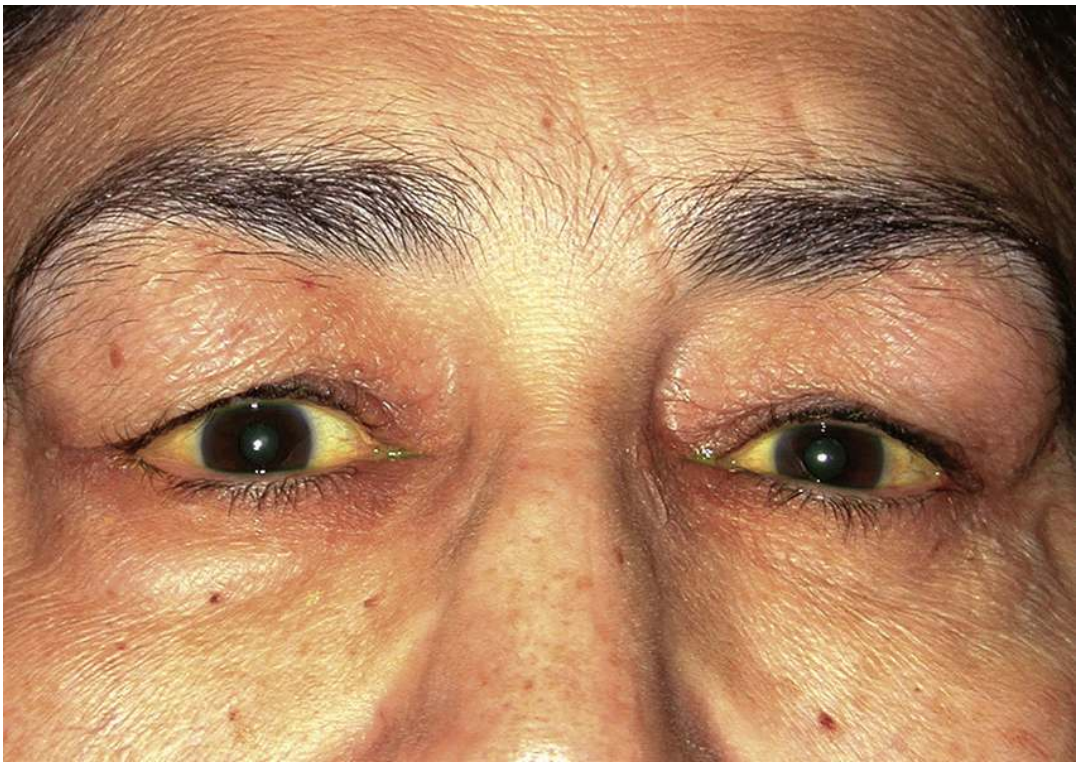

FIGURE 110.1 Rosai-Dorfman disease with bilateral upper eyelid swelling.

As mentioned previously, the most common ophthalmic presentation is with a painless soft tissue eyelid thickening and swelling (Figure 110.1) or a palpable mass, eyelid retraction, blepharoptosis, madarosis, conjunctival injection, and proptosis (Figure 110.2).[2] Other findings can include an epibulbar mass, uveitis, corneal lesions, scleritis, decreased visual acuity, serous retinal detachments, compressive optic neuropathy, limited extraocular motility, diplopia, and orbital pain.[13,14,15,20,37,38,39,40,41] Ocular involvement also has been reported with infiltration of the sclera and choroid.[37]

Differential Diagnosis

The differential diagnosis of RDD is broad due to variable clinical presentations and the large number of sites that can have extranodal involvement. RDD may mimic systemic conditions such as sarcoidosis, tuberculosis, leprosy, leukemia, granulomatosis with polyangiitis, nonspecific sinus hyperplasia, and Langerhans cell histiocytosis. Orbital RDD may clinically be misdiagnosed as an orbital inflammatory disease, juvenile xanthogranuloma, Erdheim-Chester disease, rhabdomyosarcoma, meningioma, lacrimal gland tumors, metastatic disease, lymphoma, other neoplastic tumors, and other histiocytic tumors. Definitive diagnosis is determined on histopathology, immunohistochemistry, and orbital imaging.

Treatment

There is no universally accepted treatment for RDD. Many lesions will remain relatively asymptomatic without any intervention.[42] In almost half of patients with RDD the clinical course is chronic, but with variable episodes of remission and exacerbation.[2] In a review of 80 patients with RDD from the literature, Pulsoni et al[43] reported that 50% required no treatment, and 82% of these (41% of the total) experienced complete spontaneous remission.

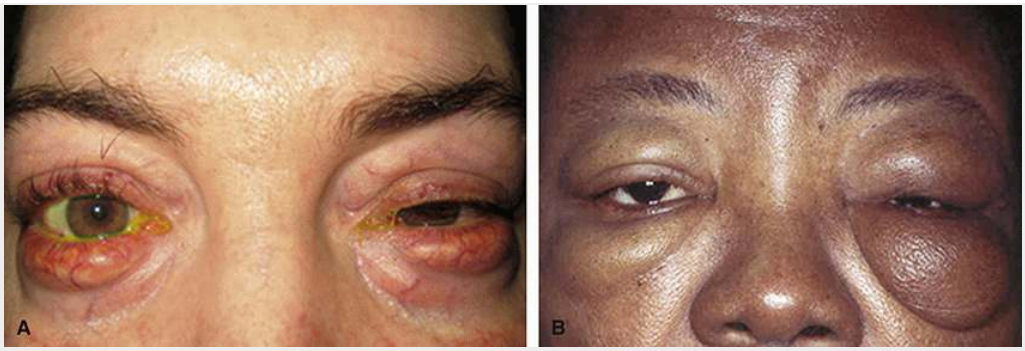

FIGURE 110.2 A, Bilateral lower eyelid thickening with telangiectatic vessels and mechanical ptosis. B, Massive edema of the eyelids with ptosis in a patient with Rosai-Dorfman disease. A, (Courtesy of Dr. Roman Shinder.) B, (Courtesy of Dr. David Jordan.)

For symptomatic or progressive disease, various treatment options have been utilized including surgical excision,[44,45] laser ablation,[46] radiation therapy,[38,47] intralesional steroids,[44,48] dapsone,[49] thalidomide,[50] and isotretinoin.[51] However, all treatments have shown variable and inconsistent results.

Complete surgical resection or debulking has provided the best results for patients with isolated, symptomatic, superficial masses or those with aesthetic or functional compromise,[13,26,37,38,44] and surgery combined with chemotherapy or radiotherapy has been advocated for cases with vital organ compression or life-threatening manifestations from nodal or extranodal involvement. Intralesional steroid injection at the time of surgery may be a useful adjunct.[52]

Chemotherapy has been advocated for cases of systemic disease with vital organ involvement[53,54] and orbital disease with compressive optic neuropathy.[37,41] But in a larger review of published cases, chemotherapy was shown to largely be ineffective.[43] Cyclosporine also has been used successfully in orbital cases.[55]

Radiotherapy is generally ineffective, with only about 33% of cases responding favorably.[44] But isolated case studies have reported good response of orbital and oral cavity involvement that were refractory to other treatments.[38]

Intralesional or systemic steroids have been reported to result in remission of orbital and systemic disease in several case reports.[26,56,57,58]

Pulsed dye laser selective photothermolysis and CO_2 laser ablation have been reported to achieve the resolution of isolated extranodal RDD.[46,59]

Prognosis

RDD often runs a lengthy, indolent clinical course.[4] Spontaneous regression is common, seen in about 41% of cases, especially in patients with localized disease.[44,60] In patients with widespread extranodal involvement, lymphadenopathy may persist for decades.[10,15,61]

While mortality is unusual, a 7% fatality rate has been reported from renal or CNS infiltration,[61] from respiratory involvement and pneumonia,[44] from a defect in immune function associated with autoimmune disease,[2,62,63,64] or from a coexistence of RDD and neoplastic diseases such as lymphoma or multiple myeloma.[2]

A poor prognosis is seen in cases of widespread systemic disease with involvement of visceral organs and those with immunological abnormalities, anemia with neutrophilia, lymphocytopenia, or an extremely high ESR.[67] Patients with an increased number of affected nodal groups and a greater number of extranodal sites also show a more unfavorable prognosis.[4]

Histopathology

The histopathological features of extranodal RDD involving the orbit[10,23] and eyelid[66] are similar to those of RDD in other extranodal[2,67,68] and cutaneous sites.[53,69,70,71,72] Orbital and eyelid RDD infiltrates typically form well-circumscribed masses surrounded by fibrous connective tissue, sometimes with satellite foci creating a lobular pattern.[10,23] Fibrosis may also be present within the RDD infiltrate, composing a majority of the excised tissue.[10] The predominant cells within the infiltrate are large histiocytes with abundant cytoplasm that may be pale staining and foamy (Figure 110.3) or brightly eosinophilic (Figures 110.4 and

110.5). Cytoplasmic borders may be poorly delineated (Figures 110.3 and 110.4) or sharply defined (Figure 110.5). Nuclei are round to oval with fine chromatin stippling and one or more small nucleoli.[10] Multinucleated histiocytes are occasionally present,[10] sometimes appearing as small, multinucleated giant cells.[23] Mitoses and cellular atypia of the histiocytes are rare.[10,23] The histocytes are accompanied by variable numbers of lymphocytes, plasma cells, scattered neutrophils, and occasionally eosinophils.[10,23] The lymphocytes may form aggregates (Figure 110.3) or follicles with germinal centers (Figure 110.4) or have a more diffuse distribution with looser aggregates (Figure 110.5). A distinctive feature of RDD, but not unique to this illness, is the presence of *(Print pagebreak 724) (Print pagebreak 725)* lymphocytes, plasma cells, or erythrocytes in the cytoplasm of occasional histiocytes,[10,23] a process termed "emperipolesis."[73] Emperipolesis in extranodal RDD is usually "much less prominent than in involved lymph nodes."[10] The histiocytes in RDD are diffusely immunoreactive for S100 protein and CD68 (Figure 110.3), which differentiates them from usual histiocytes that are positive for CD68 and negative for S100.[2] It is essential to note that S100 protein may be expressed in juvenile xanthogranuloma,[74,75] and we have seen one adult example of periocular xanthogranuloma with diffuse positivity of mononuclear and multinuclear histiocytes for CD68 and S100 protein. Thus, RDD's diagnosis requires correlating all of the histological and clinical features in a particular patient.

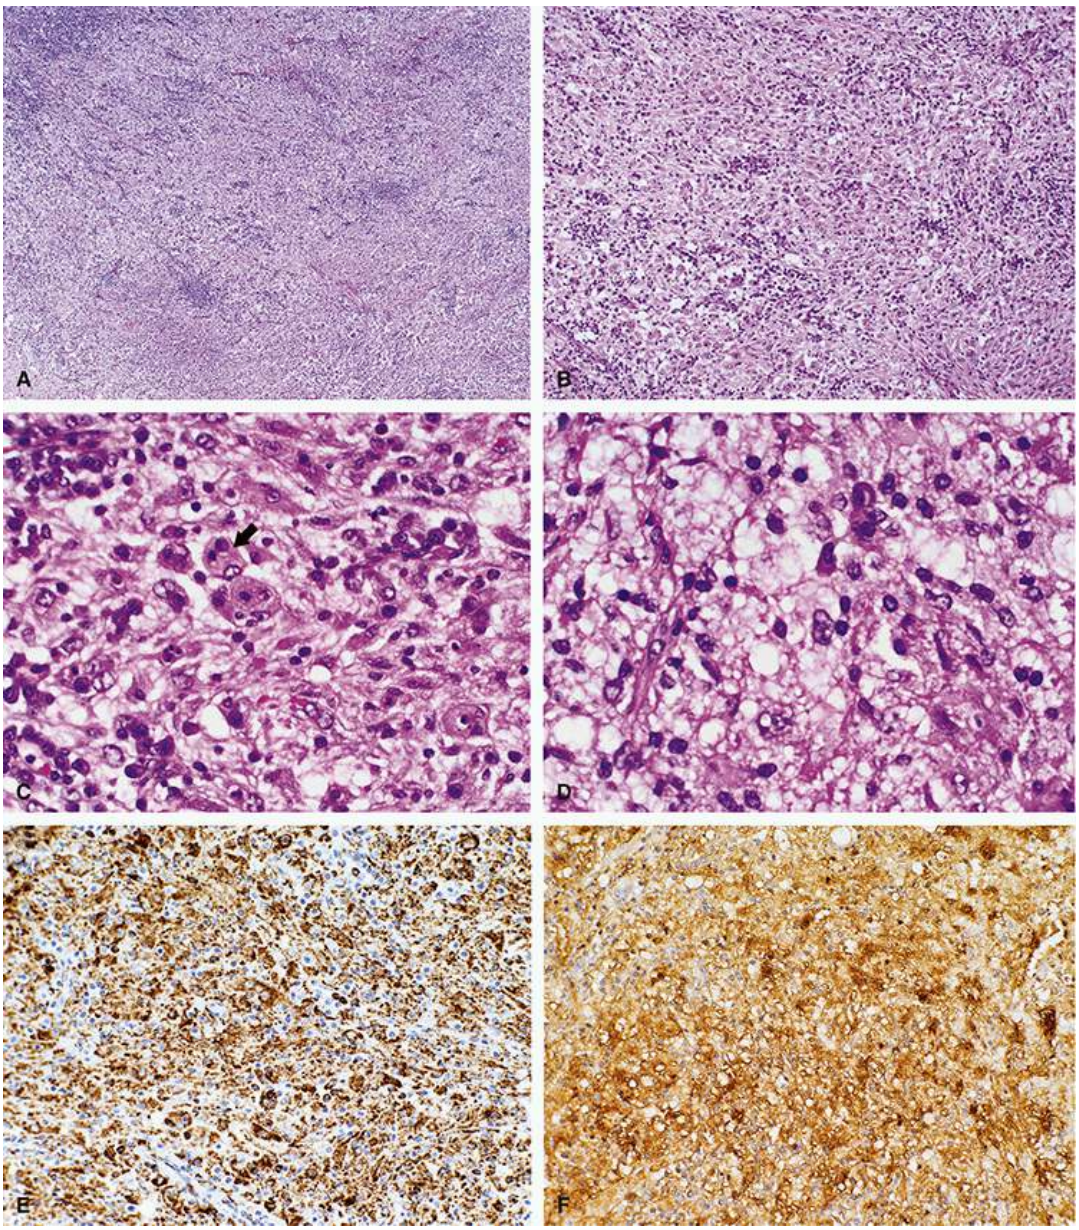

FIGURE 110.3 A-D, Rosai-Dorfman disease of the upper eyelid with predominantly pale staining, foamy histiocytes having indistinct cytoplasmic borders. There are scattered small aggregates of lymphocytes and plasma cells, as well as individual cells percolating among the histiocytes. A large histiocyte with a binucleate plasma cell and a neutrophil in its cytoplasm (emperipolesis) is in C (*arrow*). The histiocytes were all immunohistochemically positive for expression of CD68 (E) and S100 protein (F).

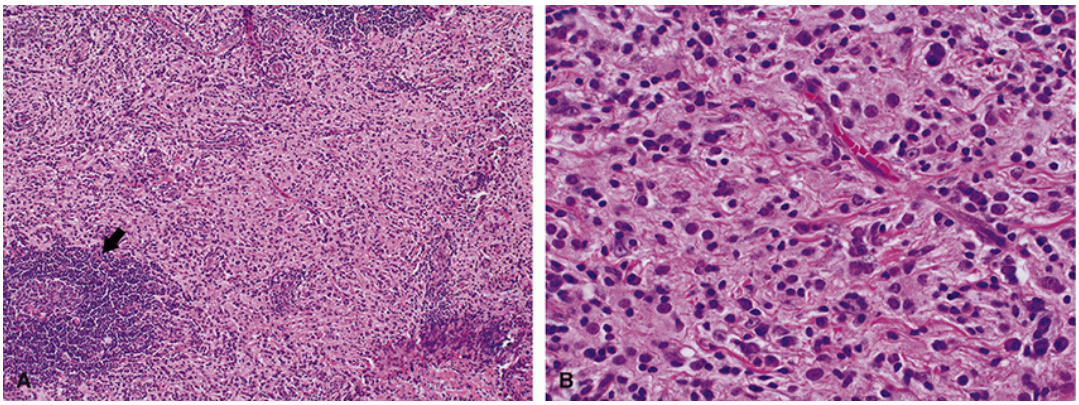

FIGURE 110.4 A and B, Rosai-Dorfman disease of the lower eyelid with histiocytes having eosinophilic, finely vacuolated cytoplasm and indistinct cytoplasmic borders. Lymphoid follicles with germinal centers are present, as seen in A (*arrow*). There is a diffuse infiltrate of lymphocytes and plasma cells among the predominating histiocytes.

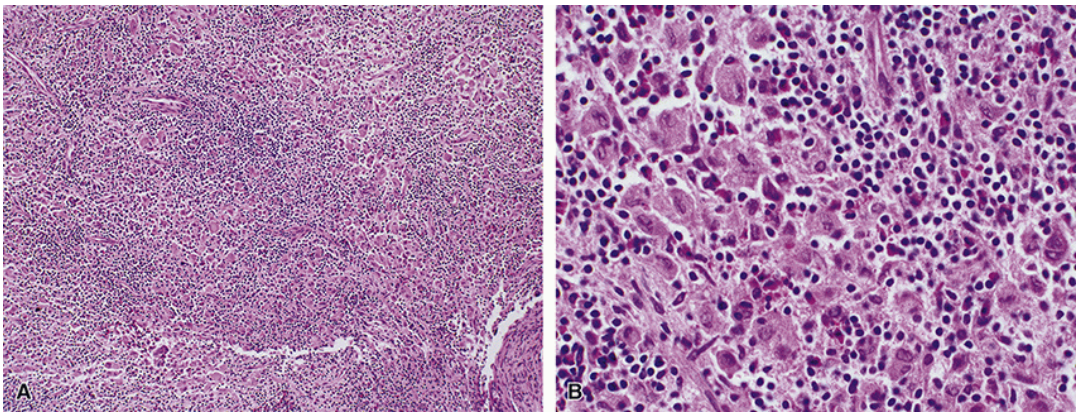

FIGURE 110.5 A and B, Rosai-Dorfman disease of the orbit featuring large, polygonal, histiocytes with eosinophilic cytoplasm and distinct cytoplasmic borders. There are numerous lymphocytes and plasma cells and scattered eosinophils among the histiocytes.

CHAPTER 111

Sarcoidosis

Key Points

- Sarcoidosis is a multisystem inflammatory disease of unknown etiology characterized by noncaseating granulomas in the involved organs
- The most common manifestation is pulmonary involvement, but extrapulmonary manifestations include the skin, central nervous system, peripheral nervous system, liver, kidney, musculoskeletal system, heart, salivary glands, the eye, and orbit
- Sarcoid uveitis is the most common ophthalmic manifestation
- Scar sarcoidosis is a rare circumscribed form of cutaneous sarcoidosis localized in scars
- Sarcoidosis develops in genetically susceptible individuals through an alteration of the immune system in response to certain environmental, occupational, or infectious exposures
- Eyelid lesions appear as yellowish to violaceous scaling, erythematous, firm small nodules, often associated with epiphora, pruritus, eyelid thickening, madarosis, and occasionally poliosis or trichiasis
- Up to 30% of patients with clinical sarcoidosis will undergo spontaneous remission
- Oral or intralesional corticosteroids are the initial treatment of choice for the management of sarcoid lesions of the eyelid
- Sarcoidosis is thought to predominantly be a benign condition, but more than 40% of patients require treatment for many years

Sarcoidosis is a multisystem inflammatory disease of unknown etiology characterized by noncaseating granulomas in the involved organs. Signs and symptoms of the disease are not specific, and it may take months to years before the correct diagnosis is made.[1] Sarcoidosis has a female predilection. Females also present at an earlier age and show a significantly higher frequency of eye, salivary gland, and skin involvement.[2] The age at onset shows peak incidences in the 3rd and 5th decades of life, but it can also be seen in children and adults over the age of 60. The disease is more common in black individuals than white, with an incidence ratio of 2:1 to 7:1[3,4,5] and a prevalence ratio of 3:1 to 5:1.[3] Serum angiotensin converting enzyme (ACE) has been used as a major biomarker for the diagnosis of sarcoidosis. ACE is produced by the epithelioid cells of the sarcoid granuloma,[6] and serum ACE levels have been used as a reflection of the granuloma burden in this disease,[7] with a sensitivity for the diagnosis between 41% and 100% and a specificity of 83% to 99%.[8]

The most common manifestation of sarcoidosis is pulmonary involvement but extrapulmonary manifestations include the skin, central nervous system, peripheral nervous system, liver, kidney, musculoskeletal system, heart, salivary glands, eye, and orbit.[9] After the lungs, the skin is the second most common organ involved in sarcoidosis, seen in 12% to 35% of patients with systemic disease.[10,11,12,13,14,15,16] Cutaneous lesions can be the presenting manifestation of the disease in about one-third of cases.[17] Cutaneous features include maculopapular eruptions, lupus pernio, and erythema nodosum.[12] Diagnosis is based on biopsy showing the presence of noncaseating granulomas, as well as the clinical features, raised inflammatory markers, elevated serum ACE, and hilar lymphadenopathy on chest radiography.

Ocular involvement has been reported in 11% to 60% of patients with sarcoidosis.[10,18,19,20,21,22,23,24] Females are affected more than males in a ratio of 2:1.[25] The occurrence of ocular involvement was reported to be 1.8 times greater in women than in men in one study[26] but 1.25 times greater in men than in women in another.[18]

Ophthalmic manifestations can involve the anterior and posterior segments of the eye, and less commonly the orbit and lacrimal

gland (Figure 111.1).[18] Sarcoid uveitis is the most common ophthalmic manifestation, presenting with bilateral mutton-fat keratic precipitates, anterior cells and flare, iris nodules, anterior and posterior synechia, and increased intraocular pressure often associated with pain, photophobia, and conjunctival injection.[20,27] Vitritis, vasculitis, choroidal lesions, and optic neuropathy characterize posterior segment involvement. Rare and atypical ophthalmic manifestations include limbal corneal nodules, retinal pigment epithelial detachments, and solitary choroidal granulomas.[28]

Granulomatous inflammation of the conjunctiva is the second most common ophthalmic finding in sarcoidosis,[29] usually involving the palpebral surface (Figure 111.2), but less frequently the bulbar conjunctiva.[30] Multiple translucent noncaseating conjunctival granulomas can occur as the first clinical signs.[31] Lesions present as one or more white, discrete conjunctival deposits that may show redness and irritation.[32] Occasionally they can present as follicular conjunctivitis[33,34] or progress to conjunctival *(Print pagebreak 729)* scarring and symblepharon formation[35,36] that may simulate a conjunctival tumor.[37]

FIGURE 111.1 Lacrimal gland involvement with sarcoidosis.

The age distribution of ocular sarcoidosis in adults is bimodal, with two peaks of incidence between 20 and 30 years and 50 to 60 years.[23] The mean age at presentation of uveitis is 42 years (range 4-82),[38] and ocular findings are reported to be higher and to occur at an earlier age in patients of African descent compared with Caucasians.[39,40]

Adnexal involvement is rarely associated with intraocular inflammation.[12] In one study of 30 patients with adnexal sarcoidosis, only 3% had concomitant intraocular inflammation.[41] The incidence of eyelid involvement in adnexal sarcoidosis may be as high as 17%.[19,20,41] It is seen in adults at a mean age of 46 years (range 29-66), and with 58% occurring in males. Eyelid erythema and swelling may be the only sign,[42,43] with lesions varying in size from small papules[44] to large masses.[45] Chronic eyelid nodules may cause eyelid deformities, with extensive scarring, entropion, trichiasis, madarosis, or symblepharon (Figure 111.3).[46,47] Isolated eyelid structures such as the Müller muscle may be involved with granulomatous inflammation causing eyelid retraction.[48]

FIGURE 111.2 Sarcoid granulomatous inflammation of the upper eyelid palpebral conjunctiva.

Scar sarcoidosis is a rare circumscribed form of cutaneous sarcoidosis localized in scars that have been described in patients with systemic sarcoidosis or patients with no evidence of systemic disease.[45] However, Ingber and Klinken showed that scar sarcoidosis can be an early sign of systemic sarcoidosis.[49] It is marked by inflammatory infiltrations and bruise-like, black and blue discoloration. Scar sarcoidosis has been described following herpes zoster infections[50] and in previous scars caused by venipuncture, trauma, tattoos, and sites of previous laser surgery.[51]

Etiology and Pathogenesis

Sarcoidosis has long been recognized as a disease with a genetic background owing to its accumulated appearance in families and within twin pairs. One twin study showed an 80-fold increased risk for the development of sarcoidosis for the monozygotic twin of an affected individual.[52] Several novel predisposing genes have been identified by genome-wide association studies, including several HLA class II alleles, tumor necrosis factor (TNF) and interleukin 23 receptor (*IL23R*) genes, the butyrophilin-like 2 (*BTNL2*) gene, and the Ras-related protein Rab-23 (*RAB23*) gene. A detailed discussion of the possible predisposing genetic associations with sarcoidosis is beyond the scope of this chapter and has been extensively discussed elsewhere.[52]

Sarcoidosis likely develops in genetically susceptible individuals through an alteration of the immune system in response to certain environmental, occupational, or *(Print pagebreak 730)* infectious exposures.[53,54] A comparison of gene expression in normal lungs and lungs affected by sarcoidosis found an upregulation of T helper-1 (Th1) immune response genes in sarcoidosis and also of genes regulating macrophage-derived proteases matrix metalloprotease 12 and ADAM-like decysin-1.[55] A study of gene expression in skin lesions and normal skin of patients with sarcoidosis and the skin of normal controls found that skin lesions showed a strong Th1 profile and expression of interleukin (IL)-23 and IL23R.[56]

FIGURE 111.3 Papular and nodular sarcoid lesions on the eyelids.

It is believed that sarcoidosis is a granulomatous reaction to one or more inciting exogenous agents in genetically susceptible individuals.[57] Epidemiologic studies support an environmental trigger with case clustering, transmissibility by organ transplantation, and an immune response typical for nonself antigens.[58] Besides an environmental trigger and a genetically mediated immune response, additional genes and exposures can likely modify the risk for the development and severity of sarcoidosis.[59] Such modifier exposures might include smoking, which is known to decrease the risk of sarcoidosis, and photocopier toner and certain insecticides, which can increase the risk.[60,61]

Granulomas are inflammatory responses consisting of mononuclear phagocytes and their derivatives.[62] The inciting event involves the deposition of antigenic material, not yet identified, into tissues where it is phagocytosed or endocytosed by macrophages or dendritic cells,[63] is transported to the cell surface, and activates CD41 T cells.[64] The granuloma organizes through the elaboration and secretion of cytokines and chemokines.[65] The ensuing immune response leads to clinical lesions of sarcoidosis characterized by elevated IFN-g, IL-2, and IL-12. TNF alpha is a critical cytokine in this process that enhances the recruitment of macrophages into the granuloma.[66]

Clinical Characteristics

Eyelid involvement in sarcoidosis is rare. Typically, the eyelid lesions appear as yellowish to violaceous scaling and erythematous, firm small nodules, often associated with epiphora, pruritis, eyelid thickening, madarosis, and occasionally poliosis or trichiasis.[13,67], They may also appear as larger nodules,[13,16,19,67,68,69,70,71] papular eruptions,[16,44,68,69,70] lupus *(Print pagebreak 731)* pernio plaques,[16,72] or swelling of the eyelids (Figure 111.3).[44] Eyelid nodules very rarely ulcerate or become necrotic.[72] Even rarer is destructive sarcoidosis affecting the full-thickness eyelid leading to tissue loss (Figure 111.4).[46,47] Scar sarcoidosis may occasionally develop at the site of old injuries or tumor resections (Figure 111.5). Dry eyes reported in patients with eyelid sarcoidosis are attributed to infiltration of the lacrimal gland and destruction of the meibomian glands.

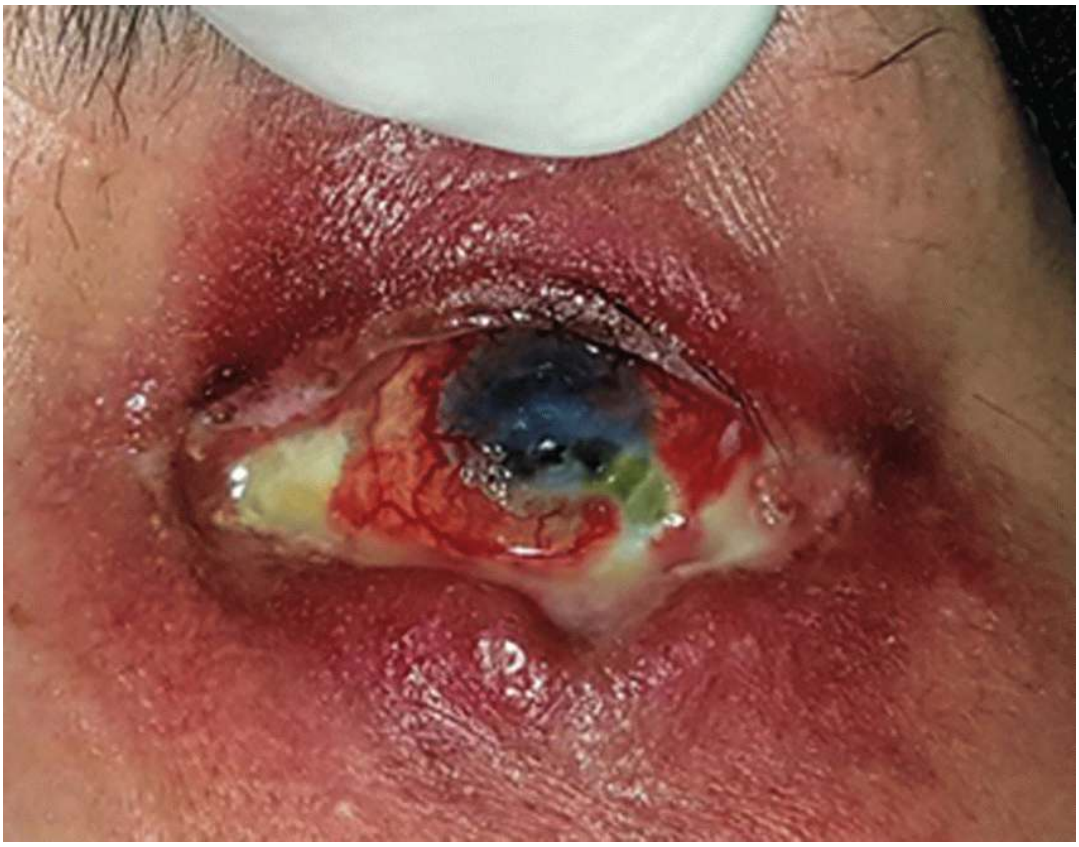

FIGURE 111.4 Necrotizing sarcoidosis with extensive tissue destruction of upper and lower eyelids.

Differential Diagnosis

The differential diagnosis of sarcoidosis includes idiopathic granulomatous inflammation, granulomatosis with polyangiitis (GPA), tuberculosis, leprosy, nontuberculous mycobacterial infection, secondary syphilis, herpes simplex, scleroderma, eosinophilic fasciitis, Behcet disease, cutaneous lupus, and fungal granulomas. The list also includes inflammatory conditions such as chalazia, cystic lesions such as epidermal cysts, various malignant and nonmalignant neoplasms, others such as xanthomas, and viral infections such as molluscum contagiosum.

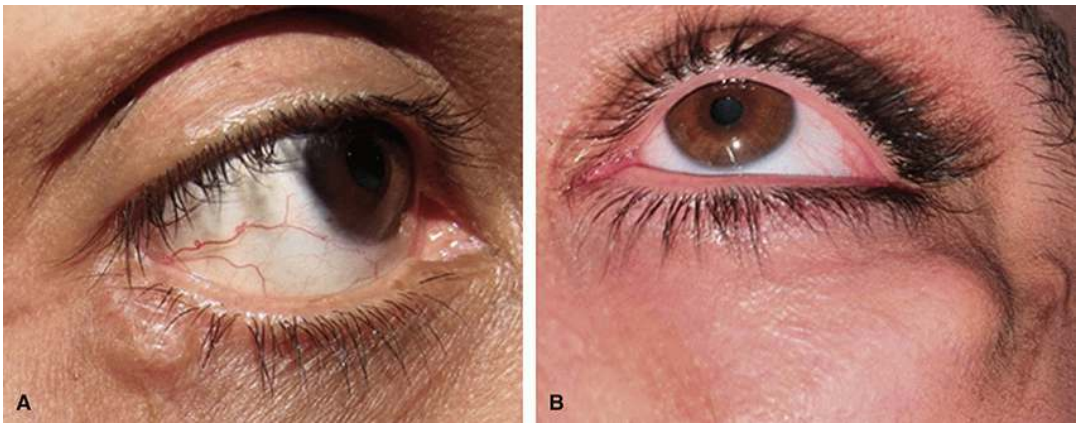

FIGURE 111.5 Scar sarcoidosis. A, Sarcoid arising in an old basal cell carcinoma scar. B, Subcutaneous sarcoidosis adjacent to an old traumatic lateral canthal scar.

Treatment

Up to 30% of patients with clinical sarcoidosis will undergo spontaneous remission.[10] Management is aimed at the relief of symptoms and minimizing the loss of function[73] and will depend on the extent of the disease, the degree of functional

impairment, and the presence or absence of systemic disease.[74] Oral corticosteroids are the initial treatment of choice for ophthalmic and active systemic sarcoidosis.[20] The use of intralesional triamcinolone in the management of sarcoid lesions of the eyelid has been reported in the literature with good effect.[45] The major risks of steroid medications include skin atrophy, dyspigmentation, and the development of telangiectasias.

In cases refractory to steroids cytotoxic agents such as methotrexate, azathioprine, leflunomide, and mycophenolate have been considered second-line therapy for sarcoidosis.[75,76,77] These agents work by inhibiting cell activation, proliferation, and migration through cytokine modulation or the generation of extracellular anti-inflammatory mediators.[78,79,80]

Tumor necrosis factor antibodies such as infliximab have also been proposed as a potential treatment for systemic and ophthalmic sarcoidosis.[81,82] These block cell activation and proliferation, inhibiting granuloma formation and promoting granuloma dissolution.[83,84] TNF antagonists also eliminate TNF-expressing cells through complement-dependent cytotoxicity and apoptosis.[85]

(Print pagebreak 732)

Other therapies for cutaneous lesions in sarcoidosis have been reported to be useful.[64] Photodynamic therapy has yielded beneficial results, but recurrence often follows after discontinuation.[86,87,88] Ultraviolet A phototherapy also has been reported to yield improvement in skin lesions after 30 to 50 treatments,[89] but, as with photodynamic therapy, it may be associated with burning, erythema, and skin discomfort. Pulsed dye, CO_2, ruby, and potassium titanyl phosphate lasers have also been reported to give good results.[90,91,92,93,94,95] Conservative surgical excision can be used when a tissue sample is necessary for diagnosis, in some scar or subcutaneous sarcoid nodules, or in severe cases refractory to medical therapies.

Prognosis

The course of sarcoidosis is variable, and there is no reliable biomarker for prognosis. Although sarcoidosis is thought to predominantly be a benign condition, a survey of major centers found that more than 40% of patients with sarcoidosis with more than 5 years of follow-up were still receiving therapy for their disease.[96] Age, pulmonary fibrosis, and pulmonary hypertension are the major factors relating to poor prognosis in patients with chronic pulmonary sarcoidosis.[97] For eyelid lesions, the prognosis is good with oral, intralesional, or systemic steroids or cytotoxic agents, or with partial or complete surgical excision depending upon the degree of tissue destruction.

Histopathology

The histopathological feature deemed typical of sarcoidosis, including that in the skin, is the so-called naked granuloma characterized by noncaseating (nonnecrotizing) epithelioid granulomas lacking a prominent cuff of lymphocytes.[98] However, sarcoidal granulomas are a morphologic spectrum based on the evolution and duration of lesions.[98,99] Early lesions have globular masses of macrophages developing into epithelioid cells, usually without the formation of multinucleated giant cells.[98] Aging sarcoidal granulomas have epithelioid cells in a radial pattern, an increasing number of giant cells, and a fine pattern of reticulin throughout the lesion.[98] Later lesions have fibrosis beginning at the periphery that may progress inward; hyalinization may accompany the fibrosis.[98] End-stage sarcoidal lesions are hyaline fibrinoid masses.[98] In addition to varying appearances of the granulomas, the histological appearance depends on the clinical subtype of cutaneous sarcoidosis: papules, plaques and nodules, subcutaneous, scars, and infrequently seen variants such as ulcerative and verrucous.[100] Papules typically have granulomas superficially in the papillary and upper reticular dermis, and plaques have granulomas throughout the entire dermis.[100]

Ball, Kho, and Martinka reported the histological findings in 28 biopsies from 24 patients with systemic sarcoidosis.[101] They classified granulomas as naked if the lymphocyte cuff was less than 25% of the granuloma diameter, tuberculoid if the lymphocyte cuff was >25% of the granuloma's diameter, interstitial if three or more adjacent single or multinucleated histiocytes were aligned in single file between two collagen fibers, and linear if the length of the granuloma was ≥4 times their smallest diameter.[101] Of 28 biopsies, 25 (89%) had naked granulomas, and in 19 (68%), these were the only types of granulomas.[101] Four biopsies (14%) contained tuberculoid granulomas: two biopsies had only tuberculoid granulomas and two had tuberculoid and naked granulomas.[101] Five biopsies (18%) had focal interstitial granulomas, and in four, there were also naked granulomas.[101] Half of the biopsies had irregular fragments of birefringent foreign material >1 μm in diameter within granulomas, and half of these were cases of scar sarcoidosis.[101] Twelve biopsies (43%) had focal necrosis: eight had fibrinoid necrosis within granulomas, and four had focal necrobiosis of dermal collagen around granulomas.[101] Linear granulomas around small dermal nerves resembling those in tuberculoid or borderline tuberculoid granulomas were in five biopsies (18%).[101] All biopsies had multinucleated giant cells, a mixture of Langhans and foreign body types.[101] The cytoplasm of multinucleated giant cells in 15 biopsies (53%) contained asteroid bodies (stellate inclusions[98]) and/or Schaumann bodies (concentric lamellated calcifications[98]).[101] Additional histological

findings were elastophagocytosis (39% of biopsies), increased dermal mucin in or near granulomas (18% of biopsies), and lichenoid inflammation (14% of biopsies).[101] The Ball, Kho, and Martinka study amply demonstrates the variable histopathological features of cutaneous sarcoidosis and the high percentage of biopsies with naked granulomas.[101]

More recent studies have confirmed and elaborated upon the varying histological features of cutaneous sarcoidosis; Table 111.1 summarizes histopathological features abstracted from data in five papers reporting 229 biopsies.[101,102,103,104,105] Naked granulomas are present in about 80% of biopsies and tuberculoid granulomas in about 20% of biopsies. The granulomas have multinucleated giant cells in 95% of biopsies, focal fibrinoid necrosis in 15%, and foreign material in about 20% of biopsies. Granulomas may occur anywhere in the dermis and less commonly in the subcutis. About 20% of biopsies have perineural granulomas, but the invasion of nerves is not present and helps differentiate sarcoidosis from tuberculoid leprosy.[106] Approximately 20% of biopsies have epidermal changes, with epidermal atrophy being the most common finding. The only histopathological feature that correlated with the clinical disease course in a study of 41 patients was the severity of the cutaneous granulomatous infiltrate.[107] Skin biopsies exhibiting a moderate or severe granulomatous infiltrate had more severe systemic clinical manifestations, a more chronic disease course, and more generalized skin involvement.[107] Granulomas in the eyelid skin[13,44] (Figure 111.6) and conjunctiva[108] (Figure 111.7) resemble cutaneous sarcoidosis occurring elsewhere on the body.

n = number of biopsies; NA = not available.

[a] Naked granulomas had few lymphocytes cuffing the granulomas; tuberculoid granulomas had moderate to marked numbers of lymphocytes.

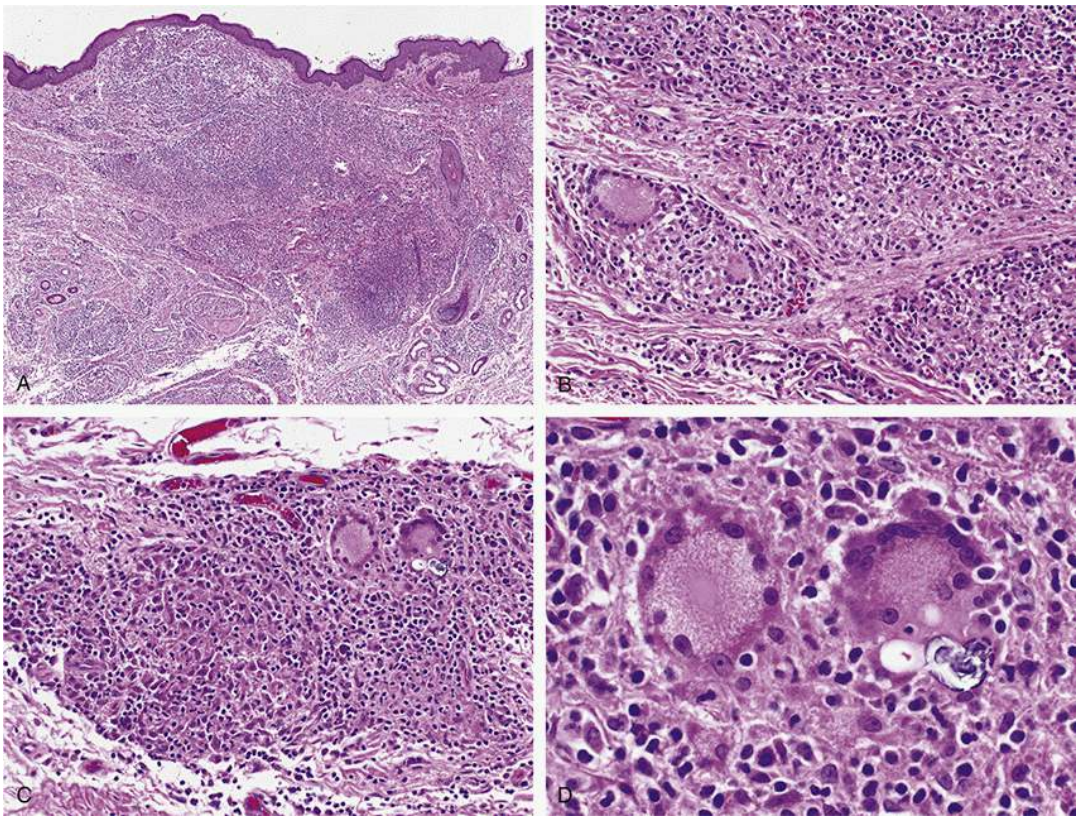

FIGURE 111.6 In his mid-20s, a man with iritis in his left eye developed an elevated, soft, mobile irregularity under the skin of the right lateral canthus with epidermal hypopigmentation. He was diagnosed with eyelid, lacrimal gland, intraocular, and pulmonary sarcoidosis. A, Numerous granulomas extend from the superficial to the deep dermis with areas of coalescence. B, Some areas have loose aggregates of epithelioid cells (top half of photomicrograph) with adjacent circumscribed, compact granulomas (bottom left and right). Epithelioid cells far outnumber lymphocytes in the granulomas. C, Coalescent epithelioid granulomas with admixed lymphocytes and two Langhans giant cells. D, Epithelioid cells and interspersed lymphocytes surround two Langhans giant cells. A basophilic Schaumann body is in the cytoplasm of one of the Langhans giant cells (right).

(Print pagebreak 735)

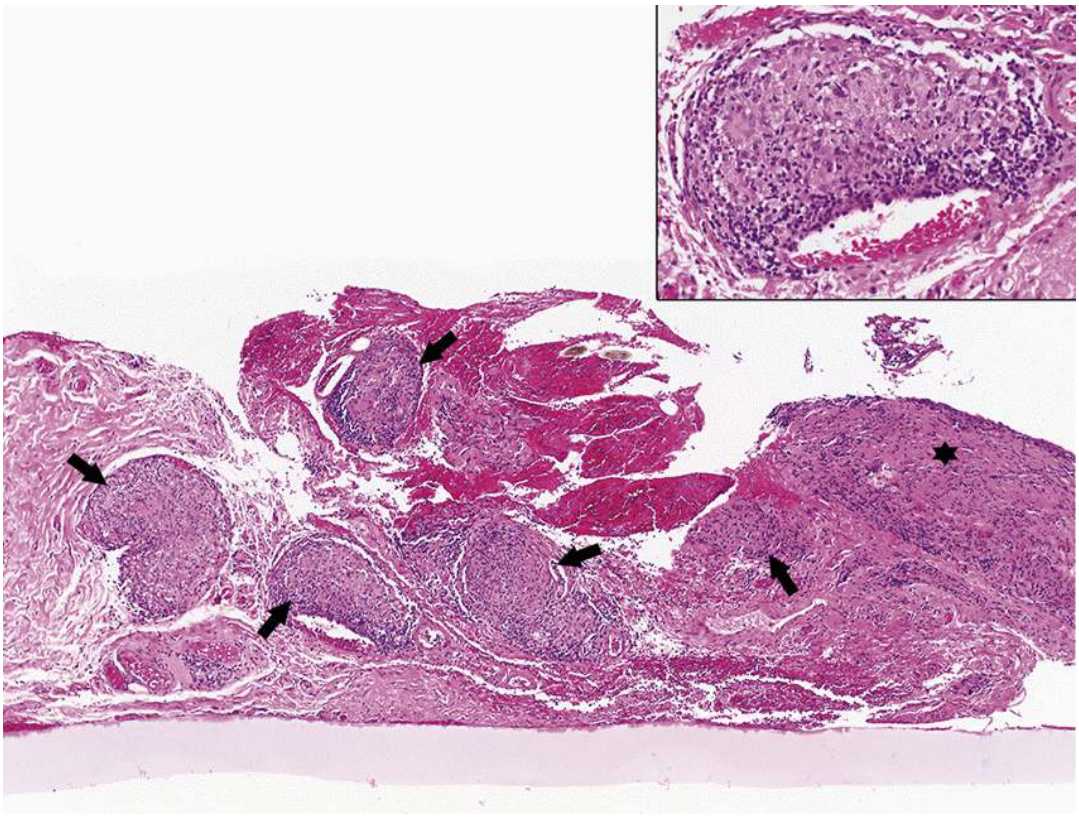

FIGURE 111.7 This conjunctival biopsy was from a woman in her late 70s with bilateral, chronic, severe conjunctivitis with minimal cicatrization. The conjunctival substantia propria contains multiple well-circumscribed granulomas (*arrows*) with focal scarring (★). The granulomas are composed of epithelioid cells, multinucleated giant cells, and a thin rim of lymphocytes (inset). Epithelium is only on the right side of the photomicrograph; most of the epithelium is artifactually detached.

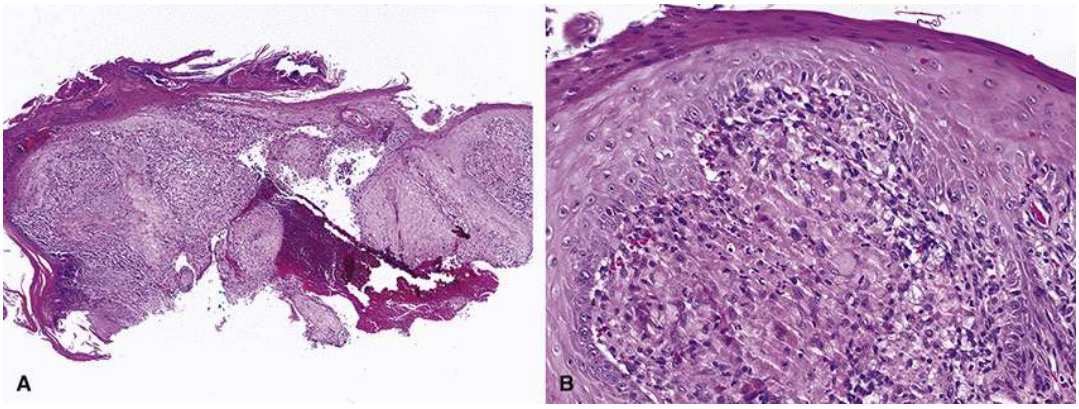

FIGURE 111.8 A man in his 30s with pulmonary and cutaneous sarcoidosis developed progressive right upper eyelid irritation, mild pain, and a 12-mm-diameter ulcer. A, The right upper eyelid lesion has healing ulceration with a thick layer of parakeratosis and pseudoepitheliomatous hyperplasia of the epidermis. B, The dermis contains nonnecrotizing granulomatous inflammation with discrete and coalescing granulomas composed of epithelioid cells and occasional multinucleated giant cells surrounded by a sparse lymphocytic infiltrate.

Subcutaneous sarcoidosis may occur with or without dermal involvement, as evident in Table 111.1. In a study of 28 patients with subcutaneous sarcoidosis, Marcoval, Penin, and Mañá reported that the 10 patients with dermal involvement had granulomas restricted to the deep reticular dermis and subcutis.[109] Fibrosis was evident in 75% (21/28) of the biopsies; the fibrosis was septal in 5, between granulomas in 4, septal and between granulomas in 3, diffuse in 3, and without a definite pattern in 6 cases.[109] Orbital sarcoidosis resembles subcutaneous sarcoidosis histopathologically.[110]

Ulcerative sarcoidosis is usually found in patients with a known history of sarcoidosis, although one review noted ulcers as the initial sign of sarcoidosis in 11 of 35 cases.[111] Ulcerative sarcoidosis occurs most commonly in adults younger than 40 years,[111,112] and there is a female and African-American preponderance.[111,112,113] It usually involves the pretibial region of the legs but has

been reported to affect the arms, trunk, face, penis, buttock, and head.[111,114] There are rare reports of ulcerative sarcoidosis of the eyelid,[47,115] and we have seen one case in our practices (Figure 111.8).

CHAPTER 112

Schwannoma

Key Points

- Schwannoma is a benign tumor that originates from the proliferation of Schwann cells of myelinated peripheral nerve sheaths
- This tumor is usually considered to be benign, but malignant transformation has been reported
- Schwannomas can be associated with syndromic disorders such as neurofibromatosis type 2, Carney complex, and schwannomatosis
- Clinically, a schwannoma presents as a slow-growing solid, painless, round to elongated, mobile mass in the upper or lower eyelid, and rarely the lateral canthus
- Management of eyelid schwannomas is usually by complete surgical excision with clear margins
- With complete surgical excision, the prognosis is excellent and recurrence is extremely rare, but excision usually requires sacrifice of the associated nerve

Schwannoma is a benign tumor that originates from the proliferation of Schwann cells of myelinated peripheral nerve sheaths. They can arise from any nerve in the body but are located most commonly in the head and neck, followed by the flexor surfaces of the limbs and the trunk.[1] Ophthalmic occurrences are seen most often in the orbit[2] and less frequently in the conjunctiva,[3,4,5,6,7,8,9,10,11,12] uveal tract, and sclera.[13] Schwannoma in the eyelid is extremely rare with fewer than 25 cases reported in the literature to date.[14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33,34] Schwannomas can occur in isolation or as multi-ple lesions in some genetic syndromes.[7] The age range in the reported cases of eyelid schwannoma is 8 to 75, with a mean of about 42 years, and with no gender predilection. The size of the eyelid lesions ranges from 2 mm to 3.5 cm, with 66% being 10 mm or less in maximum diameter.

Although this tumor is usually considered to be benign, malignant transformation has been reported, and malignant schwannomas account for 5% to 6% of malignant soft tissue tumors.[35] However, no cases of malignant schwannoma have been reported in the eyelid.

Etiology and Pathogenesis

Schwannomas are among the most common peripheral nerve sheath tumors, which also include neurofibromas, perineuriomas, granular cell tumors, and malignant peripheral nerve sheath tumors.[36] They consist of a clonal population of Schwann cells, and although most cases are sporadic, some are associated with genetic syndromes such as neurofibromatosis type 2, schwannomatosis, or Carney complex. Although all three of these conditions include the development of neural tumors, their genetic bases are distinct. The most prominent feature of all three is the appearance of peripheral nervous system Schwann cell tumors.[36]

Schwannomas associated with syndromic disorders are associated with genetic mutations. Neurofibromatosis type 2 (NF2) is an autosomal dominant disorder associated with a mutation of the *NF2* gene on chromosome 22q12.[37] About 95% of patients with NF2 are affected with vestibular schwannomas, but these tumors are also found on intracranial and spinal nerves. Carney complex is a rare, autosomal dominant, multiple endocrine neoplasia and lentiginosis syndrome, and in most patients is caused by defects in the *PRKAR1 A* gene.[38,39] Schwannomatosis is an autosomal dominant condition characterized by a predisposition to develop multiple schwannomas affecting peripheral and spinal nerves and, less frequently, meningiomas.[39] It is associated with a heterozygous germline pathogenic variant in the *SMARCB1* (22q11) or *LZTR1* (22q11) genes. In patients younger than 25 years with apparent sporadic cranial schwannomas (mostly vestibular), 20% were found to have an identifiable constitutional genetic predisposition consisting of either *NF2* or *LZTR1* mutations.[40] In another study of sporadic schwannomas in adults, 38.5% were found to harbor *SMARCB1* or *NF2* mutations, without any evidence of neurofibromatosis or schwannomatosis.

Schwannomas of the eyelid were first reported by Mishra and Sharan in 1960.[41] They usually are associated with branches of the supraorbital, supratrochlear, and infraorbital nerves. In the conjunctiva, schwannomas are believed to arise from the nasociliary nerves, and also possibly from autonomic nerves that are subconjunctival in location.[10]

Occasionally, schwannomas may occur after radiation therapy.[42,43] Postradiation schwannomas can be delayed for up to 50 years following treatment.[42,44,45,46,47]

Clinical Presentation

Clinically, schwannomas present as a slow-growing solid, painless, round to elongated, mobile mass in either the upper or lower eyelid, and only rarely the lateral canthus *(Print pagebreak 740)* (Figure 112.1).[26,32] They have a smooth nodular outline, sometimes with the nerve of origin visible, and when cut they have a tan or yellow color, often with areas of hemorrhage and cystic change.[36] Rarely, eyelid schwannomas can present with upper eyelid ptosis as the presenting symptom (Figure 112.2A).[26,48] One case has been reported with inflammatory signs of eyelid swelling, erythema, and ulceration simulating a malignancy.[26] Very rarely, malignant schwannoma can involve the eyelid (Figure 112.2).

FIGURE 112.1 Smooth, solid nodular schwannomas of the eyelid. A and B, (Courtesy of Dr. David Jordan.)

Differential Diagnosis

The differential diagnosis of schwannoma includes other solid, subepidermal masses, and when on the eyelid, it can mimic an inclusion cyst, chalazion, hidrocystoma, or papilloma, or other soft-tissue and neurogenic tumors such as neurofibroma.[15,19,21,26,31,33] They can also be confused with malignant eyelid tumors such as sebaceous gland carcinoma, sweat gland tumor, and hair follicle tumor.[49] When involving the conjunctiva, the differential includes nodular scleritis, myxoma, parasitic cyst, and hemangioma.[4]

Treatment

Management of eyelid schwannomas is usually by complete surgical excision with clear margins. Incomplete removal is

associated with recurrence and sometimes more aggressive behavior with infiltration into surrounding tissue planes.[15,16,50] Preservation of nerve continuity is desirable, but this is not always possible.

Radiotherapy has not been used for eyelid schwannomas, but reports on its use for other schwannomas, such as *(Print pagebreak 741)* the facial nerve, have shown limited benefit and risks persistence of the tumor, tumor regrowth, and possible malignant degeneration.[51]

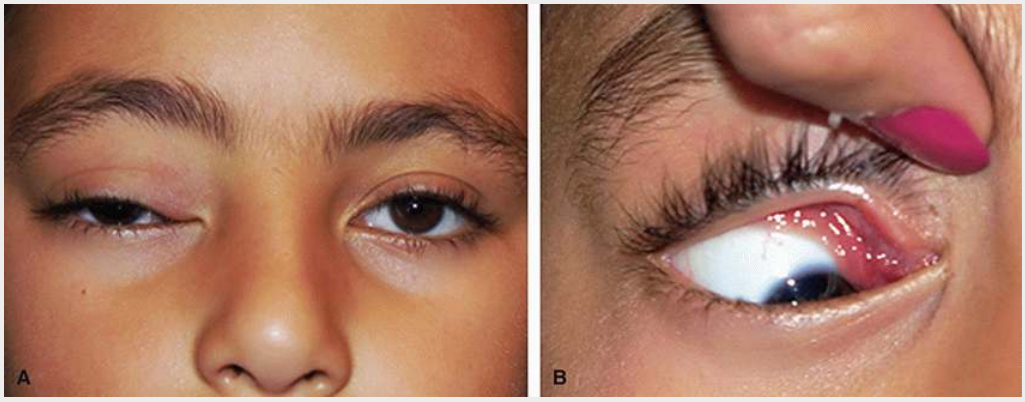

FIGURE 112.2 A rare case of malignant schwannoma of the eyelid and conjunctiva.

Prognosis

The number of reported eyelid schwannomas is too small to determine the ultimate prognosis with any form of treatment. For schwannomas elsewhere in the body, with complete surgical excision, the prognosis is excellent and recurrence is extremely rare. However, this usually requires sacrifice of the associated nerve. Recurrence of tumor can be seen where sacrifice of the nerve is not possible or not desired. In a series of 103 vestibular schwannomas treated with subtotal or near-total resection, the recurrence rate was 13.6% at a median of 41 months.[52] The decision to opt for less than a total resection is based on the intraoperative findings and the decision that more complete dissection would result in an undesired compromise of neurologic function.

Histopathology

Cutaneous schwannomas are encapsulated well-circumscribed nodules usually located in the subcutaneous fat (Figure 112.3),[53,54] although they may be in the dermis (Figure 112.4) with or without extension into the subcutis.[55] Conventional (classical) schwannomas are spindle cell tumors with varying proportions of compact areas (Antoni A areas) and loosely arranged foci (Antoni B areas).[55,56] Antoni A areas are cellular with interlacing fascicles (Figure 112.3B) of spindle-shaped Schwann cells having elongated, twisting, tapering nuclei (Figure 112.3C)[55,57] and modest amounts of eosinophilic cytoplasm without discernible cell borders.[56] The Schwann cell nuclei may align parallel to each other (palisading) separated by their eosinophilic cell processes, forming Verocay bodies (Figure 112.3C).[54,55,56,57] Antoni B tissue has a loose cobweb-like meshwork of haphazardly arranged Schwann cells in a myxoid matrix containing lipid-laden histiocytes and dilated blood vessels with thick, often hyalinized, walls.[54,55,56] Cytoplasmic nuclear inclusions and nuclear pleomorphism may be seen,[56] but mitoses are rare.[58] Longstanding ("ancient") schwannomas feature degenerative changes with nuclear atypia, sclerotic blood vessels, calcification, pseudocysts, and foci of necrosis with hemosiderin-laden macrophages (siderophages).[54,55,56] Cellular schwannomas are highly cellular, composed solely or predominantly of Antoni A tissue without Verocay bodies,[56,59] have focal mitoses[54] and Ki-67 proliferation hot spots,[56] and most often involve large nerves and nerve plexuses[56] with rare examples in the skin.[55] Other rare schwannoma variants that may occur in cutaneous tissue include plexiform schwannoma, granular cell schwannoma, collagenous spherulosis schwannoma, glandular schwannoma, epithelioid schwannoma, neuroblastic schwannoma, psammomatous melanotic schwannoma, and microcystic or reticular schwannoma.[54,55]

The neoplastic Schwann cells express vimentin, myelin basic protein, S100 protein (Figures 112.3D and 112.4D), and SOX10.[54,58] Expression of calretinin by tumor cells (Figure 112.4E) occurs in 27%[60] to 96%[61] of schwannomas and 0%[60] *(Print pagebreak 742)* to 7%[61] of neurofibromas and may assist in differentiating these tumors. Immunostaining for neurofilament protein demonstrates intratumoral axons in variable numbers and distributions in about half of sporadic[54,62] and neurofibromatosis 2-associated schwannomas.[63] Thus, demonstration of axons is unreliable as the sole basis for distinguishing schwannomas and neurofibromas when there are overlapping histological features.[62] The presence of large numbers of axons within a tumor favors the diagnosis of a solitary circumscribed neuroma.[64,65] Perineurial cells in the capsule are immunoreactive using antibodies to

epithelial membrane antigen (MUC1; Figure 112.4F).[66]

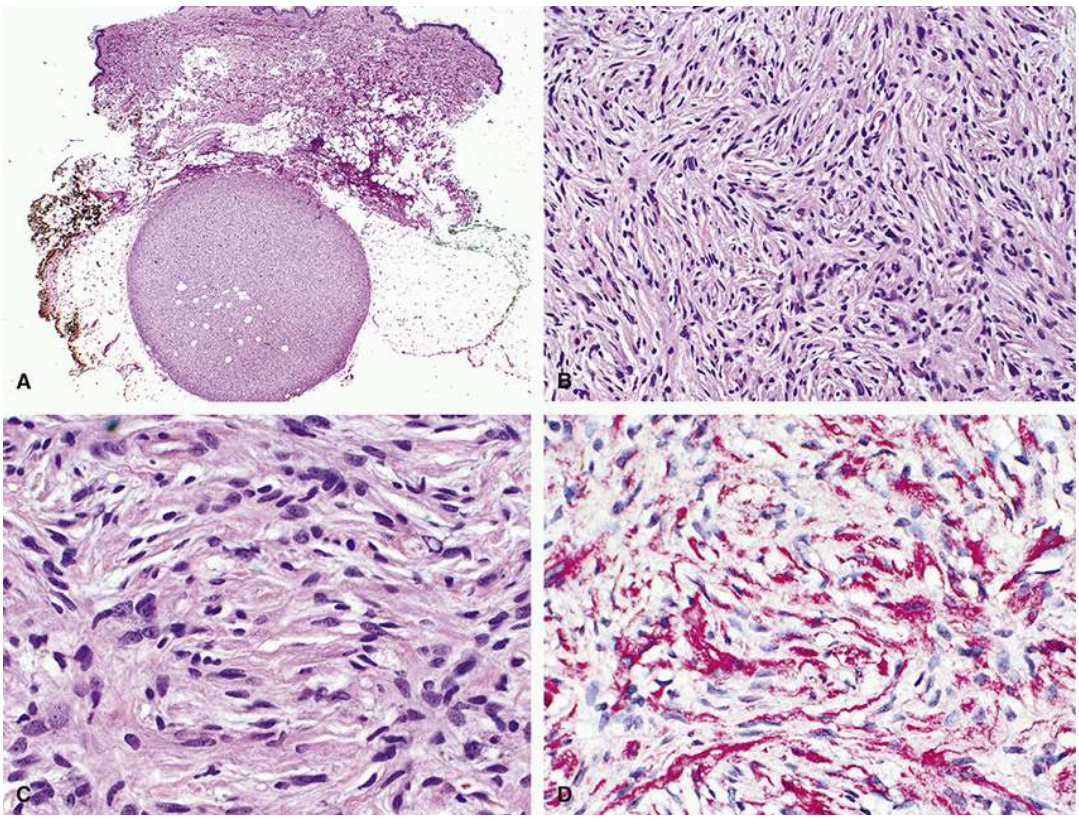

FIGURE 112.3 A, Cutaneous schwannomas are encapsulated well-circumscribed nodules usually located in the subcutaneous fat. B, This schwannoma of the left thigh is composed of interlacing fascicles of spindle-shaped Schwann cells. C, The neoplastic cells have elongated, twisting, tapering nuclei and eosinophilic cytoplasm with indiscernible cell borders. An indistinct Verocay body, formed by palisaded tumor cell nuclei with intervening eosinophilic cell processes, is in the center of the image. D, The tumor cells stain intensely and uniformly positive using antibodies to S100 protein.

(Print pagebreak 743)

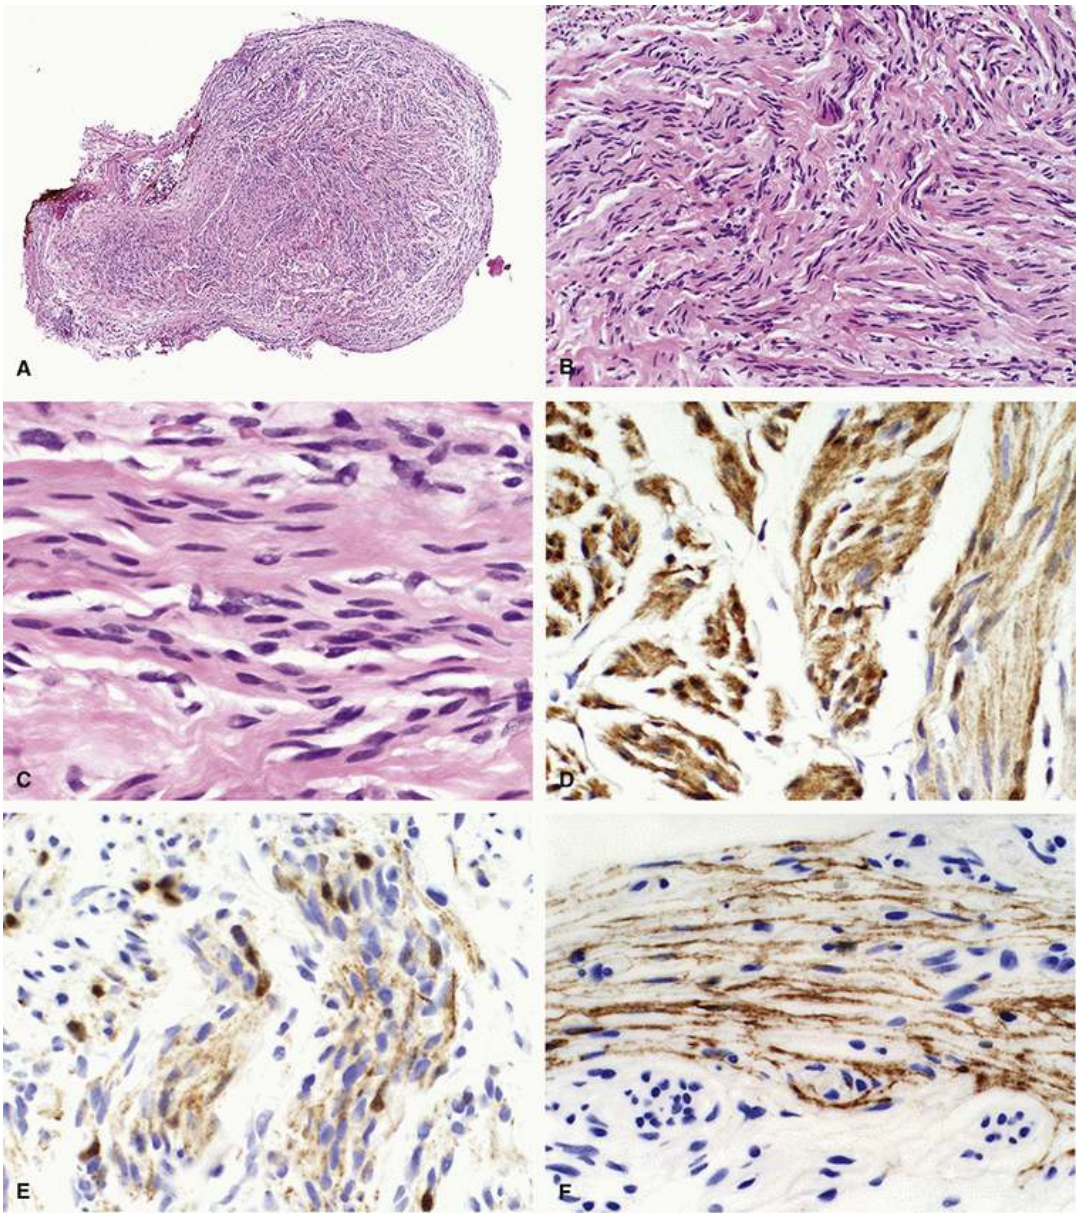

FIGURE 112.4 This schwannoma of the lateral left upper eyelid dermis presented as a 2-mm-diameter dome-shaped papule near the ciliary margin in a middle-aged woman. A, The schwannoma was encapsulated and well circumscribed. B, Interlacing fascicles of spindle-shaped Schwann cells with long, tapering, often wavy nuclei. C, Close-up photomicrograph showing tapering nuclei, lack of cytological atypia, and cytoplasmic nuclear inclusions in some of the neoplastic Schwann cells. Cell borders are not discernible. D, All of the tumor cells strongly expressed S100 protein. E, Expression of calretinin by tumor cells supports the diagnosis of schwannoma. Axons were sparse in a section stained using antibodies to neurofilament protein (not shown). F, Perineurial cells in the capsule are immunoreactive using antibodies to epithelial membrane antigen (MUC1).

CHAPTER 113

Sebaceous Adenoma

Key Points

- Sebaceous adenoma is very rare tumor often associated with Muir Torre syndrome (MTS), a rare cancer predisposition disorder
- The cutaneous tumors associated with MTS include primarily sebaceous adenoma and sebaceous carcinoma, keratoacanthoma, basal cell carcinoma, and colorectal and genitourinary carcinoma
- Sebaceous adenoma on the eyelid can be isolated and nonsyndromic, but the potential association with Muir-Torre syndrome is critical because of the high association with internal malignancies
- Patients with Muir-Torre syndrome have mutations in DNA mismatch repair genes that are essential for the maintenance of genomic integrity
- Sebaceous neoplasms have also been reported in immunocompromised transplant patients, and those with AIDS
- They are slow-growing skin tumors that usually present as yellow papules with a predilection for the face, scalp, and eyelids
- Sebaceous adenomas are benign lesions so that treatment for most individuals can be conservative
- When lesions are bothersome, they can be removed with complete surgical excision for comfort or for cosmetic reasons
- The prognosis is excellent with very few recurrences reported

Sebaceous adenoma (SA) was first reported in 1949 by Van Walbeek[1] and was characterized as a benign tumor that presents clinically as a tan, pink, or yellow nodule or papule. It is a very rare benign tumor that is a common finding in Muir-Torre syndrome (MTS), so much so that it has been regarded as pathognomonic for that disorder.[2] However, isolated nonsyndromic cases have also been described.[3]

MTS is a rare cancer predisposition syndrome characterized by unusual cutaneous tumors and internal systemic malignancies.[4,5] The cutaneous tumors associated with MTS are primarily SA and sebaceous carcinoma, keratoacanthoma, and basal cell carcinoma.[4,5,6] Colorectal adenocarcinoma and genitourinary carcinoma are the most common types of internal malignancies, occurring in 40% and 25% of cases, respectively.[6,7]

On the eyelids, SA is exceedingly rare. Jagan et al[8] identified only 9 cases of SA (0.15%) among 5884 eyelid lesions. Nevertheless, the diagnosis of a solitary SA should raise a strong suspicion of MTS, and these patients, as well as their first-degree relatives, should undergo a systemic evaluation to exclude gastrointestinal and genitourinary malignancy.[6] These systemic malignancies may occur many years after the onset of SA so that long-term surveillance is necessary. It is therefore important to counsel all patients with an SA that there is a small increased risk of internal malignancies long after the initial diagnosis of SA.[6,9]

Sebaceous glands are found abundantly in the eyelids as glands of Zeiss and meibomian glands, and SA on the eyelids can arise from these structures. The tumors are usually small in size, measuring 5 mm or less,[10,11] although rarely they can attain a much larger size of up to 2 cm associated with rapid growth.[12] SA lesions can also rarely develop in the caruncle, which contains both conjunctival and cutaneous dermal elements.[13,14,15] Less commonly they have been reported in the bulbar conjunctiva,[16,17,18,19,20] even though sebaceous glands are normally not present in the conjunctiva.[13,14,17,21] It is unclear how a tumor of sebaceous origin can arise in the bulbar conjunctiva, but it has been suggested that this might occur from faulty migration of sebaceous gland cells from the caruncle through the nasal bulbar conjunctiva or derived from pluripotent basal cells of the conjunctival epithelium.[18] One case of an SA of the cornea has been reported. The mechanism of its development is unknown, but it was suggested to derive from pluripotential limbal epithelial stem cells that differentiated into sebaceous cells, then developed into an SA with intraepithelial

growth into the cornea.[22] Alternatively, previous trauma could have initiated the development of the SA from conjunctivalization of the cornea.

Fewer than 20 cases of SA involving the eyelid or conjunctiva have been reported.[3,9,12,17,23,24,25]

The mean patient age at diagnosis of the eyelid lesion was 54.4 years (range 23-83 years), and most patients were male (93%). The upper eyelid was predominantly involved, with rare involvement of the medial canthus.[12,24,26,27]

Etiology and Pathogenesis

Although SA on the eyelid can be isolated and nonsyndromic, the potential association with MTS is critical because of the high association with internal malignancies, *(Print pagebreak 747)* and these systemic manifestations can develop years after the appearance of the cutaneous lesion. MTS is a rare genodermatosis considered a subtype of hereditary nonpolyposis colorectal cancer. It is an autosomal dominant disorder characterized by the association of cutaneous sebaceous neoplasms and keratoacanthomas associated with a visceral malignancy, characteristically colorectal, or genitourinary carcinoma.[28] While cutaneous neoplasms usually occur after the appearance of systemic malignancies in patients with MTS, they develop before any systemic manifestations in 22% of cases.[28]

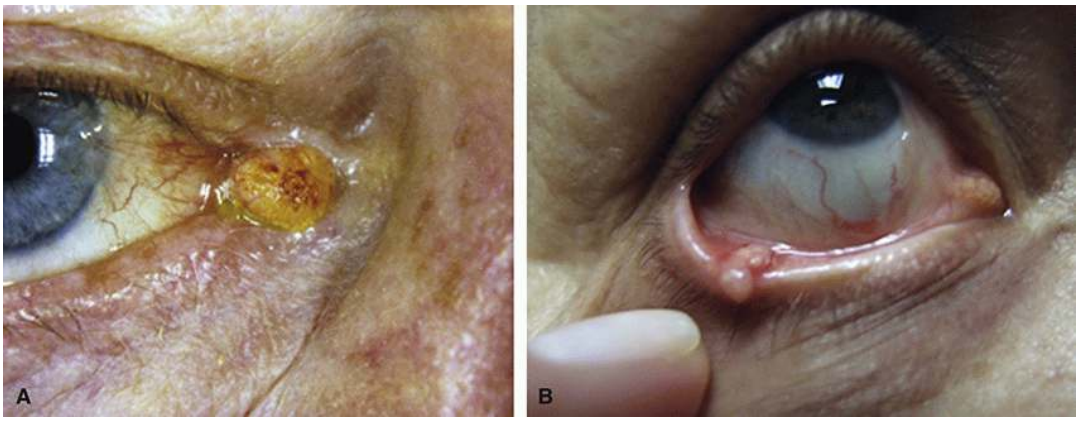

FIGURE 113.1 Sebaceous adenoma. B, (Courtesy of Dr. Suzanne Freitag.)

Patients with MTS have mutations in DNA mismatch repair genes. These genes encode MMR proteins that are essential for the maintenance of genomic integrity.[29] They normally recognize and repair erroneous insertion, deletion, and misincorporation of bases that can arise during DNA replication and recombination or in some forms of DNA damage.[30,31] There are four DNA mismatch repair genes involved in MTS that primarily include *MSH2* in more than 90% of cells and *MLH1* in less than 10%. The involvement of *MSH6* or *PMS2* is rare.[28] Patients with MTS have a germline mutation in one allele of a mismatch repair gene. With the acquisition of a somatic mutation in a second allele, mismatch repair function occurs leading to the accumulation of genetically unstable cells and increased risk of developing certain malignancies.[28] When SA is diagnosed by histopathology and immunohistochemistry is negative for MMR protein expression (*MLH2* and *MSH1*),[32,33] or the patient has a personal or family history of cancer, a workup for MTS should be conducted.[8,28]

Sebaceous neoplasms have also been reported in immunocompromised transplant patients[34] and those with AIDS.[35,36]

Clinical Characteristics

SAs are slow-growing skin tumors that usually present as yellow papules that can be mistaken for basal cell carcinoma.[29] They have a predilection for the face and scalp, particularly the eyelids due to abundant meibomian and other sebaceous glands in this region.[37] They usually are seen in older individuals with a mean age of 50 to 60 years.[10,38] Lesions associated with MTS occasionally undergo cystic change, whereas sporadic SA lesions generally do not.[39]

Eyelid SA usually present as indolent lesions that can be present for months to several years. Clinically they appear as well-circumscribed, yellowish to pink, firm, mobile nodular lesions (Figure 113.1). They may have fine papillary surface projections and telangiectasias (Figure 113.2).[40] They may rarely involve the conjunctiva (Figure 113.3) Lesions are usually less than 5 mm in diameter. Lesions can superficially look like chalazia, presenting as yellowish nodules associated with madarosis and distortion of the eyelid margin. Rarely an eyelid SA can attain several centimeters in size, with a vascular, crusted, and ulcerated surface simulating an epithelial malignancy.[12] Five cases of SA have been described presenting as a cutaneous horn, three of which showed loss of expression of mismatch repair proteins consistent with MTS.[41,42]

Differential Diagnosis

The differential diagnosis of SA includes chalazion, papilloma, sebaceous hyperplasia, seborrheic keratosis, and sebaceous and basal cell carcinoma. When on the conjunctiva, the differential should also include histiocytic, myxoid, lymphoid, lipomatous, and metastatic lesions.

(Print pagebreak 748)

FIGURE 113.3 Large sebaceous adenoma in Muir-Torre syndrome. (Courtesy of Drs. Josiah To and Paul Phelps.)

Treatment

SAs are benign lesions so that treatment for most individuals can be conservative. When lesions are bothersome, they can be removed for patient comfort or for cosmetic reasons. When removal is indicated, the treatment of choice is complete surgical

excision. In a series of 28 cases managed surgically for which follow-up data were available, there were three documented recurrences (11%).[43] One was due to incomplete excision, but the other two lesions recurred despite apparent complete excision. Long-term follow-up should, therefore, be encouraged for possible recurrence of the cutaneous lesion. Moreover, even in patients with isolated SA, regular follow-up visits must continue since the systemic findings of MTS can develop long after the skin lesion.

Prognosis

Following complete surgical excision, the prognosis is excellent with very few recurrences reported after follow-ups of up to several years. In patients with MTS, there is a persistent risk of systemic malignancy even years after the cutaneous lesion so that long-term observation is mandatory.[44,45,46]

Histopathology

SAs of the eyelid glands of Zeiss (Figure 113.4) and caruncle (Figure 113.5) resemble those at other cutaneous sites. SAs are well-circumscribed[43,47,48] papular, nodular, or polypoid tumors[47] composed of multiple lobules of varying size and shape.[43] Tumors usually are contiguous with or replace the epidermis[43,47] but may be in the middle or deep dermis.[43,49] The epidermis may be ulcerated, form a peripheral collarette creating a keratoacanthoma-like appearance, or be hyperplastic and papillomatous.[50] The tumor lobules are separated from each other by connective tissue septa,[47] while the periphery of lobules compresses the adjacent dermal collagen, creating the appearance of a capsule.[43] The sebaceous lobules comprising the tumor have a peripheral germinative (or generative[51]) layer of small basophilic cells, then a zone of transitional cells, and finally mature *(Print pagebreak 749) (Print pagebreak 750)* sebaceous cells in the center of the lobule.[43,47,51] The germinative cells form a layer of one or more cells[50] and have large, oval to elongated deeply basophilic nuclei, little cytoplasm, and indistinct cell borders.[51] Mature sebaceous cells are larger than germinative cells, are round, have reticulated cytoplasm due to lipid droplets, and have distinct cytoplasmic borders.[43,51] Transitional cells, which lie between the germinative and mature cells, have pink cytoplasm[50] with progressively increasing amounts of lipid in their cytoplasm.[43] Mature sebaceous cells outnumber germinative cells. Histological features of SAs that correlate with MTS are cystic change, intratumoral mucin deposits, squamous metaplasia without keratoacanthoma-like changes, ulceration, and intratumoral and peritumoral lymphocytes (in the absence of epidermal ulceration).[52]

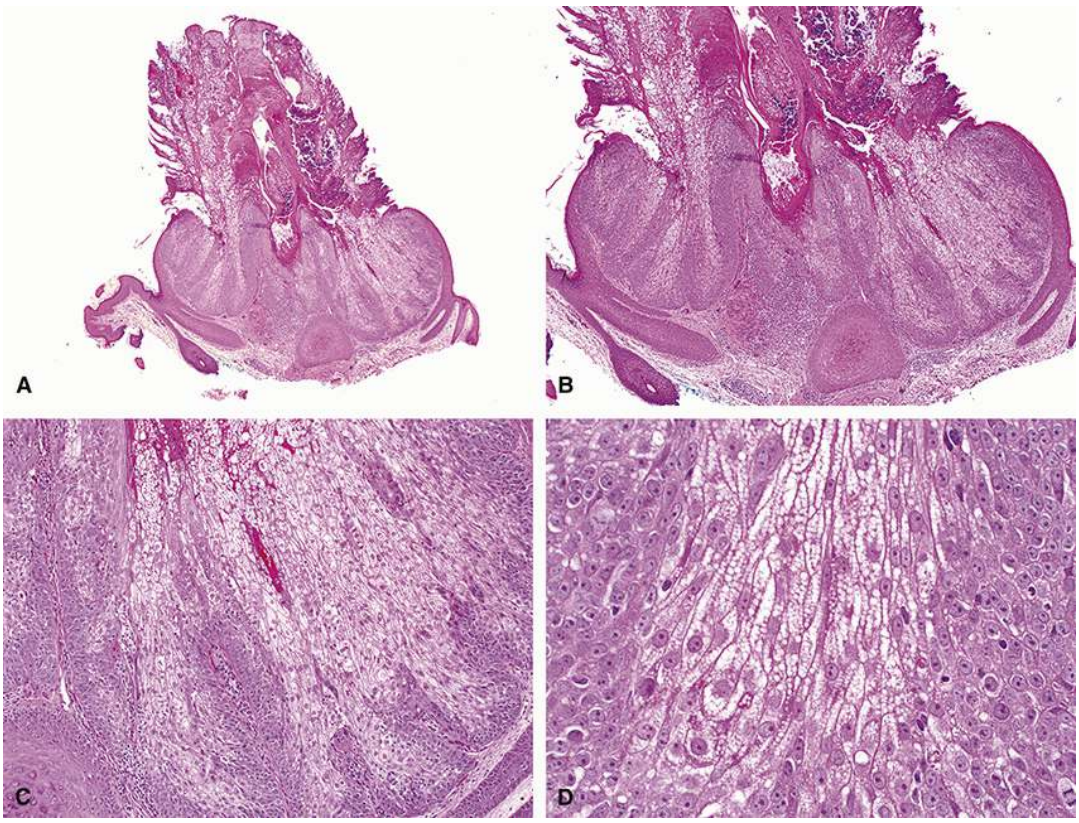

FIGURE 113.4 This sebaceous adenoma presented as a cutaneous horn of the right lower eyelid of a 60-year-old man who was subsequently diagnosed with Muir-Tore syndrome. A, The adenoma forms lobules contiguous with the epidermis and is surrounded by an epithelial collarette creating a keratoacanthoma-like appearance. The lesion's surface

has sebaceous material, foci of hemorrhage, and parakeratosis, creating the horn noted clinically. B, Mature sebaceous cells outnumber germinative cells. The overlying horn contains abundant sebaceous material released by holocrine secretion and areas of parakeratosis. C, The tumor lobules contain germinative basaloid cells, transitional cells with lightly eosinophilic cytoplasm, and mature sebaceous cells in the center of the lobules. D, The amount of cytoplasm increases and becoxmes reticulated as the germinative cells mature.

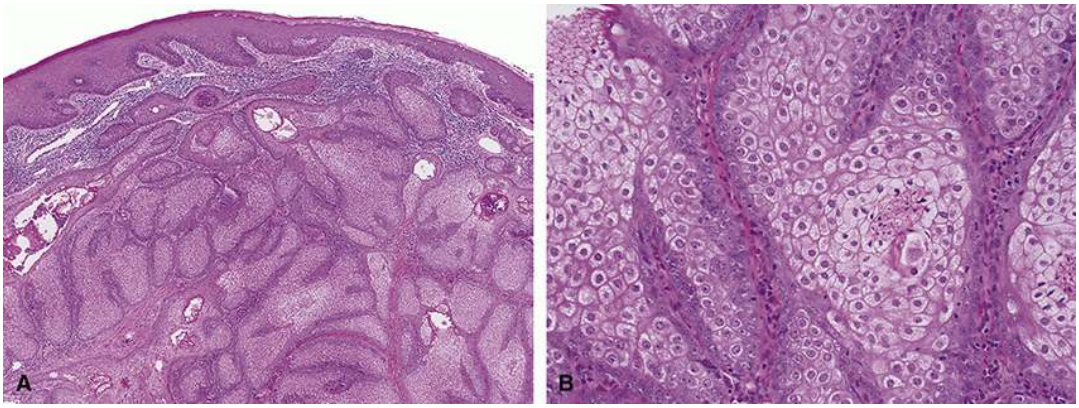

FIGURE 113.5 This sebaceous adenoma in a 67-year-old man was manifest clinically as a 5 × 5 mm pedunculated mass of the right caruncle that did not involve the right lower eyelid. A, The caruncular sebaceous adenoma has numerous lobules forming a mass that is not contiguous with the surface epithelium. B, The lobules have a one-to two-cell thick layer of germinative cells, a predominance of transitional cells with pink cytoplasm, and centrally located mature sebaceous cells with clear cytoplasm.

The differential diagnosis of SA includes sebaceous hyperplasia, sebaceoma, and sebaceous carcinoma.[50,53,54] Sebaceous hyperplasia manifests as well-differentiated sebaceous lobules usually associated with a central cystically dilated pore.[49] The hyperplastic sebaceous lobules are increased in number, are higher in the dermis than usual, are typically not much larger than expected in facial skin, and have only one or two peripheral layers of germinative cells.[49] Sebaceous hyperplasia usually has fewer germinative cells than SA and typically lacks the transitional cells that are a feature of SA.[40,49,53] Despite these descriptive differences, there is only moderate interobserver agreement among pathologists' diagnoses of sebaceous hyperplasia and SA.[54] Increased nuclear expression of survivin may assist in differentiating sebaceous hyperplasia from adenoma since adenomas have increased survivin expression.[55] Sebaceomas are well-circumscribed dermal tumors composed mainly of basaloid germinative cells (Figure 113.6).[40,49,53] Greater than 50% basaloid cells is the value usually considered as the cut-off for differentiating sebaceoma from SA,[49,53] although the number of histological sections that should be examined to determine the percentage of basaloid cells is not defined.[53] Similar to sebaceous hyperplasia, there is only moderate interobserver agreement among pathologists for diagnosing SA and sebaceoma.[54] Well-differentiated (grade 1) sebaceous carcinoma may be difficult,[40,53] if not impossible,[54] to discriminate from SA. An increased mitotic rate,[56] increased nuclear survivin expression,[55] cytological atypia,[40,53] or abnormal mitotic figures [50] favor a diagnosis of carcinoma. We concur that “If in doubt, any sebaceous tumor should be excised completely.”[53]

SAs may also arise from the eyelid meibomian glands (Figure 113.7), although reported cases are exceptionally rare.[27,57,58,59,60,61] Meibomian gland adenomas feature retained acinar organization but exhibit the loss of the normal parallel linear gland organization.[57] The sebaceous acini are generally larger than normal and have a more prominent and thicker layer of germinative cells.[57] Both of the meibomian gland SAs that we have encountered arose along the eyelid margin and were differentiated from an eyelid sebaceoma[62] by the predominance of mature sebocytes.

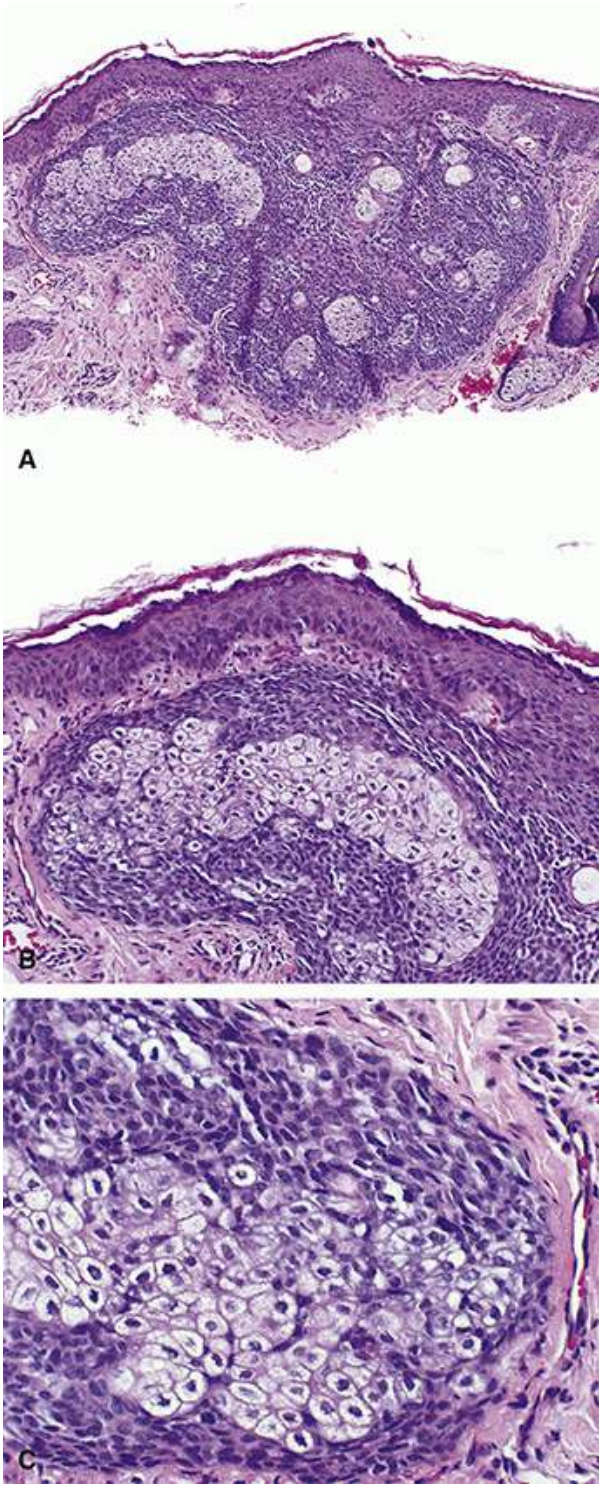

FIGURE 113.6 This sebaceoma arose in the right upper eyelid of a man in his early 50s. A, The tumor is a well-circumscribed nodule in the dermis contiguous with the epidermis. The overall predominance of basaloid (germinative) cells distinguishes sebaceoma from sebaceous adenoma. B, This tumor lobule shows continuity with the epidermis, more germinative than mature sebaceous cells, and the sharp border of the tumor and adjacent dermis. C, Maturation of germinative cells is similar to that in sebaceous adenoma.

(Print pagebreak 751)

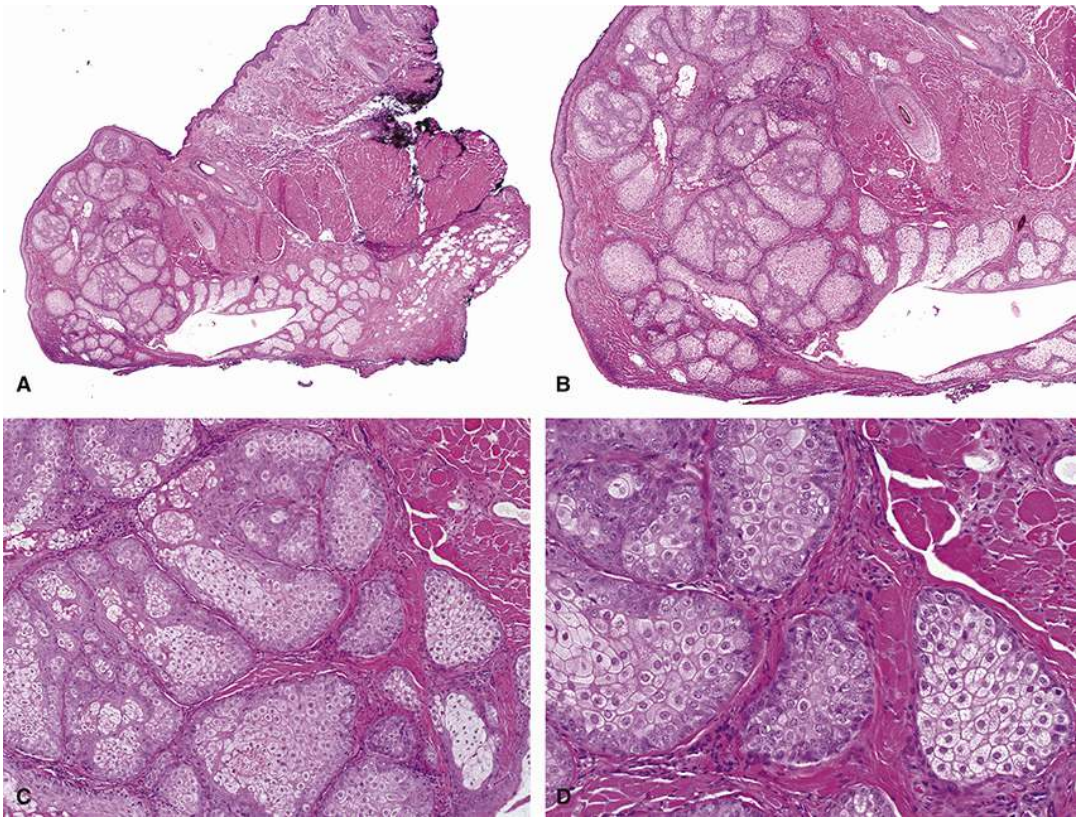

FIGURE 113.7 This meibomian gland sebaceous adenoma developed in the lateral left lower eyelid of a woman in her late 20s. It had been present for approximately 9 years, fluctuated in size, was intermittently erythematous, and itched continuously. A, The sebaceous adenoma is a nodular mass of sebaceous lobules (acini) extending anteriorly from the tarsus at the eyelid margin. The meibomian duct is dilated distal to the tumor. B, Lobules of tumor surround and compress the meibomian duct. C, The tumor lobules vary in size. The germinative layer is thicker than normal. D, The adenomatous lobules have a prominent peripheral germinative layer and abundant transitional cells with pink cytoplasm. A normal meibomian gland is at the bottom right corner of the image and has a flattened germinative cell layer surrounding mature sebaceous cells with clear reticulated cytoplasm.

CHAPTER 114

Sebaceous Duct Cyst

Key Points

- Sebaceous duct cysts are sporadic, superficial cutaneous cysts caused by obstruction of the outflow duct of the sebaceous glands associated with the pilosebaceous follicular unit
- Steatocystoma multiplex is a benign disorder that is considered a counterpart of steatocystoma simplex and is generally inherited in an autosomal dominant fashion
- The pathogenesis of sebaceous duct cysts is unknown, but immunohistochemistry has established a relationship to the draining duct of the sebaceous gland of the pilosebaceous apparatus
- It may develop in part from obstruction of the sebaceous gland duct that involves trapping of the vellus hairs produced by a pilar unit in a cystic cavity that is connected to the epidermis by a duct that is filled with cellular debris
- Clinically, they present as well-circumscribed, asymptomatic, nontender, soft, flesh-colored or yellowish, intradermal, mobile cystic nodules that contain an oily substance composed of sebum
- When removal is desired for cosmesis or for larger symptomatic lesions, complete surgical excision, including the intact cyst wall, is the treatment of choice
- Incision and drainage is associated with a high incidence of recurrence since the wall is typically left behind
- With adequate management, the prognosis is excellent with a relatively low recurrence rate

Cysts of the cutaneous appendages can occur anywhere on the skin, with most arising from the infundibular portion of the hair follicle.[1] Other cysts arise from sweat glands or within the tarsal meibomian glands or show morphological similarities to different portions of the folliculosebaceous apparatus, and these have been described under a wide variety of different names. Ackerman et al [2] suggested that cutaneous cysts should be named based on the normal epithelial structure of those portions of the folliculosebaceous unit that the lining of the cyst most closely resembles. Based on this approach, a trichilemmal cyst is an isthmic-catagen cyst and a primary epidermal cyst is an infundibular cyst. Sebaceous duct cysts and steatocystomas most closely resemble sebaceous gland duct epithelium,[1] so that both can be grouped under the term sebaceous duct cyst.

A variety of different cysts occur on the skin. In the periorbital region, these most commonly include apocrine and eccrine hidrocystomas, intratarsal keratinous cysts, and cutaneous keratinous cysts. Among the cutaneous keratinous cysts, a large number of different labels have been applied with little consistency in usage or definition, resulting in confusion of terminology in the literature. For this book, we adopt a simple definition and divide the more common cutaneous cysts into hidrocystomas (Chapter 70), cutaneous keratinous cysts (Chapter 77), intratarsal keratinous cysts (Chapter 78), and sebaceous duct cysts, all discussed in separate chapters. Hidrocystomas arise from obstruction of sweat glands. Keratinous cysts accumulate keratin of various types within the cyst cavity and derive from the epithelium of different portions of the pilosebaceous apparatus. Sebaceous duct cysts trap sebum produced from the occlusion of apocrine sebaceous glands. In 1930, Ormsby and Finnerud[3] first recognized that the lining of steatocystomas resembles a sebaceous duct and proposed that these cysts arise by pathologic keratotic blockage of the duct at its entrance onto the skin surface. Ackerman et al[4] noted that, in the diagnosis of steatocystoma, sebaceous lobules are not necessary, arguing that cutaneous keratocyst and steatocystoma be united under the term sebaceous duct cyst.

Sebaceous duct cysts (SDCs) are superficial cutaneous cysts caused by obstruction of the outflow duct of the sebaceous glands associated with the pilosebaceous follicular unit. It has also been referred to in the literature as steatocystoma simplex and keratocyst.[5] They are nonheritable, solitary, benign adnexal lesions seen most often on the forehead, nose, scalp, neck, axillae, chest, upper limbs, back, legs, and the oral mucosa.[6,7] Males and females are affected equally, and patients range in age from the second to the eight decades.[6,7,8]

SDCs are usually found on the skin, and eyelid involvement is rare.[6,9,10,11,12,13,14,15] But since the caruncle also harbors skin elements such as hair follicles, sebaceous glands, sweat glands, and accessory glands, the caruncle may develop SDCs similar to those found in the skin.[12,16,17] A case was described of a follicular hybrid cyst of the tarsus, which included foci of pilomatricoma and some foci of steatocystoma.[18]

Steatocystoma multiplex (SM) is an uncommon benign disorder that shares similar pathological features and is considered a counterpart of steatocystoma simplex. It is seen most often on the chest and less commonly on the abdomen, upper arms, armpits, and face. Unlike steatocystoma simplex which arises as a sporadic lesion, SM is generally inherited in an autosomal dominant fashion. Lesions are thought to arise from an abnormal lining of the sebaceous duct with onset at puberty, likely due to the hormonal stimulus of the pilosebaceous unit.[19,20] The cysts are generally 2 to 4 mm firm bumps that contain an oily, yellow liquid and can sometimes contain one or more hairs.

(Print pagebreak 754)

Etiology and Pathogenesis

The pathogenesis of SDC is unknown. Immunohistochemistry has established a relationship with the draining duct of the sebaceous gland of the pilosebaceous apparatus rather than with the epithelium of the isthmus.[21] It may develop in part from obstruction of the sebaceous gland duct. Plewig et al[22] proposed a mechanism that involves trapping of the vellus hairs produced by a pilar unit in a cystic cavity that is connected to the epidermis by a duct filled with cellular debris. It is not clear what triggers the formation of these cysts. One proposed factor is keratin 17, a protein normally expressed in hair follicles and sebaceous glands. Covello et al[23] investigated cases of both familial and sporadic steatocystomas and found missense mutations in keratin 17 helix boundary motifs in the familial cases. Analysis of the sporadic cases failed to demonstrate similar mutations, suggesting that other factors are involved.[24]

Clinical Presentation

Clinically, SDCs cannot be distinguished from other cystic lesions such as cutaneous keratinous cysts, so histopathologic examination is necessary for differentiation and diagnosis. They present as well-circumscribed, asymptomatic, nontender, soft, flesh-colored or yellowish, intradermal, mobile cystic nodules (Figure 114.1).[6,11,12] The cyst contains an oily yellow substance composed of sebum, a product of sebaceous gland secretion (Figures 114.2 and 114.3).[6] They may have been present for years before the patient seeks medical attention because of enlargement or cosmetic concerns. If the cyst ruptures, it may incite a lipogranulomatous inflammatory response with foreign body giant cells in adjacent tissues. Sebaceous lobules may be present within the cyst wall with a direct connection between the sebaceous lobules and the cyst's lining.

FIGURE 114.1 Sebaceous duct cyst on the medial canthus and nasal bridge. (Courtesy of Dr. Roman Shinder.)

FIGURE 114.2 Small medial upper eyelid sebaceous duct cyst.

Differential Diagnosis

The differential diagnosis of SDCs includes other cystic lesions occurring on or near the eyelids. These include chalazion,

hidrocystoma, epidermoid cyst, epidermal inclusion cyst, and trichilemmal cyst, sebaceous gland hyperplasia, sebaceous gland adenoma, lipogranuloma, eruptive vellus hair cyst, and oncocytoma.[10,11,25]

Treatment

Small cysts usually do not require treatment unless requested by the patient for aesthetic reasons. When removal is desired for cosmesis or for larger symptomatic lesions, complete surgical excision including the intact cyst wall is the treatment of choice. Incision and drainage is associated with a high incidence of recurrence since the wall is left behind. In cases of active inflammation, surgery should be delayed due to a higher risk of infection, wound dehiscence, and cyst recurrence.[26] Cryosurgery,[27] radiosurgery,[28] and laser therapy[29] have also been reported with good results.[30,31]

Medical management with oral isotretinoin has been recommended for extensive lesions of SM since it also provides a reduction in the associated inflammation.[32] However, resolution may take several months and recurrence can be seen following discontinuation.[33] Oral tetracycline or topical clindamycin have been recommended for noninfectious inflammatory lesions.[33,34]

Prognosis

With adequate management, the prognosis is excellent with a relatively low recurrence rate.

Histopathology

The histological appearances of steatocystoma simplex[6] and SM [22,35] are similar. Steatocystomas are thin-walled dermal cysts with invaginations and evaginations due to fixation and loss of cyst contents (Figure 114.4A),[22] a lining of stratified *(Print pagebreak 755)* squamous epithelium varying from three to eight cells thick[35] with the absence of a granular cell layer (Figure 114.4B-D),[22,35] a wavy cyst wall with an eosinophilic crenulated luminal surface (Figure 114.4C and D),[6,22,35] and sebaceous elements within or near the cyst wall (Figure 114.4A).[6,22,35] The cyst lumen may contain keratinous material with or without vellus hairs.[35] Serial sections and three-dimensional reconstruction reveal a vellus hair follicle associated with the cyst and a ribbon-like cord or duct connecting the cyst to the epidermis.[22]

The presence of vellus hairs within a steatocystoma may cause confusion with an eruptive vellus hair cyst, which may be single or multiple lesions and may involve the eyelids.[36] Vellus hair cysts are dermal cysts lined by stratified squamous epithelium three to seven cells thick,[37] may have focal keratohyaline granules,[37] lack sebaceous elements in the wall,[38] and contain laminated and amorphous keratinous material and vellus hairs (Figure 114.5).[37,39] The epithelial lining of vellus hair cysts expresses cytokeratin 17, while that of steatocystomas expresses both cytokeratins 10 and 17.[40]

FIGURE 114.3 Steatocystoma simplex of the lateral left upper eyelid from the patient whose histopathology is in Figure 114.4.

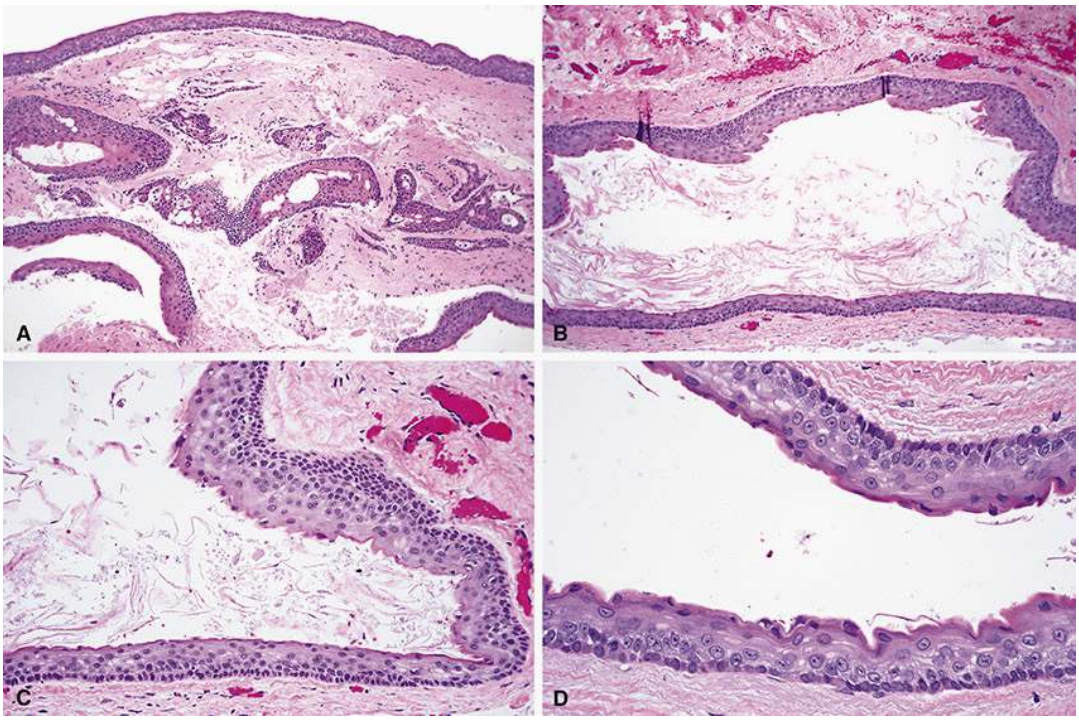

FIGURE 114.4 This steatocystoma simplex of the lateral left upper eyelid was a 7- to 8-mm-diameter cystic lesion in a man in his late 40s. It was present for 5 years, had no associated discharge or pain, and was a dark cystic lesion on slit-lamp examination. A, The cyst collapsed during sectioning causing evaginations that appear as multiple small cysts and pilosebaceous units. Sebaceous cells are in and adjacent to the cyst wall. B, The largest area of the cyst has a wavy wall, absent granular cell layer, and laminated and amorphous keratinous debris in the lumen. C, The cyst lining lacks a granular cell layer and has an eosinophilic crenulated luminal surface. Both laminated and amorphous keratinous debris is in the lumen. D, The luminal surface of the epithelial cyst lining is eosinophilic and crenulated.

(Print pagebreak 756)

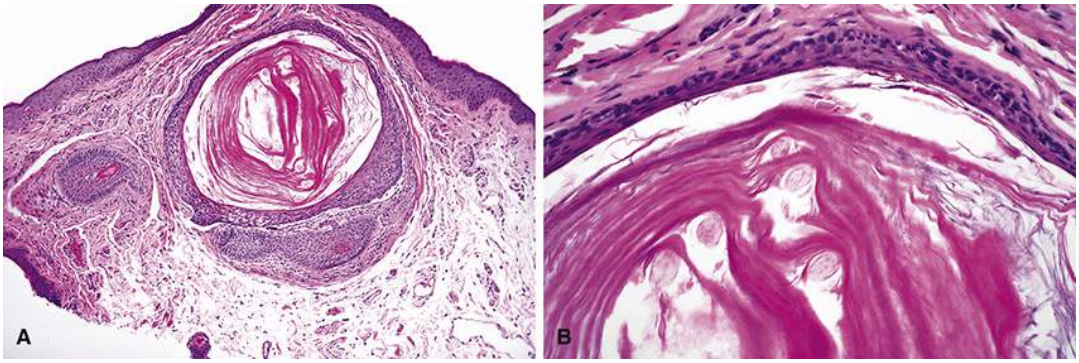

FIGURE 114.5 A vellus hair cyst developed in the right lower eyelid of a woman in her late 60s. She noted a whitish bump that increased in size over 2 to 3 months with no change in color, discharge, or pain. A, The unilocular cyst is in the dermis, is lined by stratified squamous epithelium, and is filled with laminated keratin and vellus hairs. B, The epithelial lining lacks a granular cell layer. Both laminated keratin and vellus hairs cut in cross-section are present in the lumen.

CHAPTER 115

Seborrheic Keratosis

Key Points

- Seborrheic keratosis (SK) is the most common benign epithelial tumor and accounts for about 20% of benign epithelial neoplasms seen on the eyelid
- The pathogenesis of SK is not completely understood, but they are considered to arise in aging skin associated with UV exposure
- It does not represent reactive epidermal hyperplasia but more likely results from clonal expansion of a somatically mutated keratinocyte
- Genetic mutations have been detected in SK, showing a typical UV signature
- They present as sharply demarcated, skin-colored to darkly pigmented hyperkeratotic, slightly elevated lesions with a "stuck-on" appearance, occasionally associated with a cutaneous horn
- Treatment is generally not required, but when removal is desired for cosmetic reasons, surgical shave excision, electrodesiccation, or curettage are frequently used options
- The prognosis for seborrheic keratosis is generally very good

Seborrheic keratosis (SK) is the most common benign epithelial tumor.[1] It is estimated that about 83 million people in the United States are affected with SK, primarily middle-aged and elderly adults.[2] Lesions are seen most often on the eyelids and face, but also can be seen on the chest, back, and abdomen.[3] SK accounts for about 20% of benign epithelial neoplasms seen on the eyelid.[4,5] The occurrence of SK on the conjunctiva is very rare, with only a few cases reported.[6,7,8,9] They may be pigmented or nonpigmented, and when pigmented, they can be misdiagnosed as melanoma.

Rare cases of familial SK have been reported, including lesions presenting at a younger age. These cases tend to support a hereditary background, and somatic activating mutations of *FGFR3* have been identified in some lesions.[10,11] These mutations may be early events in the pathogenesis of a subset of SK, conferring a risk factor independent of age or ultraviolet (UV) radiation exposure.[12] However, the underlying genetic alterations in familial SK are still not clearly understood.

Dermatosis papulosa nigra has been described as a clinical variant of SK with multiple tiny lesions. It is more common in patients of African and Asian descent, and females are affected twice as often as males. Positive family history is seen in up to 85% of cases.[13] Although some authors consider this a distinct entity, the histopathology is identical to that of SK.[14,15]

The Leser-Trélat sign is the sudden appearance of multiple eruptive SKs as a paraneoplastic disorder associated with an underlying malignancy such as lung, esophageal, and nasopharyngeal carcinoma, mycosis fungoides, Sézary syndrome, and plasmacytoma.[16,17,18,19,20,21] Because of this relationship, screening for systemic cancer is recommended in cases of abrupt development of multiple pruritic SKs.

Etiology and Pathogenesis

The pathogenesis of SK is not completely understood, but they are considered to arise in aging skin associated with UV exposure. Studies have shown that some benign lesions, including SK, accumulate a number of UV-induced genomic aberrations.[22,23] SK does not represent reactive epidermal hyperplasia but more likely results from clonal expansion of a somatically mutated keratinocyte.[24] Even though SK does not have a malignant potential, more than 80% have at least one mutation, and 45% have more than one oncogenic mutation.[25]

A viral etiology involving human papillomavirus has been proposed, but this has not been substantiated in recent studies.[26,27]

Amyloid precursor protein (APP) and its downstream products are expressed more strongly in SK than in adjacent normal skin tissues, and also more strongly in UV-exposed skin compared with nonexposed skin. This suggests that overexpression of APP may promote the initiation of SK in aging, UV-damaged skin.[28]

Genetic mutations have been detected in SK, showing a typical UV signature. *FGFR3* mutations are the most frequent, detected in 48% of SK lesions, followed by the *PIK3CA* (32%), *TERT* promoter (24%), and *DPH3* promoter mutations (24%).[29] Neel et al[30] reported oncogenic mutations in the receptor tyrosine kinase/phosphatidylinositol 3-kinase/Akt signaling cascade and demonstrated that SK are sensitive to Akt inhibition. SK and squamous cell carcinoma (SCC) are both clonal tumors derived from keratinocytes, and they both have similar and overlapping genomic alterations.[31] Yet SK exhibits a benign clinical behavior and remains in situ, whereas cutaneous SCC *(Print pagebreak 759)* is locally invasive and has a small but definite malignant potential. SK is not a precursor lesion to SCC.[30] In SK there is a defect in the cornification process of epithelial differentiation, where some cells live longer than normal and undergo inappropriate intraepithelial cornification, forming so-called pseudocysts.[30] The high levels of Akt activity seem to underlie this pathological condition.

Clinical Presentation

Clinically, SKs typically present as sharply demarcated, hyperkeratotic, slightly elevated lesions with a “stuck-on” appearance (Figures 115.1 and 115.2)[32] and occasionally can be associated with a cutaneous horn.[32,33] They vary from skin-colored to darkly pigmented, and from a flat macule to an elevated nodule, and can be associated with irritation or inflammation. Irritative symptoms are frequent and lesions can become ulcerated, mimicking malignant cutaneous tumors such as basal cell carcinoma and SCC.[7,34,35] Although most SKs are 4 cm or less in diameter, giant lesions occasionally develop.[36]

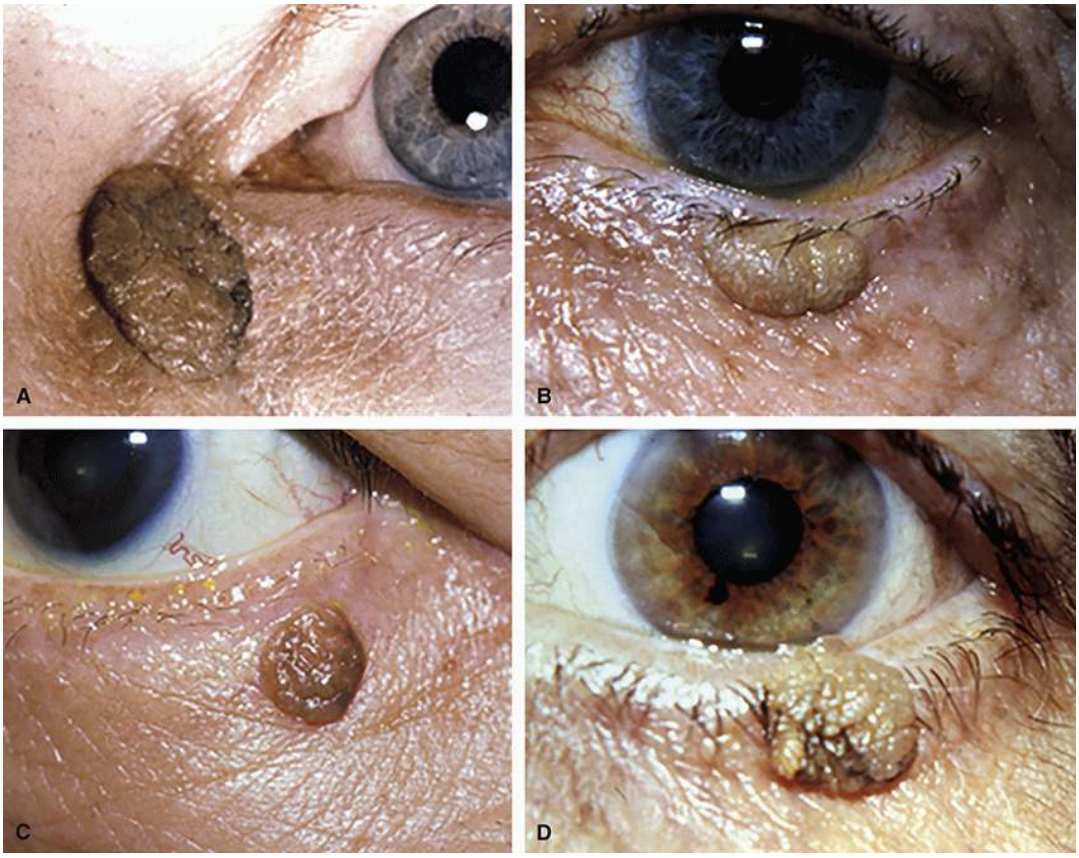

FIGURE 115.1 A-D. Sharply demarcated hyperkeratotic seborrheic keratosis. B and C, (Courtesy of Dr. Alan McNab.)

A number of dermoscopic features have been shown to characterize SK.[37,38,39] These include comedo-like openings, milia-like cysts, fissures, ridges, hairpin vessels, and multiple horn pearls.[38,40] Fissures and ridges, sometimes referred to as gyri and sulci, are thick, curved, sometimes branched lines varying from hypopigmented to brown, black, or blue that correlate with the papillomatous surface of the epidermis. Hairpin or looped vessels are two parallel vessels that form a half-looped or hairpin-like structure. They are often surrounded by a white halo and are often multiple and monomorphous in SK lesions. But they are not specific to SK and can also be observed in melanoma, SCC, basal cell carcinoma, and *(Print pagebreak 760)* other cutaneous neoplasms. Histologically, hairpin vessels correspond to enlarged capillaries of the dermal papillae.[37] Dark brown, gray, or black, round to oval clefts containing keratin plugs, called comedo-like openings, correspond to pseudohorn cysts in the epidermis that open to the surface of the lesion. Milia-like cysts are round, well-circumscribed, white to yellowish structures that correspond to intraepidermal cysts, and

multiple such cysts are characteristic of SK.

Differential Diagnosis

The differential diagnosis of SK includes melanocytic nevus, verruca vulgaris, actinic keratosis, acanthosis nigricans, pigmented basal cell carcinoma, and malignant melanoma.[41]

Treatment

SKs generally do not require treatment, although patients sometimes want them removed for cosmetic reasons or because they become irritated.[40,42] Surgery by shave excision, electrodesiccation, or curettage are frequently used options,[3] but recurrence and scarring are frequent sequelae. Lesions that are inflamed, bleeding, ulcerated, or excessively irritated should be biopsied or excised to rule out a malignancy.[43]

Among noninvasive therapies, cryotherapy is the most commonly employed procedure.[44] Cryosurgery is easy to use, is low cost, has a low risk of infection, requires minimal wound care, and is more effective in patients with multiple lesions. In one study, 68% of SK lesions treated with cryotherapy achieved complete healing.[45] However, cryotherapy is often associated with mild pain, scarring, *(Print pagebreak 761)* hair loss, and hyper- or hypopigmentation. A 40% solution of stabilized hydrogen peroxide in water plus alcohol (HP40) has been shown to cause oxidative damage to SK cells, leading to cell death.[46,47,48,49] Complete or nearly complete clearance was observed in up to 54% of cases treated with HP40 compared with 5% for the vehicle alone.[46] Side effects include stinging, pruritus, and hyper-or hypopigmentation.

The topical application of an aqueous solution containing nitric acid, zinc and copper salts, and organic acids (acetic, lactic, and oxalic acid) every other week for a maximum of four applications was reported to result in complete clearance in 75% of SK lesions with no relapses seen during a 6-month follow-up.[50] The successful uses of diclofenac gel, imiquimod, dobesilate, and calcitriol have also been reported for the treatment of SK in isolated case reports.[51,52,53,54]

Ablative laser therapy is also a common treatment option for SK.[55,56] Er:YAG laser therapy showed complete healing in 100% of treated lesions compared with 68% following cryotherapy.[45] Laser therapy was associated with less hyperpigmentation but more erythema than cryotherapy.[57] CO_2 laser is an alternative but carries a higher risk of scarring and pigmentary changes.[58]

Prognosis

Regardless of treatment, the prognosis for SK is generally very good, with clearance of lesions ranging from 40% to 90%. Incomplete clearance or recurrence is relatively common, and side effects such as burning, edema, and pruritus are usually minimal and temporary. Permanent adverse effects, such as hyper- and hypopigmentation seen with some therapies, are relatively infrequent, in the range of 0% to 8%.

Histopathology

SKs are well-circumscribed[3,59] benign tumors of epidermal keratinocytes, a subtype of benign acanthomas.[60] Wade and Ackerman defined three minimal criteria for the diagnosis of SK: "(1) a lesion that is exophytic and endophytic and of variable size, (2) benign epithelial hyperplasia of either basaloid cells, squamoid cells, or both, and (3) delicately laminated, amphophilically stained cornified cells massed above the general surface of the epidermis and within lesions as epithelial invaginations called pseudo-cysts of horn."[61] They considered melanin pigmentation and the absence of hypergranulosis to be less important histological findings. Hafner and Vogt distinguish horn pseudocysts from horn cysts that develop intradermally and are expelled transepidermally.[3] SKs have many histological patterns,[61] and approximately 20% of lesions had mixed histological features in the study by Roh and colleagues.[62] The World Health Organization[59] currently classifies SKs into seven histological variants, though these subtypes have no clinical significance:

1. Acanthotic (regular) type: This is the most common SK variant.[3,59,62] It is endophytic[60] with broad interdigitating columns of hyperplastic epidermis (Figure 115.3A and B),[59] especially basaloid cells,[3,61] many horn cysts[59] and pseudocysts,[3,61] and a flat base.[3,59] Hyperkeratosis and papillomatosis are slight.[60] There may be melanin pigmentation and a lichenoid or circumscribed lymphocytic infiltrate.[3]

2. Reticulated (adenoid) type: This type of SK has thin[59,60] double-rows[3] of anastomosing basaloid cells with[59,60] or without[3] horn cysts (Figure 115.3C).

3. Keratotic (papillomatous) type: This subtype features prominent hyperkeratosis with variable papillomatosis and acanthosis (Figure 115.3D and E). The hyperkeratotic and saw-tooth appearance of the epidermal surface may have a church-spire appearance (Figure 115.3D).[3] Massive hyperkeratosis may create a cutaneous horn (Figure 115.3E).

4. Pigmented type: Increased melanin pigmentation of keratinocytes and scattered melanophages in the dermis distinguish this variant (Figure 115.3F).[59]

5. Clonal type: This form has sharply delineated intraepidermal nests of benign basaloid[3] or pale[3,59] larger keratinocytes. These intraepidermal nests are referred to as the Borst-Jadassohn phenomenon; they are considered characteristic of the clonal variant of SK,[3,59] even though Mehregan and Pinkus demonstrated them in inflamed and "activated" (irritated) SKs.[63]

6. Irritated type: Irritated SKs have hyperkeratotic stratum corneum with superficial scale crust,[59] onion skin-like aggregates of eosinophilic squamous cells (squamous eddies),[3,59,61] inflammation of the dermis that may appear lichenoid,[3,59] and sometimes acantholysis, dyskeratosis, spongiosis, and apoptotic basal cells (Figure 115.3G and H).[3]

7. Macular type: Macular SKs have mild acanthosis, subtle clonal nests, and increased melanin pigmentation of the basal layer.[59] Macular SKs may be challenging to distinguish from solar lentigines.[59]

All variants of SK may have small foci of clear cells, small foci of sebaceous differentiation, or small amyloid deposits. The histopathological features of eyelid SKs are the same as those located elsewhere on the body, with the acanthotic subtype being by far the most common in our experience.

(Print pagebreak 762)

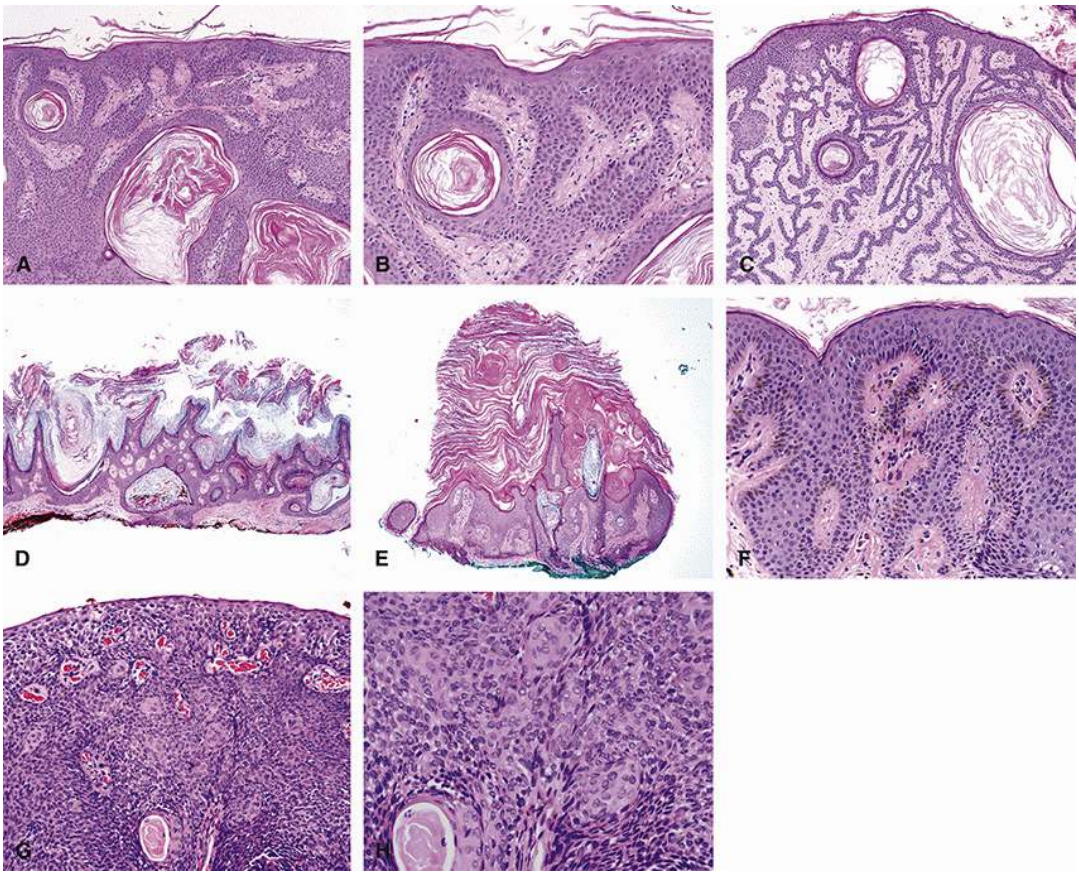

FIGURE 115.3 A and B, Acanthotic (regular) seborrheic keratosis (SK) of the left lower eyelid with broad interdigitating columns of hyperplastic epidermis and many horn cysts. C, Reticulated (adenoid) type of SK of the left lower eyelid with thin, mostly double-rows, of anastomosing basaloid cells with horn cysts. D, Keratotic (papillomatous) SK with a hyperkeratotic and saw-tooth appearing epidermal surface creating a church-spire appearance. E, This keratotic SK of the right upper eyelid had massive hyperkeratosis creating a cutaneous horn. F, Pigmented type of SK of the left lower eyelid with increased melanin pigmentation of keratinocytes. G and H, This irritated SK of the right upper eyelid had numerous aggregates of eosinophilic squamous cells (squamous eddies). The dermis, not seen in this image, had prominent chronic inflammation.

CHAPTER 116

Solitary Fibrous Tumor

Key Points

- Solitary fibrous tumor (SFT), previously known as hemangiopericytoma, comprises a histologic spectrum of fibroblastic mesenchymal neoplasms
- The SFT group includes SFT and related lesions ranging from heterogeneous, multinodular, partially sclerotic tumors to monotonous, highly cellular ones
- The etiology remains unknown, but data support the notion that these tumors are rare spindle cell neoplasms that arise from cells of mesenchymal origin
- SFTs are associated with *NAB2-STAT6* gene fusions that arise from recurrent intrachromosomal rearrangements on chromosome 12q13
- They usually present as a painless, hard, immobile, slow-growing palpable subcutaneous mass and eyelid swelling and can cause mechanical obstruction to eyelid function, such as ectropion
- Surgical management with wide and negative resection margins and the preservation of critical surrounding organs or tissues has been the mainstay treatment
- The clinical behavior of SFT is generally benign, but recurrence can be seen and tumors considered histologically benign may behave more aggressively

Solitary fibrous tumor (SFT) comprises a histologic spectrum of fibroblastic mesenchymal neoplasms that rarely metastasize.[1] Although Wagner[2] provided the first detailed histologic description of a SFT tumor of the pleura in 1870, the lesion was only recognized as a distinct clinical entity by Klemperer and Rabin in 1931.[3] It has been recognized under several different names in the past, including benign mesothelioma, localized mesothelioma, solitary fibrous mesothelioma, pleural fibroma, submesothelial fibroma, subserosal fibroma, and localized fibrous tumor.

Hemangiopericytoma (HPC) was first described in 1942 and initially believed by Stout and Murray[4] to be a vascular tumor related to smooth muscle pericytes. However, over the years since its original description, it has become evident that HPC is simply a descriptive term to characterize a heterogeneous group of neoplasms that share a common growth pattern.[5] Three categories have been individualized within this heterogeneous group of HPC-like neoplasms. One corresponds to some non-HPC neoplasms that occasionally display HPC-like features, such as synovial sarcoma, infantile liposarcoma, and leiomyosarcoma. Another contains lesions that show evidence of myoid/pericytic differentiation such as glomangiopericytoma/myopericytoma, infantile myofibromatosis, and some sinonasal tumors.[5] The final category is the SFT group, which includes SFT and related lesions ranging from heterogeneous, multinodular, partially sclerotic tumors to monotonous, highly cellular ones.[6,7,8,9,10] Proposed variants of SFT include the fibrous variant (conventional SFT), cellular variant (conventional HPC), a fat-forming variant (lipomatous HPC), and a giant cell-rich variant (giant cell angiofibroma).[5] With the discovery of a unique fusion gene in SFT and other tumors histologically identified as HPC, these two tumor groups are now generally considered to be the same entity with the term “SFT” as the preferred name.[1,11]

SFT has an equal distribution among men and women[12,13] and occurs in adults of all ages, most commonly in the fifth and sixth decades.[12,13,14] They may be found in almost any site of the body with intrathoracic being the most common location where the pleura is most often involved, followed by lung parenchyma, mediastinum, and the diaphragm.[12,15] The most common extrapleural site is the abdomen,[6,12,16] followed by the trunk, extremities, head and neck, and intracranial sites.[17,18,19,20,21,22,23,24,25] SFT arising in the head and neck most often arises in the sinonasal tract, oral cavity, orbit, or intracranially from the meninges.[26,27,28,29,30] Primary eyelid SFT is uncommon with fewer than 40 cases reported.[10,31,32,33,34,35,36,37,38] However, the majority of the lesions involving the eyelids represent anterior extensions or coexisting eyelid lesions associated with orbital tumors.[33,39,40,41,42]

Most SFTs behave benignly, but a minority of patients will develop metastatic disease to the lungs, bones, and liver.[43] In lesions arising from the pleura, 13% to 23% are classified as malignant, whereas most extrapleural SFTs behave in a more benign fashion.[7] Larger tumor size (>10 cm), high mitotic rates, increased cellularity, pleomorphism, hemorrhage, and necrosis are predictive of a greater potential for recurrence, local invasion, and metastatic spread.[15,44]

Etiology and Pathophysiology

The etiology of SFTs remains unknown but data support the notion that these tumors are rare spindle cell neoplasms that arise from cells of mesenchymal origin.[7,45,46] In 1931, Klemperer and Rabin[3] documented the occurrence of a distinctive localized pleural-based tumor and proposed a submesothelial cell origin. Later, Stout and Murray[4] proposed a derivation from mesothelial cells based on tissue culture experiments. Since then, immunohistochemistry studies *(Print pagebreak 766)* have established a fibroblastic origin, occasionally with myofibroblastic differentiation.[8]

SFTs are associated with *NAB2-STAT6* gene fusions[47,48] that arise from recurrent intrachromosomal rearrangements on chromosome 12q13.[49] Gene expression analyses show that *NAB2-STAT6* fusions lead to altered function of the transcriptional corepressor NAB2, an important regulator of the growth response 1 transcription factor,[50] and SFTs have been shown to deregulate the expression of target genes of early growth response 1 and other developmentally important genes. The detection of this gene fusion in most cases of SFT strongly implies that this fusion gene may play a significant role in its pathogenesis.[50] Several studies have suggested that different NAB2-STAT6 fusion types may be associated with different clinicopathologic subgroups of SFT.[51] The most common fusion variant, NAB2ex4-STAT6ex2/3, corresponds to the classic pleural SFT,[52] whereas tumors with NAB2ex6-STAT6ex16/17 are found in younger patients with deep soft tissue tumors that display a more aggressive clinical behavior.[52]

Steroid hormone receptors, particularly progesterone receptors, rarely are expressed in extrapleural SFTs.[32,53] It has been proposed that progesterone may participate as a growth factor in many CD34+ neoplasms, and that progesterone receptor positivity is a feature of SFTs showing a higher proliferative activity and a trend toward recurrence.[54]

FIGURE 116.1 Solitary fibrous tumor (SFT) of the lower eyelid and conjunctiva.

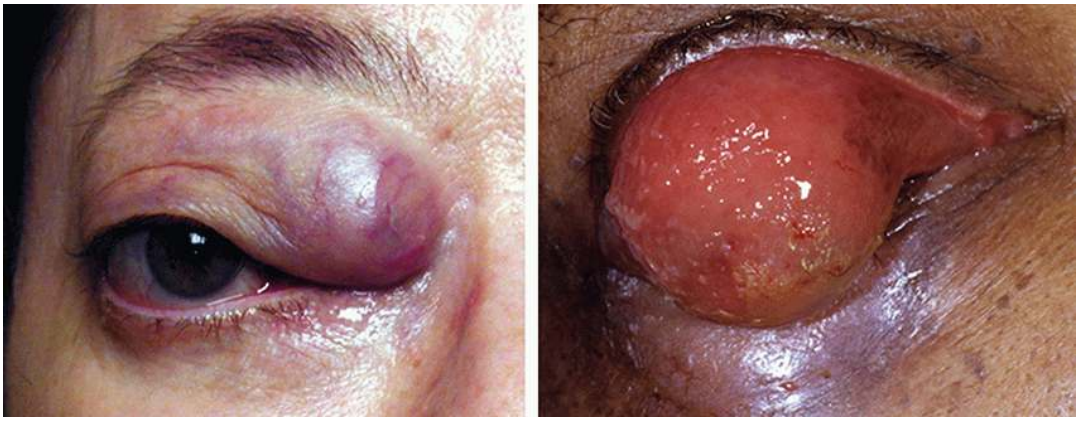

FIGURE 116.2 Solitary fibrous tumor (SFT) of the upper eyelid causing mechanical ptosis. (Courtesy of Dr. Robert A. Goldberg.)

Clinical Presentation

SFT lesions in the head and neck usually present as a painless, hard, immobile, slow-growing palpable eyelid or conjunctival mass (Figure 116.1). When present in the eyelid and periorbital region, the most frequent presenting symptoms are a palpable subcutaneous mass and eyelid swelling, and when large can cause mechanical obstruction to eyelid function, such as ectropion (Figure 116.2). Lesions involving both the eyelid and orbit are also associated with proptosis, diplopia, limited ocular motility, and occasionally decreased vision. Other rare symptoms of head and neck SFTs may include *(Print pagebreak 767)* facial swelling, bleeding, and even facial palsy. Of 18 head and neck lesions summarized by Liu et al,[55] 7 (38%) originated from the orbit, 3 (17%) from the cheek, 2 (11%) each from the masticator space and the parapharyngeal space, and 1 (6%) each from the infratemporal fossa, the maxillary, the submandibular space, and the parotid gland. Initially, 78% were clinically misdiagnosed as other lesions such as cavernous hemangioma, schwannoma, pleomorphic adenoma, granulomatous lesions, and adenolymphoma.

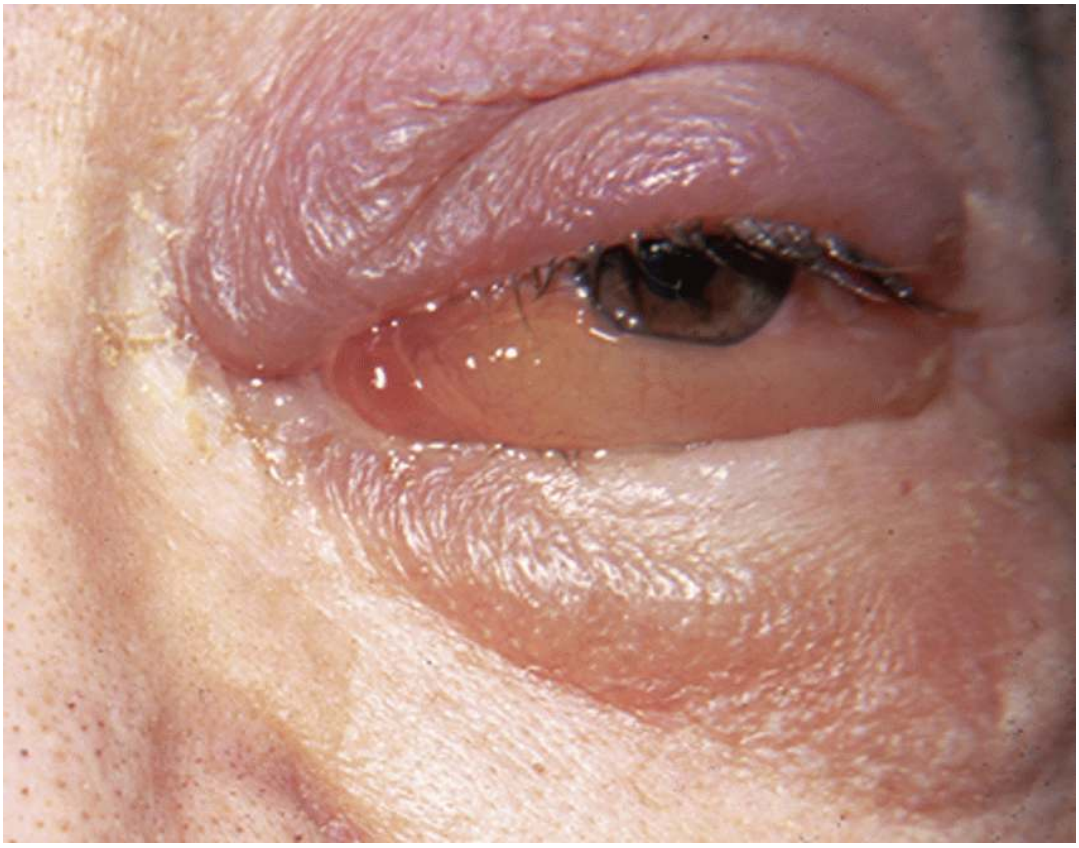

FIGURE 116.3 Solitary fibrous tumor (SFT) metastatic to the eyelid and orbit.

Higher histologic grade can be associated with recurrence and metastasis. Distant metastases have occasionally been reported.[8,56,57] In a review of 145 cases of SFT, Yamada et al[58] reported 11.8% of cases developed distant metastases, mostly associated with central nervous system (CNS) location and dedifferentiation. Rarely, SFT can metastasize to the eyelid and orbit (Figure 116.3).

Differential Diagnosis

Skin SFTs are very rare and typically present as well-circumscribed nodular lesions that can be confused with a wide variety of benign and malignant tumors. Eyelid involvement is mostly associated with orbital lesions, and neuroimaging usually shows a well-defined or less commonly diffuse mass that may be infiltrate into adjacent structures such as extraocular muscles, but the bone may be unaffected or remolded. The differential diagnosis of lesions with these characteristics is very broad and can include benign lesions such as hemangioma, schwannoma, and pleomorphic adenoma, as well as malignant tumors.

Treatment

The management of SFT usually involves a multidisciplinary team consisting of surgeons, medical oncologists, radiation oncologists, and additional ancillary support which has been shown to improve outcomes in other soft tissue sarcomas.[59,60,

[61] Surgical management has been the mainstay treatment with the goal of wide and negative resection margins and the preservation of critical surrounding organs or tissues.[6,62] After complete surgical resection, long-term follow-up has shown local recurrences as low as 8%, but this may be an underestimate since recurrence has been reported as long as 17 years following resection.[45,63] Malignant SFT tumors are more difficult to manage, with recurrence rates up to 63% even after apparent complete resection.[45]

Radiation therapy generally has not been recommended except in cases of unresectable tumors or when wide margins are not possible.[64] In a large series of intracranial STF, overall survival following surgery plus adjuvant radiotherapy compared with surgery alone was not statistically significant.[65] However, some benefit from radiotherapy has been reported in other studies, suggesting potentially improved outcomes with radiation therapy in cases of nonresectable or incomplete resection.[66,67,68,69,70]

There have been multiple retrospective studies evaluating the effectiveness of cytotoxic chemotherapy for SFTs. However, most results have shown poor results or questionable response rates.[71,72] The use of chemotherapy is best reserved for metastatic or symptomatic nonresectable SFTs. Although SFTs are relatively chemoresistant, the most effective drugs have been anthracyclines and ifosfamide, followed by gemcitabine and dacarbazine, which are commonly used in other soft tissue sarcomas.[73]

Retrospective analysis using targeted therapy with temozolomide and bevacizumab has shown a partial response in 79% of patients, stable disease in 14%, and progressive disease in 7%.[74] Antiangiogenic agents including pazopanib, sorafenib, sunitinib, regorafenib, and axitinib have also been investigated and have achieved stabilization of disease in about 50% of cases.[75,76,77,78,79]

Prognosis

Although the clinical behavior of SFT is generally benign, recurrence is not uncommon and was reported in 22.5% of 145 cases, mostly associated with CNS lesions and dedifferentiation.[57] Even tumors considered histologically benign may behave more aggressively and can demonstrate malignant behavior.[43,80] Yamada et al[57] reported metastatic disease in 11.8% of 145 cases. Even so, the overall prognosis for SFT is considered good, with 5-year survival rates between 59% and 100%, and 10-year survival rates between 40% and 89%.[13,45,62]

Poor prognostic factors include macroscopic or microscopic positive resection margins, tumor size >10 cm, more than 4 mitoses/10 HPF, increased nuclear pleomorphism, increased cellularity, tumor necrosis or hemorrhage, and the presence of malignant components.[12,13,15,81] SFT with malignant features is predictive of poorer outcomes with overall median survival ranging from 59 to 94 months. While the prognosis is usually good for most SFTs without malignant histologic features, because of the unpredictable nature of this disease, long-term follow-up of patients is mandatory.

(Print pagebreak 768)

Histopathology

Noncutaneous SFTs are usually circumscribed, unencapsulated tumors composed of cytologically bland ovoid or spindle cells that most often lack a pattern of cellular organization (Figure 116.4).[49] The cellularity of SFTs is variable, and there may be some areas of low cellularity (Figure 116.4B) and others of higher cellularity (Figure 116.4C) within a tumor.[49] There may be sparse stroma in high cellularity areas (Figure 116.4C) and abundant collagen in low cellularity areas (Figure 116.4B).[49] The collagen may form sheets or bundles and may resemble the appearance of collagen in keloids.[49] There may be focal myxoid stroma, or it may be a prominent feature of the tumor. The tumors tend to be prominently vascularized with large, dilated, thin-walled vessels (Figure 116.4D) that may branch, creating a staghorn appearance, and small- and medium-sized vessels that may have perivascular hyalinization.[49] Morphological variants of SFTs include fat-forming (lipomatous HPC) and giant cell-rich (giant cell angiofibroma).[49] Immunohistochemical analysis is critical to confirm the diagnosis of SFT due to the wide variation in the histological appearance and overlaps with other soft tissue neoplasms.[82,83] A large majority of SFTs, including those in the skin, stain positively using antibodies to CD34, CD99, Bcl-2, and STAT6.[83] Nuclear expression of STAT6, a surrogate for detecting *NAB2-STAT6* gene fusion, is especially beneficial for discriminating SFTs from other soft tissue tumors.[82]

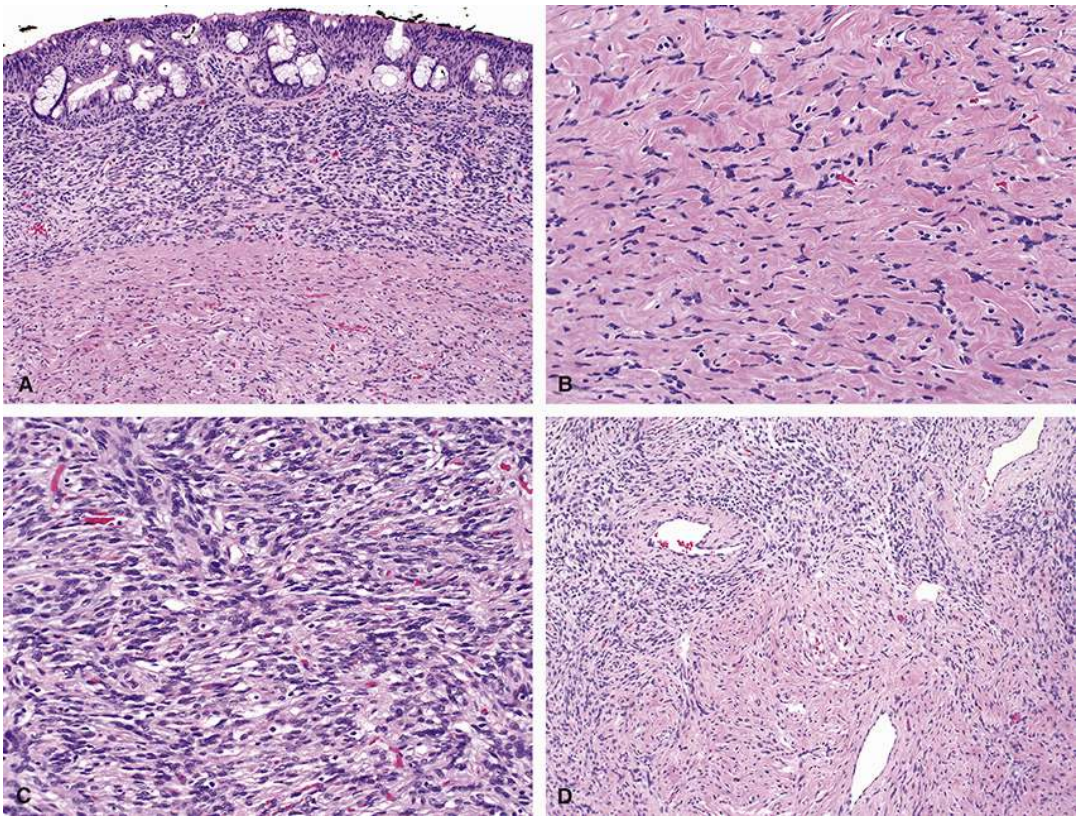

FIGURE 116.4 A man in his middle 30s developed tearing due to a solitary fibrous tumor (SFT) involving the left medial canthus and left lacrimal sac. A, SFT is present in the lacrimal sac subepithelium and extends into the adjacent connective tissue. The lacrimal sac epithelium has goblet cells individually and forming mucous glands.[87] B, The cellularity of SFTs is variable. This area of the tumor has low cellularity and abundant collagen. C, This area of the tumor has high cellularity and sparse stroma. D, The SFT has areas of prominent vascularization with large thin-walled vessels. (Reprinted with permission from Paulsen F. *The Human Nasolacrimal Ducts*. Springer; 2003:19.)

Cutaneous (superficial) SFTs involve the dermis or subcutis (Figure 116.5).[84,85] Erdag and coworkers examined 10 cutaneous SFTs, six located on the head.[84] All tumors were centered in the reticular dermis or superficial subcutis.[84] Seven tumors were circumscribed multinodular neoplasms, and three had a diffuse growth pattern.[84] Cytologically bland fusiform cells were usually haphazardly arranged, though *(Print pagebreak 769) (Print pagebreak 770)* three tumors had a vaguely fascicular pattern (Figures 116.5B and C).[84] Supporting vasculature was prominent in only five of the tumors.[84] All cases had collagenized and focally sclerotic stroma.[84] Of the 10 tumors, 8 were immunoreactive for CD34 (Figure 116.4D), and 6 were positive for CD99 (Figure 116.4E).[84] More recently, Feasel et al reported a series of 26 superficial SFTs.[85] Four tumors were in the dermis, 6 were in the dermis and subcutis, 15 were in the subcutis, and the depth was not available for one tumor.[85] Eleven of the superficial SFTs were on the head, with 2 being eyelid neoplasms.[85] Around 70% of the superficial SFTs were "in the cellular end of the spectrum with irregular fascicles of spindled cells with staghorn-like vessels and variable amounts of collagen."[85] One eyelid tumor was classified morphologically as a fat-forming giant cell angiofibroma, and the other had a focally storiform classic pattern.[85] Around 94% (17/18) of the tumors were positive for immunohistochemical expression of STAT6 (Figure 116.5F), 95% (21/22) expressed CD34, and none expressed S100 protein (0/8) or cytokeratins (0/5).[85] The one tumor that lacked STAT6 expression had classic histologic features of SFT and expressed CD34.

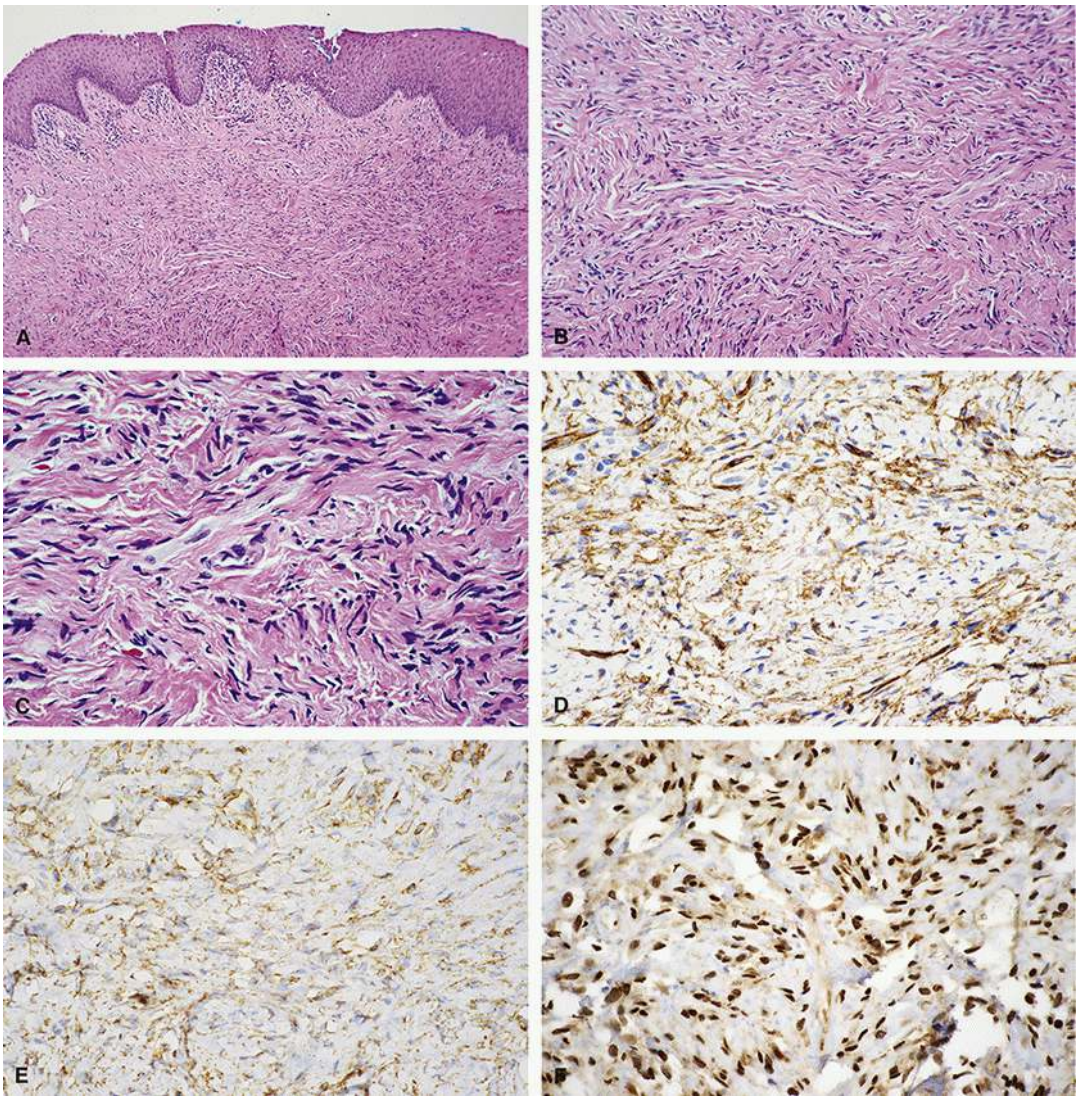

FIGURE 116.5 This solitary fibrous tumor (SFT) of the right lower eyelid mucocutaneous junction lateral to the punctum was from a woman in her late 60s. The lesion was raised, had a diameter of about 1 mm, and there was telangiectasia but no madarosis. It was present for about 1 to 2 years before biopsy during ectropion repair. A, The SFT is in the conjunctival substantia propria with a thin zone of normal connective tissue between the tumor and thickened conjunctival epithelium. B, The SFT is cellular, with spindle cells forming fascicles with interspersed stromal collagen. Some areas had many blood vessels. C, The spindle cells are cytologically bland, mitotic figures and necrosis are absent, and abundant eosinophilic collagen is present among the fascicles of spindle cells. The tumor cells exhibit cytoplasmic staining using antibodies to CD34 (D) and CD99 (E). The tumor cells did not express smooth muscle actin, S100 protein, or glial fibrillary acidic protein (not shown). F, Approximately 95% of superficial SFTs exhibit nuclear expression of STAT6.

Histological features of malignancy are infiltrative margins, hypercellularity, at least focal cellular pleomorphism, and more than four mitotic figures per 10 high-power microscopic fields.[49] In the modified risk assessment model developed by Demicco and colleagues,[86] the risk of metastasis by SFTs is based on a cumulative score of age (0 for age <55 years and 1 for age ≥55 years), mitotic activity (score 0 for <1 mitotic figure/10 HPF, 1 if 1-3 mitotic figures/10 HPF, and 2 if ≥4 mitotic figures/10 HPF), tumor size (score 0 if ≤5 cm, 1 if 5 to <10 cm, 2 if 10 to <15 cm, and 3 if ≥15 cm), and necrosis (0 if <10% necrosis and 1 if ≥10% necrosis). A cumulative score of 0 to 3 is low risk, 4 to 5 is intermediate-risk, and 6 to 7 is high risk.[86] Demicco et al found no metastases at 10 years of follow-up in patients with low-risk SFTs, a 7% 10-year metastatic risk in the intermediate-risk group, and a 49% 5-year metastatic risk for the high-risk patients.[86] Feasel and coworkers found that all (23/23) of their patients with superficial SFTs were low risk using this scheme, even two patients with malignant histology.[85] None of their seven patients with follow-up had recurrence or metastasis of their SFT with a mean follow-up of 100 months (range, 2-241 months).[85]

CHAPTER 117

Stevens-Johnson Syndrome

Key Points

- Stevens-Johnson syndrome (SJS) is a severe T-cell-mediated, usually drug-induced, acute blistering disease of the skin
- SJS, together with toxic epidermal necrolysis, represents a wide spectrum of adverse cutaneous drug reactions
- It is an idiosyncratic reaction to drug intake where the accumulation of drug metabolites in the epidermis in genetically predisposed individuals initiates an immunologic process that causes massive keratinocyte cell death, eventually leading to full-thickness necrosis of the epidermis
- Acute conjunctivitis typically precedes or occurs concurrently with skin eruptions in more than 65% of patients with SJS
- Palpebral anomalies are mostly attributable to tarsal conjunctival scarring, which can result in entropion, trichiasis, distichiasis, ectropion, and symblepharon formation
- Studies have reported significantly better visual outcomes with topical steroid use
- Management of trichiasis and entropion is recommended in patients with frank cicatricial entropion
- The ultimate prognosis is related to how quickly the proper clinical diagnosis is established, how rapidly the causative drug can be identified and discontinued, and how aggressively appropriate treatment can be initiated

Stevens-Johnson syndrome (SJS) is a severe T-cell-mediated, usually drug-induced, acute blistering disease of the skin and at least two mucosal surfaces, which, together with toxic epidermal necrolysis (TEN) and their intermediate variety (SJS/TEN overlap), represents a spectrum of adverse cutaneous drug reactions. These conditions may be complicated with high mortality or significant long-term ocular morbidity.[1,2,3,4,5,6,7,8,9,10]

Etiology and Pathogenesis

SJS/TEN is essentially an idiosyncratic reaction to drug intake where the accumulation of drug metabolites in the epidermis in genetically predisposed individuals initiates an immunologic process that causes massive keratinocyte cell death, eventually leading to full-thickness necrosis of the epidermis.[10] The list of implicated medications exceeds 200 drugs, but the most common ones include antibiotics (sulfonamides like trimethoprim or sulfamethoxazole, beta-lactam antibiotics, tetracyclines, or quinolones), antiepileptic medications, nonsteroidal anti-inflammatory agents, antigout medications, and vaccinations.[1,2,6,10] Rarely, nonpharmaceutical factors like exposure to industrial chemicals, traditional Chinese herbal medications, infections with *Mycoplasma pneumoniae*, herpes virus, or HIV may initiate SJS/TEN.[1,2]

Regardless of the exact etiologic risk factor, the etiopathogenetic mechanisms underlying the onset of SJS/TEN complex have not yet been fully elucidated but are postulated to have both an immunologic and a genetic basis, which when acting together both lead to keratinocyte cell death by apoptosis and secondary epidermal necrosis, usually with irreversible consequences.[1,2,5] Granulysin, a powerful cytolytic protein secreted by the immune system, is hypothesized to play a decisive role underlying the massive epidermal cell death and mucous membrane pathology in SJS.[5] Genetic associations include abnormalities in the *HLA-B12* allele and several of its subgroups, the *IKZF-1* gene, as well as several other genes.[2] Because each of these different genes or HLA alleles may predispose an individual of a certain race to a specific drug and not any other,[2,5] a full review of those genetic/immune-mediated mechanisms and the various theories associated with SJS or TEN are beyond the scope of this chapter and are discussed in detail elsewhere.[2,5]

Lid margin keratinization is a chronic ocular sequela of SJS, causing progressive ocular surface damage. The exact etiopathogenesis remains elusive, but possible pathophysiologic mechanisms included loss of the mucocutaneous junction barrier leading to

epidermalization, dyskeratosis involving the meibomian gland orifices, altered lid margin microbiome, and de novo squamous metaplasia of the marginal conjunctival epithelium. Findings support a role for inflammation in the pathogenesis.[11]

Clinical Presentation

SJS/TEN is a rare disease with an annual incidence that ranges from 0.4 to 7 cases per million, but with a high mortality rate of 25% to 40% in TEN and 1% to 5% in SJS.[1,8] SJS is predominantly a disease of children and adolescents, whereas TEN may occur in all ages, although the mortality rate is higher in the elderly. Both conditions may recur (16 recurrences/1000 person-years), but recurrences tend to decline with age.[4] SJS is defined when 10% or less of the body surface area is involved, while in TEN 10% to 30% of the cutaneous surface area is involved.[2] Patients with acute SJS rarely present to the *(Print pagebreak 774)* ophthalmologist, but any bilateral conjunctivitis associated with an extremely high fever with or without oral involvement and with paronychia should alert the clinician to the possibility of SJS.[6] Acute conjunctivitis typically precedes or occurs concurrently with skin eruptions in more than 65% of patients with SJS.[6] If an ophthalmologist is consulted in the ICU later, after the diagnosis is established, 75% of these patients typically have bilateral conjunctivitis. This may progress to corneal ulceration in 25% of patients,[2] and occasionally tarsal ulceration may also be present.[6,7] Patients with SJS are often seen by an ophthalmic specialist after they have been released from the hospital, but in fact, the residual ocular side effects of SJS are frequently the most debilitating part of the disease.[2,3,4]

FIGURE 117.1 Hyperemia and scarring of the upper eyelid tarsal conjunctiva in SJS.

FIGURE 117.2 SJS with eyelid blisters and skin sloughing. (Courtesy of Dr. Charles Soparkar.)

Palpebral anomalies in SJS are mostly attributable to tarsal conjunctival hyperemia and scarring (Figure 117.1), which can result in entropion, trichiasis, distichiasis, or even ectropion.[10] If not removed, misdirected eyelashes, or the distichiatic ones originating from metaplastic meibomian glands, can mechanically abrade the corneal epithelium causing repeated blink-related microtrauma.[2,3,8] The exact incidence or prevalence of eyelid malpositions in SJS is difficult to conclude from the literature and varies from as low as 3% to as high as 71%.[3,8,9,10] This dramatic variability may be attributable to the lack of medical care in some rural areas, lack of standardization of diagnostic criteria for palpebral anomalies in SJS,[3] or earlier evaluation before chronic sequelae have set in.[9] More importantly, it may also be attributable to a difference in genetic backgrounds.[3] An often overlooked cause of persistent ocular inflammation in SJS/TEN is chronic irritation of the ocular surface due to lid margin keratinization.[8,9] Tarsal ulceration, which occurs in the acute phase, eventually leads to destruction of the mucocutaneous junction with subsequent keratinization of the eyelid margin that usually extends 2 to 3 mm into the tarsal conjunctiva.[8,9]

Symblepharon formation can result in lagophthalmos and extensive corneal exposure and even ankyloblepharon as late sequelae of the conjunctival ulceration observed in the acute phase.[8] Other abnormalities include eyelid erythematous macules and patches, bullae, and sloughing of skin (Figure 117.2). Severe dryness with a reduction of both the aqueous and lipid layers also is encountered frequently. This is multifactorial, occurring as a result of scarring of the lacrimal ducts, chronic reduction of lacrimal gland function, meibomian gland atrophy/orifice metaplasia, or reduction in conjunctival goblet cells.[2,3,8] In addition to the aforementioned cicatricial problems, destruction of corneal limbal stem cells combined with repeated mechanical trauma to the corneal epithelium by the trichiatic or distichiatic lashes, or by the keratinized lid margin itself, may lead to recurrent corneal abrasions, infections, corneal pannus, corneal neovascularization, and scarring. All these factors eventually lead to end-stage disease with corneal blindness[2,3] and may even progress to corneal melting and perforation.[7]

Systemically, the chronic manifestations of SJS/TEN may vary among patients, as some patients may survive their disease without apparent sequelae. However, if they do occur, chronic sequelae may include skin scarring or pigmentation; penile phimosis; vulvar adenosis; vaginal, urethral, or anal strictures; dental abnormalities; esophageal strictures; and dry mouth.[1] The psychological toll is also quite high, and these patients may become chronically afraid of becoming sick or receiving any medications or transmitting the disease to their children.[1]

Differential Diagnosis

While establishing the diagnosis of SJS may be straightforward from the history and is easy to diagnose in the chronic phase of the disease, several peculiar conditions, such as chickenpox, measles, or a herpetic infection may be confused with the acute phase of SJS. However, the presence of very high fever, oral mucosal lesions, and paronychia at the onset should raise the suspicion of SJS.[6]

(Print pagebreak 775)

Treatment

The ophthalmologist's role in the acute management of SJS/TEN has been limited to prescribing topical medications, including antibiotics and corticosteroid preparations, as well as preservative-free lubricating agents.[3] The use of topical steroids in the acute stage is controversial,[3] but some studies have reported significantly better visual outcomes with topical steroid use.[6] Covering areas of tarsal conjunctival ulcerations with a temporary amniotic membrane graft in the acute stage of the disease may help suppress inflammation and prevent late palpebral changes and consequently corneal pathology.[3] The sloughing and inflammation of mucosal epithelium during the acute phase may lead to keratinization of the eyelid margins and scarring sequelae of the ocular surface, resulting in pain and vision loss. Amniotic membrane transplantation to the eyes and eyelids during the initial 1 to 2 weeks of the disease can decrease the chronic sequelae.[12] However, eyelid-related complications in the chronic phase of the disease after AMT can include trichiasis, distichiasis, eyelid margin keratinization, and cicatricial entropion.[13]

While eyelash epilation or a large-diameter contact lens may provide temporary relief in patients with SJS,[3] lash ablating procedures are the treatment of choice for trichiasis manifesting in SJS without frank entropion.[3] Failure to address these eyelashes will result in further morbidity to the cornea, which is already compromised by the keratinized lid margin and the limbal stem cell deficiency. Getting rid of those misdirected eyelashes rubbing against the cornea also helps eliminate the confusion about the exact cause of ocular redness, whether it is of mechanical nature from the eyelashes or due to an alternative concomitant pathology such as irritation by a keratinized eyelid margin, which should be addressed.[7,8]

Tarsal rotation procedures, like anterior lamellar reposition with a gray line split or anterior lamellar recession, are generally recommended in patients with frank cicatricial entropion.[11] However, surgeons should not overlook the fact that symblepharon formation may pose a special problem in patients with SJS.[14] While a single symblepharon band may lend itself to simple division, fornix reconstruction with a mucosal graft[14] or amniotic membrane transplantation[15,16] may be advocated for more extensive symblepharon formation.[14,15,16] As was mentioned earlier, another unique situation that is not uncommonly encountered in patients with SJS/TEN is lid margin keratinization.[7,8] Excision of the keratinized area with replacement by a mucous membrane graft helps restore the integrity of the mucocutaneous junction by creating a barrier to prevent the crossover of keratinized epithelium.[7,8] It should be borne in mind that the strip of oral mucosa should cover as much of the length of the lid margin as possible.[7] It is also important to bear in mind that the keratinization process usually extends 2 or 3 mm into the tarsal conjunctiva; therefore, the strip of oral mucosa used should have an average size of 20 × 5 mm or even more if adequate oral mucosa is available.[7] Although the oral mucosa is involved in SJS, these lesions are probably self-limiting manifesting only in the acute phase, therefore the lip is the preferred donor site.[7]

Prognosis

The ultimate prognosis for SJS/TEN is related to how quickly the proper clinical diagnosis is established, how rapidly the causative drug can be identified and discontinued, and how aggressively appropriate treatment can be initiated.

A validated severity-of-illness score for TEN and SJS, called SCORTEN, was developed by Bastuji-Garin et al to determine the variables useful as predictors of prognosis and risk of death.[17] They identified seven independent clinical and laboratory risk factors for death, and a higher score was related to a higher mortality rate. In a later report, they showed excellent performance of the SCORTEN in predicting prognosis during the first 5 days of hospitalization.[18]

In a series of 460 patients with SJS, SJS/TEN, and TEN, Sekula et al reported the mortality rates at 6 weeks of 12% for SJS, 29% for SJS/TEN, and 46% for TEN.[19] The 1-year mortality rates were 24% for SJS, 43% for SJS/TEN, and 49% for TEN. The prognosis does not seem to be affected by the type or the dose of the causative drug.[20]

Histopathology

The histopathology of SJS/TEN overlaps with those of erythema multiforme (EM), and different studies have yielded varying results.[21,22,23] Côté et al examined biopsies from 18 patients with EM and 15 with SJS.[21] Of 18 EM biopsies, 12 had a predominantly inflammatory pattern with a lichenoid infiltrate of lymphocytes and macrophages at the dermal-epidermal junction; a sparse, deep, perivascular inflammatory infiltrate; exocytosis; and a variable degree of epidermal necrosis that was predominantly in the lower epidermal layers.[21] Confluent epidermal necrosis was associated with subepidermal and intraepidermal bullae.[21] Of 15

SJS biopsies, 12 had a predominantly necrotic pattern with “intense” epidermal necrosis and minimal dermal inflammation that, if present, was sparse and localized around vessels in the superficial vascular plexus (Figure 117.3).[21] The epidermal necrosis in the SJS biopsies resulted in subepidermal separation.[21] Features that differentiated EM from SJS were more severe epidermal necrosis in SJS while EM had more significant dermal inflammation and exocytosis.[21]

Rzany and coworkers[22] examined 16 biopsies from patients with EM, 34 from patients with SJS, and 61 from patients with TEN and concluded that all were a spectrum of the epidermal variant of EM reported by Orfanos et al.[24] All biopsies had necrotic keratinocytes ranging from individual cells to confluent total epidermal necrosis, with the amount of total necrosis being higher in patients diagnosed clinically with SJS, SJS/TEN overlap, and TEN than those with EM.[22] All biopsies had basal epidermal changes varying from vacuolar change to subepidermal bullae *(Print pagebreak 776)* that was independent of the clinical diagnosis.[22] Dermal inflammation was superficial and perivascular, and the degree of inflammation was greater in EM than in SJS or TEN.[22] Extravasated erythrocytes were more common in EM than in SJS or TEN.[19] The finding by Rzany et al[22] that SJS/TEN has greater epidermal necrosis and less dermal inflammation than EM agrees with the report by Côté and colleagues.[21]

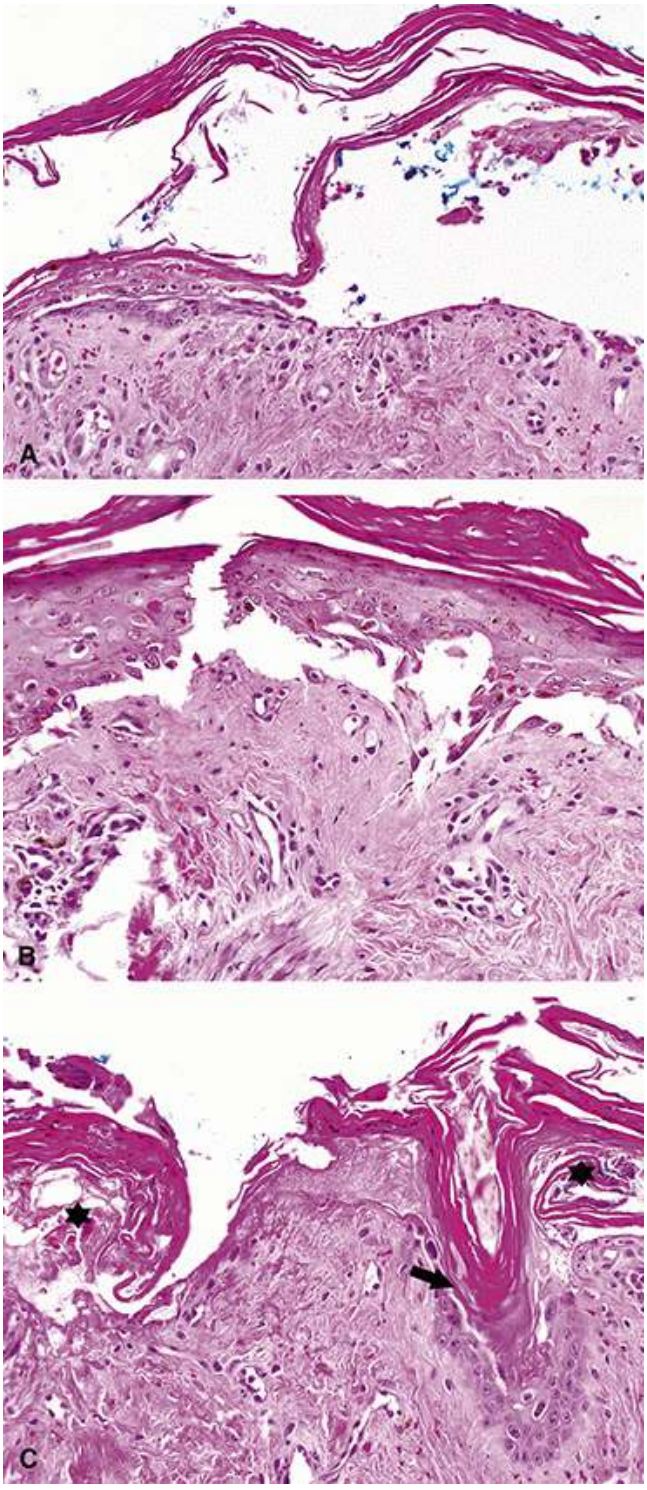

FIGURE 117.3 A, This SJS biopsy has full-thickness epidermal necrosis, a subepidermal blister, and a scant dermal inflammatory infiltrate. B, Individual hypereosinophilic necrotic keratinocytes are in this SJS biopsy, along with a subepidermal bulla and a sparse perivascular dermal inflammatory infiltrate of lymphocytes and macrophages. C, The epidermal necrosis in this SJS biopsy varies from full thickness (★) to partial thickness (*arrow*). There are subepidermal blisters and minimal dermal inflammation.

More recently, Wetter and Camilleri reported histological findings in 15 biopsies from 13 patients with SJS.[23] Epidermal necrosis was present in 8 of 13 patients (62%) and was full thickness in 6 patients (46%).[23] Basal vacuolar change occurred in 77% of patients, with moderate to severe change in 38%.[23] Subepidermal bullae were present in 77% of the patients.[23] A histological finding that differed from the reports of Côté and colleagues[21] and Rzany and coworkers[22] was that 11 of 13 patients (85%) had either a moderate (8 patients) or severe (3 patients) dermal inflammatory infiltrate of predominantly lymphocytes.

As these three studies demonstrate, there is no sharp demarcation of histological features between EM and SJS/TEN. Thus, histopathological diagnosis requires clinical correlation.

CHAPTER 118

Subepidermal Calcinosis

Key Points

- Subepidermal calcinosis is a form of localized cutaneous soft tissue calcium deposit
- It is classified as dystrophic, metastatic, calciphylaxis, iatrogenic, and idiopathic types
- The pathogenesis is poorly understood, and of the various causes proposed, none are supported by convincing evidence
- Clear clinical characteristics are generally absent so that the diagnosis is usually made only after histopathologic examination
- Lesions appear as a round to oval; painless; yellow, white, gray, or pink; solitary; mobile; hard nodule located in the upper dermis of the skin
- The definitive treatment is not established, but complete surgical excision has been the treatment of choice in most reports
- The prognosis is excellent following surgical excision, even when the resection is incomplete

Subepidermal calcinosis (SC) is a form of soft tissue calcium deposit that was first recognized by Winer in 1952[1] and later named by Woods and Kellaway in 1963.[2] A wide variety of synonyms have been used in the literature including idiopathic calcinosis cutis, localized cutaneous calcinosis, subepidermal calcified nodule, cutaneous calculi, and solitary nodular calcification.[3,4]

SC is classified as dystrophic, metastatic, calciphylaxis, iatrogenic, and idiopathic types.[5] Dystrophic calcification is the most common form and usually occurs in association with autoimmune and other diseases that cause chronic inflammation and alterations within connective tissue.[4] Metastatic calcification is characterized by abnormal calcium and or phosphate metabolism.[4] Calciphylaxis refers to calcification in the media of small and medium-sized dermal blood vessels and subcutaneous tissues sometimes seen in end-stage renal disease.[6] Idiopathic SC occurs in otherwise healthy individuals without any associated systemic disease, abnormal laboratory studies, or history of trauma.[7,8,9,10,11,12,13]

Subepidermal calcinosis is a rare dermatological condition with only about 150 cases described in the literature. Of these, fewer than 60 cases have involved the ocular adnexa.[9,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28] Among the eyelid lesions, there is a marked male predominance of about 67%.[3] These lesions have been seen in patients aged from 3 to 90 years, but about 90% occur in patients ≤21 years of age, and the mean age at presentation is about 12 years.[5] About 42% of reported cases occurred in Caucasian, 24% in Hispanic, 21% in black, and 13% in Asian patients.[3]

Etiology and Pathogenesis

The pathogenesis of subepidermal calcinosis is poorly understood, but numerous possible etiologies have been proposed. Dystrophic calcification that forms in devitalized tissues or in preexisting lesions within the connective tissue of the dermis following trauma seems unlikely for many cases because there is no consistent history of trauma.[5,29] Calcified lesions have been associated with syringomas and milia,[20,30] especially in patients with Down syndrome,[31] but this association is rare. Nanobacterial activity has been proposed as a cause, but ultrastructural analysis of a series of dystrophic calcifying conditions of the skin failed to show any evidence of nanobacteria.[32] A hypersensitivity reaction followed by degranulation of mast cells with subsequent deposition of calcium and phosphate has also been proposed,[33,34,35] but there is little evidence to support this view. Another proposal suggested that SC might arise from calcification of sweat ducts or hair follicles.[28]

Clinical Characteristics

As a general rule, all patients with cutaneous calcification should be examined for underlying conditions, particularly serum calcium and phosphorus dysfunction, as well as rheumatologic conditions.[9] Idiopathic SC is rare, and clear clinical characteristics are generally absent so that the diagnosis is usually made only after histopathologic examination. On the eyelids, lesions are usually present for weeks to years, with 76% more than 6 months, and 27% more than 12 months.[5] Lesions appear as a round to oval, painless, solitary, mobile, hard nodule (Figure 118.1). They generally are small, being less than 5 mm in 81% of cases, but can be up to 10 mm in diameter. Nodules are located in the upper dermis of the skin, and in the eyelid, the calcification can occur along the superior border of the tarsus[5] or between the tarsus and the palpebral conjunctiva.[17] The overlying epidermis can appear verrucous, hyperkeratinized, or papillomatous and can be yellow, white, gray, or pink. There typically is no history of trauma or systemic disease. Calcium, phosphate, and parathyroid hormone levels are in the normal range. Lesions involve the upper eyelid in 63% of cases, the *(Print pagebreak 779)* medial canthus in 28%, and the lower eyelid in 9% of cases.[5] Lesions are single in 82% of cases but may be multiple in 18%.[3] When multiple, lesions can occur on several different eyelids and can be seen bilaterally.

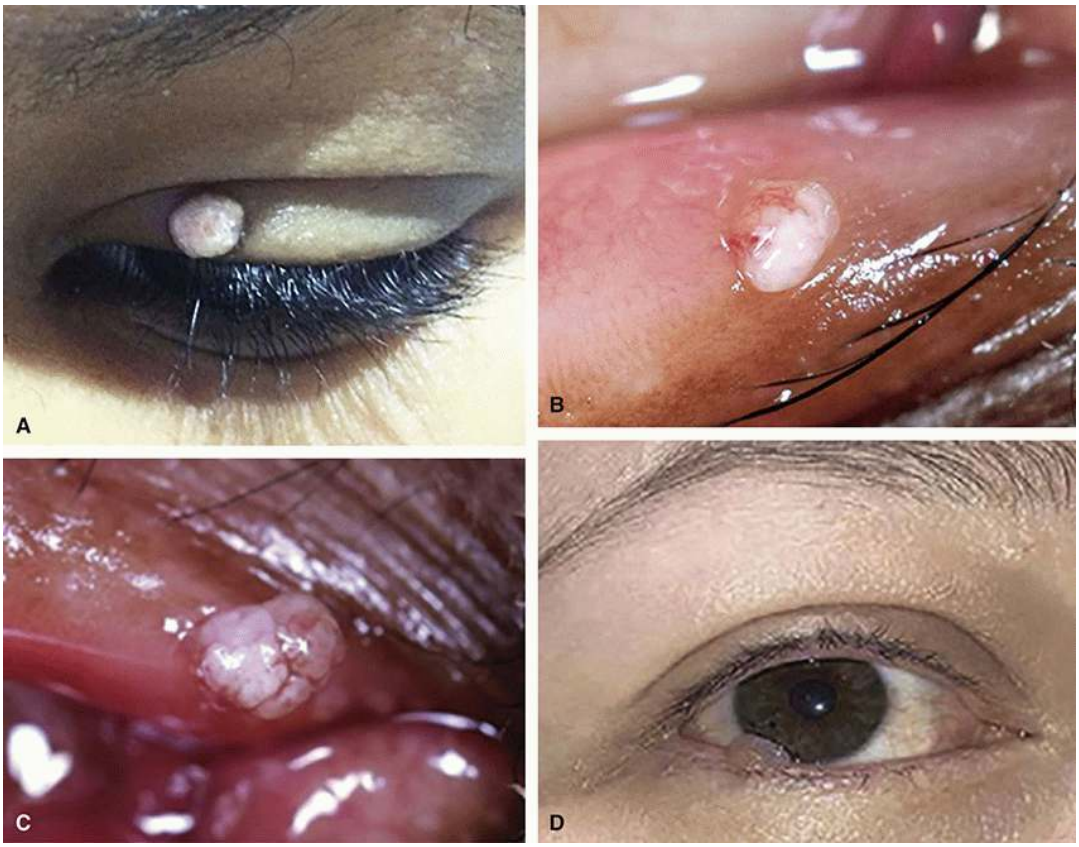

FIGURE 118.1 Calcinosis cutis. A, Papillomatous nodule on the upper eyelid. B, Small lower eyelid lesion. C, Nodular calcinosis lesion around the lower eyelid punctum. D, Calcinosis lesion on the lower eyelid margin. B and C, (Courtesy of Dr. Javed Mohammad Ali.) D, (Courtesy of Dr. Norman Charles.)

Differential Diagnosis

Subepidermal calcinosis is almost always misidentified clinically as a more common lesion. These include pilomatrixoma, warty papilloma, cutaneous horn, juvenile xanthogranuloma, chalazion, syringoma, milia, molluscum contagiosum, epidermoid cyst, seborrheic keratosis, xanthelasma, hemangioma, or sebaceous cell carcinoma.[3,9,14,19,21,22,36,37]

Treatment

Although the definitive treatment of SC is not established, complete surgical excision has been the treatment of choice in most reports.[14,15,17,19,21,22,23,37,38,39] Recurrence even after incomplete excision is rare, reported in only one of eight incompletely removed cases by Kim et al.[19] CO_2 laser ablation has been reported in several cases for multiple lesions or where surgery was deemed cosmetically inappropriate.[40,41,42] Topical and intralesional steroids have been ineffective.[21,22,37]

Prognosis

In cases of idiopathic SC, the prognosis is excellent following surgical excision, even when the resection is incomplete. Even though most eyelid cases are idiopathic with no systemic associations, any presentation of calcinosis cutis can sometimes occur with serious underlying diseases of calcium metabolism including hyperparathyroidism, renal disease, rheumatologic conditions, systemic sclerosis, and CREST (calcinosis cutis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) syndrome, and with dermatomyositis.[9]

(Print pagebreak 780)

Histopathology

Subepidermal calcified nodules (SCNs) account for the vast majority of SC in the periocular region and appear similar to SCNs at other body sites (Figure 118.2).[9,14,18] Woods and Kellaway first defined the histological appearance of SCNs in 1963 in a review of 22 biopsies from 20 patients.[2] The age range of their patients was from birth to 56 years. All but four of the patients were below 16 years of age.[2] SCNs consisted of calcified material in the upper dermis abutting the epidermis. Larger nodules extended deeper into the dermis but never into the subcutis. Calcified material formed irregular basophilic granules 20 to 40 μm in diameter and larger masses. The granules stained more intensely than the larger deposits using periodic acid-Schiff stain. The authors identified well-preserved nuclei in occasional granules and masses, suggesting a cellular origin for the calcified deposits.[2] The overlying epidermis was verrucous, often thickened by acanthosis, and had hyperkeratosis and sometimes patchy parakeratosis. Narrow-pointed rete pegs and keratin-filled pits commonly extended far into the nodules. Early SCNs had granules in a moderately cellular stroma containing fibroblasts, macrophages, and multinucleated giant cells, often forming rings around the granules. Granules often invaginated the epidermis and were present in the keratin layer. Early lesions often contained calcified granules and large masses of calcified material composed of finely granular particles. Woods and Kellaway thought that the masses resulted from focal degeneration of the stroma with the inclusion of the granules in the degenerating area. Larger masses abutting the epidermis sometimes caused degeneration and calcification of the prickle cell layer. The calcific masses in early lesions were poorly outlined by stromal cells. Mononuclear cells and multinucleated giant cells bordered calcified masses in later lesions. The stroma of older SCNs was usually dense acellular collagen. Woods and Kellaway stated: “In this description there has been a considerable amount of interpretation of the way in which the lesions evolve. The histological appearances suggest that calcified granules in a cellular stroma form the essential lesion and that large masses may result from degeneration and calcification of the stroma.”[2]

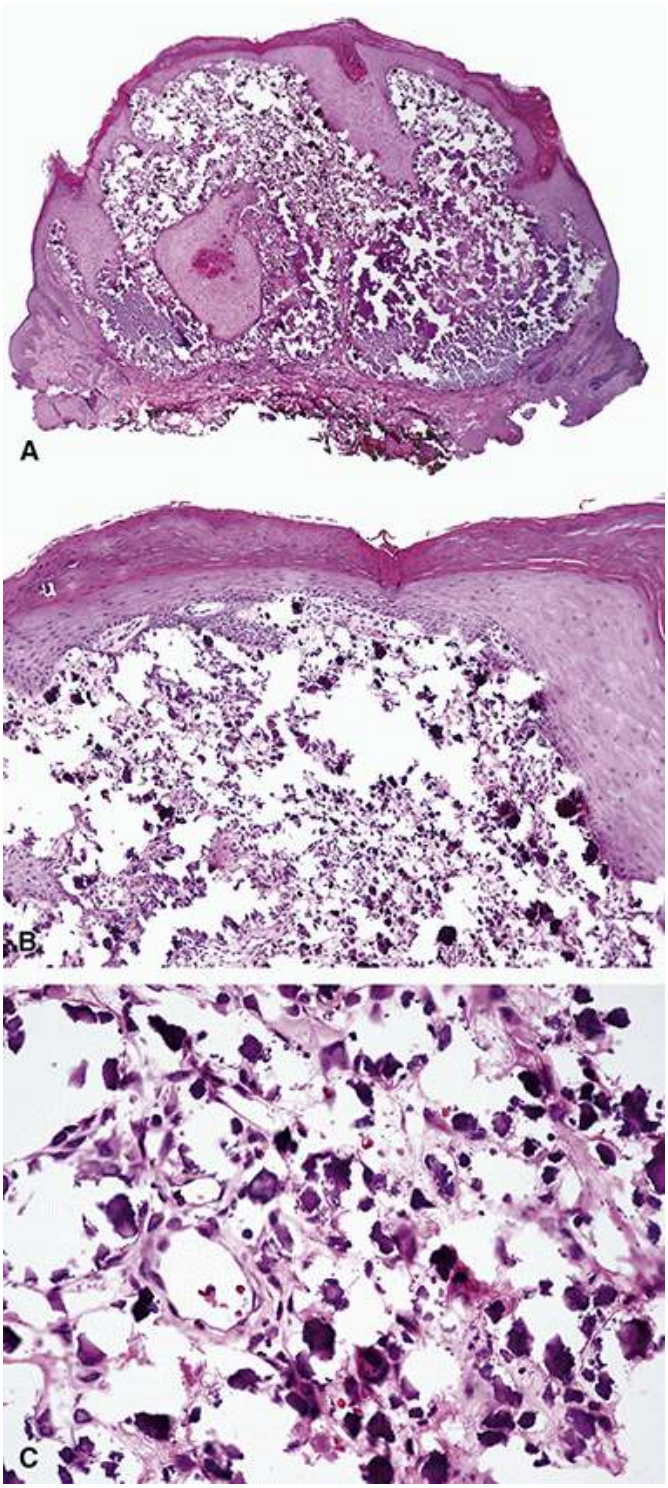

FIGURE 118.2 This subepidermal calcified nodule arose on a young girl's medial left upper eyelid (shown in Figure 118.1A). The nodule was diagnosed clinically as a pilar (trichilemmal) cyst, and it was treated with hot compresses and massage three times per day. It went entirely away after 1 week of treatment, but it then recurred at the same site with intermittent drainage and swelling. It was excised 8 months after its appearance. A, The SCN is well circumscribed in the dermis and abuts the acanthotic epidermis. Numerous clefts are present in the nodule, at least partially reflecting artifacts from the extensive calcification. B, The epidermis has prominent hyperkeratosis. There are innumerable calcific deposits, some directly in contact with the basal epidermis. C, The calcific deposits vary widely in size from punctate particles to small, irregular, but primarily round to oval deposits. Larger deposits tend to be more basophilic than the minute particles.

Evans, Blessing, and Gray confirmed and extended our knowledge of SCN histopathology by examining 21 specimens from children ranging in age from one to 17 years.[29] One specimen was from the eyelid of a 17-year-old boy. Calcium deposits were small globules or large amorphous deposits. Three specimens had mainly large deposits, 10 had small globules, and 8 had a mixture of small and large deposits. There was epidermal ulceration and transepidermal *(Print pagebreak 781)* elimination of calcium

deposits in six specimens. Based on the duration between clinical appearance and biopsy, younger lesions had a more verrucous appearance with calcium predominantly in large amorphous clumps. Older lesions featured small globular spherules of calcium. Only two specimens had a focal foreign body giant cell reaction.

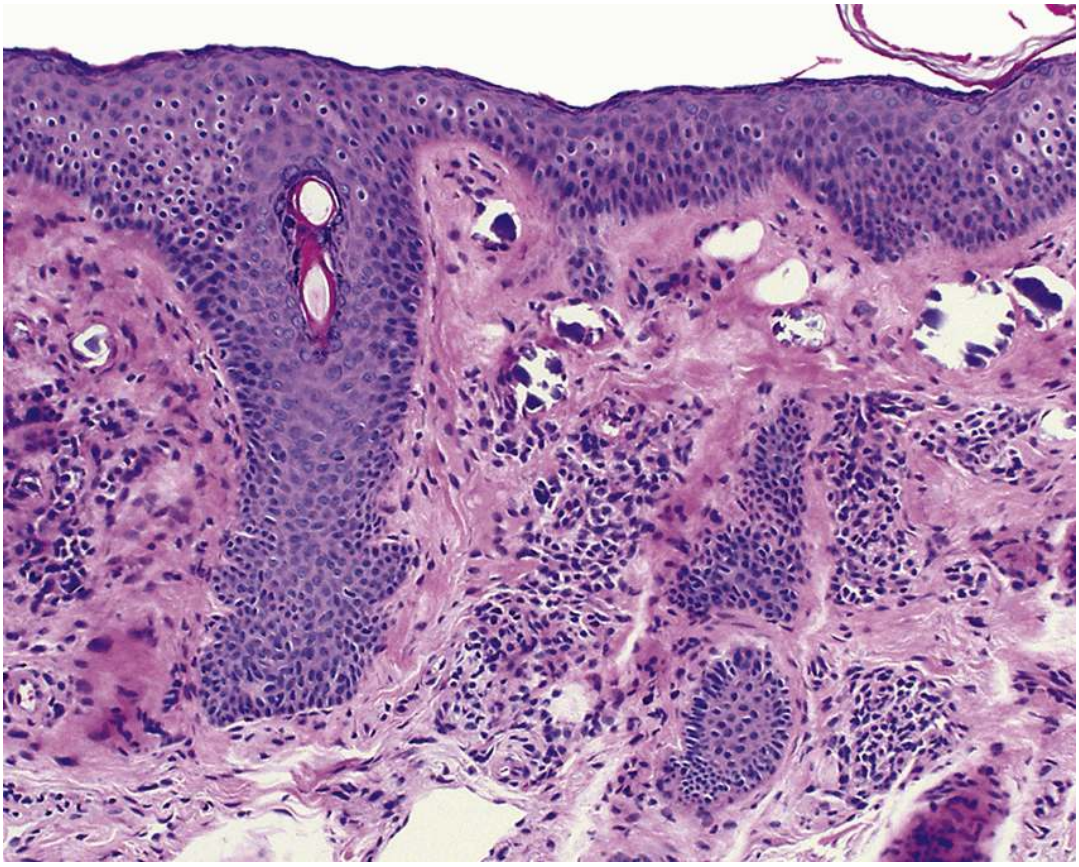

FIGURE 118.3 Subepidermal calcinosis (calcinosis cutis) developed in the medial left upper eyelid near the medial canthus of a man in his early 30s. The lesion started as a 2 × 3 mm keratotic papule thought to be a verruca vulgaris. There was no response to two cryotherapy applications, and the lesion was excised about 4 months later. Deposits of basophilic calcification in clear lacunae are in the superficial dermis and are typical of idiopathic calcinosis cutis. The empty spaces around the calcific deposits result from fragmentation and loss of deposits during histological sectioning.

More recently, AlWadani and coworkers examined 14 eyelid SCNs.[14] In three SCNs the calcific deposits were from people aged 70, 84, and 88 years, and the other 11 were from individuals ranging from 13 to 19 years old. The duration of lesions ranged from one to 228 months before the biopsy. The SCNs from younger patients were dermal nodules containing numerous small round to oval calcified bodies, while the biopsies from the older adults featured a single, large, well-demarcated deposit of amorphous calcified material. The calcific deposits of all younger individuals were surrounded by a lymphoplasmacytic inflammatory infiltrate, and 10/11 had a foreign body giant cell reaction. The SCNs from the older people lacked chronic inflammation and a foreign body reaction. The calcific bodies from all specimens stained using von Kossa's method,[14] which "demonstrates the presence of phosphates, soaps, and amorphous but not crystalline carbonates, rather than calcium itself."[43]

There are only rare reports of eyelid calcification other than cutaneous SCNs. Jun et al reported a 42-year-old woman with a papillomatous mass involving the tarsus that histologically was characterized by a large mass of amorphous calcium.[17] This mass may represent the tarsal analog of the large calcific masses noted by AlWadani and coworkers in cutaneous SCNs of older adults.[14] More recently, Charles and Belinsky reported flecks of calcium in the substantia propria between the conjunctival epithelium and an intradermal and subepithelial melanocytic nevus.[44] We have seen one example of eyelid calcification resembling that noted in the conjunctiva by Charles and Belinsky[44] (Figure 118.3).

CHAPTER 119

Syringocystadenoma Papilliferum

Key Points

- Syringocystadenoma papilliferum (SCAP) is a benign adnexal skin tumor presenting as a proliferating lesion of apocrine, eccrine, or pluripotential appendageal cells, mostly located on the head and neck
- It is associated with nevus sebaceous of Jadassohn in 40% of cases
- Human papillomavirus (HPV) DNA and mutations in the RAS/mitogen-activated protein kinase signaling pathway have been detected in both sporadic cases and lesions arising in nevus sebaceous
- SCAP may present as a flat, flesh-colored or dark brown plaque with a smooth or raised verrucous or papillomatous surface
- Papular lesions are skin-colored to pink or reddish, and when multiple they are usually arranged in a linear configuration
- Symptoms include an enlarging mass, localized eyelid swelling, pruritus, discomfort, and bleeding
- Treatment most often is by complete surgical excision with clear margins
- The prognosis of SCAP is good following surgical excision, and recurrence is uncommon

In 1917, John Stokes described a cutaneous neoplasm on the thigh of a patient that he termed naevus syringadenomatosus papilliferus.[1] Additional early cases were added by Biberstein,[2] Reuterwall,[3] and Sachs and Lewis.[4] Since then, several hundred additional cases have been reviewed from the literature, and several large series have reviewed these cases.[5,6,7]

Syringocystadenoma papilliferum (SCAP) is a benign adnexal skin tumor presenting as a proliferating lesion of the apocrine or eccrine type of differentiation. It is located on the head and neck in 75% of cases, followed by the trunk (20%) and the extremities (5%), especially the lower limbs.[5,6,7] More than half of these tumors are present since birth,[6] although most cases present for medical attention 2 to 4 decades later.

The mean age at presentation for SCAP is 45 years with a range of 8 to 82 years.[6] In patients with a known duration of symptoms, the lesions were present for 2 to 70 years with an average of 23 years. Most lesions enlarge slowly over time, but a small number of tumors may show accelerated growth over several months. In younger patients, the lesions present as a cluster of papules or small nodules, often with a cystic component.[8]

SCAP has been associated with other benign adnexal neoplasms including tubulopapillary hidradenoma, apocrine cystadenoma, hidrocystoma, eccrine spiradenoma, apocrine adenoma, poroma folliculare, apocrine acrosyringeal keratosis, verrucous cyst, trichoepithelioma, trichilemmoma, sebaceous epithelioma, condyloma acuminatum, acanthoma, and nevus sebaceous.[9,10,11,12,13] However, most often it is associated with nevus sebaceous of Jadassohn (Chapter 96) where 40% of histologically documented cases show SCAP contiguous with a nevus sebaceous.[5,6] Cases arising from nevus sebaceous are more frequently associated with malignancy, and about 9% of SCAP is associated with basal cell carcinoma.[5,6] The well-known relationship between basal cell carcinoma and nevus sebaceus[14] suggests that the occurrence of BCC may not always be etiologically related to the SCAP but to the nevus sebaceous. However, several reports suggest that SCAP can transition to basal cell and squamous cell carcinoma.[5,15,16,17,18,19]

Syringocystadenocarcinoma papilliferum (SCACP) is a rare malignant tumor of apocrine glands that most often arises in association with SCAP.[20,21,22,23] It is typically described as a long-standing lesion, most commonly on the head and neck of middle-aged or elderly individuals.[20,24,25] Lesions usually are raised and nodular and may be associated with ulceration, secretion, or pain.[25,26] One case of SCACP of the eyelid was reported with orbital invasion, requiring orbital exenteration.[27] Verrucous carcinoma is

another tumor that has been associated with SCAP in a small number of patients.[28,29] This tumor is classified as a low-grade, extremely differentiated, squamous cell carcinoma with a propensity for localized growth and recurrence.[30]

SCAP on the eyelid is very rare. In Helwig and Hackney's series of 100 cases, only five were on the face and none involved the eyelid. Since then, fewer than 40 histopathologically documented cases on the eyelids have been reported.[9,10,11,32,33,34,35]

Etiology and Pathogenesis

Decapitation secretion of the glandular epithelium is seen in SCAP, suggesting that SCAP is of apocrine origin. However, although light microscopy suggests an apocrine origin of SCAP, immunohistochemistry and electron microscopy have yielded conflicting data, with some authors documenting eccrine characteristics in this tumor.[6,11,32,36] Several theories have been advanced to reconcile these conflicting observations and to explain the range of other neoplasms associated with SCAP. Mammino and Vidmar[6] suggested that perhaps the final answer is that SCAP develops from pluripotential *(Print pagebreak 784)* appendageal cells. An alternative theory involves the derivation of SCAP from a hybrid-type gland described as an apoeccrine gland.[37,38] This type of gland exhibits microscopic, immunohistochemical, and ultrastructural features that combine both eccrine and apocrine elements, including decapitation secretion.

Although the pathogenesis of SCAP remains unclear, in both sporadic cases and lesions arising in nevus sebaceous, the human papillomavirus (HPV) DNA and mutations in the RAS/mitogen-activated protein kinase signaling pathway have been detected. *BRAF V600E* and *HRAS* mutations are the most common molecular alterations found in sporadic SCAP. The detection rate of *HRAS* mutation has been reported in 10%-26.1% of SCAP lesions,[39,40,41] and the frequency of *BRAF* mutations reported in 40%-66.7% of cases.[39,41,42] These suggest an etiologic role in the pathogenesis of SCAP.

Human papillomavirus DNA has been reported in a small number of SCAP cases.[43,44] While features such as wart-like acanthosis and papillomatosis may be suggestive of HPV infection, clear-cut HPV-related cytomorphology has not been recognized.[39]

Clinical Presentation

SCAP has no clinically specific features so that a biopsy is usually required for diagnosis. Two different primary lesions have been described: a solitary plaque or a cluster of small papules. Plaques are usually flesh colored or dark brown and 4 cm or less in diameter. They may be flat and smooth or raised with a verrucous or papillomatous surface[5,7,8,35,45] and may be devoid of hair.[46] Papular lesions are skin colored to pink or reddish, and when multiple they are usually arranged in a linear configuration.[47,48] Some lesions have a central umbilicated depression,[8,15] which can ooze fluid. Larger lesions demonstrate a hyperkeratotic or verrucous surface, may be cystic, and tend to crust, ooze, and bleed (Figures 119.1 and 119.2). Although most lesions are painless, they may be pruritic.[6]

FIGURE 119.1 Syringocystadenoma papilliferum of the upper eyelid with trichiasis and madarosis. (Courtesy of Dr. Philip Custer.)

FIGURE 119.2 SCAP of the medial left lower eyelid with a rugose surface surrounding the punctum.

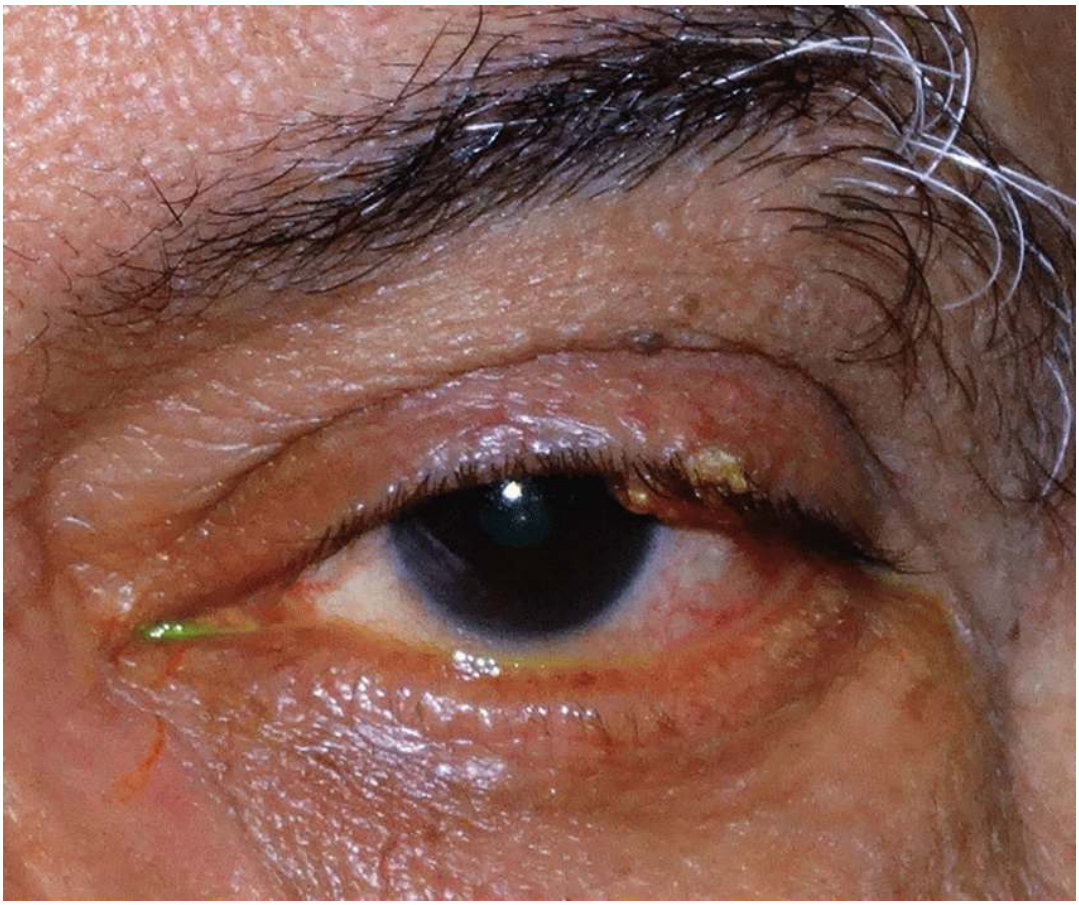

FIGURE 119.3 An elevated, yellow/tan multilobulated SCAP on the left lateral upper eyelid margin. (Courtesy of Dr. Anne Barmettler.)

Tseng et al[31] identified 26 patients with SCAP of the eyelid in the literature published between 1981 and 2015 and summarized their clinical features.[8,9,10,32,33,34,35,45,49,50] Of these 26 patients, the mean age at presentation was 43.9 years, with a range from 8 to 82. Females were affected in 62% of the cases. The duration of these lesions before presentation was between 2 months and 70 years with a mean of 24.3 years. Symptoms included an enlarging mass, localized eyelid swelling, pruritus, discomfort, and bleeding. Most cases presented as fleshy, verrucous, ulcerated, crusted, nodular, papular, or cystic lesions ranging in size between 4 and 25 mm (Figure 119.3).[31] Ten additional cases of eyelid SCAP not listed in that review or published since then show similar demographics and characteristics.[11,15,31,51,52,53,54,55]

(Print pagebreak 785)

Differential Diagnosis

The differential diagnosis of SCAP includes other benign tumors including those with exophytic pedunculated structure and eroded surfaces. These include numerous benign lesions such as poroma, eccrine adenoma, sebaceous cyst, hidrocystoma, chalazion, verruca vulgaris, and tuberculous verruca cutis. Because of the central ulcerated crater that is often seen, the differential also includes cutaneous malignancies such as basal cell carcinoma and squamous cell carcinoma.

Treatment

The number of cases of SCAP of the eyelid is too small to establish definitive treatment recommendations. However, the recommended treatment most often is by complete surgical excision with clear margins. Incomplete excision can lead to local recurrence.[8,51] Malignant tumors can be associated with SCAP, and although SCAP transition to syringocystadenocarcinoma is exceedingly rare, it has been reported.[56] Because of the possibility of malignant association or transformation, most authors have recommended conservative surgical excision with close follow-up as the treatment of choice.[5,8,53]

In cases of SCACP, surgical resection with wide margins is recommended. Chemoradiotherapy with chemotherapy and

radiotherapy has been proposed as an alternative option.[57] In the rare event of eyelid SCACP with orbital invasion, orbital exenteration may be required.[27]

Prognosis

The prognosis of SCAP is good following surgical excision, and recurrence is uncommon. Even in cases of malignant transformation, in 20 cases reviewed from the literature only 1 showed local recurrence, 2 had progression to regional lymph nodes, and 2 developed distant metastasis.[31]

Histopathology

Helwig and Hackney reviewed 100 examples of SCAP in 1955; they opined that the distinguishing feature was “the presence of duct-like structures containing papillary processes covered by two layers of epithelial cells” (Figures 119.4 and 119.5).[5] Small flattened or cuboidal cells with scanty cytoplasm and “relatively large” round or oval nuclei formed the papillae's outer or basal cell layer.[5] The inner layer was columnar cells with oval nuclei and eosinophilic cytoplasm that was more abundant toward the luminal surface than at the base and scant lateral to the nuclei.[5] Helwig and Hackney did not see decapitation secretion in any of the 100 lesions.[5] Papillae varied in shape and size. Small papillae were formed only of epithelial cells projecting into the lumen with an occasional bridging pattern.[5] Larger papillae had a central core of connective tissue, often with a dense infiltrate of plasma cells.[5] The large ducts were usually lined by stratified squamous epithelium near the epidermal surface, transitioning to a *(Print pagebreak 786)* double-layered epithelium in the deeper aspect of the ducts.[5] Squamous-lined ducts occasionally formed cysts containing keratin.[5] The lesion's surface varied. Some SCAPs had a shallow cup-like depression composed of small papillae lined by double-layered epithelium.[5] Other SCAPs had large irregular papillary projections covered with acanthotic stratified squamous epithelium, usually with hyperkeratosis.[5] Ducts “of various sizes and contours” extended from the lesion's surface to connect with the underlying dilated ducts.[5] SCAPs varied considerably in thickness based mainly on the degree of exophytic growth.[5] Hair follicles and sebaceous glands were absent or sparse in SCAPs occurring in the absence of nevus sebaceous.[5] Eccrine sweat glands were usually present beneath the lesion.[5] Eccrine glands were sometimes dilated and occasionally cystic, with pale eosinophilic material in their lumina.[5] This histopathological description of SCAPs by Helwig and Hackney has remained chiefly unchanged,[58,59] but decapitation secretion by the inner columnar lining cells of papillae is now considered a common feature.[59]

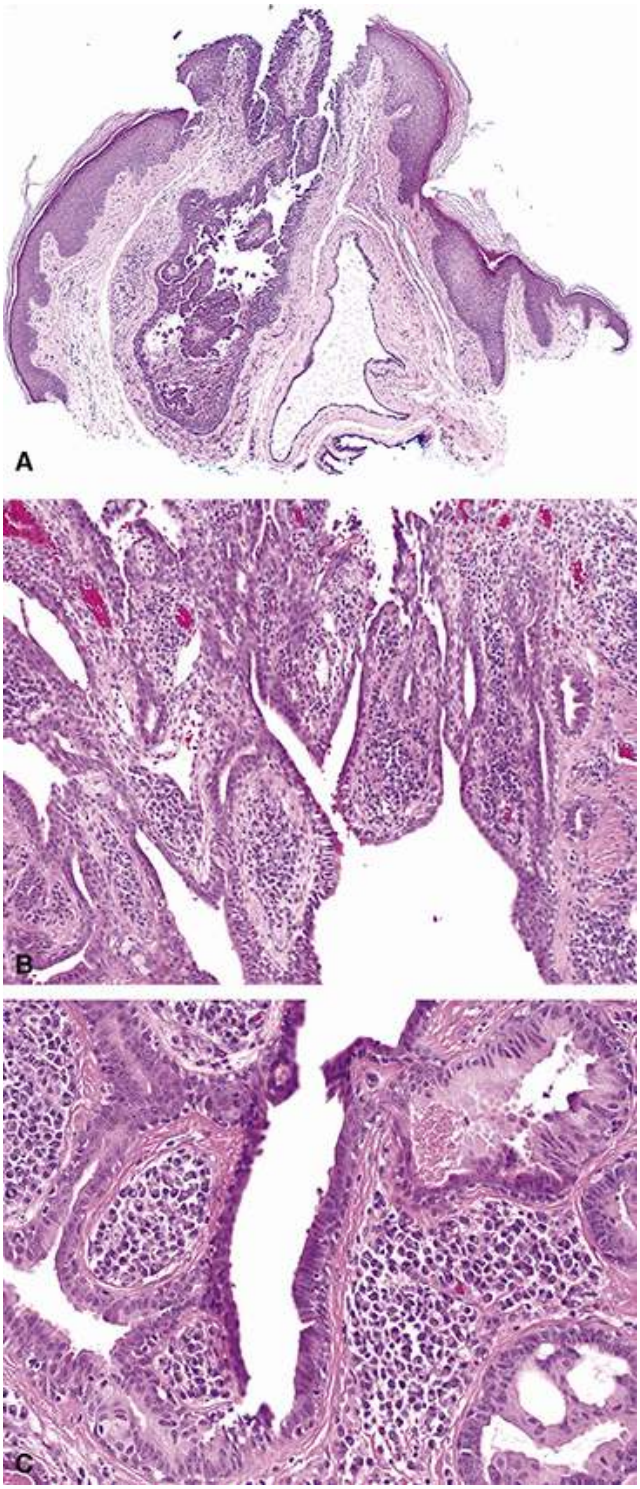

FIGURE 119.4 A, This SCAP of the neck has large irregular papillary projections covered with acanthotic stratified squamous epithelium with hyperkeratosis. A duct extends from the lesion's surface to an underlying dilated duct containing papillae. A cystically dilated eccrine duct resembling a hidrocystoma is in the dermis to the right of the SCAP. B, Numerous papillae having plasma cell-rich connective tissue cores are within the dilated duct. C, Two layers of epithelium line the papillae. The outer layer of cells is cuboidal, while the inner layer is columnar. The papillae have a dense infiltrate of plasma cells in their connective tissue cores.

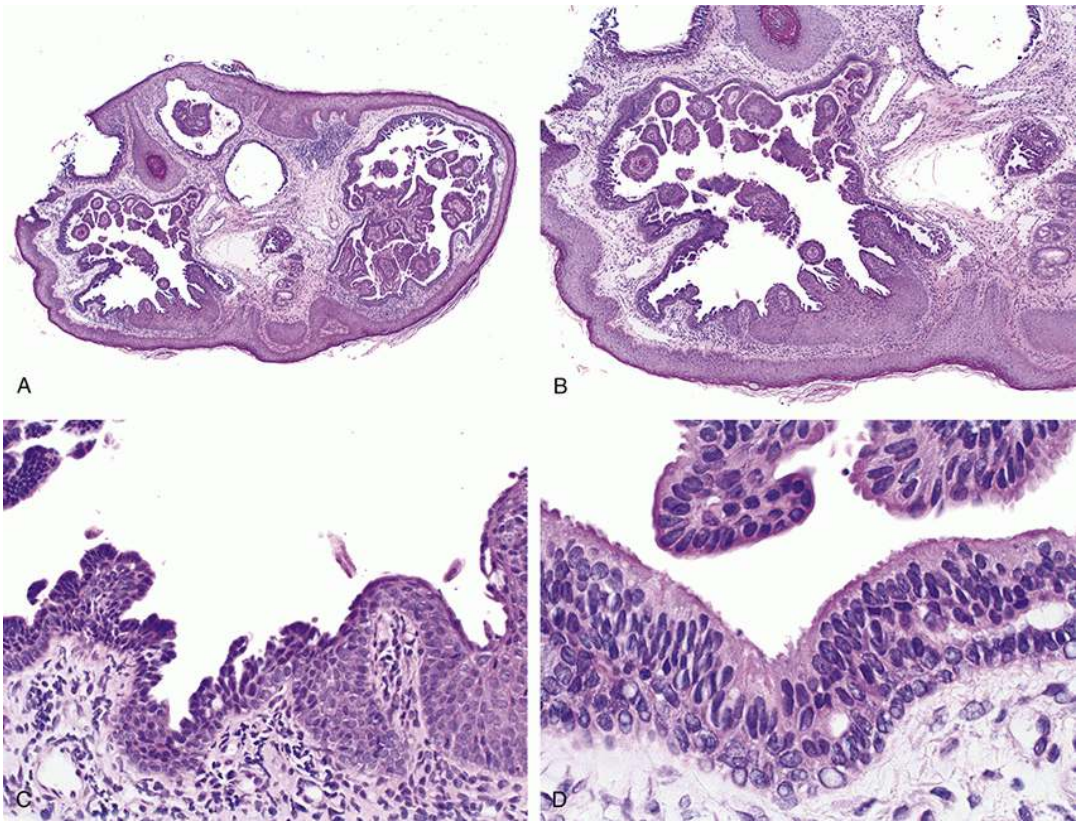

FIGURE 119.5 This SCAP from the right upper eyelid of a woman in her early 30s was present since childhood. The recent onset of irritation and bleeding prompted its removal. A, Sectioning parallel to the epidermis has resulted in epidermis surrounding the SCAP. A dilated duct connects focally to the epidermis at the top left of the photomicrograph. The dermis contains dilated ducts with many papillae. B, Dilated ducts with papillae are easily seen at higher magnification. Stratified squamous epithelium transitions to a two-layered epithelium in the dilated duct at the bottom left. C, Close-up of the transition zone between stratified squamous epithelium and the two-layered epithelium characteristic of SCAP. The fibrovascular cores of papillae are laden with plasma cells. D, The inner columnar epithelial layer of epithelium had areas of decapitation secretion typical of apocrine differentiation.

The histopathological differential diagnosis of eyelid SCAPs includes hidradenoma papilliferum,[60] apocrine cystadenomas,[61] apocrine tubular adenomas,[62,63] and SCACP.[23] Hidradenoma papilliferum has papillae with thinner connective tissue shafts and a lack of plasma cells, assisting their distinction from SCAP.[59] Apocrine cystadenomas resemble apocrine hidrocystomas but have a proliferation of the cyst lining with the formation of papillae, pseudopapillae, and cribriform areas of lining cells.[61] Apocrine cystadenomas lack the two-layer papillary epithelial lining and connection with the epidermal surface characteristic of SCAP. Tubular apocrine adenomas may be impossible to differentiate from SCAP due to overlapping histological *(Print pagebreak 787)* features.[64] SCACP differs from SCAP by having poorly delimited lateral and deep margins, cellular atypia, nuclear pleomorphism, mitotic figures, and often necrosis of isolated cells or groups of cells.[59]

CHAPTER 120

Syringoma

Key Points

- Syringoma is a benign adnexal tumor derived from the intraepidermal eccrine duct
- It can be associated with several systemic syndromes including diabetes mellitus, Down syndrome, Brooke-Spiegler syndrome, and Nicolau-Balus syndrome
- Syringoma is classified into four clinical variants: a localized form, a familial form, a milia-like form, and a generalized form
- The pathophysiology is largely unknown but has been proposed to be a benign hyperplastic growth that arises from the intraepidermal acrosyringium portion of eccrine ducts in response to an inflammatory reaction or as a hamartoma of pluripotent stem cells
- Syringomas typically appear as 1- to 3-mm, soft to firm, skin-colored, yellowish, or translucent papules
- Treatment for cosmetic improvement can include laser ablation, electrodesiccation, cryosurgery, trichloroacetic acid, dermabrasion, and chemical peels
- Syringomas have been reported to spontaneously regress in rare cases, and improvement following treatment can range from 60% to 100%

Syringoma is a benign adnexal tumor derived from the intraepidermal eccrine duct. It may present as single or multiple papules at puberty or later in life where it affects females more frequently than males, and is seen in about 1% of the population.[1,2] Syringoma was first described by Kaposi in 1872,[3] and Darier and Jacquet later described the eruptive form as a variant.[4]

In a large series of 244 cases, Ciarloni et al[5] reported a male:female ratio of 1:3.7 and a mean age at presentation of 42 years (range 8-85). Lesions were multiple in 76% of cases, and in 29% the type was eruptive. More than half of these cases involved the face, with 36% occurring on the eyelids. Other sites included the chest (18%) and the neck (17.5%).

Several systemic syndromes have also been associated with syringoma, including diabetes mellitus, Down syndrome, Brooke-Spiegler syndrome, and Nicolau-Balus syndrome. Diabetes mellitus is associated with a clear cell variant of syringoma, consisting of nests of clear cells containing glycogen.[6,7] It is thought that elevated glucose accumulates in the skin and within the clear cells.[8] In Down syndrome, the incidence of syringomas has been reported in up to 40% of individuals and can be associated with calcinosis cutis.[9,10,11] Brooke-Spiegler syndrome is a rare autosomal dominant syndrome with cutaneous manifestations that include syringomas and trichoepitheliomas.[12] Nicolau-Balus is a rare autosomal dominant disorder consisting of atrophoderma vermiculata and syringomas.[13]

In 1987, Friedman and Butler[14] proposed a classification of syringoma consisting of four clinical variants: a localized form, a familial form, a generalized form that involved multiple eruptive syringoma lesions, and a milia-like form. Localized syringomas typically occur as isolated or multiple lesions on localized regions of the body and have been reported on the foot, penis, vulva, scalp, face, and eyelids. They usually present as small, firm dermal papules that are flesh colored to red, tan, or brown.

Syringomas can have a rare familial occurrence,[15] and a positive family history was reported in 11.5% of 61 patients with syringoma in one study.[16] Familial syringomas may be inherited as an autosomal dominant trait or result from either germline or somatic mutations.[17,18,19] The most commonly involved site for familial syringomas is the face, particularly the eyelids, followed by the trunk, and less frequently the neck.[2,20] An eruptive or generalized presentation is very rare and is most prominent on the trunk.[2,21] Milia-like syringoma is a rare variant with a white center similar to milia. Most patients with this variant are Asian with a single lesion.[22]

The incidence of syringoma in patients with Down syndrome has been reported to be 30 times greater than that in the general population,[23] with a prevalence reported to be approximately 18% to 40%.[24] While these usually are located in the periorbital region,[24] widespread eruptive syringomas associated with Down syndrome are common and have also been reported.[25,26] Milia-like syringomas associated with Down syndrome have a higher rate of calcification, which may progress to calcinosis cutis.[9,10,11,27,28,29,30] Eruptive syringoma is a rare variant, typically occurring in a generalized form.[2,18,31] They usually present at puberty or during childhood in successive crops on the chest, abdomen, neck, arms, eyelids, and upper cheeks. It has been suggested that cases of eruptive syringoma may represent a hyperplastic response to an inflammatory reaction rather than a true adnexal neoplasm.[32]

The plaque type of syringoma was first described in 1979 by Kikuchi et al[33] as another rare distinct variant that is more commonly associated with symptoms, such as pruritus. Cases have been reported on the face, neck, trunk, penis, and acral areas.[33,34,35,36,37,38] Plaque-type syringomas are more frequently misdiagnosed as malignant lesions such as morpheaform basal cell carcinoma and microcystic adnexal carcinoma from which they can be differentiated on histopathology.[34,35,38]

(Print pagebreak 790)

Etiology and Pathogenesis

The pathophysiology of syringomas is largely unknown, but several hypotheses have been proposed for the pathogenesis of the various types.[18,21,31] One is that syringomas are benign hyperplastic growths that arise from the intraepidermal acrosyringium portion of eccrine ducts in response to an inflammatory reaction.[39,40] Another is that syringomas represent a hamartoma of pluripotent stem cells that precede the pathological process in eruptive syringomas.[32,41] An alternate hypothesis suggests that phosphorylase deficiency, resulting from hyperglycemia seen in diabetes, leads to an accumulation of glycogen in the skin and within the clear cells of syringomas.[42] Additionally, syringomas may be under hormonal influence. Some vulvar syringomas exhibit estrogen and progesterone receptors demonstrated by immunohistochemical staining.[43,44] One report showed that syringomas of the vulva exacerbated during pregnancies with regression in the periods between pregnancies.[45]

Immunohistochemistry of syringomas demonstrates the presence of eccrine straight duct CK6 and CK10, supporting previous suggestions that syringomas are tumors of the eccrine origin arising from the dermal and lower intraepidermal duct.[46] An electron microscopy study demonstrated ductal cells with numerous short microvilli, desmosomes, luminal tonofilaments, and lysosomes.[42] The histogenesis of syringomas is most likely related to eccrine ductal elements or pluripotential stem cells.

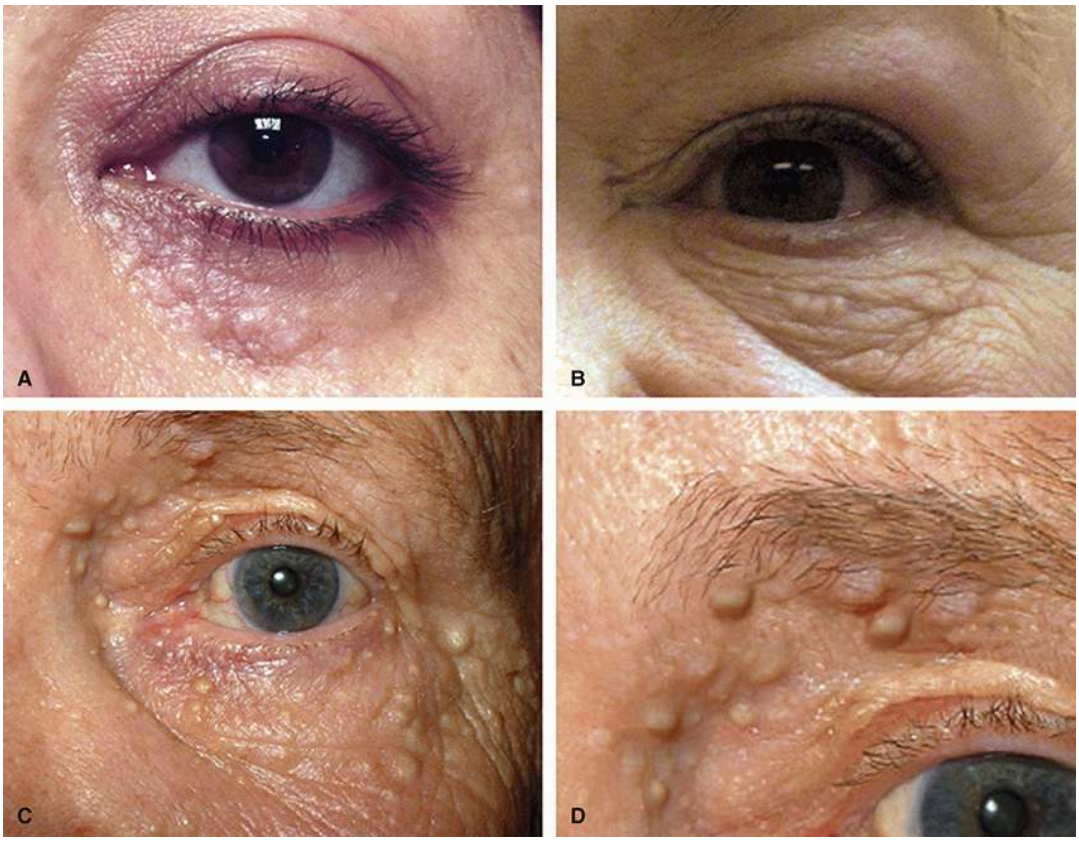

FIGURE 120.1 Syringomas of the eyelids as soft, skin-colored papules. A, (Courtesy of Dr. Robert Goldberg.)

Clinical Presentation

Syringomas typically appear as soft to firm, skin-colored, yellowish, or translucent papules 1 to 3 mm in diameter (Figure 120.1).[2,18,21,31,47] The age distribution shows a peak in the third and fifth decades.[16] Lesions most often present in the periorbital area, although they can also be found on the face, in the armpits, and on the abdomen, chest, extremities, and genitalia. Lesions usually are multiple and symmetrical in distribution, but occasionally they appear as unilateral, linear, nevoid lesions.[16,48] Syringoma usually is asymptomatic, but in rare cases, they are associated with pruritus.[49]

Eruptive syringomas may present as an asymptomatic diffuse papular rash with flesh-colored lesions 1 to 5 mm in diameter. Occasionally they may be hyperpigmented. Plaque syringomas *(Print pagebreak 791)* are usually asymptomatic, bilateral, symmetric, ill-defined flesh-colored papules that gradually enlarge and coalesce. They may be large,[50] up to 1 to 2 cm in diameter with peripheral smaller 1- to 2-mm papules. Milia-like syringomas are globoid papules, whitish to slightly erythematous in color, with small calcium deposits that may progress to calcinosis cutis.

Differential Diagnosis

Clinically, syringomas on the face can be confused with milia, trichoepithelioma, xanthelasmas, and basal cell carcinoma. Eruptive syringomas can be confused with other papular dermatoses that appear during childhood. These include common warts, acne vulgaris, lichen planus, disseminated granuloma annulare, papular sarcoidosis, sebaceous hyperplasia, eruptive xanthoma, urticaria pigmentosa, Darier disease, pseudoxanthoma elasticum, verruca plana, bowenoid papulosis, keratosis pilaris, sarcoidosis, sebaceous hyperplasia, and hidrocystoma.[51,52] Plaque-type lesions may be mistaken for microcystic adnexal carcinoma.[35,53]

Treatment

Treatment for syringoma is offered primarily for the improvement of cosmetic appearance. However, because syringomas are embedded within the dermis, complete removal is often not possible and recurrence is common.[54] Destructive options include laser ablation, electrodesiccation, cryosurgery, trichloroacetic acid, dermabrasion, and chemical peels.[2,55,56,57,58] In dark-skinned individuals, success has been reported with a combination of trichloroacetic acid and CO_2 laser ablation,[59] but laser therapy and cryosurgery may cause pigmentary changes.[15,60,61] Medical therapies have included topical retinoids with variable results.[62,63] Oral tranilast, which inhibits the release of histamine and prostaglandins from mast cells, was successfully used in one patient.[64,65] Topical atropine has been used to relieve pruritus.[54] Application of topical adelmidrol, a semisynthetic cannabinoid that may act via downregulation of mast cell activation, was beneficial in a case of giant vulvar syringoma.[66]

Prognosis

Syringomas have been reported to spontaneously regress in rare cases,[45] but in most cases, they remain stable.[1] Improvement following treatment can range from 60% to 100%, but recurrences are common.

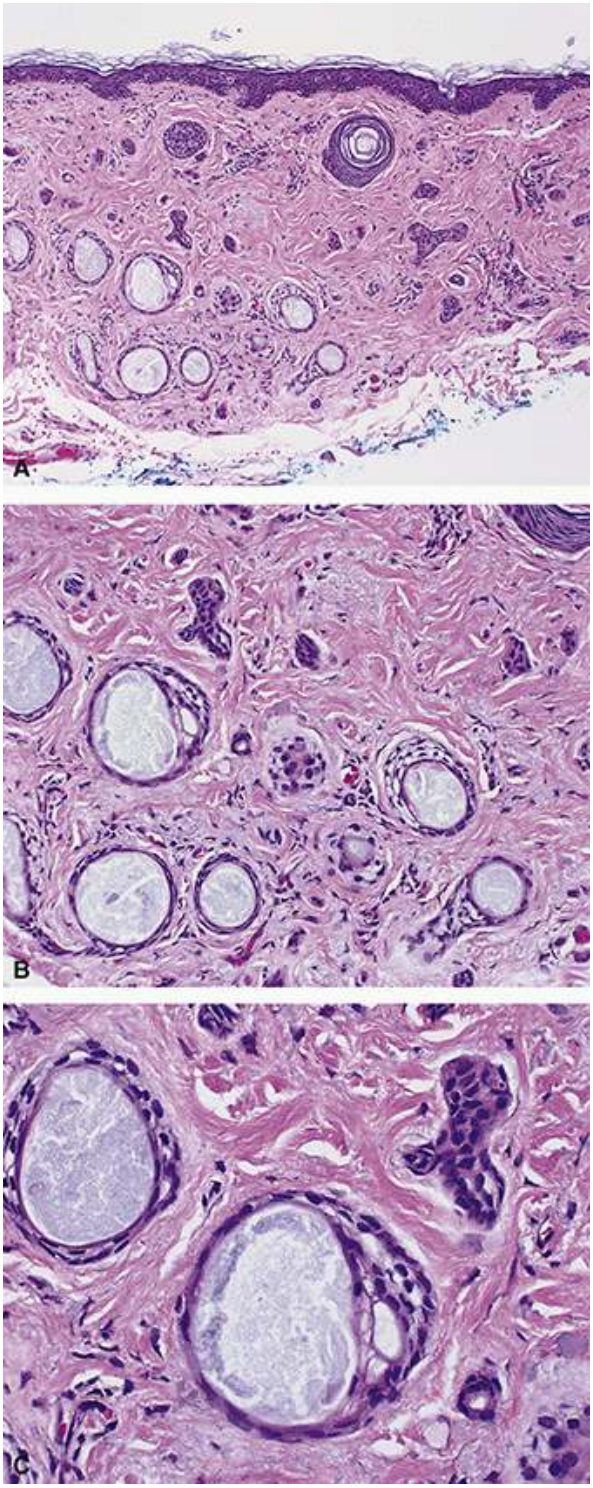

FIGURE 120.2 This conventional syringoma was one of many involving all four eyelids in a woman in her middle 50s. A, The syringoma is well circumscribed and in the mid and upper dermis without connecting to the overlying epidermis. B, The tumor is composed of small nests and ducts (tubules) embedded in a collagenous eosinophilic stroma. An epithelial strand at the end of the ductule at the bottom right creates a tadpole appearance. C, Two layers of flattened to low cuboidal cells form the ducts. The ductal lumens contain homogeneous material. Tumor cells are cytologically bland with small nuclei and eosinophilic cytoplasm.

Histopathology

The typical (conventional) syringoma (Figure 120.2) is symmetrical,[1,67] relatively well circumscribed,[1,67,68] and in the mid[67] or upper[1,68,69] dermis without connecting to the overlying epidermis.[69] Small nests, cords, and ducts (tubules)[1,67,69] *(Print pagebreak 792)* embedded in a collagenous eosinophilic stroma[67] that may appear sclerotic[21,68,70] comprise the tumor. Ducts are usually formed of two layers of flattened to cuboidal cells, and an epithelial strand at the end of a ductule may create a tadpole or

comma-like appearance.[5,40,67,68] Ductal lumens often contain homogeneous material that stains positively using periodic acid-Schiff stain and resists diastase digestion.[67] Ductal structures may predominate in some syringomas.[67,70] Tumor cells are cytologically bland with small nuclei and eosinophilic cytoplasm.[69] Mitotic figures are absent.[68] Inflammation is present in about 10% of tumors, and the overlying epidermis is acanthotic with basal layer pigmentation in about 70% of cases.[5] Mast cells may be numerous in the stroma.[67,68] Sweat glands adjacent to the tumor may be normal, abnormal, or absent.[71]

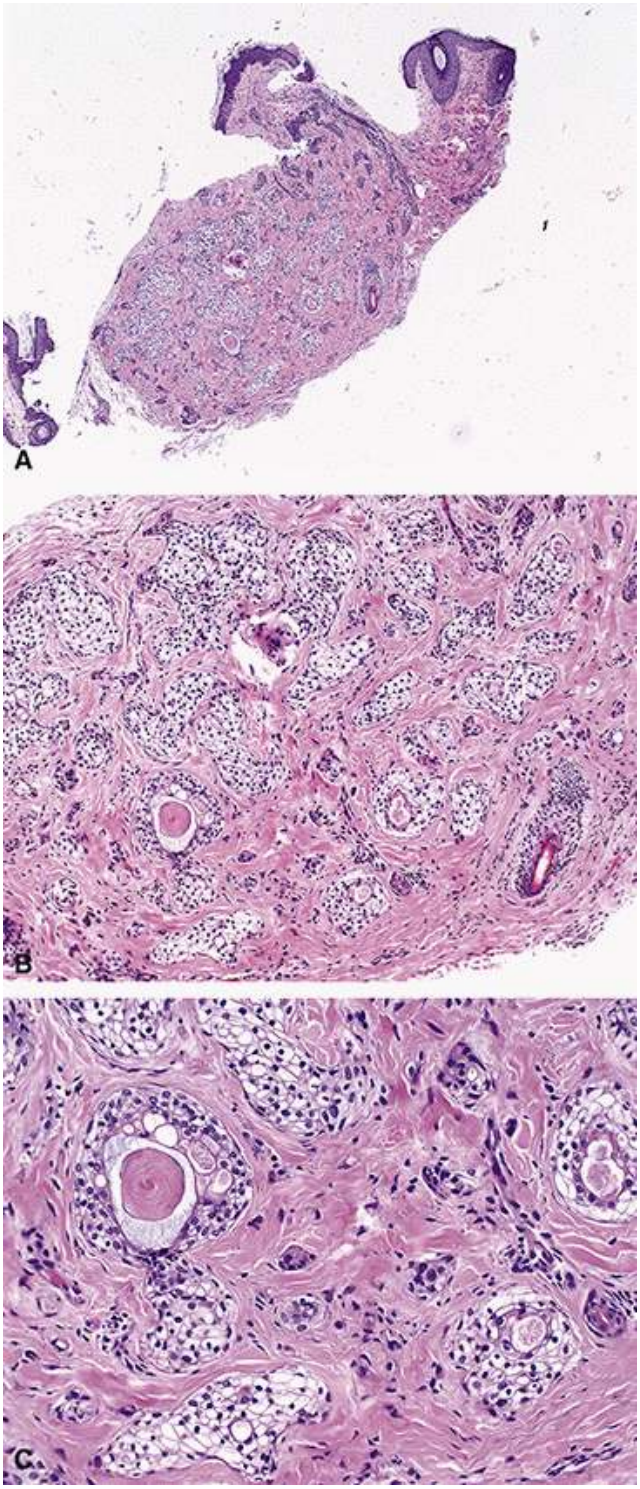

FIGURE 120.3 This clear-cell syringoma was from the right lower eyelid of a woman in her early 50s with well-controlled diabetes mellitus. She had multiple tumors of both lower eyelids. A, The syringoma is well circumscribed and mainly in the mid-dermis. The epidermis and superficial dermis near the center of the biopsy are artifactually disrupted. The tumor is difficult to see at low magnification due to the clear cytoplasm in the tumor cells. B, The tumor is composed mostly of small nests and cords with a few ducts (tubules) embedded in a collagenous eosinophilic stroma. C, Almost all of the cells have clear cytoplasm due to glycogen accumulation. Eosinophilic material is in duct lumens.

Clear cell syringomas (Figure 120.3) are composed predominantly of cells with clear cytoplasm[5,21,40,72,73] due to glycogen

accumulation[73] secondary to reduced cellular phosphorylase activity.[72] Clear cell syringomas otherwise have the same histological appearance as conventional syringomas.[40,67,72] Clear cell syringomas were 8.5% of the 244 lesions in the study by Ciarloni and colleagues, and about one-fifth of the lesions were on the eyelids.[5]

Features that help distinguish a syringoma from a microcystic adnexal carcinoma include good circumscription, confinement to the upper and mid dermis, lack of deep extension into the dermis and underlying tissues, and lack of perineural invasion.[69] In a superficial biopsy, it may not be possible to differentiate these two neoplasms.[68]

CHAPTER 121

Trachoma

Key Points

- Trachoma is a chlamydial infection characterized by recurrent episodes of conjunctival inflammation with lymphoid follicles and, in some cases, severe papillary hypertrophy
- Chlamydial antigens are believed to induce cell-mediated immune and delayed hypersensitivity responses with the production of proinflammatory cytokines and cellular infiltration forming lymphoid follicles
- Active disease is more commonly found in children and is characterized by a chronic, recurrent follicular conjunctivitis, most prominently seen on the upper tarsal conjunctiva
- The late-stage scarring sequelae develop in later life promoted by the inflammatory process but can be seen earlier in cases of more severe disease
- Scarring can be relatively mild with only a few linear or stellate scars or severe with thick fibrotic bands, shortening of the fornix, and symblepharon formation. Contraction of the conjunctiva results in cicatricial entropion
- Antibiotic therapy, mostly tetracycline eye ointment, has been used to reduce the burden of trachoma infection
- For late-stage disease, surgical correction of trichiasis and entropion are needed to prevent corneal scarring and blindness
- Surgery for trachomatous eyelid trichiasis and entropion is associated with a significant recurrence rate and adverse outcomes from surgery include can be seen in 5% to 30% of cases

Trachoma is the third most common cause of blindness worldwide, after cataracts and glaucoma.[1] It is estimated that about 1.2 billion people live in trachoma-endemic areas in 51 countries.[2] More than 40 million people have active trachoma, 8.2 million have trachomatous trichiasis,[2] and 5.6 million are already blind from trachoma.[3] Endemic regions for trachoma involve large parts of Africa, some regions of the Middle East, the Indian subcontinent, Southeast Asia, and South America.[4] In some regions, such as Ethiopia, trachomatous inflammation may be seen in more than 30% of children.[5]

Trachoma is caused by the obligate intracellular bacterium *Chlamydia trachomatis*. Chlamydial infection usually starts in childhood,[6] characterized by recurrent episodes of conjunctival inflammation with lymphoid follicles and, in some cases, severe papillary hypertrophy.[7] Conjunctival scarring gradually develops from the repeated tissue damage.[7,8] With more severe conjunctival scarring the eyelashes become distorted and trichiatic, where they come into contact with the cornea.[8] If left untreated, loss of vision can result from corneal scarring and opacification.[9] The prevalence of active disease peaks in preschool children and declines in adulthood.[10,11,12,13,14] The prevalence of late-stage trachomatous conjunctival scarring, on the other hand, increases with age as a result of cumulative damage.[10,13] Male and female children with active trachoma are generally affected equally, but the late blinding sequelae are usually seen more frequently in females.[10,13] It has been suggested that close exposure to children in endemic countries is a risk factor for women contracting the active disease.[15]

Chlamydia is probably transmitted from an infected individual to an uninfected one. This likely occurs through direct spread from eye to eye during close contact, spread on fingers, indirect spread on fomites, and transmission by flies.[16]

Etiology and Pathogenesis

C. trachomatis is an obligate intracellular bacterium with 19 different serovars. Endemic trachoma is caused by serovars A-C,[17] whereas genital chlamydial infection is associated with serovars D-K. During its developmental cycle, *C. trachomatis* exists as reticulate bodies that are metabolically active in the intracellular stage and as elementary bodies that are the metabolically inactive extracellular form of the organism that can transfer between host cells and organisms.[18] The infectious cycle begins with the

attachment of the elementary bodies to the surface of epithelial cells, followed by endocytosis of the bacteria. Inside the host cell, within 6 to 9 hours, the elementary bodies transform into the reticulate form and replicate by binary fission.[18] Chlamydial antigens are believed to induce cell-mediated immune and delayed hypersensitivity responses with the production of proinflammatory cytokines and cellular infiltration forming lymphoid follicles. Some immune cell infiltrates have shown a phenotype suggestive of NK cells.[19] Chronic conjunctival inflammation associated with enriched expression of proinflammatory factors and altered expression of extracellular matrix regulators appear to be important factors in the development of conjunctival scarring.[20] Some reticulate bodies transform back into elementary bodies that become extracellular and can transmit the infection to another host.

(Print pagebreak 796)

Individual and environmental risk factors that may facilitate the introduction and transmission of *C. trachomatis* into vulnerable communities probably include migration of infected individuals who transmit new strains of the bacterium into areas with crowded living conditions.[21,22] Children with active disease in areas where water is scarce, and face washing less common, often have ocular and nasal secretions that can be a source of bacterial spread.[23] Flies that feed on ocular secretions can also act as vectors for disease transmission.[24]

Clinical Characteristics

Clinically, trachoma is subdivided into early active and late-stage cicatricial disease. Active disease is more commonly found in children and is characterized by chronic, recurrent follicular conjunctivitis, most prominently seen on the upper tarsal conjunctiva. More severe cases may have papillary hypertrophy with engorgement of small vessels, surrounding edema, and inflammatory thickening of the conjunctiva.[25] Recurrent or persistent ocular infection leads to conjunctival scarring (Figure 121.1A). During the active phase the superior corneal limbus develops follicles composed of lymphocytes surrounding a reticuloendothelial cell germinal center. When these follicles heal and regress, they result in round, thinned depressions, referred to as Herbert pits, which are a characteristic and pathognomonic finding of trachoma (Figure 121.2).

The late-stage scarring sequelae develop in later life promoted by the inflammatory process but can be seen earlier in cases of more severe disease. Scarring can be relatively mild with only a few linear or stellate scars (Figure 121.1B) or severe with thick fibrotic bands, shortening of the fornix, and symblepharon formation. Contraction of the conjunctiva results in cicatricial entropion that rotates the eyelid margin toward the globe (Figure 121.3). Distortion of the eyelash follicles manifests as secondary trichiasis (Figure 121.4).

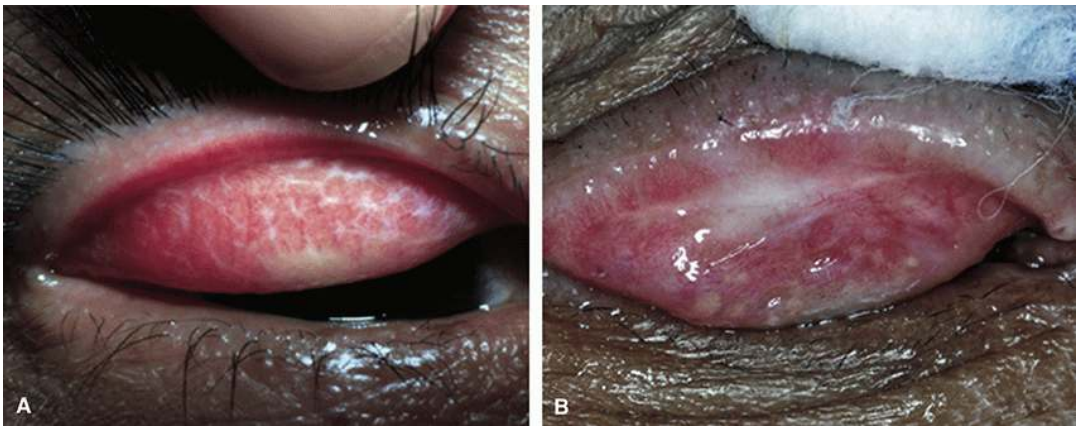

FIGURE 121.1 A, Conjunctival scarring from repeated or persistent ocular infection with *Chlamydia trachomatis*. B, Late-stage trachomatous scarring with linear von Arlt line on the superior tarsal conjunctiva and follicular conjunctivitis. A and B, (Courtesy of Dr. Antonio Augusto Cruz.)

FIGURE 121.2 Herbert pits within a pannus along the superior corneal limbus. (Courtesy of Dr. Antonio Augusto Cruz.)

In individuals infected with trachoma, progression to conjunctival scarring develops in 23% to 30% over 2 years, and there is a strong relationship between progressive scarring and an increasing number of episodes of clinical inflammation.[6] Studies have reported progression of conjunctival scarring in 47% of patients followed for 5 years[26] and 68.5% followed for 14 years.[27] The development of trachomatous trichiasis varies with the presence and degree of conjunctival scarring from less than 10% in patients followed up to 12 years[28,29] to more than 38% in cases of severe scarring over 14 years.[27]

The most severe complication of trichiasis and entropion is corneal abrasion and opacification (Figure 121.5). It *(Print pagebreak 797)* has been reported to develop in 5% to 10% of cases over 2 to 10 years,[29,30,31] but as high as 34% in cases with severe trichiasis.[32]

FIGURE 121.5 Corneal opacification from trachomatous entropion and trichiasis.

Differential Diagnosis

Several conditions can produce chronic follicular conjunctivitis with a similar appearance to active trachoma. These include conjunctivitis caused by viruses and bacteria, adult inclusion conjunctivitis, and infection with genital strains of *C. trachomatis*.[25] Cicatricial entropion and trichiasis can be seen with mucous membrane pemphigoid, Stevens-Johnson syndrome, systemic sclerosis, involutional changes, chemical injuries, and drugs. Epiblepharon and distichiasis are characterized by eyelash-to-ocular contact, with possible corneal abrasion and opacification.

(Print pagebreak 798)

Treatment

Topical and systemic antibiotic therapy has been used to reduce the burden of trachoma infection, and several different antibiotics have antichlamydial activity. The most commonly used are tetracycline eye ointment applied twice a day for 6 weeks or a single oral dose of azithromycin (20 mg/kg up to a maximum dose of 1 g).[12,21,33,34,35,36,37,38] However, azithromycin is not used in infants under the age of 6 months. Since this group can be a significant reservoir of infection, it is

recommended that infants under 6 months be treated with a 6-week course of topical tetracycline.

There are about 8 million people with trachomatous trichiasis worldwide who are at risk of developing blinding corneal opacification. Surgical correction of trichiasis can usually reduce the risk of this complication. Various surgical procedures are in use, from epilation of individual trichiatic lashes to more extensive tarsal rotation procedures (see Chapter 42).[39] In countries where ophthalmologists are in short supply, trained ancillary personnel can perform simple procedures such as epilation to reduce the risk of corneal damage.[40,41] However, even with surgery, recurrence of trichiasis can be as high as 40% to 60%.[42]

Various factors may contribute to the choice of a procedure to treat trichiasis. These include preoperative disease severity, surgical technique, and current infection. Perioperative antibiotics may reduce the risk of recurrence.[43,44] Despite the high recurrence rate, there can be some improvement in vision following surgery.[39,43]

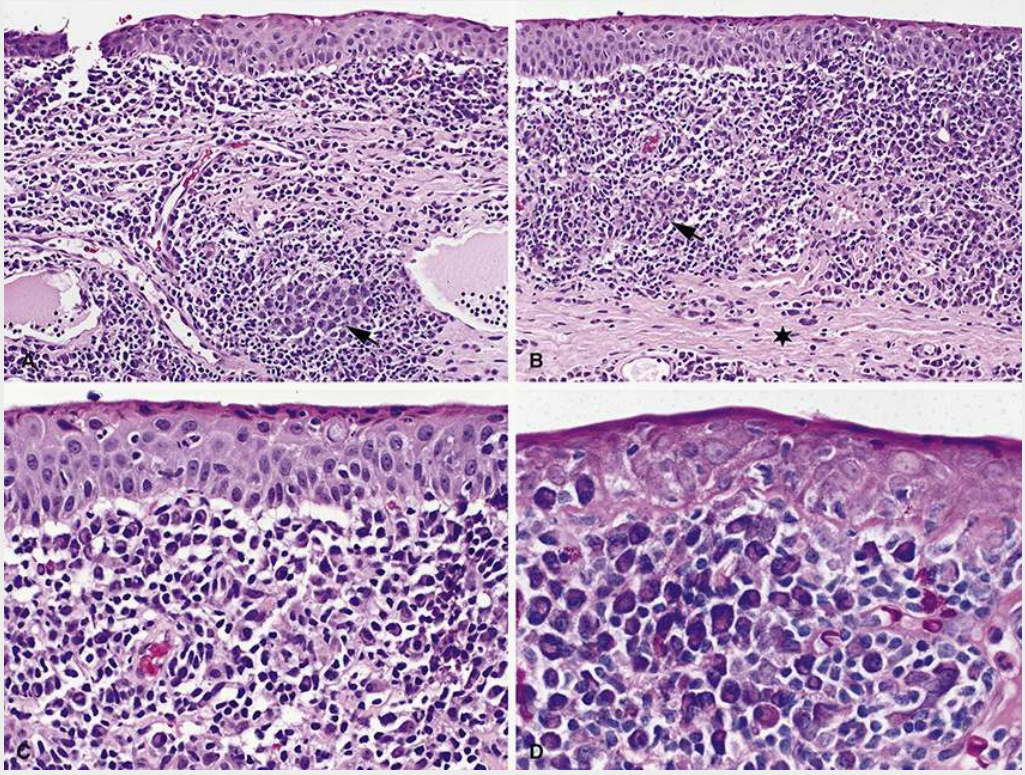

FIGURE 121.6 This biopsy was from the right inferior fornix of a young woman with bilateral chronic follicular conjunctivitis, confirmed as *Chlamydia trachomatis* infection using the cobas CT/NG v2.0 Test (Roche Diagnostics). A, A band of chronic (mononuclear) inflammatory cells is beneath the epithelium, and a follicle is present in the deeper substantia propria (*arrow*). The follicle center cells are large, pale, activated B lymphocytes with admixed macrophages and some T cells.[54] B, In this biopsy area, there is a band of dense subepithelial mononuclear inflammation with a vague follicle (*arrow*). A band of fibrosis is beneath the inflammation (★). C, The epithelium is superficially keratinized, and there is a marked reduction in the number of goblet cells customarily found at this location.[56] The inflammatory infiltrate contains numerous plasma cells along with lymphocytes and macrophages. D, Giemsa stain highlights the numerous plasma cells, including several in the epidermis (*arrows*). A few eosinophils are also present (*arrowheads*).

(Print pagebreak 799)

Prognosis

Surgery for trachomatous trichiasis is associated with a significant recurrence rate and may have to be repeated to prevent corneal damage.[42,45,46,47,48] Adverse outcomes from surgery include eyelid contour abnormalities and granuloma formation, which occur in 5% to 30% of cases.[40,45,47,49,50] Several clinical trials reported unfavorable surgical outcomes to be associated with surgical quality, type of procedure, and preoperative disease severity.[45,47,49] Management of unfavorable surgical outcomes is often challenging and usually requires more advanced surgical skills.

Histopathology

The histopathology of trachoma was reviewed in exquisite detail by Sir Stewart Duke-Elder.[51] The earliest changes are found in the palpebral conjunctiva near the fornix and include epithelial hyperplasia with lymphocytic infiltration, the formation of epithelial crypts with collections of neutrophils, and flattening of the superficial epithelial cells with nuclear degeneration, exfoliation, and chlamydial inclusion bodies.[51] The epithelial changes progress with the formation of papillae and pseudoglands.[51] In chronic trachoma, the epithelium becomes attenuated and ultimately develops squamous metaplasia ("epidermalization") with prickle cell and horny layers[51] and loss of goblet cells.[52]

The earliest changes in the substantia propria are capillary dilation with diffuse infiltration by lymphocytes, plasma cells, and macrophages (Figure 121.6).[51] The inflammatory infiltrate increases in intensity over time with the formation of lymphoid follicles.[51] Lymphoid follicles are characteristic of trachoma,[51,53,54,55] but they are not invariably present.[51] Macrophages predominate in fully developed follicles, and there are usually large macrophages containing phagocytosed nuclear debris (phagocytic cells of Leber).[51] "In the submucosa, the general cellular infiltration eventually contains, in addition to the preponderating lymphocytes, elements such as eosinophils and mast cells in considerable numbers especially deep in the tissues, plasma cells in enormous numbers especially under the epithelium, wandering through it and into the discharge, an occasional large macrophage, and relatively few polymorphs, usually aggregated in heaps and usually associated with secondary infection."[51] Scarring of the substantia propria progresses over time, the histological correlate of the cicatrization noted clinically.[51,52] Diagnosis of *C. trachomatis* infection can be confirmed using cultures or nucleic acid amplification techniques of ocular swabs.[9]

CHAPTER 121

Trachoma

Key Points

- Trachoma is a chlamydial infection characterized by recurrent episodes of conjunctival inflammation with lymphoid follicles and, in some cases, severe papillary hypertrophy
- Chlamydial antigens are believed to induce cell-mediated immune and delayed hypersensitivity responses with the production of proinflammatory cytokines and cellular infiltration forming lymphoid follicles
- Active disease is more commonly found in children and is characterized by a chronic, recurrent follicular conjunctivitis, most prominently seen on the upper tarsal conjunctiva
- The late-stage scarring sequelae develop in later life promoted by the inflammatory process but can be seen earlier in cases of more severe disease
- Scarring can be relatively mild with only a few linear or stellate scars or severe with thick fibrotic bands, shortening of the fornix, and symblepharon formation. Contraction of the conjunctiva results in cicatricial entropion
- Antibiotic therapy, mostly tetracycline eye ointment, has been used to reduce the burden of trachoma infection
- For late-stage disease, surgical correction of trichiasis and entropion are needed to prevent corneal scarring and blindness
- Surgery for trachomatous eyelid trichiasis and entropion is associated with a significant recurrence rate and adverse outcomes from surgery include can be seen in 5% to 30% of cases

Trachoma is the third most common cause of blindness worldwide, after cataracts and glaucoma.[1] It is estimated that about 1.2 billion people live in trachoma-endemic areas in 51 countries.[2] More than 40 million people have active trachoma, 8.2 million have trachomatous trichiasis,[2] and 5.6 million are already blind from trachoma.[3] Endemic regions for trachoma involve large parts of Africa, some regions of the Middle East, the Indian subcontinent, Southeast Asia, and South America.[4] In some regions, such as Ethiopia, trachomatous inflammation may be seen in more than 30% of children.[5]

Trachoma is caused by the obligate intracellular bacterium *Chlamydia trachomatis*. Chlamydial infection usually starts in childhood,[6] characterized by recurrent episodes of conjunctival inflammation with lymphoid follicles and, in some cases, severe papillary hypertrophy.[7] Conjunctival scarring gradually develops from the repeated tissue damage.[7,8] With more severe conjunctival scarring the eyelashes become distorted and trichiatic, where they come into contact with the cornea.[8] If left untreated, loss of vision can result from corneal scarring and opacification.[9] The prevalence of active disease peaks in preschool children and declines in adulthood.[10,11,12,13,14] The prevalence of late-stage trachomatous conjunctival scarring, on the other hand, increases with age as a result of cumulative damage.[10,13] Male and female children with active trachoma are generally affected equally, but the late blinding sequelae are usually seen more frequently in females.[10,13] It has been suggested that close exposure to children in endemic countries is a risk factor for women contracting the active disease.[15]

Chlamydia is probably transmitted from an infected individual to an uninfected one. This likely occurs through direct spread from eye to eye during close contact, spread on fingers, indirect spread on fomites, and transmission by flies.[16]

Etiology and Pathogenesis

C. trachomatis is an obligate intracellular bacterium with 19 different serovars. Endemic trachoma is caused by serovars A-C,[17] whereas genital chlamydial infection is associated with serovars D-K. During its developmental cycle, *C. trachomatis* exists as reticulate bodies that are metabolically active in the intracellular stage and as elementary bodies that are the metabolically inactive extracellular form of the organism that can transfer between host cells and organisms.[18] The infectious cycle begins with the

attachment of the elementary bodies to the surface of epithelial cells, followed by endocytosis of the bacteria. Inside the host cell, within 6 to 9 hours, the elementary bodies transform into the reticulate form and replicate by binary fission.[18] Chlamydial antigens are believed to induce cell-mediated immune and delayed hypersensitivity responses with the production of proinflammatory cytokines and cellular infiltration forming lymphoid follicles. Some immune cell infiltrates have shown a phenotype suggestive of NK cells.[19] Chronic conjunctival inflammation associated with enriched expression of proinflammatory factors and altered expression of extracellular matrix regulators appear to be important factors in the development of conjunctival scarring.[20] Some reticulate bodies transform back into elementary bodies that become extracellular and can transmit the infection to another host.

(Print pagebreak 796)

Individual and environmental risk factors that may facilitate the introduction and transmission of *C. trachomatis* into vulnerable communities probably include migration of infected individuals who transmit new strains of the bacterium into areas with crowded living conditions.[21,22] Children with active disease in areas where water is scarce, and face washing less common, often have ocular and nasal secretions that can be a source of bacterial spread.[23] Flies that feed on ocular secretions can also act as vectors for disease transmission.[24]

Clinical Characteristics

Clinically, trachoma is subdivided into early active and late-stage cicatricial disease. Active disease is more commonly found in children and is characterized by chronic, recurrent follicular conjunctivitis, most prominently seen on the upper tarsal conjunctiva. More severe cases may have papillary hypertrophy with engorgement of small vessels, surrounding edema, and inflammatory thickening of the conjunctiva.[25] Recurrent or persistent ocular infection leads to conjunctival scarring (Figure 121.1A). During the active phase the superior corneal limbus develops follicles composed of lymphocytes surrounding a reticuloendothelial cell germinal center. When these follicles heal and regress, they result in round, thinned depressions, referred to as Herbert pits, which are a characteristic and pathognomonic finding of trachoma (Figure 121.2).

The late-stage scarring sequelae develop in later life promoted by the inflammatory process but can be seen earlier in cases of more severe disease. Scarring can be relatively mild with only a few linear or stellate scars (Figure 121.1B) or severe with thick fibrotic bands, shortening of the fornix, and symblepharon formation. Contraction of the conjunctiva results in cicatricial entropion that rotates the eyelid margin toward the globe (Figure 121.3). Distortion of the eyelash follicles manifests as secondary trichiasis (Figure 121.4).

FIGURE 121.2 Herbert pits within a pannus along the superior corneal limbus. (Courtesy of Dr. Antonio Augusto Cruz.)

In individuals infected with trachoma, progression to conjunctival scarring develops in 23% to 30% over 2 years, and there is a strong relationship between progressive scarring and an increasing number of episodes of clinical inflammation.[6] Studies have reported progression of conjunctival scarring in 47% of patients followed for 5 years[26] and 68.5% followed for 14 years.[27] The development of trachomatous trichiasis varies with the presence and degree of conjunctival scarring from less than 10% in patients followed up to 12 years[28,29] to more than 38% in cases of severe scarring over 14 years.[27]

The most severe complication of trichiasis and entropion is corneal abrasion and opacification (Figure 121.5). It *(Print pagebreak 797)* has been reported to develop in 5% to 10% of cases over 2 to 10 years,[29,30,31] but as high as 34% in cases with severe trichiasis.[32]

FIGURE 121.5 Corneal opacification from trachomatous entropion and trichiasis.

Differential Diagnosis

Several conditions can produce chronic follicular conjunctivitis with a similar appearance to active trachoma. These include conjunctivitis caused by viruses and bacteria, adult inclusion conjunctivitis, and infection with genital strains of *C. trachomatis*.[25] Cicatricial entropion and trichiasis can be seen with mucous membrane pemphigoid, Stevens-Johnson syndrome, systemic sclerosis, involutional changes, chemical injuries, and drugs. Epiblepharon and distichiasis are characterized by eyelash-to-ocular contact, with possible corneal abrasion and opacification.

(Print pagebreak 798)

Treatment

Topical and systemic antibiotic therapy has been used to reduce the burden of trachoma infection, and several different antibiotics have antichlamydial activity. The most commonly used are tetracycline eye ointment applied twice a day for 6 weeks or a single oral dose of azithromycin (20 mg/kg up to a maximum dose of 1 g).[12,21,33,34,35,36,37,38] However, azithromycin is not used in infants under the age of 6 months. Since this group can be a significant reservoir of infection, it is

recommended that infants under 6 months be treated with a 6-week course of topical tetracycline.

There are about 8 million people with trachomatous trichiasis worldwide who are at risk of developing blinding corneal opacification. Surgical correction of trichiasis can usually reduce the risk of this complication. Various surgical procedures are in use, from epilation of individual trichiatic lashes to more extensive tarsal rotation procedures (see Chapter 42).[39] In countries where ophthalmologists are in short supply, trained ancillary personnel can perform simple procedures such as epilation to reduce the risk of corneal damage.[40,41] However, even with surgery, recurrence of trichiasis can be as high as 40% to 60%.[42]

Various factors may contribute to the choice of a procedure to treat trichiasis. These include preoperative disease severity, surgical technique, and current infection. Perioperative antibiotics may reduce the risk of recurrence.[43,44] Despite the high recurrence rate, there can be some improvement in vision following surgery.[39,43]

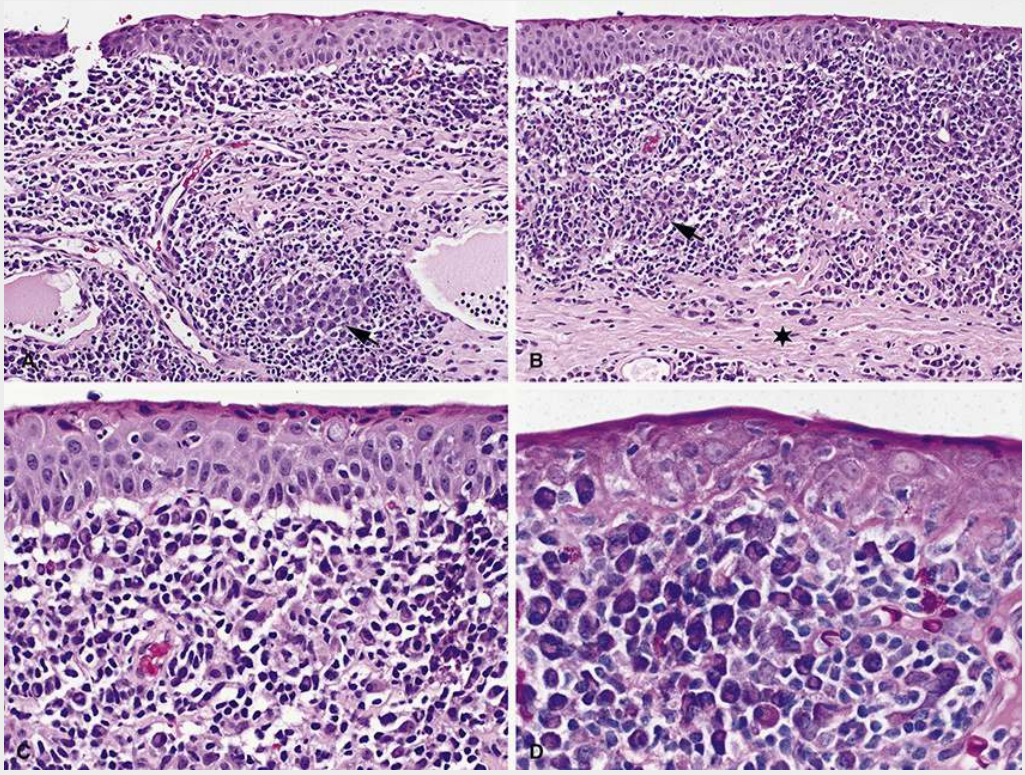

FIGURE 121.6 This biopsy was from the right inferior fornix of a young woman with bilateral chronic follicular conjunctivitis, confirmed as *Chlamydia trachomatis* infection using the cobas CT/NG v2.0 Test (Roche Diagnostics). A, A band of chronic (mononuclear) inflammatory cells is beneath the epithelium, and a follicle is present in the deeper substantia propria (*arrow*). The follicle center cells are large, pale, activated B lymphocytes with admixed macrophages and some T cells.[54] B, In this biopsy area, there is a band of dense subepithelial mononuclear inflammation with a vague follicle (*arrow*). A band of fibrosis is beneath the inflammation (★). C, The epithelium is superficially keratinized, and there is a marked reduction in the number of goblet cells customarily found at this location.[56] The inflammatory infiltrate contains numerous plasma cells along with lymphocytes and macrophages. D, Giemsa stain highlights the numerous plasma cells, including several in the epidermis (*arrows*). A few eosinophils are also present (*arrowheads*).

(Print pagebreak 799)

Prognosis

Surgery for trachomatous trichiasis is associated with a significant recurrence rate and may have to be repeated to prevent corneal damage.[42,45,46,47,48] Adverse outcomes from surgery include eyelid contour abnormalities and granuloma formation, which occur in 5% to 30% of cases.[40,45,47,49,50] Several clinical trials reported unfavorable surgical outcomes to be associated with surgical quality, type of procedure, and preoperative disease severity.[45,47,49] Management of unfavorable surgical outcomes is often challenging and usually requires more advanced surgical skills.

Histopathology

The histopathology of trachoma was reviewed in exquisite detail by Sir Stewart Duke-Elder.[51] The earliest changes are found in the palpebral conjunctiva near the fornix and include epithelial hyperplasia with lymphocytic infiltration, the formation of epithelial crypts with collections of neutrophils, and flattening of the superficial epithelial cells with nuclear degeneration, exfoliation, and chlamydial inclusion bodies.[51] The epithelial changes progress with the formation of papillae and pseudoglands.[51] In chronic trachoma, the epithelium becomes attenuated and ultimately develops squamous metaplasia ("epidermalization") with prickle cell and horny layers[51] and loss of goblet cells.[52]

The earliest changes in the substantia propria are capillary dilation with diffuse infiltration by lymphocytes, plasma cells, and macrophages (Figure 121.6).[51] The inflammatory infiltrate increases in intensity over time with the formation of lymphoid follicles.[51] Lymphoid follicles are characteristic of trachoma,[51,53,54,55] but they are not invariably present.[51] Macrophages predominate in fully developed follicles, and there are usually large macrophages containing phagocytosed nuclear debris (phagocytic cells of Leber).[51] "In the submucosa, the general cellular infiltration eventually contains, in addition to the preponderating lymphocytes, elements such as eosinophils and mast cells in considerable numbers especially deep in the tissues, plasma cells in enormous numbers especially under the epithelium, wandering through it and into the discharge, an occasional large macrophage, and relatively few polymorphs, usually aggregated in heaps and usually associated with secondary infection."[51] Scarring of the substantia propria progresses over time, the histological correlate of the cicatrization noted clinically.[51,52] Diagnosis of *C. trachomatis* infection can be confirmed using cultures or nucleic acid amplification techniques of ocular swabs.[9]

CHAPTER 123

Xanthelasma Palpebrarum

Key Points

- Xanthelasma is a condition characterized by the development of flat yellowish papules or plaques near the medial canthal region in the upper or lower eyelids or both
- About half of the patients who develop xanthelasma have a primary lipid disorder or secondary hyperlipidemia
- Secondary hyperlipidemia is seen with pregnancy, obesity, diabetes mellitus, hypothyroidism, nephrotic syndrome, or cholestasis
- The exact etiology is unknown, but trauma and inflammation can alter vascular permeability and may be a factor in the pathogenesis
- Xanthelasma typically presents as bilateral, symmetrical, flat or slightly elevated, soft, yellowish papules or plaques in the periorbital region, which usually grow over time
- Xanthelasma should be differentiated from some cutaneous histiocytic disorders that may present with xanthelasma-like lesions, including necrobiotic xanthogranuloma, Erdheim-Chester disease, adult-onset asthma and periocular xanthogranuloma (AAPOX), and to a lesser extent juvenile xanthogranuloma
- If there is any abnormality in the lipid profile, medical management is advised in the form of lifestyle change and lipid-lowering drugs (statins)
- Lipid-lowering drugs may have little effect on xanthelasma that have already developed and may be associated with ptosis
- In the absence of lipid abnormalities, surgical excision is usually offered for cosmetic improvement
- Surgical excision of xanthelasma directly involving the medial canthal region should be carried out conservatively
- The recurrence rate is high regardless of the method of treatment; however, the depth of the lesion is an important prognostic factor, the deeper the lesion involvement (dermal or underlying muscle) the higher the possibility of recurrence

Xanthelasma palpebrarum (XP) is a lesion characterized by localized infiltrates of lipid-laden macrophages appearing on various areas of the skin or in visceral organs[1] and is the most common cutaneous xanthoma occurring in the eyelids. It is usually found in the superficial and middle dermal layers of the skin but can extend into the underlying muscle in some cases. One case of XP has been described located within the orbicularis muscle with no cutaneous involvement.[2] Lesions are characterized by yellowish papules that occur more commonly near the medial canthus of the upper and lower eyelids. They are usually symmetrical from one side to the other, may be multiple, and occur more commonly in women than in men. It is a benign condition that usually does not cause functional problems but is of cosmetic concern to most patients.

The prevalence of xanthelasma is estimated at 4%,[3,4] with an incidence of 1.1% in women and 0.3% in men.[5,6] The age of onset can range from teens to old age but typically peaks in the fourth and fifth decades. In about 50% of cases, XP is associated with underlying hyperlipidemia,[5] and it has been suggested that a presentation in patients younger than 40 years should prompt screening to rule out inherited disorders of lipoprotein metabolism.[7] Patients with XP associated with familial hyperlipidemia syndromes may also have concomitant xanthomas, such as xanthoma tuberosum or xanthoma tendinosum.[8]

Etiology and Pathophysiology

About 52% of patients who develop xanthelasma have a lipid disorder.[9] Primary lipid disorders include familial hypercholesterolemia (hyperlipidemia type IIa), familial combined hyperlipidemia (hyperlipidemia type IIb), and familial hypertriglyceridemia (hyperlipidemia type IV). Secondary hyperlipidemia may be seen with pregnancy, obesity, diabetes mellitus, hypothyroidism, nephrotic syndrome, and cholestasis.[10,11,12,13] Some medications, such as estrogens, prednisolone, cyclosporine, tamoxifen, oral retinoids, and protease inhibitors can also cause secondary hyperlipidemia.[14,15,16] XP has also been reported in patients who previously had erythroderma,[17] generalized cutaneous inflammatory dermatoses,[18] or contact dermatitis.[19]

The exact etiology of XP is not clear. Trauma and inflammation can alter vascular permeability, and it has been demonstrated experimentally that the rate of capillary leakage of low-density lipoprotein (LDL) is increased in areas exposed to friction and constant movement.[20,21] This suggests that trauma, inflammatory cells, and mediators may be a factor in the pathogenesis of XP.[3,5]

The dermis of the eyelid is thin and vascular-rich, and pulsatile blood pressure, as well as local heat, may increase dermal capillary pressure during repeated blinking. This may play a role in the rate of lipid leakage and subsequent deposition in the eyelid by allowing lipoproteins to enter the dermis where they become oxidized by free radicals or ultraviolet *(Print pagebreak 808)* light, phagocytosed by dermal cells, and transformed into xanthoma cells.[5,22,23] These cells have a perivascular arrangement, suggesting that their stored lipid might originate from plasma lipids. Cholesterol entering cells along the capillary walls is mostly LDL, suggesting that the accumulated cholesterol is derived from blood.[21] These cells form foamy histiocytes causing inflammation and fibrosis in surrounding tissues. The yellowish cholesterol-rich foam cells accumulate in the skin, resulting in the clinical findings of xanthelasma.[24]

The inciting events leading to the formation of xanthelasma remain obscure. However, the inflammatory environment surrounding their formation is similar to that seen in the early stages of the formation of cardiac atherosclerotic plaques,[25] and it has even been suggested that XP may be a predictor of ischemic heart disease, myocardial infarction, or systemic atherosclerosis.[4,26] Atheromagenesis is believed primarily to be an inflammatory process, driven by oxidized LDL and elevated iNOS, COX, metallopeptidase, and MPO levels. These result in the recruitment of blood monocytes to the vessel wall, monocyte activation, and transformation into lipidized macrophages, or “foam cells” that accumulate cholesterol.[27,28,29]

Xanthelasmas do not develop in most patients with hypercholesterolemia, suggesting that other factors may contribute to the pathogenesis.[5] In vitro lipogenesis studies have shown in situ synthesis of all major lipid groups in xanthoma tissue in both hyperlipidemic as well as normolipidemic patients.[5,20] Impaired cholesterol removal from the tissues resulting in decreased levels of high-density lipoprotein (HDL) may also play a role in the formation of xanthelasma.[5,20]

A xanthelasma-like reaction has been reported as a complication of filler injections.[30,31] The mechanism of macrophage lipid accumulation and foam cell formation in patients with no lipid abnormalities before filler injection is not understood. However, it has been proposed that hyaluronic acid injections may bind extravasated LDL lipoprotein and that the LDL-glycosaminoglycan complex becomes internalized by macrophages and histiocytes more avidly than does native LDL, resulting in xanthelasma formation.[32]

Clinical Presentation

XP typically presents as bilateral, symmetrical, flat or slightly elevated, soft, yellowish papules or plaques in the periorbital region, and they usually grow over time (Figure 123.1). Occasionally they can appear darker red or even brown[1] and can be semisolid or rarely even calcareous (Figure 123.2A). In patients with hypercholesterolemia, lesions tend to be more nodular and tendinous (Figure 123.2B).[5] Less commonly, lesions can be seen on the neck, trunk, shoulders, and axillae.[5]

XP lesions most commonly occur near the medial canthal portion of the eyelids, more frequently on the upper lid.[33] They typically present in middle-aged and older individuals and are seen more frequently in females.[1,6] Lesions progress slowly and do not regress without treatment. When very large on the upper eyelid, they may cause mechanical ptosis (Figure 123.3).[34]

About 50% of individuals with xanthelasma have a lipid disorder, so that evaluation of the serum lipid profile is recommended in most cases. The cholesterol and triglyceride levels may be elevated, and the HDL level is often reduced.

Differential Diagnosis

The differential diagnosis of XP includes necrobiotic xanthogranuloma, orbital lipogranuloma, juvenile xanthogranuloma, Erdheim-Chester disease, granulomatosis with polyangiitis, lipoid proteinosis, primary systemic amyloidosis, necrobiosis lipoidica, sarcoidosis, atypical lymphoid infiltrate, syringoma, microcystic adnexal carcinoma, milia, sebaceous hyperplasia, steatocystoma multiplex, trichoepithelioma, and apocrine hidrocystoma.

Treatment

The choice of treatment depends on the size of the lesion and the patient's lipid status. If there is any abnormality in the lipid profile, medical management is recommended before treatment of the lesions. In patients with elevated cholesterol and triglycerides, initial treatment involves changes in lifestyle and taking medications to lower serum lipids. Even though a low-fat diet and statins are often recommended, they have little effect on the xanthelasmas once they develop.

In the absence of lipid abnormalities, removal of the lesions is usually offered for cosmetic improvement. When the size is small, this can be performed by laser therapy, radiofrequency ablation, cryosurgery, or trichloroacetic acid (TCA) chemical peel. Systemic interleukin-1 blockade and cyclosporine-A therapy have also been reported to achieve good results.[15,35] However, when the size is large, surgical excision is usually a more appropriate option.[33,36]

TCA is a destructive topical chemical peel therapy that is applied in concentrations of about 50% to 70% in one or more applications.[37,38] Good to excellent results in cosmetic improvement have been reported in up to 80% of patients,[39] although recurrence may be seen in 25% to 35%.[38,40] Postinflammatory hyperpigmentation has been reported in 9% to 12.5%,[38] and hypopigmentation at a frequency of 22% to 33%.[39]

In rare cases, TCA may be associated with extension of the lesion, suggested to occur as a Koebner phenomenon.[41] The Koebner phenomenon, also called the isomorphic response, refers to the appearance of new lesions along a site of injury. It can be seen with a variety of conditions such as lichen planus, warts, molluscum contagiosum, psoriasis, lichen nitidus, and the systemic form of juvenile rheumatoid arthritis.

Probucol is a bisphenol antioxidant with antilipidemic activity. It inhibits the oxidation of LDL and lowers the level of cholesterol in the bloodstream by increasing the rate of LDL catabolism.[42] Several studies have shown regression of xanthelasma after oral probucol therapy.[43,44]

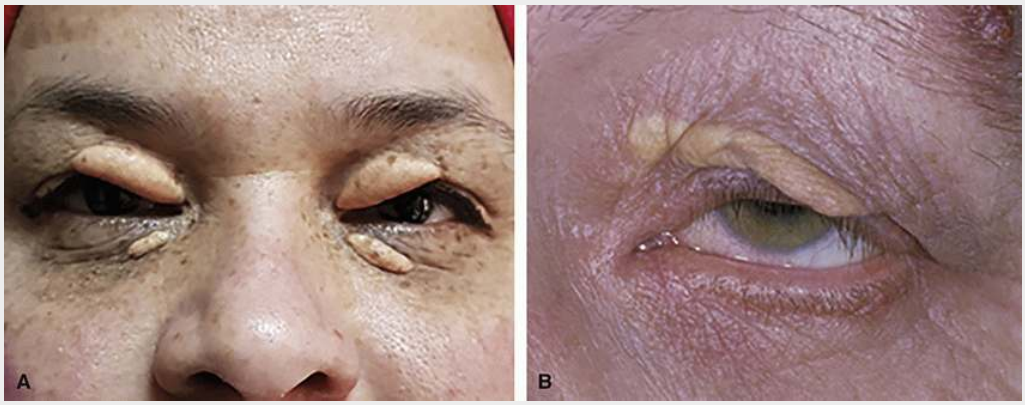

FIGURE 123.3 A and B, Large upper eyelid xanthelasma causing mechanical ptosis.

Alirocumab is a monoclonal antibody approved for anticholesterol therapy through inhibition of proprotein convertase subtilisin/kexin type 9 (PCSK9), which plays an important role in the regulation of cholesterol homeostasis. It is used primarily in the treatment of hypercholesterolemia. Rapid resolution of XP, associated with the lowering of LDL cholesterol concentrations, was reported after treatment with alirocumab.[45]

Radiofrequency (RF) ablation of XP has been reported to achieve cosmetic improvement in more than 75% of cases.[46] Although RF ablation can achieve improvement scores similar to those with TCA and with fewer treatment sessions, it is associated with more scarring and pigmentation.[47]

Laser ablation for the treatment of XP results in the destruction of perivascular foam cells and coagulation of dermal vessels in the stratum corneum leading to blockage of further lipid leakage into the surrounding tissues.[48] Various lasers, including carbon dioxide, argon, erbium, and pulsed dye lasers have been used.[49,50,51,52,53] CO_2 is considered the gold standard, and treatment of XP has resulted in excellent initial resolution in the majority of cases with little or no scarring.[54,55,56]

Cryosurgery is an outpatient procedure that is safe, relatively painless, and effective for the treatment of small XP. The results are usually cosmetically acceptable, and it is associated with few complications. However, it usually requires multiple sessions, and postinflammatory hypopigmentation can be seen.[57]

Surgical excision for the treatment of XP is widely used and often yields excellent cosmetic outcomes. It is particularly preferred in cases of deep dermal or underlying muscle involvement. For smaller upper eyelid lesions, simple surgical excision is enough, however, for larger lesions involving a significant portion of the eyelid or the eyelid plus the medial canthus, excision can be combined with local flaps or grafts. Lee et al.[9] classified periocular XP into four grades according to the location and extent of the lesion. Grade I involves only the upper eyelid; grade II involves the upper eyelid and medial canthus; grade III involves the medial canthus and the medial portions of both upper and lower eyelids; grade IV diffusely involves the medial and lateral portions of the upper and lower eyelid. Among 95 cases managed with either surgical excision alone, or excision combined with local flaps or grafts for larger lesions, recurrence was reported in 3.1% of patients at 12 months regardless of the grade.[9] However, in other reports, the incidence of recurrence has been reported to be up to 40% after primary surgical excision, 60% after secondary excision, and 80% after excision for bilateral upper and lower eyelid

involvement.[58] Regardless of the extent of surgery, slight scarring, dyspigmentation, and ectropion are possible complications.[59,60,61] Care should be taken when excising large xanthelasmas involving the upper and lower eyelids if they coalesce or join each other in the medial canthal region. Total excision of these lesions may result in cicatrix formation and shortening in the medial canthus and could result in the development of cicatricial canthal webs or medial canthal webbing. This may be difficult to correct because available skin in the medial canthus is already in short supply and is relatively fixed in position to the skin of the bridge of the nose. Lesions confined to the upper or lower eyelids usually have ample and more mobile skin so that a more generous excision may be permissible.[62,63]

Prognosis The recurrence rate of xanthelasma is high regardless of the method of treatment. Depth of the lesion is important, and those involving the deeper dermis or underlying muscle may be associated with higher rates of recurrence.[58] For patients with lipid disorders like hyperlipidemia, liver diseases, diabetes, and thyroid disorders, it is important to treat the underlying medical condition and to control hyperlipidemia. However, the prolonged use of some lipid-lowering drugs may be associated with the development of ptosis (anti-cholesterol-associated ptosis) due to statin-induced myositis.[64]

(Print pagebreak 811)

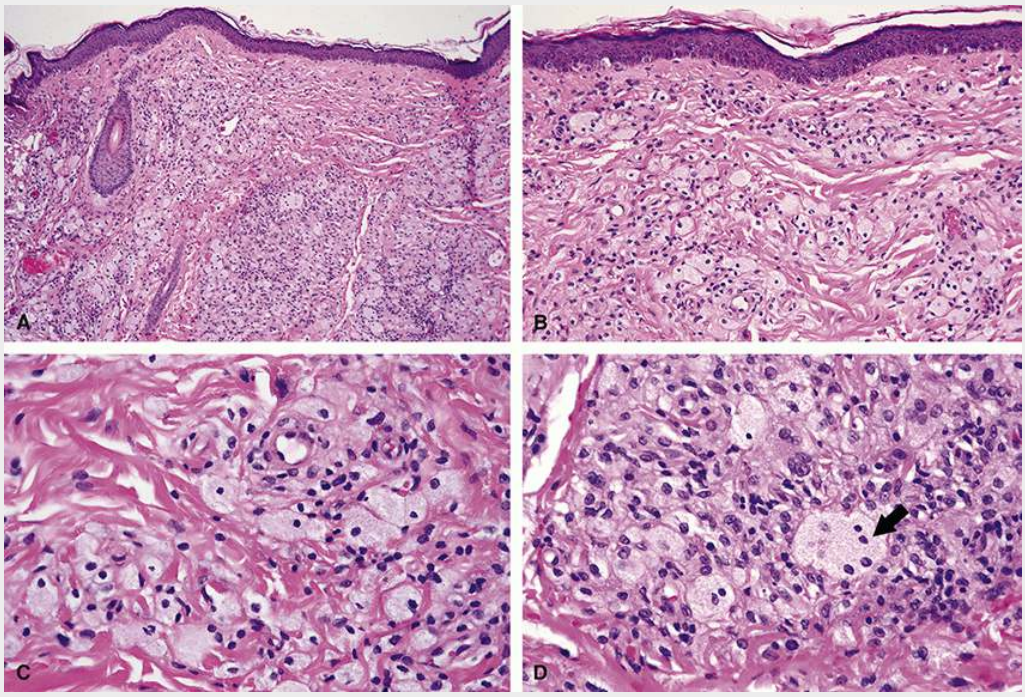

FIGURE 123.4 A, Typical xanthelasma with clusters of vacuolated, lipid-laden macrophages (foam cells) in the papillary and upper reticular dermis forming nodules separated by dermal connective tissue with scattered individual foam cells. B, Foam cells have a perivascular predilection, although they are usually present as individual cells and small clusters between the larger aggregates of perivascular foam cells. Lymphocytes and nonxanthomatous macrophages are common but often inconspicuous. C, Lipid vacuoles within the macrophages create a finely reticular, pale-staining cytoplasm. D, Xanthelasma may have occasional multinucleated foam cells (arrow), but Touton giant cells are rare.

Histopathology

The earliest stage of XP involves increasing macrophages and lymphocytes in the dermis, predominantly around small veins and the subpapillary venous plexus.[65,66] The macrophages imbibe lipids that have passed through the vessels, resulting in xanthelasma's characteristic feature: collections of vacuolated, lipid-laden macrophages (foam cells) around blood vessels in the papillary and upper reticular dermis (Figure 123.4).[65,66,67,68,69] Although often inconspicuous, the foam cells are accompanied by small numbers of lymphocytes, nonxanthomatous macrophages, and mast cells.[65,67,69,70] Xanthelasmas may have foreign-body or Touton giant cells,[65,66,69,71,72] although these are uncommon and rarely Touton giant cells.[72] Fibrosis is usually minimal,[73,74] although it may accompany regression of older lesions.[66,67] Histological diagnosis of XP does not pose a problem in patients with a typical clinical appearance. In patients lacking typical clinical features, other xanthomatous lesions such as Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy), Erdheim-Chester disease, or xanthogranulomas must be excluded.[75]

CHAPTER 124

Xanthogranuloma and Histiocytoses

Key Points

- The pathogenesis of xanthogranulomas is unknown, but it is believed that they arise from a reactive, metabolic, or inflammatory process that results in the proliferation of free tissue macrophages
- Xanthogranulomas were previously classified in 1987 as class II histiocytosis (non-Langerhans cell histiocytosis)
- The updated classification of 2016 reclassified all cutaneous manifestations of histiocytic disorders under the C group (cutaneous and mucocutaneous manifestations)
- The C group is further divided into the xanthogranuloma (XG) family and non-XG family
- The xanthogranuloma family consists of juvenile xanthogranuloma (JXG) and adult xanthogranuloma (AXG)
- The nonxanthogranuloma family includes cutaneous Rosai-Dorfman disease and necrobiotic xanthogranuloma (NXG)
- Juvenile xanthogranuloma (JXG) is the most common variant of non-Langerhans xanthogranuloma disease
- Eyelid lesions vary according to the specific disease, but they are either nodular skin lesions or xanthelasmas and they may become necrotic in NXG
- Systemic manifestations are relatively uncommon in the xanthogranuloma family, but they vary according to the type
- Systemic manifestations are more frequent in Erdheim-Chester disease and Rosai-Dorfman disease
- The cutaneous lesions should be differentiated from xanthelasma, molluscum contagiosum, hemangioma, or neurofibroma
- Treatment consists of surgical excision/debulking, radiotherapy, or systemic immunosuppression
- Fatalities are rare in conditions like juvenile xanthogranuloma, while other conditions like Erdheim-Chester disease carry a poor prognosis

Xanthogranulomatous diseases of the eyelids and orbit represent a group of non-Langerhans cell histiocytic granulomatous disorders characterized histologically by the presence of foamy histiocytes, Touton giant cells, lymphocytes, plasma cells, and varying degrees of necrosis or necrobiosis and fibrosis.[1,2] They are all similar in their cell types but differ significantly in clinical presentation and prognosis, varying from benign and self-limited disorders to systemically aggressive conditions with potentially fatal outcomes. Although distinct clinical syndromes involving xanthogranulomatous inflammation have been described, there is an overlap of some clinical findings, so that all of these diseases may represent segments of a pathophysiological continuum. The most important of these syndromes include juvenile xanthogranuloma (JXG), which primarily affects children, and at least four other adult syndromes.

Adult xanthogranulomatous diseases involving ocular adnexal or orbital tissues are rare and are often associated with other systemic manifestations. The four most commonly identified syndromes in this group are based on specific systemic associations. These are adult-onset xanthogranuloma (AOX), adult-onset asthma and periocular xanthogranuloma (AAPOX), necrobiotic xanthogranuloma (NXG), and Erdheim-Chester disease (ECD).[1,3] In their review of 137 cases of adult xanthogranulomatous disease of the orbit and adnexa, Sivak-Callcott et al. identified 8 cases of AOX (5.8%), 21 AAPOX (15.3%), 72 NBX (52.6%), and 36 ECD (26.3%).[1]

Rosai-Dorfman disease (RDD), also known as sinus histiocytosis with massive lymphadenopathy, is another rare non-Langerhans cell reactive histiocytic disorder with periorbital cutaneous and orbital manifestations.[4,5] The clinical course can vary from benign and self-limited to persistent and recurrent. It classically presents with massive neck lymphadenopathy in children and young adults

at a mean age of 20 years,[4,6] with a slight male predominance and a greater incidence among individuals of West African and Caribbean descent.[4,6]

The first classification of histiocytosis, published in 1987 by the Working Group of the Histiocyte Society, consisted of three categories (Langerhans cell, non-Langerhans cell, and malignant histiocytosis). In this older classification, the family of xanthogranulomatous diseases was grouped under the rubric of non-Langerhans cell histiocytic disorders. However, in light of recent insights, the Langerhans/non-Langerhans dichotomy noted in the prior classification system has become questionable. As a result, the histiocytosis society proposed a revised classification in 2016 that subclassified histiocytic disorders into five groups: (1) The L group (Langerhans-related including ECD, and extracutaneous JXG); (2) the C group (cutaneous and mucocutaneous), which is divided into the xanthogranuloma (XG) family (JXG, AAPOX, AOX), and non-XG family that includes cutaneous RDD and NXG; (3) the M group (malignant histiocytoses); (4) the R group (RDD); and the H group (hemophagocytic lymphohistiocytosis and macrophage activation syndrome).[7]

(Print pagebreak 815)

When any of these conditions is present in the orbit and periorbita, there is a significant clinical and ultrastructural overlap. Because all of these conditions are closely related and fall under the rubric of histiocytosis, in this chapter we discuss NXG, ECD, and RDD, in addition to disease conditions belonging to the xanthogranuloma family (JXG, AAPOX, AOX). A more detailed description of RDD is in Chapter 110.

Etiology and Pathogenesis

Xanthogranulomatous disease is a non-Langerhans (type II [older classification], C group [new classification]), histiocytosis that is characterized by a proliferation of histiocytes. These histiocytes originate from bone marrow stem cells where they mature into monocytes.[8] They then differentiate into one of two pathways, the mononuclear-phagocytic system or the dendritic cell system.[9] The mononuclear-phagocytic system consists of phagocytic monocytes as well as free and fixed tissue macrophages.[8] The dendritic cell system includes follicular cells of the lymph nodes and Langerhans cells in the skin. Both of these cell types function as antigen-presenting cells.[8] Although the pathogenesis of xanthogranulomatous diseases is not clearly understood, it is believed that they arise from a reactive proliferation of free tissue macrophages. The inciting factors remain elusive, but some evidence suggests a possible relation to virus infection. In a case of an infant with JXG, involvement of the salivary gland was associated with cytomegalovirus infection.[10] In another case of oral JXG, cytomegalovirus antigens in the histiocytes were identified by immunohistochemistry.[11] In addition, several patients with JXG have been shown to have chromosomal instability within the lesions and peripheral blood cells.[12] It is unclear if these chromosomal abnormalities represent a fundamental genetic defect or just aberrations resulting from a cellular response to external factors such as viral infections.

The differences or variations in the pathogenesis of specific subtypes of xanthogranulomatous disease are poorly understood. The pathogenesis of JXG is unknown, but it is presumed to develop after unknown infectious or physical stimuli that then provoke a granulomatous histiocytic reaction. The reactive lesion is derived from monocytes or macrophages in response to unknown etiologic physical or infectious agents.[13,14,15] Although the pathophysiologic relationship is not understood, JXG has been associated with juvenile chronic myelogenous leukemia, juvenile myelomonocytic leukemia, and neurofibromatosis.[16] Other diseases associated with JXG include urticaria pigmentosa, insulin-dependent diabetes mellitus, aquagenic pruritus, and even cytomegalovirus infection.[17]

In NXG, an association with paraproteinemia is well known, and this immunoglobulin monoclonal gammopathy is present in at least 80% of cases. The paraprotein may serve as the primary inciting factor or act as a cofactor that facilitates a giant cell granulomatous reaction.[18] To date, however, the precise pathogenesis of NXG and the other adult orbital xanthogranulomas is unknown.

The pathogenesis of ECD is speculated to be associated with a T-helper 1 (Th1) immune response. Patients with ECD have high levels of IFN-α, interleukin-6, IL-7, IL-12, and monocyte chemoattractant protein-1, supporting the idea of an inflammatory condition.[19,20,21] An oncogenic etiology has also been suggested because of the detection of a mutation in the BRAF proto-oncogene that has been identified in 40% to 80% of patients with ECD.[22,23] The mutation causes the amino acid substitution of glutamic acid for valine at position 600 of the BRAF protein (V600E). The BRAFV600E mutation is usually detectable in biopsies and in circulating monocytes from patients with ECD, demonstrating that ECD is a clonal disease.[22] It has been shown that patients with ECD treated with the selective BRAFV600E inhibitor, vemurafenib, showed dramatic clinical and radiographic improvement.[24]

NXG originates from the mononuclear-phagocytic system, which consists of phagocytic monocytes and free and fixed tissue macrophages. The specific pathogenesis is not known, but it has been postulated to occur secondary to a reactive proliferation of free tissue macrophages. Possible causes for this proliferation include induction by a virus, paraproteinemia, immunoglobulin or lipid-Ig complex deposition, *Borrelia* species infection, or chromosomal instability.[2]

The cause of RDD is unknown, but autoimmune diseases and viruses such as human herpesvirus 6 or Epstein-Barr virus have been proposed as possible sources.[7,25,26] The pathogenesis involves recruitment of monocytes from the peripheral blood to lymph nodes or extranodal sites, and these are then transformed into RDD histiocytes.[25] Emperipolesis, a process whereby histiocytes phagocytize intact lymphocytes or plasma cells, is characteristic of RDD and distinguishes it from other cutaneous xanthogranulomatous diseases.[6,7] These histiocytes can release cytokines, such as tumor necrosis factor-α, which result in fever and other systemic symptoms.[25]

Clinical Presentation

JXG is a childhood form of xanthogranulomatous disorders[27] and is the most common variant of non-Langerhans xanthogranuloma disease. It is most commonly found in early childhood with 5% to 17% of cases occurring shortly after birth and 75% within the first 9 months of life.[15] In children, there is a slight predilection to affect males in a ratio of 1.1:1 to 1.4:1,[28] but in adults, there is no sex prevalence. About 10% of cases may appear in adulthood.[29] In up to 90% of patients, JXG manifests with nodular cutaneous lesions that clinically appear as a well-defined papule or nodule mainly affecting the head and neck.[30] Eyelid lesions most often are solitary, firm, and asymptomatic and range in size from 5 mm to 2 cm (Figure 124.1).[27,31] Initially lesions appear pink to red, but in later stages, they tend to acquire a brownish-yellow color and may develop telangiectasias.[15] The most common site of extracutaneous involvement is a solitary mass in the subcutis or deep soft tissues, but various organs may be involved.[15,32] *(Print pagebreak 816)* Eye involvement is usually unilateral and commonly presents with an asymptomatic iris tumor, red eye, uveitis, or heterochromia iridis.[15] The iris is most often involved and can be associated with spontaneous intraocular hemorrhages, glaucoma, and blindness.[33]

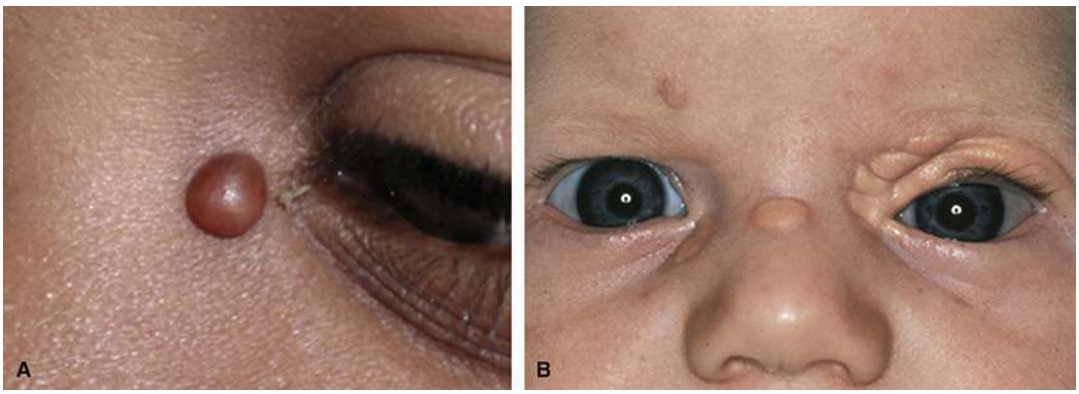

FIGURE 124.1 A and B, Juvenile xanthogranuloma nodules on the eyelids. A, (Courtesy of Dr. Brian Brazzo.) B, (Courtesy of Dr. David Lyon.)

Systemic manifestations may develop in 4% of children with JXG and 5% to 10% overall. This may involve muscles, liver, lung, pericardium, and spleen.[15,33] The central nervous system is involved in 1% to 2 % of systemic cases,[17,34] mostly manifesting with multiple intracerebral lesions and/or leptomeningeal involvement with seizures,[35] diabetes insipidus,[36] or ocular disturbance.[37] As mentioned above, JXG rarely may be associated with childhood leukemia[27,38] and neurofibromatosis type 1.[39]

AOX is the least common form and is sometimes referred to as late-onset JXG. It affects patients from teens to the ninth decade, with a median age at onset of 35 years.[32] There is no significant gender preference, and it occurs mostly without significant systemic involvement.[1] AOX lesions involve the eyelids and periorbital skin in 50% of cases and are located in the orbit in 50%.[1] Cutaneous lesions occur predominantly in the head and neck region and are similar to those of JXG, although the nodules are often larger. They generally present as bilateral isolated or diffuse yellowish lesions on swollen eyelids (Figures 124.2 and 124.3). They involute spontaneously in about 54% of cases.[40] In rare reports, both AOX and AAPOX have been associated with IgG4-related disease.[41,42,43]

AAPOX was described by Jakobiec et al. in 1993.[44] It is associated with late-onset asthma that often precedes the periocular lesions by several years.[41] Bilateral preseptal cutaneous or anterior orbital xanthomatous lesions affect adults aged between 20 and 70 years. Males are affected more frequently than females at a ratio of 2:1. Simultaneous involvement of conjunctiva has also been reported.[45] In addition to asthma, paraproteinemia and lymphadenopathy are found in 35% to 40% of patients, suggesting an underlying disorder of B cell proliferation.[1]

AAPOX presents with progressive bilateral yellow or orange, indurated xanthomatous periocular masses. The anterior orbit and lacrimal gland are often infiltrated, but intraconal involvement is very rare.[1,41] Visual function can be impaired by eyelid occlusion from mechanical ptosis or diplopia from infiltration into extraocular muscles.[44] Although this variant is usually limited to the

periocular region, mandibular gland infiltration has been described,[44] as has diffuse cervical, hilar, and inguinal adenopathy.[41] No internal organ involvement has been reported.

NXG usually involves the periorbital region, trunk, and proximal extremities. It affects men and women equally in their sixth decade of life.[46] Lesions initially may resemble xanthelasmas, but gradually increase in number and size to become indurated yellowish plaques, 0.5-5 cm in diameter, that tend to ulcerate (Figure 124.4). Ocular manifestations include skin nodules and plaques, conjunctivitis, scleritis, keratitis, anterior uveitis, and orbital infiltration with extraocular limitation. Eyelid function can become compromised with mechanical ptosis and lagophthalmos, and corneal exposure has resulted in perforation with loss of the eye.[47] NXG can be associated with hypocomplementemia and cryoglobulinemia, and with monoclonal paraproteinemia in 80% of cases. It has also been associated with multiple myeloma, non-Hodgkin lymphoma, and other hematologic dyscrasias in 25% to 30% of cases,[48] so that NXG is a more life-threatening subtype of xanthogranuloma.[1,44]

ECD is a rare infiltrative xanthogranulomatous disease.[49] The disease usually becomes apparent in adulthood between 40 and 60 years of age with a median age at diagnosis of 53 years,[50] but a few cases have been described in the pediatric population.[51] The male to female ratio is 3:1.[52] The diagnosis is made on a combination of clinical presentation and imaging features and is confirmed on histopathology. The clinical picture of ECD may vary from indolent focal disease to multiorgan involvement with a fatal outcome. Radiological characteristics are pathognomonic and skeletal involvement occurs in more than 95% of patients. Bone *(Print pagebreak 817)* pain may be the presenting symptom in 50% of cases,[53,54] and the distal ends of the femurs and proximal and distal tibia are the most frequently involved sites.[50] More than 50% of cases have other extraskeletal and internal organ involvement such as diabetes insipidus, progressive lung disease, and renal failure.[55] In about half of the patients the central nervous system is involved.[50] Cardiovascular manifestations are the major cause of death in patients with ECD, and about 60% of patients die due to a cardiac complication.[56] Orbital and periorbital lesions result in proptosis, papilledema, and nodular skin lesions. Xanthelasmas are the most frequent skin lesions in ECD, present in about 30% of patients, and are indistinguishable from those found in JXG.[57] Orbital infiltration is often bilateral and manifests as exophthalmos in about 25% of patients with ECD. Occasionally it is associated with retro-orbital pain, diplopia, or visual impairment from optic nerve compression.[57]

FIGURE 124.2 A-D, Adult-onset xanthogranuloma. C, (Courtesy of Dr. Charles Soparkar.)

RDD usually presents with fever, elevated erythrocyte sedimentation rate, leukocytosis, weight loss, malaise, sweats, anemia, and hypergammaglobulinemia (see Chapter 110).[4,6,7] Although the lymph nodes are the most common sites of involvement, extranodal involvement is seen in 25% to 43% of cases.[58,59] Extranodal disease tends to affect older individuals, and these patients show a higher tendency for a chronic relapsing course.[60] The skin is a common site for extranodal involvement, and occasionally the skin can be the only involved site.[58] Cutaneous lesions typically are red to red-brown[7] and can include infiltrated erythematous, yellowish xanthelasma-like papules, ulcerated nodules, subcutaneous masses, and rosacea-like lesions affecting the face or less commonly other parts of the body.[59,61,62] Orbital lesions may cause proptosis, blepharoptosis, uveitis, impaired extraocular

motility, and diplopia and decreased vision.[61]

Differential Diagnosis

The clinical differential diagnosis of JXG includes xanthoma, molluscum contagiosum, hemangioma, and neurofibroma, although all of these have features that help to distinguish them, such as the absence of lipid abnormalities in xanthomas, a dome shape with central umbilication in molluscum, *(Print pagebreak 818) (Print pagebreak 819)* and café-au-lait spots in most patients with neurofibromas. Lesions with at least partially similar histopathologic features include Langerhans cell histiocytosis, benign fibrous histiocytoma, xanthomas, and reticulohistiocytoma.

FIGURE 124.3 A-D, Adult-onset xanthogranuloma. A, (Courtesy of Dr. Robert Goldberg.) B, (Courtesy of Dr. Robert Machemer.) C, (Courtesy of Dr. Charles Soparkar.)

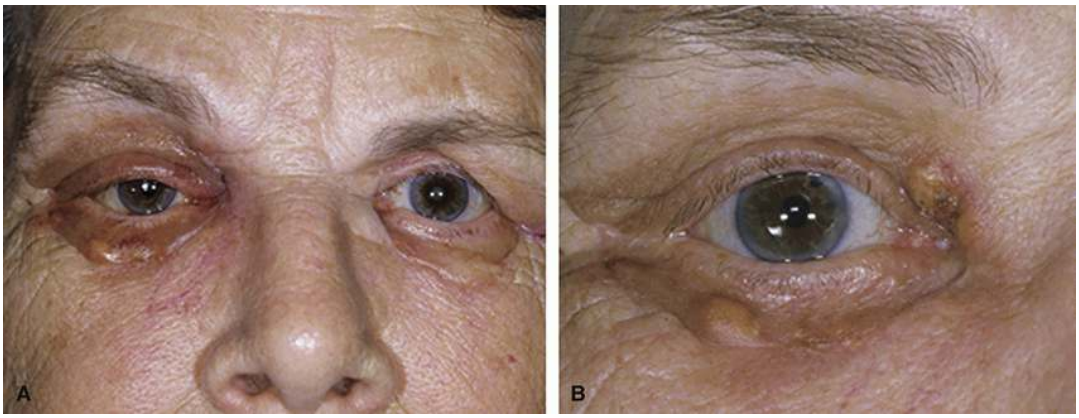

FIGURE 124.4 Necrobiotic xanthogranuloma. A, Bilateral granulomas with orbital involvement and secondary ptosis of the right eye. B, Close-up view of the right eye of the patient in 1A.

The clinical differential diagnosis of AOX includes xanthelasma, thyroid disease, sarcoidosis, allergic granulomatosis, JXG, papular

xanthoma, xanthoma disseminatum, AAPOX, NXG, and ECD.

There are a number of conditions that show symptoms and signs similar to those of ECD. These include histiocytosis X, multiple sclerosis, amyloidosis, neurosarcoidosis, metabolic diseases, mucopolysaccharidosis, Paget disease, Ormond disease, granulomatosis with polyangiitis, Whipple disease, Gaucher disease, RDD, chronic recurrent multifocal osteomyelitis, Takayasu arteritis, primary hypophysitis, cerebrotendinous xanthomatosis, cancers, and mycobacterial infections.[63]

Treatment

Xanthogranuloma diseases are very rare, so there is no agreement on the most effective treatments. Various treatments have been applied, including surgical excision or debulking,[64,65] but surgical excision is often followed by disease recurrence and scarring.[44,66] Radiotherapy has been used in some cases, but with variable results.[46,66,67]
Systemic immunosuppression and/or chemotherapy is another option,[68,69,70,71,72] but the disease often recurs after corticosteroid withdrawal. Intralesional steroid injections may be useful for isolated eyelid lesions, but there is a risk of central retinal artery occlusion, ophthalmic artery occlusion, glaucoma, eyelid necrosis, and subcutaneous fat atrophy.[73] The BRAF inhibitors, Infliximab and Vemurafenib, have been used for patients whose histiocytes contain the V600-BRAF mutation and may be considered for patients whose response to IFN-α is unsatisfactory.[24,74,75] Local and systemic proinflammatory cytokines and chemokines seem to be responsible for the recruitment and activation of histiocytes into lesions,[19,20,21] so that blockade of Th1-induced proinflammatory cytokines may be an effective therapeutic option.[19,20,76,77] Treatment of RDD varies widely depending on the disease course. Up to half of affected patients may have spontaneous resolution, making aggressive initial therapy undesirable.[2] Surgical intervention may be necessary if the airway is threatened. Corticosteroids have been helpful in some cases, but the benefit decreases after cessation.[78] Other modalities including radiotherapy, chemotherapy, and interferon are of uncertain benefit.[79] Methotrexate alone or in combination with other therapies has been helpful in some cases.[80]

Prognosis

ECD is the most severe form of the xanthogranulomatous diseases because it is associated with internal organ and bone infiltration, retroperitoneal fibrosis, severe lung disease, pericardial and pleural effusions, cardiomyopathy, central neural system lesions, and diabetes insipidus.[81] A fatal outcome is frequent despite aggressive treatment.[1,54] With INF-α treatment, the prognosis improves, with a 5-year survival rate of 70%.[82] This is a chronic condition for which there is no cure, and the goal of treatment is to prolong survival and improve the quality of life. That requires patient support. Management requires a multidisciplinary approach.

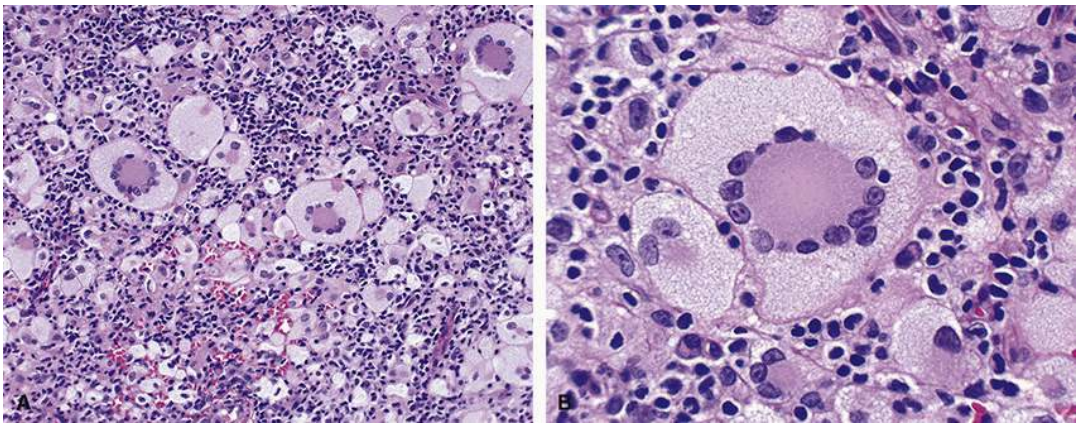

FIGURE 124.5 A, Juvenile xanthogranuloma with lipid-laden macrophages (foam cells), Touton giant cells, and numerous interspersed lymphocytes. B, Touton giant cells have a ring of nuclei surrounding eosinophilic nonvacuolated cytoplasm centrally and lipid-filled foamy cytoplasm peripherally.

Histopathology

Cutaneous JXGs are usually solitary lesions extending from just beneath the epidermis into the reticular dermis (Figure 124.5).[83,84] Lesions vary from sheets of nonxanthomatous histiocytes without Touton giant cells to the classic appearance *(Print pagebreak 820)* of foamy histiocytes mixed with Touton giant cells, lymphocytes, and scattered eosinophils.[13,83,84,85,86] Due to the variable

histological appearance, Janssen and Harms classified JXG into early JXG (≈27% of cases), classic JXG (≈47%), transitional (late) JXG (≈16%), and combined JXG (≈10%).[84] Early JXG has small- to intermediate-sized mononuclear histiocytes forming a sheet-like dermal infiltrate.[84] The histiocytes in early JXG have pale, eosinophilic cytoplasm with sparse, if any, lipid vacuoles.[84] Touton giant cells[87,88] are generally absent or few in early JXG.[84] Classic JXG has histiocytes with more abundant and vacuolated cytoplasm (xanthoma cells) and giant cells that may be foreign-body type, Touton, or Langhans type.[84] Approximately 15% of classic JXG lesions lack giant cells, most have 2 to 20 giant cells per high power field (HPF), and about 15% have >60 giant cells/HPF.[84] Janssen and Harms observed emperipolesis of lymphocytes by multinuclear giant cells in two of 68 cases of classic JXG.[84] Transitional JXGs show predominantly spindle-shaped cells with a storiform pattern with foci of foam cells and giant cells.[84] Combined JXG, as the name implies, has more than one histological pattern side by side. The histiocytes in JXG immunohistochemically express the macrophage markers CD68,[87] fascin,[85] Ki-M1P,[84,86] and CD163[85] and lack expression of CD1a,[84,85] distinguishing them from Langerhans cell histiocytoses. S100 protein was detected immunohistochemically in 7/123 cases examined by Janssen and Harms, with the positive staining in scattered cells, less than 5% of those in the lesion.[84] Kraus and coworkers cautioned against using S100 positivity to exclude a diagnosis of JXG since 8/27 JXG cases had immunoreactivity for S100 protein using a polyclonal antibody, and 6 of those cases were also immunoreactive using a monoclonal anti-S100 antibody.[85]

Cutaneous AOX resembles JXG histologically and immunohistochemically, although giant cells are more prominent in AOX.[86] Periocular AOX often accompanies orbital AOX,[89,90] and the histiocytic infiltrate extends deeply into the subcutaneous tissue and orbicularis muscle.[1] Periocular AOX features xanthoma cells, foreign-body and Touton giant cells, and lymphocytes that may be diffusely distributed, aggregated, or in lymphoid follicles (Figure 124.6).[1,89,91,92] We have seen only one example of a localized eyelid AOX similar to early JXG with only mild lipid accumulation in the histiocytes.

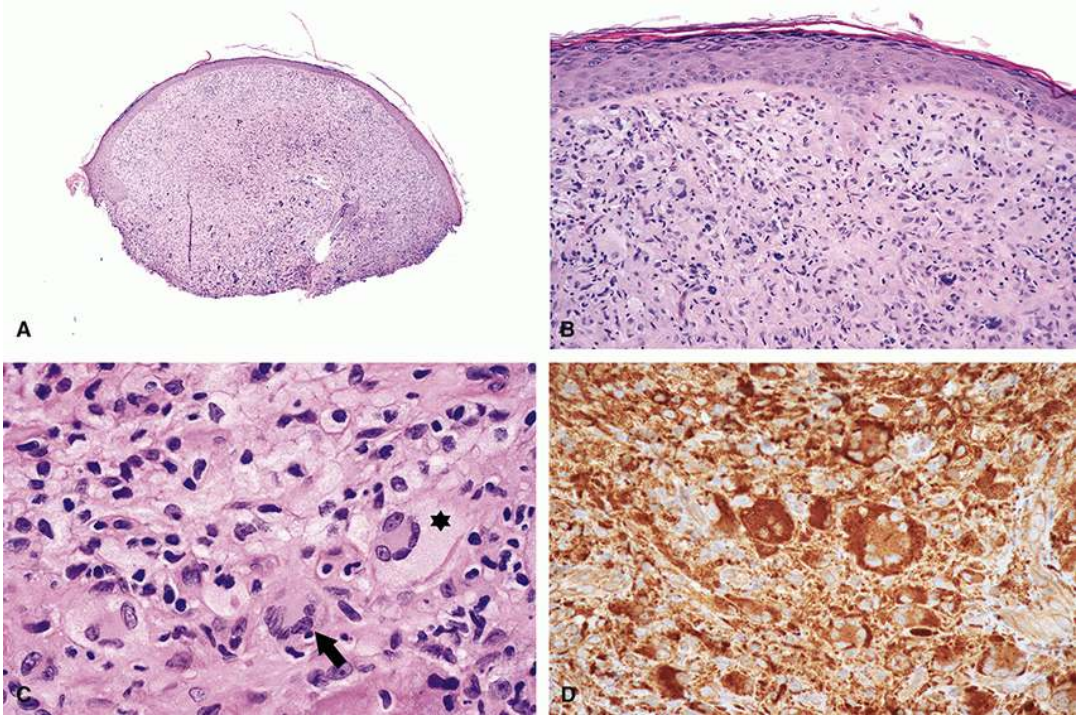

FIGURE 124.6 A, This adult-onset xanthogranuloma presented as a left lower eyelid dome-shaped nodule. B, A thin band of collagen separates the epidermis from the dermal infiltrate containing foam cells, numerous giant cells, and occasional lymphocytes. C, Both Touton (★) and foreign-body (arrow) giant cells were present in the dermal infiltrate. D, All of the mononuclear and multinuclear foam cells expressed CD68.

(Print pagebreak 821)

AAPOXs have sheets of xanthoma cells with Touton and foreign-body giant cells, lymphocytes, and a few plasma cells infiltrating the dermis, orbicularis muscle, and subcutaneous tissues, usually with involvement of the anterior orbit.[44,92,93,94] Lymphoid follicles are present in most lesions,[44,92,93,94] and two of the cases reported by Jakobiec and colleagues[44] had eosinophilia that was perivascular and interstitial in one patient and around lymphoid follicles in the other. None of the histological changes are distinctive enough to allow differentiation of AAPOX from other periocular xanthogranulomatous processes.[1,44,92]

NXG manifests as palisading xanthogranulomas with zones or bands of necrobiosis ("degeneration of the interstitial collagen, reflective either of necrosis or of hyalin homogenization with effacement of the normal tinctorial properties"[44]) in the middle dermis and subcutis (Figure 124.7).[46,95,96] There are sheets of histiocytes, foam cells, foreign-body, and Touton giant cells, and

lymphocytes that may form aggregates or nodules.[46,95,96] The foreign-body giant cells are often atypical with irregular size and shape, hyperchromatic nuclei, and clumping or polarization of nuclei to one end of the cell.[46,96] Cholesterol clefts are in the areas of necrobiosis in about 25% to 30% of biopsies.[95,96] Proposed diagnostic criteria for NXG include two major and two minor criteria, with "both major criteria and at least one minor criterion required for diagnosis, applicable only in the absence of a foreign body, infection, or other identifiable cause."[97] Major diagnostic criteria are "1. Cutaneous papules, plaques, and/or nodules, most often yellow or orange color; and 2. Histopathological features demonstrating palisading granulomas with lymphoplasmacytic infiltrate and zones of necrobiosis. Characteristic features that are variably present include cholesterol clefts and/or giant cells (Touton or foreign body)."[97] Minor diagnostic criteria are "1. Paraproteinemia, most often IgG-κ plasma cell dyscrasia, and/or other associated lymphoproliferative disorder; and 2. Periorbital distribution of cutaneous lesions."[97]

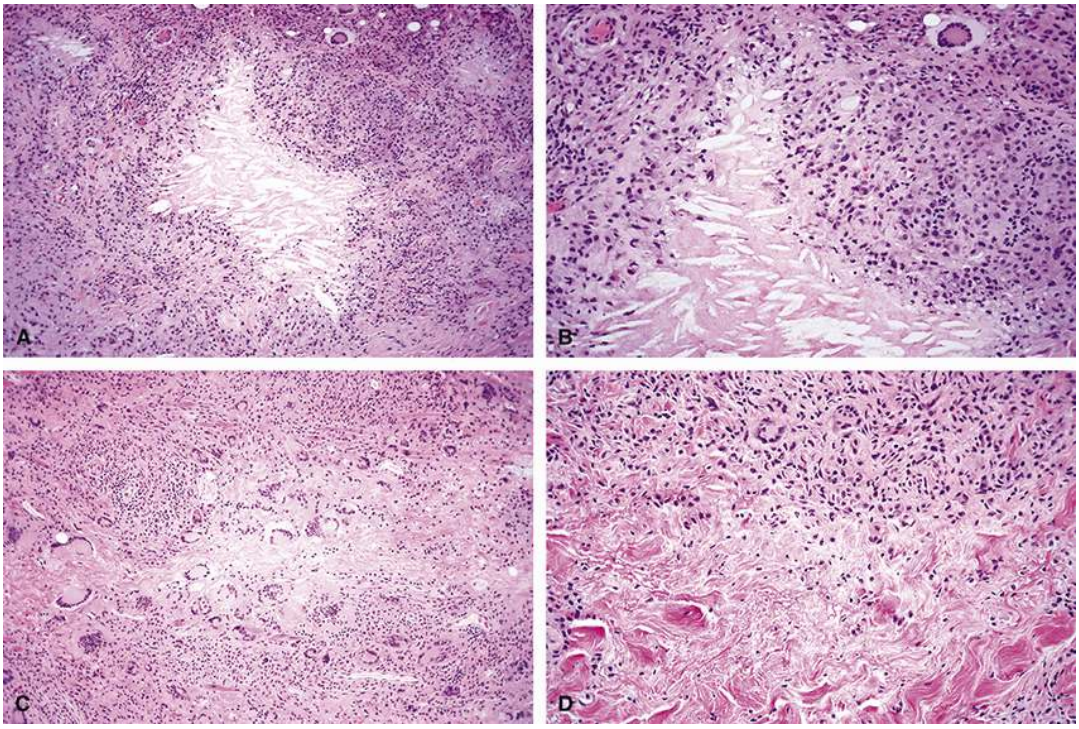

FIGURE 124.7 A and B, Necrobiotic xanthogranuloma with macrophages, foam cells, Touton giant cells, and lymphocytes surrounding necrobiotic tissue having numerous cholesterol clefts. C and D, Necrobiotic xanthogranuloma with macrophages, foam cells, Touton and foreign-body giant cells, and lymphocytes surrounding bands of necrobiotic collagen without cholesterol clefts.

The histology of cutaneous ECD is variable.[98,99,100] Approximately 25% of patients with ECD have xanthelasma-like lesions (XLLs) with foamy histiocytes, multinucleated cells, and Touton giant cells.[98] The XLLs of ECD differed significantly from xanthelasma palpebrarum by extending deeper into the reticular dermis, having more Touton giant cells, and having less fibrosis.[98] Many Touton giant cells were evident in 7/7 of the XLLs but only 1/14 classic xanthelasmas.[98] More than 30% of the foam cells were immunoreactive *(Print pagebreak 822)* using antibodies to factor XIIIa in all XLLs of ECD but only 3/14 classic xanthelasmas.[98] The *BRAF* ^{V600E} mutation was present in all 10 XLLs.[98] Kobic et al.[99] identified cutaneous lesions in 15 of 71 patients with ECD, 8 of which were XLLs and 5 subcutaneous nodules having deep dermal and pannicular xanthogranulomatous infiltration of epithelioid and foamy histiocytes with scattered lymphocytes and occasional Touton giant cells.[99] One patient had a granuloma annular-like lesion.[99] Ozkawa and coworkers reported histological findings from 19 skin biopsies in 7 patients.[100] Ten biopsies had small aggregates of xanthomatous histiocytes in the dermis with Touton giant cells, two lesions had a neutrophilic infiltrate with microabscesses, and four had histiocytes in an interstitial and perivascular pattern.[100] There was a varying degree of stromal fibrosis in the skin lesions.[100] Orbital ECD exhibits nodular to diffuse sheets of foamy histiocytes, variable numbers of dispersed and/or aggregated lymphocytes and plasma cells, and sclerotic bands separating the histiocytes (Figure 124.8).[100]

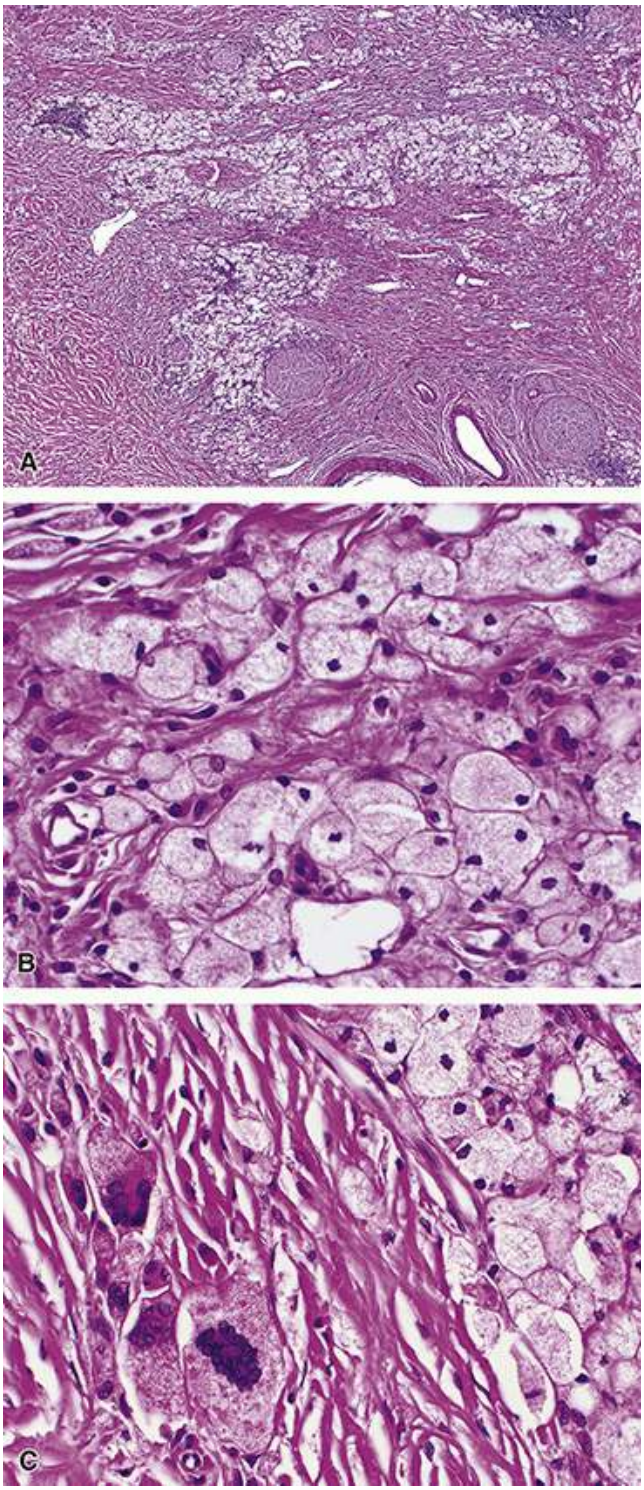

FIGURE 124.8 A, Orbital Erdheim-Chester disease showing islands of pale-staining foam cells separated by whorls of dense fibrosis. Several lymphoid aggregates are also evident. B, The foam cells are histologically similar to those in juvenile and adult xanthogranuloma and xanthelasma. C, High magnification showing Touton giant cells separated from foam cells by dense fibrous tissue.

Chapter 110 provides a detailed description of the histopathology of RDD. Briefly, cutaneous RDD has dermal or dermal and subcutaneous infiltration of large, S100+ histiocytes mixed with plasma cells, lymphocytes, and neutrophils.[101,102,103,104] Leukocytes within the cytoplasm of the histiocytes (emperipolesis[105]) is a constant feature of RDD, but it is less common in extranodal than nodal RDD.[6]

As can be seen from the above descriptions, there is a significant overlap in the histopathological features of the xanthogranulomatous processes affecting the periocular tissues. Diagnosis requires correlating clinical and histological features, and even then, a definitive diagnosis may not be possible for these rare lesions.

CHAPTER 125

Xeroderma Pigmentosum

Key Points

- Xeroderma pigmentosum (XP) is an autosomal recessive hereditary disease
- It is a congenital sensitization of the skin to ultraviolet radiation, due to a defect in normal nucleotide excision and repair pathways involved in repairing the DNA damaged by ultraviolet radiation
- More than 90% of patients with XP may have nonmalignant ocular manifestations including photophobia, blepharospasm, conjunctivitis, corneal neovascularization, dry eye, keratitis and corneal scarring, ectropion due to skin atrophy, blepharitis, conjunctival melanosis, or cataracts
- The risk of developing cancer in these patients is extremely high, and malignant and premalignant conditions include conjunctival intraepithelial neoplasia, squamous cell carcinoma, basal cell carcinoma, malignant melanoma, or keratoacanthoma
- Neurologic manifestations are seen in approximately 25% of patients
- There is no cure for XP, although a complete and consistent UV radiation protection is paramount
- Localized ocular surface tumors can be treated by surgical excision with cryotherapy to the remaining conjunctival margins; however, diffuse lesions are more difficult to treat
- With early diagnosis, appropriate protection from sunlight, and timely surveillance and management of cutaneous and ocular complications, the prognosis is generally good

Xeroderma pigmentosum (XP) is a rare autosomal recessive disorder. The worldwide prevalence is variable, affecting one per million population in the United States, 2.3 per million in Western Europe, and 45 per million in Japan.[1,2,3] Higher frequencies have also been reported in North Africa and the Middle East.[1,2,4,5,6,7]

XP was first described in 1874 by Hebra and Kaposi[8] based on four patients having thin, parchment-like dry skin, with wrinkling of the epidermis, checkered pigmentation, dilatations of blood vessels, and skin contraction. They also mentioned a red, fissured tumor that had developed on the skin within 1 year. The disease was further defined in later reports where neurologic abnormalities were described in some patients.[9] In 1932, de Sanctis and Cacchione described three brothers from the same family with features of XP and mental deficiency, associated with dwarfism, gonadal hypoplasia, and progressive neurologic degeneration beginning at 2 years of age.[10]

As early as 1926, the disease was recognized as a congenital sensitization of the skin to ultraviolet (UV) radiation,[10,11] and subsequent investigations confirmed the role of UV radiation in its pathogenesis.[12] Cleaver[13] described defective DNA repair in cultured skin fibroblasts, and other studies showed that XP cells were not able to eliminate UV photoproducts or to repair areas of UV-damaged DNA.[14,15,16,17,18]

In 1971, a variant of XP was described with normal DNA repair mechanisms and normal UV sensitivity.[19,20,21,22,23] Patients with the XP variant (XPV) retain a normal nucleotide excision repair (NER) pathway but have a defect in *POLH,* which encodes the protein DNA polymerase *eta* required to replicate DNA containing unrepaired damage.[20] While mostly uncommon, XPV may comprise as much as 25% of the patients with XP in Japan.[6,24,25] Patients with XPV may have a clinical presentation distinct from those with NER-deficient XP and may display a delayed onset of symptoms and lack of neurologic findings, and show disease with variable severity.[6,24,26] Patients with XPV typically do not sunburn or present with severe sunlight sensitivity. They tend to be spared the neurologic findings seen in many NER-deficient patients,[6,24,26] and also often have a better prognosis and longer life expectancy.[24] There are reports of patients with XPV having their first skin cancer as early as 7 years of age[26] to as late as 71 years.[6] In one study, up to 40% of patients with XPV developed melanoma, and most had nonmelanoma skin cancers.[24,26]

There are eight XP complementation groups, corresponding to eight genes involved in the repair of UV-induced damage in DNA. The first seven genetic groups of XP (A through G) are related to defects of genes in the NER system that are required to remove UV damage from the DNA. The eighth genetic group, XP-variant, is related to an abnormality in transcription that is required to replicate DNA containing unrepaired damage. These genetic defects are responsible for the wide variability in clinical features both between and within XP groups.[27,28,29,30,31,32,33,34,35] Patients with XP from complementation groups C, E, and V (where TC-NER is preserved) have normal sunburn reactions and do not develop manifest neurodegeneration,[36] but they have an earlier age of onset of first skin cancer. However, patients with XP from complementation groups A, B, D, F, and G (where TC-NER is impaired) have severe and exaggerated sunburn reactions on minimal sun exposure and suffer neurodegeneration.[36]

(Print pagebreak 827)

The diagnosis of XP is made largely on clinical presentation and manifestations. These include acute sunburn reaction from birth, early lentiginosis, or onset of skin cancers at a very young age[4] and can be confirmed by cellular tests for defective DNA repair.

Etiology and Pathogenesis

UV light is the most mutagenic component of sunlight.[37] Solar UV radiation is grouped into three ranges of wavelength: UVC (200-280 nm), UVB (280-320 nm), and UVA (320-400 nm) light.[38] UVB and UVA can pass through the Earth's ozone layer, and UVA contributes 95% of the total UV energy that reaches the surface.[39] Moreover, the wavelengths of UVA can penetrate more deeply into exposed skin, where they can initiate cell damage.[39,40,41]

UV-induced mutagenesis is characterized by a high frequency of transition mutations at dipyrimidine sequences containing cytosine,[42] resulting in dipyrimidine DNA photoproducts. In XP, unrepaired DNA segments lead to errors during replication, incorporating the wrong nucleotides in regions of UV damage. In addition, UVA photons induce photosensitization reactions that form reactive oxygen species that cause DNA damage,[43,44,45,46,47] by oxidation, single- and double-stranded breaks, and cross-links between DNA and proteins.[48,49,50]

UV-damaged DNA bases are repaired by the NER system. This involves two distinct pathways. The global genome repair (GG-NER) pathway recognizes damage in DNA that is not being transcribed and is capable of repairing photodimers in chromatin of different compaction levels and different functional states. The transcription-coupled repair (TC-NER) pathway recognizes when RNA polymerase stops in transcriptionally active genes and enables quick resumption of UV-inhibited transcription by efficient repair of the photodimers.[51] Mutations affecting individual components of these subpathways result in clinical syndromes. Defects in the GG-NER components (seen in XPC and XPE types) usually lead to pure XP with no neurologic abnormalities. Defects in TC-NER lead to XP with severe neurologic abnormalities.

The repair of UV-induced DNA damage involves several steps.[52] The UV-induced nucleic acid-based photoproducts serve as a substrate for DNA repair that is mediated by the transcription-coupled and global genome NER repair pathways.[51] These lead to unwinding of the DNA helix in the region of damage, excision of small fragments of the damaged genome, and repair by DNA synthesis pathways that involve DNA polymerase and ligases.

Clinical Characteristics

The clinical manifestations of XP are seen most commonly in sun-exposed areas of the skin and mucous membranes. Some patients show a relatively normal response to sun exposure, but about 60% have an exaggerated response to UV exposure with pronounced burning and blistering even with minimal exposure to sunlight. All affected patients develop freckle-like pigmentary changes in skin areas exposed to the sun and eventually develop poikiloderma, which consists of areas of hyperpigmentation and hypopigmentation, skin atrophy, and telangiectasias (Figure 125.1). This freckling pigmentation usually appears before the age of 2 years.

More than 90% of patients with XP may have ocular manifestations including photophobia and secondary blepharospasm, conjunctivitis (51%), corneal neovascularization (44%), dry eye (38%), keratitis and corneal scarring (26%), ectropion from atrophic skin (25%), blepharitis (23%), conjunctival melanosis (20%), and cataracts (14%).[1,53,54] Other findings may include pterygium, pinguecula, loss of lashes, Bowman layer breaks, ciliary body hamartoma, macular edema, chorioretinal adhesions, pigmentary retinal degeneration with pigment migration, cystoid degeneration, gliosis, drusen, and optic nerve atrophy.[53,55] In the iris, iritis, stromal atrophy, pigment abnormalities, and, rarely, melanoma have all been described.[56] The posterior ocular segment is protected from UV damage by the cornea and lens so that fundus abnormalities are not common. Nevertheless, choroidal melanoma can rarely develop.[57]

Malignant lesions are a common finding in patients with XP, but the reported frequencies of occurrence vary widely. Brooks et al reported ocular surface neoplasia in 10% of 87 patients with XP in the United States,[53] whereas Kaliki et al[58] found 72% of 120

patients with XP in India with ocular surface cancers. Nevertheless, the risk of developing cancer in these patients is extremely high. The mechanism of carcinogenesis appears to be the same in XP and the general population, but the age of onset of these tumors in patients with XP is in the first to second decades, compared with the sixth and seventh decades in the general population.

Compared with the general population, patients with XP under age 20 years have a 10,000-fold increase in the frequency of nonmelanoma skin cancer, a 2000-fold increase in melanomas, a 1000-fold increase in cancer of the sun-exposed tissues of the eye, and a 100,000-fold increase in tongue cancers.[59,60] About 80% of nonmelanoma cancers occur on the face, head, and neck.[59] In contrast, more than 45% of melanomas in patients with XP occur on the extremities. In the report by Kaliki et al,[58] among 120 patients with XP, 72% had conjunctival or corneal tumors of which squamous cell carcinoma was the most common (41%) and 44% were bilateral. Eyelid tumors were seen in 13% of patients, of which 50% were basal cell carcinomas and 7% were bilateral.

Intraepithelial neoplasia (CIN) is a premalignant lesion of the conjunctiva that is seen in patients with XP and may vary from mild to severe depending on the depth of conjunctival epithelial dysplasia.[1,61] Invasive cancers affecting the ocular surface and adnexa include squamous cell carcinoma, basal cell carcinoma, and malignant melanoma. Other less common skin tumors include keratoacanthoma and fibrosarcoma.[1] Angiosarcoma of the tongue has also been reported.[62] The median age for the first appearance of *(Print pagebreak 828)* skin cancer is 9 years (age range of 1-32 years) for nonmelanocytic skin cancer and 22 years for melanoma (age range 2-47 years).[60] Patients with XP also have a 50-fold increased risk of developing brain tumors, such as medulloblastoma, glioblastoma, spinal cord astrocytoma, and schwannoma.[52]

Neurologic manifestations are seen in approximately 25% of patients and do not occur in all XP types. It is most commonly associated with XPA, XPB, XPD, XPF, and XPG and rarely with XPC and XPE.[52,60,63] Defects include microcephaly, diminished or absent deep tendon reflexes, ataxia, cortical atrophy and ventricular dilatation, progressive sensorineural hearing loss, and progressive cognitive impairment.[60] DeSanctis-Cacchione syndrome is a rare form of XP characterized by severe neurologic disease with dwarfism and immature sexual development.

Differential Diagnosis

The classic clinical features of XP distinguish it from other diseases that superficially can appear similar. These include other solar dermatoses such as solar urticarial and polymorphic light eruption.[4] Cockayne syndrome is a rare genetic disorder affecting children from birth to 1 year and is characterized by a prematurely aged face, growth disorders, intellectual deficits, and decreased vision and hearing, but it is not associated with pigmentary changes and results from different DNA repair defects. Rare genetic disorders with

lentiginous pigmentary changes include Peutz-Jeghers syndrome, a hereditary cancer syndrome with increased risk for a wide variety of malignancies most commonly gastrointestinal, and also gynecologic cancers in females and testicular cancer in males. Leopard syndrome is another rare genetic disorder characterized by multiple lentigines, cardiac conduction defects, growth retardation, and sensorineural deafness. Carney Complex is an autosomal dominant disorder with lentiginoses and multiple endocrine neoplasms. But in these disorders, the pigmentary abnormalities are not associated with UV exposure.

Common freckles may appear similar to the lentiginoses of XP, but their presence is limited to the face and does not extend to the neck, the dorsum of the hand, and the upper chest, and patients do not have photosensitivity.[64] *(Print pagebreak 829)* Dyschromatosis symmetrica hereditaria is an autosomal dominant disorder mainly affecting patients from East Asia, in whom skin areas develop mixed hyper- and hypopigmentation on the face, as well as the dorsum of the hands and feet. Several patients have also been described with mental deterioration. Erythropoietic protoporphyria is another autosomal dominant inherited disease characterized by loss of function of ferrochelatase, an enzyme of the heme biosynthesis process. Acute reactions such as edema, erythema, and blistering occur on the skin after sun exposure leaving a small scar.

Treatment

There is currently no cure for xeroderma pigmentosum. Complete and consistent UV radiation protection is of major importance in reducing the risk of severe sunburn and the occurrence of skin cancers. These include layered clothing, the use of sunscreen, and eye protection with UV-absorbing sunglasses and artificial tears.[65,66] Systemic retinoid treatment may also offer some benefit in reducing the number of skin cancers.[67] Early resection of premalignant and malignant lesions is important for survival.

Localized ocular surface tumors can be treated by surgical excision with cryotherapy to the remaining conjunctival margins.[68] Topical chemotherapy with 0.04% Mitomycin C has been used as monotherapy for treatment or as adjuvant therapy following surgical excision.[69] Diffuse lesions are more difficult to treat and are associated with a higher rate of recurrence.[70,71] Malignant limbal tumors have been removed with iridocyclectomy, and rare cases of extensive disease may require enucleation.[72] XP-associated neoplasia of the eyelids and ocular surface have been treated with subconjunctival injections of pegylated interferon-alpha 2b and topical mitomycin C with promising results.[73] Iris tumors have been managed with local excision, plaque radiotherapy, or enucleation.[74]

Premalignant skin lesions such as actinic keratosis can be treated by freezing with liquid nitrogen or topical applications of 5-fluorouracil. For malignant skin tumors, surgical extirpation with negative surgical margins is the appropriate standard, followed by eyelid reconstruction as needed. Patients should be encouraged to undergo regular skin surveys by a dermatologist every 3 to 6 months to examine for the presence of new premalignant or malignant neoplasms.

There is no useful therapy for the neurodegeneration seen in XP, and rehabilitation is offered for motor impairment and intellectual disabilities. Hearing loss often affects children of school age, so that hearing tests should be carried out at regular intervals and a hearing aid device prescribed early if indicated.

Because XP is a hereditary disease, genetic counseling should be given to all patients with XP and their parents. Genetic analysis can be conducted by polymerase chain reaction-restriction fragment length polymorphism for XPA, or by a sequence of all exons for other XP types.

Prognosis

Once the diagnosis of XP is made, the strict requirement for protection from sunlight and the limitations of going outdoors during the day often has a significant effect on the quality of life for both patients and their families. Patients with neurological symptoms experience a significant functional disability that may require lifelong rehabilitation and care. Patients can sometimes experience choking and dysphagia from vocal cord paralysis and larynx dystonia.

The frequent occurrence of skin cancers requires constant surveillance and treatment, often with surgery whenever indicated. Death from skin malignant tumors is not common because of the early diagnosis of XP in most cases, and in one large series of 120 patients from India followed over a mean of 61 months, only 2% developed regional lymph node involvement and 1% died from distant metastasis.[58]

With early diagnosis, appropriate protection from sunlight, and timely surveillance and management of cutaneous and ocular complications, the prognosis is generally good.

Histopathology

The nonneoplastic cutaneous histopathological manifestations of XP were characterized in the late 1800s and early 1900s.[75,76,77,78,79,80,81] Unna provided detailed histological findings from skin biopsies of two brothers with XP, although biopsies were not available for the initial stage of "erythrodermia."[75] During the second stage of the disease, manifest clinically as "small, brown, freckled pigmentation, with persistent roughness of the surface," Unna noted dense melanin pigmentation at angles of the rete pegs (ridges) and in small areas of the basal prickle cells elsewhere. In the least pigmented spots, melanin was present in basal cells with scattered intercellular streaks of melanin in the upper stratum spinosum (prickle cell layer) and smaller intercellular streaks in the stratum granulosum (granular cell layer) and stratum corneum (horny layer). The prickle cell layer was not widened overall, but the rete pegs were more numerous and broader than normal.[75] The granular cell layer was two to three rows thicker than normal, and the horny layer was "much thickened" with "distinct hyperkeratosis."[75] There was a diffuse widening of the papillary dermis by dilated veins having swollen endothelial cells.[75] Brayton noted a similar prominence of melanin accumulation in the lower layers of the rete pegs.[82]

Unna described the third or "acme" stage of XP as clinically having "white or mother-of-pearl spots" without pigment or blood vessels located between pigmented spots that have increased in number, size, and color.[75] Dilated veins *(Print pagebreak 830)* (telangiectasias) often surrounded the white spots.[75] Unna histologically noted increased thickening of the horny layer, further thickening of the granular cell layer in most areas, and deformation of the prickle cell layer with marked accumulation of melanin in the basal prickle cells. There was thinning of the prickle cell layer to only two to three cells at the sites of most abundant melanin. Areas of maximum epithelial pigmentary change had associated abnormalities in the papillary dermis and upper half of the "cutis": there was thickened papillary dermis having "active multiplication of the connective tissue cells, which are usually smaller, spherical, and show little protoplasm."[75] Melanin permeated the papillary dermis and cutis, both extracellularly and within the connective tissue cells, appearing as a black network.[75] Unna reported, "Several of the small, warty spots before me show a striking collection of cells and pigment in the papillary body and in the upper half of the cutis, so that these parts are three to four times thicker than the neighborhood, and the epidermis is arched over them."[75] Dilated lymphatics were within the pigmented cellular masses.[75] The white spots had broad prickle, granular, and horny layers without overall epidermal atrophy, and there was "almost complete" absence of dermal papillae with diminished capillaries.[75] The reticular dermis was sclerotic, resembling that in scleroderma. Pollitzer[77] and Councilman and Magrath[78] also noted sclerotic dermis. The telangiectasias observed clinically corresponded to dilated veins surrounding the areas of capillary loss,[75] as also recorded by Pollitzer.[77] Follicular and sebaceous gland atrophy were present only in areas of dermal sclerosis.[75,77]

Montgomery and Reuter examined the histopathological features in skin biopsies from a 32-year-old woman with a mild case of XP.[80] A pigmented macule had hyperkeratosis and marked atrophy of the prickle cell layer, especially over the dermal papillae, with areas of stratum corneum overlying a pigmented basal layer.[80] Rete pegs featured marked irregular proliferation of pigmented basal cells with extension deep into the dermis.[80] The papillary dermis contained "many large chromatophores" (presumably melanophages) and melanin-laden fibroblasts.[80] Epidermis adjacent to the macule had hyperkeratosis, mild intracellular edema of the basal and prickle cells, normal stratum granulosum, and normal melanin pigmentation.[80] The authors opined that the diagnostic histopathologic features of XP are a "relative and absolute hyperkeratosis; a varying degree of atrophy of the prickle cell layer, especially over the papillary bodies; irregular proliferation and prolongation of the rete ridges; intracellular edema of the cells of the epidermis, with pyknosis or karyorrhexis resulting therefrom; edema of the papillary bodies and upper part of the cutis, with resultant narrowing of the rete ridges; some dilation of the superficial vessels; a varying degree of perivascular infiltrate; a spotted melanin pigmentation of the epidermis, and in the upper part of the cutis, chromatophores laden with pigment."[80] Lynch observed similar changes in the skin from a 7-year-old child with XP and that parakeratosis occurred 24 hours after exposure to radiation.[81]

Malignant tumors in patients with XP do not differ from those in people not afflicted with the disease (Figure 125.2),[75,76,77,78,80,81,83,84,85,86] and the reader is referred to other chapters for a description of those lesions.

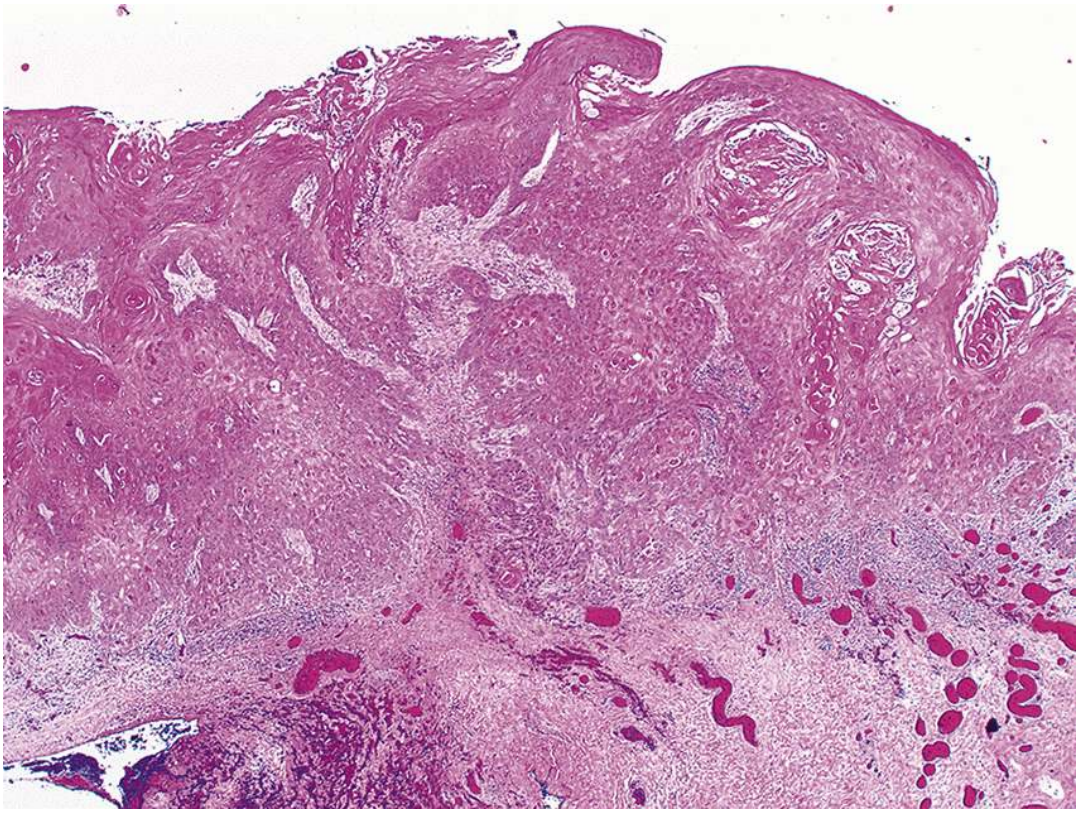

FIGURE 125.2 Invasive squamous cell carcinoma of the conjunctiva in a child with XP. The tumor is histologically the same as invasive squamous cell carcinoma of the conjunctiva in individuals without XP. (Photomicrograph prepared from a histological slide distributed by Dr. Fausto Rodriguez at the 2012 meeting of the Eastern Ophthalmic Pathology Society.)

CHAPTER 126

Adenoid Cystic Carcinoma

Key Points

- Adenoid cystic carcinoma (ACC) is an epithelial tumor that occurs primarily in the major salivary and lacrimal glands, and the skin can be involved secondarily through direct or perineural invasion or as a site of distant metastasis
- Primary cutaneous adenoid cystic carcinoma (PCACC) is a rare form mostly seen on the scalp and chest
- Eyelid PCACC has a propensity for middle-aged to elderly males and occurs equally in the upper and lower eyelids
- PCACC can arise from accessory glands in the conjunctiva and cutaneous accessory lacrimal glands of Krauss and Wolfring
- It has a predilection for older individuals, is slow growing, usually over months to years, and is locally aggressive with a tendency for perineural invasion
- Perineural invasion is found in more than 60% of cases
- The recommended treatment for PCACC is wide local excision with tumor-free margins established on permanent histologic sections
- Local recurrence is seen in up to 59%, and metastases in 17% of cases

Adenoid cystic carcinoma (ACC) is an epithelial tumor that occurs primarily in the major salivary and lacrimal glands. It is also seen rarely in other sites including the esophagus, bronchus, lungs, breast, vulva, cervix, and prostate.[1,2,3,4,5,6] The skin can be involved secondarily through direct or perineural invasion or as a site of distant metastasis.[7] A rare form of primary cutaneous adenoid cystic carcinoma (PCACC) was first described in 1975 by Boggio,[8,9] and since then just over 100 cases have been reported in the literature,[10,11,12] where it most often arises on the scalp in 40% and the chest in 18% of cases.[13] To date only about 12 cases involving the eyelid have been reported.[14,15,16] Eyelid PCACC has a propensity for middle-aged to elderly males and occurs equally in the upper and lower eyelids. An epidemiologic study using the Surveillance, Epidemiology, and End Results (SEER) program found 152 cases of PCACC diagnosed in the United States between 1976 and 2005, with an annual incidence of 0.23 cases per 1,000,000 population.[17]

Etiology and Pathogenesis

PCACC can arise from accessory glands in the conjunctiva and cutaneous accessory lacrimal glands of Krauss and Wolfring.[11] It is usually considered to originate from eccrine glands, but this tumor can occur in the ear canal, where there are no eccrine glands.[18] Some pathologic data indicate a more likely apocrine origin.[19]

Stenman et al described a t(6;9)(q22-23;p23-24) *MYB-NFIB* translocation in salivary gland and breast ACCs.[20,21,22] Additional studies showed that this chromosomal aberration in ACCs arises from other gland-bearing tissues, including the skin.[23] This translocation results in a fusion of the two transcription factor genes *MYB* and *NFIB* with activation of *MYB*. The *MYB* gene is amplified in carcinomas of the esophagus, colon, and breast, and North et al described the *MYB-NFIB* fusion product in 9 of 10 PCACC tumors.[23]

Clinical Presentation

PCACC preferentially affects older individuals with a median age of 60 years and a range from teens to old age. It is slow growing, usually over months to years, and is locally aggressive with a tendency for perineural invasion. They present as asymptomatic, flesh-colored, nontender, firm, indurated, and well-circumscribed nodules, often associated with madarosis (Figure 126.1). They may be

associated with eyelid edema, ectropion, or ptosis. Eyelid cases involve males more frequently than females, with an equal distribution between upper and lower eyelids, and range in diameter from 3 to 25 mm. The mean duration between the onset of disease and the final diagnosis is about 10 years.[12] Most reported cases were initially misdiagnosed as a chalazion, and the diagnosis of PCACC was established only on histopathology.[1,24,25]

PCACC is known to be locally aggressive and prone to metastasis. However, sentinel lymph node involvement may or may not be found on initial examination.[1,2] Perineural invasion (PNI) has been reported in more than 60% of cases, and recurrence after excision due to PNI has been observed in up to 59% of cases.[1,12,26]

Differential Diagnosis

Primary cutaneous adenoid cystic carcinoma of the eyelid most commonly mimics a chalazion. It may also simulate other benign lesions including syringoma, cylindroma, *(Print pagebreak 836)* apocrine cystadenoma, clear cell hidradenoma, and spiradenoma. It is also sometimes confused with other malignant tumors such as sebaceous carcinoma, adenoid basal cell carcinoma, other sweat gland tumors such as adenocarcinoma of Moll glands, polymorphous sweat gland carcinoma, and apocrine cribriform carcinoma.[16,27,28,29,30]

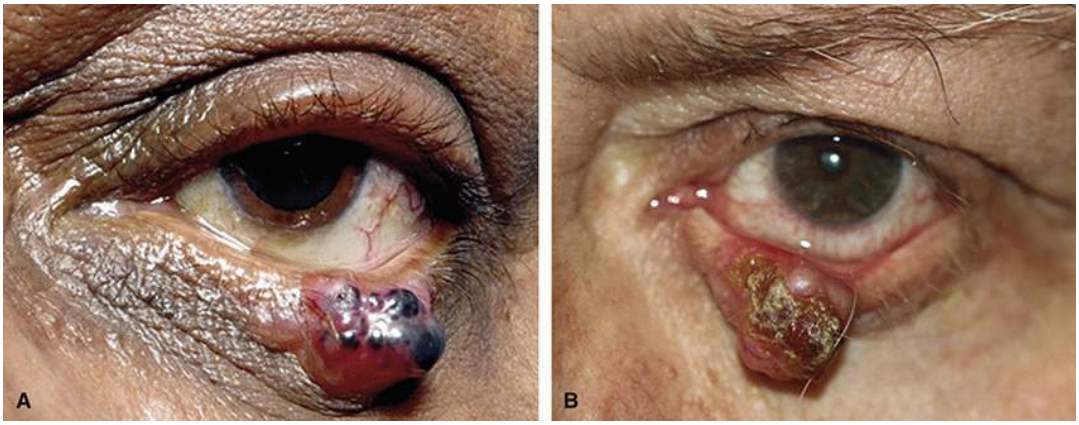

FIGURE 126.1 A and B, Indurated, nodular adenoid cystic carcinoma of the lower eyelids with madarosis.

Treatment

The recommended treatment for PCACC is wide local excision with tumor-free margins established on permanent histologic sections. Mohs surgery is felt to have greater sensitivity in the detection of PNI.[13,26,31,32,33] For tumors that exhibit PNI, Mohs surgery has been shown to result in lower rates of recurrence.[3,34]

Data are limited with regard to adjuvant radiotherapy, but some authors have advocated this modality to reduce local recurrence. When PNI is encountered in the surgical specimen, postoperative radiation therapy may be indicated to decrease the risk of local recurrence.[35] Radiation therapy in the periocular region must be carefully planned because of the risk of ocular damage. The total dose of radiation for PNI is usually in the range of 50 to 60 Gy.[25] Chemotherapy and radiotherapy remain the recommended therapeutic options in cases where total removal is not possible.[1,26]

Prognosis

Local recurrence is seen in up to 59%, and metastases in 17% of cases.[36] Both often appear many months or even decades after the initial surgery. Thus, long-term follow-up is warranted and should be performed in these patients.

PNI is found in more than 60% of cases[2,26,36] and is an important mode of tumor spread resulting in the high reported local recurrence rates. The interval from surgical excision to recurrence ranges from 4 months to 40 years.[26] Cases with multiple recurrences after standard local excision have also been reported.[26] Regional lymph node metastasis from primary cutaneous ACC can occur.[2,37,38,39,40] Distant metastasis represents a rare and late event primarily to the lungs, and less commonly to the liver and brain.[4,41,42,43]

Histopathology

PCACCs are poorly demarcated infiltrative tumors of the dermis and/or subcutaneous tissue (Figure 126.2A) with a predilection for PNI.[44,45,46] Basaloid tumor cells form cribriform, tubular, and solid patterns of varying shapes and sizes (Figure 126.2B-D), identical to those in salivary gland and lacrimal gland ACCs (Figure 126.3A and B).[44] The individual tumor cells are small to medium sized with scanty cytoplasm, hyperchromatic to vesicular nuclei, and variably sized nucleoli.[44] Mitotic activity is low, and tumor necrosis is rare.[45,46] Bilayered ducts and pseudocysts are the diagnostic features of PCACCs.[46] Pseudocysts contain lightly basophilic to lightly eosinophilic mucin (Figure 126.2C) that can be highlighted using alcian blue stain at pH2.5.[36,46] Most PCACCs are histologic grade 1 of 3, with grade 1 tumors having no solid areas, bland cytology, and few or no mitoses; grade 2 tumors having <30% solid area, more cytological atypia than grade 1; and grade 3 tumors having >30% solid areas, necrosis may be present, cellular atypia is increased, and mitoses are present.[36] The stroma is most often paucicellular and hyalinized, but it may have myoid change or fibrosis. Pathological staging of eyelid PCACC is similar to that of other eyelid malignant neoplasms.[47]

The immunohistochemical profile of PCACCs is the same as that of ACCs arising in the salivary and lacrimal glands.[44] Tumor cells stain positively for cytokeratins AE1/AE3, cytokeratin (CK) 7, and using CAM5.2 antibodies against CK8,[48] while staining for CK5/6 and podoplanin (D2-40) is variable.[44,45,46] If true ducts are present, the luminal cells express epithelial membrane antigen, carcinoembryonic antigen, and CK15, and myoepithelial cells stain for smooth muscle *(Print pagebreak 837) (Print pagebreak 838)* actin, p63, and calponin.[46] SOX10 is expressed in the nuclei of both basaloid and myoepithelial cells. Tumors diffusely stain for CD117, and most tumors express MYB.[46] Eyelid PCACC cannot be differentiated histologically from metastasis of a visceral ACC or direct extension from a lacrimal gland ACC (Figure 126.3A and B), which rely on clinical correlation. Primary cutaneous malignancies that require differentiation from PCACC are adenoid basal cell carcinoma and cribriform carcinoma. Adenoid basal cell carcinomas have peripheral palisading of tumor cells, lack true ducts, have at least focal areas of conventional basal cell carcinoma, and exhibit stromal cleft (retraction) artifact.[44,46] Cribriform carcinoma, also known as cribriform apocrine carcinoma, has more eosinophilic tumor cells; lacks myoepithelial cells, mucinous pseudocysts, and an infiltrative growth pattern; has focal solid areas; and exhibits thin, thread-like, intraluminal bridges.[44,46] Spirademonas may occasionally have areas resembling ACC but can be distinguished from PCACC by areas of typical spiradenoma with a dual cell population and lack of cytological atypia, mitoses, and PNI.[44]

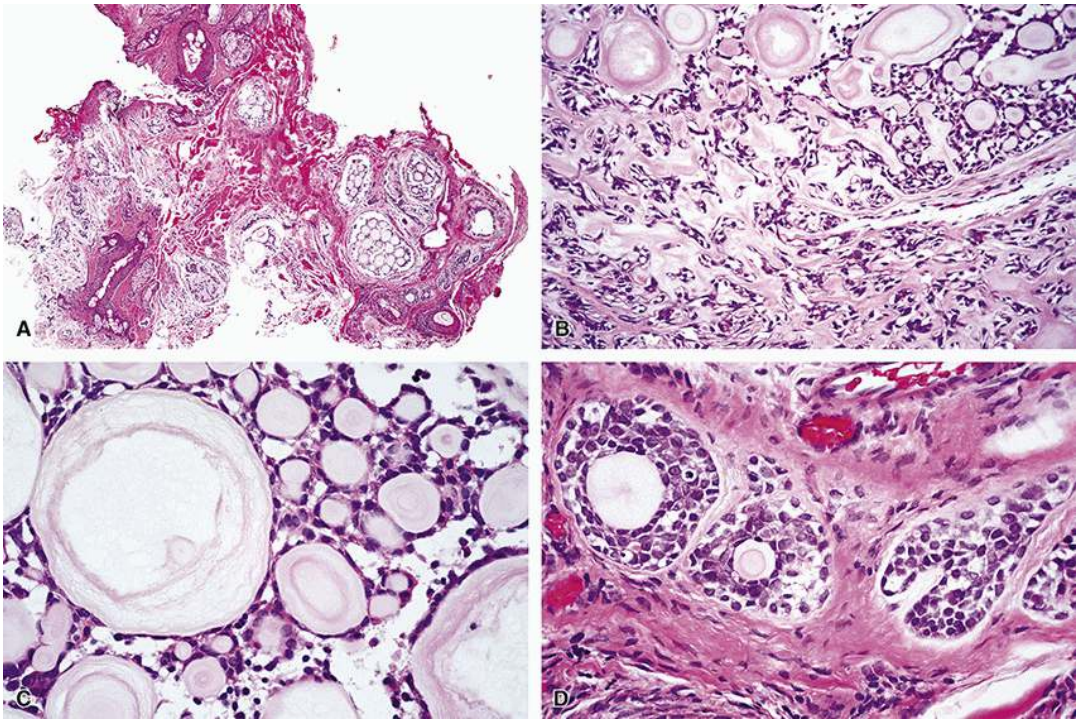

FIGURE 126.2 This adenoid cystic carcinoma arose in the left upper eyelid of a man in his mid-30s. A, Tumor infiltrated the dermis and orbicularis oculi. B, The tumor cells formed tubules (bottom of image) or a cribriform pattern with pseudocysts containing lightly eosinophilic mucin. C, Higher magnification showing tumor cells with hyperchromatic nuclei and scant eosinophilic cytoplasm having a cribriform pattern with pseudocysts. D, In another area of the tumor (bottom right of Figure 126.2A), the tumor cells are multilayered and form pseudocysts or solid islands. (Photomicrographs were prepared from a slide distributed by Dr. Ahmed Hidayat at the 1994 meeting of the Eastern Ophthalmic Pathology Society.)

CHAPTER 127

Angiosarcoma

Key Points

- Angiosarcoma is a rare aggressive malignant tumor of vascular origin
- About 62% occur in the head and neck region, more common in men in the 6th to 8th decades
- The pathogenesis is poorly understood, and the tumor may originate from vascular or lymphatic endothelium
- It usually presents as single or multiple benign-appearing bruise-like macules or nodules, often associated with erythema, chronic edema, or cellulitis
- They are often misdiagnosed as more common lesions such as basal cell carcinoma or pyogenic granuloma
- The role of surgery alone as initial treatment has decreased to less than 20%, over the past several decades, and positive margins are common even after wide resection
- Radiotherapy combined with surgery offers the best chance for long-term tumor control
- The ultimate prognosis remains poor with a mean 5-year survival of 33.5%

Angiosarcoma is a rare, aggressive malignant tumor of vascular origin that may originate anywhere in the body. It represents 1 in 10,000 cases of malignant neoplasms and accounts for 1% to 2% of all soft tissue sarcomas. About 62% occur in the head and neck region most often in men over the age of 55 years,[1,2,3] with a mean age at presentation of 71 years.[4] The eyelids are affected less often,[5,6,7] and orbital involvement is very rare.[8]

Etiology and Pathogenesis

The pathogenesis of angiosarcoma is poorly understood. The tumor may originate from vascular or lymphatic endothelium or both.[9] In most cases, it develops de novo without predisposing conditions, although its predilection for sundamaged skin of the head and neck suggests a role for solar damage.[5] It has been reported to develop 5 to 10 years following radiation therapy for preexisting lesions,[10,11,12] at sites of chronic lymphedema in Stewart-Treves syndrome,[8,13] and after exposure to some imaging contrast agents and insecticides.[4,8,14] Four cases of angiosarcoma arising from malignant transformation of benign/vascular malformations have been described.[15] Angiosarcoma has also been associated with xeroderma pigmentosum in six reported cases, possibly related to the nucleotide excision repair defect resulting in defective repair of DNA damaged by ultraviolet and ionizing radiations.[16,17,18,19] Since angiosarcomas are endothelial-cell tumors, it has been suggested that angiogenic factors might be associated with their pathogenesis, which could allow for novel targeted treatment. VEGF and its receptors are overexpressed in angiosarcomas at higher concentrations than in benign vascular or normal tissue controls.[20]

The cytogenetics of angiosarcomas shows a wide range of nonspecific chromosomal abnormalities including trisomy 5; deletions on chromosome 7p; abnormalities on chromosomes 8, 20, and 22; and loss of chromosome Y.[20] No consistent genetic abnormalities are found in cutaneous angiosarcoma, but some cases have mutations in *TP53*, *PTPRB, PLCG1, CDKN2A,* or *MYC*. *NUP160-SLC43A3* gene fusion occurs in 36% of cases.[21]

Clinical Presentation

Angiosarcomas usually present as single or multiple benign-appearing bruise-like macules or nodules, often associated with erythema, chronic edema, cellulitis, or even as a hematoma.[22,23,24,25,26] Occasionally, they may appear as rosacea-like lesions and can simulate localized bacterial or fungal infections.[27] When on the eyelid, they may be violaceous, yellow, or flesh colored; may bleed intermittently; and occasionally are associated with pain (Figure 127.1). Demirci and Christanson[28] reviewed 22 published

cases of eyelid angiosarcoma and noted that 38% presented as an erythematous nodule, 25% as a violaceous maculopapular lesion, 13% as a yellow plaque or infiltrative lesion, and 13% as a yellow nodule. Tumors may be more extensive into deeper tissues, beneath a relatively less conspicuous surface lesion.[29]

When more advanced, angiosarcomas can become very large, elevated, and even ulcerated (Figure 127.2).[30] Because of their variable appearance, definitive diagnosis is often delayed up to 18 months.[29] They are often misdiagnosed as more common lesions such as basal cell carcinoma or pyogenic granuloma.[4] They characteristically spread widely through the skin and soft tissue of the head and neck region, and eyelid tumors may extend into the orbit in about 4% of cases.[29,31]

Differential Diagnosis

The differential diagnosis includes ecchymosis, hemangioma, Kaposi sarcoma, xanthelasma, contact dermatitis, lupus-related lesions, intravascular papillary endothelial hyperplasia, angiolymphoid hyperplasia with eosinophilia, and focal infections.

Treatment

The treatment of angiosarcoma remains without any accepted standard guidelines. Local surgical excision was the mainstay of therapy several decades ago. However, the role of surgery as the initial treatment modality has decreased significantly over the past 30 to 40 years, from 80% to less than 20%.[32] It is common to see positive microscopic margins even after wide surgical resection. Pawlik et al[33] reported that, among 18 patients with a clinical estimate of tumor size <5 cm (stage T1), 11 (38%) were >5 cm (stage T2) after histopathologic evaluation of margins. Also, when the eyelids and especially the medial canthus are involved, complete surgical removal may not be possible. As a result, surgery is now usually combined with electron-beam radiotherapy.[33]

Angiosarcomas have been treated with wide-field radiotherapy at doses >50 Gy. Although radiation therapy alone is generally thought to be an inadequate treatment for curative intent, Ogawa et al[34] reported that, among 25 patients who received radiation monotherapy alone, 79% who received >70 Gy achieved local control, whereas only 27% who received <70 Gy achieved similar control. A study by Scott et al[35] of 41 patients treated with radiation therapy recommended at least 60 to 65 Gy for the postoperative tumor bed after surgery and 70 to 75 Gy for patients who receive radiation monotherapy. However, current opinion is that radiotherapy combined with surgery offers the best chance for long-term tumor control.[36] Mark et al[4] reported better survival after 32 months when surgery was combined with radiotherapy, compared with surgery without radiotherapy. In difficult cases where complete surgical excision is not possible, radiotherapy alone may be the only reasonable alternative, but this usually results in only a partial response.

(Print pagebreak 842)

The role of chemotherapy remains undefined. While it has been shown in some studies to improve local tumor control,[32] chemotherapy does not appear to change overall survival.[32,37,38,39] Chemoradiation is a newer option employing chemotherapy with taxanes combined with radiotherapy without surgery. This has been reported to achieve a 5-year survival of 56% compared with 8% for conventional surgery and radiotherapy.[40]

Eyelid angiosarcoma has been treated with intravenous recombinant interleukin-2 (rIL-2) into the external carotid or facial arteries and intralesionally through a catheter-port system into the lesion.[41] IL-2 is an activator of lymphokine-activated killer T cells that damage vascular endothelial cells causing lysis. Angiosarcoma cells have been shown to be sensitive to lymphokine-activated killer cells in a mouse model.[42] IL-2 has been reported to be effective either as monotherapy in cases of recurrent tumor or in combination with radiotherapy or chemotherapy.[43,44]

Cutaneous angiosarcomas show high levels of PD-L1 expression, making them potential candidates for targeted immune checkpoint inhibitor therapy.[45] Emerging data suggests that immune checkpoint blockade may be efficacious against some types of angiosarcomas, especially head and neck cutaneous tumors. In one study of 35 patients with a histologically confirmed angiosarcoma treated with immune checkpoint blockade, a durable clinical benefit, defined as a progression-free survival (PFS) of ≥16 weeks, was seen in 13/35 (37%).[46] Analysis showed that responsive tumors were more likely to be on the head and neck, and to have a higher tumor mutational burden, greater upregulation of angiogenesis, inflammatory response, and KRAS signaling pathways, as well as higher levels of cytotoxic T cells, dendritic cells, and natural killer cells.

Prognosis

Despite various available treatment options, long-term survival with angiosarcoma remains poor.[47] In a meta-analysis of prognostic factors, Shin et al[47] evaluated 10 studies with a total of 379 patients and found a mean 5-year survival of 33.5% (11.1% to 53.8%), with major negative risk factors being age >70 years, tumor size >5 cm, tumor site, and resection margin status. In a Surveillance, Epidemiology, and End Results Program (SEER) analysis of 1250 patients with primary head and neck angiosarcomas, of which 93.5% were cutaneous, the overall and disease-specific 5-year survivals were 26.5% and 48.3%, respectively.[47] Older age, increased tumor size, and the presence of distant disease were independent predictors of poor overall survival, while lower histologic grade and surgery did not improve survival when other risk factors were controlled.[47]

The results of wide-margin surgery alone have not been favorable for survival, with reported recurrence rates of 26% to 100%, the higher percentages possibly due to more advanced staging at the time of treatment.[48,49] Multifocal lesions with skip lesions require wide surgical margins of 3 to 5 cm, and because of the often delayed diagnosis, subclinical metastases may be fairly common. Tumor spread is by hematogenous dissemination and is often present at the time of diagnosis. Metastases to the cervical lymph nodes, lung, liver, and bone occur in approximately one-third of patients.[50,51] The overall prognosis for life is relatively poor, with reported 5-year survival rates of 9% to 54%.[52,53] Eyelid tumors may have a lower metastatic potential and a somewhat better prognosis.[31]

Positive prognostic factors include early detection, small size <5 cm, negative surgical margins, absence of metastases, and the presence of inflammatory infiltrate.[4,54,55,56,57]

Histopathology

The appearance of cutaneous angiosarcomas varies widely, depending mostly on the degree of differentiation.[30,58,59,60,61] Tumors are usually graded from I to IV with grade I being well differentiated, II moderately differentiated, III poorly differentiated, and IV undifferentiated.[57] However, differentiation is not a component of tumor staging since all cutaneous angiosarcomas are considered aggressive tumors.[58,62] Angiosarcomas isolated to the eyelid, which is much less common than those involving the eyelid and other structures, tend to be well differentiated.[31]

Well-differentiated cutaneous angiosarcomas feature anastomosing dilated vascular channels with inconspicuous endothelial cells (Figure 127.3A). Well-differentiated tumors are distinguished from hemangiomas by their architecture, with dissection through dermal collagen, fascia, and subcutaneous adipose tissue, along with isolation of adnexal structures in a network of vessels. Papalas and coworkers found that neoplastic blood vessels surrounding adnexal structures were a helpful clue in diagnosing well-differentiated angiosarcomas of the eyelid.[31] Moderately differentiated angiosarcomas have more irregular anastomosing vascular channels with more prominent and cytologically atypical endothelial cells (Figure 127.3B). Poorly differentiated tumors have sheets of pleomorphic mitotically active cells with poorly defined vascular channels (Figure 127.3C). Immunohistochemical stains using antibodies to CD31 (Figure 127.3D) and ERG (erythroblast transformation-specific transcription factor) are particularly useful for confirming the diagnosis of poorly differentiated or undifferentiated angiosarcomas,[61,63] although staining for ERG is less specific than that for CD31.[64] Immunohistochemistry is also useful in diagnosing other variants such as epithelioid, clear cell, foam cell, signet ring, and granular cell angiosarcomas. It is critical to remember, however, that none of the immunostains are specific for angiosarcomas.[61] Positive immunohistochemical staining using antibodies to CAMTA1 or demonstration of *WWTR1-CAMTA1* gene fusion is found in 85% to 90% of epithelioid hemangioendotheliomas, a tumor that is less aggressive and more sensitive to chemotherapy than angiosarcoma.[65]

The differential diagnosis of cutaneous angiosarcoma is broad, depends on the degree of differentiation and tumor *(Print pagebreak 843)* variant, and was reviewed in an excellent update by Shustef and colleagues.[61] Milman et al reported a well-differentiated angiosarcoma of the eyelid mimicking a hobnail hemangioendothelioma, emphasizing the challenge in diagnosing some well-differentiated tumors.[66]

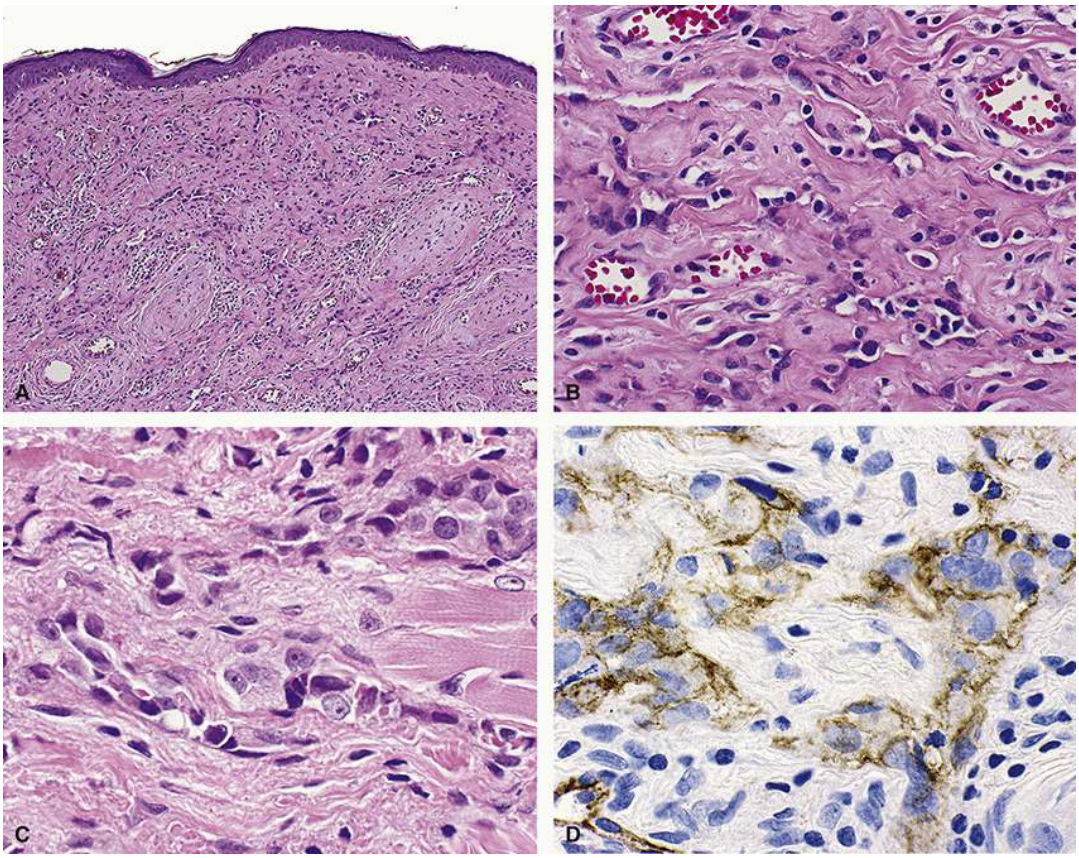

FIGURE 127.3 This angiosarcoma arose in the left lower eyelid of a woman in her middle 50s. There were multiple tumor recurrences, followed by tumor metastatic to cervical lymph nodes. A, Irregular vascular channels, some lined with plump endothelial cells, dissect through the eyelid dermis (hematoxylin and eosin). B, Plump, pleomorphic endothelial cells are evident at higher magnification. Some of the endothelial cells line slit-like spaces, while others line spaces containing erythrocytes (hematoxylin and eosin). C, Vascular channels are hard to identify in poorly differentiated angiosarcoma. D, Immunohistochemical staining using antibodies to CD31 is useful for confirming a diagnosis of angiosarcoma, especially in poorly differentiated tumors. CHAPTER 128

Basal Cell Carcinoma

Key Points

- Basal cell carcinoma (BCC) is the most common malignant neoplasm of the skin, and in the eyelids it accounts for about 80% to 85% of all malignant cutaneous tumors
- It occurs more commonly in fair-skinned adults, with a peak incidence between the 5th to the 8th decades of life
- Ultraviolet sunlight exposure-driven mutagenesis is believed to be the major risk factor for BCC causing inappropriate activation of the hedgehog signaling pathway
- Nodular BCC presents as an indolent, firm, indurated, elevated lesion with smooth rolled, pearly, shiny borders, and fine telangiectasias are seen around the borders
- The morpheaform or sclerosing subtype is more aggressive and presents as an infiltrative, locally destructive lesion with ill-defined margins
- Treatment is primarily with wide surgical excision with clear margins
- Targeted inhibition of the sonic hedgehog pathway now offers a promising treatment option in selected patients
- The prognosis depends upon the histologic type, anatomic location, and the size of the lesion
- Metastatic potential is reported but is very low

Basal cell carcinoma (BCC) was first mentioned in the literature by Arthur Jacob in 1827 and referred to as “ulcus rodens.”[1] The tumor was clinically described later as a malignant, locally invasive, destructive cancer by Krompecher in 1900.[2]

BCC is the most common malignant neoplasm of the skin, and in the eyelids, it accounts for about 80% to 85% of all malignant cutaneous tumors. It arises from keratinocyte precursor cells of the interfollicular epithelium where it undergoes mutagenesis.[3,4] Basal cell carcinoma occurs more commonly in fair-skinned adults, with a peak incidence between the 5th to the 8th decades of life. The incidence has been increasing in the United States, Europe, and Australia.[5,6,7,8] In 1996, it was estimated that more than two million individuals were affected annually in the United States, with a lifetime risk of at least 20% to 30%.[9] In 2012, the age-adjusted rate of treatment procedures for BCC in the United States was 3280 per 100,000 Medicare beneficiaries.[5] BCC can be seen in younger individuals, particularly those who have predisposing genetic syndromes. However, tumors have been described in healthy young individuals with no predisposing factors. While this is a true malignant tumor, it only rarely metastasizes to distant sites. When neglected, periorbital BCC can be very destructive locally and can invade adjacent structures such as the orbit and paranasal sinuses.

Etiology and Pathogenesis

Ultraviolet sunlight exposure-driven mutagenesis is believed to be the major risk factor for BCC. Sporadic BCCs arise from long-term resident keratinocyte progenitor cells of the interfollicular epidermis and upper infundibulum that undergo mutagenesis, mostly ultraviolet (UV) induced.[3,10] Most cases of BCC are UV exposure-induced and 76% have UV signature mutations.[11] Daylight UV induces a characteristic UV-specific DNA mutation occurring preferentially at methyl-CpG sites, seen after exposure to both UVA and UVB, but not UVC.[12]

Focal trauma, scars, previous ionizing irradiation, and systemic immunosuppression are other factors that can predispose to the development of eyelid BCC. Age is an independent risk factor, and the incidence doubles between the ages of 40 and 70 years.[13] Cigarette smoking is not believed to be a factor in men but has been implicated as a predisposing factor in women.[14] The most important risk factors for the development of BCC include light skin pigmentation, freckling in childhood, and a history of severe

sunburn.[15] Other factors include occupational UV exposure and the presence of actinic cheilitis, actinic keratosis, and solar lentigo.[16] Chronic infection of the pilosebaceous follicle by the mite *Demodex folliculorum* has also been suggested as a causative factor.[17]

Most BCCs show inappropriate activation of the hedgehog signaling pathway. The sonic hedgehog protein is necessary for the embryonic development of neural, musculoskeletal, hematopoietic, and skin tissue, and for adult tissue homeostasis. A mutation in the hedgehog pathway may lead to sonic hedgehog protein binding to the transmembrane receptor Patched (Ptc), encoded by a tumor suppressor gene (*PTCH-1*) that normally inhibits the downstream transmembrane receptor, smoothened (Smo).[18] Reversal of this inhibition leads to the release of cytoplasmic sequestration of the transcription factor glioma-associated oncogene homolog 1 (Gli1), allowing it to enter the nucleus to induce gene transcription.[19] This results in cellular proliferation and tumorigenesis.

(Print pagebreak 847)

Clinical Presentation

Most cases of BCC occur in individuals between 40 and 80 years of age, with a mean of about 60 years. There may be a slight predilection for males. Solitary lesions most commonly appear on the sun-exposed skin of the face. The lower eyelid is involved in about two-thirds of cases, and the upper eyelid is rarely involved, likely due to protection from sun exposure by the brows. Tumors are typically painless, associated with hair loss, and grow slowly over many months to years before diagnosis.

There are several different clinical variations seen on the eyelids. These include nodular, noduloulcerative, pigmented, cystic, superficial, and morpheaform or sclerotic forms.[20,21,22] The nodular form is the most common, accounting for 50% to 80% of all BCCs,[15], and has a predilection for sun-exposed areas in the head and neck. Clinical appearance varies greatly but usually presents as an indolent, firm, indurated, elevated lesion with smooth rolled, pearly, shiny borders (Figure 128.1). Fine telangiectasias are seen around the borders. When located near the eyelid margin, distortion or loss of cilia may be seen. Central ulceration is a common finding, often filled with crusty exudate. The ulcerated lesion may bleed easily. Pigmentation is a rare variant seen in up to 5% to 6% of cases and may be difficult to distinguish clinically from malignant melanoma (Figure 128.2).

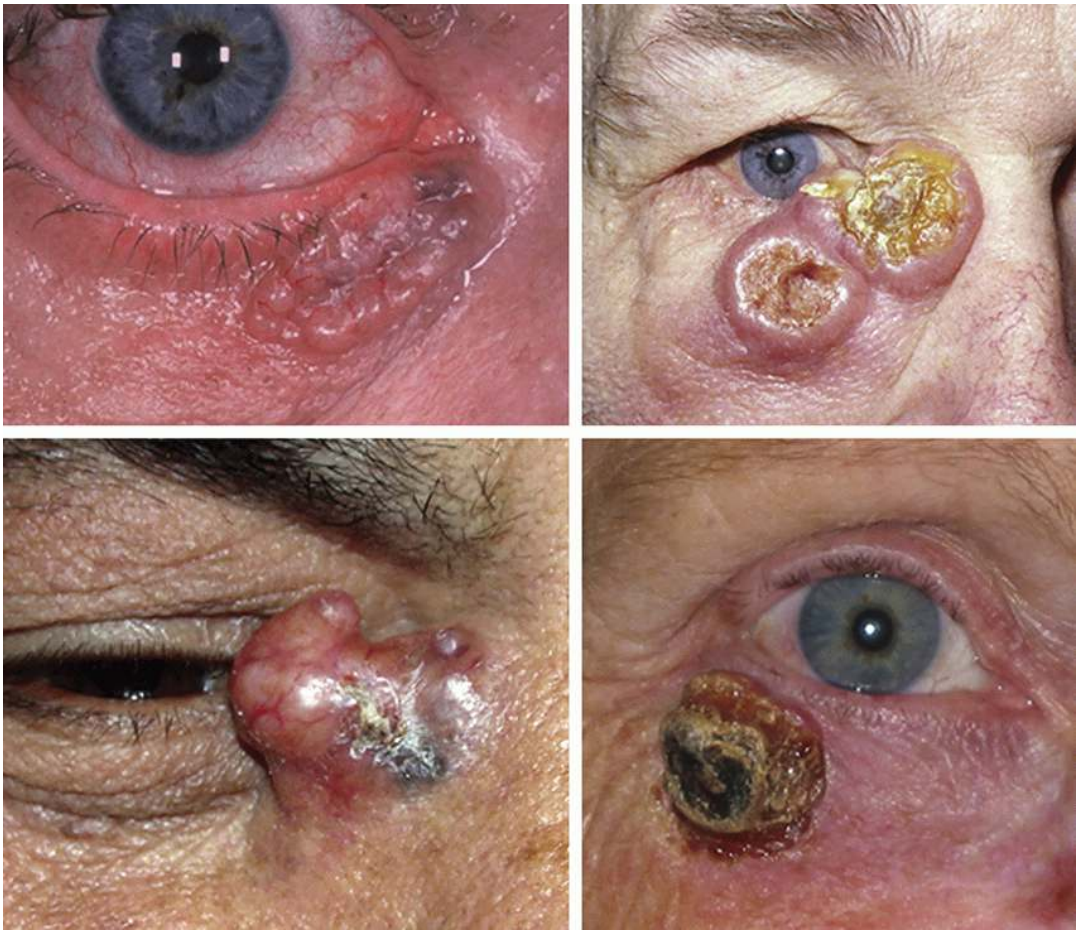

FIGURE 128.1 Nodular basal cell carcinoma.

The superficial subtype accounts for approximately 10% to 30% of BCCs and is the second most common type. Some studies have shown a younger average age of onset for this subtype and a relatively higher incidence in females.[23] Superficial BCCs present as a

thin, well-circumscribed, erythematous plaque or patch with scales (Figure 128.3) and may have central clearing and narrow rolled borders. They occur most commonly on sun-unexposed or intermittently *(Print pagebreak 848)* exposed areas of the trunk[10] but can be seen less commonly on the head and neck. Like the nodular subtype, they rarely can be pigmented.

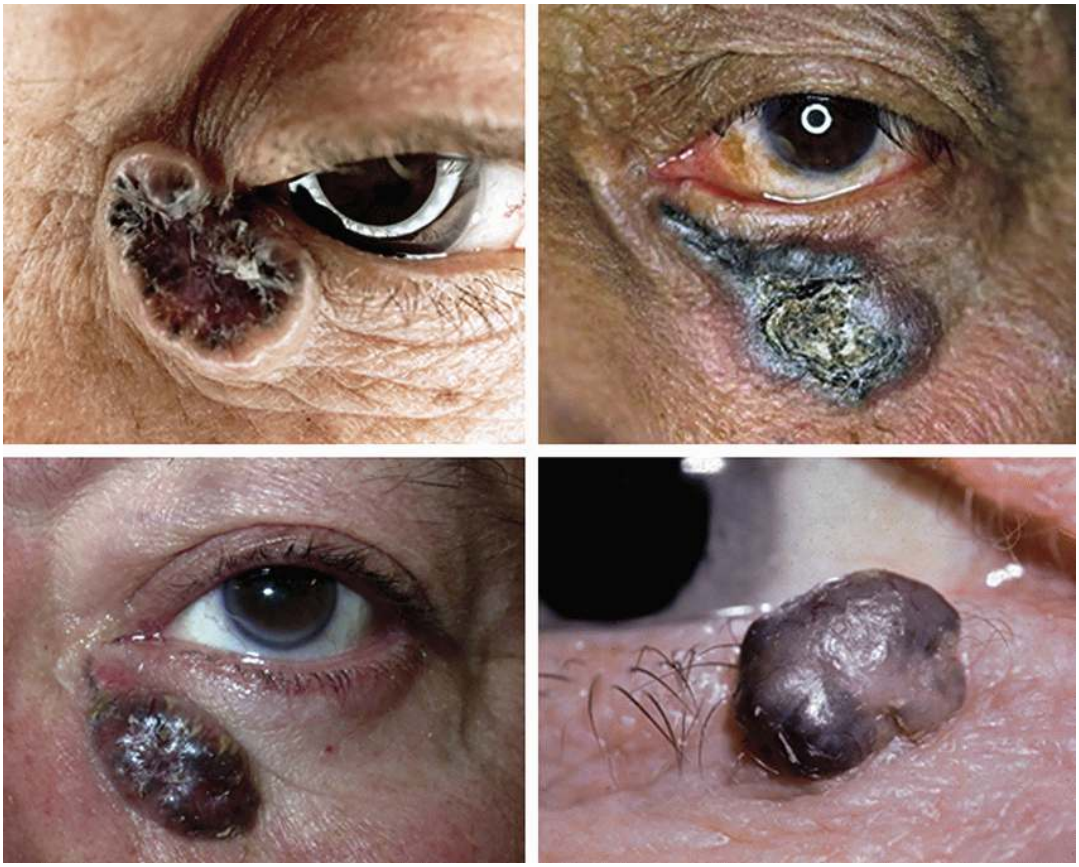

FIGURE 128.2 Pigmented basal cell carcinoma.

FIGURE 128.3 Flat superficial basal cell carcinoma with erythema, fine scales, and a small area of ulceration.

The morpheaform or sclerosing subtype is less common, comprising less than 10% of BCCs. Among 13,457 BCCs diagnosed at a single center, Scrivener et al found the morpheaform subtype in 6.2% of cases, of which 94.8% occurred on the head.[24] This form of BCC is more aggressive, with a greater potential for recurrence and for metastatic spread. Clinically, it appears as a pale, infiltrative, and locally destructive lesion with ill-defined margins (Figure 128.4). Neglected or recurrent tumors can be locally invasive where they may extend into the lacrimal drainage system, orbit, paranasal sinuses, and even the cranial cavity (Figure 128.4). Orbital invasion generally produces displacement of the globe, and motility restriction, and less commonly proptosis (Figure 128.5).

The basosquamous subtype is more aggressive in clinical behavior and has histologic features of both basal cell and *(Print pagebreak 849)* squamous cell carcinomas. It is a rare subtype representing less than 2% of all BCCs. It has nonspecific clinical features differentiating it from other subtypes, and the diagnosis is made primarily on biopsy. Because of its higher recurrence rate and metastatic potential, early diagnosis and treatment are essential.

Differential Diagnosis

The clinical differential diagnosis for BCC is very broad and includes numerous malignant and benign lesions. Confusing lesions include dermatofibroma, trichoblastoma, trichofolliculoma, sebaceous carcinoma, squamous cell carcinoma, keratoacanthoma, Merkel cell carcinoma, microcystic adnexal carcinoma, and metastatic carcinoma. Immunohistochemistry can help differentiate BCC from its mimics.[25] Pigmented BCC may be confused clinically with a melanocytic nevus, melanoma, and seborrheic keratosis. Cystic BCC can mimic an eccrine or apocrine hidrocystoma.

FIGURE 128.4 Infiltrative morpheaform basal cell carcinoma.

FIGURE 128.5 Medial canthal basal cell carcinoma with orbital invasion.

(Print pagebreak 850)

Treatment

For eyelid BCC lesions where the diagnosis is uncertain, an incisional biopsy is indicated. This will allow a firm histologic diagnosis and allow for preoperative planning of resection and subsequent reconstruction. For smaller, low-risk tumors, surgical excision with a 4-mm margin is the treatment of choice. The goal should be to achieve complete tumor eradication to prevent a recurrence, local destruction, and possible metastatic spread. Resection should include frozen-section control of margins, preferably by Mohs microsurgery. Small, nonmarginal defects can heal by spontaneous granulation with acceptable aesthetic results. Larger defects are repaired by primary layered closure or with more complex reconstructions using myocutaneous flaps and grafts. A wide variety of reconstructive techniques are available depending upon the size and location of the defect and the specific tissues involved.[26]

Radiotherapy can be used as adjunctive therapy to surgical excision or in combination with orbital exenteration in cases of high-risk aggressive BCC with perineural invasion. It can also be used for patients who are not suitable surgical candidates. The use of radiotherapy remains controversial for smaller low-risk tumors, but some studies have shown good tumor control in many cases.[27] Radiotherapy has some potential side effects including dry eye; cataract; punctal, and lacrimal duct stenosis; neovascular glaucoma; and radiation retinopathy.

Electrodissection and curettage use mechanical debridement and electrocoagulation to remove the visible tumor. This technique does not allow for histologic assessment of margins so that it is more prone to leaving some tumors untreated. Complications include loss of eyelashes and some visible scarring following spontaneous granulation of the wound.

Cryosurgery is an alternative option, and some studies have reported high 5-year cure rates. Cosmetic outcomes tend to be inferior to surgery, and the technique generally is contraindicated in hair-bearing areas.

Photodynamic therapy (PDT) is an alternative treatment for BCC. Methyl aminolevulinate or aminolevulinic acid is used as the photosensitizing agent. Activation of the photosensitizer by visible light creates cytotoxic oxygen species and free radicals, which selectively destroy rapidly proliferating cells. A recent meta-analysis concluded that PDT is a useful method for the treatment of BCC that is similar in efficiency to cryosurgery and pharmacologic treatment such as with imiquimod. While it is less effective than surgical excision, PDT results in better cosmetic outcomes.[28]

For patients in whom surgery is not possible or is declined, topical immunotherapy has emerged as an alternative treatment for periocular BCC. Imiquimod is an immune modulator that stimulates innate immunity and induces apoptosis in tumor cells. For nodular BCC a topical 5% cream once a day for 8 to 16 weeks is applied. Clinical remission and histological clearance of the tumor have been reported in 80% to 100% of patients at follow-up periods of up to 2 years.[29,30,31]

Given the role of hedgehog signaling in the pathogenesis of BCC, targeted inhibition of the sonic hedgehog pathway now offers a promising treatment option for patients with advanced or recurrent disease not amenable to local resection. Vismodegib is a small-molecule compound that selectively inhibits the transmembrane receptor SMO. Early studies have shown this to be an effective treatment option for locally recurrent cases that have failed surgery, for metastatic BCC, and for advanced cases not amenable to surgery or radiotherapy. Vismodegib has been shown to have manageable side effects in most patients.[32,33,34,35,36,37] Neoadjuvant vismodegib therapy has been used followed by eye preserving surgery.[33] Sonidegib, another SMO antagonist, also has been approved for similar indications and carries a toxicity profile comparable with that of vismodegib.[38]

Prognosis

The prognosis for BCC depends upon the histologic type, anatomic location, and the size of the lesion. For nodular lesions, the prognosis is very good following complete surgical excision. With incomplete removal, the tumor can invade adjacent tissues along paths of least resistance. Destruction of muscle, cartilage, and bone can be associated with aggressive recurrences, leading to a poor prognosis. Orbital invasion is rare but is more common with lesions in the medial canthus. With local infiltrative growth patterns, the prognosis is significantly reduced and is associated with multiple recurrences. Recurrence rates average from 4% to 9% for lesions followed less than 5 years or more than 5 years, respectively.[39] However, the overall mortality rate is low, less than 1%. Spontaneous regression was reported in 25 of 400 (6%) BCCs, and another 56 (14%) showed foci of regression within the tumor.

BCCs rarely metastasize. The reported rate has been 0.0028% to 0.55%,[40] but a more recent study reported a rate of 1%.[41] Dissemination to regional or distant sites may occur via lymphatic spread (100%), hematologic spread (25%), or local subcutaneous routes. About 75% of tumors that metastasize are of the morpheaform type and usually involve the regional lymph nodes, lungs, bone, skin, liver, and spleen.[42] In one literature review of 100 cases of BCC with regional metastasis (N = 50) or distant metastasis (N = 50), the median survival for patients with regional metastases was 87 months and for distant metastasis it was 24 months.[43]

Predisposing Genetic Syndromes

Nevoid Basal Cell Carcinoma Syndrome

The basal cell nevus syndrome is also known as Gorlin-Goltz syndrome or Goltz syndrome. It is a rare, autosomal-dominant syndrome, more common in males, and involves both ectoderm and mesoderm tissues.[44,45] The clinical manifestations were originally reported simultaneously by Jarisch[46] and by White, both in 1894.[47] It was later classified as a syndrome with multiple manifestations.[20] The condition is characterized by multiple basal *(Print pagebreak 851)* cell carcinomas, odontogenic keratocysts, palmar and/or plantar pits, ectopic calcifications of the falx cerebri, and skeletal abnormalities such as bifid ribs and sometimes other tumors such as medulloblastoma and meningioma (Figure 128.6).[48] Other less common ocular abnormalities include congenital cataracts, uveal and optic nerve coloboma, strabismus, nystagmus, and microphthalmos. It is estimated that the prevalence is approximately 1 in 60,000 to 1 in 250,000, depending upon geographic locality and ethnicity. About 0.7% of patients with BCC may have this syndrome. The incidence is greater in regions with higher ultraviolet sunlight exposure, and tumors are more commonly seen in sun-exposed areas such as the face, chest, and back. The syndrome may be more common in young adults presenting with periocular BCCs.[49]

FIGURE 128.6 Nevoid basal cell carcinoma (Gorlin-Goltz) syndrome.

A gene believed to be responsible for this disorder has been mapped to chromosome 9q23.3-q31 that encodes the patched gene (*PTCH-1*) which translates into the transmembrane receptor protein for the secreted molecule Sonic Hedgehog in the Hedgehog signaling pathway responsible for the regulation of development and tumor suppression.[50,51] Patients may have a few to 1000 or more BCCs that vary in size from 1 to 10 mm in diameter. They may be skin colored and pedunculated or nodular, or even ulcerated. The mainstay of management of the BCCs associated with basal cell nevoid syndrome is surgical excision, preferably by Mohs microsurgery. Adjunctive therapies often include cryosurgery or electrodesiccation. PDT for diffuse BCCs has been used, but this is limited to smaller thin tumors less than 2 mm in thickness. Vismodegib has shown some promise in achieving tumor regression.[52]

Bazex-Dupre-Christol Syndrome

This is a very rare X-linked dominant disorder characterized by diffuse hypotrichosis, follicular atrophoderma, and basal cell carcinomas.[53] Milia cysts, trichoepitheliomas, hypohidrosis, and facial hyperpigmentation may also be seen. BCCs usually develop in the face during the first decade of life.

Xeroderma Pigmentosum

Xeroderma pigmentosum (Chapter 125) is a group of inherited autosomal recessive tumor predisposition disorders characterized by impaired DNA repair and hypersensitivity to UV-induced mutagenesis. It is characterized by photosensitivity of sun-exposed skin, premature skin aging, development of cutaneous neoplasms including BCC, photophobia, and pigmentary changes. Extracutaneous manifestations include keratosis, corneal opacification, ectropion, hearing loss, and microcephaly.[54] Patients have a 1000-fold increased risk of cutaneous malignancies compared with normal individuals. Tumors begin to develop at a median age of 8.5 years.[53]

Nevus Sebaceous of Jadassohn

Nevus sebaceous (Chapter 96) is a congenital hamartomatous malformation of the pilosebaceous follicular unit that includes both surface epithelial and adnexal structures. It primarily occurs on the scalp, head, and neck region and is usually clinically apparent at birth. In childhood, the epithelium is relatively normal with immature pilosebaceous units and alopecia. In adults, epidermal hyperplasia is seen and secondary neoplasms develop in 8.5% to 22.5% of cases.[55,56] About 80% of secondary neoplasms are benign, most commonly trichoblastoma. BCC is the most common malignant neoplasm but is quite rare, seen in only 1% to 5% of

cases.

Histopathology

Basal cell carcinomas are classified into histological subtypes by their architectural pattern, which correlates with the risk of recurrence.[10,57,58,59,60,61,62] Mixed patterns are common, occurring in from 10% to 15%[60] to ≈40%[58] of biopsies, and "can be reported as such."[60] Bonner et al reported a mixed pattern in 12.4% of 97 eyelid BCCs.[63] Superficial and infiltrative patterns tend to be located at the lateral or deep margins of the tumor,[60] leading to the upstaging of 7% to 31% of BCC subtypes at the time of definitive surgery.[64]

The WHO sorts BCCs into lower and higher risk patterns.[62] Low-risk architectural patterns of BCC are:

1. *Nodular BCC*: Nodular BCC, also known as nodulocystic BCC,[61] accounted for 35 of 51 (68.6%) eyelid BCCs reported by Salomon and colleagues,[65] which is similar to our experience (Figure 128.7A and B). Nodular BCCs often show an origin from the overlying epidermis[66] and feature discrete, variably shaped, large, or small nests of basaloid cells (basophilic tumor cells with hyperchromatic nuclei and little cytoplasm), often interconnected, in the papillary and reticular dermis.[61,66] Along the periphery of the tumor lobules, the cells are usually *(Print pagebreak 852) (Print pagebreak 853)* arranged radially with their long axes parallel to each other, creating so-called peripheral palisading.[62] Tumor cells in the center of the islands have randomly arranged nuclei, often with interspersed apoptotic tumor cells.[62] Mitoses are numerous.[67] Uncommon cases of nodular BCC have adnexal tumor-like features such as shadow cells (hair matrix differentiation), clear cells (trichilemmal differentiation), sebocytes (sebaceous differentiation), or tubular structures (ductal and glandular [sebaceous, apocrine] differentiation).[68] Stroma surrounding the tumor is often myxoid (mucinous)[61] and artifactually shrinks away from the tumor islands during histological processing, creating thin clefts (retraction artifact).[61,62] Clefts and mucinous matrix help to distinguish poorly differentiated basal cell carcinoma from poorly differentiated squamous cell carcinoma. Some BCCs have stromal keloidal-type collagen,[62] calcification,[61] thickened basement membrane,[68] or fibrocyte-rich collagen resembling a perifollicular adventitial sheath.[68] Small amyloid deposits are present in about half of BCCs but are evident in routine hematoxylin and eosin-stained sections in only about 10% of tumors.[69] Variants of nodular BCC include keratotic BCC with mature keratinization in the center of tumor islands, nodulocystic or cystic BCC with cystic degeneration of tumor islands, and adenoid BCC with cribriform nests (Figure 128.7C).[62]

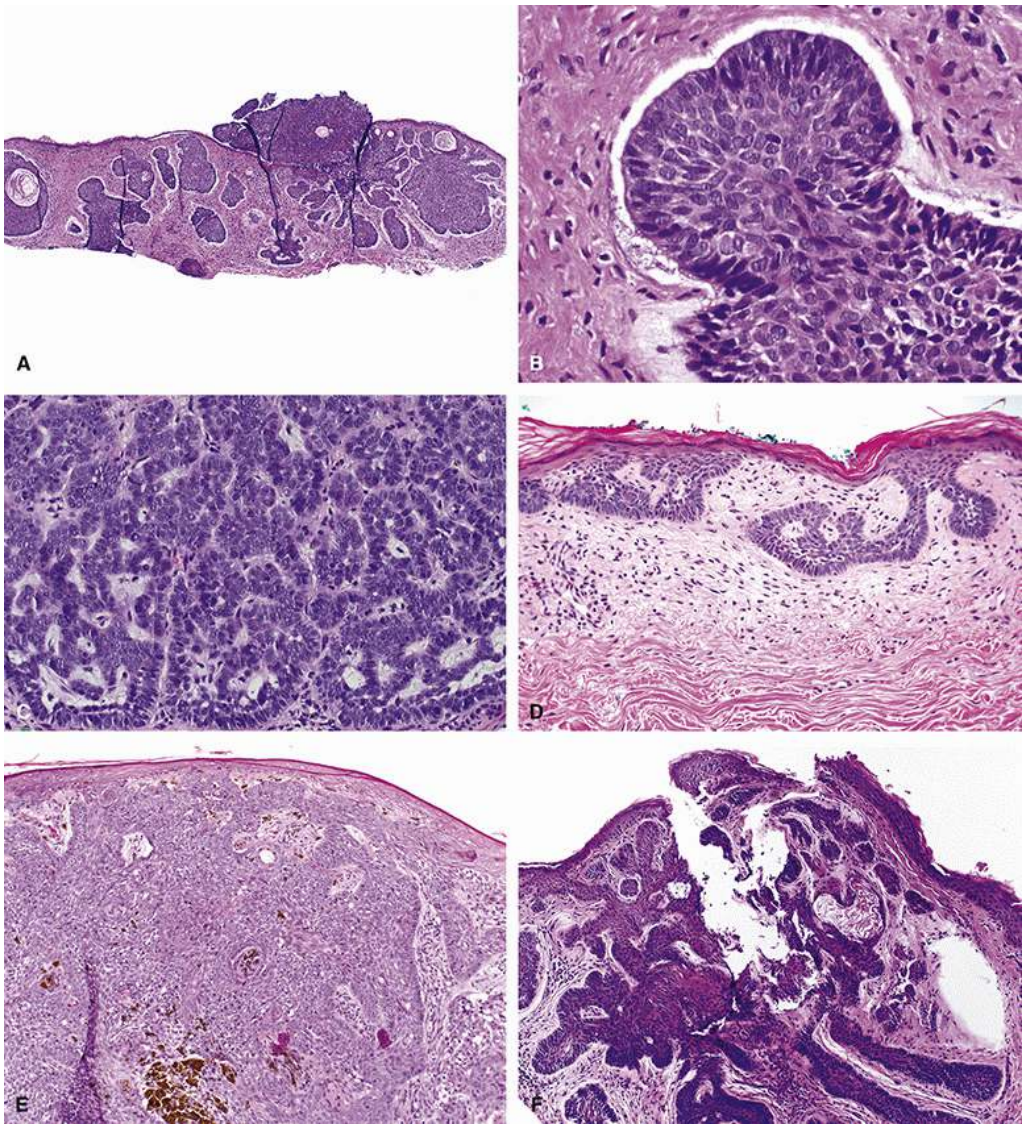

FIGURE 128.7 Histopathology of low-risk basal cell carcinoma subtypes. A, *Nodular BCC* of the left lower eyelid with discrete and interconnecting, variably shaped, large and smaller nests of basaloid cells (basophilic tumor cells with hyperchromatic nuclei and little cytoplasm) in the papillary and reticular dermis. B, Same *nodular BCC* as in A, showing peripheral radially arranged cells with their long axes parallel to each other, creating so-called peripheral palisading. The stroma surrounding the tumor lobule is mildly myxoid and artifactually shrank away from the tumor island during histological processing, creating a narrow cleft (retraction artifact). C, *Adenoid variant of nodular BCC* of the medial left lower eyelid. This tumor area has peripheral cribriform nests; other areas had solid islands of basaloid tumor cells typical of nodular BCC. D, *Superficial BCC* with basaloid tumor cells projecting from the epidermis forming lobules in the papillary dermis with an axis parallel to the epidermal surface. E, *Pigmented BCC* of the left lower eyelid with prominent melanin pigmentation. The architecture is otherwise typical of nodular BCC. F, This *infundibulocystic BCC* of the left upper eyelid was one of many 1-to 2-mm-diameter lesions involving all four eyelids in a young child with nevoid basal cell carcinoma (Gorlin-Goltz) syndrome. The tumor is sharply circumscribed, has a single infundibular cyst-like structure, central squamoid (eosinophilic) cells, and peripheral palisading. The large gap in the tumor is an artifact from sectioning the small tumor.

2. *Superficial BCC*: This BCC variant has basaloid tumor cells projecting from the epidermis or the sides of hair follicles, forming lobules in the papillary dermis with an axis parallel to the epidermal surface (Figure 128.7D).[61,62] The stroma around the tumor is myxoid, and there are typically clefts around the tumor islands.[61,62] Salomon and coworkers reported 5 of 51 eyelid BCCs were superficial type (9.8%).[65] Superficial BCC represented 13.6% of 1292 BCCs excised by Mohs surgery in Australia between 1993 and 1999; 73 cases involved the lower eyelid, 8 the upper eyelid, and 86 the medial canthus.[71] 3. *Pigmented BCC*: Pigmented BCCs have a nodular or superficial BCC pattern but differ by increased dendritic melanocytes within tumor islands.[71] In several large studies, pigmented BCCs accounted for 3.7%,[65] 5.1%,[72] and 9%[73] of eyelid BCCs. Basal cell melanization and melanophages contribute to the pigmentation of eyelid pigmented BCCs (Figure 128.7E).[72]

3. *Infundibulocystic BCC*: This rare BCC variant differs from other BCCs by occurring only on the face, small size (usually <5 mm in diameter), sharp circumscription, clefts within the connective tissue, absent ulceration, and follicular differentiation manifest as infundibular cyst-like structures.[74,75] The infundibular cyst-like structures are few in early lesions and many in larger tumors.[76] Infundibulocystic BCCs of the eyelids, although rare,[77] are a common form of BCC in nevoid basal cell carcinoma syndrome (Figure 128.7F).[78]

4. *Fibroepithelial BCC*: This BCC variant, also known as fibroepithelioma of Pinkus, has elongated, anastomosing cords of basaloid cells extending downward from the epidermis surrounding fibrotic stroma.[62] These lesions are most common on the intergluteal cleft and trunk.[61,62] They have not been reported on the eyelid to our knowledge.

High-risk BCC subtypes are:

1. *Micronodular BCC*: These tumors have small (more than 50% of nodules <0.15 mm in diameter)[62,79] discrete nodules of BCC widely scattered throughout the dermis and/or subcutis (Figure 128.8A).[61,62] The tumor nodules are often asymmetrically distributed[61] with infiltrative peripheral and deep borders.[62] A thin rim of myxoid or collagenous stroma[61] surrounds tumor micronodules dispersed in the normal dermis.[62] Retraction artifact is uncommon.[61] To minimize interobserver disagreements, the diagnosis of micronodular BCC should be restricted to tumors "with an irregular/tentacular, infiltrative deep or peripheral edge (an irregular interface at the deep or peripheral margins of the tumour with its adjacent stroma) composed predominantly (ie, >50%) of small discrete nodules (<0.15 mm in diameter)."[79] Micronodular BCCs were 9.8% of eyelid BCCs in the Salomon and coworkers study[65] and 5.2% of periocular BCCs in the 1993 to 1999 Australian Mohs registry report (33% lower eyelid, 5% upper eyelid, and 62% medial canthus).[70]

2. *Infiltrating BCC*: Infiltrating (infiltrative) BCCs (Figure 128.8B) have variably sized and shaped nests of basaloid tumor cells in the dermis that is often fibrotic.[62] The tumor islands are usually >5 to 8 cells thick,[61,62] angulated,[61] have occasional foci of retraction artifact,[61] and there are frequent mitoses and individual cell necrosis.[61] Infiltrating BCCs have irregular infiltrating margins,[61,62] approximately one-third have a nodular component,[61] and perineural invasion was present in 4.7% of infiltrating BCCs in an Australian Mohs registry between 1993 and 2002.[80] Infiltrating BCCs were 34.8% of periocular BCCs in the Australian 1993 to 1999 Mohs registry (54% lower eyelid, 4% upper eyelid, and 42% medial canthus).[70] The frequency of infiltrative BCCs in the Australian Mohs registry study may be skewed by selective referral of patients for Mohs surgery since Salomon et al noted only 4 of 51 eyelid BCCs (7.8%) were infiltrative.[65]

   (Print pagebreak 854)

3. *Sclerosing/morpheic BCC*: This form of BCC, also termed morpheaform BCC,[61] has thin cords of basaloid tumor cells compressed in a dense collagenous stroma (Figure 128.8C).[61] The tumor cords are one to five cells thick,[61,62] but typically one to two cells thick.[61] Individual cell necrosis and mitoses are common,[61] retraction artifact from the stroma is uncommon,[61,62] and the tumors are deeply infiltrative with tumor tentacles extending into the adjacent tissue.[62] Of the 1292 periocular BCCs in the 1993 to 1999 Australian Mohs registry, 4.1% were sclerosing/morpheic BCC, with all but one involving the lower eyelid or medial canthus.[70] In another Australian Mohs registry study, perineural invasion occurred in 8.3% of cases.[80]

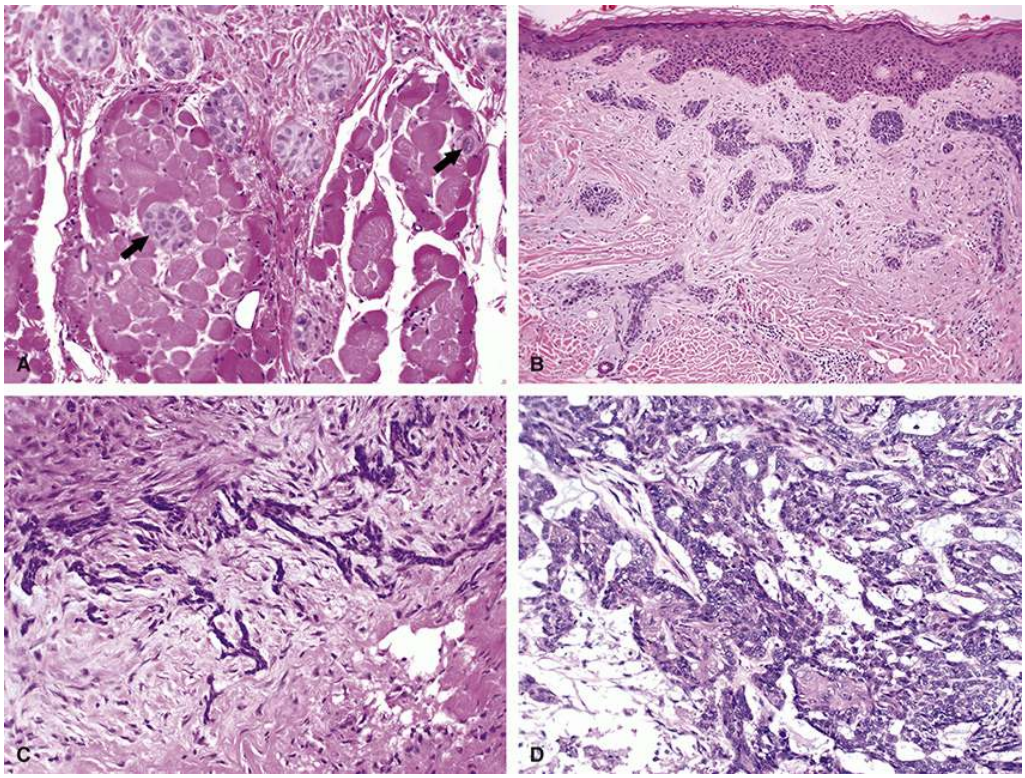

FIGURE 128.8 Histopathology of high-risk basal cell carcinoma subtypes. A, *Micronodular BCC* of the right upper eyelid with small nests of tumor in the deep reticular dermis and infiltrating the orbicularis oculi muscle (*arrows*). The larger tumor micronodule surrounded by orbicularis oculi muscle fibers is 0.05 mm in diameter. The anterior eyelid dermis contained typical nodular BCC with the micronodular subtype at the lateral and deep edges of the tumor. B, *Infiltrating BCC* with variably sized and shaped nests of basaloid tumor cells in the dermis surrounded by myxoid fibrotic stroma. Many of the tumor islands are angulated, and most are >5 to 8 cells thick. C, *Sclerosing/morpheic BCC* of the right medial canthus demonstrating thin cords of basaloid tumor cells surrounded by dense collagenous stroma. The tumor cords are 1 to 3 cells thick in this tumor. BCC also involved the glabella, and there was extensive perineural invasion. D, *Basosquamous carcinoma* involving the right lower eyelid and face with extension into the orbit. This area is a mixture of adenoid BCC and squamous cell carcinoma (SCC; cells with pink cytoplasm). Other areas of the tumor had a mixture of nodular BCC and SCC with areas of transition.

4. *Basosquamous carcinoma*: Basosquamous carcinoma, also referred to as metatypical BCC, has histological features of BCC and squamous cell carcinoma and transition zones between the two (Figure 128.8D).[61,62] Atypical squamous cells have abundant eosinophilic cytoplasm and may be focal or more widespread throughout the tumor.[62] About 10% of basosquamous carcinomas have perineural invasion.[62] The basaloid cells express epithelial cell adhesion molecule (Ber-EP4 antibody), while the squamous cells express epithelial membrane antigen.[62] Basosquamous carcinoma differs from keratotic BCC by the presence of malignant squamous epithelium and the absence of mature squamous pearls.[62] There are only a few reports of basosquamous carcinoma of the eyelid,[70,81,82] but periocular involvement is more common, although still far less frequent than nodular BCC.[83] There were 20 basosquamous carcinomas out of 1292 cases (1.6%) of periocular BCC in the Australian Mohs surgery registry between 1993 and 1999.[70] Nine of the basosquamous carcinoma arose in the lower eyelid, and 11 were in the medial canthus.[70]

5. *BCC with sarcomatoid differentiation*: This variant has BCC admixed with sarcomatous stroma that may be pleomorphic undifferentiated sarcoma, osteosarcoma, chondrosarcoma, leiomyosarcoma, and/or rhabdomyosarcoma.[62] We are aware of only one report of an eyelid BCC with sarcomatoid (osteosarcoma) differentiation.[84]

(Print pagebreak 855)

Adnexal tumors, squamous cell carcinoma, and sebaceous carcinoma are tumors that must be distinguished from BCC.[25] In the eyelid, trichoepitheliomas are the most common adnexal mimic of BCCs in our experience. Stanoszek, Wang, and Harms, in their excellent review,[25] discuss histological and immunohistochemical features that differentiate adnexal neoplasms from BCC. We discuss immunohistochemical characteristics that separate poorly differentiated BCC from squamous and sebaceous carcinomas in Chapter 144 (Sebaceous Carcinoma).

CHAPTER 129

Cutaneous T-Cell Lymphoma

Key Points

- Primary cutaneous T-cell lymphoma is a heterogeneous group of non-Hodgkin lymphomas that is responsible for two-thirds of all cutaneous lymphomas
- The most common forms are mycosis fungoides, which primarily involves the skin, and Sézary syndrome, which involves the skin and blood
- The etiology remains unknown, but genetic, environmental, and infectious agents have been implicated as possible risk factors
- Chromosomal abnormalities, including loss at 10q and abnormalities in *p15, p16,* and *p53* tumor suppressor genes have also been described, especially in advanced stages of the disease
- In the eyelids, it usually presents with localized cutaneous patches or plaques with flaking blepharitis, and eyelid thickening that advances to skin tumors, erythroderma, and extensive node or visceral involvement
- Other ophthalmic findings include conjunctival injection, episcleral infiltrates, punctate keratitis, stromal opacification and melts, retina infiltrates, vascular occlusions, and optic neuropathy
- Treatment is primarily palliative with topical therapies to improve quality of life that can include BCNU (corticosteroids, nitrogen mustard, carmustine), topical bexarotene gel, imiquimod, interferon alpha, receptor-targeted cytotoxic fusion proteins, radiotherapy, total skin electron beam radiotherapy, and phototherapy
- Patients with limited patch or plaque-stage disease have a 10-year disease-specific survival reported as 97% to 98%
- In cases with more advanced tumor stage disease and lymph node involvement, the disease-specific survival is reduced to 42%

Primary cutaneous T-cell lymphoma (CTCL) encompasses a heterogeneous group of non-Hodgkin lymphomas (NHL), which are responsible for two-thirds of all cutaneous lymphomas. Mycosis fungoides (MF), also known as Alibert-Bazin syndrome, is the most common variant of CTCL, accounting for over half of all cases. It was first described in 1806 by the French physician Baron Jean-Louis Alibert[1] as mycotic-like plaques in the early phases of the disease and mushroom-like tumors that can be seen late in the disease.[2,3]

While MF is the most common cutaneous lymphoma, it is still a relatively rare, extranodal, non-Hodgkin lymphoma that consists of a proliferation of helper T cells that exhibit an affinity for the epidermis.[4] It most often presents in individuals aged 45 to 60 years but occasionally has been seen in children and adolescents.[2,5,6,7] It is more common in black than in white or Asian patients and twice as frequent in men as in women. According to the Surveillance, Epidemiology and End Results (SEER) program of the United States National Cancer Institute, the incidence of MF is estimated at 5.6 per million persons, and this has remained constant for the past 2 decades.[8]

MF has been classified by its clinical presentation as a patch, plaque, or tumor.[9]
Patch or plaque lesions have a predilection for non-sun-exposed areas of the skin, although any area of the skin may be affected.[10] They are frequently misdiagnosed as chronic contact dermatitis, atopic dermatitis, or psoriasis and may show areas of hypopigmentation or hyperpigmentation, atrophy, and petechiae.[10]

The behavior and prognosis of primary cutaneous lymphomas are often different from histologically similar systemic non-Hodgkin lymphomas that secondarily involve the skin so that they are classified as separate entities by the European Organization for Research and Treatment of Cancer and the World Health Organization.[11,12] MF has been divided into several subtypes with

slightly different clinical characteristics and different prognostic implications. Classical MF runs an indolent clinical course and usually progresses slowly over years or even decades as a patch or plaque. The skin lesions tend to occur in sun-protected areas and may progress from patches and plaques to tumors that often show ulceration.[13] Regional lymph nodes and visceral organs may become involved in later stages of the disease.

In addition to the classical Alibert-Bazin type of MF, a long list of clinical and/or histologic variants have been reported. Bullous, hyperpigmented, and hypopigmented MF clinically behave in a similar fashion to that of classical MF. They are, therefore, not considered as separate entities. Folliculotropic MF and pagetoid reticulosis, on the other hand, do have distinctive clinicopathologic characteristics and, usually, are considered to be distinct variants. Folliculotropic MF is a localized form of CTCL characterized by the presence of folliculotropic infiltrates and lymphomatous changes around hair follicles and most commonly involves the head and neck.[14] It occurs more often in adults but is seen occasionally in children and adolescents, and men are more often affected than women.

(Print pagebreak 858)

Lesions may present as groups of follicular papules, acneiform lesions, indurated plaques, or tumors and may be associated with alopecia.[15,16] Pagetoid reticulosis is characterized by the presence of localized patches or plaques, with a proliferation of intraepidermal neoplastic T cells.[11,17,18] Lesions generally present as a slowly progressive solitary psoriasiform or hyperkeratotic patch or plaque, usually localized on the extremities, and have a relatively good prognosis. A newer variant is papular mycosis fungoides characterized by the presence of papules in the absence of the usual patches and plaques. This variant has a relatively nonaggressive behavior and a good prognosis.[19,20]

Sézary syndrome (SS) is a variety of T-cell cutaneous lymphoma that develops most frequently in men during their fifth decade of life and progresses rapidly.[3] It has an annual incidence rate of about 1/10,000,000 and represents about 3% of all cutaneous lymphomas. It affects the skin of the entire body as a scaling erythroderma and infiltration. SS is also known as red man syndrome because the skin is usually bright red. Alopecia, palmoplantar keratoderma, nail onychodystrophy, and lower eyelid ectropion may also be present. Neoplastic T cells (Sézary cells) are located in the skin, enlarged lymph nodes, and in the peripheral blood. The disease can advance to involve the liver, spleen, and bone marrow.

Etiology and Pathogenesis

The etiology of MF remains unknown, but genetic, environmental, and infectious agents have been implicated as possible risk factors in initiating lymphocyte activation.[21,22] Clonal T-cell receptor gene rearrangements have been found in most cases of classic MF. Chromosomal abnormalities, including loss at 10q and abnormalities in *p15, p16,* and *p53* tumor suppressor genes have also been described, especially in advanced stages of the disease.[13,23] MF has been observed related to mature CD4+ memory cells, and a hypothesis of persistent antigen stimulation leading to a breakdown in immune surveillance and eventually malignancy has been proposed as an initial event.[24]

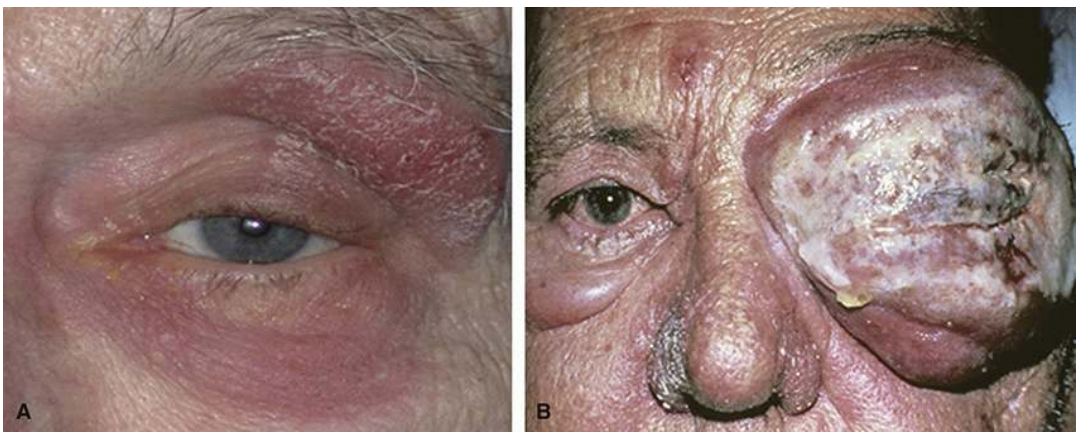

FIGURE 129.1 A, Early manifestation of mycosis fungoides as erythematous induration of the eyelids. B, Late-stage tumorous mycosis fungoides. A, (Courtesy of Dr. Bita Esmaeli.)

Malignant T cells in MF arise from skin-homing T cells, and the tumor microenvironment is critically involved in supporting tumor growth.[25] Cytokine expression and functional variations in the immune system have been seen in the various stages of MF. Early-stage disease expresses a Th1 type helper T-cell cytokine pattern, which limits the disease to the skin. With progression to late stages, there is a shift from Th1 to a Th2 type helper T-cell profile,[26,27,28,29] and this cytokine shift may promote malignant lymphocyte proliferation.[25] In addition, resident skin T cells express various chemokine receptors, which are necessary for

migration into the skin.[30,31]

SS has been linked to a wide range of chromosomal anomalies, particularly rearrangements in the 6q23-27 region that lead to alterations in the *MYB* proto-oncogene and the interleukin-22 receptor subunit alpha-2 gene (*IL22RA2*). However, the etiology remains unknown.

Clinical Presentation

The diagnosis of mycosis fungoides is usually difficult, especially in early stages, and often requires multiple biopsies for confirmation because of its clinical similarity to other conditions.[32,33,34] Erythematous plaques are usually the initial manifestation, similar to other mild skin disorders such as eczema, atopic dermatitis, psoriasis, and pityriasis lichenoides (Figure 129.1A). As the disease progresses, infiltrative lesions appear, and in the late stage, tumorous lesions develop (Figure 129.1B) and metastasis to lymph nodes and distant organs may follow.

MF is more common in males at a median age at diagnosis of 55 years.[35] Blacks are almost twice as likely to develop *(Print pagebreak 859)* MF compared with whites and Asians.[36] In the eyelid, the disease usually presents with localized cutaneous patches and/or plaques in the early stages. More advanced stages include erythroderma and extensive node or visceral involvement. Flaking blepharitis is a common finding, followed by eyelid thickening with eyelash and eyebrow flaking. The most frequent complaints are burning, impaired vision, redness, itching, and crusting of the eyelids and eyebrows.[37] Other findings include conjunctival injection; episcleral infiltrates; punctate keratitis with stromal opacification, melts, and subepithelial infiltrates; retina, choroid, and vitreous infiltrates; uveitis and vascular occlusions; and optic nerve infiltration and neuropathy.[38,39,40,41,42,43,44,45,46] Nonspecific manifestations include dry eyes, cataracts, glaucoma, and peripheral nerve palsy, among others.

The frequency of ophthalmic involvement in mycosis fungoides is not well established. Among 30 patients described by Stenson and Ramsay,[47] 11 (36.7%) had ophthalmologic manifestations. Most common were dry eyes (37%), ectropion (33%), and eyelid tumors (27%), with conjunctival tumors, keratitis, uveitis, and optic atrophy all reported in 10% of cases or less. Leib et al[37] described 17 cases of MF, and the eyelids were the most frequently affected region (76%), characterized by seborrheic blepharoconjunctivitis, cicatricial ectropion, meibomiantitis, chalazion, and madarosis. Cook et al[48] assessed 42 cases of cutaneous T-cell lymphoma and reported that ectropion was the most prevalent condition, seen in 40.4% of cases.

The disease usually follows a protracted course, through three stages: patch, plaque, and tumor. In some cases the disease may not advance to other stages,[49] but up to one-third of cases it will progress to a more aggressive form with infiltration or tumors, and in some cases can develop with erythroderma.[32,34,50]

In SS, the cutaneous involvement is characterized by reddened, thickened, peeling, and painful skin patches, plaques, and tumors all over the body (Figure 129.2). Sézary cells are also found in the blood and lymph nodes.

FIGURE 129.2 T-cell cutaneous lymphoma in Sézary syndrome. (Courtesy of Dr. Timothy Sullivan.)

Differential Diagnosis

MF is easily confused with other more common skin disorders. The differential diagnosis includes eczema, psoriasis, drug reactions, atopic and contact dermatitis, pityriasis lichenoides, and other lymphomas.

Treatment

MF usually runs an indolent, uncontrollable course, and treatment is primarily palliative.[32,34,50] The only treatment that can cure the disease is a bone marrow transplant, which is rarely used.[51,52] When MF is confined to the skin, skin-directed therapies are preferred. These include topical BCNU (corticosteroids, nitrogen mustard, carmustine), topical bexarotene gel (retinoid), imiquimod cream, interferon alpha and other cytokines, receptor-targeted cytotoxic fusion proteins, radiotherapy, total skin electron beam radiotherapy, and phototherapy.[53,54,55,56,57] However, the role of these treatments, as single-agent therapies or in combination with others, remains unclear.

The benefit of skin-directed therapies in preventing MF progression is not clear,[53] and these approaches have been used principally to improve quality of life,[58] to help control pruritus and pain, and to improve physical appearance. However, there is no firm evidence that more aggressive topical therapies prolong survival. In one randomized controlled clinical trial, parenteral chemotherapy combined with external beam irradiation was compared with topical treatment. There was a higher rate of complete response in the systemic group (38%) compared with the topical group (18%), but there was no significant difference in the disease-free or overall survival rates after a median follow-up period of 75 months.[59]

Emollients are frequently prescribed for patients with MF, and their use may reduce pruritus and scaling. They reduce transepidermal water loss and can reduce corneocyte loss and alter the lipid barrier.[58,60] Emollients may also be of some value as moisturizers, which may be a useful adjunctive therapy alongside other topical therapies. Topical corticosteroids are frequently used as palliation for patients with patches or plaques. Zackheim et al[61] reviewed 79 patients with early-stage MF and reported a partial or complete response rate of 94% in T1 stage tumors and 82% in T2 stage tumors. But the response durations were not prolonged, and recurrences were common following discontinuation of the topical steroids.

Bexarotene gel is an antineoplastic agent that selectively activates retinoid X receptors to induce cell differentiation and apoptosis. It has been used in patients with MF where other topical therapies have not been effective. In several clinical trials, the overall response rate was 54% to 63%.[62,63] Although not evaluated in clinical trials, imiquimod 5%,[64,65,66,67] 5-fluorouracil cream,[68] topical methotrexate-laurocapram,[69] and topical alkylating agents like chlormethine gel (also referred to as mechlorethamine)[70] have been reported to be beneficial in case reports and small case series.

(Print pagebreak 860)

Phototherapy with broadband UVB light and psoralen plus ultraviolet A light photochemotherapy (PUVA) is frequently used in the management of MF and has been reported to result in a high complete remission rate.[71,72,73] MF is extremely radiosensitive, and radiotherapy has been used for all stages of the disease.[74,75,76] Localized radiotherapy is often employed as palliation for isolated plaques and tumors, and this may be performed in combination with other skin-directed therapies.[53,77]

Chemotherapy is generally used in more advanced cases or where there are widespread cutaneous tumors refractory to skin-targeted therapies. The main goals of systemic treatment are long-term disease control, effective symptom management, and control of life-threatening complications.[78] Numerous systemic chemotherapy agents have been used, but they have not provided long-term disease control.[79] Chemotherapy is reserved for the treatment of patients with advanced disease and relapses after previous therapy.[80], It may also be considered for patients with aggressive disease, bulky nodes, and visceral involvement.[81]

There are many other systemic therapies available that are beyond the scope of this chapter. They are comprehensively discussed by Alpdogan et al.[82]

Prognosis

The prognosis of patients with MF depends on the stage of the disease and the presence of any extracutaneous involvement.[6,83] Patients with a limited patch or plaque-stage MF do not have a reduced life expectancy compared with age-matched controls, and the 10-year disease-specific survival is reported as 97% to 98%.[54] But since the disease is not usually cured, the expected quality of life is poor from painful, itchy, and disfiguring lesions.[84] However, for patients with more advanced tumor stage disease and lymph node involvement, the disease-specific survival is reduced to 42%.[6,83] Patients in the most advanced stages with bulky tumors, diffuse lymphadenopathy, elevated lactic dehydrogenase, high circulating tumor burden, and visceral disease have a very poor survival, regardless of systemic therapy.[85,86,87]

The prognosis for SS is poor. The disease is not felt to be curable, and the median survival of patients is approximately 5 years.

Histopathology

The histopathological features of eyelid T-cell lymphomas depend on its subtype.[11,88,89,90,91] The frequency of eyelid involvement by T-cell lymphoma and its subtypes is uncertain. In Svendsen and Heegaard's review of 199 published cases of primary eyelid lymphoma, 44% were of T-cell origin.[92] Of the T-cell lymphomas, 29% were mycosis fungoides, 14% were cutaneous anaplastic large-cell lymphoma (C-ALCL), and 14% were extranodal natural killer/T-cell lymphoma, with a smattering of many other subtypes.[92] The published reports are biased, as evidenced by the data for 86 patients from seven international eye centers seen between 1980 through 2015.[93] T-cell lymphomas accounted for 15 (17%) of the 86 patients with eyelid lymphoma.[93] The subtypes of eyelid T-cell lymphoma were mycosis fungoides (eight patients [53%]), peripheral T-cell lymphoma (two patients [13%]), lymphomatoid papulosis (two patients [13%]), C-ALCL (one patient [7%]), systemic ALCL (one patient [7%]), and systemic T-cell lymphoma, not otherwise specified (one patient [7%]).[93] Of the patients with mycosis fungoides, one (13%) had primary disease involving the eyelid and seven (88%) had relapsed disease.[93]

Mycosis fungoides is an epidermotropic CTCL featuring small to medium-sized T lymphocytes with cerebriform nuclei.[94] MF exists as a classic form that progresses through patch, plaque, and tumor stages,[94] as well as folliculotropic MF, granulomatous slack skin, and pagetoid reticulosis variants.[32,95] The patch stage of classic MF (Figure 129.3) has a superficial dermal band-like, patchy lichenoid, perivascular, or periadnexal infiltrate of mostly lymphocytes and macrophages, with a few small to medium-sized atypical lymphocytes having cerebriform nuclei.[32,94,96] The atypical lymphocytes are usually in the lower epidermis and may be single, form small clusters, or be arranged linearly.[32,94] Approximately one-fifth of biopsies have intraepidermal collections of atypical lymphocytes (“Pautrier microabscesses”).[96] The intraepidermal atypical lymphocytes may have a clear cytoplasmic rim (halo cells) that assists in diagnosing patch stage MF.[32,94] Other histological changes in patch-stage MF are focal parakeratosis and papillary dermal fibrosis with coarse collagen bundles.[32,96] Classic MF plaques (Figure 129.4) have more prominent dermal inflammation and more epidermotropism and Pautrier microabscesses than the patch stage.[32,94] The tumor stage of MF (Figure 129.5) has a dense, diffuse, nodular infiltrate of atypical lymphocytes with pleomorphic and hyperchromatic nuclei and prominent nucleoli.[32,94] Epidermotropism and Pautrier abscesses may be absent in the tumor stage of MF.[32,94] “The typical phenotype is positivity for CD2, CD3, TCRβ chain, CD5, and CD4 and negativity for CD8 and TCRγ chain. Cases with a cytotoxic phenotype (ie, positivity for CD8 and/or TCRγ chain) are well-recognized.”[94] T-cell receptor gene rearrangement analysis facilitates diagnosis of early MF infiltrates.[94] The histopathological features of SS are similar to the patch and plaque stages of MF, although the infiltrate is often more monotonous and epidermotropism may be absent.[89,97]

Cutaneous anaplastic large cell lymphoma (Figure 129.6) is a form of primary cutaneous CD30+ T-cell lymphoproliferative disorder[89,98] having a diffuse dermal infiltrate of large anaplastic tumor cells with or without epidermotropism.[89,90,98] The tumorous lymphocytes have round, oval, or irregularly shaped nuclei, prominent nucleoli, and abundant cytoplasm.[89,90,98] Ulceration is frequent.[89] “The neoplastic cells show an activated CD4+ T-cell phenotype, with variable loss of CD2, CD5, CD7, and CD3 and frequent expression of cytotoxic proteins (granzyme B, TIA1, and perforin). Some cases may have a CD4-/CD8+ or CD4+/CD8+ T-cell phenotype. CD30 is by definition expressed by a majority (>75%) of the neoplastic cells.”[98]

(Print pagebreak 861)

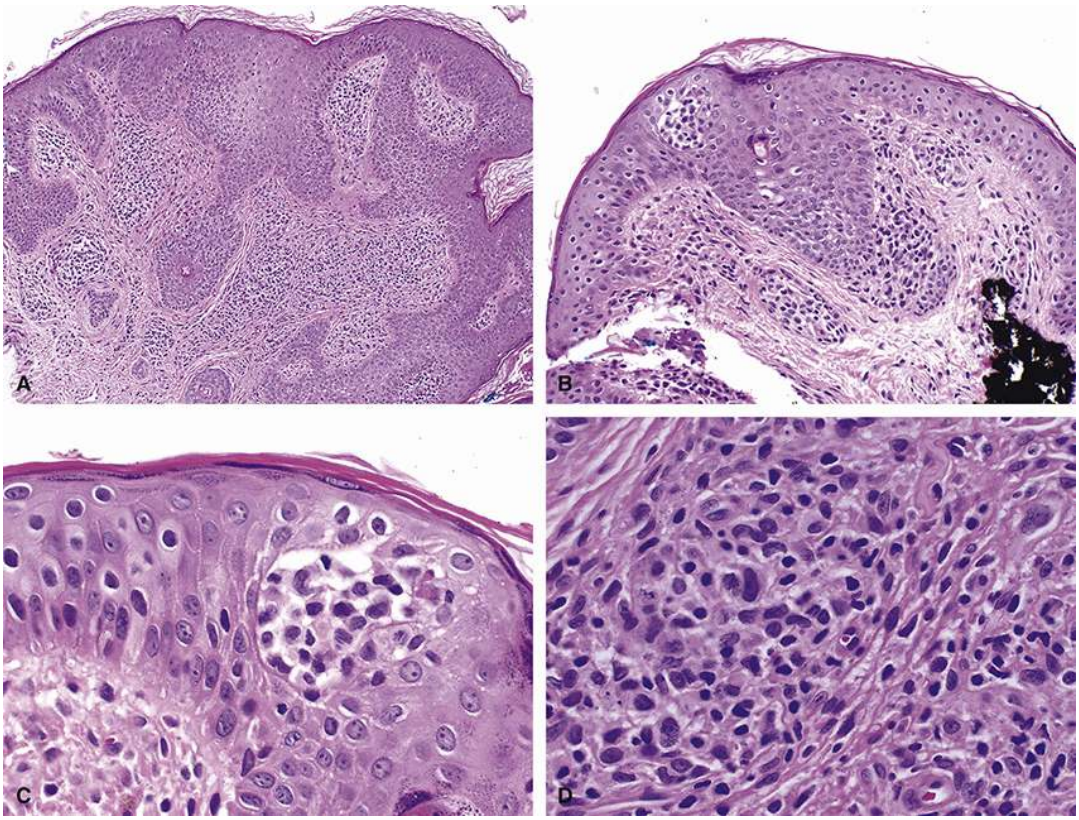

FIGURE 129.3 A man in his late 50s, clinically in remission from CTCL, developed an itchy, faint erythematous patch under his left eyelid. A, The epidermis is acanthotic, and there is a papillary and reticular dermal perivascular infiltrate of lymphocytes and macrophages in this patch-stage MF. B, The papillary dermis has a perifollicular and perivascular infiltrate of macrophages and lymphocytes and one collection of atypical lymphocytes in the epidermis (Pautrier microabscess). The black at the bottom right is ink used for orienting the biopsy. C, Atypical lymphocytes with pleomorphic convoluted (cerebriform) nuclei form the Pautrier microabscess. D, The dermal infiltrate contains scattered atypical lymphocytes with irregular nuclear configurations.

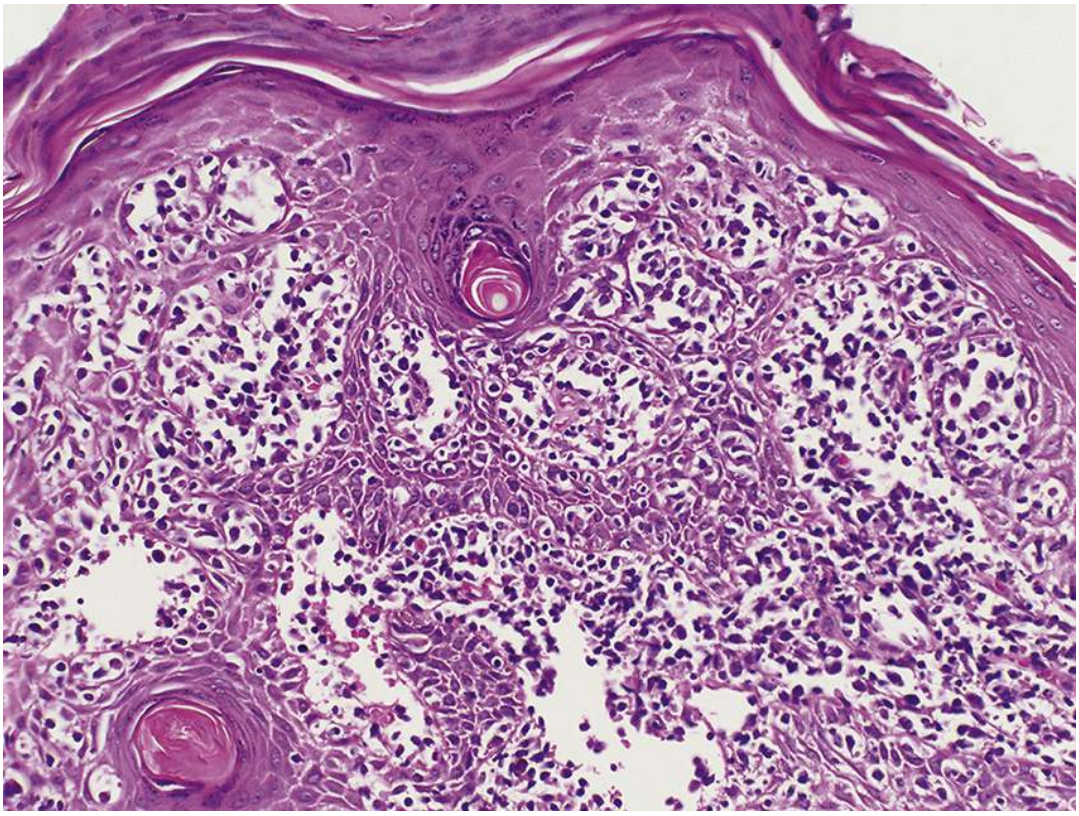

FIGURE 129.4 A woman in her upper 30s with a 1-year history of CTCL developed an erythematous, scaly plaque on

her left upper eyelid. This plaque-stage MF has a dense papillary dermal infiltrate of atypical lymphocytes with extensive epidermotropism and numerous Pautrier microabscesses. Many of the individual lymphocytes in the basal epidermis have clear cytoplasmic rims (halo cells). The lymphocytes were CD3+, CD4+, and CD5+.

(Print pagebreak 862)

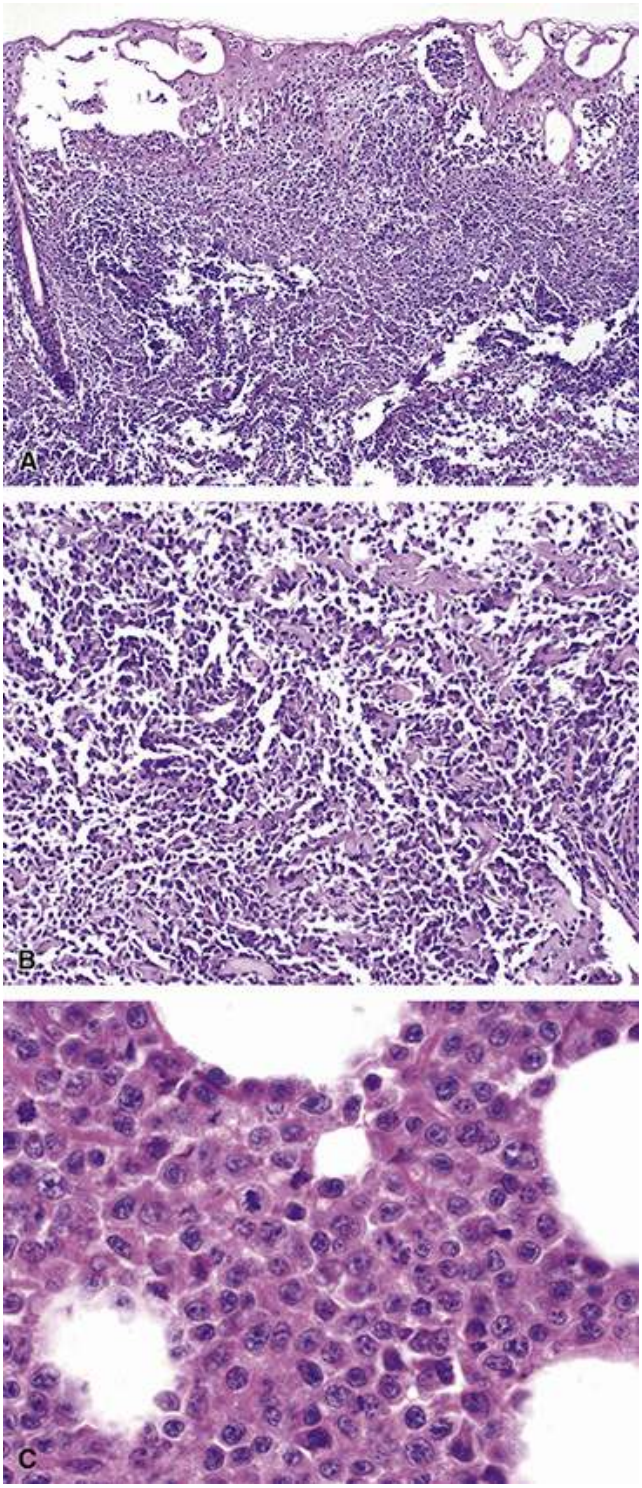

FIGURE 129.5 This biopsy is from the lower eyelid of the MF tumor shown in Figure 129.1B. A, Atypical lymphocytes extensively infiltrate the epidermis and efface the dermis. B, Only a few bands of collagen are present in the dermis among the diffuse infiltrate of atypical lymphocytes. C, Sheets of atypical lymphocytes extensively replace the subcutaneous adipose tissue. Some of the atypical lymphocytes feature cerebriform nuclei, others have prominent nucleoli, and a mitotic figure is near the center of the photomicrograph.

(Print pagebreak 863)

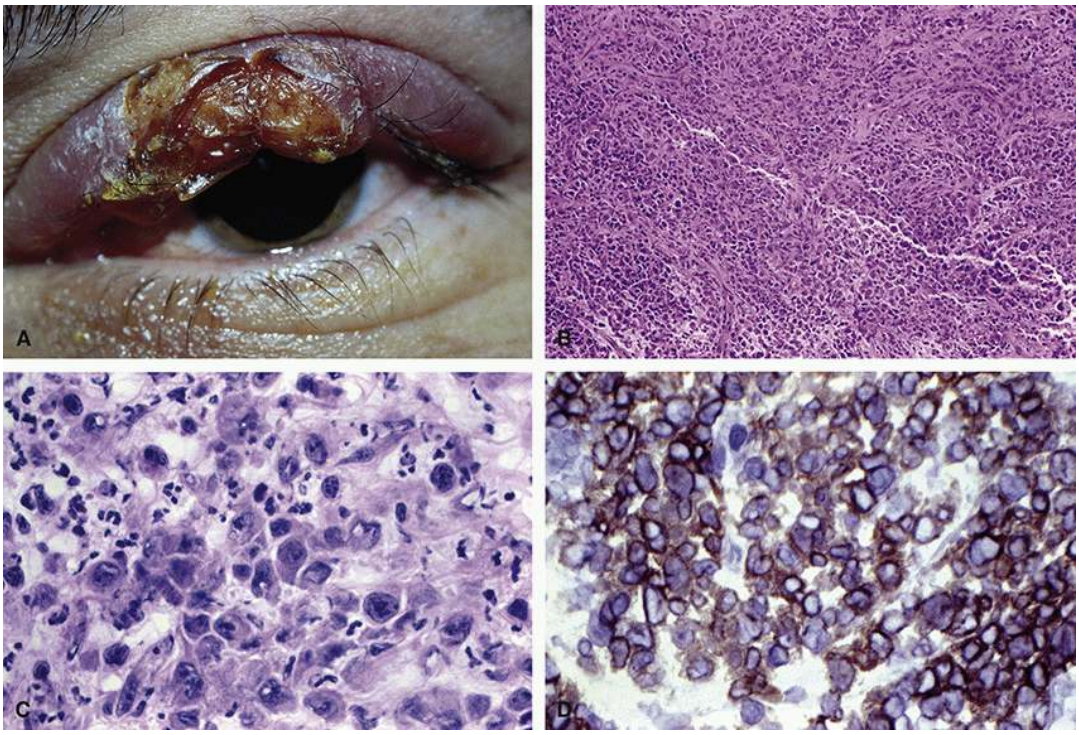

FIGURE 129.6 A, A man in his middle 30s developed an ulcerated 2-cm-diameter lesion of his left upper eyelid over 2 months. B, The dermis has a diffuse infiltrate of mostly large lymphocytes with fewer intermixed small lymphocytes and neutrophils. C, The large lymphocytes are anaplastic with irregularly shaped nuclei, large nucleoli, and a moderate amount of amphophilic cytoplasm. There are neutrophils between the lymphoma cells. D, The large anaplastic lymphocytes express CD30 on their cell membrane. The CD30+ anaplastic lymphocytes also expressed CD4 (T helper lymphocyte marker). They were negative for the expression of B-lymphocyte markers CD19 and CD22. There was no evidence of systemic lymphoma, and he received chemotherapy and radiotherapy and had resolution of his eyelid disease with no recurrence after 10 years.

CHAPTER 130

Dermatofibrosarcoma Protuberans

Key Points

- Dermatofibrosarcoma protuberans is a fibroblastic cutaneous sarcoma that represents the most common dermal sarcoma
- It has a very low metastatic potential but has a tendency for local recurrence when incompletely resected
- It typically arises within the dermis and subcutaneous fat and runs an indolent, low-grade course
- Cases have been associated with tattoos and areas of previous trauma and radiation exposure
- Lesions present as an asymptomatic, skin-colored to red-brown, slowly growing, indurated, superficial soft tissue plaque
- The mainstay of treatment is surgical resection with negative margins
- The prognosis is generally very good if the tumor is widely excised

Dermatofibrosarcoma protuberans (DFSP) is a fibroblastic cutaneous sarcoma that represents the most common dermal sarcoma.[1] It generally runs an indolent course and is associated with a high cure rate when completely resected.[2] The classic form of DFSP has a very low metastatic potential but has a tendency for local recurrence when incompletely resected. However, this tumor may undergo a fibrosarcomatous transformation in 5% to 15% of cases, and this is associated with an increased risk of metastases, of about 10% to 15%.[3] The presence of transformed fibrosarcomatous features can often be detected in the primary tumor, but in some cases, it is identified only in relapsed tumors.[3,4] DFSP was first established as a distinct disease by Darier and Ferrand in 1924.[5] The term dermatofibrosarcoma protuberans was coined in 1925 by Hoffman,[6] and in 1962 Taylor and Helwig emphasized its histopathologic findings.[7]

DFSP is an indolent, low-grade cutaneous soft tissue sarcoma that typically arises within the dermis and subcutaneous fat, and in some cases infiltrates deeper into muscle and fascia.[8] Rarely, this tumor can arise within subcutaneous fat, either without involvement of the dermis or with only minimal dermal involvement.[8] It represents less than 0.1% of all malignancies, less than 5% of adult soft tissue sarcomas, about 18% of all cutaneous soft tissue sarcomas,[9] and fewer than 1% of all malignant tumors of the head and neck.[10,11] It has an incidence of 0.8 to 4.2 cases per million persons per year.[12,13]

DFSP is a soft tissue sarcoma that usually originates from the dermis of the skin. It rarely metastasizes (less than 5%), but there is a high propensity for local recurrence, often associated with significant morbidity.[14] The tumor can be locally aggressive when it extends into deeper subcutaneous layers.[15]

This tumor usually occurs in the third to sixth decades of life, but it has also been reported in infants, children, and adolescents, with pediatric patients accounting for about 6% of cases.[16,17] Males are affected slightly more frequently than females (about 57%),[18,19] and blacks have an incidence that is almost double that reported among Caucasians.[20]

DFSP occasionally exhibits fibrosarcomatous transformation (DFSP-FS), seen in 7% to 16% of cases.[18,21] In these instances, it exhibits a more aggressive course, shows an increased capacity for hematogenous dissemination, and is associated with a risk of metastasis of about 10%.[22,23,24,25] The main sites for DFSP-FS metastasis are the lungs, bones, soft tissue, and brain.[26,27] Clinically, DFSP-FS is indistinguishable from classic DFSP and requires histopathology for differentiation.[28]

Etiology and Pathogenesis

The etiology of DFSP remains unknown. Cases have been associated with tattoos,[29,30] and can occur in areas of previous trauma such as vaccination scars, central venous lines, and burn scars, and have been associated with tanning bed use.[31,32,33,34] Postradiation DFSP has been reported in seven cases.[35,36,37,38,39,40]

The histogenesis of DFSP remains controversial and has been attributed to fibroblastic, myofibroblastic, and neural origins. Dominguez-Malagon et al[41] presented ultrastructural evidence supporting a dendritic dermal cell origin. DFSP is characterized by the chromosomal translocation t(17;22) (q22;q13) between chromosomes 17 and 22. This translocation is present in more than 90% of DFSP and is thought to be a key factor in its pathogenesis. This leads to the fusion of the genes encoding for platelet-derived growth factor-beta polypeptide (*PDGFB*) and collagen type 1A1 gene (*COL1A1*). The resulting fusion gene upregulates PDGFB, resulting in overproduction of PDGF and leading to cellular proliferation and tumor formation.[1,42]

Molecular profiling in a small number of cases (five DFSP and five DFSP with FS transformation) indicated that the FS progression was sustained by a transcriptional reprogramming, paralleled by a loss of genomic material from a nontranslocated chromosome 22q, and occasional loss of the short arm of chromosome 22.[22]

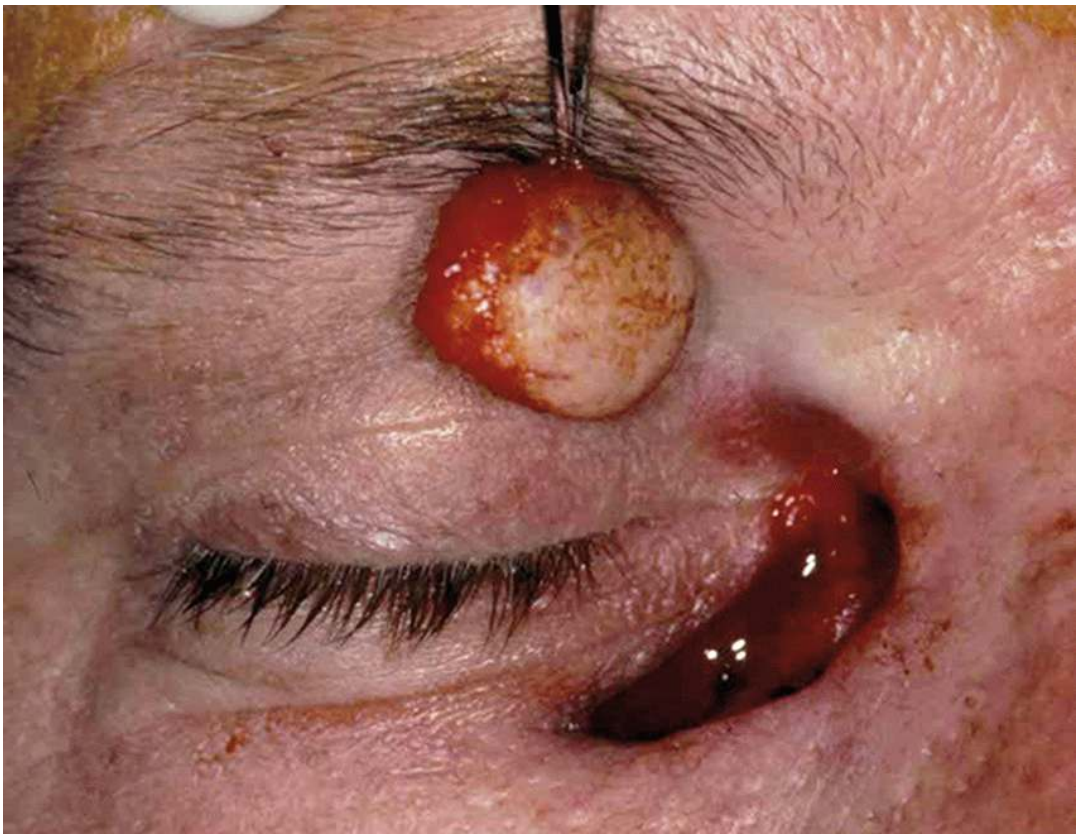

FIGURE 130.3 Surgical excision of the lesion in Figure 130.1 showing the subcutaneous location. (Courtesy of Drs. John Holds and Scott Fosko.)

Clinical Presentation

DFSP usually presents as an asymptomatic, skin-colored to red-brown, slowly growing, indurated, superficial soft tissue plaque that eventually develops single or multiple raised violaceus nodules in early to middle adult life (Figures 130.1 and 130.2). Tumors are usually firm, and hemorrhages or cystic degeneration may be seen. A pigmented variant (known as Bednar tumor) is seen in less than 5% of cases. Necrosis is rare and suggests the possibility of high-grade transformation.[43]

The mean duration of symptoms before presentation is 2 to 3 years but can range from a few months to as much as 60 years.[44] The most common sites of occurrence are the trunk (40%-60%), proximal extremities (20%-40%), and head and neck (10%-15%).[18,45,46]

Most lesions remain localized within the dermis and subcutaneous tissue (Figure 130.3), but recurrent or long-standing tumors can invade more deeply into the fascia, muscle, periosteum, and even bone. In the early growth phase, tumors are fixed to the overlying skin without involvement of deeper tissues, but later they can begin a rapid growth phase where they can infiltrate into deeper fascial planes. Rapid tumor enlargement often reflects fibrosarcomatous transformation.[47]

Differential Diagnosis

The differential diagnosis for DFSP is extensive and includes neurofibroma, schwannoma, solitary fibrous tumor, dermatofibroma, leiomyoma, keloid, desmoid tumor, nodular fasciitis, sarcoidosis, malignant melanoma, morpheaform basal cell carcinoma, Kaposi sarcoma, and fibrosarcoma.[12]

Treatment

The mainstay of treatment for DFSP is surgical resection. When complete excision is accomplished with negative margins, a cure without recurrence can be achieved. However, excision with conservative margins of 1 to 1.5 cm can lead to unacceptable tumor control, with published local recurrence rates varying from 26% to 60%.[45,48,49,50,51,52] To improve local control after surgery, many authors have recommended wide excision with a 2 cm or greater margin of resection. In cases where the resection margin was larger than 2 cm, the mean local recurrence rate was reported to be 18%.[52]

Wide resection margins of 2 cm or more are impractical or impossible for most eyelid lesions without sacrificing vital structures. Mohs micrographic surgery (MMS) is an alternative approach in such cases where preservation of cosmesis and function are a priority. MMS has been shown to achieve tumor clearance with smaller margins of resection and greater preservation of healthy tissue than with conventional surgery.[53,54] Recurrence rates of 0% to 8% have been reported with MMS over follow-up intervals of 38 to 60 months.[55,56,57,58]

(Print pagebreak 868)

The role of radiotherapy alone as the primary treatment for DFSP remains unclear. As an adjuvant treatment along with surgery, the difference in local recurrence is not significant compared with surgery alone. However, in a recent meta-analysis, there was a positive trend in the direction of a positive benefit.[59] Nevertheless, radiotherapy in doses of 50 to 60 Gy as an adjuvant to surgical resection should be considered if margins are positive and further resection is not possible, or where wide excision alone would result in major cosmetic or functional deficits.[60]

Systemic cytotoxic therapy for locally advanced or metastatic DFSP plays a limited role in treatment. The most common regimens include doxorubicin and ifosfamide, and case reports using methotrexate and vinblastine or vincristine, actinomycin, and cyclophosphamide have shown little to no effect in treating DFSP.[61] Overall, there is a minimal role for conventional chemotherapy, and clinical outcomes have been poor.[52]

Molecular targeted therapy based on identification of the t(17;22) translocation prompted the use of tyrosine kinase inhibitors for the treatment of DFSP.[62,63,64] Imatinib mesylate, an oral tyrosine kinase inhibitor, has been used for recurrent, unresectable, and metastatic DFSP in adults. This agent competitively inhibits ATP binding to the PDGF-beta receptor, a tyrosine kinase, slowing down kinase activity, thus limiting tumor growth and promoting apoptosis. Patients with the t(17;22) translocation show a greater response to imatinib mesylate, and the majority of such patients show a favorable response to therapy. In a meta-analysis of nine studies involving advanced or metastatic DFSP, complete response to imatinib was reported in 5.2%, partial response in 55.2%, stable disease in 27.6%, and progression in 9.2%.[65] Sorafenib, a BRAF and vascular endothelial growth factor receptor inhibitor, was reported to show a dramatic response in the treatment of a DFSP that failed all previous treatments, with no recurrences over a 6 month follow-up interval.[66]

Prognosis

The prognosis of DFSP is generally very good if the tumor is widely excised with negative margins.[48] The 2- and 5-year survival rates have been reported as 97% and 92%.[49,67] In a retrospective analysis of 5249 patients diagnosed with DFSP during 2003 to 2012 from the National Cancer Database for patients, the mortality rate was 3.1% over an average of 51.4 months of follow-up.[68]

DFSP with fibrosarcomatous transformation has been reported to have a higher rate of local recurrence, distant metastases, and death.[24] Hoesly et al[23] reported a 42% recurrence-free survival rate at 5 years. Other studies reported local recurrence rates of 36% and metastatic rates of 13%, both of which are greater than in the classic form of DFSP.[25]

Histopathology

DFSP is histologically subclassified by the World Health Organization into classic (conventional) DFSP, giant cell fibroblastoma, myxoid DFSP, pigmented DFSP (Bednar tumor), myoid DFSP, and fibrosarcomatous DFSP.[69] Other variants include atrophic DFSP, giant cell DFSP, granular cell DFSP, and sclerotic DFSP.[70,71]

The early nonprotuberant stage of classic DFSP has scattered elongated spindle cells in the upper dermis with a thin layer of normal papillary dermis between the tumor and overlying epidermis (grenz zone).[70] Protuberant DFSP lesions have uniform (monomorphic) spindle cells in the dermis that usually "extend into the subcutaneous fat or deeper" (Figure 130.4A, C).[7] Subcutaneous fat infiltration usually creates a lace-like or honeycomb pattern.[69] Tumor cell nuclei are elongated with minimal pleomorphism or hyperchromasia, the cytoplasm is scanty and moderately eosinophilic, and cell borders are ill-defined.[72] Mitotic figures are infrequent.[7,72] Taylor and Helwig noted, "the striking architectural characteristic was the disposition of tumor cells around a central 'hub', producing a pattern resembling the spokes of a wheel or whirligig. This cartwheel pattern was present in every lesion and usually dominated the microscopic picture" (Figure 130.4B, C)[7] Tumors are most cellular centrally, becoming less cellular peripherally, "where the cells appeared more mature and were associated with collagen. The lesions invariably blend into the adjacent normal corium despite the gross appearance of circumscription."[7] Centrally located tumor cells are plumper with rounder nuclei than the peripheral cells that tend to resemble typical fibroblasts.[7] Tumor cells may surround, but they do not invade skin appendages.[72] The epidermis overlying the tumor is usually thinned with flattened rete ridges,[7,72] and about 75% of tumors have a grenz zone of sparing in the upper dermis.[72] Tumor cells typically have strong and diffuse staining of their cytoplasm using antibodies to CD34 (Figure 130.4D).[1,70] The tumor cells can variably express CD99, and there may be focal expression of smooth muscle actin and epithelial membrane antigen.[1] Expression of factor XIIIa, S-100 protein, melan A (MART-1), and podoplanin are typically absent.[1] In cases where the diagnosis of DFSP is unclear, detection of the fusion gene *COL1A1-PDGFB* using fluorescent in situ hybridization confirms the diagnosis.[73] However, this fusion gene is absent in about 10% of cases, so failure to detect it does not rule out a diagnosis of DFSP.[73]

Fibrosarcomatous DFSP accounts for about 10% to 20% of DFSP cases, with the proportion of fibrosarcoma ranging from 5% to >75% of the tumor area.[71] The fibrosarcomatous areas have a fascicular or herringbone pattern, hypercellularity, atypical cytological features, increased mitotic activity, and focal or complete loss of CD34 expression.[69,71] The fibrosarcomatous area should be assigned a histological grade.[73,74]

Giant cell fibroblastomas occur most commonly in childhood[69,75] and accounted for 5 of 28 childhood DFSPs in a French Federation of Cancer Centers Sarcoma Group study.[17] Giant cell fibroblastomas are "characteristically hypocellular, consisting of loosely textured fascicles of slender wavy spindle cells set in an abundant and well-vascularized collagenous to *(Print pagebreak 869)* myxoid extracellular matrix."[17] A variable number of pleomorphic mononucleated and multinucleated giant cells are mixed with the tumor spindle cells or spread throughout the tumor.[17] Hybrid tumors with classic DFSP and giant cell fibroblastoma areas were 4 of the 28 childhood DFSPs in the French Federation of Cancer Centers Sarcoma Group study.[17]

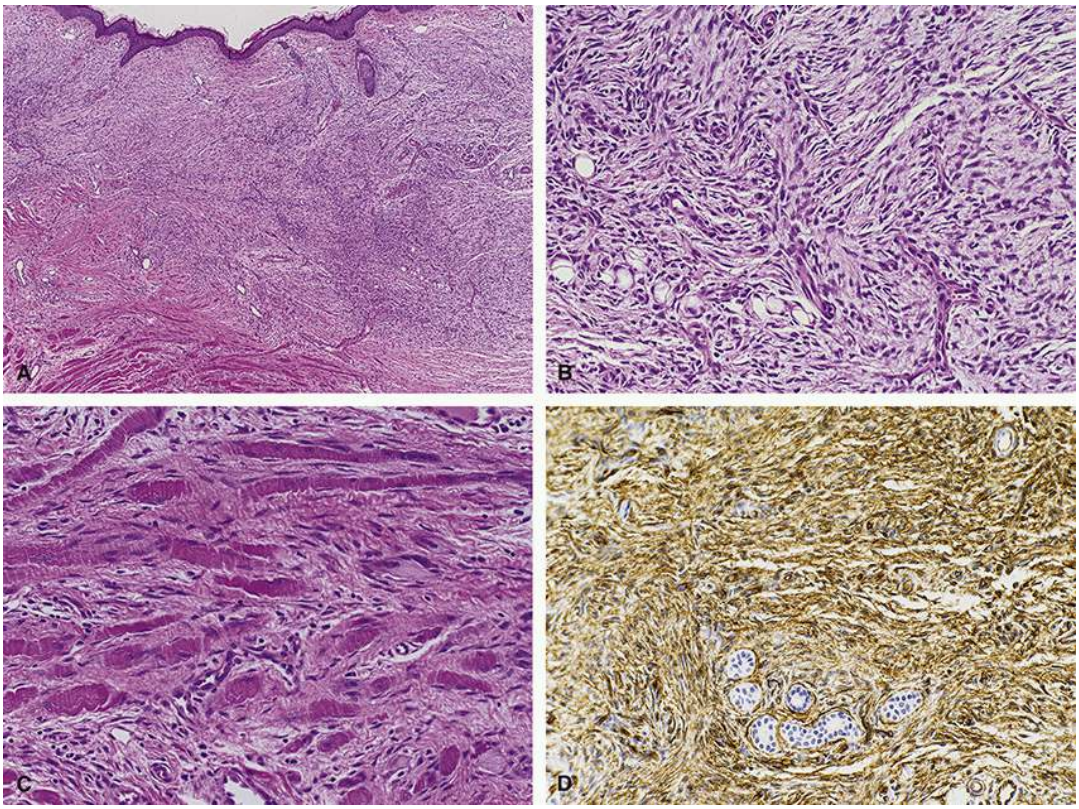

FIGURE 130.4 This classic dermatofibrosarcoma protuberans involved the left forehead and eyebrow of a child. A, The dermis has a proliferation of spindle-shaped tumor cells resulting in a blue hue compared with the underlying eosinophilic frontalis muscle. B, The tumor cells have a storiform (cartwheel) architecture typical of DFSP. The individual tumor cells have a uniform appearance without mitotic figures. C, Tumor cells infiltrate the frontalis muscle. D, The tumor cells are diffusely and strongly positive for CD34 expression. Tumor cells surround but do not infiltrate the eccrine glands near the bottom of the photomicrograph.

CHAPTER 131

Fibrosarcoma

Key Points

- Fibrosarcoma (FS) is a highly malignant tumor of fibrous tissue
- These tumors predominantly arise from tendons and fascia of deep soft tissues, most often in the extremities, trunk, head, and neck
- The infantile type is classified as a tumor of intermediate malignancy that rarely metastasizes
- The adults type is a very malignant tumor with a high metastatic potential
- The etiology has not been identified, but genetic mutations and predisposing factors, such as scar tissues, former burns, foreign material, and radiotherapy, may be influential
- It usually presents as a painless, firm, spherical, sharply demarcated mass
- Treatment is with wide surgical resection, and for larger deep tumors radiation therapy after surgical resection
- The prognosis is poor with an overall 5-year survival rate of 40% to 60%, and the 10-year survival rate is 60% for low-grade and 30% for high-grade tumors, respectively

Fibrosarcoma (FS) is a highly malignant tumor of fibrous tissue. These tumors predominantly arise from tendons and fascia of deep soft tissues and most often involve soft tissues of the extremities, trunk, head, and neck. There have been reports of FS in visceral organs and retroperitoneum, but these have been questioned and it has been suggested that they represent other malignant lesions.[1] FS can occur inside bones as a primary tumor, and the periosteum also can be a site of origin.[2] Areas of preexisting bone injury or radiotherapy may give rise to secondary FS tumors.[3]

Two types of FS have been distinguished, an infantile/congenital type (IFS), and an adult type. FS in adults is classified as a highly malignant tumor with high metastatic potential. While this was previously believed to be the most common malignant soft-tissue sarcoma in adults,[1] more recent data show that FS accounts for only 3.6% of all adult sarcomas.[4]
Adult FSs mainly arise in middle-aged and older individuals between the ages of 25 and 80 years, with a median of 50 years,[1] and may be slightly more common in males.[5]

Several clinically, morphologically, and genetically distinct subtypes of adult FS have been recognized.[1] Low-grade fibromyxoid sarcoma occurs most often in young adults but can affect children in about 20% of cases.[6,7,8,9] It most commonly involves the deep soft tissues of the extremities and has a low risk of metastasis of approximately 15%. Sclerosing epithelioid FS has been considered to represent a distinct variant of FS, but some data suggest a link between this variant and low-grade fibromyxoid sarcoma.[10,11,12,13] It may exhibit aggressive behavior, metastatic spread, and a mortality rate of 25% to 57%.[12]

The infantile type of FS is classified by the World Health Organization as a tumor of intermediate malignancy that rarely metastasizes. It represents about 5% to 10% of all sarcomas in infants younger than 1 year.[14,15,16,17,18,19] The incidence in the United States is estimated to be five new cases per million infants. Infantile fibrosarcoma (IFS) is similar to adult FS histologically, but these two tumors differ in that *ETV6-NTRK3* gene fusion expression is present in IFS but absent in adult FS.[20]

FS can develop in the eyelid and orbit either as a primary lesion or as a secondary malignancy in children with retinoblastoma, with or without a history of radiotherapy.[21]

Etiology and Pathogenesis

A definitive etiology for FS has not been identified, but some genetic mutations and other predisposing factors, such as scar tissues,

former burns, foreign material, and radiotherapy, may be influential.[22,23,24] Adult FS has been reported to show multiple nonspecific numerical and structural chromosomal abnormalities, including complex karyotypes, unbalanced translocations, deletions, and inversion.[25,26] However, there do not appear to be any characteristic chromosomal changes.

IFS is associated with the characteristic t(12;15) (p13;q26) translocation encoding a novel fusion protein (ETV6-NTRK3) containing the protein-protein interaction domain of ETV6 and the tyrosine kinase domain of NTRK3. This results in an active fusion oncoprotein that is capable of transforming cultured fibroblasts.[20] This translocation does not occur in adult-type FS. Trisomy of chromosomes 8, 11, 17, and 20 are also frequent findings in IFS.[27]

Clinical Presentation

FS mainly arises in regions of deep connective tissue rich in collagen. The adult type is seen predominantly in the lower extremities, particularly around the thighs, knees, arms, and trunk.[28] Occurrence in the head or neck is less common. The tumor usually presents as a painless, firm, spherical, sharply demarcated mass (Figures 131.1 and 131.2).[29] Deep-seated *(Print pagebreak 873)* lesions become symptomatic when surrounding tissues are compressed.

FIGURE 131.1 Infant with a 5-cm nonpulsatile congenital fibrosarcoma of the glabella. (Reprinted with permission from Elsevier; Nicholas RG, Brennan TE. Congenital infantile fibrosarcoma of the glabella: Nuances of achieving surgical cure without cosmetic or functional deformity. Int J Pediatr Otolaryngol 2019;117:110-114.)

FIGURE 131.2 A massive fibrosarcoma of the eyelids, glabella, and forehead in an infant. (Courtesy of Dr. Peter Dolman.)

IFS affects infants and young children. About 30% to 40% of cases present at birth,[30] and it is rarely seen after the age of 2 years. Clinical presentation is a painless, localized, rapidly growing tumor, involving the upper and lower extremities in 60% of cases.[31] However, lesions on the abdomen and retroperitoneum have also been reported. The head and neck are involved in 10% of cases,[31] but occurrence on the eyelids is extremely rare.[32] The tumor is usually highly vascularized and occasionally causes ulceration of the overlying skin.[33] IFS occurs more commonly in males, with a male to female ratio of 3:2.

Differential Diagnosis

The presentation of FS is nonspecific, and the diagnosis is usually one of exclusion.[22] Clinically it can be confused with a wide variety of benign lesions and other sarcomas. Because of the highly vascular nature of these lesions, IFS may be confused with vascular tumors or malformations.[34] Immunohistochemical and molecular techniques help differentiate the various subtypes of FS, which otherwise can be very similar in morphology and clinical manifestations. Other spindle-type tumors such as the monophasic fibrous synovial sarcoma, malignant peripheral nerve sheath tumor, solitary fibrous tumor, aggressive fibromatosis, spindle-cell types of angiosarcoma, rhabdomyosarcoma, leiomyosarcoma, and epithelioid sarcoma must be distinguished from FS.[1,3,29,34]

Treatment

Treatment of localized FS of the eyelid consists of wide surgical resection. In cases with extension into the orbital, exenteration may be necessary.[21] For larger deep tumors radiation therapy after surgical resection is often recommended. Adjuvant chemotherapy for soft-tissue sarcomas remains controversial[28,35] and is not considered a standard treatment for these tumors except in patients with advanced disease. The response of FS to chemotherapy is generally not good, partly due to drug coresistance against vincristine, actinomycin D, vinblastine, and etoposide.[36] First-line chemotherapy in patients with advanced-stage FSs is based on anthracyclines such as doxorubicin. Improvement of overall survival rate has been seen in only 4% to 11% of patients with sarcoma treated with chemotherapy.

Prognosis

Poor prognostic factors for FS include high histologic grade, significant necrosis of greater than 50%, a high number of mitotic figures, increased cellularity, larger size, and deep localized tumors.[29,37] Histopathological grade is considered to be the most important prognostic indicator,[38,39] and patients with high-grade FS have a greater risk for metastases. About 80% of adult-type FSs are high-grade malignancies.[5] However, regardless of grade, the overall 5-year survival rate is only about 40% to 60%.[5,29,37] The 10-year survival rate is 60% for low-grade and 30% for high-grade tumors, respectively.[22]

Metastatic spread is seen in 9% to 63% of patients with adult-type FS.[40] The lungs and bones of the axial skeleton are the major sites of metastatic spread. In a small number of cases, regional lymph node involvement can also be seen.[2,40] IFS carries a more favorable prognosis with a 5-year overall survival rate of about 89%.[19,20] Tumor-associated *(Print pagebreak 874)* mortality is associated with larger tumor size and location in the head and neck and other locations where complete excision might not always be possible.[33]

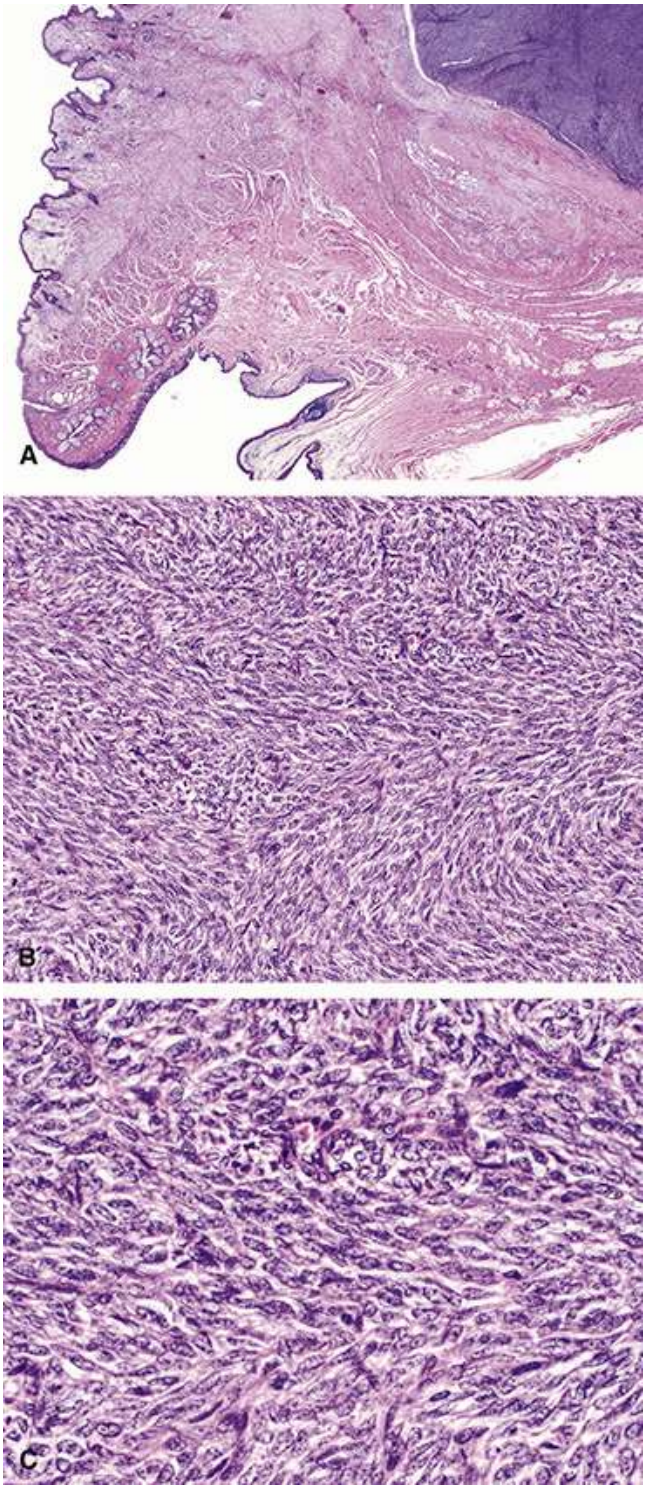

FIGURE 131.3 This fibrosarcoma arose in the right orbit of a 7-year-old boy and recurred 8 years following excision. The recurrent tumor was 25 × 28 × 17 mm and extended into the lower eyelid. A, At scanning magnification, the tumor extends anterior to the orbital septum. B, The tumor is composed of interlacing fascicles of spindle-shaped cells, creating a herringbone pattern. C, The tumor cells are spindle shaped and have oval nuclei, minimal cytoplasm, and indistinct cytoplasmic borders. There are scattered hyperchromatic nuclei. (Photomicrographs were prepared from a slide distributed by Dr. Ahmed A. Hidayat at the 1984 meeting of the Eastern Ophthalmic Pathology Society.)

Histopathology

The diagnosis of FS is one of exclusion.[1,41,42] IFSs are most commonly a cellular neoplasm with monomorphic spindle to oval cells arranged randomly or in a herringbone pattern (Figure 131.3).[43] Tumor cells have scant cytoplasm and slightly angulated nuclei, and the stroma ranges from collagenous to myxoid.[43] IFSs often have a hemangiopericytoma-like vascular pattern.[43] Mitoses may be infrequent to numerous, atypical mitotic figures are absent, and the tumors infiltrate adjacent tissues.[43] IFSs have a nonspecific immunohistochemical staining profile, but the diagnosis can be supported by demonstrating *ETV6-NTRK3* gene fusions or other gene rearrangements, including *NTRK1*, *BRAF*, and *MET*.[43]

Adult FSs are formed of relatively monomorphic spindle cells[1,42,44] "characteristically arranged in long, sweeping fascicles that may be angled in a chevron-like or herringbone pattern."[44] Tumor cells have tapering hyperchromatic nuclei, variably prominent nucleoli, and scant cytoplasm.[44] Variable numbers of mitoses are present, and the amount of interstitial collagen ranges from a delicate intercellular network to zones of keloid-like sclerosis.[42,44] There is no diagnostic immunohistochemical or molecular profile for adult FS, but immunohistochemistry and molecular analyses help exclude other soft-tissue tumors.[42,44]

CHAPTER 132

Kaposi Sarcoma

Key Points

- Kaposi sarcoma (KS) is a low-grade, multicentric, vascular neoplasm
- Classic KS occurs in elderly men of southern European ancestry, typically on the lower extremities
- Endemic KS predominates in young black HIV-negative sub-Saharan African men
- Iatrogenic KS occurs in patients with solid-organ transplantation on immunosuppression therapy
- Epidemic KS is the most common type, seen with AIDS
- The pathogenesis remains controversial, but viral infection is thought to be the major factor
- Eyelids and conjunctival lesions present as solitary or multifocal, painless, reddish or violaceous, flat to elevated macules, papules, or nodules
- Surgical excision and radiotherapy are appropriate for isolated lesions, chemotherapy and immunomodulation for systemic disease, and highly active antiretroviral therapy (HAART) for AIDS-related KS
- The prognosis is favorable for patients with KS lesions limited to the skin, but the mortality rate in patients with visceral involvement is high

Kaposi sarcoma (KS) is a low-grade, multicentric, vascular neoplasm that was first described by Moriz Kaposi in 1872.[1] It is widely accepted that KS occurs in four clinical forms: classic, African endemic, epidemic, and idiopathic (transplant, immunocompromised-related).[2,3] Classic KS is an indolent disease that most often occurs on the lower extremities of men of southern Mediterranean, eastern European, or Middle Eastern descent in the sixth decade of life.[4,5] Risk factors associated with this form include never smoking, diabetes, and oral corticosteroid use.[6] The male:female ratio is about 17:1, and the clinical course is usually mild, with only rare involvement of visceral organs.[7,8]

African endemic KS is a subtype that predominates in sub-Saharan Africa and is typically seen in young black HIV-negative men 25 to 40 years of age.[9] There was a dramatic increase in KS since the onset of the HIV epidemic in Africa so that now it is the most common cancer among males and the second most common among females in Africa.[10] Clinical manifestations vary from indolent to aggressive and lethal. There are four subtypes of endemic KS recognized: benign nodular, locally aggressive, disseminated, and lymphadenopathic. Lymphadenopathic is the most aggressive form, seen most often in African children aged 1 to 5 years.[11]

Iatrogenic or posttransplantation, immunosuppressed-related KS occurs in patients following solid-organ transplantations treated with immunosuppression, or those on chronic immunosuppression for autoimmune disease.[12,13,14,15,16] Risk factors include male sex, nonwhite race, lung transplant, HLA-B mismatch, and older age at the time of transplant. The incidence is highest within the first year after transplantation.[17] Lesions are primarily limited to cutaneous involvement. Corticosteroids and cyclosporine A are the more common agents involved. Maintaining immunosuppression might be necessary for transplant patients to prevent organ rejection, but this can lead to further progression of iatrogenic KS. However, restoring immune defenses by reducing or discontinuing immunosuppression can often induce spontaneous tumor remission.[18]

The epidemic form of KS is the most common subtype, associated with the acquired immunodeficiency syndrome (AIDS), and is the most aggressive form of the disease. It frequently occurs in multiple locations involving the skin, mucous membranes, lymph nodes, and visceral organs including the gastrointestinal and pulmonary tracts.[19] Before the 1980s, KS was a very rare tumor occurring primarily in the classic and iatrogenic forms. But since that time, the occurrence of KS has significantly increased, primarily as the AIDS-related epidemic form. Up to 30% of patients with HIV not taking highly active antiretroviral therapy (HAART) will develop KS.[20] Since the appearance of the epidemic form of KS, there have been sporadic case reports of this tumor

in middle-aged HIV-seronegative homosexual males who have no evidence of immunodeficiency.[21,22,23,24] Clinical presentation in this group is similar to classic KS but occurs at a younger age. As with the classic form, cutaneous involvement usually involves the lower limbs, arms, genitals, and trunk. Also like the classic form, KS in this HIV-negative group runs an indolent course. This form has sometimes been recognized as a distinct subtype termed "nonepidemic KS."[19] A high percentage of patients with nonepidemic KS are positive for human herpesvirus-8 (HHV-8).[25,26,27]

Etiology and Pathogenesis

Infectious agents are known to contribute to the development of many human cancers.[18] Although the exact pathogenesis of KS remains controversial, a viral infection is thought to be a major factor. In 1994, Chang et al[26] first linked the etiology of *(Print pagebreak 877)* KS to a herpes-like virus (also known as human herpesvirus 8 [HHV-8]), where the viral genome was identified in approximately 90% of HIV-positive patients with KS. It was subsequently also found in classic Kaposi lesions of Mediterranean patients,[28,29] in KS lesions in HIV-negative individuals,[30] and in KS of bone marrow and organ transplant patients.[29] HHV-8 has also been identified in KS of the eyelid and conjunctiva.[31,32]

This virus belongs to the gamma-herpesvirus subgroup of Rhadinoviruses,[33] of which the best-known type is the Epstein-Barr virus. A high HHV-8 infection rate is found in Central and Southern Africa, with intermediate rates in the Mediterranean and Eastern European countries, and in some ethnic groups. These are locations and groups associated with the classic and endemic forms of KS. Infection is transmitted mainly by saliva, sexual contact, blood transfusion, or organ donor contamination and is thought to precede the development of KS. HHV-8 interferes with many normal cell functions and requires cofactors like cytokines or specific proteins to cause KS.[34] Although HHV-8 appears to be a promoting factor in pathogenesis, environmental and other cofactors such as inflammation and genetic or iatrogenic immune suppression are probably also required for disease development.[35]

KS is characterized by abnormal neoangiogenesis, inflammation, and the proliferation of tumor cells of endothelial cell origin, but the origin of the endothelial cell remains elusive.[36] The exact mechanism through which HHV-8 participates in oncogenesis is not completely understood, but some studies have identified HHV-8 viral oncogenes that may contribute to tumor development.[37] During the primary infection, HHV-8 induces interleukin-6 (IL-6) by modulating multiple mitogen-activated protein kinase pathways.[38] IL-6 is a proinflammatory cytokine secreted by cells including T cells, macrophages, and fibroblasts in response to trauma or pathogens. It induces *STAT3* (signal transducers and activators of transcription 3) gene activation, resulting in oncogene expression.[39,40]

It has been suggested that, after infecting endothelial cells, HHV-8 activates the mTOR pathway, alters the cells to undergo mesenchymal differentiation, and promotes aberrant angiogenesis.[33] Through immune suppression and inflammation, the HHV-8-infected cells proliferate. Expression of latency-associated nuclear antigen causes binding of p53 and suppresses apoptosis.[33,41] The nuclear factor kappa B signaling pathway, a regulator of innate immunity, is activated by HHV-8 and upregulates VEGF and bFGF resulting in neoangiogenesis.[41]

KS can also occur concomitantly with other HHV-8-associated diseases such as primary effusion lymphoma, multicentric Castleman disease, or KSHV-inflammatory cytokine syndrome.[42] Primary effusion lymphoma is a large cell non-Hodgkin lymphoma seen most commonly in body cavities and occasionally in extracavitary regions.[43] Clinically, it presents without a solid tumor mass but with lymphomatous effusions of the pleural, peritoneal, and pericardial cavities. The condition is usually associated with HHV-8 infections in immunocompromised individuals.[43] Castleman disease is a heterogeneous group of disorders, divided into unicentric and multicentric forms associated with enlarged lymph nodes, fever, night sweats, and nausea. The multicentric form is associated with KS and HHV-8 infection, often in the setting of HIV infection.[44] KSHV-inflammatory cytokine syndrome (KICS) is a systemic illness that typically occurs in association with KS.[45] Unlike most KS, KICS shares mechanisms of viral pathophysiology with KSHV-associated multicentric Castleman disease.

Clinical Characteristics

KS can present as a slow-growing localized lesion or as widespread systemic involvement. Most commonly, it involves the skin of the lower legs, genitalia, oral mucosa, and face, but it can also occur in the digestive tract, lymph nodes, bones, lungs, and liver.[46,47] Pulmonary involvement is the most common visceral manifestation and can be found in 47% of patients with AIDS KS at autopsy.[48] Visceral involvement of the gastrointestinal tract and lungs manifests with nausea, vomiting, weight loss, cough, hemoptysis, and pleural effusion.[49] Lymphatic spread can occur with resultant edema and palpable lymph nodes.[50]

The incidence of KS increased significantly after the onset of HIV infection in the 1980s, and ocular adnexal KS tumors were seen in about 20% of patients with KS.[35] Before HAART, ophthalmic manifestations were seen in 20% to 30% of patients with HIV/AIDS,[51] but now the prevalence is reported at 0.4% to 3.4%.[52,53] The eyelids and conjunctiva are typically involved equally, but with conjunctival lesions, the most common area of involvement is in the lower fornix.[35]

More than 300 cases of KS involving the eyelids and conjunctiva have been mentioned in the literature since 1984.[32,35,54,55,56,57,58,59,60,61,62,63,64,65,66,67] Although most ophthalmic cases are of the endemic type, several cases of classic KS of the eyelid or conjunctiva have been reported.[54,60,68,69] Where data were available from these reports, 85% to 90% of affected patients were male with a mean age at presentation of 39 years, and a range from infancy to beyond the ninth decade. The duration from the initial appearance of lesions to clinical presentation ranged from 3 weeks to 3 years, with most being 12 months or less. More than 50% of eyelid cases may be associated with disseminated systemic disease involving the oral cavity, pharynx, gastrointestinal tract, lower extremities, and regional lymph nodes. Eight cases were reported to involve bilateral eyelids. When ocular manifestations are present, KS may involve the skin of the eyelids; the bulbar, tarsal, and forniceal conjunctiva; plica semilunaris; and caruncle.

KS lesions on the eyelids generally present as solitary or multifocal, painless, flat to elevated macules, papules, or nodules, ranging in size from 5 mm to 1.5 cm[51] (Figure 132.1). Lesions vary in color from red and purple to dark brown in older lesions.[70] They usually are surrounded by tortuous dilated vessels and can be associated with eyelid edema, trichiasis, ptosis, and ectropion. Lesions can be sessile or pedunculated[66] and may occasionally become necrotic, with bleeding and pain.

Isolated conjunctival lesions are rare, and although they usually occur late in AIDS, there are reported cases presenting as an initial manifestation of AIDS.[64,71,72,73] Conjunctival KS lesions may be small and nodular or diffuse, elevated, and globular (Figure 132.2). Rare cases of orbital involvement have also been reported.[67,74,75]

(Print pagebreak 878)

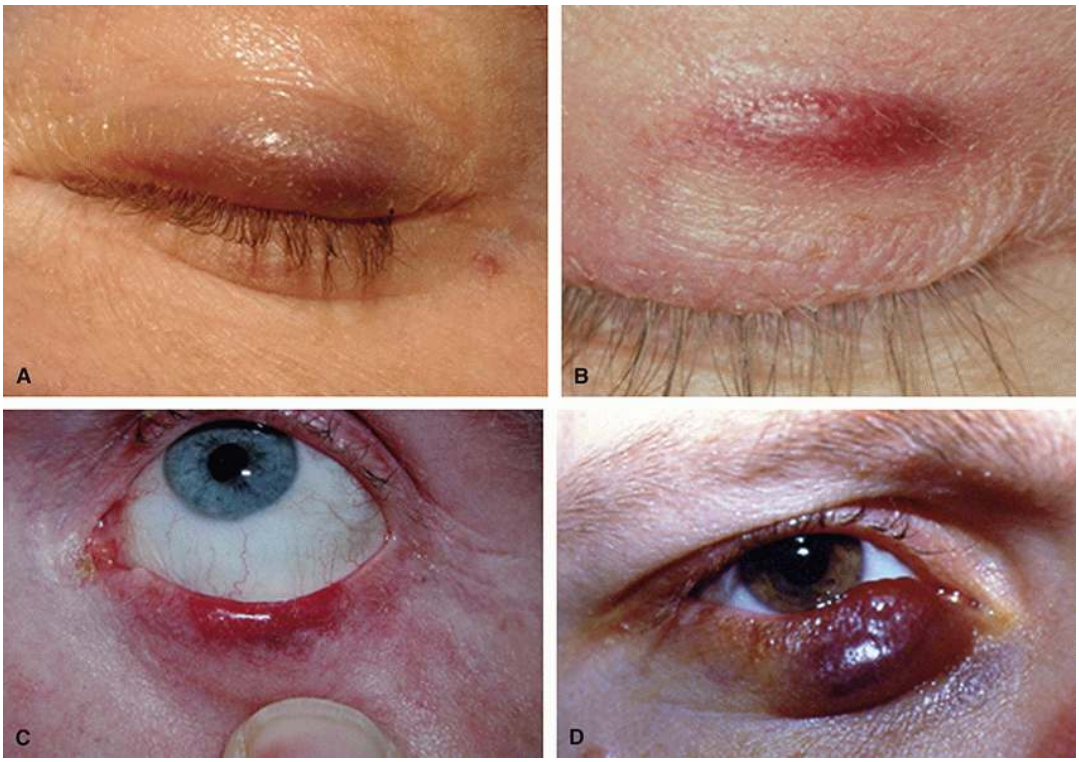

FIGURE 132.1 A-D, Kaposi sarcoma involving the eyelid skin. (A and C, Courtesy of Dr. Timothy Sullivan; D, Courtesy of Dr. Thomas Johnson.)

Differential Diagnosis

KS lesions may mimic benign lesions such as inflammatory dermatoses, pyogenic granuloma, foreign body granuloma, chalazion, hordeolum, chronic subconjunctival hemorrhage, melanocytic nevus, cavernous hemangioma, and dermatofibroma. It is also commonly mistaken for other neoplasms including angiosarcoma, malignant melanoma, or Merkel cell tumor. A biopsy is necessary to confirm the diagnosis.

Treatment

There is no cure for KS. Treatment goals include palliation of symptoms, prevention of progression and visceral organ

compromise, and in some cases cosmetic improvement. For epidemic HIV-related KS, combined antiretroviral therapy (cART) usually allows regression and prolonged stabilization of lesions, especially with mild forms of the disease.[76] A recent report suggested that patients with HIV on cART with sustained HIV viral control and restored CD4 T cell counts might develop a more limited form of KS, with restricted and less inflammatory skin lesions.[42,77]

For each of the other epidemiologic forms of KS, treatment options are similar and include conventional surgery, cryotherapy, laser therapy, intralesional injections of vinblastine or bleomycin, interferon-α (INF-α), radiotherapy, and systemic chemotherapy with liposomal daunorubicin or paclitaxel.[54] Local therapy is preferred for isolated KS lesions, whereas systemic treatment is indicated for widespread tumor dissemination, marked symptomatic edema, rapidly progressive disease, visceral involvement, and KS recurrence not responsive to local therapy. Although liposomal anthracyclines and taxanes are the mainstays of systemic cytotoxic therapy, novel therapies, including INF-α, thalidomide, antiherpes therapy, imatinib, and matrix metalloproteinase inhibitors, have been attempted with some success.

In AIDS-related KS with localized disease, therapy includes surgical excision, radiotherapy, cryotherapy, or intralesional INF-α injections.[57,78,79,80,81,82] The introduction of HAART in 1991 significantly altered the epidemiology and disease course of KS in HIV-infected patients.[76] Chemotherapy is combined with HAART in patients with more extensive, rapidly progressive disease, visceral involvement, or absence of improvement with HAART alone.[81]

Radiotherapy is an effective treatment modality for localized skin and mucosal lesions,[81] resulting in remission rates of 90% or greater with fractionated doses of 24 to 35 Gy.[58,70,83,84,85,86,87,88,89,90] Although the dose needs to be tailored for each patient, greater *(Print pagebreak 879)* doses are associated with a higher response rate, a lower incidence of residual pigmentation, and a longer duration of tumor control.[61] However, eyelid and conjunctival KS seem to be more radiosensitive than those in other sites, and lower fractionated and even single doses have been recommended. Ghabrial et al[58] reported a complete response rate of 32% and a partial response rate of 68% in the treatment of 31 eyelid and conjunctival KS after a single radiation dose of 800 cGy.

FIGURE 132.2 A-C, Kaposi sarcoma involving the conjunctiva. (B, Courtesy of Dr. Roman Shinder; C, Courtesy of Dr. Timothy Sullivan.)

Chemotherapy in combination with doxorubicin, bleomycin, and vincristine is indicated for disseminated disease. Several studies have shown that intravenous pegylated-liposomal doxorubicin is more effective and less toxic and is more effective than antiretroviral therapy alone when used as first-line systemic chemotherapy,[91] with a partial or complete response rate of 46% compared with 25% for standard chemotherapy alone.[92] With the addition of HAART, a complete or partial response rate was reported in 78% of patients.[93]

Successful treatment of classic KS with taxanes has been reported.[94,95] These agents have significant antiangiogenic activities in vivo by downregulating Bcl-2-induced antiapoptotic effects, blocking the growth, migration, and invasion of KS cells.[96] Paclitaxel, a cytotoxic taxane, has become a second-line treatment agent for patients with KS recurrent or refractory to chemotherapy.[97,98,99] This has achieved 45% to 59% partial or complete response rates, but with higher levels of toxicity.

INF-α is a less toxic alternative. Interferons are low-molecular-weight glycoproteins with antiviral and antineoplastic properties that bind to cell surface receptors causing upregulation of tumor-specific antigens and adhesion molecules. Studies have reported regression of KS with systemic INF-α in up to 45% of patients.[80,81,82] However, the side effects are significant. The pegylated formulations show greater efficacy and less toxicity compared with nonpegylated forms.[81] Topical or intralesional IFN has also been used for conjunctival and adnexal KS.[82]

Immunotherapy is aimed at reversing the anergy of immune cells induced by the tumor and its microenvironment, to kill tumor cells.[41] This restoration of immune function is based on the blockade of immune checkpoints by monoclonal antibodies. Ipilimumab blocks CTLA-4; nivolumab and pembrolizumab block PD-1; and atezolizumab blocks PD-L1. Recent reports demonstrated a positive response of KS to checkpoint inhibition therapy after 3 to 6 months in a majority of cases, with approximately 60% of partial responses, 10% of complete remissions, and 30% of stable diseases.[98,99]

For small localized eyelid KS tumors, surgical excision, with or without adjunctive cryotherapy, has been reported to provide long-term regression.[57,63]

Prognosis

The prognosis of KS in both transplant recipients and HIV-infected patients predominantly depends on the extent of disease, rate of tumor growth, and the patient's immune status. Both forms of KS have a variable prognosis that may depend on CD4 cell count and the presence of associated opportunistic infections. In patients with iatrogenic KS, the prognosis also depends on their underlying medical status and their ability to undergo a reduction in immunosuppression. A worse prognosis is usually found in patients with visceral organ involvement, particularly the lungs.[41]

Patients with KS lesions limited to the skin without systemic involvement have more favorable outcomes compared with the high mortality rate seen in patients with visceral involvement.[100] In patients with epidemic KS that is rapidly *(Print pagebreak 880)* progressive or with visceral involvement, the prognosis is good with HAART combined with liposomal chemotherapy.

Histopathology

The histopathological features of the four clinical forms of KS are similar.[101,102] Typical (usual) KS progresses through patch, plaque, and nodular stages with different histological features.[101,103] The patch stage is the earliest evolutionary stage of KS and has a subtle endothelial proliferation with irregular, often jagged, vascular channels within the dermis.[103] The vessels are thin walled, lined by flattened inconspicuous endothelial cells; some have perivascular lymphocytes and plasma cells; and there may be extravasated erythrocytes and hemosiderin-laden macrophages (“siderophages”).[103] The neovascular spaces have a predilection for the vicinity of native dermal blood vessels and cutaneous appendages.[103] The plaque and nodular stages of KS are more cellular with haphazardly intersecting fascicles of spindle cells and poorly defined, slit-like vessels within the dermis that may extend into the subcutis (Figure 132.3).[101,103] There is a background of chronic inflammation rich in plasma cells, extravasated erythrocytes, and siderophages.[101,103] There may be intracellular or extracellular small, eosinophilic hyaline globules that are positive using periodic acid-Schiff stain and resist diastase digestion.[102] These globules are most often seen in the nodular stage of KS and are thought to represent degenerated erythrocytes.[102,103] Mild cytological atypia and occasional mitoses may be present.[101,103] KS lesional cells are immunoreactive for HHV-8-associated latent nuclear antigen, CD31, CD34, and podoplanin (recognized by D2-40 antibodies).[101] Factor VIII-related antigen (von Willebrand factor) is expressed by the endothelial cells of the best-differentiated vessels and variably by the spindle cells.[102] There are numerous histological variants of KS, but these are much less common than typical KS lesions.[101,102,103,104,105]

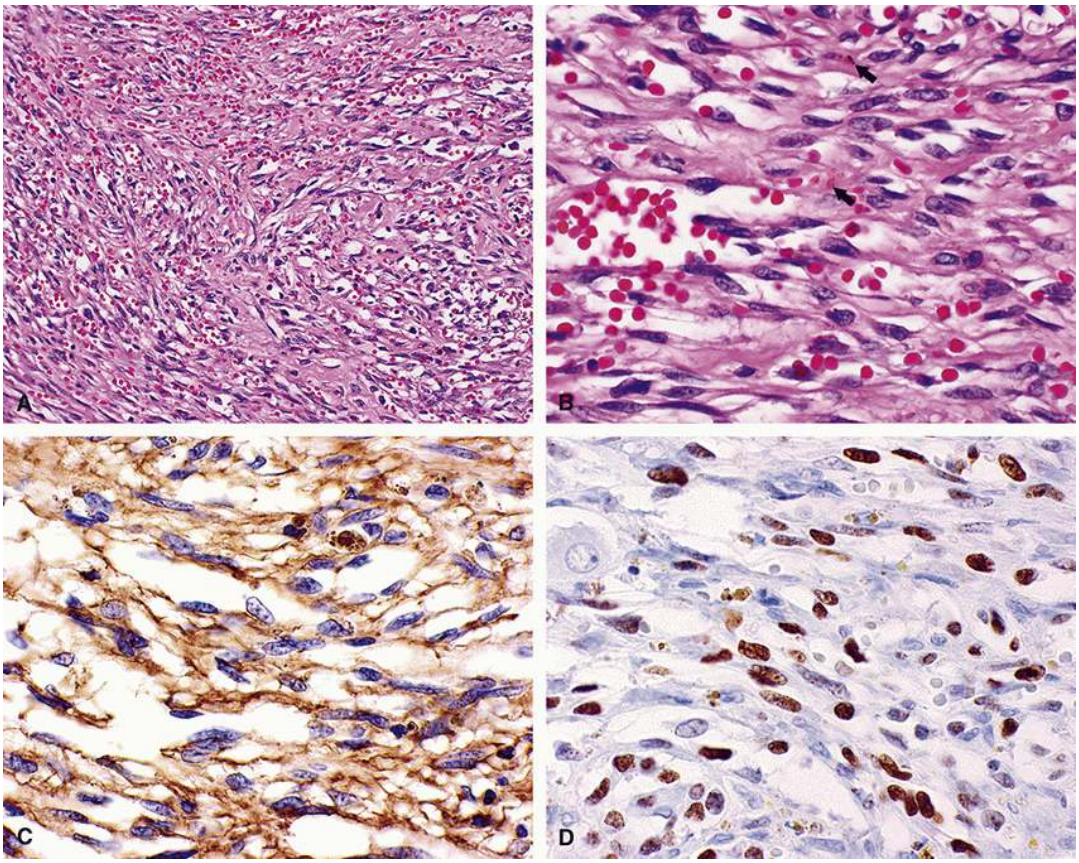

FIGURE 132.3 A man in his middle 40s developed Kaposi sarcoma due to chronic immunosuppression following orthotopic solid organ transplantation. The chest and abdominal skin had many KS nodules, with the largest being 2.1 cm in diameter. Innumerable nodules of Kaposi sarcoma were in both lungs and in the stomach and jejunum walls. A, Interlacing fascicles of spindle cells with slit-like vascular channels form the plaques and nodules of Kaposi sarcoma. B, Erythrocytes are present in the slit-like vessels, and there are a few macrophages with intracellular hemosiderin granules (arrows). C, Tumor cells uniformly express factor VIII-related antigen (von Willebrand factor). D, Most tumor cells express human herpesvirus-8 (HHV-8) latent nuclear antigen.

CHAPTER 133

Leukemia Cutis

Key Points

- Leukemia is a cancer of myelogenous and lymphatic precursor blood-forming cells, and with infiltration of the epidermis, dermis, and subcutis it results in extramedullary lesions such as cutaneous leukemia cutis
- Leukemia cutis (LC) is seen most often with acute myelocytic leukemia
- In the periorbital region, LC presents as eyelid edema, with rubbery pink, violet, or red papules or nodules
- Extramedullary leukemia is a manifestation of current or impending systemic disease, so that treatment should anticipate systemic involvement
- Surgery is not effective, and periocular radiotherapy can have significant ocular complications
- Systemic chemotherapy is recommended for systemic disease

Leukemia is a cancer of myelogenous and lymphatic precursor blood-forming cells. These leukemic blast cells develop in the bone marrow and spread into the circulation. Several types of leukemia are based on whether the disease is acute or chronic, and whether it involves myeloid cells or lymphoid cells. According to the Surveillance, Epidemiology, and End Results (SEER) Program database, the estimated number of new cases of leukemia in the United States in 2022 is 60,650, or 5 3.2% of all new cancers. Of these, the estimated number of tumor-related deaths will be 24,000. The age-adjusted incidence is 12.9/100,000 population.[1]

Peripheral circulating leukemic cells possess the ability to leave the circulation and pass through soft tissues as a cellular infiltration, resulting in extramedullary leukemia. Myeloid sarcoma (MS), also known as chloroma or granulocytic sarcoma, is an extramedullary form of acute myeloid leukemia (AML) that can infiltrate soft tissues, bone, periosteum, and lymph nodes.[2,3,4,5] Because several variants of AML are not of granulocytic lineage, the term myeloid sarcoma is preferred over granulocytic sarcoma.[6] When the infiltration of neoplastic leukocytes is limited to the epidermis, dermis, and subcutis, and when this results in clinical cutaneous lesions, it is often referred to as leukemia cutis (LC). The latter is mostly seen with AML and acute lymphocytic leukemia (ALL), where it can occur in up to 10% of cases, but it can also be seen less commonly with other leukemia subtypes. In pediatric patients with acute leukemia, Russo et al identified specific orbital and ocular lesions (papilledema, Roth spots, leukemic hypopyon, optic nerve infiltration, exophthalmos, optic pallor, retinal infiltration, vitreal opacities) in 16.1% of 180 patients.[7] Orbital and ocular lesions occurred in 66.6% (10/15) of children with AML and 11.5% (19/159) with ALL.[7] The eyelid skin is very thin, and it has been suggested that this may predispose the patient to leukemic infiltrates.[8] Cutaneous infiltrates may develop during therapy for systemic leukemia or may signify relapse. Rarely, extramedullary cutaneous MS by a leukemic infiltrate may be the initial manifestation of disease, where it occurs in the absence of peripheral blood or bone marrow involvement by leukemia, a condition referred to as aleukemic leukemia.[9] Approximately one-third of patients with adult MS are cases of de novo aleukemic disease, with the skin being the most common site of involvement.[10,11]

In the periorbital region, the orbit is the most common site for MS, followed in frequency by the conjunctiva and eyelid.[12,13,14,15,16,17,18] It has been suggested that the higher frequency of cutaneous lesions in AML is a reflection of the more aggressive behavior of AML.[19] Bilaterality is reported in about 10% of cases. Many of the reported cases of orbital, conjunctival, or eyelid MS are lesions presenting as the initial manifestation of the disease, preceding the development of systemic leukemia.[6]

MS is reported in 2.5% to 21.2% of patients with AML[20,21] and can occur before, concurrent with, or following the onset of systemic bone marrow leukemia. Isolated MS may occur in the absence of leukemia, and these patients are often misdiagnosed with lymphoma.[22,23] MS can also develop during a relapse or after allogeneic hematopoietic cell transplantation.[24,25]

LC is much less common than MS, occurring in about 3% of patients with AML,[26] and is even less frequent in chronic leukemias.[27] Certain subtypes of AML are more commonly associated with skin infiltration, the most frequent associations being with acute myelomonocytic and monocytic differentiation with involvement in up to 50% of patients.[26,28,29] The incidence of LC may be

higher in children, particularly infants with myeloid leukemia.[30]

Leukemia is a cancer of myelogenous and lymphatic precursor blood-forming cells. In most patients, LC occurs after a diagnosis of leukemia has been established.[31] However, LC can develop before the onset of systemic leukemia, and most of these patients eventually will develop AML. The cutaneous lesions produced by different leukemia subtypes may *(Print pagebreak 885)* develop distinctly different morphologies over the course of the disease.[19,32] The most commonly involved anatomic locations are the lower extremities, followed by the upper extremities, back, trunk, and face.[33] Interestingly, LC may have a predilection for sites of previous or current inflammation.[34]

Etiology and Pathogenesis

There is no one cause of leukemia, and both genetic and environmental factors likely play a role. Most forms contain genetic or chromosomal alterations such as translocations, deletions, and inversions that block cellular differentiation or that promote the cellular proliferation of precursor lymphoid cells. AML is the most common congenital leukemia, and the most frequent chromosomal abnormalities are t(15:17) (q22;q12), t(8;21) (q22;q22), and inv (16) (p13;q22) rearrangements. Germline chromosomal abnormalities have been correlated with the prognosis of some leukemias such as AML.[35] ALL is the most common leukemia in children under the age of 15 years. The most common cytogenetic abnormalities are reciprocal translocations, t(12;21) in children and t(9;12) in adults. CML is more common in adults with a translocation between chromosomes 9 and 22, whereas in CLL the most common abnormality is del 13q14-23.1.[36]

Human T-cell leukemia virus type 1 (HTLV-1) was the first retrovirus discovered that caused human disease, and it has since been shown to cause adult T-cell leukemia (ATL), in addition to a form of myelopathy, and uveitis.[37] A genetic susceptibility was established because patients with some genetic syndromes, such as Bloom syndrome, neurofibromatosis, Fanconi anemia, ataxia telangiectasia, and trisomy 21, have a high risk of leukemia.[38] The role of other infectious agents has also been suspected in the pathogenesis of leukemia.[39,40] It is not clear how viruses could play a role in the development of leukemia, but theories include a direct transforming mechanism[41] or the result of abnormal immunological responses to congenital, neonatal, or postneonatal infections that promote secondary genetic or immunological alterations.[42]

Infants and young children with Down syndrome have a 500-fold increased risk of developing acute megakaryoblastic leukemia.[43,44] Acquired mutations of *GATA-1*, a gene responsible for megakaryocytic differentiation, are detected in the leukemia cells of these patients.[45]

Clinical Presentation

Approximately 50 cases of eyelid leukemia have been reported. Females were represented slightly more commonly than males (55% vs 45%). All ages have been affected from 10 weeks to 80 years, with a mean of 37 years.[15] The duration of symptoms until final diagnosis ranged from 10 days to 36 months, with a mean of about 8 months. All forms of leukemia can be involved, with the most common being acute myelogenous leukemia, ATL, and chronic lymphocytic leukemia.[15] Other forms that have rarely involved the eyelid include ALL, T-cell prolymphocytic leukemia, acute megakaryocytic leukemia, aleukemic leukemia, chronic myelogenous leukemia, and T-cell large granular lymphocyte leukemia.

The most common presenting symptoms and signs are one or more exophytic eyelid masses,[14,15] eyelid edema, conjunctival injection, and chemosis[19] (Figure 133.1). Fleshy pink, blue-violet, or red-brown papules or nodules are the most frequent lesions,[28,30] followed by infiltrated plaques, generalized cutaneous eruptions, and erythroderma. The nodules are typically firm or rubbery in consistency and can sometimes become purpuric.[17] Pain is rare, as is ocular involvement with uveitis, scleritis, and retinal flame hemorrhages, but lesions can frequently be asymptomatic.[46] Concurrent orbital involvement can be seen in some cases.[36] Many patients have no prior history of systemic leukemia, so that initial misdiagnosis is common. With a high index of suspicion, tissue biopsy, and appropriate histology, immunohistochemistry, and flow cytometry, will lead to a diagnosis.[15]

Differential Diagnosis

The differential diagnosis for cutaneous leukemic infiltrates is similar to that for lymphoma. These include other nonmelanoma malignancies, such as basal cell and squamous cell carcinoma, dermatofibrosarcoma, and metastatic lesions. It can also be mistaken for a variety of benign lesions such as reactive lymphoid hyperplasia, rosacea, *Herpes zoster*, erythema nodosum, and pyoderma gangrenosum. In addition, since common findings in eyelid LC are edema and chemosis, the differential diagnosis should include medication-induced hypersensitivity reaction, allergic contact dermatitis, angioedema, interstitial granulomatous dermatitis, allergic rhinitis, hyperthyroidism, Fabry disease, systemic lupus erythematosus, lymphatic obstruction, and orbital cellulitis.

Treatment

Since extramedullary leukemia is likely to be a manifestation of current or impending systemic disease, treatment should anticipate systemic involvement. Treatment depends on the location of the disease and whether it is the initial manifestation or a recurrence. In one study of MS,[22]
25% (4/16) of patients did not go on to develop acute systemic leukemia during a follow-up period of 3.5 to 16 years. Two of these four patients did not have any cytogenetic abnormalities and, given the wide variety of known anomalies in MS and AML, the authors suggested that, in some variants, no or certain cytogenetic abnormalities might confer a better prognosis and if present might spare some patients chemotherapy or radiotherapy.

Studies have demonstrated the effectiveness of systemic chemotherapy for primary MS, and this is currently the recommended therapy.[47,48,49] Systemic chemotherapy has been shown to decrease the rate of progression to acute leukemia and to increase survival time.[50]

Radiotherapy for isolated MS carries some potential toxicity depending upon the tumor location. It has also been shown to be associated with a high rate of progression to AML after a short nonleukemic period.[51] Also, Tsimberidou *(Print pagebreak 886)* et al reported that combined chemotherapy and radiotherapy for nonleukemic MS had a lower failure-free survival rate than chemotherapy alone,[52] and other studies showed that radiotherapy had no added effect on survival.[50,53]

FIGURE 133.1 Leukemia cutis involving the eyelids. (A, B, & C, Courtesy of Dr. Charles Soparkar.)

Surgery for MS is even less effective, and patients frequently relapse or progress to systemic disease.[54] Patients treated with surgery alone without any systemic treatment have been shown to progress to AML sooner.[51] Surgery alone is not considered an effective treatment for primary MS, and surgery should be considered only in acute situations where rapid tumor debulking and symptomatic relief is needed.[47]

Prognosis

The presence of skin involvement with AML has been suggested to be an indication of aggressive disease with a poor outcome and shortened survival.[31,55] However, more recent studies on patients with AML did not find that the presence of cutaneous involvement was associated with a statistically significant worse response to treatment or a reduced survival rate.[26,52,53] For patients with extramedullary MS or LC disease, treatment outcome depends in part on whether it occurs alone in an otherwise

nonleukemic patient or is associated with systemic AML. Event-free survival and overall survival were found to be better in patients with isolated MS compared with those also having AML. In nonleukemic cases of MS, the 2-year event-free survival rate was reported at 32% and the overall survival rate at 43%, compared with 18% and 29%, respectively, in cases of MS with AML.[48] While most cases of nonleukemic isolated MS will develop acute leukemia, those who do not develop leukemia seem to have a better prognosis.[56]

Histopathology

LC infiltrates may be perivascular and/or periadnexal, diffuse interstitial, or form nodules in the dermis and subcutis.[57,58,59] The cellular appearance of the leukemic infiltrate reflects the underlying form of leukemia (Figure 133.2) and requires immunophenotyping to render a more specific *(Print pagebreak 887)* diagnosis.[57,58,60,61] The immunophenotype of the leukemic cells in the skin is not always concordant with that of leukemic bone marrow cells,[60] so final diagnosis should correlate bone marrow and skin findings. In biopsies of aleukemic LC, several algorithms assist in rendering an immunohistochemical diagnosis.[58,60]

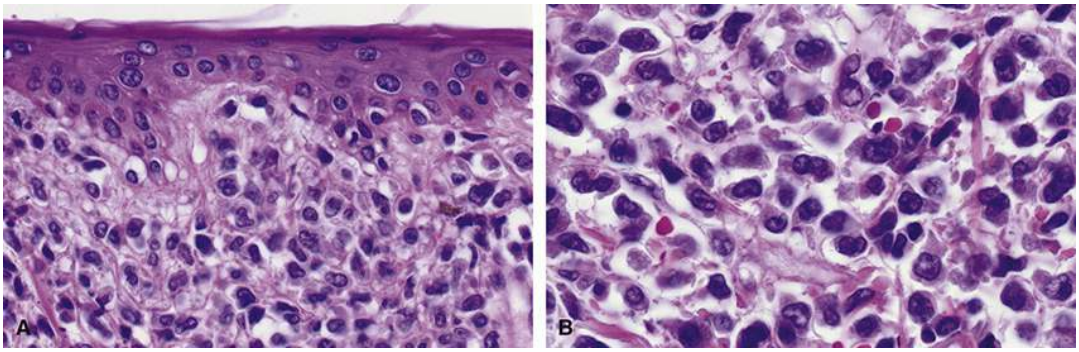

FIGURE 133.2 A man in his late 30s with acute myeloid leukemia, probable M5a (acute monoblastic leukemia) by cytogenetic analysis, developed numerous papules on his legs and papules and nodules on his abdomen. This biopsy is from an abdominal skin nodule. A, The leukemic cells form a sheet in the dermis with only a few in the zone immediately beneath the epidermis. B, The leukemic cells have mostly oval nuclei with irregular borders, fine chromatin, an occasional prominent nucleolus and scant to small amounts of faintly basophilic cytoplasm.

CHAPTER 134

Liposarcoma

Key Points

- Liposarcoma (LPS) is the most common soft tissue sarcoma in adults
- In the periorbital region, liposarcomas may present in the orbit or on the eyelid
- They originate from primitive mesenchymal cells rather than from mature fat cells and usually develop in deep structures
- They usually present as a firm, mobile, nodular to lobulated, painless mass with well-defined to indistinct margins
- Complete wide surgical excision is considered the treatment of choice
- Incomplete surgical excision is associated with a high local recurrence rate of 80%
- Radiotherapy is ineffective, and results of chemotherapy are inconsistent
- The histologic subtype is an important prognostic indicator. Well-differentiated and myxoid LPS are low-grade lesions with 5-year survival rates of 83% to 100%; pleomorphic LPS is more aggressive, with a 20% to 60% 5-year survival rate

Liposarcoma (LPS) is a malignancy first described by Virchow in 1857.[1] It is the most common soft tissue sarcoma, accounting for 15% to 25% of all soft tissue malignancies in adults.[2] Most are located in the lower extremities, the retroperitoneum, and the mesenteric region of middle-aged individuals. LPS is uncommon in the head and neck area where it represents only approximately 1% of all sarcomas.[3,4,5] In the head and neck, liposarcomas have been reported in the neck, larynx, lip, oral cavity, cheek, larynx, thyroid gland, tongue, parapharyngeal region, temporal and frontoparietal regions, eyelid, and orbit.[6,7,8,9]

According to the 2020 World Health Organization classification scheme, there are five subtypes of liposarcoma: atypical lipomatous tumor/well-differentiated liposarcoma, dedifferentiated liposarcoma (DDLPS), myxoid liposarcoma, pleomorphic liposarcoma, and the exceptionally rare myxoid pleomorphic liposarcoma.[10] Goldblum, Folpe, and Weiss[2] advocated classifying liposarcomas into three large groups: well-differentiated/dedifferentiated (54%-64%; including spindle cell, atypical, inflammatory, and sclerosing subtypes), myxoid (25%-35%), and pleomorphic (8%-10%).[2,8,10,11,12] Generally, the well-differentiated and myxoid types behave as low-grade tumors and are more likely to occur in the head and neck.[13] The well-differentiated variety can undergo dedifferentiation, where it behaves more aggressively. The pleomorphic and round cell types demonstrate a more aggressive, high-grade behavior.[11]

Most liposarcomas are seen in adults, with a median age of 57 years, a predominance in males of about 76.5%, and 82% occur in white individuals.[13] The well-differentiated subtype is reported to occur in slightly older individuals and myxoid and pleomorphic subtypes in younger patients.[14]

In the periorbital region, liposarcomas may present in the orbit or on the eyelid. Primary orbital tumors have been reported in fewer than 50 cases, with the most common types being myxoid and well-differentiated subtypes.[15,16] Occasionally, orbital LPS can present initially as an eyelid mass.[9] Primary liposarcoma of the eyelid, on the other hand, is extremely rare, with only three cases reported in the literature.[17,18,19]

Etiology and Pathogenesis

Liposarcoma is thought to originate from primitive mesenchymal cells rather than from mature fat cells, and it usually develops in deep structures, whereas benign lipomas generally arise within subcutaneous and submucous tissues.

The classification scheme of LPS reflects distinct chromosomal aberrations in each category. About 90% of well-differentiated and dedifferentiated lesions have amplified chromosomal sequences of the 12q13-15 region, which carry the oncogenes *MDM2, CDK4,* and *HMGA2*.[20] In myxoid liposarcomas, 95% carry a translocation of t(12;16) (q13;p11) involving the *DDIT3 (CHOP)* and *FUS* genes.[21,22] Pleomorphic LPSs are high-grade malignancies that show complex karyotypes often with the loss of the tumor suppressor genes *P53* and *Rb*.[20]

Clinical Presentation

LPSs are slow-growing tumors. On clinical examination, they usually present as a firm, mobile, nodular to lobulated, painless mass with well-defined to indistinct margins. Lesions can be present for months to many years, and they are usually not associated with regional lymphadenopathy. In the head and neck, they are most commonly located in the subcutaneous connective tissue of the face, neck, and scalp, with relatively rare occurrences in the oral cavity and salivary glands.[13]

LPS of the eyelid is exceedingly rare and presents as a soft to firm, mobile subcutaneous mass (Figure 134.1). Only three cases in the eyelid have been reported.[17,18,19] One was a 67-year-old Chinese man who presented with a left lower *(Print pagebreak 890)* eyelid mass that had been present for 11 years. After a long period of slow growth, the lesion rapidly enlarged over 2 months.[17] On presentation, the subcutaneous mass was mobile, 60 mm in diameter with indistinct margins, and was initially diagnosed as a lipoma or neurofibroma. On histopathology, it was diagnosed as a well-differentiated LPS. Another case was a 25-year-old man, with a slowly growing left eyelid mass for 2 years.[18] It also was a well-differentiated LPS. The third case was an 11-year-old girl with a small left upper lid round cell LPS.[19] Despite multimodal therapy, the tumor recurred, and the child died from widespread metastases to the central nervous system and soft tissues.

FIGURE 134.1 A large, lobular subcutaneous liposarcoma of the lower eyelid. (Courtesy of Dr. Santha Amrith.)

Differential Diagnosis

Clinically liposarcoma can be misdiagnosed as a cyst or benign soft tissue neoplasms, such as lipoma and neurofibroma, as well as other malignant tumors including dermatofibrosarcoma protuberans, low-grade malignant peripheral nerve sheath tumor, low-grade sarcoma, and low-grade myxofibrosarcoma.

Treatment

The treatment of liposarcoma is related to the tumor histologic type and grade.[4] Well-differentiated LPSs tend to recur locally (45%) but do not metastasize without dedifferentiation.[23] Myxoid and dedifferentiated LPSs rarely metastasize, but they are more locally invasive and show a greater tendency to recur compared with the well-differentiated type. Pleomorphic and round cell liposarcomas are more aggressive with higher recurrence rates (70%-100%) and a 5-year survival rate of 50% to 60%.[4,24] The anatomic location also influences potential treatment options, and for head and neck LPS, the survival rate is better than for those at most other locations.[4]

Complete wide surgical excision is considered the treatment of choice for LPS. In a review of 22 cases with sufficient documentation, McCulloch et al[24] reported that, with incomplete surgical excision, the local recurrence was 80% at 2 years, compared with a rate of 17% at 5 years with complete excision. Local recurrence may occur many years after surgical excision so that long-term follow-up is necessary.[25]

Radiotherapy does not appear to be very effective in the management of LPS,[24] and its value has been controversial. Some studies reported no benefit with radiotherapy added to surgery,[26] whereas others reported reduced recurrence and improved survival with radiotherapy combined with surgery.[23,27] Radiotherapy is especially recommended for high-grade tumors, surgical resections with positive margins, larger tumors, and sites where complete surgical excision may not be possible.[5] More recently, several authors have proposed that postoperative adjuvant radiation might delay or prevent local recurrence.[14,28,29]

The use of chemotherapy is variable since the various subgroups of LPS differ in chemosensitivity, with pleomorphic most sensitive and well-differentiated/dedifferentiated relatively resistant. In a study of 105 patients with liposarcoma, chemotherapy with doxorubicin, ifosfamide, docetaxel, gemcitabine, and/or trabectedin, complete response was seen in 3.8%, partial response in 32.4%, stable disease in 30.5%, and progressive disease in 30.5%, and the median overall survival was 16.3 months.[30] In a study of high-risk surgically resected soft tissue sarcomas treated with adjuvant doxorubicin and ifosfamide combined with radiotherapy, the 5-year overall survival was 76.1% compared with 50% for adjuvant radiotherapy alone,[31] suggesting a possible survival benefit for the addition of adjuvant chemotherapy. Another study of 16,370 patients with stage III soft tissue sarcomas treated with adjuvant chemotherapy showed increased survival compared with those who did not receive chemotherapy.[32] However, a large randomized trial of adjuvant chemotherapy (doxorubicin and ifosfamide) in 351 patients with macroscopically resected soft tissue sarcoma showed no benefit from chemotherapy in terms of local control, relapse-free survival, or overall survival.[33,34]

The vast majority of well-differentiated and dedifferentiated LPSs have cytogenetic abnormalities of supernumerary rings and giant chromosomes, which frequently contain amplifications in the long arm of chromosome 12 containing the oncogenes cyclin-dependent kinase 4 (*CDK4*) and murine double minute-2 (*MDM2*).[35] Palbociclib is an oral inhibitor of CDK4 and CDK6 that prevents downstream phosphorylation of the retinoblastoma protein.[36] In a phase II trial, patients with advanced well-differentiated and dedifferentiated LPSs treated with palbociclib achieved a 57.2% progression-free survival (PFS) at 12 weeks and a median PFS of 17.9 weeks.[37] This is not as good a response as with targeted therapy for other soft tissue sarcomas. Recently, a retrospective analysis of efficacy endpoints and outcomes among patients treated with palbociclib monotherapy in a large volume sarcoma center demonstrated that there was no *(Print pagebreak 891)* clear benefit from treatment, and few patients achieved prolonged tumor control.[20]

The role of adjuvant and neoadjuvant chemotherapy for soft tissue sarcomas has been studied in various trials on patients with high-risk tumors. Doxorubicin remains the first-line standard for systemic treatment of liposarcoma, and multiagent therapy with ifosfamide may improve response rates. The response rates are only 12% to 25% with median PFS periods of 5 to 7 months, but there has been no significant benefit in terms of overall survival.[38,39,40,41,42]

Prognosis

The histological subtype of liposarcoma is the most important prognostic factor related to its clinical behavior. Well-differentiated and myxoid LPS are considered low-grade lesions that rarely metastasize and have 5-year survival rates of 83% to 100%.[12,43] However, they tend to recur locally in approximately 40% to 60% of cases.[24,44,45] The pleomorphic subtype is more aggressive, with a 20% to 60% 5-year survival rate.[44,46,47] DDLPS is a malignant neoplasm showing a transition from atypical or well-differentiated LPS to a nonlipogenic sarcoma.[48] It behaves aggressively, with a local recurrence rate of 41% and a 5-year survival rate of 44%.[44]

Local recurrence is related to tumor location and the difficulty in obtaining adequate surgical margins in some regions. Patients with microscopically positive margins have a significantly lower survival rate.

Histopathology

Primary liposarcomas arising in the dermis or subcutaneous tissue are exceptionally rare,[49,50,51,52,53] and most liposarcomas of the skin are extensions from a deeper location.[54] Of 318 head and neck liposarcomas in the Surveillance, Epidemiology, and Results (SEER) Program of the National Cancer Institute between 1973 and 2009, only 13 (4.1%) were primary skin tumors.[13] Pleomorphic liposarcomas are the most commonly reported superficial liposarcoma subtype,[49,50] although all subtypes may occur.[49,50,51,52,53]

There are three main morphological subtypes of atypical lipomatous tumor/well-differentiated liposarcomas (ALT/WDLPSs): adipocytic (lipoma-like), sclerosing, and inflammatory.[55] Tumors may be composed of more than one subtype.[55] Adipocytic ALT/WDLPSs are formed of mature adipocytes that have more cell size variation than in benign lipomas, along with nuclear atypia in adipocytes or stromal spindle cells (Figure 134.2).[55] Lipoblasts range from none to many.[55] Sclerosing ALT/WDLPSs have scattered hyperchromatic bizarre stromal cells within a fibrillary stroma, multivacuolated lipoblasts can be observed, and fibrous areas may overshadow lipogenic areas.[55] Inflammatory ALT/WDLPSs are distinguished by a chronic inflammatory infiltrate predominating over the adipocytic component of the tumor.[55] *(Print pagebreak 892)* Most ALT/WDLPS have nuclear expression of MDM2 proto-oncogene and/or CDK4 (cyclin-dependent kinase 4) using immunohistochemical staining or *MDM2* and/or *CDK2* gene amplification.[55]

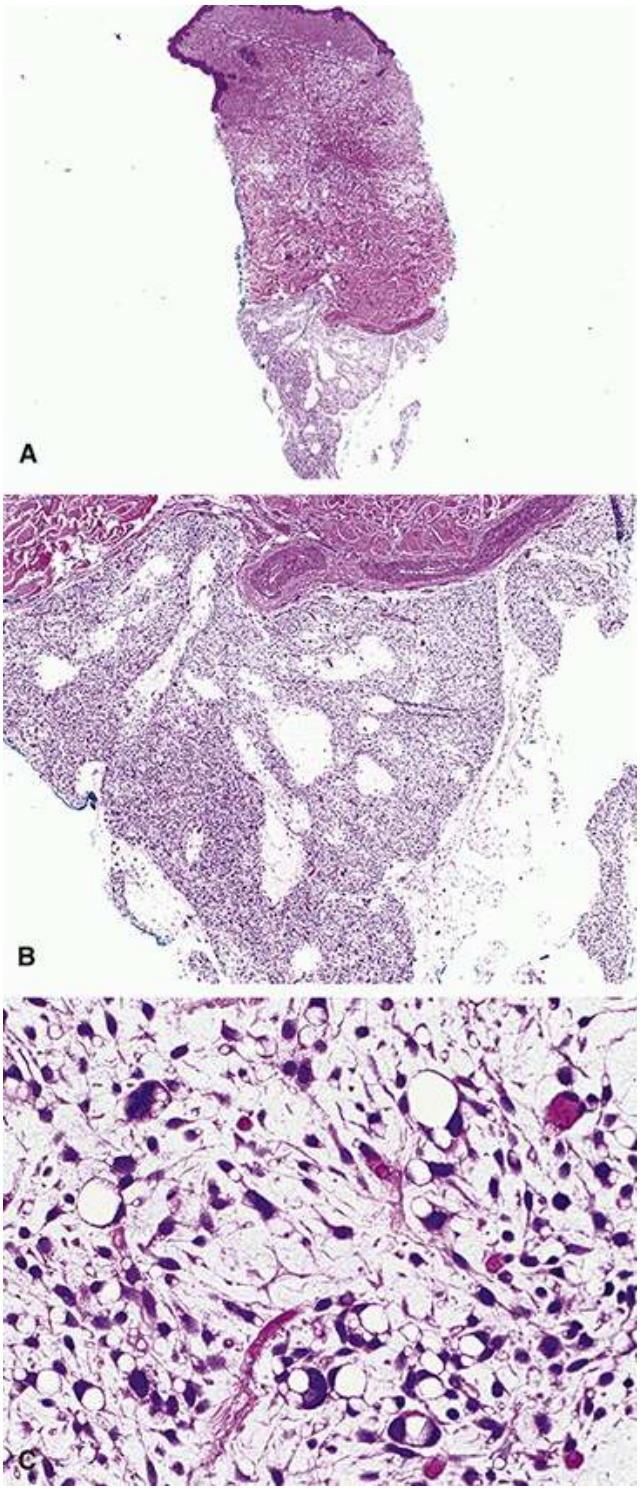

FIGURE 134.2 A, This punch biopsy of the back shows a liposarcoma in the subcutaneous tissue that arose at the site of prior radiation therapy. B, Lobules of tumor cells have a lightly basophilic myxoid stroma. C, The tumor cells are pleomorphic adipocytes with admixed lipoblasts. In a subsequent wide local excision, liposarcoma extended from the superficial dermis to the deep subcutis and had predominantly myxoid features.

DDLPS features a transition from ALT/WDLPS to nonlipogenic sarcoma, usually high grade.[56] Transition is usually abrupt, and dedifferentiated areas are most often undifferentiated pleomorphic sarcoma or intermediate- to high-grade myxofibrosarcoma.[56] DDLPSs almost invariably exhibit diffuse nuclear expression of MDM2 and/or CDK4.[56]

Myxoid liposarcomas (MLPSs) are moderately cellular, lobulated tumors with a patternless array of small, ovoid cells without morphological adipocytic differentiation and variable numbers of small lipoblasts.[57] Cellularity is increased peripherally.[57] The tumors have abundant myxoid (lightly basophilic) stroma with an arborizing capillary network.[57] Most MLPSs have a t(12;16)(q13;p11) translocation that generates a *FUS-DDIT3* fusion transcript, which can be detected using molecular techniques.[57]

Pleomorphic liposarcomas have infiltrative borders and "a varying proportion of pleomorphic lipoblasts in a background of high-grade, usually pleomorphic, undifferentiated sarcoma."[58] Identification of lipoblasts is required for diagnosis, but their numbers vary widely between tumors and within areas of a tumor.[58] Approximately one-half of pleomorphic liposarcomas have intermediate- to high-grade myxofibrosarcoma-like areas containing pleomorphic lipoblasts.[58] Pleomorphic liposarcomas lack MDM2 amplification, and this helps distinguish them from DDLPS.[58]

CHAPTER 135

Lymphoma

Key Points

- Lymphoma is a malignant neoplasm originating from clonal proliferations of monoclonal B cell, T cell, and natural killer cell lymphocytes
- The ocular adnexa is involved in 2% of extranodal lymphomas, and 5% of these are located in the eyelid
- The majority of eyelid lymphomas are non-Hodgkin B-cell lymphomas
- They are associated with several chronic inflammatory disorders, such as chronic infection by *Helicobacter pylori* in the stomach, and unique genetic abnormalities have been seen in each specific subtype
- Most eyelid lymphomas extend from the orbit or conjunctiva; primary eyelid lymphoma typically involves the anterior lamella or preseptal tissues of the skin, subcutaneous tissue, and orbicularis oculi muscle
- Symptoms include painless eyelid swelling, epiphora, irritation or pain, ptosis, chemosis, ectropion, and a palpable mass
- Treatment of primary cutaneous lymphoma can be with surgery, radiotherapy, or chemotherapy depending upon the subtype and extent of the disease
- Prognosis varies and depends on the stage at presentation, tumor histology, primary or secondary status, and whether the tumor is unilateral or bilateral

Lymphoma is a malignant neoplasm originating from clonal proliferations of white blood cells, including monoclonal B cell, T cell, and natural killer (NK) cell lymphocytes. Lymphomas are usually divided into several broad types, Hodgkin and non-Hodgkin. Hodgkin lymphomas (HLs) are uncommon, and the classic form accounts for about 90% of HLs. It arises from a large, abnormal, multinucleated transformed type of B-cell lymphocyte called Reed-Sternberg cell. HLs rarely involve the periorbital region. Non-Hodgkin lymphomas (NHLs) are far more common. They constitute a large heterogeneous group of tumors mostly consisting of B-cell lymphomas (80%), and less frequently T-cell lymphomas (14%) or NK-cell lymphomas (6%), and all can occur in the eyelid.[1]

Based on the US Surveillance, Epidemiology, and End Results (SEER) database, it is estimated that in 2022 there will be 80,470 new cases of NHL and 20,250 tumor related deaths. Less than 5% of these will be primary cutaneous lymphomas. The incidence of primary cutaneous lymphoma has been increasing, and the condition occurs with an incidence of about four per million persons per year,[2,3,4] and cutaneous B-cell lymphomas make up about 25% to 30% of these. The majority of primary cutaneous lymphomas are cutaneous T-cell lymphomas. The highest incidence rates are among males, non-Hispanic whites, and adults over the age of 50 years.[5]

Lymphomas can occur within lymph nodes or extranodally in a variety of soft tissues. Those involving the ocular adnexa constitute about 2% of all extranodal lymphomas, and 5% of ocular adnexal lymphomas are located in the eyelid.[1,6] The majority of eyelid lymphomas are non-Hodgkin B-cell lymphomas, including extranodal marginal-zone lymphoma (EMZL), follicular center cell lymphoma (FCL), and diffuse large B-cell lymphomas (DLBCL), and follicular lymphomas (FCL).[7,8,9,10,11] Less common B-cell lymphoma subtypes in the eyelid include lymphoplasmacytic lymphoma/immunocytoma, plasmocytoma, and immunoblastic lymphoma in decreasing freque ncy.[8,9,12,13] Burkitt lymphoma very rarely involves the ocular adnexa in children.[14,15] The nonendemic form can also occur in adults, typically associated with acquired immunodeficiency syndrome and other forms of immunosuppression.[13,16]

Adnexal lymphomas of non-B-cell type are uncommon, representing approximately 1% to 3% of all ocular adnexal lymphomas.[8,12,17] The majority of non-B-cell lymphomas represent secondary manifestations of a systemic T-cell lymphoma, or they occur as an eyelid extension of mycosis fungoides (MF).[17,18,19] Very few cases of primary T-cell lymphomas of the ocular adnexa have been

reported in the literature,[17,20,21,22,23] although it has been debated whether some of these represent true clonal T-cell proliferations.[24]

Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (EMZL-MALT) represents 8% of all NHLs.[25] It is the second most common primary cutaneous B-cell lymphoma in the skin, and the eyelid is the third most common site for MALT-type lymphomas (12%) after the gastrointestinal tract (70%), and the lung (14%).[25] It comprises about 75% of all ocular adnexal lymphomas of which 46% occur in the orbit, 35% in the lacrimal gland, 10% in the conjunctiva, and 8% in the eyelid.[26]

EMZL is an indolent lymphoma that accounts for approximately 25% of patients with cutaneous lymphoma.[2] The median age at presentation is 50 to 53 years, with a range of 6 to 93 years, and it occurs more commonly in men than in women.[27,28,29]

FCL is another indolent subtype comprising 60% of primary cutaneous B-cell lymphomas. Patients present at a *(Print pagebreak 895)* median age of 50 years, and it is slightly more common in men than in women. DLBCL, leg type, comprises 10% to 20% of primary cutaneous B-cell lymphomas and usually presents at a median age of 70 to 75 years.[2,30] DLBCL is more common in females, and Asians and Pacific Islanders are at increased risk of developing this subtype.[31]

Mycosis fungoides (MF) is the most common type of cutaneous T-cell lymphoma. It originates in the peripheral skin-tropic memory T-lymphocytes.[32,33] The incidence is about six cases per million population, it is more common in adults over the age of 50 years, there is a slight male predominance, and it is more common in blacks than in Caucasians and Asians (Chapter 129).[34] Sézary syndrome is a related condition in which malignant T cells are present in the blood in addition to skin involvement. It is unclear if this represents an advanced form of MF or a distinct disease.

Etiology and Pathogenesis

Extranodal marginal zone lymphoma (MALT lymphoma) originates from the marginal zone B cells of the mucosa-associated lymphoid tissue. These lymphomas occur at diverse anatomic sites and have been associated with several chronic inflammatory disorders, such as chronic infection by *Helicobacter pylori* in the stomach, *Borrelia burgdorferi* in the skin,[35] *Chlamydia psittaci* in the ocular adnexa,[36,37,38] and *Campylobacter jejuni* in the small intestine.[39] Evidence suggests that genetic abnormalities and antigenic drive in MALT lymphoma involve dysregulation of the molecular pathways that regulate nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB),[40] a small family of inducible transcription factors that control transcription of DNA, cytokine production, and cell survival. Recently, a Chinese study on ocular adnexal MALT lymphoma patients showed novel mutations in the *IGLL5* gene in 24% of patients, and mutations of *MSH6*, *DIS3*, *FAT1*, and *TMEM127* in 10%.[40] The exact function of the IGLL5 gene is not known at present, but it encodes a protein that plays a critical role in B-cell development.[40]

FIGURE 135.1 Superficial cutaneous lymphoma of the eyelids. B, (Courtesy of Dr. Jurij Bilyk.)

Genetic abnormalities in lymphomas are unique to each specific subtype. In mantle cell lymphoma (MCL), t(11;14) (q13;q32) translocation and (11)(q21;q23) deletion have been described in more than 95% of tumors.[41,42] It leads to overexpression of nuclear cyclin D1, and its upregulation leads to cell cycle progression.[43] Genetic abnormalities in EMZL include trisomy 3 and 18, as well as the translocations t(11;18) (q21;q21), t(1;14)(p22;q32), t(14;18)(q32;q21), and t(3;14) (p14.1;q32).[44] Most of these translocations induce the upregulation of proteins that lead to the activation of nuclear factor κB.[44] The translocation t(14;18) (q32.3;q21.3) is seen in 34% of DLBCL[45] and in 85% of FCL. This translocation leads to upregulation of the *BCL2* oncogene and prevents apoptosis.[45]

In MF, there is a clonal expansion of CD4-positive cells that often lack normal T-cell antigens such as CD7, CD5, or CD2.[46] These cells are attracted to the skin by keratinocytes and accumulate in the dermis.

Clinical Presentation

Most lymphomas of the eyelid are secondary extensions from the orbit or conjunctiva and can invade all tissue layers. Primary lymphoma in the eyelid typically involves the anterior lamella or preseptal tissues of the skin, subcutaneous tissue, and the orbicularis oculi muscle (Figure 135.1). In this location primary lymphoma is rare, accounting for only 1% to 2% of NHL.[47]

Of ocular adnexal lymphomas, 41% occur in the orbit, 31% in the conjunctiva (Figure 135.2), 18% in the lacrimal gland, and 10% in the eyelid.[48] The distribution of subtypes for eyelid lymphomas is reported as EMZL (35%-55%), FCL (15%-25%), DLBCL (15%-20%), MCL (8%-12%), and MF (9%).[48] This is in contrast to orbital lymphoma where FCL and DLBCL predominate at 63% and 50%, respectively, and in the conjunctiva where EMZL-MALT lymphoma and DLBCL predominate at 41% and 38%, respectively.[48] Eyelid and orbital adnexal lymphomas generally affect males more than females (60%-80%), except for EMZL, which has *(Print pagebreak 896)* been reported to predominate in females in 60% to 70%.[7,48] Although the disease can be seen at any age, most periocular lymphomas occur in older patients, in the 6th to 8th decades of life. Except for MF, which is typically bilateral, more than 70% of other subtypes in the ocular adnexa occur unilaterally. The AJCC T stage is T3 in the 8th edition, which now stages these tumors according to the anatomic extent of disease.[49]

FIGURE 135.2 Lymphoma involving the conjunctiva.

The clinical signs and symptoms are usually nonspecific depending upon the size and location of the tumor and on the specific subtype. Low-grade tumors (EMZL and FCL) typically have a more indolent course and therefore may remain unrecognized for many years. High-grade lesions (DLBCL and MCL) are more aggressive and show rapid growth. EMZL usually presents as a solitary, red to violaceous, indurated plaque or nodule that may be surrounded by annular or diffuse erythema.[25,27,50] Presenting symptoms and signs include painless, nonulcerative eyelid swelling (28%-67%), epiphora (15%), irritation or pain (2%-22%), upper eyelid ptosis (5%-25%), erythema (14%-38%), a palpable mass (30%-60%), chemosis (10%-22%), and eyelid margin malposition (0%-63%) (Figure 135.3).[7,48,51] Patients may present with a single lesion (28%-58%) or multiple lesions (24%%-72%) and are otherwise asymptomatic.[27,28,52] Tumor may spread posteriorly into the orbit in up to 60% of cases and to the lacrimal sac in up to 10%.[7]

The clinical presentation of MF varies depending upon the disease stage. The earliest patch stage is a single or multiple lesion, which is an erythematous brown scaly patch that may show some atrophy. This is followed by a plaque stage, which is larger, annular, elevated lesions with cellular infiltration. The final phase is the erythematous popular or nodular tumor stage. As the lesions progress, so does the risk or lymph node and visceral organ involvement.

Differential Diagnosis

The differential diagnosis for cutaneous lymphoma is extensive given the various presentations of both B-cell and T-cell lymphoma subtypes. From case reports in the literature, lymphomas can be mistaken for other cutaneous nonmelanoma malignancies, such as basal cell and squamous cell carcinoma, and dermatofibrosarcoma, as well as metastatic lesions. Benign lesions include reactive lymphoid *(Print pagebreak 897)* hyperplasia, inflammatory dermatoses, and autoimmune inflammatory lesions, rosacea, discoid lupus erythematosus, *Herpes zoster*, cellulitis, erythema nodosum, pyoderma gangrenosum, dermatomyositis, lymphadenitis, and even sebaceous cyst. For MF, the differential diagnosis includes atopic dermatitis, drug eruptions, psoriasis, and other lymphomas.

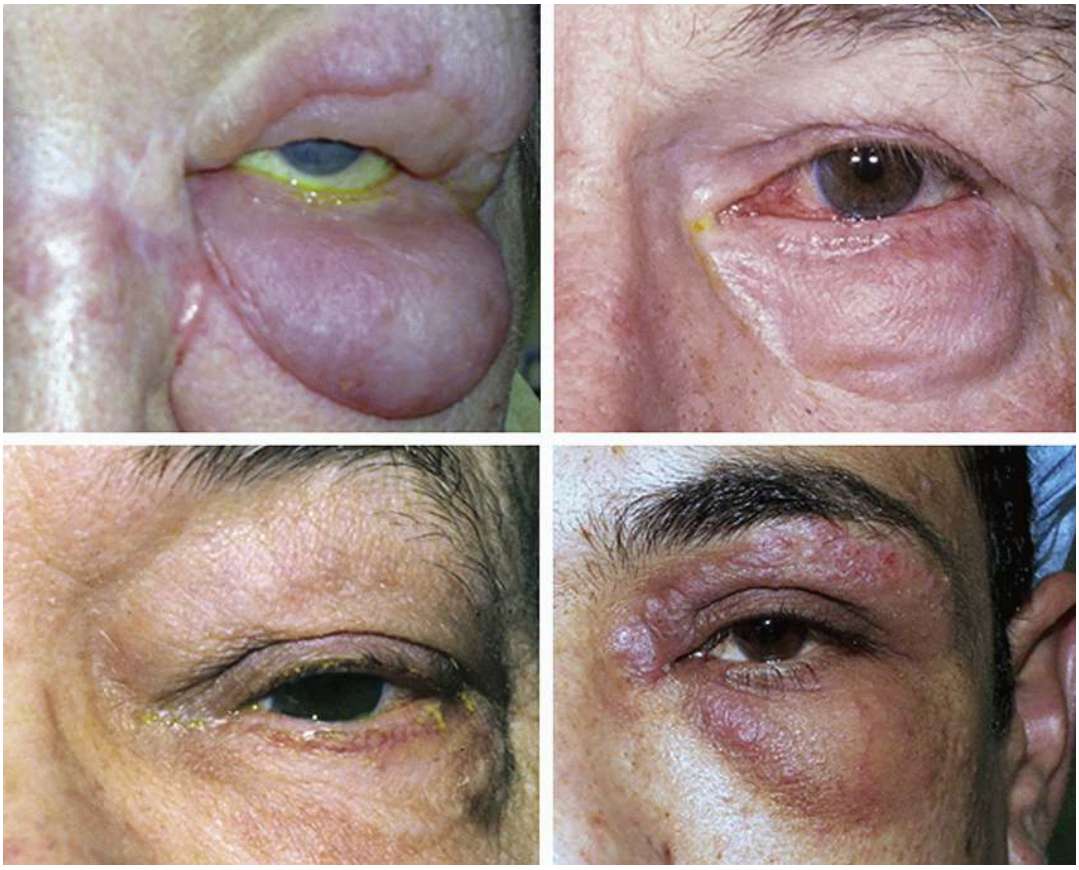

FIGURE 135.3 Cutaneous lymphoma manifesting as eyelid edema and palpable mass.

Treatment

Treatment of primary cutaneous lymphoma can be with surgery, radiotherapy, or chemotherapy or combinations depending upon the subtype and extent of disease. In patients with stage IE ocular adnexal lymphomas (single extralymphatic site with no nodal involvement) and IIE (contiguous extralymphatic extension from a nodal site on the same side), localized external beam radiotherapy is considered the therapy of choice.[52,53,54,55,56,57,58] Radiotherapy has been shown to give a high rate of local tumor control that ranges from 80% to 100%.[59,60,61,62,63] Zinzani et al[64] reported local control with radiotherapy of 98% for FCL, 95% for EMZL, and 82% for DLBCL.

For ocular adnexal lymphoma with disseminated disease, systemic chemotherapy is required. Most regimens are based upon the CHOP scheme.[65,66,67] Combined radiotherapy and chemotherapy is used in cases where the tumors are vision threatening and cannot be completely resected.[7]

Immunotherapy has been utilized to treat lymphoma with good results and few side effects. Rituximab is a monoclonal antibody that binds to the CD20 antigen[68] and makes B cells more susceptible to chemotherapy.[69] Treatment with rituximab has been described for EMZL, MCL, and DLBCL of the eyelid with a low percentage of tumor recurrence.[70,71] Combination multiagent chemotherapy combined with rituximab may be appropriate for patients with more aggressive DLBCL who tend to be elderly and sometimes too frail for chemotherapy alone.[35,72,73,74] Observation alone for low-grade EMZL has been advocated especially in older patients or those with significant comorbidities.[75,76] Studies have shown that, in a significant

number of cases (57%) followed for 5 to 10 years, no therapy was required, and more than half of conjunctival lesions regressed spontaneously.

Prognosis

Disease stage at presentation, tumor histology, primary or secondary status, and whether the tumor was unilateral or bilateral are major determinants of prognosis.[77] One study found *(Print pagebreak 898)* that women with periocular lymphoma had a worse prognosis.[48] For patients with periocular lymphoma, those with the EMZL-MALT and FCL subtypes have the best prognosis with a 5-year disease-specific survival (DSS) of 88%, whereas those with DLBCL and MCL have the worst prognosis with 5-year DSS of 21% and 50%, respectively.[7] MF generally shows a good prognosis with a DSS of 86%. Primary periocular lymphomas tend to have a better prognosis than secondary lesions (84% vs 64%).[7]

Local tumor control is generally excellent for all subtypes with almost all forms of treatment, ranging from 82% to 98% with radiotherapy, 76% to 86% with chemotherapy, and 97% to 100% with surgery.[64] While the prognosis for life with low-grade lymphomas is excellent, recurrence rates tend to be high, reported at 46% to 66% for EMZL and FCL and 80% to 100% for the DLBCL and MCL subtypes.[7] EMZL rarely exhibits extracutaneous spread,[27,78] although node dissemination and large cell transformation have been reported.[27] Nevertheless, the disease remains in the skin in a vast majority of patients (90.2%).[64]

The prognosis for FCL is generally excellent, with a 5-year DSS rate of 95%, although the recurrence rate can be 30%, and 10% may progress to extracutaneous involvement. DLBCL is associated with a DSS rate of 50% to 70%. Negative prognostic factors include location on the leg, multiple lesions, and age greater than 75 years.[7,35,79]

Histopathology

Eyelid skin biopsies with lymphoma are rare. Deprez and Uffer had no example of lymphoma in their study of 5504 cases of eyelid skin tumors,[80] while Svendsen and Heegaard identified 199 cases of primary eyelid lymphoma reported over a span of "more than 50 years."[7] Both B-cell and T-cell lymphomas may occur as primary cutaneous processes[81,82,83,84,85,86] or spread secondarily to the skin, and the histopathology reflects the specific entity. Primary cutaneous lymphomas are classified using the 2018 update to the World Health Organization-European Organization for Research and Treatment of Cancer guideline.[81] Kempf and Mitteldorf[83] outlined histopathological features that help guide the diagnosis and choice of immunohistochemical stains:

1. *Epidermotropic infiltrates* are most common in cutaneous T-cell lymphomas (CTCLs).
2. *Nodular and diffuse dermal infiltrates* occur in progressive CTCLs, peripheral T-cell lymphoma, and cutaneous B-cell lymphomas (CBCLs).
3. A *subcutaneous growth pattern* occurs in subcutaneous panniculitis-like T-cell lymphoma and subcutaneous γ/δ T-cell lymphoma and rarely with other forms of CTCL and CBCL.
4. *Angiocentric and angiodestructive infiltrates* are a feature of aggressive T- and T-/natural killer (NK)-cell lymphomas, nasal type, and cutaneous γ/δ T-cell lymphoma. They may be seen less commonly with lymphomatoid papulosis and the angioinvasive variant of primary cutaneous anaplastic large-cell lymphoma.
5. *Intravascular growth* is characteristic of intravascular T-and B-cell lymphomas.

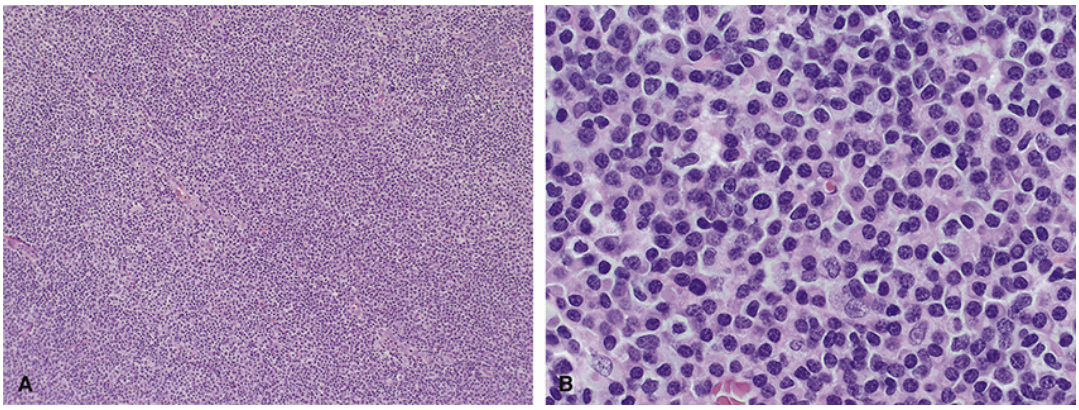

FIGURE 135.4 A woman in her early 70s developed a nodule in her right upper eyelid. Following the biopsy diagnosis of lymphoplasmacytic lymphoma (immunocytoma), radiotherapy resulted in the complete resolution of her eyelid tumor. A, The dermis has a diffuse infiltrate of small and medium-sized lymphocytes, plasmacytoid lymphocytes, and a few plasma cells. B, A majority of the cells are plasmacytoid lymphocytes resembling a plasmacytoma. Lymphoplasmacytoid lymphocyte cells expressed CD20 and kappa light chains. Uniform expression of CD20 helps differentiate lymphoplasmacytic lymphomas from plasmacytomas, which are usually negative for CD20 or have expression by only a small subset of the cells.[88] (Reprinted with permission from McKenna RW, Kyle RA, Kuehl WM, et al. Plasma cell neoplasms. In, Swerdlow SH, Campo E, Harris NL, et al, eds. *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues, Revised*. 4th ed. International Agency for Research on Cancer; 2017:241-258.)

In Svendsen and Heegaard's review of 199 primary eyelid lymphomas, there were 56% B-cell and 44% T-cell lymphomas.[7] The most common B-cell lymphomas were low-grade extranodal marginal zone lymphoma (14% of cases) and high-grade diffuse large B-cell lymphoma (9%).[7] Lymphoplasmacytic lymphoma (Figure 135.4) accounted for approximately 3% of *(Print pagebreak 899)* primary eyelid lymphomas.[7] MF (Chapter 129; Figures 129.3, 129.4, 129.5) was the most frequent T-cell lymphoma (13% of cases), followed by low-grade primary cutaneous anaplastic large-cell lymphoma (6%; Figure 129.6).[7] Secondary involvement of the eyelid by systemic lymphomas accounted for 18 of 264 consecutive lymphoproliferative lesions at Erasmus Medical Center between 1987 and 2016.[87] MCL was the most frequent systemic lymphoma involving the eyelid (four cases), followed by chronic lymphocytic leukemia/small lymphocytic lymphoma (three cases), follicular lymphoma (two cases; Figure 135.5), and diffuse large B-cell lymphoma (two cases).[87]

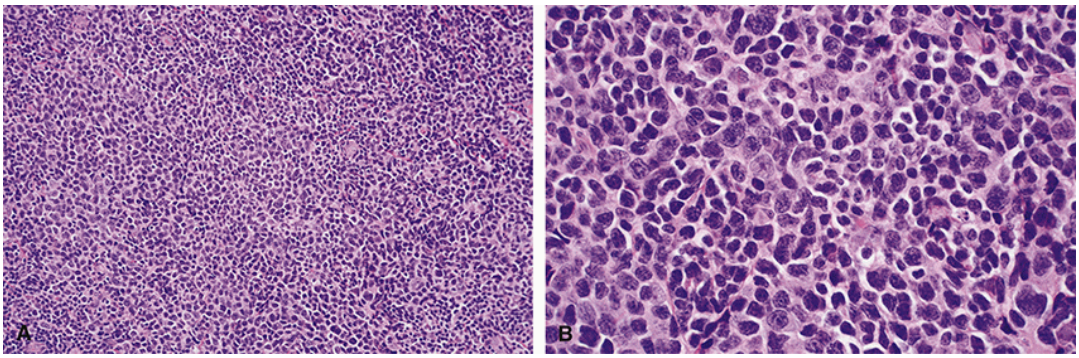

FIGURE 135.5 A man in his middle 70s with a history of follicular lymphoma developed firm periocular swelling around his left eye. A, This biopsy of the left lower eyelid has a dense lymphoid infiltrate in the dermis with a vaguely follicular appearance manifest as the central area of lymphocytes being paler than the surrounding lymphocytes. B, The vaguely defined follicle center is composed of small cleaved cells with occasional larger centroblast-like cells. The immunophenotype was characteristic of follicular lymphoma,[89] and a monoclonal B-cell population was detected by immunoglobulin heavy chain polymerase chain reaction analysis. CHAPTER 136

Malignant Melanoma

Key Points

- Cutaneous malignant melanoma is an invasive tumor of malignant melanocytes
- On the eyelid, malignant melanoma accounts for about 1% of all eyelid malignancies
- On the eyelids, the nodular and lentigo maligna melanoma types are the most common
- UV light in the pathogenesis of melanoma is well established
- Approximately 50% of all cutaneous melanomas harbor *BRAF* and less commonly *NRAS* mutations
- Cutaneous melanomas usually appear as asymmetric lesions with irregular borders, uneven distribution of color, diameters over 6 mm, and a history of growth
- The treatment of choice is complete surgical excision with wide tumor-free margins
- Radiotherapy is rarely used as a primary treatment but is used as an adjuvant therapy in cases of advanced nodal or primary disease following surgical resection
- Cutaneous melanoma accounts for two-thirds of all deaths from skin cancer. Early diagnosis and treatment are critical to improved outcomes

Cutaneous malignant melanoma is an invasive tumor of malignant melanocytes. Worldwide, it is the 12th most common cancer and has an estimated age-standardized incidence rate of 3.0 per 100,000 population.[1] The incidence varies in different populations, with the highest rates reported in Australia and New Zealand and the lowest rates in South-Central and South-Eastern Asia. The annual incidence is increasing and is estimated to continue to increase due to the increasing lifespan and aging of the population.[2] While it accounts for only a small percentage of skin cancers, malignant melanoma is responsible for the majority of skin cancer-related deaths.[3] On the eyelid, malignant melanoma accounts for about 1% of all eyelid malignancies, with an annual incidence of 0.6 per million white residents over the age of 20 years.[3]

Cutaneous melanoma has been classified into subtypes recognized by the World Health Organization (WHO)[4] and less common variants.[5] The four major subtypes and their relative incidences are superficial spreading melanoma (30%-60%), lentigo maligna melanoma (10%-40%), nodular melanoma (15%-35%), and acral lentiginous melanoma (5%-10%).[5] More recently (2018), the WHO has classified melanomas into melanomas arising in sun-exposed skin and those arising at sun-shielded sites or those without known etiological associations with ultraviolet (UV) radiation exposure.[4] Melanomas arising in sun-exposed skin are subdivided into those with low- or high-cumulative sun damage (CSD), as assessed by grading the degree of solar elastosis in a skin biopsy.[4] Melanomas arising in sun-exposed skin are (1) low-CSD melanoma/superficial spreading melanoma; (2) high-CSD melanoma/lentigo maligna melanoma; and (3) desmoplastic melanoma.[4] Melanoma arising at sun-shielded sites or those without known etiological associations with UV radiation exposure are malignant Spitz tumor, acral melanoma, mucosal melanoma, melanoma arising in a congenital nevus, melanoma arising in blue nevus, and uveal melanoma.[4]

Superficial spreading, lentigo maligna, nodular, and desmoplastic melanoma are the most common subtypes of eyelid cutaneous melanoma (Figures 136.1 and 136.2).[6,7] In a review of clinical series of eyelid skin melanomas between 1990 and 2018, there were 297 invasive melanomas with approximately 35% superficial spreading, 31% lentigo maligna melanoma, 19% nodular, and 16% other melanomas.[7] An analysis of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database between 1975 and 2016 identified 2257 patients with primary melanoma of the eyelid region, with 1380 in situ melanomas (61.1%) and 877 invasive melanomas (38.9%).[7] In situ melanomas were 53.6% lentigo maligna, 3.2% superficial spreading melanoma, and 43.2% unknown subtype.[7] The major subtypes of invasive melanomas were 20.9% lentigo maligna melanoma, 20.0% superficial spreading, 8.1% nodular, 2.1% desmoplastic, 1.7% spindle, and 45.4% unknown subtype.[7] Eyelid skin melanomas can arise from

congenital nevi, cutaneous moles, and excessive sun exposure. They are far more common in Caucasians,[7] in those with a history of chronic sun exposure and severe sunburns, and in patients with dysplastic nevus syndrome. Eyelid lesions can be primary tumors or less commonly represent tumor extension from the conjunctiva, metastasis from a distant primary site, or even a metastasis from the contralateral choroid.[8,9,10] The diagnosis of cutaneous melanoma may be difficult due to variability in its appearance. The clinical suspicion for lesions later histologically confirmed to be melanomas has been reported at between 15% and 57% and even lower for amelanotic variants.[11,12] Approximately 80% of eyelid melanomas occur on the lower eyelid.[13] Eyelid cutaneous melanoma may rarely extend posteriorly into the orbit.[14]

The amelanotic variant of cutaneous melanoma is a rare form characterized by the clinical absence of pigmentation. *(Print pagebreak 903)* Because of this, it is often diagnosed late. The incidence of amelanotic melanoma has been estimated at approximately 2% to 8% of all melanoma cases,[15] but in a series of 24 patients with eyelid skin melanoma, Garner et al reported that 50% were amelanotic.[16] Any of the four histopathological subtypes can be amelanotic. In general, amelanotic melanomas may present as erythematous macules or plaques or have a scaly appearance.[17,18,19] They may also resemble inflammatory lesions such as eczema, psoriasis, rosacea, and contact dermatitis[17,20,21] or a variety of benign neoplasms such as nevi, hemangiomas, and seborrheic keratosis. Some lesions may mimic more common malignant tumors such as basal cell carcinoma or Bowen disease.[21,22,23] There are no specific clinical criteria for diagnosing eyelid amelanotic melanomas,[22] but dermatoscopy findings are helpful by showing diagnostic vascular patterns such as serpentine, irregular linear, pinpoint, and hairpin vessels.[24,25]

D, Very diffuse, variably pigmented flat lesion on the medial canthus, lower eyelid, and nasal bridge. (A, Courtesy of Dr. Robert Kersten.)

Conjunctival melanoma is distinct from cutaneous eyelid melanoma, but anatomically the posterior lamellae of the eyelids and the caruncle are conjunctival tissue, so any discussion of eyelid melanoma must include conjunctival lesions. Malignant melanoma of the conjunctiva is rare compared with uveal or cutaneous melanoma.[26] Its incidence has been reported as 0.2 to 0.8 per million population in non-Hispanic Caucasians,[27] with lower incidences in Hispanics, Blacks, Asians, and Native Americans.[28] As with cutaneous melanoma, its rate has been increasing, and for Caucasian men in the United States, the age-adjusted incidence rate increased by 295% from 1973 to 1999.[29] It is a potentially lethal tumor with an average 10-year mortality rate of 30%.[27] These tumors occur primarily in the fourth to seventh decades of life, but rare cases have been described in children.[30] The perilimbal bulbar conjunctiva is the area most commonly involved, although these tumors can occur on any conjunctival surface, including the eyelid and caruncle. In a recent multicenter international study of 288 patients with conjunctival melanoma, the melanoma involved the bulbar conjunctiva in 83.5% of eyes and was nonbulbar in 16.5% of eyes.[31]

(B, Courtesy of Dr. Bita Esmaeli.)

Conjunctival melanoma can arise de novo (19%), from a preexisting conjunctival nevus (7%), or from primary acquired melanosis (PAM) with atypia (74%).[32,33,34] As with cutaneous melanomas, they may be amelanotic, where they can resemble other lesions such as squamous cell carcinomas, lymphoid hyperplasia, or pterygia.

Etiology and Pathogenesis

Cutaneous melanoma has a high burden of oncogenic mutations, most of which display an UV light signature.[35,36] The role of UV light in the pathogenesis of melanoma is well established, and the frequency of melanoma in Caucasian populations correlates with latitude, and by implication, with sunlight intensity.[13]

Approximately 50% of all cutaneous melanomas harbor *BRAF* and less commonly *NRAS* mutations[37] that contribute to oncogenesis by driving uncontrolled growth, suppressing apoptosis, and leading to melanoma invasion.[38,39] Both *BRAF* and *NRAS* mutations occur as early events in oncogenesis, but neither alone seems sufficient to trigger malignant transformation.[13] Also, about 35% of melanoma cell lines demonstrate deletions or mutations in the *PTEN* gene,[40] and loss of function of the PTEN enzyme results in increased mitogenic signaling involved in cell proliferation, apoptosis, and immune activation.

Other factors involved in the pathogenesis of cutaneous melanomas have been suggested, but studies vary in research designs, protocols, and patient populations so that further research is needed. However, oxidative stress is involved in several chronic diseases and the progression of some cancers, including melanomas.[41] Reactive oxygen species interact with inflammatory and immune processes and may participate in the melanogenic process.[41] Dietary factors may also affect the development of melanoma, particularly citrus fruits and alcohol through enhancement of UV-induced apoptosis and increased photosensitivity.[42]

(Print pagebreak 905)

Clinical Presentation

Primary cutaneous melanoma evolves from a lesion of aberrant melanocytes with cytological atypia limited to the basal layers of the epidermis, as lentigo maligna, a form of melanoma in situ.[7] These lesions typically appear clinically as flat to slightly elevated, irregular papules or plaques with variable pigmentation (Figures 136.1).[7] They grow slowly over years or even dacades, often changing in color and morphology. Lentigo maligna progresses to early invasive melanoma as lentigo maligna melanoma with cellular invasion into the papillary dermis, and then to more advanced deeply invasive malanoma with the potential for hematogenous and lymphatic spread.

In the eyelids, melanoma is more frequently seen in the lower eyelid (56.8%), followed by the upper eyelid (13.3%), lateral canthus (10.3%), and medial cnathus (2.2%).[7]

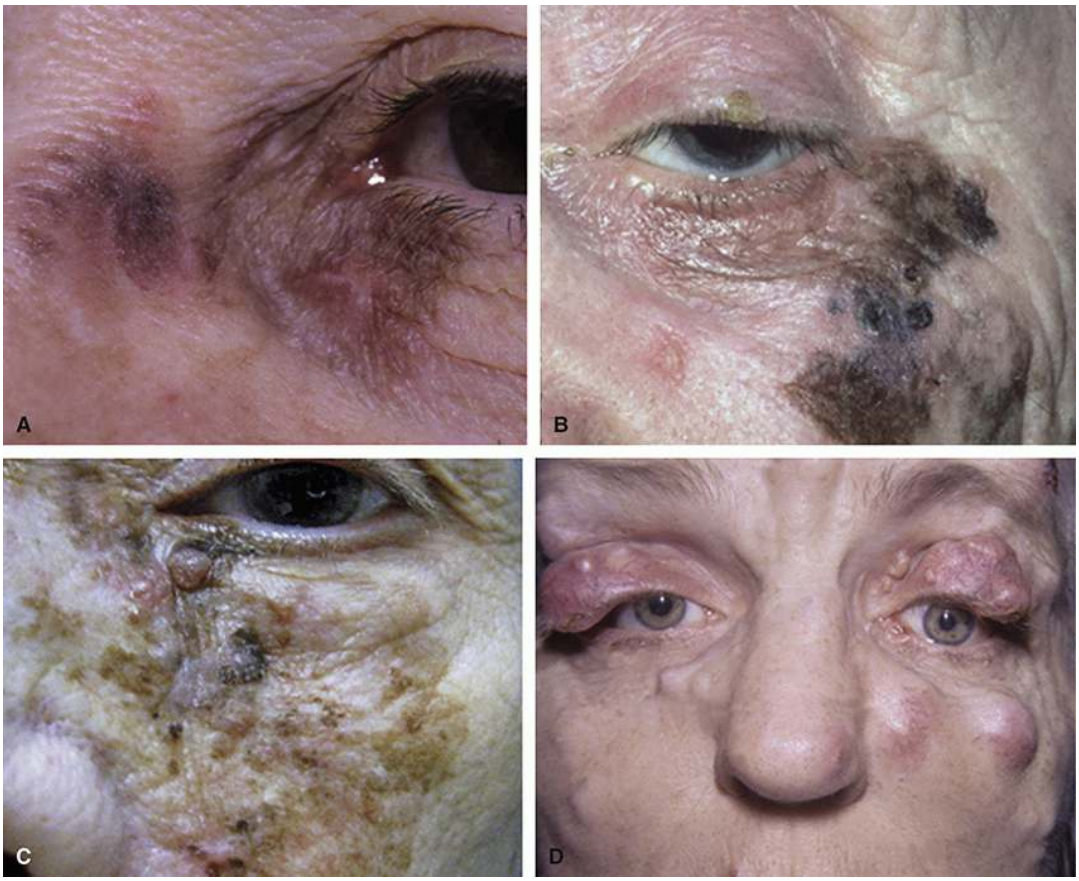

FIGURE 136.3 Melanoma involving the eyelid and adjacent areas of the face. A, Diffuse melanoma on the nose and lower eyelid. B, Multicentric melanoma at the lateral canthus and adjacent cheek. C, Widespread diffuse lightly pigmented melanoma of the lower eyelid and cheek. D, Multiple nodules of metastatic cutaneous melanoma in the eyelids, forehead, and face. (C, Courtesy of Dr. Bita Esmaeli.)

Clinically, cutaneous melanomas usually appear as asymmetric lesions with irregular borders, uneven distribution of color, diameters over 6 mm, and a history of growth. They may show ameboid projections, eccentric expansion, and notching of the borders. Superficial spreading melanoma presents as a pigmented lesion that is flat to mildly elevated. It may go through a period of relatively flat horizontal growth but eventually tends to become elevated and nodular. Nodular melanomas present as a pigmented or amelanotic bulky irregular growth that rapidly increases in size and may be associated with ulceration and bleeding (Figure 136.2). On the eyelids, melanomas may involve the eyelid skin, mucocutaneous border, and adjacent areas of the face (Figure 136.3).

Acquired pigmented lesions on the periocular skin of middle-aged and elderly patients should raise the possibility of in situ melanoma (lentigo maligna) (Figure 136.1).[43,44] These usually begin as a lightly pigmented macule that slowly enlarges over *(Print pagebreak 906)* several years or even decades. As many as 50% of these lesions may show histologic evidence of invasive lentigo maligna melanoma,[45,46] and the risk increases with continued growth.

Clinical diagnosis of eyelid melanoma is often difficult, and although in-person visual inspection greatly increases diagnostic accuracy compared with image-based evaluations, visual inspection alone is not entirely adequate. Diagnostic accuracy can be enhanced with ancillary tests such as dermoscopy,[47] reflectance confocal microscopy, impedance spectroscopy, and digital

epiluminescence microscopy.[48,49,50,51] Each of these techniques has advantages over clinical observation alone, but all also have limitations and are not widely available. Conjunctival melanoma typically presents as a nontender flat to nodular pigmented lesion, often associated with increased vascularity, prominent feeder vessels, and progressive thickening (Figures 136.2C and 136.4).[52,53] They may be associated with hemorrhage and bloody tears, and areas of ulceration. As with cutaneous and uveal melanoma, they may also be amelanotic.

C, Small nodular melanoma arising in the caruncle with surrounding vascular congestion. D, Extensive amelanotic melanoma arising in the caruncle and adjacent lower eyelid. (B, Courtesy of Dr. Bita Esmaeli.)

Differential Diagnosis

The differential diagnosis for cutaneous melanoma includes nonmalignant pigmented melanocytic nevi, pigmented basal cell carcinoma, pigmented actinic keratosis, pigmented seborrheic keratosis, dysplastic nevi, apocrine hidrocystoma, varix, hemangioma, inflammatory dermatosis, and ocular argyrosis. For conjunctival melanoma, several other clinical entities are included in the differential diagnosis. Most common are conjunctival melanocytic nevi, especially those that show growth, which can be seen in about 8% of such nevi.[54] Other lesions in the differential should include melanosis oculi, oculodermal melanocytosis, sclerouveal staphyloma, foreign body, polymerized epinephrine, nerve loop of Axenfeld, amyloidosis, ochronosis, pigmented epithelial tumors such as papilloma and squamous cell carcinoma, and pigmented pinguecula.[27,55]

(Print pagebreak 907)

Treatment

The treatment of choice for periocular melanoma is complete surgical excision with wide tumor-free margins confirmed histologically. Studies have shown that a margin less than 1 cm is associated with a poorer prognosis than those with 1 to 2 cm margins.[56,57,58] However, for eyelid lesions, a 1 to 2 cm margin is usually not possible. In such cases, Mohs micrographic surgery is recommended, especially with the use of MART-1 or other immunostains.[59,60,61,62] In addition to surgery, regional lymph nodes should be evaluated, and a metastatic evaluation performed for all patients.

Radiotherapy for head and neck melanoma is rarely used as primary treatment but is used principally as adjuvant therapy in

advanced nodal or primary disease cases following surgical resection and lymph node dissection.[63] It is also used for the palliation of distant metastases. Radiotherapy to the primary tumor site can be considered for patients who are medically precluded from surgery, cases where surgical morbidity is considered to be high, or for surgically resected tumors with persistent positive margins and where further resection is not possible.[63] When radiotherapy is used as postoperative therapy following primary surgery, excellent local and regional control can be obtained with acceptable toxicity, but there is little added benefit for the development of metastasis and overall survival.[64]

During the past decade, innovative treatment options for metastatic melanoma have been introduced based on tumor biology, oncogenic mutations, and immune surveillance, and these have improved treatment responses and survival.[65,66,67,68] These options include immune checkpoint inhibitors that inhibit the activity of regulatory T cells and enhance effector T cell function to promote an antitumor immune response.[65] Approximately 50% of cutaneous melanomas contain an oncogenic *V600-BRAF* mutation that activates the MAPK/ERK signaling pathway.[38,69] Inhibitors of mutated *BRAF*, such as vemurafenib and dabrafenib, either alone or combined with MEK inhibitors, have significantly benefited patients with mutated *BRAF* metastatic melanoma.[66,70,71]

Treatment of conjunctival melanoma usually involves wide surgical excision with 3 to 5 mm margins without direct manipulation of the tumor.[72,73] The underlying Tenon capsule is included to the level of bare sclera, and the sclera can be treated with absolute alcohol or mitomycin C. The residual conjunctival margins are then treated with double freeze-thaw cryotherapy.[74] Some authors advocate treatment with CO_2 laser,[75] or radiotherapy with external beam or proton beam, or with brachytherapy using iodine, strontium, or ruthenium plaques.[76,77] In advanced cases invading into the orbit, exenteration of the orbital contents may be the only life-saving option if there is no systemic spread of the tumor.[33] Iodine-125 brachytherapy has been recommended as an alternative to exenteration in some cases.[78]

Prognosis

Cutaneous malignant melanoma accounts for two-thirds of all deaths from skin cancer.[79] As with most tumors, early diagnosis and treatment are critical to improved outcomes. Prognosis and metastatic potential are linked to the thickness of the tumor and depth of invasion, and poor prognosis for tumors of the eyelid is correlated with a Breslow depth greater than 1.5 mm (Clark level 4).[79] Lesions with a depth less than 0.75 mm have a 5-year survival rate of 98%, while lesions greater than 4 mm have a less than 50% survival rate. This is particularly true in cases where clinical characteristics typically used for the diagnosis of melanoma, such as pigmentation, are absent. In addition, melanomas involving the eyelid margin may have a poorer prognosis.[12,80]

In a meta-analysis of treatment options for metastatic cutaneous melanoma, Pasquali et al[81] concluded that compared to chemotherapy, biochemotherapy (chemotherapy plus cytokines), immune checkpoint inhibitors, and *BRAF* inhibitors all improve progression-free survival, with variable benefit for overall survival, and in some cases increased toxicity. For conjunctival melanoma, the 1-, 5-, and 10-year tumor-related mortality rates were 3.8%, 30.5%, and 37.4% in 57 Chinese patients.[32] Jain et al reported that 1, 5, and 10-year cumulative mortality rates varied according to clinical and pathological stages in an international multicenter study of 288 patients.[82] The cumulative rates of mortality at 1, 5, and 10 years were 0%, 2.5%, and 15.2%, respectively, for patients with cT1 tumors and 0%, 28.6%, and 43.6% for cT2 tumors.[82] cT3 tumors had 1- and 5-year cumulative mortality rates of 21.1% and 31.6%, respectively.[82]

Histopathology

The histological features of cutaneous eyelid melanomas are similar to those of other cutaneous melanomas.[83] Lentigo maligna, the in situ precursor lesion of lentigo maligna melanoma, has two patterns.[84] Classic lentigo maligna has a broad, contiguous proliferation of uniformly atypical melanocytes that may be nevoid or epithelioid along the dermoepidermal junction.[84] A few irregularly distributed nests of atypical melanocytes may hang down from the dermoepidermal junction in a drop-like pattern (Figure 136.5A).[84] The second pattern of lentigo maligna, termed nevoid or dysplastic nevus-like lentigo maligna, has more nests of tumor cells, and some nests may bridge adjacent elongated rete ridges.[84] Lentigo maligna has little pagetoid spread of tumor cells into the more superficial epidermis.[85] The epidermis often has thinning and loss of rete ridges.[84] Lentigo malignant melanoma features the epidermal changes of lentigo maligna with tumor invading into the dermis, which has severe solar elastosis. Immunohistochemical staining using antibodies to MART-1 (melan-A) or SOX10 helps demonstrate the confluence of the atypical basal melanocytes (Figure 136.5B). Superficial spreading melanoma (low-CSD melanoma) is characterized by a proliferation of atypical melanocytes, singly and in nests, within all levels of the epidermis.[85,86] The atypical melanocytes may be confined to the epidermis (in situ melanoma), or they may be associated with tumor cells invading the dermis. The tumor cells may be epithelioid, nevus cell-like, or spindle-shaped.[85] The degree of melanin pigmentation is highly variable, with some tumors having *(Print pagebreak 908) (Print pagebreak 909)* little pigment (Figure 136.5C) and others being heavily pigmented (Figure 136.5D). Nodular

melanomas are invasive dermal tumors with little or no intraepidermal atypical melanocytes extending laterally to the invasive tumor.[85,86] The epidermis may form a collarette around the dermal tumor.[87] Nodular malignant melanoma is commonly composed of round to oval epithelioid cells with varying amounts of melanin pigment.[85] Desmoplastic melanomas are paucicellular dermal-based tumors formed by strands of elongated spindle-shaped tumor cells surrounded by fine, sclerotic, or mature collagen bundles (Figure 136.5E).[85,88] The epidermis over the tumor may have lentigo maligna or atypical melanocytic proliferation, but about half of desmoplastic melanomas have little or no overlying junctional melanocytic change.[88] Neurotropism is present in about 30% of desmoplastic melanomas.[88] Desmoplastic melanomas usually lack expression of HMB-45 and MART-1, but they are positive for S100 protein (Figure 136.5F) and SOX10, which assists in distinguishing these tumors from other spindle cell neoplasms.[77] Pathological staging of cutaneous eyelid melanomas is the same as for melanomas at other sites.[89] The most important predictors for survival in patients with eyelid skin melanoma are age ≥75 years, T4 stage, the presence of lymph node metastasis, and nodular melanoma subtype.[90]

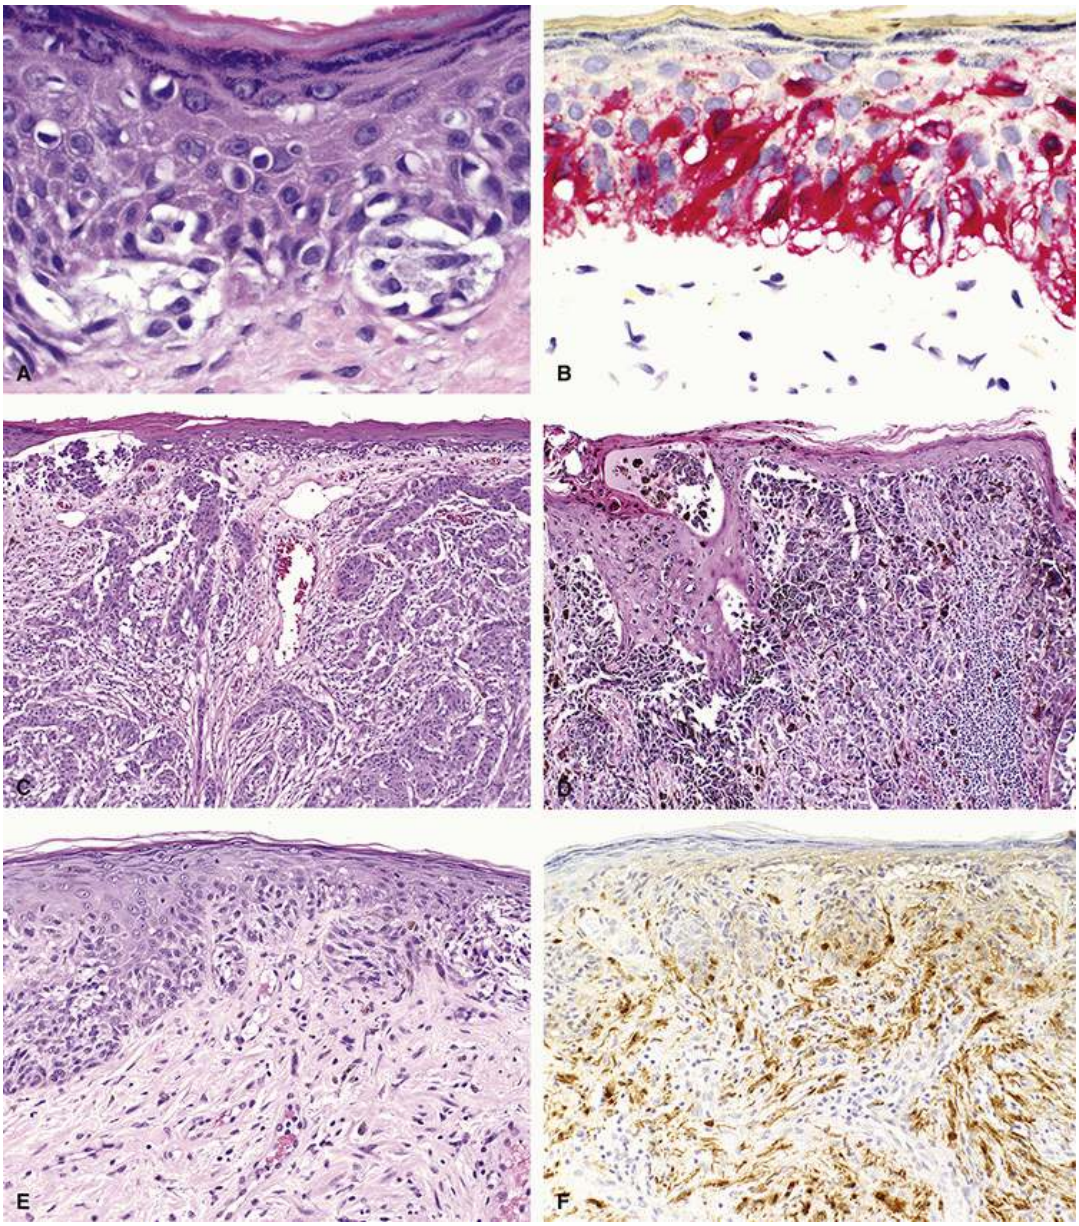

FIGURE 136.5 A, This example of lentigo maligna, the in situ precursor lesion of lentigo maligna melanoma, has the classic pattern with a broad, contiguous proliferation of atypical epithelioid melanocytes along the dermoepidermal junction with a few nests of atypical melanocytes hanging down from the dermoepidermal junction in a drop-like pattern. B, Antibodies to the melanocyte marker MART-1 highlight the contiguous atypical melanocytes along the dermoepidermal junction in the lentigo maligna. C, This invasive superficial spreading melanoma has scant melanin pigmentation. The epidermis over the invasive tumor has intraepidermal melanoma with tumor nests and areas of confluent melanoma cells along the dermoepidermal junction with pagetoid spread into the more superficial epidermis. D, This superficial spreading melanoma is heavily pigmented, making the pagetoid spread in the epidermis readily apparent. E, This desmoplastic melanoma of the right lower eyelid shows a paucicellular dermal tumor composed of spindle-shaped cells with intervening collagen bundles and occasional lymphocytes and macrophages. The epidermis

over the tumor has a lentigo maligna melanocytic proliferation. F, The desmoplastic melanoma cells stain strongly using antibodies to S100 protein.

Melanomas of the palpebral and forniceal conjunctiva are rare, and tumors may be in situ or invasive.[91] The terminology for intraepithelial melanocytic proliferations is in flux since the classification of these lesions as "primary acquired melanosis (PAM) of the conjunctiva" in the early 1980s and the subsequent demonstration that the risk for progression to melanoma depends on the degree of cytological atypia.[92,93] At Wills Eye Hospital, PAM without atypia "was defined as pigmentation of the conjunctival epithelium with or without benign melanocytic hyperplasia, PAM with atypia was characterized by the presence of atypical melanocytic hyperplasia, PAM with mild atypia was defined as atypical melanocytes confined to the basal layer of the epithelium, and PAM with severe atypia was defined as atypical melanocytic hyperplasia that extended into the more superficial nonbasal portion of the epithelium in a pagetoid fashion and/or contained epithelioid cells."[94] None of the cases of PAM without atypia or PAM with mild atypia progressed to melanoma. In contrast, 13% of patients with PAM with severe atypia developed melanoma out of 112 patients with a follow-up of at least 3 years.[94]

The WHO currently classifies intraepithelial melanocytic proliferations as conjunctival melanocytic intraepithelial neoplasia/PAM in *Classification of Skin Tumours*, 4th Edition[95] and conjunctival melanocytic intraepithelial neoplasia in *Classification of Tumours of the Eye*, 4th Edition.[96] Grading of conjunctival melanocytic cytological atypia as mild, moderate, or severe is similar to that for skin and other mucosal sites.[95] Conjunctival melanocytic intraepithelial neoplasia grading employs a scoring system from 1 to 10 based on the extent of atypical melanocytes' horizontal and vertical epithelial involvement and their degree of cytological atypia.[96] The classification systems for conjunctival intraepithelial melanocytic neoplasms correlate as follows, as adapted from Table 1.02 in the *WHO Classification of Tumours of the Eye*, 4th Edition[96]:

Primary acquired melanosis grade, modified to include melanoma in situ	**Conjunctival melanocytic intraepithelial neoplasia (C-MIN) score**	**WHO proposed simplified terminology**
PAM without atypia	C-MIN score = 1	Low-grade conjunctival melanocytic intraepithelial lesion
PAM with mild atypia	C-MIN score = 2	Low-grade conjunctival melanocytic intraepithelial lesion
PAM with moderate atypia	C-MIN score = 3	High-grade conjunctival melanocytic intraepithelial lesion
PAM with severe atypia (atypical melanocytes in ≤75% of epithelial thickness)	C-MIN score = 4-5	High-grade conjunctival melanocytic intraepithelial lesion
Melanoma in situ (atypical melanocytes in >75% of epithelial thickness)	C-MIN score > 5	Melanoma in situ

We support the proposed simplified WHO terminology since it will standardize terminology and facilitate clinical management. *WHO Classification of Tumours of the Eye*, *4th Edition*, provides excellent illustrations and descriptions for grading radial and vertical spread and cytological atypia of conjunctival melanocytes.[96] An example of conjunctival melanoma in situ is shown in Figure 136.5A.

In a study of 382 consecutive patients with conjunctival melanoma by Shields and coworkers, the tumor arose from PAM in 74% of patients, from a preexisting nevus in 7%, and de novo in 19% of patients.[97] Conjunctival melanomas have nests (Figure 136.6B) or sheets (Figure 136.6C) of atypical melanocytes[98] that may be polyhedral, epithelioid, spindle shape, or a combination of these.[99] Melanin pigmentation is variable, with spindle cells usually being less pigmented than polyhedral or epithelioid melanoma cells.[99] Neoplastic cells express melanocytic markers such as S100 protein, MART-1 (melan-A), HMB-45, and melanocyte-inducing transcription factor (MITF; also termed microphthalmia-associated transcription factor).[98] Pathological staging incorporates tumor location, tumor thickness, and local invasion.[100]

(Print pagebreak 910)

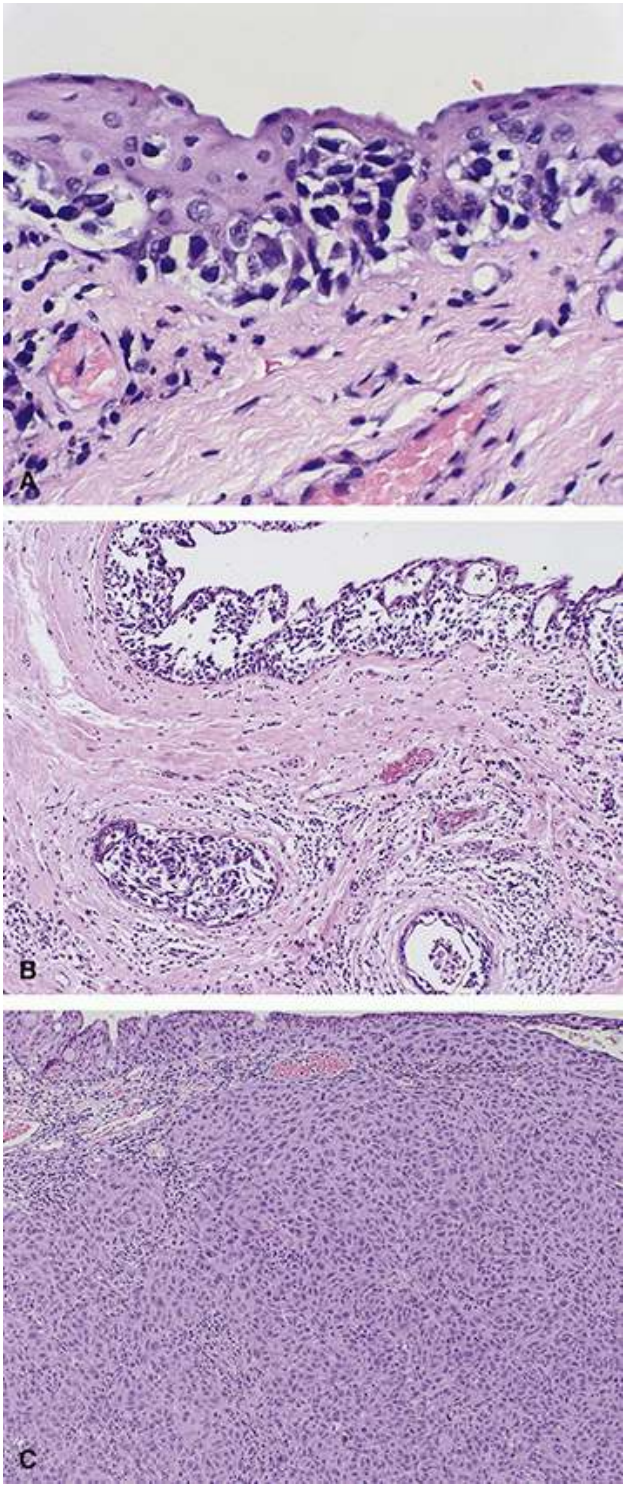

FIGURE 136.6 A, Conjunctival melanoma in situ features cytologically atypical melanocytes extending through >75% of the epithelial thickness. B, This invasive melanoma of the right superior fornix has two nests of invasive melanoma in the stroma beneath epithelium replaced by in situ melanoma. The invasive melanoma cells are predominantly spindle-shaped, and the nest on the right is cystic. C, This invasive melanoma of the left lower eyelid conjunctiva arose in association with in situ melanoma. The sheet of epithelioid melanoma cells is amelanotic.

CHAPTER 137

Merkel Cell Carcinoma

Key Points

- Merkel cell carcinoma (MCC) is a rare, aggressive, cutaneous neuroendocrine malignancy
- The majority of MCC tumors occur on the face and head, but only 5% to 10% involve the eyelids and the periocular region
- The pathophysiology of MCC is controversial, but the tumor is likely derived from a population of cells that represents earlier stages in the Merkel cell differentiation pathway
- Ultraviolet exposure is considered a major risk factor for MCC
- Tumors typically present near the eyelid margin as a rapidly expanding, painless, indurated, erythematous, violaceous, solitary dermal nodule with dilated telangiectatic blood vessels and loss of eyelashes
- Wide local surgical excision is currently the standard of care
- The prognosis for all body sites combined is relatively poor with local recurrence seen in about one-third of patients and one-half of patients developing distant metastases

In 1875, Friedrich Merkel first described clear, oval, nondendritic cells located in the basal layer of the epidermis around hair follicles and in the mucosa, with neuroendocrine features.[1] It was not until 1972 that an undifferentiated neuroendocrine tumor found in the skin was initially described by Cyril Toker as trabecular cell carcinoma of the skin.[2] But later, he speculated that the cellular origin of this cancer was Merkel cells and the tumor was renamed Merkel cell carcinoma (MCC). The exact origin of Merkel cells remains unsettled, but they are thought to have characteristics of both epithelial and neuroendocrine origins and to arise from a common pluripotential precursor.[3,4,5]

MCC is a rare, aggressive, cutaneous neuroendocrine malignancy. The highest worldwide incidence is found in Australia at 1.6 cases per 100,000 population.[6] While the incidence is very low, it has increased over the last several decades, with an annual increase of about 8%.[7] In the United States, about 1500 new cases of MCC are diagnosed each year, with a male preponderance of about 60%.

MCC is extremely uncommon in younger patients, with only 12% younger than 60 years of age.[8] The median age at diagnosis is about 75 years old, and the incidence increases rapidly with advancing age, suggesting an accumulation of oncogenic factors.[9] The incidence is also increased in immunocompromised individuals with AIDS or those who have undergone organ transplantation.[10,11] The risk is higher among persons of European ancestry, and the incidence is inversely related to latitude suggesting its occurrence is related to a deficiency of protective melanin in the skin. Patients with MCC have a higher risk of other sun exposure-related skin tumors and also have an increased risk for multiple myeloma, non-Hodgkin lymphoma, and chronic lymphocytic leukemia.[12]

The majority of MCC tumors are present on the face and head. Only 5% to 10% involve the eyelids and the periocular region,[13] of which only about 100 cases have been reported to date. These tumors are characterized by rapid progression, a high rate of recurrence after surgical resection, and early regional and metastatic spread.[14,15]

This carcinoma has been referred to under several different names in the published literature including Toker tumor, cutaneous neoplasm of Merkel cells, neuroendocrine carcinoma of the skin, and primary undifferentiated carcinoma of the skin. Campill et al[16] proposed that primary cutaneous neuroendocrine carcinoma best describes the relevant identifying characteristics of this tumor, but this has not gained general usage.

Two patterns of clinical presentation have been recognized.[17] The first pattern includes Merkel cell polyomavirus-positive tumors (MCPyV+) and represents about 80% of cases. These arise in a slightly younger population and present as benign-appearing flesh-

colored to violaceous dome-shaped nodules on the limbs and head and neck. The second pattern is MCV-negative (MCPyV-) tumors seen more frequently in patients with tumors in sun-damaged skin of the head and neck, often associated with other nonmelanoma skin cancers.

Etiology and Pathogenesis

Identifying the cell type from which any cancer arises is important for understanding the mechanisms of tumor origin and conceivably in discovering therapeutic interventions. The etiology of MCC is controversial: while evidence for the cell of origin is lacking, MCC cells do have some similarities to benign Merkel cells in both immunophenotype and ultrastructure, though normal Merkel cells are not most densely present in the same areas where MCC is most common.[18,19] Most investigators do not consider mature Merkel cells to be the cell of origin for MCC.[20] Rather, MCCs are more likely to be derived from a population that represents earlier stages in the Merkel cell differentiation pathway.[21] In addition, polyomavirus-negative MCCs have ultraviolet mutational signatures that are not present in papillomavirus-positive MCCs, suggesting that these two tumor types might arise from distinct cells of origin.[22]

(Print pagebreak 914)

Although Merkel cells are found in the epidermis, MCC arises predominantly in the dermis.[23] Despite the similarities between Merkel cells and MCC, there is evidence against the belief that MCC originates from epidermal Merkel cells. This includes the observation that MCC is localized in the dermis, lacks the neuroendocrine peptides typical of normal Merkel cells, and the frequent presence of neurofilament proteins (NFPs).[24] The most accepted hypothesis is that MCC originates from a common precursor cell of keratinocytes and Merkel cells.[24,25]

In 2008, a novel virus, named Merkel cell polyomavirus (MCPyV), was identified in MCC tissue and can be detected in 80% of all MCC samples.[26,27,28,29,30] This virus has been tentatively linked to the pathogenesis of some MCC. The oncogenic potentials of this virus are attributed to two of its proteins, large T-antigen that regulates cell cycle transit and small t-antigen that activates cap-dependent translation critical for cancer cell growth. These have been shown to transform cells in vitro and induce tumors in an animal model.[30]

There are significant differences between MCPyV-positive and MCPyV-negative MCCs in cellular morphology, as well as in chromosomal alterations, activating mutations, and inactivation of tumor suppressor genes.[21] This adds to the speculation that MCC may arise from multiple cells of origin. Jankowski et al[31] discussed the expression of early B cell lineage markers in 80% of MCC that are also MCPyV-positive. They hypothesized that MCC may be a heterogeneous entity with separate subtypes: a pluripotent dermal epidermal stem cell-derived MCPyV-negative MCC with epidermal tropism (20%) and an MCPyV-positive MCC possibly originating from precursor B cells (80%). However, in a review of recent studies on cancer genomics, mouse genetics, and virology experiments, Sunshine and Jahchan[22] concluded that MCPyV-positive MCCs originate from mesodermal dermal fibroblasts, and MCPyV-negative MCCs arise from ectodermal epidermal keratinocytes.

Ultraviolet exposure is considered a major risk factor for MCC. The frequency of MCC is higher at lower latitudes and is significantly lower in patients of non-white ethnicities. This tumor has a predilection for sun-exposed areas of the skin and is more common in light-skinned individuals. Australia currently has the highest reported incidence of MCC with a higher percentage of MCPyV-negative MCCs, possibly reflecting a higher risk of ultraviolet exposure.[32,33]

Immunosuppressive status is another known risk factor with organ transplant recipients and acquired immune deficiency syndrome patients disproportionately affected.[34] A significantly increased risk of MCC has been observed among patients with a history of previous hematologic and cutaneous malignancies.[35,36] MCC was also observed in patients with a history of breast cancer, but a significant association between the two entities has not been established.[36,37]

Clinical Presentation

MCC is more common in the head and neck where it accounts for about 40% to 50% of all such lesions.[14,38] About 10% involve the eyelid or periocular region.[24] The diagnosis is challenging due to its variable appearance. Tumors typically present as an asymptomatic, rapidly expanding, painless, indurated, solitary dermal nodule near the eyelid margin (Figure 137.1). The color is erythematous to deeply violaceous, with dilated telangiectatic blood vessels and minimal to significant loss of eyelashes.[34] The upper eyelid is more commonly involved than the lower eyelid, representing about 80% of all eyelid MCC. The overlying epidermis is usually intact,[24] but ulceration may occasionally be present (Figure 137.2).

The involvement of regional lymph nodes is present in up to two-thirds of patients with MCC. The rate of sentinel lymph node involvement is correlated with greater tumor diameter and thickness, those with a higher mitotic rate, and tumors with infiltrative

growth patterns. Pfieffer et al[39] found that 68% of patients with MCC > 2 cm had positive sentinel lymph nodes, whereas only 23% of patients with tumors < 1 cm had positive nodes.

Multiple lesions are exceedingly rare and there is one case report of a recurrent lesion in the lower lid associated with a second lesion on the ipsilateral upper lid 1 year after initial presentation and surgical excision.[40] Thakur S et al[41] described a patient with MCCs involving the bilateral upper eyelids.

Differential Diagnosis

As many as 56% of MCCs are initially thought to be clinically benign.[42,43] They are most commonly mistaken for chalazion, eccrine cyst, keratoacanthoma, dermatofibroma, and lipoma leading to delayed diagnosis and treatment.[41,44,45,46] It is also often mistaken for other more common nonmelanoma malignancies such as basal cell, squamous cell, and sebaceous cell carcinomas, as well as lymphoma, and metastatic neuroendocrine tumors.[15] The diagnosis is usually made following a biopsy and relies heavily on immunohistochemistry.[42] Once confirmed, further evaluation should include a total body evaluation with a PET/CT scan since MCC is highly avid for FDG (18 fluorodeoxyglucose).[7] As for all tumors, AJCC staging should be determined.

Treatment

Given the high tendency of MCC to recur locally, wide local surgical excision is currently the standard of care. The recommendation for the optimal minimum normal tissue margins elsewhere in the body is 3 cm. However, such margins do not apply to eyelid lesions. Atamney et al[7] employed excision of eyelid tumors with 5-mm margins, along with intraoperative biopsy samples confirmed by frozen section to be free of tumor cells. Other studies have confirmed that a margin width of 5 mm may be reasonable for local control of eyelid of periocular lesions, particularly for lesions <2 cm.[15,45] MCC is very radiosensitive and radiotherapy is commonly used as an adjuvant modality for patients at risk for recurrence or for patients not suitable for primary surgical resection.[47] Although postoperative radiotherapy has been associated with improved local and regional control, improvement in disease-specific survival has been variable.[47] *(Print pagebreak 915)* After appropriate postsurgical healing, adjuvant radiotherapy targeting the tumor bed for patients with localized MCC, for those with narrow resection margins, and for immunosuppressed patients, has been recommended by the National Comprehensive Cancer Network (NCCN). Fractionated radiotherapy at 50 to 66 Gy is recommended depending on whether the resection margins are negative or positive.[47]

FIGURE 137.1 Nodular Merkel cell carcinoma involving the eyelid margins. (A, Courtesy of Dr. Robert

Kersten. B and C, Courtesy of Dr. Bita Esmaeli. D, Courtesy of Dr. Robert Goldberg.)

Because MCC has a propensity for early invasion of dermal lymphatics, surgical excision of the primary lesion may not be adequate for the prevention of local and regional recurrence and metastases even with adequate margins. Esmaeli et al[48] reported the first case of a positive sentinel lymph node biopsy (SLNB) in a patient with MCC of the eyelid. They suggested that SNLB may allow for the detection of subclinical nodal metastases and therefore allow for a more prompt institution of adjuvant therapy. Because MCC is highly radiosensitive, many authors have recommended adding adjuvant radiation therapy to the primary site and to the draining nodes as standard of care in addition to surgery. This is especially relevant in the eyelids where surgical margins are necessarily limited, and local recurrence may have significant visual consequences. A recent study by Lamberti et al demonstrated that radiotherapy was associated with improved overall survival not just in patients with node-positive MCC (N+), but also in node-negative patients (N0), and even in nonmetastatic MCC (M0).[49] This study found that radiotherapy was interdependently associated with a 25%, 27%, and 26% reduction in the risk of death in M0, N0, and N+ respectively. However, there was no survival benefit in T4 tumors.[49] Also, in a meta-analysis of 1254 MCC patients comparing surgery alone to surgery with adjuvant radiotherapy at all anatomic sites, the use of surgery plus local radiotherapy decreased the risk of local and regional recurrence.[50]

When palpable lymphadenopathy or positive SLNB is present at the initial presentation, lymph node dissection may be useful as the first-line treatment for micrometastatic disease.[15] If this is unacceptable to the patient, then radiotherapy can be considered. The use of chemotherapy for MCC is inconclusive and available data are limited. Chemotherapy currently has no established role for localized or regional disease, but in patients with distant metastatic disease, palliation including chemotherapy may be appropriate and provides overall response rates *(Print pagebreak 916)* of approximately 70%.[51] Combination chemotherapy is more effective when two or more drugs are given concurrently.[52,53] Cisplatin plus etoposide, cyclophosphamide plus doxorubicin plus vincristine, or cyclophosphamide plus epirubicin plus vincristine are the most commonly used regimens.[25] The response rate is 70%, with a complete response in 35%.[54] However, the disease often recurs within a few months.

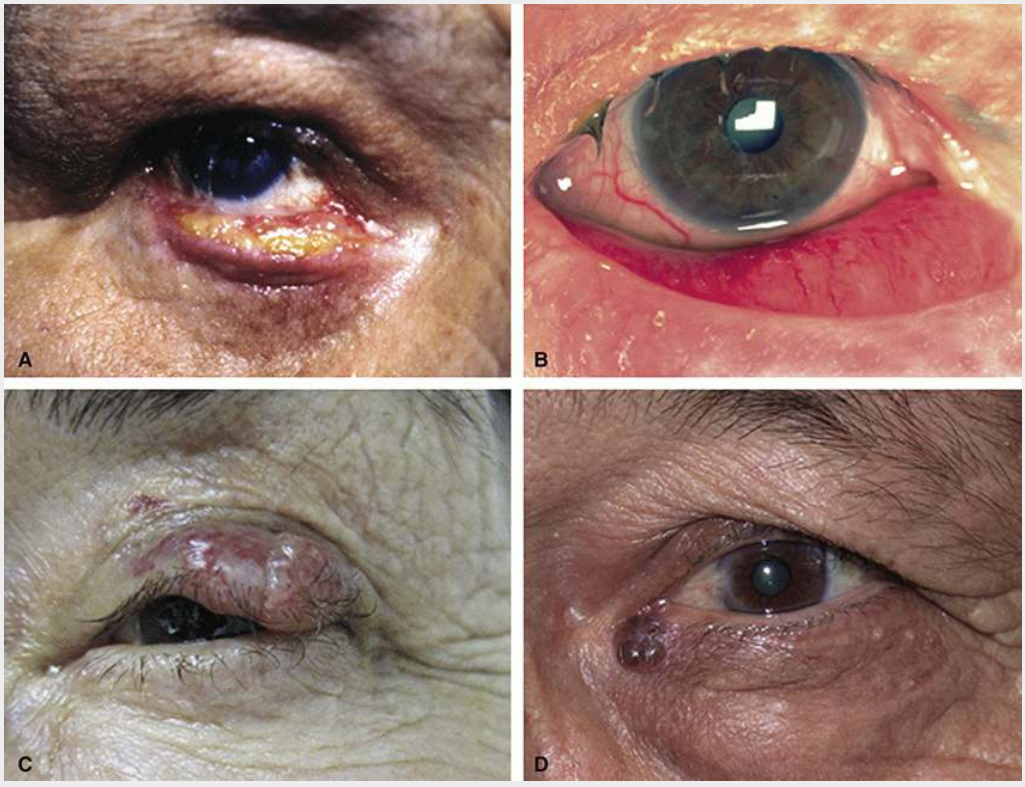

FIGURE 137.2 A, Ulcerated Merkel cell carcinoma on the eyelid margin. B, Diffuse infiltration of the lower eyelid and conjunctiva. C, Upper eyelid marginal Merkel cell carcinoma. D, Subcutaneous lower eyelid Merkel cell carcinoma. (A, Courtesy of Dr. Charles Soparkar. B, Courtesy of Dr. Robert Goldberg. C, Courtesy of Dr. Bita Esmaeli. D, Courtesy of Dr. Charles Soparkar.)

Insights into the pathogenesis of MCC have led to several clinical trials on the use of immunotherapy.[55] Recently, immune checkpoint inhibitors have shown very good durable responses, leading to the approval of a programmed death-ligand 1 inhibitor, Avelumab, for these patients.[56] In a clinical trial using Avelumab as first-line treatment for MCC patients with metastatic or locally advanced disease, objective response was achieved in 31.8% of cases, with a favorable toxicity profile, and an overall survival of 31% at 42 months.[47] However, despite initial successes, more than 50% of patients with MCC do

not benefit from PD-1 pathway blockade in any persistent fashion.[57]

Prognosis

The overall prognosis for Merkel cell tumor for all sites combined is relatively poor. Local recurrences are seen in about one-third of patients, usually within 1 year. Two-thirds have regional lymph node metastases, mostly within 18 months. More than one-half of patients develop distant metastases, usually within 2 years.[24,47]

Except for malignant melanoma, MCC is the second most common cause of skin cancer deaths in the United States with 5-year overall survival rates of 70% to 90%, 39% to 64%, and 18% to 30% for local, regional, and distant metastases, respectively.[39,58,59,60] The mortality rate within 2 years of diagnosis is 28% to 40%, with a median survival time of 6.8 months.[61,62,63]

Spontaneous regression of MCC tumors has been reported in more than 40 cases.[63,64,65] All cases were followed up to 18 months from diagnostic biopsy, and the regressions occurred rapidly over 1 to 3 months. Most *(Print pagebreak 917)* cases resulted in a cure over follow-up intervals of 1 to 15 years, although recurrence in regional lymph nodes has been reported.[66,67] Although the pathogenesis of the regression phenomenon has not yet been elucidated, it has been proposed that biopsy of the tumor may serve as the triggering mechanism by activating a T cell immune response.[68,69] Connelly et al[70] estimated the incidence of regression to be 1.67%.

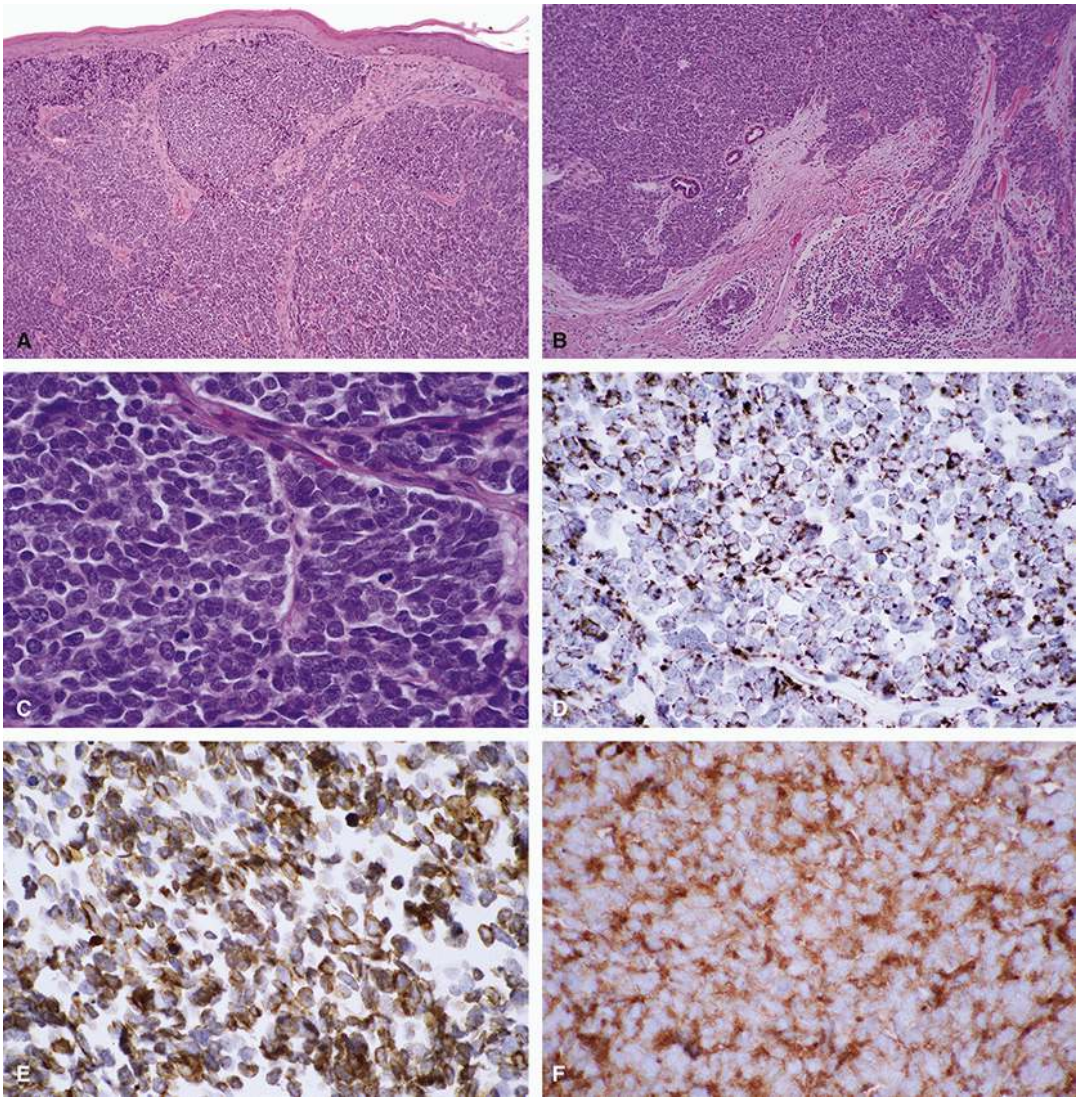

FIGURE 137.3 This Merkel cell carcinoma of the left cheek was located in the dermis of a man in his middle 70s. A, A narrow zone of normal dermis separates the anastomosing nodules of tumor from the overlying epidermis. B, Sheets of tumor cells form the nodules. The edges of the tumor are infiltrative into the adjacent dermis. C, The tumor cells are discohesive, intermediate size, and mostly round to oval. The chromatin is finely granular, and nucleoli are not apparent. The tumor cells are immunoreactive using broad-spectrum antibodies to cytokeratins (AE1/AE3; D), CK20

(E), and synaptophysin (F).

Histopathology

MCCs are dermal and/or subcutaneous tumors.[71,72,73,74] They are composed of cells that may be small, intermediate size, or large, with intermediate cell type MCC most common.[73] Epidermal involvement is uncommon,[58,74] with most MCCs having a zone of normal dermis between the epidermis and tumor (Figure 137.3A).[71] Tumor cells may form anastomosing *(Print pagebreak 918)* trabeculae (trabecular pattern) or diffuse noncohesive sheets reminiscent of lymphoma (solid pattern; Figure 137.3A-C).[71,75] The growth pattern was infiltrative in 71% of tumors, nodular in 20%, multinodular in 6%, and polypoid in 2% of the 156 tumors examined by Andea and coworkers.[72] Tumor cells vary from round to oval to spindle[75] and are usually basophilic with round nuclei, finely granular chromatin, absent or small inconspicuous nucleoli, and scant amphophilic cytoplasm (Figure 137.3C).[71] Mitotic figures are usually numerous,[71] there are scattered apoptotic tumor cells,[74] and zones of "geographic" coagulative necrosis occur in about half of MCCs.[71] Lymphovascular invasion is considered an early event in MCC,[76] and it was identified by Andea and colleagues in 60% of 156 tumors.[72] The tumor stroma is highly vascularized,[75] and tumor-infiltrating lymphocytes vary from absent to brisk.[72] MCCs may sometimes exhibit areas of squamous, glandular, sarcomatous, follicular, or porocarcinoma differentiation.[77]

MCC tumor cells usually express broad-spectrum keratins such as AE1/AE3 (Figure 137.3D), cytokeratin 20 (CK20; Figure 137.3E), neuroendocrine markers (chromogranin A, synaptophysin [Figure 137.3F], CD56), NFP, special AT-rich sequence-binding protein-2 (SATB2), and often MCPyV.[74] CK20 expression is usually a perinuclear dot pattern "often admixed with circumferential cytoplasmic staining."[74] A dot-like pattern of CD99 expression is strongly associated with MCPyV-positive tumors (sensitivity = 81% and specificity = 90%).[78] MCPyV-negative MCCs are frequently positive for expression of thyroid transcription factor 1 (TTF1) and CK7 and negative for expression of NFP, and they more frequently have larger tumor cells with more abundant cytoplasm.[78] Identification of blood vessel and lymphatic invasion is facilitated using antibodies to blood vessel endothelium (eg, CD31 or factor VIII-related antigen) or podoplanin for lymphatics (Figure 137.4A and B). Locating minute metastases or single-tumor cells in lymph nodes is aided by using antibodies to cytokeratins or neuroendocrine markers (Figure 137.4C and D).

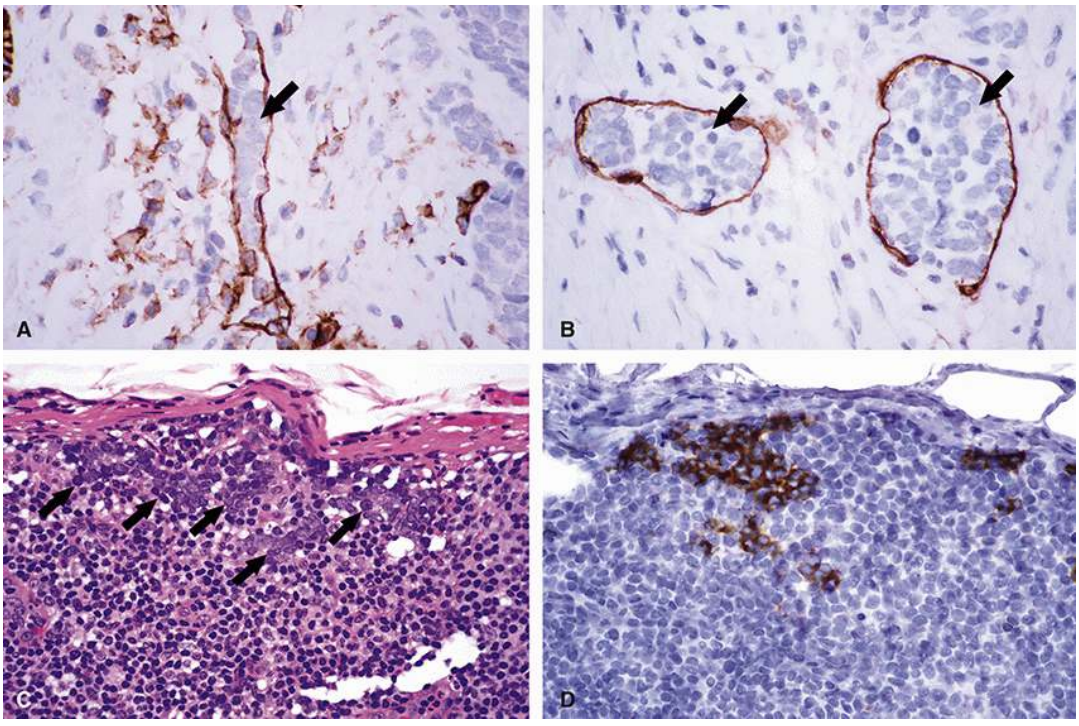

FIGURE 137.4 Merkel cell carcinomas (MCCs) commonly have lymphovascular invasion (LVI). Identifying LVI is aided using immunohistochemical stains for blood vessel (A; anti-CD31 antibodies) and lymphatic endothelium (B; D2-40 anti-podoplanin antibody). Endothelial cells (brown) surround tumor cells in the lumen of a vein (A, arrow) and two lymphatics (B, arrows). C, Small MCC lymph node metastases (arrows) are often difficult to distinguish from large lymphocytes. D, Small subcapsular metastases and individual tumor cells are highlighted brown using antibodies to synaptophysin.

Pathological staging of eyelid MCC is similar to these tumors at other sites and incorporates tumor size, invasion of other structures (fascia, muscle, cartilage, or bone), lymph node status, and distant metastases.[79] Histological features of likely prognostic

significance that are in the College of American Pathologists protocol for MCC include tumor thickness, *(Print pagebreak 919)* lymphovascular invasion (not identified or present), mitotic rate (<1/mm^2 or >1/mm^2 [specify number]), tumor-infiltrating lymphocytes (not identified; present, nonbrisk; present, brisk), and tumor growth pattern (nodular or infiltrative).[80]

CHAPTER 138

Metastatic Tumors to the Eyelids

Key Points

- Eyelid metastasis is very rare accounting for less than 1% of malignant eyelid lesions
- Breast carcinoma is most frequent, followed by skin melanoma, gastric carcinoma, uveal melanoma, lung carcinoma, and kidney carcinoma
- Clinically, metastatic lesions generally appear as a painless diffuse eyelid swelling, or solitary acutely inflamed tender nodule mimicking acute chalazion, but may show no specific clinical features that distinguish them from primary eyelid malignancies
- They typically occur as a late event in the course of systemic disease, and in the case of breast cancer may appear 2 to 10 years after the initial diagnosis
- The management of metastases is directed at the systemic disease with systemic chemotherapy and immunotherapy
- Local eyelid treatment may include observation, excisional biopsy, and external beam radiotherapy
- The prognosis of patients with eyelid metastatic tumors varies depending on the type of malignancy, primary tumor stage, and extent of systemic metastatic disease

Eyelid metastasis is a very rare condition that accounts for less than 1% of malignant eyelid lesions.[1,2,3,4,5] In a survey of 892 eyelid lesions, of which 214 were malignant, only 3 cases (0.3%) were metastatic tumors.[2] In another review, out of 1502 eyelid lesions evaluated histopathologically, only 1 case (0.07%) of eyelid metastasis was found.[3] Up to 50% of cases are derived from a breast carcinoma, which explains why eyelid metastasis occurs more frequently in women than in men. However, no sex differences have been observed for metastases of other origins.[6] Eyelid metastases predominantly occur in adulthood, although very rare cases related to sarcoma or embryonic tumors of a neural origin can occur in children.[7] The majority of metastatic lesions to the eyelid are carcinomas, with the breast, gastrointestinal tract, and lung as common sites for the primary lesion.[8,9] Most eyelid metastases appear in patients with a known history of systemic cancer, but eyelid metastasis can be the first symptom of systemic cancer in 7% to 45% or the first sign of metastatic recurrence from known cancer.[1,6,8,10] There should be a high level of suspicion for the possibility of metastatic disease when dealing with rapidly growing lesions of the ocular adnexa, especially when there is a known history of malignancy elsewhere in the body.

Three clinical presentations of eyelid metastases have been observed. The most frequent is a painless, subcutaneous, skin-colored nodule, seen in up to 62% of all cases. These lesions are often mistaken clinically for a chalazion. The second type of presentation is a diffuse, infiltrative, inflammatory pattern seen in 30% of cases. Such lesions are characterized by a red to brown induration of the eyelids, with a morpheaform appearance. Finally, the ulcerated type (8%) results from invasion of the epidermis by neoplastic cells and may appear in conjunction with either of the aforementioned types.[3,8] Zimmermann et al[11] described a fourth, edematous variant of eyelid metastasis presentation, but this may just be an earlier stage of the diffuse type. This is seen more commonly with breast metastases.

Three surveys plus several later individual case descriptions totaling 76 cases have reported the distribution of eyelid metastases by primary tumor site.[1,6,8,12,13,14,15,16,17] Taken together, breast carcinoma was the most common primary site (32%), followed by skin melanoma (20%), gastric carcinoma (8%), uveal melanoma (8%), lung carcinoma (5%), and kidney carcinoma (4%). Other rarely reported primary sites for eyelid metastases include salivary duct carcinoma, leiomyosarcoma, osteogenic carcinoma, Kaposi sarcoma, carcinoid tumor, neuroendocrine carcinoma, lymphoma, thyroid carcinoma, rectal carcinoma, bladder urothelial carcinoma, mediastinal teratoma with malignant transformation, hepatocellular carcinoma, prostate cancer, and uterine cervical carcinoma.[18,19,20,21,22,23,24,25,26,27,28,29,30,31]

Etiology and Pathogenesis

Metastasis is a complex, multistage process that requires carefully timed, diverse stages and properties acquired by cancer cells. Metastatic cells must move from the primary tumor site, enter the bloodstream and survive there, and then exit the bloodstream at the arrest organ. They then must colonize the distant tissue and grow into a macroscopic metastatic lesion.[32] Circulating tumor cells represent an intermediate stage between the primary tumor and the metastatic tumor.

Specific tumor-host cell interactions facilitate the initiation of metastatic spread and determine the distribution of metastatic tumor deposits in various organs and tissues.[33,34,35,36,37] Individual tumor types form metastatic tumors in specific organs, unrelated to the route of tumor cell migration.[33] Studies have shown that breast cancer cells obtained from *(Print pagebreak 922)* metastasis-free organs of mice that suffer from lung and lymph node metastases are not only alive but can resume neoplastic growth and metastatic behavior if reinoculated into compatible organs. This supports the idea that metastatic tumor cells are dependent on suitable stromal environments for their growth.[33] As a result, mature metastases are not just aggregations of tumor cells, but consist of a mixed population of neoplastic and non-neoplastic cells.[38] Among the non-neoplastic cells are various cell lineages including fibroblasts, macrophages, and endothelial cells, among others. Over time, the architecture of the lesion becomes organized into a distorted histologic version of the original organ that produced the primary tumor.

Intrinsic properties, such as gene expression patterns in the metastasizing cells, help drive the metastatic event,[33] and individual tumor cells differ in their metastatic potential.[39,40,41,42] The programmed steps initiated in metastatic cells follow an orderly sequence that has been speculated to superficially resemble embryonic cell migration,[33] and the orderly migration of lymphocytes as they move around the body.

Primary tumor cells that invade surrounding tissue lose E-cadherin function resulting in decreased intercellular adhesion. This is a molecule that links cells together through their actin cytoskeleton. This loss of function is caused by mutations or gene downregulation. These epithelial tumor cells can then migrate across the basement membrane to enter the tissue stroma facilitated by enzymes, such as matrix metalloproteinases, which cleave proteins.

Emerging evidence supports the concept that different stromal components in the primary tumor microenvironment also contribute to the regulation of cancer formation and promote the development of metastasis. These include cancer-associated fibroblasts, macrophages, neutrophils, myeloid-derived suppressor cells, regulatory T cells, natural killer cells, and extracellular matrix, among others.[43] Certain tumor cells acquire the ability to induce epithelial-to-mesenchymal transition, which helps them to break loose from the primary tumor.[44]

The metastatic process begins when cells from the primary tumor separate from other cells and invade the surrounding stroma where they are directed toward blood vessels by growth factor gradients. Through the process of intravasation, they penetrate the vessel, aided by increased permeability and fragility of the vessel wall from tumor-associated dysregulation of angiogenic signaling,[45] and inflammatory signaling.[46] Cancer cells can also access the bloodstream indirectly via the lymphatic system.[32]

When the circulating tumor cells reach the bloodstream they are subjected to attack by immune cells, especially by natural killer cells.[47] However, they can employ several mechanisms to avoid immune surveillance, such as coupling to reactive platelets and allowing them to imitate host cells and to be protected from shear forces.[48,49] The platelets also release transforming growth factor-β, which can downregulate a surface receptor that in turn downregulates the antitumor function of CD8+ T lymphocytes and natural killer cells.[50]

These circulating tumor cells are also characterized by an increased ability to survive in the bloodstream,[51] although over time a majority of these cells die. In one study, only 2.5% went on to form micrometastases, and far fewer (0.01%) of these cells induced macrometastases.[52] They are also believed to possess stem-like properties that are capable of self-renewal and tumor formation.[53,54]

Anatomical and molecular factors determine the organs in which circulating cancer cells arrest. The microvasculature of the arrest organ and its relation to the primary tumor influence the development of the metastasis. Organs with rich capillary beds, such as the liver and lungs, become major metastatic sites for many primary tumor types. Structures such as the eyelids have limited vascular access, which partially explains the rarity of eyelid metastasis. It is also proposed that certain organ tissues are predisposed to metastasis because their microenvironment is compatible with specific tumor cells.[55] This stromal interaction between metastatic cells and the arrest organ is essential to the proliferation of metastatic cells.

At the distant organ sites of tumor arrest, extravasation from the blood vessel occurs by several mechanisms. One is thought to proceed in a manner similar to the extravasation of leukocytes, enabling them to transmigrate the endothelial barrier at the metastatic site.[56] This occurs primarily in the small capillaries at branch points between blood vessels.[57,58] The tumor cell interacts with the blood vessel endothelium[59,60] and penetrates the wall of the blood vessel in response to factors produced by the tumor cell.[61,62]

Another mechanism involves blood vessels in organs such as the liver and bone marrow that are normally fenestrated, thus providing less of a barrier to the extravasation of circulating tumor cells. In other organs, extravasation can occur through small gaps in the blood vessels created by the normal turnover in endothelial cells or through vessel wall damage that attracts platelets and tumor cells associated with them.[55] Once extravasated from the circulation, the tumor cells cross the basement membrane and enter the tissue stroma where they can proliferate.

Clinical Presentation

Metastases to the eyelids can manifest with several different characteristics. Morgan et al[21] reported that metastases from breast cancer tend to appear as a painless diffuse eyelid swelling, whereas those from lung cancer tend to be solitary nodular lesions. Others have reported no specific clinical features to distinguish metastatic lesions from different primaries.[1]

Metastasis from breast carcinoma is typically a late event in the course of the disease. In these patients the primary breast cancer is usually already known, preceding the eyelid lesions by 2 to 10 years. Regional lymph node involvement is known in most cases at the time of the mastectomy. When eyelid involvement occurs, patients often already have metastases to the viscera, bones, or skin (Figure 138.1). The orbit, as *(Print pagebreak 923)* well as the eyelid, may also be involved by metastasis, and both may have bilateral involvement. Rarely, the eyelid, orbit, and choroid can all be involved simultaneously.[8] Malignant melanoma constitutes another major primary tumor giving rise to metastatic eyelid tumors (Figure 138.2A). Most cases result from cutaneous lesions, with rare occurrences from a uveal primary. In some instances, the primary melanoma tumor is already known, but occasionally the eyelid metastasis may occur with no indication of a primary site. These may represent cases of spontaneous involution of lentigo maligna.[8,63] Contrary to the relatively late metastatic spread of breast carcinoma and cutaneous melanoma, where the eyelid lesions occur as part of a more generalized carcinomatous process, metastatic eyelid lesions from gastrointestinal sites may be the initial manifestation of the disease.[8]

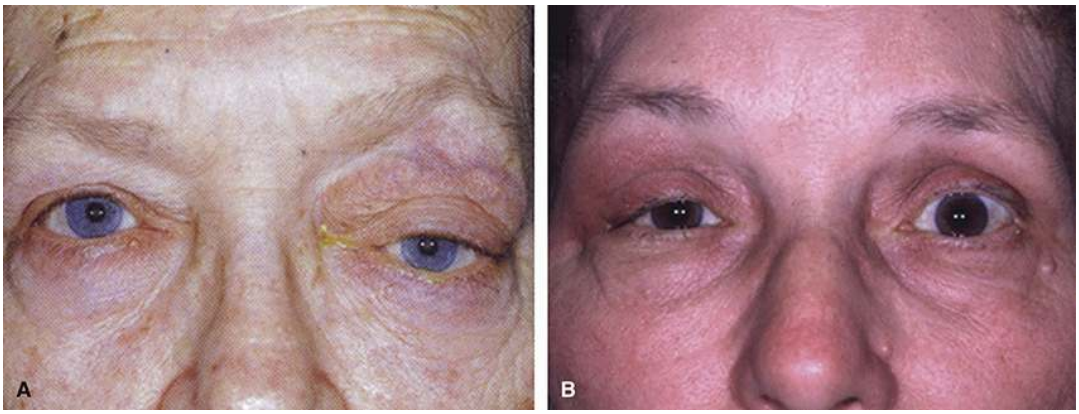

FIGURE 138.1 A and B, Metastatic breast carcinoma to the eyelids in patients with a previous history of breast cancer and systemic metastases.

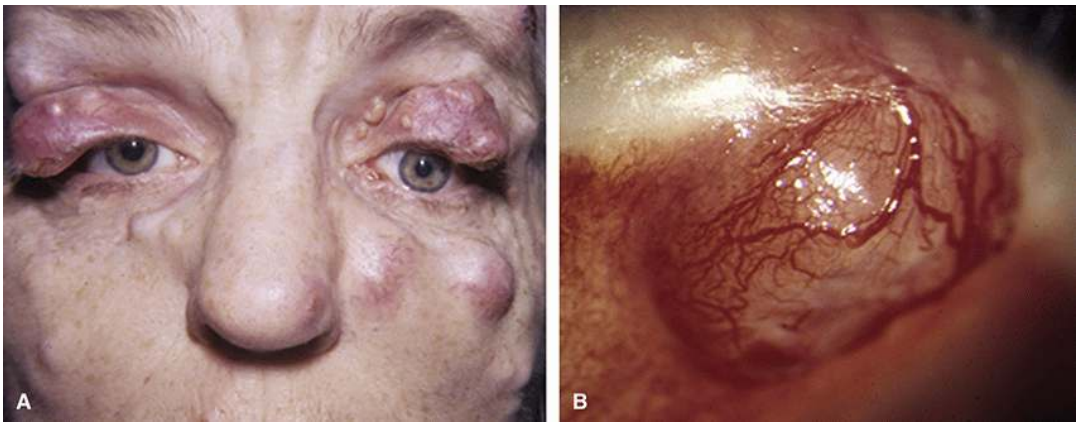

FIGURE 138.2 A, Multiple metastatic cutaneous melanoma nodules to the bilateral eyelids and face. B, Nasopharyngeal metastasis to the eyelid.

Riley[8] described three forms of clinical presentation of metastasis to the eyelid: a nontender and uninflamed solitary subcutaneous nodule (Figure 138.2A), a diffuse nontender indurated lesion causing relative immobility of the eyelids, and an ulcerative lesion. Arnold et al[3] introduced a fourth presentation category as an acutely inflamed tender nodule, mimicking acute chalazion (Figures

138.2B and 138.3). Most commonly, metastases to the eyelid present as a painless nodule, a diffuse swelling, or an ulcerated lesion, and both the lower and upper eyelids are involved equally.[6,64] Most patients are between 50 and 80 years of age, and women are involved more commonly because of the high percentage of breast carcinoma. Clinically, most of these lesions are unilateral or single and less commonly multiple. Bilateral lesions are rare and involvement of all four eyelids is exceptional.[8,9,11,65,66,67,68]

Differential Diagnosis

Metastatic eyelid tumors often can be mistaken for a chalazion because of their location and possible associated inflammatory signs. The differential diagnosis also includes other benign lesions such as cyst, pyogenic granuloma, and xanthoma.[1,3] Malignant lesions should also be considered, including basal cell carcinoma, squamous cell carcinoma, melanoma, sebaceous carcinoma, primary neuroendocrine tumors of the skin, and Merkel cell carcinoma.[6,64,69] In an analysis of 31 patients with eyelid metastasis, only 10 of 17 cases (59%) with a known primary carcinoma were clinically suspected to be malignancies.[6]

Treatment

The management of eyelid metastases is not directed at a cure since these patients already have systemic involvement. Treatment is usually palliative to preserve eyelid function and protect vision. This can include observation, excisional biopsy, external beam radiotherapy, systemic chemotherapy, and immunotherapy. The choice of treatment depends upon clinical features of the tumor such as size and location, the degree of eyelid dysfunction, and a threat to vision, as well as the systemic status of the patient. Observation may be appropriate for patients undergoing treatment for active systemic disease. Small, solitary nodular eyelid lesions are usually managed with excisional biopsy alone.

Radiotherapy is indicated in patients with multiple or recurrent lesions. It is usually administered to control tumor growth and to preserve visual function, improve patient comfort, and relieve symptoms.[7] The recommended dose is 20 to 40 Gy delivered in fractions over 1 to 2 weeks.[7,70] Systemic chemotherapy may also be helpful in the treatment of ocular adnexal metastases, especially for lesions that are chemosensitive, such as small cell lung cancer and neuroblastoma.[71] Hormonal therapy can sometimes be indicated in the treatment of metastases from hormone-sensitive tumors, such as breast or prostate cancer.

Prognosis

The survival of patients with eyelid metastatic tumors varies greatly and depends on the type of malignancy, primary tumor stage, and extent of systemic metastatic disease. The prognosis varies from good to dismal for different tumors. Patients with multiple metastases carry a worse prognosis, regardless of treatment. A somewhat better prognosis may be seen in patients with single nodules that are surgically excised and do not recur.

Histopathology

The histopathological features of tumors metastatic to the eyelid reflect their site of origin. As noted in the introduction to this chapter, adenocarcinoma of the breast is the primary tumor that most frequently metastasizes to the eyelid. Metastatic breast adenocarcinoma resembles the primary tumor, forming islands and cords of tumor cells within the dermis. Vacuolation of tumor cells reflects their glandular differentiation, and "signet ring" cells may be present (Figure 138.4).[70] Cutaneous melanomas metastatic to the eyelid may be recognizable by the presence of melanin, or they can be identified using immunohistochemistry. Immunohistochemistry[72] and gene expression[72] profiling assist in narrowing the possible primary sites for other tumors metastatic to the eyelid when the primary site is uncertain.

(Print pagebreak 925)

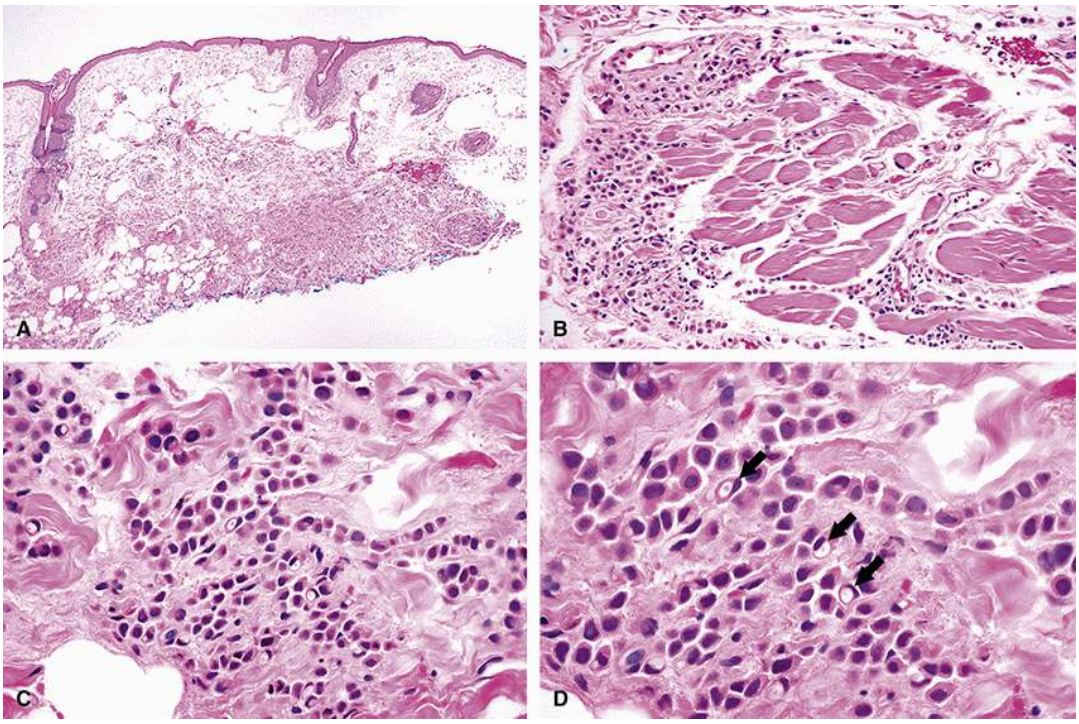

FIGURE 138.4 A woman in her late 50s presented with eyelid swelling and ptosis. Following a biopsy of her right upper eyelid, she was found to have a lobular carcinoma of the breast metastatic to the eyelid and orbit. A, The papillary dermis and superficial reticular dermis are edematous. The metastatic tumor is in the deeper reticular dermis, orbicularis oculi muscle, and the subcutis crating the more cellular appearance evident at low magnification. B, Tumor cells surround and infiltrate between orbicularis oculi muscle fibers. C, Tumor cells are found individually, as small clusters, and in one to two cell-wide columns. D, Many of the tumor cells have a histiocytoid appearance, while others have a signet ring character due to large cytoplasmic vacuoles displacing the nucleus peripherally (arrows).

Primary signet ring cell/histiocytoid carcinoma of the eyelid (Figure 138.5) must be considered before diagnosing breast carcinoma metastatic to the eyelid based on morphology and immunohistochemistry. Primary signet ring cell/histiocytoid carcinoma arises mainly in the eyelid,[73,74,75,76,77,78,79,80,81,82,83] with fewer cases reported in the axilla.[81] These tumors are rare, with fewer than 50 eyelid tumors reported.[80,81,82,83] Primary periocular signet ring cell/histiocytoid carcinomas affect predominantly older men (mean age of approximately 67 years) and present as gradual swelling, thickening, and firmness of the eyelid.[78] The tumor usually starts in one eyelid but may spread to the other, creating a monocle's appearance.[79,84] They are aggressive tumors that recur locally, metastasize, and may cause death.[75,76,78] Clinical and radiological findings must be employed to distinguish primary signet ring cell/histiocytoid carcinoma from a metastatic tumor since there are no immunohistochemical or molecular markers capable of differentiating primary and metastatic lesions.[80] Neoplastic cells may react to antibodies against CAM5.2, CK7, AE1/AE3, high molecular weight cytokeratins (34βE12 antibody), MNF116 cytokeratins, carcinoembryonic antigen, epithelial membrane antigen, gross cystic disease fluid protein-15, p63, mucin-1, epithelial cell adhesion molecule (BerEP4), E-cadherin, α-smooth muscle actin, vimentin, thyroid transcription factor 1, mucin 2, podoplanin, N-cadherin, GATA-3, and sometimes nuclear estrogen and/or progesterone receptors.[76,80] Tumor cells are characteristically negative for expression of CK20, S100 protein, muscle-specific actin (MNF116 antibody), calponin, CD68, CDX-2, mammaglobin, calretinin, HER2-neu, and placental alkaline phosphatase.[76,79,80] Molecular profiling has been reported in only two tumors, but in both cases identified potential targets for chemotherapy.[81,82]

(Print pagebreak 926)

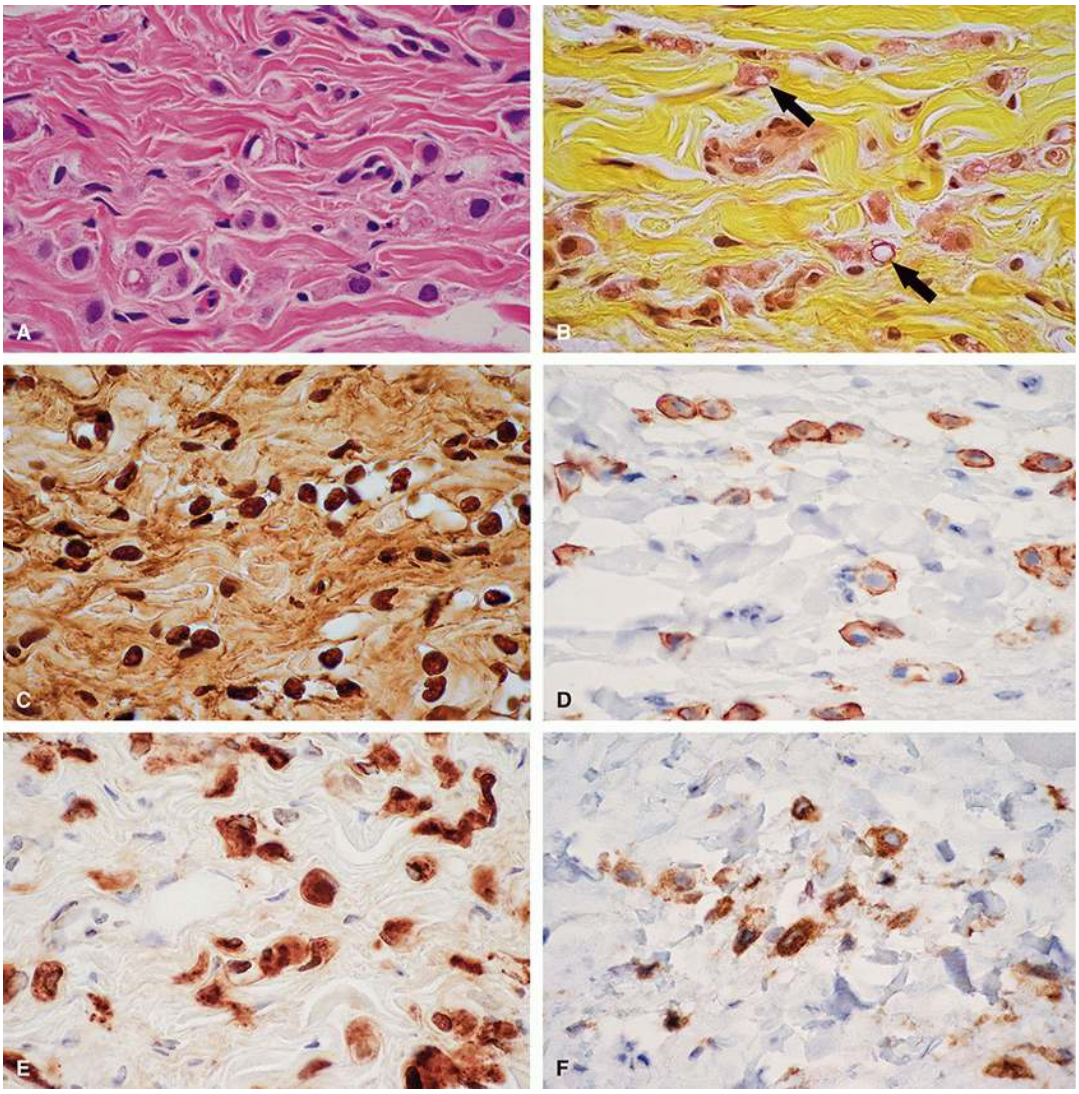

FIGURE 138.5 This primary signet ring cell/histiocytoid arose in the left upper eyelid of a man in his early 60s. The diagnosis was based on the histological and immunohistochemical appearance of the tumor and the lack of a primary tumor detectable elsewhere in the body by clinical and radiological examination. A, Histiocytoid and signet ring tumor cells dissect individually and in small clusters between the dermal collagen fibers. B, The tumor cells have finely vacuolated pink-brown cytoplasm using mucicarmine stain. The rim of large cytoplasmic vacuoles (arrows) stains red. The tumor cells were immunoreactive using a cocktail of antibodies to low-and high molecular weight cytokeratins, CK7 (C), E-cadherin (D), gross cystic disease fluid protein-15 (E), carcinoembryonic antigen (F), epithelial membrane antigen, and p63. The tumor cells were negative using antibodies to CK20, CD68, mammaglobin, epithelial cell adhesion molecule (BerEP4), thyroid transcription factor 1, CDX-2, podoplanin, S100 protein, and prostate-specific antigen.

CHAPTER 139

Microcystic Adnexal Carcinoma

Key Points

- Microcystic adnexal carcinoma (MAC) is a slow-growing, locally aggressive cutaneous adnexal malignancy derived from eccrine sweat glands
- It occurs predominantly on the head and neck region in about 85% to 90% of cases
- The etiology is unknown, but ultraviolet radiation exposure has been suggested to be a major risk factor
- It generally presents as an asymptomatic, slowly growing, flesh-colored or pale yellow, solitary, indurated subcutaneous nodule, plaque, or cyst-like tumor
- Perineural invasion is usually associated with a more aggressive course and a higher recurrence rate
- MAC tends to be local aggressive with deep infiltration and a high recurrence rate
- Complete tumor excision with histologic control of surgical margins is the treatment of choice
- Recurrence rates range between 17% and 60% but distant metastases occur in less than 1%
- The overall 10-year survival rate is excellent at 97.7%

Microcystic adnexal carcinoma (MAC) is a slow-growing, locally aggressive cutaneous adnexal malignancy derived from eccrine sweat glands. The appellation MAC was first applied by Goldstein, Barr, and Santa Cruz[1] in 1982, based on the review of six tumors, two of which had been reported previously as sweat gland carcinomas. MAC is one of several malignant adnexal tumors, including adenoid cystic carcinoma, apocrine carcinoma, cylindrocarcinoma, digital papillary adenocarcinoma, endocrine mucin-producing sweat gland carcinoma, hidradenocarcinoma, porocarcinoma, and primary cutaneous mucinous carcinoma.[2] As noted by Goldstein and coworkers, MAC "may be synonymous with previously reported cases called malignant syringoma, sweat gland carcinoma with syringomatous features, or aggressive trichofolliculoma."[1] It is a very rare tumor,[3] and occurs at a reported incidence of 1.6 to 6.5 per 1,000,000 population.[4]

MAC occurs predominantly in the head and neck region in about 85% to 90% of cases.[5,6] However, very few cases have involved the eyelids and periorbital region.[7,8,9,10,11,12,13] The tumor can be highly invasive and destructive locally and can invade dermis, muscle, adipose tissue, nerves, periosteum, and bone, causing significant morbidity.[14,15,16] However, regional lymph node involvement and distant metastases are rarely reported.[17,18] The tumor occurs mainly in Caucasians (90%),[4,19] and only seven cases have been described in patients of African descent.[20,21,22,23,24,25,26] Patients usually present in the fourth to seventh decades of life, with a median age of 68 years.[4] The age range is very broad, extending well into old age, but only about a dozen reported cases have been younger than 18 years, the youngest only 2 months of age.[6,19,27,28]

A male predominance is often cited in the literature, and some reports note an equal sex distribution.[29] But, in the largest analysis involving 223 patients from the Surveillance, Epidemiology and End Results (SEER) database the sex ratio was male 43% vs female 57%.[4]

Etiology and Pathophysiology

Fewer than 700 cases of MAC have been reported in the world's literature,[3] and its rarity makes it difficult to determine its etiology. Ultraviolet exposure, ionizing radiation, and immunosuppression have all been proposed.[4,30,31,32] Ultraviolet radiation exposure has been suggested to be a major risk factor for MAC.

Not only are the head and neck the most common sites for MAC, but in a large series of patients in the United States, 52% of tumors

were located on the left side (driver's side). This compared with an Australian series where the driver's side is the right side, and 56% of MAC tumors were on the right.[4] MAC has also been reported following ionizing radiation therapy with an incidence of about 10% to 19%.[19,30,33] The average latency period between radiation exposure and MAC was reported to be 7 to 30 years.[34]

The risk of nonmelanoma skin cancer in immunocompromised patients is well known for other tumors. Several cases of MAC developing in an immunocompromised patient have been reported, but a firm relationship has not been established.[30,31]

Clinical Presentation

Eyelid MAC is frequently misdiagnosed as a benign lesion or another more common skin malignancy such as squamous cell carcinoma.[11] Clinically, MAC can present as eyelid swelling with surface ecchymoses (Figure 139.1A). More *(Print pagebreak 930)* commonly, they appear as an asymptomatic, slowly enlarging eyelid thickening or a flesh-colored or pale yellow, solitary, indurated subcutaneous nodule, plaque, or cyst-like tumor (Figure 139.1B). It is firm with ill-defined margins and has prominent overlying telangiectatic vessels. The surface is smooth, and ulceration is uncommon (Figure 139.1C).[7,35] Pain, burning, anesthesia, and paresthesia can be seen with perineural invasion.[36] The average size at presentation is usually less than 2 cm in 80% of patients; however, the absolute size may be difficult to determine due to its indistinct borders (Figure 139.1D).[37] The tumor spreads by local invasion into deeper tissues early in its course[38] but only rarely metastasizes to regional lymph nodes or distant sites.[30,36,39,40] Orbital invasion by periocular MAC is very rare with only six cases reported.[7,41,42,43,44]

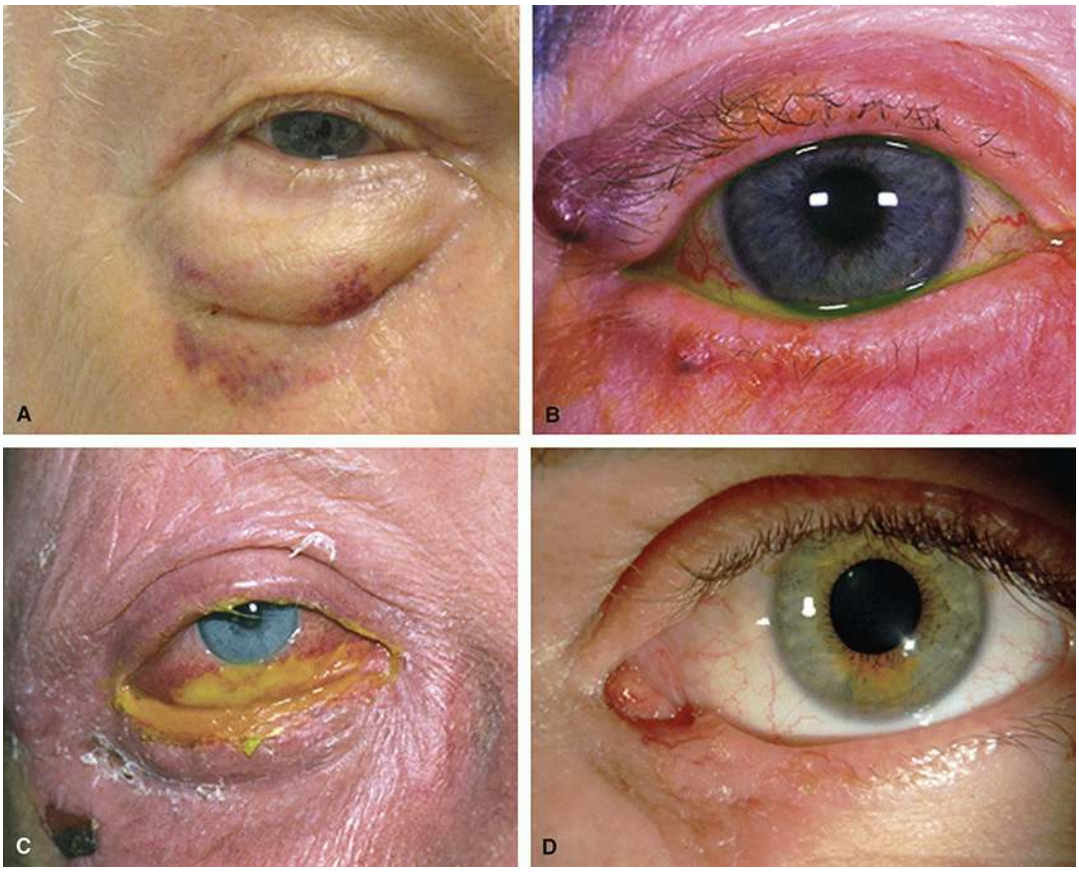

FIGURE 139.1 A, MAC presenting as lower eyelid swelling with ecchymoses. B, Reddish MAC nodule on the medial upper eyelid. C, Eyelid margin ulceration with diffuse eyelid and lateral canthal infiltration of tumor. D, Indistinct tumor margins infiltrating the medial lower eyelid, with madarosis. B, (Courtesy of Dr. David Jordan) D, (Courtesy of Dr. Alan McNab.)

A biopsy is necessary to confirm the diagnosis of MAC. However, a full-thickness biopsy is necessary to recognize infiltration into deeper tissues. Several recent studies have reported optical coherence tomography and reflectance confocal microscopy to be useful in evaluating tumor extent.[45,46]

Perineural invasion is usually associated with a more aggressive course and a higher recurrence rate. For skin malignancies in general, perineural invasion is seen in less than 5% of patients.[47,48] For MAC, the occurrence of perineural invasion was found to be 12% to 32%, possibly related to the infiltrative nature of this tumor.[31,49,50]

Differential Diagnosis

The clinical differential diagnosis includes both benign and neoplastic adnexal tumors and lesions. These include chalazion, trichoepithelioma, trichoadenoma, syringoma, desmoplastic trichoepithelioma, scars, and cysts, as well as other skin malignancies such as morpheaform basal cell carcinoma and squamous cell carcinoma.[10,37,51,52] This can make MAC difficult to diagnose.

(Print pagebreak 931)

Treatment

Because of the local aggressiveness, deep infiltration, and high recurrence rate of MAC, complete tumor eradication with histologic control of surgical margins is the treatment of choice.[53] However, even with wide local excision, the recurrence rates are high, ranging between 17% and 60%.[5,6,14,16,19,27] Mohs micrographic surgery has shown better results, with recurrence rates ranging from 0% to 22% at 5 years.[4,10,27,37,54,55,56]

Radiation therapy is not considered an effective therapy because MAC is relatively radioresistant, and there is little evidence to support its use as monotherapy. However, in one study on the use of adjuvant radiation therapy in 14 patients following surgery, 11 of whom had positive margins, 93% had good local control at a median follow-up of 5 years.[57] Recurrence rates following radiotherapy are higher than with surgery.[7]

The role of chemotherapy for MAC is unsettled. Two cases of metastatic MAC did respond to chemotherapy.[58,59] Only one case of primary MAC has been reported treated with chemotherapy but with unsuccessful results.[36]

Prognosis

Even with wide-margin surgical resection recurrences of MAC are very common, with 40% to 60% of patients having one or more recurrences between 6 months and 30 years after initial treatment.[7,36] This is despite the fact that about 74% of these tumors initially occur in the skin only, with only 7% invading the subcutaneous tissue and 9% invading underlying muscle or bone.[4] However, the involvement of regional lymph nodes is low at only 1% of cases, and distant metastases occur in less than 1% so that the overall 5- and 10-year survival rates are excellent at 97.7%.[4] Long-term follow-up of the patients with MAC is recommended given the high recurrence rate.

Histopathology

Goldstein, Barr, and Santa Cruz described MACs as composed of islands and strands of basaloid keratinocytes embedded in a desmoplastic stroma with rare tumor communication with the overlying epidermis.[1] Some tumors had abundant horn cyst formation with peripherally palisaded keratinocytes having minimal atypia, and a few cysts had early calcification.[1] Tumor cells also formed epithelial strands and ductal structures often lined by two layers of cuboidal cells.[1] The proportion of horn cysts and ductal structures varied between tumors.[1] All tumors had extensive infiltration of subcutaneous fat, and perineural and intramuscular invasion were common.[1] Mitoses were rare.[1]

Cooper and coworkers noted two histological patterns in their study of 20 sclerosing sweat duct (syringomatous) carcinomas.[14] Twelve tumors (group 1; Figure 139.2) mainly had cords and nests of uniform squamous cells with glassy eosinophilic cytoplasm, and some had blunt or pointed tails. The tumor cells often formed squamous whorls, and a variable number of nests had central cores of laminated keratin. Keratinization was abrupt, and keratohyaline granules were usually absent. Tumor nests were in a hyalinized collagenous stroma, and all tumors infiltrated subcutaneous tissue and associated skeletal muscle. There were sparse mitoses, usually <1 per 10 high power fields. Of the 12 group 1 tumors, 10 had perineural tumor invasion. Eight tumors (group 2) lacked well-developed squamous features but had “innumerable small cellular aggregates that were often sparse in the superficial dermis and were concentrated, instead, in the deep dermis and underlying tissues. The aggregates were in the form of round to oval nests, elongate or branched strands, and parallel cords” with polygonal or cuboidal cells having dense eosinophilic cytoplasm and distinct cell borders. Many of the nests, cords, and strands had lumens, some with eosinophilic material. All group 2 tumors had dense sclerotic stroma that sometimes formed nodules surrounding the subcutaneous tumor. Six of the eight group 2 neoplasms had perineural or intraneural invasion. Mitoses were sparse, similar to group 1 tumors.

More recent publications on MAC have emphasized a stratified pattern to MAC (Figure 139.3), with the upper part of the neoplasm having tumor islands[50] and cornifying cysts.[60] The midzone has basaloid strands rather than islands[50] or solid nests, strands, and

columns of cells.[60] The deep portion of the tumors have "even smaller nests and strands of cells"[50] or "duct-like structures composed of two layers of small cuboidal cells (empty or filled with eosinophilic material)."[60]

Immunohistochemical studies of MAC have given conflicting results,[61] and the immunohistochemical profile is not specific.[50,61] A key tumor to differentiate from MAC is desmoplastic trichoepithelioma (DTE).[1,50,60] Tse and colleagues compared the expression of cytokeratin 19 (CK19) in MAC and DTE biopsies.[50] Of 20 MACs, 14 (70%) expressed CK19: 6 tumors had CK19 expression by 51% to 100% of tumor cells, 3 had CK19 expression in 26% to 50% of cells, and 5 had CK19 expressed by 6% to 25% of tumor cells.[50] In contrast, only 4 of 18 (22%) DTEs expressed CK19: 2 had CK19 expressed by 26% to 50% of cells, and 2 tumors had CK19 expression by 6% to 25% of the cells.[50] Tse et al concluded that "a tumor that exhibits CK19 expression by >51% of tumor cells is "probably a MAC despite the overlapping immunoprofile."[50] Evangelista and North compared CK20 and androgen receptor (AR) expression in 15 DTEs and 6 MACs.[62] All 15 DTEs were positive for CK20 and negative for AR expression, while all 6 MACs were negative for CK20 and 5/6 were negative for AR expression.[62] In cases with an equivocal immunoprofile or when immunostains are not performed, the presence of subcutaneous involvement,[1,50] perineural invasion,[1,50] and ductal differentiation [50] are usually adequate to distinguish MAC from DTE.[63]

(Print pagebreak 932)

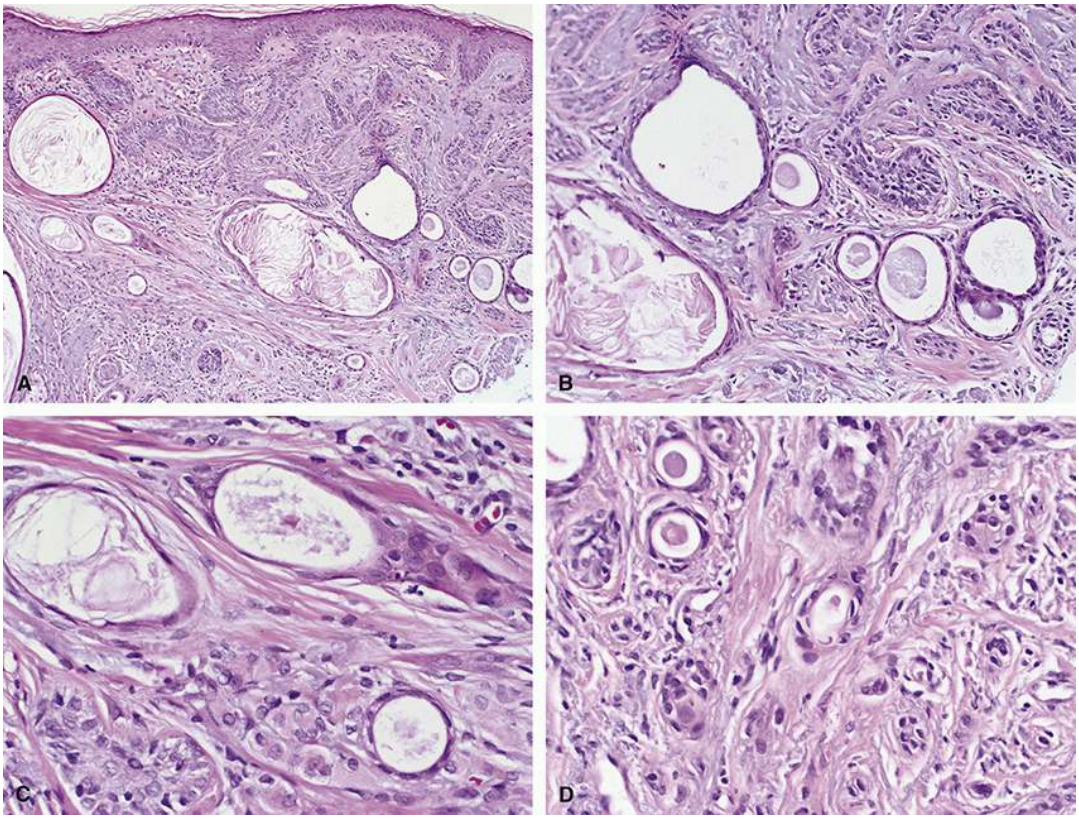

FIGURE 139.2 A man in his early 60s developed a MAC in his left lower eyelid margin. A, Cords and nests of cytologically uniform squamous cells and horn cysts within a desmoplastic stroma form the tumor. The superficial tumor islands have palisaded tumor peripherally. B, A horn cyst filled with keratin is at the bottom left. Other tumor nests are solid or have ductal differentiation with empty lumens or intraluminal amphophilic to lightly eosinophilic amorphous material. C, A small horn cyst is on the left. The tumor nest at the top right has ductal differentiation and a tail of tumor cells. The collagenous tumor stroma is partially hyalinized (top left corner). D, The deep aspect of the tumor is composed of small tumor nests, with lumens indicating ductal differentiation. Two layers of cells line the ducts.

A negative immunostain using Ber-EP4 antibodies to epithelial cell adhesion molecule favors a diagnosis of MAC vs sclerosing/morpheic basal cell carcinoma (BCC).[60,64] Krahl and Sellheyer reported no expression of Ber-EP4 in 13 MACs,[63] while 28/28 infiltrating BCCs expressed Ber-EP4.[63] The infiltrating BCCs had Ber-EP4 expression by >80% of tumor cells in 23/28 (82%) tumors.[63] Hoang et al noted 10/10 infiltrative BCCs had Ber-EP4 expressed by >50% of tumor cells, while 8/13 MACs were negative for Ber-EP4 expression.[65] Three MACs had Ber-EP4 expressed by >50% of tumor cells, and two tumors had Ber-EP4 expression by 10% to 49% of tumor cells.[65]

(Print pagebreak 933)

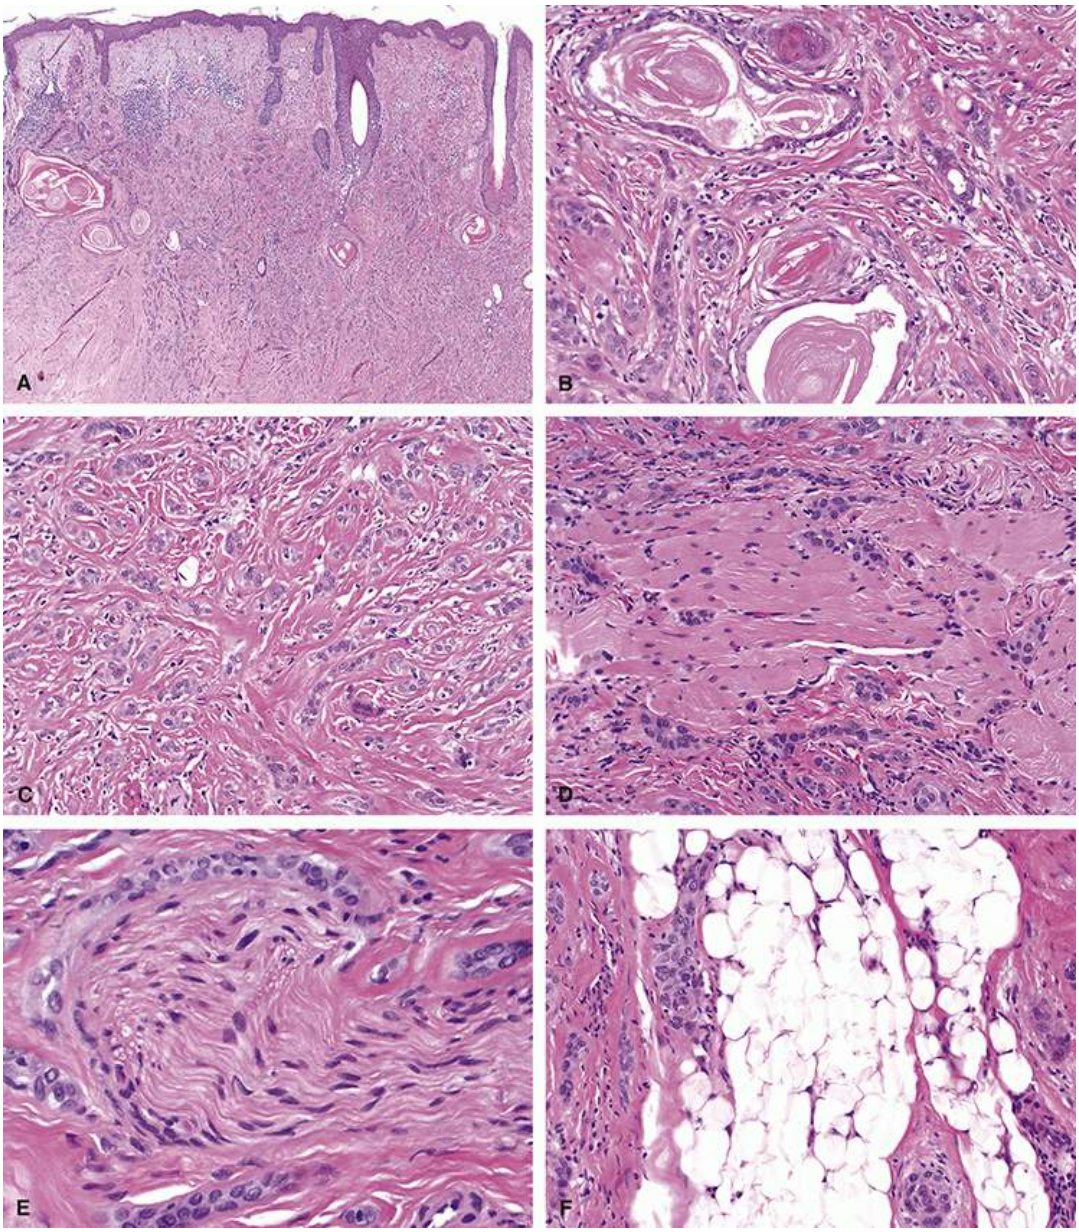

FIGURE 139.3 This MAC arose in the left eyebrow of a man in his early 50s. A, This tumor has a stratified appearance with tumor islands, cornifying cysts, and tumor strands in a sclerotic dermis. The midzone has mostly strands of tumor cells, while the deeper tumor (not seen in this photomicrograph) was smaller nests and strands of cells, often with two layers of small cuboidal cells. B, This tumor area in the superficial dermis shows the characteristic cornifying cysts along with small tumor islands, strands, and a small duct-like structure. C, The middle and deeper dermis had two-cell thick cords of tumor cells embedded in densely sclerotic, hyalinized stroma. D, Tumor widely infiltrates the frontalis muscle. E, Small tumor nests and cords are in sclerotic stroma around a nerve and invade the perineurium. F, Tumor within the subcutaneous adipose tissue forms nodules surrounded by dense sclerotic stroma.

CHAPTER 140

Mucoepidermoid Carcinoma

Key Points

- Mucoepidermoid carcinoma (MEC) is a highly malignant epithelial neoplasm comprising mucus-secreting, proliferating squamous, and nondescript intermediate epidermoid cells
- Although the pathophysiology is unclear, a novel translocation fusion oncogene, MECT1-MAML2, is present in 34% to 81% of MECs of the salivary glands, but it has not been identified in eyelid or lacrimal sac MECs
- In the ocular adnexa, about 80% of cases involve the conjunctiva, followed by the lacrimal sac (17%), and the eyelid skin (3%)
- It appears as a red, pink, yellow, brownish, or leukoplakic nodular or pedunculated conjunctival mass
- When the lacrimal sac is involved, symptoms may include epiphora, associated with dacryocystitis, or a palpable medial canthal mass
- The recommended treatment is surgical excision with wide margins; with orbital extension, enucleation or even orbital exenteration may be indicated
- MEC tends to be aggressive locally and regionally and recurrence rates after surgical excision range from 70% to 100%

Mucoepidermoid carcinoma (MEC) is a highly malignant epithelial neoplasm comprising mucus-secreting, proliferating squamous, and nondescript intermediate epidermoid cells. The term “mucoepidermoid” tumor was originally introduced by Stewart et al in 1945,[1] for tumors having two principal histologic elements, mucus-secreting cells and epidermoid cells. Mucoepidermoid tumors primarily occur in the major salivary glands.[1,2,3] They have also been reported in the minor salivary glands,[4,5] in the upper respiratory tract (larynx, trachea, or bronchi),[4,5,6,7,8] and in the nasal mucosa,[9] liver,[10] anus,[9] maxilla,[11] mandible,[12] uterine cervices,[9] and penis.[13] These tumors rarely arise from the skin.[14,15,16] In the periocular region, MEC primarily involves the conjunctiva,[17,18,19,20,21,22,23,24] lacrimal sac,[25,26] and lacrimal gland.[27,28] It very rarely arises in the eyelid skin.[20,29,30,31,32,33,34]

Etiology and Pathogenesis

There have been very few studies on the genetic changes associated with MEC. A novel translocation fusion oncogene, MECT1-MAML2, between chromosomes 11 and 19 was described in 2003.[35,36,37] This gene product is present in 34% to 81% of MECs of the salivary glands.[38] It is related to tumorigenesis, and knockdown of the protein product inhibits tumor growth.[39] However, MAML2 rearrangement has not been identified in the eyelid or lacrimal sac MECs.

Several studies examined epidermal growth factor receptor (EGFR) signaling in the etiology of MEC and suggested that this pathway might play a role in its pathogenesis. Also, mutations in p53 have been identified in MEC of the salivary gland.[37,40] There is a correlation between *p53* expression and the proliferation marker Ki-67, suggesting that mutations in *p53* might represent a genetic switch associated with the transformation of a low-grade tumor to a high-grade one.[41]

Clinical Presentation

In the ocular adnexa, about 80% of cases involve the conjunctiva, followed by the lacrimal sac (17%), and the eyelid (3%). Only 11 cases of eyelid MEC have been reported in the literature.[29,30,31,32,34,42,43,44,45,46] Males are affected more commonly than females (76%-80%) for periocular MEC,[47] but for eyelid lesions, there is no gender predilection.[42] About 80% of eyelid lesions involve the lower eyelid.[42] The duration of symptoms before presentation is relatively short, usually 2 to 6 months, but occasionally progression can be indolent over many years.[30,42]

In most cases, the lesion involves the bulbar conjunctiva near the corneal limbus (70%), with rare occurrences in the conjunctival fornix or eyelid skin (Figure 140.1).[24] Aggressive lesions may invade the orbit, seen in about 20% of cases, and rarely the tumor can invade an adjacent paranasal sinus.[29,47,48,49] The most common periocular presentation is a painless, rapidly progressive conjunctival or eyelid cutaneous mass.[42] Lesions may appear as a red, pink, yellow, brownish, or leukoplakic nodular or pedunculated mass that may be irritated or occasionally ulcerated. When the lacrimal sac is involved, symptoms may include epiphora associated with dacryocystitis and a palpable medial canthal mass. Regional lymph node involvement has been described, but distant metastasis is very unusual.[18,43]

Differential Diagnosis

The differential diagnosis of MEC includes conjunctivitis and conjunctival squamous cell carcinoma (SCC), both of which need to be excluded by critical analysis of representative tissue sections.

(Print pagebreak 937)

C, Extensive MEC of the lateral canthal conjunctiva and eyelid margin. D, Nodular MEC on the upper eyelid margin. (A and B, Courtesy of Dr. Charles Soparkar; C, Courtesy of Dr. Seymour Brownstein; D, Courtesy of Dr. Rachel Sobel.)

Treatment

The recommended treatment for conjunctival MEC is surgical excision with wide margins. For cases with only superficial invasion, adjuvant cryotherapy, topical interferon, or mitomycin have been recommended, with follow-up biopsies at regular intervals to confirm the adequacy of treatment.[50] For more invasive lesions, a superficial or deep sclerectomy is performed. In some cases with orbital extension, radical surgery, such as enucleation or even orbital exenteration, may be indicated.[51]

Fractionated epibulbar I^{125} plaque brachytherapy has been used for some MECs with good results.[52,53] However, other studies using laser therapy, brachytherapy, and external beam radiotherapy have not been promising.[18,19,54]

For eyelid lesions, more conservative therapies such as local excision and radiotherapy have not proven sufficient, with high recurrence rates. The longest reported follow-ups without recurrence were 3 and 4 years following Mohs microsurgical excision.[42]

Prognosis

Compared to basal cell carcinoma and SCC, MEC has a higher malignant potential and tends to be more aggressive, both locally and regionally,[47,55] and has even been reported to invade the globe.[22] Recurrence rates after surgical excision range from 40% to 100%, so that prolonged follow-up after surgery is necessary.[29,49,54,55,56] From the very limited eyelid cases reported, Mohs surgery may provide the best long-term results.

Histopathology

The existence of primary MEC of the skin as a distinct entity is controversial.[57,58] Some authors distinguish cutaneous MEC from adenosquamous carcinoma,[57,59,60] while others use the terms synonymously.[16] In salivary glands, "MEC is a malignant epithelial tumor composed of varying proportions of mucous, epidermoid, intermediate, columnar, clear, and occasionally, oncocytic cells."[61] Stewart, *(Print pagebreak 938)* Foote, and Becker defined epidermoid cells as including cells resembling those in basal cell carcinoma and those "resembling squamous cells without intercellular bridges and keratohyaline granules."[1] They noted, "another frequent cellular component of the malignant tumors was the intermediate cell which, it must be admitted, is difficult to distinguish verbally from the basal cells other than by saying that they are slightly larger, have somewhat more vesicular nuclei and more abundant cytoplasm."[1] Intermediate cells predominate in most salivary gland tumors,[61] and tumors featuring "appreciable numbers of every cell type described were rather exceptional even when many blocks of tissue were sectioned."[1] The ambiguity in defining intermediate cells and the wide variability in proportions of intermediate, epidermoid, and mucous cells has undoubtedly been a significant contributor to the difficulty in classifying tumors as MEC in nonsalivary gland sites. Salivary gland adenosquamous carcinoma lacks intermediate cells and is defined as a "malignant neoplasm that simultaneously arises from mucosal surface epithelium and salivary gland ductal epithelium as squamous cell carcinoma and adenocarcinoma, respectively."[61]

Riedlinger and colleagues[57] applied the histological features of the salivary gland neoplasms to differentiate primary cutaneous MEC from adenosquamous carcinoma, as follows:

Histological Feature	Mucoepidermoid Carcinoma	Adenosquamous Carcinoma
Intraepidermal carcinoma	-	+
Well-differentiated adenocarcinoma	-	+
Dermal-based solid/cystic tumor	+	-
Papillary features	+	-
Mucigenic cells	+	-
Peritumoral fibrosis	+	-
High-grade nuclear features	-	±

They used these criteria to conclude that MEC of the skin, while extremely rare, is distinct from adenosquamous carcinoma.[57] Kazakov et al, however, disagree that MEC exists as a primary skin neoplasm.[58] They opine that "many, if not all, of these so-called primary cutaneous MEC, including purported 'bona fide' cases," are hidradenocarcinoma or nodular hidradenoma with mucinous differentiation, SCC with mucinous differentiation, or MEC of a salivary gland with secondary skin involvement.[58] Since the eyelids contain accessory lacrimal glands (glands of Wolfring), they are a potential source from which MEC could arise. Other purported cases of eyelid MEC may represent endocrine mucin-producing sweat gland carcinoma unless endocrine markers, such as synaptophysin,[62,63,64] chromogranin,[62,63,64] CD56,[62,64] or CD57,[63] and negative staining for Wilms tumor 1 (WT1)[65] protein have excluded this possibility. Excluding endocrine mucin-producing sweat gland carcinoma is particularly important since these tumors have a predilection for the eyelids.[66]

The terminology for conjunctival MECs is also contentious.[67] Historically, tumors arising from the conjunctiva that exhibit both epidermoid and mucus-secreting cells have been classified as MEC since the seminal publication of Rao and Font in 1985.[17] Rao and Font reported five conjunctival tumors, three located at the corneoscleral limbus, one in the superior bulbar conjunctiva, and one in the lower cul-de-sac.[17] All tumors originated in the epithelium and were a mixture of epidermoid cells and mucus-secreting cells in different proportions, with four being predominantly epidermoid.[17] Rao and Font did not mention intermediate cells as a component of any of the tumors.[17] Since then, conjunctival tumors with a mixture of epidermoid and mucus-secreting cells have

been classified as MEC,[68,69] until 2018, when the World Health Organization (WHO) reclassified such tumors as adenosquamous carcinoma due to lack of intermediate cells and the presence of in situ neoplasia in some tumors.[70] Most recently, Mudhar et al[67] examined 14 "MECs" of the conjunctiva (9 involved the tarsal and forniceal conjunctiva) and classified the 11 tumors with an invasive component into four morphological groups:

1. Group 1: One tumor (9%) had in situ carcinoma with mucinous differentiation and *invasive SCC*.

2. Group 2: Six tumors (55%) had *invasive SCC with mucinous differentiation* (Figure 140.2). Three tumors had nonkeratinizing SCC, two had nonkeratinizing SCC with acantholysis, and one had keratinizing SCC with acantholysis. Mucinous differentiation was manifest as scattered cells with intracellular mucin with or without extracellular mucin. These tumors lacked true glandular differentiation.

3. Group 3: Three tumors (27%) were *adenosquamous carcinoma* with invasive SCC and invasive adenocarcinoma (Figure 140.3). There was invasive nonkeratinizing SCC in two cases and invasive keratinizing SCC in one case. The adenocarcinomatous component varied from well-formed glands composing at least 50% of the tumor to focal glandular differentiation manifest as confluent groups of goblet cells. The invasive SCC and adenocarcinoma "tended to be side-by-side."[67]

4. Group 4: One tumor (9%) was pure *adenocarcinoma*. This tumor was in the caruncle and was a well-differentiated adenocarcinoma with prominent goblet cells and luminal mucin.

None of the 14 tumors had intermediate cells, and none were diagnosed as MEC using criteria applied to salivary gland tumors. Based on their findings, the authors proposed that the WHO classification of conjunctival tumors be revised to include SCC with mucinous differentiation and adenosquamous carcinoma.[67] We concur with this *(Print pagebreak 939) (Print pagebreak 940)* proposal and recommend that pathology reports include a diagnostic comment noting that these tumors were previously classified as MEC. This diagnostic comment will allow the treating ophthalmologists and oncologists to place the tumor in a historical context for treatment and prognostic guidance.

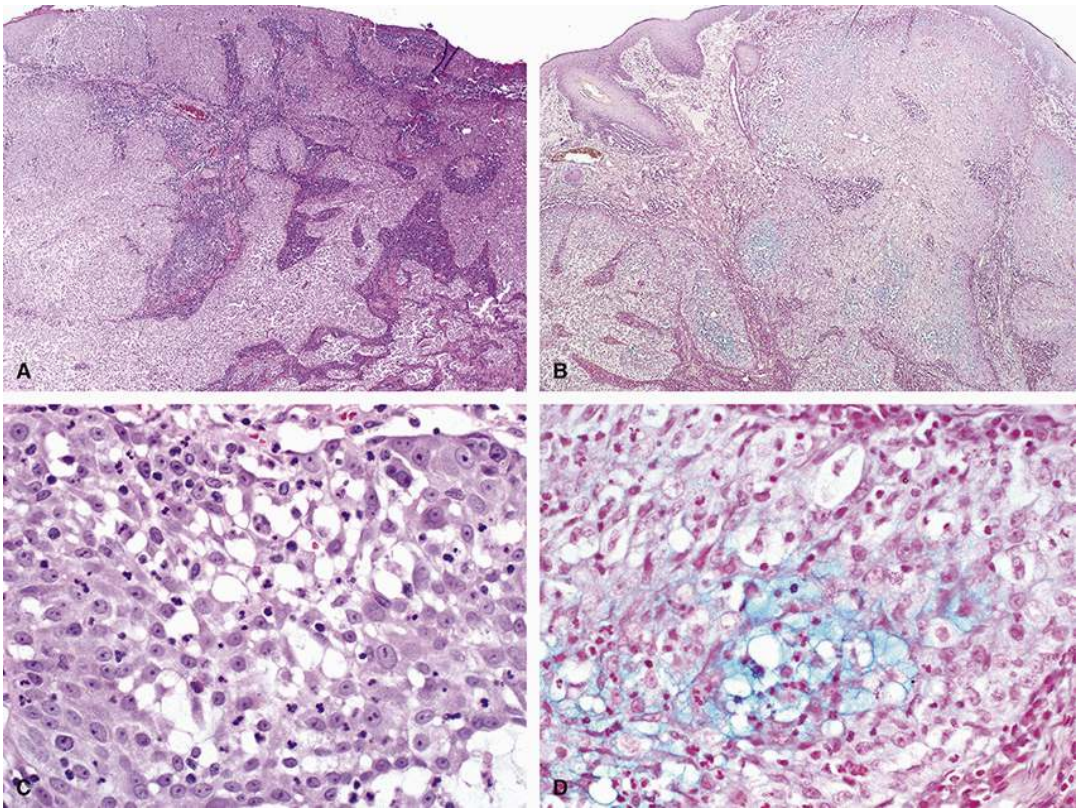

FIGURE 140.2 This tumor arose from the tarsal conjunctiva of the left upper eyelid and invaded the orbit. It was originally classified as mucoepidermoid carcinoma but is better classified as squamous cell carcinoma with mucinous differentiation using the terminology proposed by Mudhar et al.[67] A, The tumor features neoplastic conjunctival epithelium and extensive substantia propria invasion. B, Alcian blue stain highlights areas of mucinous differentiation. C, Most of the tumor is nonkeratinizing squamous cell carcinoma with areas of acantholysis. D, Alcian blue stain shows the intracellular location of the mucin.

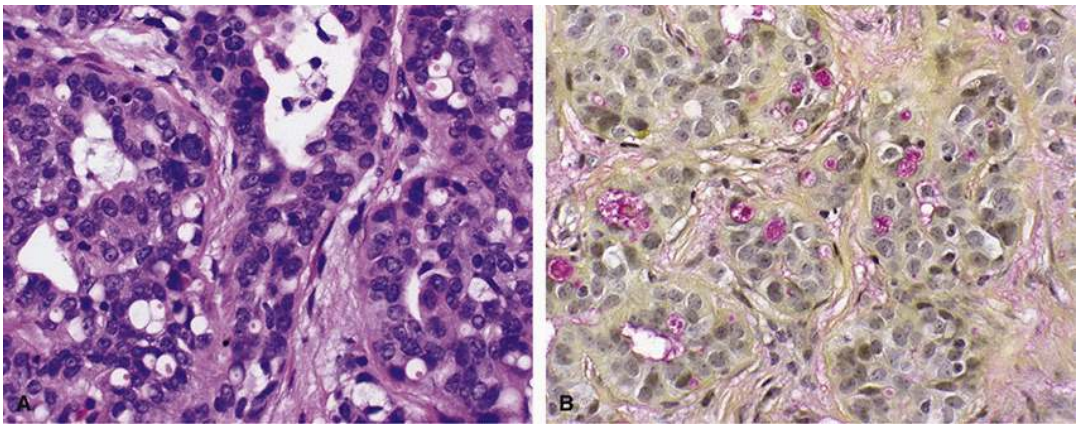

FIGURE 140.3 This "mucoepidermoid carcinoma" arose in the limbal conjunctiva of the left eye. It is better classified as an adenosquamous carcinoma using the terminology proposed by Mudhar et al.[67] A, The tumor has areas of glandular differentiation with intracellular and intraluminal mucin. B, This area stained with mucicarmine shows nests of nonkeratinizing squamous epithelium, cells with intracellular mucin, and glands with intraluminal mucin.

(Print pagebreak 942)

CHAPTER 141

Plasmacytoma

Key Points

- Plasma cell tumors are derived from a terminally differentiated cell in the B-lymphocyte lineage
- They originate in the bone marrow during the maturation process from B-blasts to plasmablasts
- Clinically, they present as multiple myeloma, as a solitary bone and extramedullary plasmacytoma without multiple myeloma, or as plasma cell leukemia
- Eyelid plasmacytoma is a rare extramedullary form occurring in the conjunctiva, orbit, or in the eye
- It is hypothesized that primary extramedullary plasmacytoma may represent a special type of marginal zone cell lymphoma with extensive plasmacytic differentiation initiated by inflammatory infiltrate
- Eyelid lesions generally appear as a slow-growing, well-circumscribed, painless, firm, mobile, discrete, violaceous, or reddish-blue nodule that may be associated with eyelid swelling and ecchymosis
- Management must begin with systemic evaluation to rule out multiple myeloma or other lymphoproliferative disorders
- Radiation therapy is considered the treatment of choice with a response rate as high as 93%
- Surgical excision is an alternative option and chemotherapy is used for cases that progress to multiple myeloma
- For eyelid lesions the prognosis is very good, but progression to multiple myeloma is reported in about 14% of cases

Plasma cell tumors are neoplasms derived from a terminally differentiated cell in the B-lymphocyte lineage, which is generally believed to only undergo a limited number of cell divisions before it exits the cell cycle.[1] They originate in the bone marrow during the maturation process from B-blasts to plasmablasts that dedifferentiate and transform into malignant plasmablasts.[2,3] These tumors usually develop in the bone marrow and less commonly in extramedullary sites.

Plasma cell neoplasms can present clinically in several different forms including multiple myeloma, solitary bone and extramedullary plasmacytoma without multiple myeloma, and plasma cell leukemia.[4] Multiple myeloma is usually located in the bone marrow,[5] but neoplastic cells can invade or migrate to soft tissues including the skin.[6,7] Plasmacytomas are immunoproliferative, monoclonal plasma cell tumors that are classified as a non-Hodgkin lymphoma.[8] While most are associated with multiple myeloma, others are solitary lesions not associated with any systemic disease. Solitary plasmacytomas are rare and are further subclassified as either solitary plasmacytoma of bone (SPB) or as extramedullary plasmacytoma of soft tissue (EMP).

In a large study of 1354 patients with plasma cell neoplasms, 94% had multiple myeloma, 4% had SPB, and 2% had EMP.[9] In a recent Swedish study,[10] solitary bone plasmacytoma in vertebrae, femurs, pelvis, and ribs represented 70% of all solitary plasmacytomas.

Extramedullary plasmacytomas are lesions that are not associated with a bony focus or any evidence of multiple myeloma.[8,11] They are seen most often in the upper respiratory passages (80%) and less frequently in the gastrointestinal and genitourinary tracts, skin, lung, kidney, bladder, breast, thyroid, lymph nodes, and other locations.[6,8,12,13,14,15,16,17,18,19] Patients with a solitary plasmacytoma are usually aged from 50 to 80 years, but rarely this tumor can be seen in children.[20] Occurrence on the eyelid is uncommon,[2,6,21,22,23,24,25,26] and very rare cases have been described in the conjunctiva,[27,28,29,30] orbit,[20,24,31,32,33] and even in the eye.[6,34]

Solitary plasmacytoma has a predilection to progress to multiple myeloma. This is especially true for SPB with an overall progression rate of 30% to 40%. However, patients with SPB plus evidence of occult clonal bone marrow plasma cell involvement by flow cytometry in areas distant from the plasmacytoma have a greater progression rate of 60% to 70%.[35,36] In contrast, the

progression of EMP to multiple myeloma is less, with most reported rates ranging between 9 and 14%,[8,37,38,39,40] although Liebross et al[9] reported a rate of 32%. Risk factors that increase the likelihood of progression include presence of the lesion in bone, larger tumors greater than 5 cm in diameter, lymph node involvement, and older age of patients.[41]

Etiology and Pathogenesis

In 1976, Wiltshaw[40] proposed that EMP is distinct from SPB and multiple myeloma, based on several distinct differences. These included a predilection for EMP to arise from plasma cells located in mucosal surfaces, particularly the upper pulmonary passages, as opposed to SPB and multiple myeloma which originate from bone marrow plasma cells. Also, while most cases of SPB will eventually progress to multiple myeloma of bone, when EMP progresses, it more often spreads to other soft tissue sites. Also, the overall prognosis of EMP is significantly better with a longer median survival period.[42] The definition and classification adopted in a recent WHO update also support a divergence of EMP from SPB based on their biologic differences.[43]

It has been hypothesized that primary EMP, whether occurring in mucosal sites or lymph nodes, may represent a *(Print pagebreak 943)* special type of marginal zone cell lymphoma with extensive plasmacytic differentiation.[44] Like EMP, marginal zone B cell lymphomas (MZL) are found in nodal (monocytoid B cell lymphoma) and extranodal (mucosa-associated lymphoid tissue lymphoma) sites,[44] and plasma cell differentiation is a common feature seen in MZL.[44,45,46,47,48,49] It is also interesting to note that inflammatory cells can be seen on histopathological examination of EMP,[20,21,23] and it has been postulated that an inflammatory infiltrate could initiate a monoclonal plasma cell proliferation.[50]

Clinical Characteristics

The diagnosis of EMP is based on the morphologic appearance as well as the immunophenotypical finding of monoclonal plasma cells without other systemic plasma cell or lymphocytic collections, including in the bone marrow.[8] Males are affected more often than females in a ratio of about 3:1,[24] and the age at presentation is usually in the sixth and seventh decades of life.

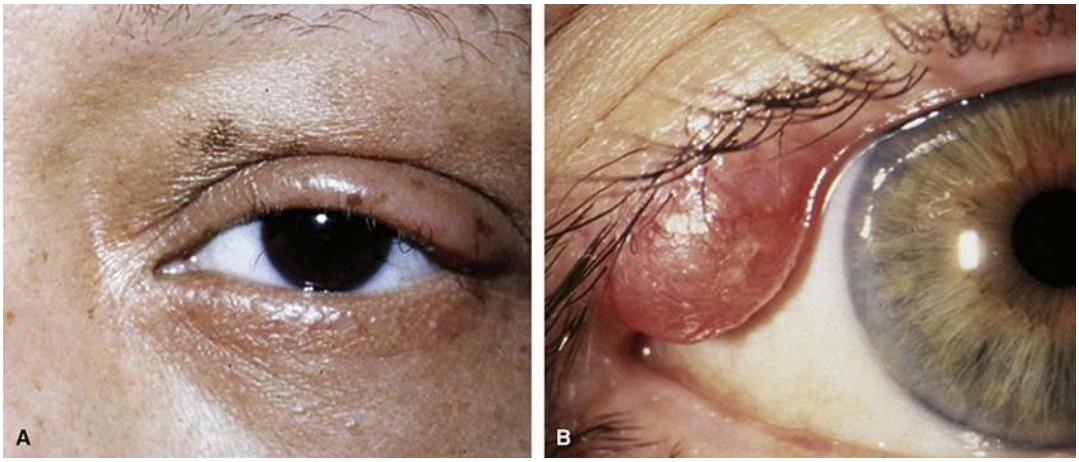

FIGURE 141.1 Plasmacytoma of the eyelids. A, Circumscribed nodular mass on the medial eyelid margin. B, Diffuse eyelid swelling from lateral eyelid plasmacytoma. (A, Courtesy of Dr. Henry D. Perry.)

FIGURE 141.2 Large plasmacytoma of the posterior eyelid lamella. (Courtesy of Dr. Jurij Bilyk.)

Eyelid lesions generally appear as a slow-growing, well-circumscribed, painless, firm to hard, mobile, discrete nodule that may be violaceous or reddish-blue in color (Figure 141.1A).[2,6,21,22,23,25,26] Occasionally, more diffuse eyelid swelling may be seen, and ecchymosis can be an initial finding (Figure 141.1B). The lesion may infiltrate into deeper eyelid structures such as the tarsal plate and posterior lamella (Figure 141.2). Rarely ulceration may occur.[22] EMP involving the surface of the eye can occur on the palpebral or bulbar conjunctiva and present as pink to reddish-tan, smooth, mobile vascularized nontender nodules ranging from 2 mm to 2 cm in diameter (Figure 141.3).

FIGURE 141.3 Recurrent plasmacytoma involving the lower eyelid conjunctiva. (Courtesy of Dr. Philip Custer.)

(Print pagebreak 944)

Extension into the orbit can be associated with proptosis, diplopia, orbital cellulitis, hemorrhage, decreased vision, and increased intraocular pressure.[6,51] Lesions that involve the paranasal sinuses can present as sinusitis.[52]

Differential Diagnosis

Eyelid EMP is rarely diagnosed clinically and is most often misdiagnosed as a chalazion or a malignant tumor such as sebaceous carcinoma. Conjunctival lesions have been misidentified clinically as vascular or inflammatory lesions or conjunctival amyloid.

Treatment

Management of solitary extramedullary plasmacytoma must begin with a systemic evaluation, including a complete blood cell count with differential, serum and urine protein electrophoresis, bone marrow biopsy, CT skeletal survey, and MRI of the chest and abdomen to rule out multiple myeloma or other lymphoproliferative disorders.

Plasma cell tumors are highly sensitive to radiation,[9,53,54] so that radiation therapy is considered the treatment of choice for both SPB and EMP. The response rate has been reported as high as 93%.[55,56,57] Ozsahin et al. retrospectively assessed the outcome in 266 patients with SPB and EMP treated with radiotherapy, radiotherapy combined with chemotherapy, or surgery alone.[58] The local response rate to radiotherapy was greater than 80%, and the 5-year overall survival, disease-free survival, and local control rates were 74%, 50%, and 86%, respectively. Radiotherapy was associated with a lower relapse rate of 12%, compared to 60% for patients who did not receive radiotherapy. Based on the available clinical data, the recommended treatment for most patients with solitary plasmacytomas is localized, fractionated radiotherapy given at a dose of 40 to 50 Gy over approximately 4 weeks.[59] Despite the widespread use of radiotherapy for solitary plasmacytomas, few cases of eyelid EMP have been treated with this modality.[23,28,60]

Surgery is an alternative option.[55] Alexiou et al.[8] reported a rate of progression to multiple myeloma of 6.3% in patients with EMP treated with surgery compared with 17.5% of those treated with radiation. For patients treated with both surgery and radiotherapy, the rate was 13.5%. For large tumors, surgery can be followed by radiotherapy.[4,20,25] For eyelid and conjunctival EMP, most cases have been treated with surgery alone,[2,21,23,25,26,27] which avoids the risk of ocular exposure to radiotherapy and its potential complications. Of eight reported eyelid cases managed with surgery alone, none experienced recurrence in follow-up intervals of 3 months to 5 years.

Chemotherapy is used for those patients who progress to multiple myeloma and those refractory to other therapies.[59] However, its role after radiation therapy remains controversial. Holland et al[57] reported no benefit from adjuvant chemotherapy with respect to the overall incidence of progression to multiple myeloma (36%), although the transition was delayed from 29 to 59 months. Tokita et al[61] reported a case of extraosseous plasmacytoma with multiple metastases treated with chemotherapy that failed to control the disease.

Autologous stem cell transplantation has been used for patients having multiple myeloma with bone and soft tissue plasmacytomas.[62] Multiple myeloma patients with soft tissue plasmacytoma showed worse survival outcomes compared to those with skeletal plasmacytoma. The median progression-free survival was 12 months for EMP versus 28 months for SPB.[63]

Prognosis

Multiple myeloma with extramedullary spread is usually associated with a poor prognosis. Extramedullary plasmacytoma generally has a better prognosis, but solitary bone plasmacytoma can be associated with a rate of progression to multiple myeloma ranging up to 53%.[57,58] In contrast, the progression of EMP to multiple myeloma is generally reported at 36%.[57]

For eyelid EMP, the prognosis is very good, with most cases managed surgically resulting in a cure with no recurrence. However, the number of reported eyelid cases is very limited so that these data may not be reliable. Treatment of EMP in other regions carries a small but real risk of both recurrence and progression to systemic disease. In a literature review of 155 cases of non-upper aerodigestive EMP, 55.6% were treated with surgery, 19.8% with surgery plus radiotherapy, and 11.1% with radiotherapy alone,

and patients were followed for up to 140 months.[8] The authors reported that 64.7% had no recurrence after treatment, 21.2% had a recurrence, and 14.1% progressed to multiple myeloma.

Histopathology

Plasmacytomas,[43] including those in the skin,[64,65,66] are composed of normal-appearing and/or atypical plasma cells. Normal plasma cells are oval with an eccentrically placed round nucleus and abundant amphophilic or basophilic cytoplasm with a perinuclear pale-staining area corresponding to the Golgi apparatus (Figure 141.4).[67,68] Nuclear chromatin is clumped and often arranged in a distinctive radial ("cartwheel/spoke wheel," "clock face") pattern.[68] Atypical plasma cells have various morphological changes, including reduced cytoplasm (in lymphoplasmacytoid myeloma); altered nuclear appearance with diffuse chromatin, a prominent nucleolus, irregular nuclear membrane contour, and/or an increased nuclear size; or they may resemble plasmablasts with an enlarged nucleus, very prominent centrally located nucleolus, and a moderate rim of basophilic cytoplasm.[68] Atypical plasma cells may be binucleated or multinucleated with nuclei differing in size, having only one nucleolus, and having finely dispersed chromatin.[68] The plasma cells may have inclusions *(Print pagebreak 945)* such as Dutcher bodies (intranuclear vacuolation due to invagination of dilated Golgi cisternae), Russell bodies (globular eosinophilic immunoglobulin inclusions), or rarely rhomboidal crystalline immunoglobulin inclusions.[68] Amyloid may accompany cutaneous plasmacytomas (Figure 141.5A).[69] The neoplastic plasma cells express CD138 (Figures 141.5C and 141.6B)[70] but usually lack or have a weak expression of CD45, an antigen ordinarily present on the cell surface of plasma cells.[43] The neoplastic plasma cells express either kappa or lambda light chain, confirming their clonal origin. The expression of immunoglobulin light chains is evaluated in paraffin tissue sections using immunohistochemistry (Figure 141.5D) or chromogenic in situ hybridization (CISH) with probes against kappa and lambda light chain mRNA (Figure 141.6C). In our experience, CISH is preferred over immunohistochemistry due to less background staining and is beneficial in distinguishing cutaneous plasmacytomas from polytypic plasma cell infiltrates.[43,66]

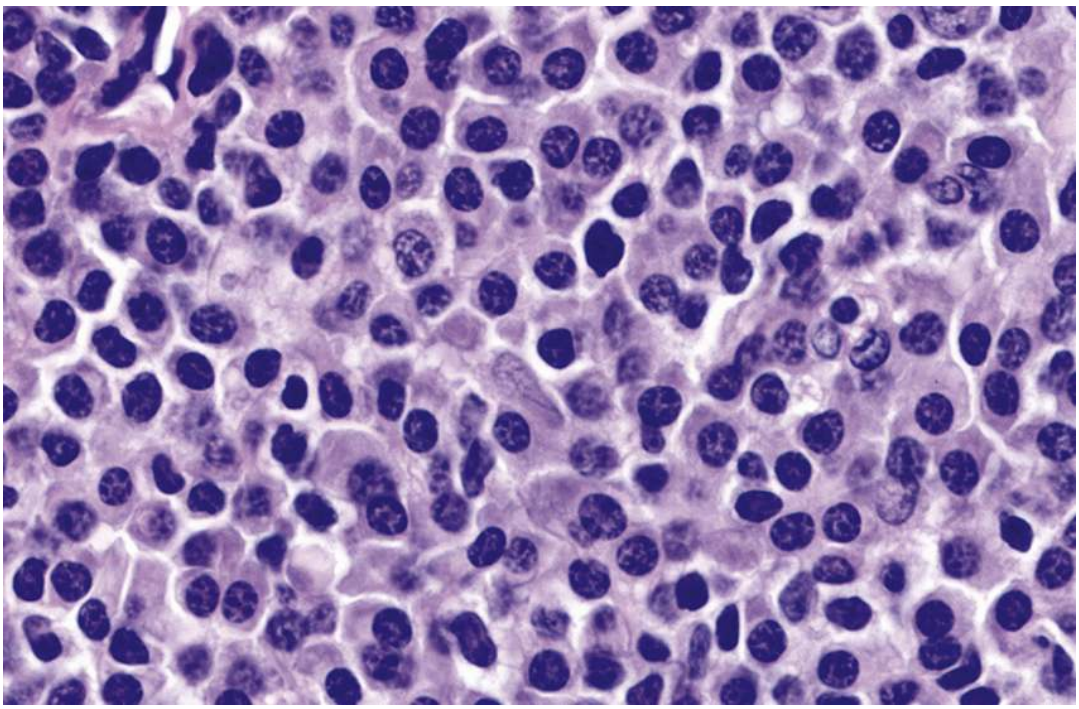

FIGURE 141.4 A sheet of normal-appearing plasma cells forms this plasmacytoma. The cells are oval with an eccentrically placed round to slightly oval nucleus and abundant amphophilic cytoplasm. The nuclear chromatin is clumped, and some cells have chromatin arranged around the periphery of the nucleus in a radial pattern.

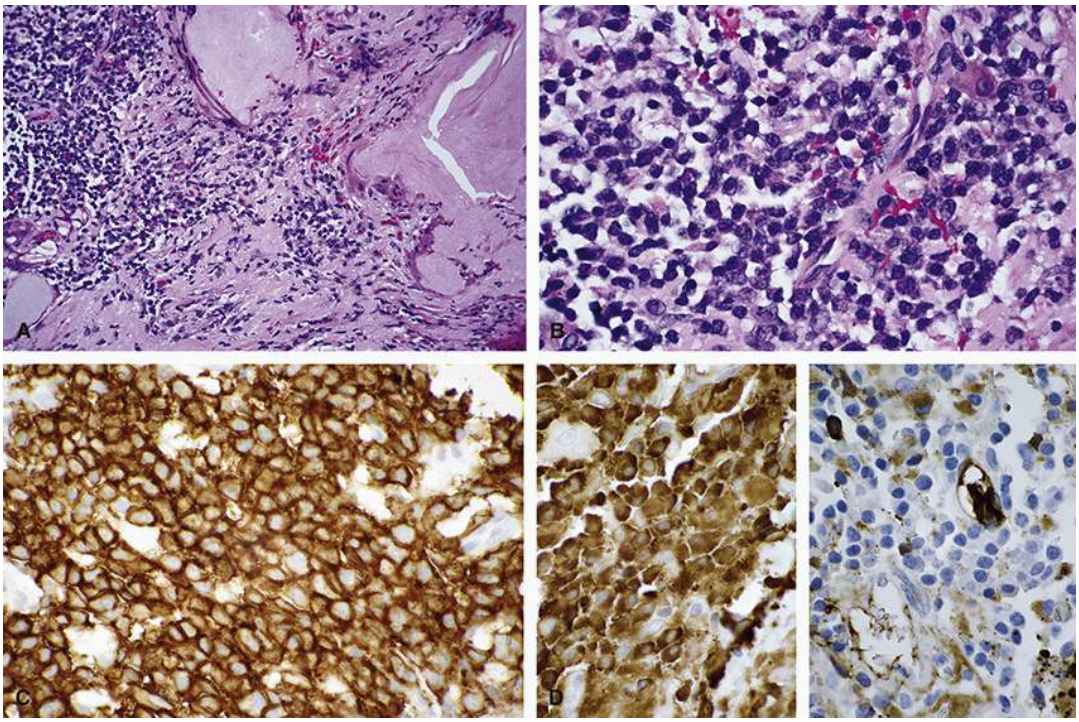

FIGURE 141.5 A woman in her middle 30s developed a nodule in her lateral left upper eyelid. The tumor was located in the eyelid posterior to the orbicularis oculi, extended into the superolateral orbit, and involved the lacrimal gland palpebral lobe. The lesion was resected in its entirety and has not recurred after more than 10 years. A, The plasmacytoma features sheets of lymphoid cells and abundant pink amyloid. B, The plasma cells have a variable appearance. Some resemble normal plasma cells, but many have enlarged nuclei with irregular nuclear borders, diffuse chromatin, and decreased cytoplasm. C, The plasma cells uniformly express CD138 (syndecan-1). D, Immunohistochemical staining showed a vast majority of the plasma cells strongly expressed kappa light chains (left panel) while only rare cells expressed lambda light chains.

(Print pagebreak 946)

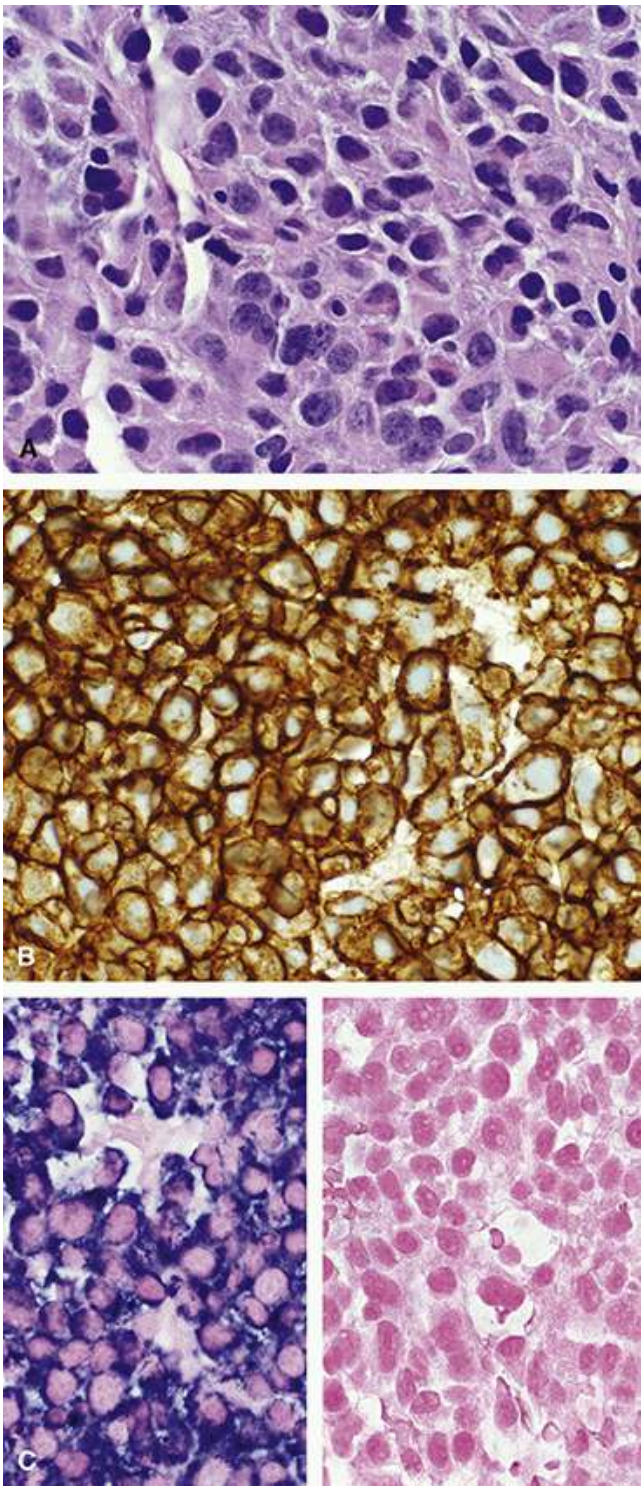

FIGURE 141.6 This octogenarian developed ptosis with a mass in the temporal fossa. A, The plasmacytoma is composed of sheets of cytologically atypical plasma cells with irregular nuclear contours, diffuse chromatin, diminished cytoplasm, and frequent mitoses. B, The tumor cells strongly and uniformly express CD138. C, Chromogenic in situ hybridization shows that 100% of the plasma cells are positive for lambda light chain mRNA (left panel), while none of the cells has kappa light chain mRNA (right panel).

CHAPTER 142

Primary Cutaneous Mucinous Carcinoma

Key Points

- Sweat gland tumors comprise a large variety of rare lesions that mostly include eccrine carcinomas and less commonly apocrine and mixed eccrine/apocrine tumors
- Primary cutaneous mucinous carcinoma was originally believed to be of eccrine gland origin, but more recent evidence suggests apocrine differentiation
- The role of ultraviolet radiation exposure in the pathogenesis remains unclear, but distribution on the head and neck and the greater occurrence in light-skinned individuals suggest that UV exposure may be a risk factor
- On the eyelids, lesions generally appear as slow-growing, nontender, soft to firm, skin-colored, blue, pink, or red nodular, papular or cystic lesions measuring 5 mm to 2 cm
- The recommended treatment is surgical excision with wide margins
- The roles of radiotherapy and chemotherapy are controversial and inconsistent
- Local recurrence is seen in 30% or more of cases, but lymphatic spread is uncommon and distant metastasis is rare

Sweat gland tumors were first described in 1859 by Lotzbeck (in Hanby et al)[1] and later recognized as a malignancy by Cornil in 1865.[2] They comprise a large variety of rare tumors that mostly include eccrine carcinomas and less commonly apocrine and mixed eccrine/apocrine tumors.[3,4,5,6] The classification of these lesions has been confusing and inconsistent in the literature. However, most schemes subdivide these into eccrine or apocrine subtypes.[7]

Mucinous carcinoma can involve a variety of sites including major and minor salivary glands, lacrimal gland, breast, and the gastrointestinal tract and have been described under a diverse group of names.[8] Primary cutaneous mucinous carcinoma (PCMC) involving the skin is one of the better known terms for these mucinous malignancies. It was first described as a scalp lesion by Lennox et al. in 1952[9] and later more completely defined by Mendoza and Helwig in 1971.[8] Most PCMC lesions present on the head and neck, but they can occur in various other sites, including the axilla, foot, and chest.[10] Males are affected more commonly than females, and most patients tend to be older, in the 7th decade of life.[11] These tumors are biologically indolent, but they are associated with a high local recurrence rate. Regional node involvement is uncommon, and distant metastases are very rare.[11,12,13]

Etiology and Pathogenesis

Primary cutaneous mucinous carcinoma was originally believed to be of eccrine gland origin.[8] However, more recent evidence suggests apocrine differentiation, although this remains somewhat controversial.[14,15,16,17,18] The role of ultraviolet radiation exposure in the pathogenesis of sweat gland carcinomas remains unclear, but the primary distribution on the head and neck and the greater occurrence in light-skinned individuals suggest that this may be a risk factor.[19]

Clinical Presentation

PCMC has a predilection for the head and neck with about 65% to 70% occurring in this region.[20] The most common sites are the scalp, face, eyelids, and neck. The eyelid is one of the more common sites of presentation, but still, only about 60 cases have been described.[11,14,21,22,23,24,25,26,27,28,29,30] On the eyelids, these tumors may present with a variety of clinical presentations but generally are slow-growing, nontender, soft to firm, nodular, papular, or cystic lesions measuring 5 mm to 2 cm (Figures 142.1 and 142.2), but some lesions may be 4 cm or more in size. They are usually single and unilateral but rarely may be multiple or even bilateral.[31,32] Lesions may be skin colored, blue, pink, or red with or without telangiectasias, and rarely may be ulcerated.[27,33] Although growth is usually slow, there have been several reports of rapid enlargement and more aggressive behavior.[8,34]

The upper and lower eyelids are involved equally at about 45% each, and in 10% of cases, the tumor involves the medial canthus. On other parts of the body, PCMC has a high male predominance of about 70% to 80%, but on the eyelids, the sexes seem to be more equivalent with a male predominance of about 56%. They occur primarily in patients from middle to old age with a mean age at presentation of 62 years, but rare cases have been described in children.[22]

Differential Diagnosis

The clinical differential diagnosis includes basal cell carcinoma, squamous cell carcinoma, melanoma, sebaceous carcinoma, cutaneous metastasis, papilloma, chalazion, keratoacanthoma, nevus, apocrine hidrocystoma, and epidermal inclusion cyst.

(Print pagebreak 949)

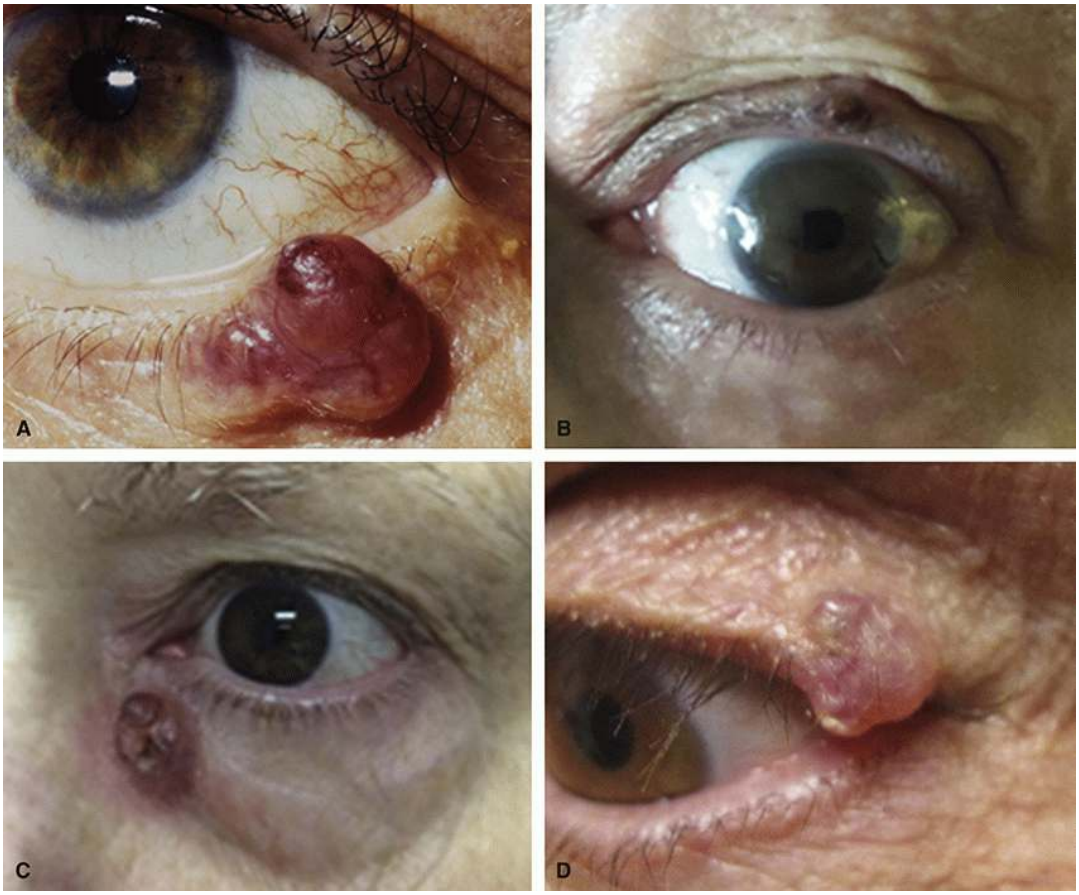

FIGURE 142.1 A, Nodular PCMC on the lateral lower eyelid. B, Small lightly pigmented eccrine carcinoma on the upper eyelid margin. C, Mulitinodular MCMC on the medial lower eyelid. D, Large nodular eccrine tumor on the medial upper eyelid. (B and C, Courtesy of Dr. Roman Shinder.)

Treatment

Although the recommended treatment of PCMC is surgical excision with wide margins of at least 1 to 2 cm,[23,35] such wide margins are usually not possible for eyelid lesions. However, a relatively narrow margin of only 5 mm has been reported with good results.[36] Incomplete excision is associated with a high recurrence rate of 30% to 40% and regional lymph node spread of 10%. Relatively few cases have been treated with Mohs micrographic surgery, but the recurrence rate is reported to be lower at 15% to 25% over 2 years.[37,38,39]

Some early publications of case series noted no benefit from radiotherapy or chemotherapy for PCMC,[40,41,42] and this has been repeated in most subsequent reports.[43,44,45] However, in a paper involving nine patients with a variety of adnexal skin carcinomas of the head and neck including PCMC treated with surgery plus adjuvant radiotherapy, 100% achieved local control with a 5-year progression-free survival of 89%.[46] Several other individual case reports also showed complete response to radiotherapy, either as primary therapy or adjunctive therapy following surgical excision.[47,48,49] Chemotherapy has been

studied in very few cases and has variably been reported to be ineffective[50] or to show some success.[51] There are no accepted guidelines for chemotherapy in this disease.

Prognosis

Following surgical excision, primary cutaneous mucinous carcinomas are associated with a high local recurrence rate of 30% or more.[11,27,34,52,53] However, lymphatic spread to regional *(Print pagebreak 950)* lymph nodes is uncommon with a rate of about 10%, and distant metastasis is rare at about 2%.[11] Tumor recurrence and metastasis are associated with poor outcomes.[38]

FIGURE 142.2 A, Small nodule of PCMC in the eyelid margin. B, A large protruding PCMC in the lateral lower eyelid. (A, Courtesy of Dr. John Holds; B, Courtesy of Dr. Philip Custer.)

Histopathology

Histopathologic examination reveals an unencapsulated, dermis-based tumor that may show extension into the subcutis and deeper tissues when located outside the eyelid.[8,17] In the eyelid, the tumor often invades the orbicularis oculi muscle.[14] The tumor contains islands of neoplastic basaloid cells having solid to cribriform arrangements within slightly basophilic, PAS-positive mucinous pools, sometimes partitioned by thin fibrous septa (Figure 142.3A-C).[8,18] The mucin is alcian blue positive (pH 2.4-2.5)[8,27,54] and stains with mucicarmine[54,55,56,57] and colloidal iron.[8,54] As a sialomucin, it is hyaluronidase resistant and sialidase labile.[8,54] Cytologically, the tumor cells are characteristically round to cuboidal with moderate amounts of cytoplasm and typically with a low mitotic count and little nuclear atypia.[8,14]

The tumor cells of PCMC may stain positively using antibodies to AE1/AE3 cytokeratins,[15] α-lactalbumin,[25,58] beta-2-microglobulin,[58] carcinoembryonic antigen (CEA),[15,25,58,59] CD56,[57] chromogranin,[15,57,60] CK5/6,[59] CK7/8 (CAM5.2),[57] E-cadherin,[15] epithelial cell adhesion molecule (BerEP4),[59] epithelial membrane antigen (EMA),[15,58,60] gross cystic disease fluid protein-15 (GCDFP-15),[14,15,25,57,59] high-molecular-weight cytokeratin (34βE12),[59] low-molecular-weight cytokeratin,[60] lysozyme,[15] MUC1,[15] MUC2,[15] MUC6,[15] neuron specific enolase,[60] S100 protein,[25,58,59] salivary-type amylase,[58] synaptophysin,[57,61,62] trefoil factor-1 (TFF-1),[63] WT1,[57] and estrogen (ER)[15,57,60,61,62,63] and progesterone (PR)[15,57,60,61,62,63] receptors. PCMC tumor cells are CK7+ and CK20-,[14,15,57,59,61,62,64] similar to breast cancer but different from gastrointestinal adenocarcinoma, which is CK7- and CK20+.[15] Thus, approximately half of cases of mucinous carcinomas (ie, those from the gastrointestinal tract) can be effectively eliminated from consideration using CK7 and CK20 immunostains.[15] The tumor cells are negative for expression of CD10,[15] CDX2,[57] p53 protein,[15,60] prostate-specific antigen (PSA),[15,59] prostate-specific alkaline phosphatase,[15] smooth muscle actin,[15] and thyroid transcription factor 1 (TTF1).[59] Most primary mucinous carcinomas are CK7+, E-cadherin+, EMA+, GCDFP-15+, ER+, PR+, and CK20-.[15]

The expression of p63 by myoepithelial cells in PCMC assists in distinguishing a primary versus metastatic mucinous neoplasm.[15,65,66,67,68,69,70] When p63 immunostaining highlights a peripheral layer of myoepithelial cells (Figure 142.3D), it is considered diagnostic of an in situ tumor component, indicating an origin in the skin.[15,18,69] The significance of p63 expression by invasive tumor cells is uncertain since some cutaneous metastases from breast[68,70] and lung cancer[70] may express this protein. In the absence of an in situ component to the tumor, we recommend complete immunohistochemical, clinical, and radiological examination since lung, gastrointestinal, and breast cancer may rarely present with cutaneous metastasis.[71]

PCMC of the eyelid may coexist with endocrine mucin-producing sweat gland carcinoma (EMPSGC), with EMPSGC likely

representing a precursor.[57,72,73,74,75] EMPSGC is a rare, slow-growing, low-grade neuroendocrine neoplasm with a marked predilection for the eyelids and ocular adn exa.[72,73,74,76] EMPSGCs are typically well circumscribed, multinodular tumors with solid, cribriform, cystic, or papillary architecture (Figure 142.4). Myoepithelial cells, highlighted using antibodies to calponin, smooth muscle actin, or p63 protein,[72,77] are present in areas of in situ *(Print pagebreak 951)* carcinoma. Most large tumor nodules lack myoepithelial cells,[72] but an in situ component was identified in 42 of 63 EMPSGCs (67%) either by immunohistochemistry or light microscopy.[74] EMPSGC tumor cells may react with antibodies to carcinoembryonic antigen,[72,78] chromogranin (Figure 142.4D),[57,72,75,77,78,79] CD56,[57] CD57,[72] CK7,[72,77,78,79] CK7/8 (CAM5.2),[57,72,77] epithelial cell adhesion molecule (BerEP4),[77] epithelial membrane antigen,[72,78,79] estrogen receptor (Figure 142.4E),[72,74,78,79,80] GATA3 (Figure 142.4H),[81] gross cystic disease fluid protein-15,[57] mammaglobin (Figure 142.4I),[82] MYB,[77] neuron-specific enolase,[72,74,77,79] progesterone receptor (Figure 142.4F),[57,72,74,75,80] synaptophysin,[57,72,75,77,78,79] and WT1 (Figure 142.4G).[57,78] Tumor cells are negative for CDX2,[57] CK20,[57,72,77,78,79] and S100 protein.[72] Staining for neuroendocrine markers is often focal,[72,74,78] while CK7, nuclear hormone receptors, and WT1 are typically widespread. When PCMC and EMPSGC coexist in a tumor, the two components have a similar immunohistochemical profile supporting a derivation of PCMC from EMPSGC.[57,73] Owing to a striking resemblance of many hidradenomas to mucin-poor EMPSGC, we recommend using a panel of immunostains including nuclear estrogen receptor, neuroendocrine markers (chromogranin and synaptophysin), and WT1. The tumor should be classified as EMPSGC if it expresses nuclear estrogen receptors, a neuroendocrine marker, and WT1. Complete excision with clear margins is the recommended therapy for EMPSGC.[76] Tumor recurs in about 14% of cases, with recurrence more frequent in tumors with an invasive mucinous component (21%).[74] Metastasis from EMPSGC is not reported.[74]

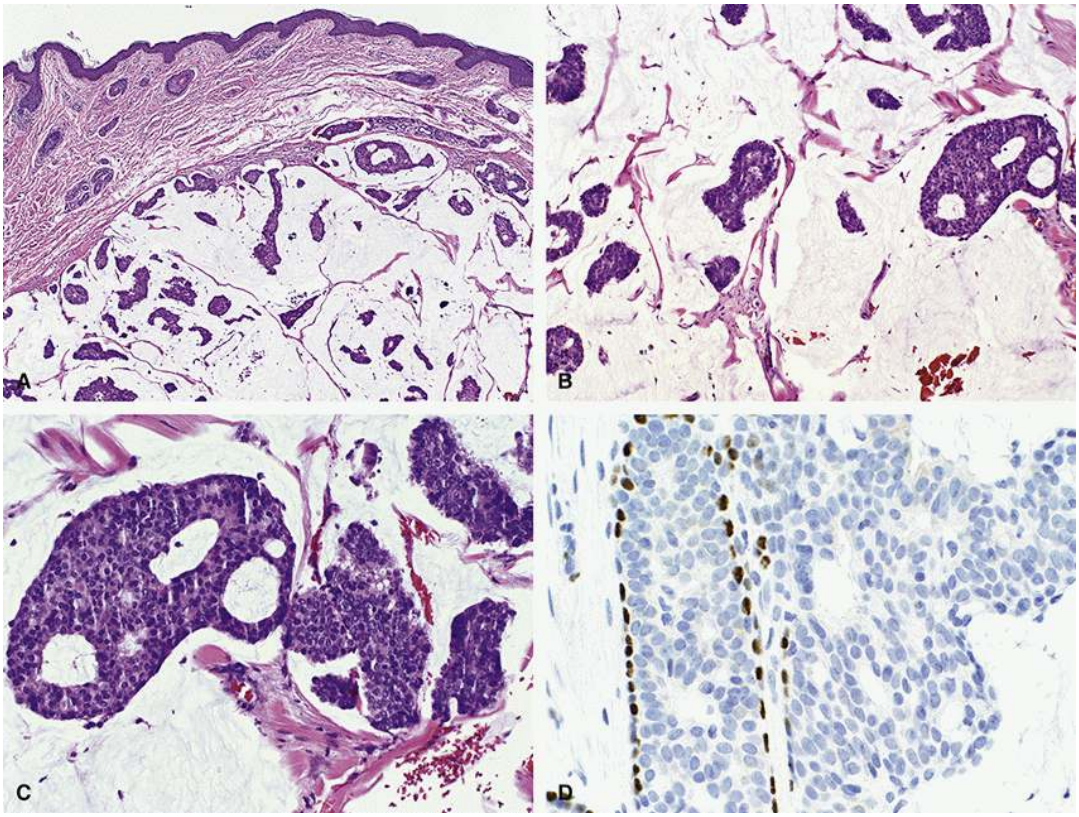

FIGURE 142.3 This PCMC arose in the left lower eyelid of a woman in her late 50s. A, The dermal tumor is well circumscribed with islands of tumor suspended in mucin and separated by delicate fibrovascular septa. B, Some of the tumor islands are solid, and others have a cribriform architecture. The mucin appears clear at this magnification. C, The tumor cells have a basaloid appearance with round to slightly oval nuclei and small amounts of lightly eosinophilic cytoplasm. The mucin is faintly basophilic. D, This tumor has foci of tumor cells surrounded by p63+ myoepithelial cells indicating an in situ tumor component, supporting a PCMC.

(Print pagebreak 952)

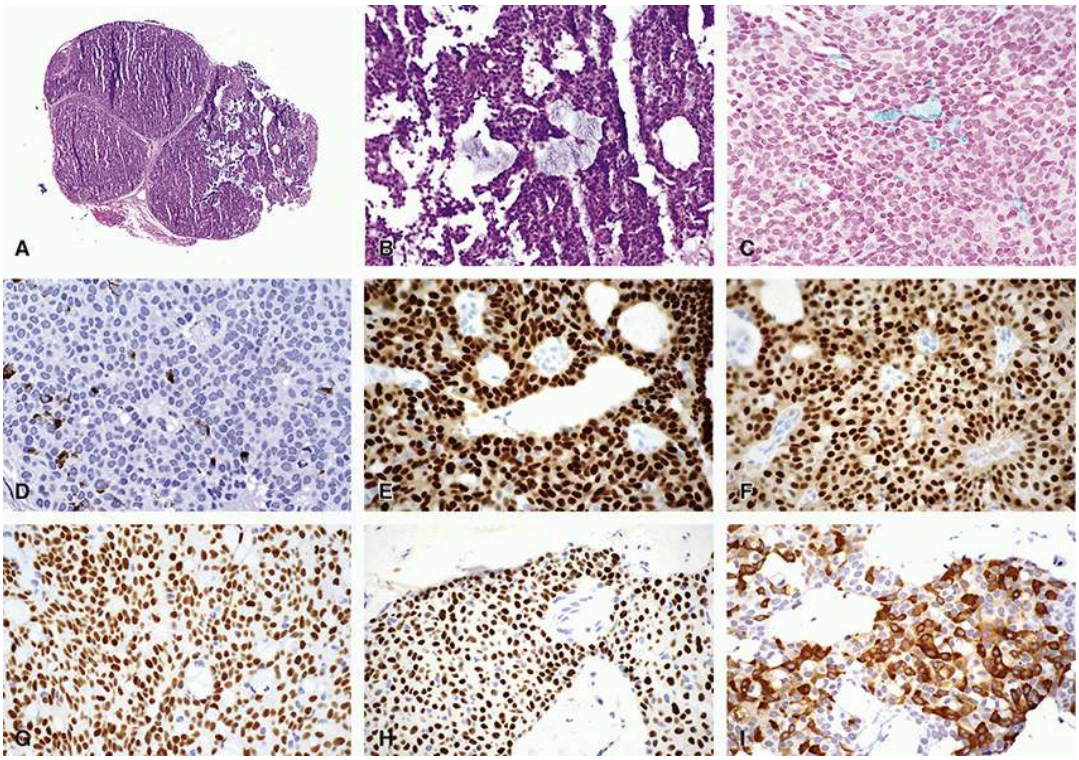

FIGURE 142.4 This endocrine mucin-producing sweat gland carcinoma was in the medial right lower eyelid of a woman in her early 60s. A, The tumor is well circumscribed and multinodular with thin fibrous bands between tumor nodules. Only the nodule on the right has obvious mucin creating the light areas surrounded by tumor cells. B, The small foci of mucin are lightly basophilic. The tumor cells have mostly round nuclei with minimal eosinophilic cytoplasm. C, Colloidal iron stain highlights extracellular and focal intracellular mucin. D, The neuroendocrine marker chromogranin was expressed by scattered tumor cells. E-I, The tumor cells diffusely expressed nuclear estrogen (E) and progesterone (F) receptors, WT1 (G), and GATA3 (H). I, Areas of the tumor had mammaglobin expression by a majority of the tumor cells.

CHAPTER 143

Rhabdomyosarcoma

Key Points

- Rhabdomyosarcoma (RMS) is an aggressive tumor that develops from mesenchymal cells of uncertain origin
- It can occur in any anatomic location of the body where there is skeletal muscle
- The most common subtype is embryonal, which accounts for about 60% to 70% of cases
- It is believed that the embryonal subtype arises from undifferentiated mesenchymal progenitor cells that have the capacity to differentiate into striated muscle
- Embryonal RMS may show allelic gains in chromosomes 2, 7, 8, 11, 12, 13, 17, 18, and 20, losses in chromosomes 10, 14, 15, and 16, and 35% contain mutant *NRAS* or *KRAS* genes
- For ophthalmic RMS, only 3% occur in the eyelids and most cases represent subcutaneous extensions from anterior orbital tumors
- Clinically, eyelid RMS presents as a firm, immobile, nontender mass with eyelid swelling and occasional ulceration, chemosis, superficial bleeding, and ecchymosis
- Treatment is with radiation therapy and systemic chemotherapy
- Embryonal RMS carries a favorable prognosis if the tumor remains localized, with a 5-year overall survival of about 70%-80%

Rhabdomyosarcoma (RMS) is an aggressive tumor that develops from mesenchymal cells of uncertain origin.[1] While RMS can occur at any age, and case reports occur in patients ranging from 3 weeks to 78 years of age,[2,3] this tumor is far more common in children. It represents 3% to 5% of all childhood cancers and accounts for about 40% to 50% of pediatric soft tissue sarcomas in childhood and adolescence.[1,4,5,6] RMS can occur in any anatomic location of the body where there is skeletal muscle, as well as at sites without skeletal muscle, such as the urinary bladder and common bile duct.[7,8] These tumors occur most commonly in the head and neck (35%), genitourinary tract (24%), extremities (19%), and at other locations (22%).[9]

Ophthalmic RMS accounts for about 10% of all localizations.[10] In a series of 33 ophthalmic RMS cases examined by Shields and coworkers, the tumor had an orbital epicenter in 75%, conjunctival in 12%, intraocular in 9%, and palpebral in 3% of cases.[10] Of the 30 cases of extraocular RMS in the Shields et al study, "all had an orbital component, despite apparent tumor origin in the conjunctiva or eyelid."[10] About 90% of RMS are diagnosed in patients less than 25 years of age, and 60% to 70% less than 10 years old.[11] In the head and neck area, RMS occurs most commonly in the orbit, the nasopharynx, middle ear, paranasal sinuses, and infratemporal and pterygopalatine fossae, and in the larynx, oropharynx, oral cavity, parotid gland, cheek, and scalp.[7,8] Eyelid involvement is uncommon and most cases represent extension from anterior orbital tumors. Primary isolated RMS of the eyelid is exceedingly rare with only 13 cases described. In the early stages, they may be misdiagnosed as a benign lesion, such as chalazion, hordeolum, or an epithelial tumor.[12,13]

RMS has been categorized into several subtypes according to histopathological differences. The most common subtype is embryonal, which accounts for about 60% to 70% of cases in children less than 10 years of age.[5] About 350 new RMS cases are diagnosed per year in the United States,[14] and the estimated incidence is 4.5 cases per million population among individuals aged 0 to 14 years.[5,11] This subtype occurs most commonly in the head and neck region and genitourinary tract.[14] Embryonal RMS has been further subdivided into a botryoid subtype. Botryoid RMS represents 10% of embryonal RMS and characteristically occurs in mucosal-lined organs such as the bladder, vagina, nasopharynx, and respiratory tract and carries a better prognosis than other types.[15]

Alveolar RMS is the second most common subtype and accounts for about 20% to 25% of RMS cases.[4] It is equally distributed among all age groups but is the most common type in teenagers and young adults.[14] This subtype is most common in the extremities and less commonly in the head and neck or on the torso.[14]

The World Health Organization now includes pleomorphic and spindle cell/sclerosing RMS as rare but distinct subtypes of RMS. Pleomorphic RMS is most common in adults in their 50s and often involves the legs.[14] Adult pleomorphic RMS has a poor prognosis with a median overall survival of about 13 months for people with localized disease.[14] Spindle cell/sclerosing RMS accounts for 3% to 10% of RMS, affects all age groups of both sexes, and is most common in the head and neck region followed by the extremities.[16] Congenital and infantile spindle cell/sclerosing RMS have a favorable prognosis when gene fusions are present but a poor prognosis if there is an *MYOD1* mutation.[16]

(Print pagebreak 956)

Etiology and Pathogenesis

RMSs are generally thought of as skeletal muscle tumors, mainly because they usually arise in or near muscle beds and show features of myogenic differentiation.[17] They exhibit diverse phenotypes that may reflect differences in their genetic mutations and cells of origin.[18] While the specific cell lineage of origin remains uncertain for all subtypes, the pleomorphic subtype is thought to originate from muscle stem cells,[19,20] whereas the alveolar subtype has been proposed to originate from mature differentiating skeletal muscles cells, not satellite cells.[21,22] It is believed that the embryonal subtype arises from undifferentiated mesenchymal progenitor cells that can differentiate into striated muscle,[17] although it has also been suggested that it may develop from a range of muscle lineage cells, including muscle satellite cells and downstream myogenic progenitors such as maturing myoblasts.[23,24]

Environmental risk factors have been associated with RMS. These include paternal smoking, maternal recreational drug use, advanced maternal age, and radiation exposure in utero.[5] Genetic risk factors include several hereditary syndromes including neurofibromatosis type 1 and Li-Fraumeni, Beckwith-Wiedemann, nevoid basal cell carcinoma, Rubinstein-Taybi syndromes, as well as hereditary retinoblastoma.[1,5] Oncogene mutations have been identified in 28% of embryonal and 3.5% of alveolar RMS. Embryonal RMS shows an increased incidence in syndromes with RAS/MAPK pathway and *BRAF* mutations, including cardiofaciocutaneous syndrome, Costello syndrome, and Noonan syndrome.[25,26,27,28]

Eighty percent of alveolar RMS exhibit a translocation between chromosomes 2 and 13 (t(1;13)(q35;q14) (*PAX3-FOX1A*).[1,4,26,29,30,31,32] Embryonal RMS often shows allelic gains in chromosomes 2, 7, 8, 11, 12, 13, 17, 18, and 20, losses in chromosomes 10, 14, 15, and 16,[33,34] and translocations in the 1p11-1q11 region.[33] Moreover, studies have shown that 35% (5 of 14) of embryonal RMS samples contain mutant *NRAS* or *KRAS* genes.[35] P53, RAS, Hedgehog, and PI3K pathways are potentially necessary for the pathogenesis of embryonal RMS and could thus be important for targeted therapy.[35]

FIGURE 143.1 A, Child with a rhabdomyosarcoma of the left upper eyelid presenting as eyelid swelling and ecchymoses. B, Rhabdomyosarcoma of the medial canthus and upper eyelid. (A, Courtesy of Dr. Ilya Leingold. B, Courtesy of Dr. Antonio Augusto Cruz.)

Clinical Presentation

For ophthalmic RMS, 76% occur in the orbit, 12% in the conjunctiva, and 3% in the eyelids.[10] Localized eyelid involvement is quite rare and most cases represent subcutaneous extensions from anterior orbital tumors.[10] Conjunctival and subconjunctival lesions appear as a fleshy, pink lesion often in the fornix. Early stages of eyelid RMS in children may be misdiagnosed as a benign

lesion. For periorbital lesions, the size can vary considerably, from pimple size to 6 cm or more.[36]

Eyelid RMS occurs at all ages with a mean of 11.3 years, a median of 8.0 years, and a range of 1 day to 54 years. Males and females are equally affected, and there is a slight predilection for the right side (70%). All subtypes are represented, with 58% embryonal, 25% anaplastic, and 17% alveolar. The specific localizations are upper eyelid (64%), lower eyelid (18%), caruncle (9%), and medial canthus (9%). Eyelid RMS usually present as a firm, immobile, nontender mass with eyelid swelling and occasional ulceration, chemosis, superficial bleeding, and ecchymosis (Figure 143.1).

Differential Diagnosis

Eyelid RMS usually grows rapidly so that suspicion for a neoplastic process is common. But initially, these tumors can be small, associated with ptosis, dilated vessels, and sometimes *(Print pagebreak 957)* inflammation. They can initially be confused with a variety of benign lesions such as chalazion, hordeolum, epithelial cyst, an epithelial tumor, vascular lesions such as hemangioma, or a subcutaneous hematoma. As they enlarge, they are confused with other primary cutaneous malignancies, lymphoma, or metastases particularly in a patient with a history of prior systemic malignancy. Histologically, RMS can be mistaken for round cell and spindle cell tumors such as leukemia, lymphoma, metastatic neuroblastoma, extraocular spread of retinoblastoma, Ewing sarcoma, peripheral ectodermal tumors, fibrosarcoma, and rhabdoid tumor. Immunohistochemistry and electron microscopy are required for definitive diagnosis.[37]

Treatment

Treatment for RMS of the head and neck has evolved significantly since 1965. Previously, the gold standard was a primary, often radical, surgical excision in all cases, followed by radiation therapy when complete excision could not be achieved. The survival rate was only 5% to 9%. Since 1965, radiation therapy and systemic chemotherapy have become the standard primary treatment, based on the guidelines set forth by intergroup RMS studies. Metastasis from orbital RMS is uncommon because lymphatics are very sparse in the orbit. However, conjunctiva and eyelid RMS are exposed to lymphatic vessels so that metastasis to preauricular or cervical lymph nodes can occur more easily.

Chemotherapy consists of combinations of vincristine, dactinomycin, and cyclophosphamide.[38] Success has been reported with low- and intermediate-risk RMS patients, but the 5-year failure-free survival for high-risk groups has not changed very much over the past 25 years.[4,39] For patients with disseminated tumor having the worst prognosis, chemotherapy with subsequent autologous myogenic stem cell transplantation has been proposed.[40,41]

Radiation therapy at doses of 35 to 50 Gy is used for local tumor control, combined either with surgery or chemotherapy. For eyelid and facial tumors, there is a risk of neuroendocrine dysfunction, intellectual delay, decreased vision, hearing and dental problems, facial asymmetry, thyroid dysfunction, and secondary malignancies.[42] Conformal radiotherapy, intensity-modulated radiation therapy, and proton therapy are mostly recommended.[43,44] Brachytherapy applied directly to the tumor surgical bed has been associated with fewer complications in some sites, but its use in the treatment of head and neck RMS has been limited.[45,46]

Targeted therapies may show some promise. Huang et al[47] showed the sensitivity of RMS cell lines to an IGF-1 receptor small-molecule inhibitor. Other studies showed that dual blockade of the PI3K/AKT/mTOR and RAS/MEK/ERK (AZD6244) pathways, or a combined targeted inhibition of the bromodomain 4 (BRD4) and the Akt/mTOR signaling pathways are highly effective in combating RMS.[48,49] Adjuvant immunotherapy with infusions of the patient's lymphocytes with dendritic cells pulsed with the fusion peptide plus IL2 showed an improvement in overall survival.[50]

Prognosis

Favorable prognostic factors include age less than 9 years, botryoid variant, location such as the orbit, and absence of metastasis at the time of initial treatment. Embryonal RMS is considered more favorable if the tumor remains localized with a 5-year overall survival of about 70%-80%. Alveolar RMS has a higher incidence of metastasis and generally has a worse prognosis.[1,28] Regional lymph node involvement and distant metastases from orbital RMS are relatively rare, but tumors located in the conjunctiva show a higher incidence of regional lymph node involvement.[10] Nevertheless, in general, RMS involving the orbit, conjunctiva, or eyelid has a better prognosis than tumors at other head and neck locations.[10]

RMS in adults at all sites has a poorer prognosis than pediatric tumors, possibly related to a higher incidence of the pleomorphic

histological subtype and more advanced disease at presentation.[51] The 5-year survival is reported to be only about 53%.[52]

About 70% of newly diagnosed cases of RMS that do not involve metastases can be managed with combined chemotherapy, radiation therapy, and more limited surgery.[15,53] However, patients with distant metastases at the time of diagnosis have a significantly worse prognosis, with a 5-year survival rate of only 20% to 30%.[6,54,55,56]

Histopathology

Primary cutaneous RMSs are rare[57,58,59,60,61,62,63,64,65,66,67,68] and include embryonal,[59,60] alveolar,[60,61,62,63,64] pleomorphic,[60,65,66] and epithelioid[67,68,69,70] subtypes. Reports of primary RMS in the eyelid[70,71,72,73] and conjunctiva[74,75,76,77,78,79,80] are even rarer. Reports of primary eyelid RMS include embryonal,[71,72] alveolar,[73] and epithelioid[70] variants, while reported conjunctival RMS includes embryonal[76,77] and botryoid embryonal[74,75,78,79,80] subtypes.

Embryonal RMS has a variable histological appearance (Figures 143.2 and 143.3) depending on the stages of myogenesis exhibited by the tumor cells.[81,82] Tumor cells range from poorly differentiated, recognizable as having muscle differentiation only using immunohistochemical stains, to well-differentiated tumor cells resembling fetal muscle.[81,82] Poorly differentiated tumor cells are small, round or spindle-shaped, with hyperchromatic nuclei and scant cytoplasm.[82] Better differentiated tumor cells have an appearance of rhabdomyoblasts with larger, round or oval cells, with eosinophilic cytoplasm.[82] As the rhabdomyoblasts differentiate, they have increasing amounts of eosinophilic cytoplasm and become elongated with an appearance denoted as "tadpole" or "strap" (Figure 143.2B) cells.[81] Around 50% to 60% of embryonal RMSs have identifiable cross-striations, though they are usually more irregularly distributed than in normal muscle cells.[82] Glycogen is present in tumor cells of most cases of embryonal RMS. Glycogen dissolution during processing may result in multivacuolated cells or cells with thin strands of cytoplasm traversing the cell, causing the appearance of "spider cells."[82] Embryonal RMS has variable cellularity from *(Print pagebreak 958)* one area of the tumor to another, and tumor cells are within a matrix having little collagen and varying amounts of myxoid substance.[82] Embryonal RMS may have a prominent spindle cell morphology (Figure 143.3C and D), though areas of more typical embryonal RMS are usually present.[81] Embryonal RMS, botryoid type, has less cellularity than typical embryonal RMS, abundant mucoid stroma, and a cambium layer "characterized by a subepithelial condensation of tumor cells separated from an intact surface epithelium by a zone of loose stroma."[82] Virtually all embryonal RMS are immunoreactive using antibodies to desmin, myogenin, and MyoD1, though there is variable extent of immunoreactivity.[81] There is frequent expression of muscle-specific actin (Figure 143.2C) and smooth muscle actin.[81]

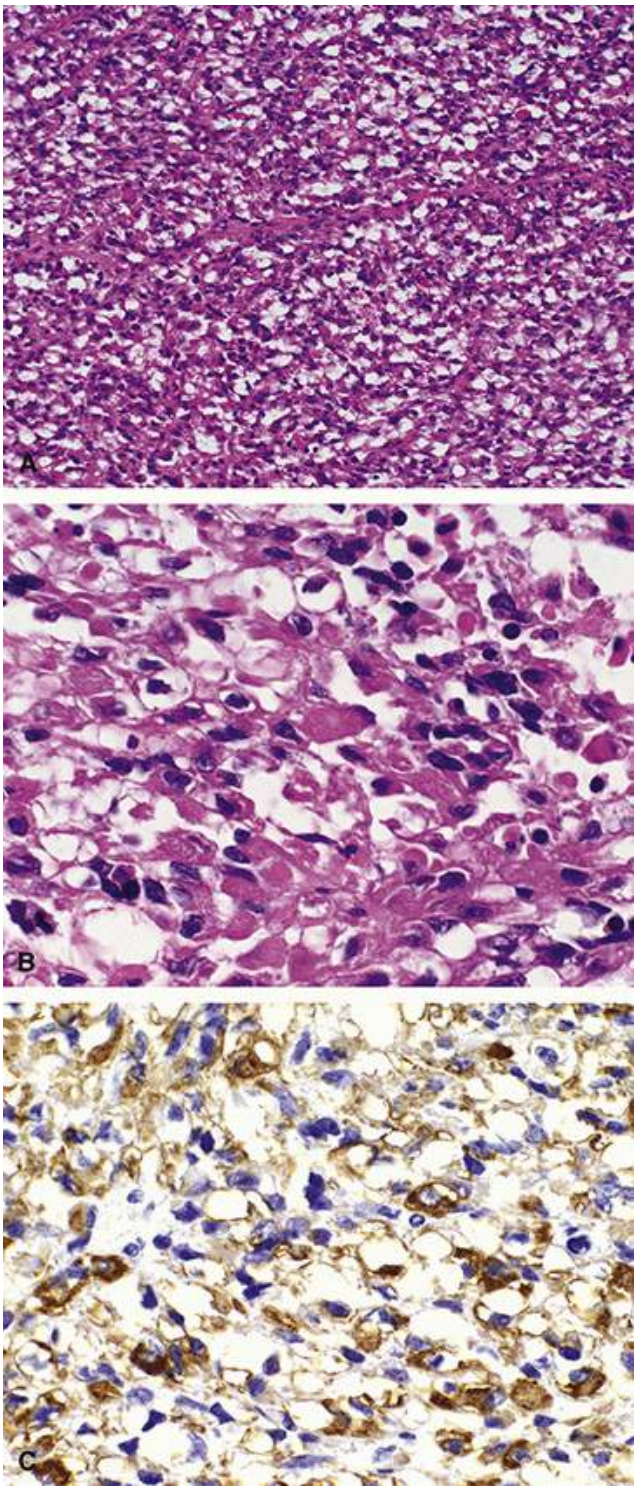

FIGURE 143.2 This embryonal rhabdomyosarcoma was from the right orbit of a 9-year-old girl. A, The tumor is a patternless sheet of small tumor cells. B, Most tumor cells have variable amounts of eosinophilic cytoplasm, while a minority have clear cytoplasm. Some cells, often termed "strap cells," have elongated eosinophilic cytoplasm and their nucleus displaced to one end of the cell. C, All of the tumor cells are immunoreactive using antibodies to muscle-specific actin.

Alveolar RMS is a highly cellular tumor "composed of primitive round cells with scant cytoplasm and hyperchromatic nuclei. Tumor cells are arranged in nests separated by fibrovascular septa, which frequently exhibit loss of cellular cohesion in the center, conferring a pattern of irregular alveolar spaces and a varying degree of cystic change. The solid subtype of ARMS is composed of sheets of neoplastic cells that have cytomorphological features of ARMS but lack septa or discohesion."[83] There is strong and diffuse nuclear expression of myogenin in alveolar RMS, in contrast to embryonal and other subtypes of RMS that have focal staining.[83] Alveolar RMS also express desmin and MyoD1,[83,84] and about one-fifth of tumors express neuroendocrine markers (synaptophysin, chromogranin, neuron-specific enolase, CD56).[84] About 85% of alveolar RMSs have fusion genes, the most common being *PAX3-FOX01* and *PAX7-FOX01* fusions, accounting for 70%-90% and 10%-30% of the fusions, respectively.[83]

Pleomorphic RMS features "sheets of large, atypical, and frequently multinucleated polygonal, spindled, or rhabdoid cells with eosinophilic cytoplasm."[85] There is usually strong expression of desmin and often limited expression of MyoD1 and myogenin.[85] There are no diagnostic molecular abnormalities.[85]

Spindle cell/sclerosing RMS has a variable histological appearance.[16] There may be intersecting fascicles of spindle cells creating a herringbone pattern, undifferentiated areas of round cells, and prominent hyalinization/sclerosis, sometimes with a pseudovascular growth pattern.[16] Spindle cell RMS may have bland cytological features in very young children.[82] There is diffuse expression of desmin in all cases, focal expression of myogenin in most cases, focal or diffuse staining for MyoD1 in spindle cell RMS, and usually diffuse MyoD1 expression in sclerosing RMS.[16] Molecular analyses of spindle cell/sclerosing RMS is important since congenital and infantile tumors with gene fusions have a favorable clinical course, while *MYOD1*-mutant spindle cell/sclerosing RMSs are aggressive tumors with a poor clinical prognosis.[16]

Epithelioid RMS, not yet classified as a distinct RMS subtype by the World Health Organization, has sheets of "uniformly sized epithelioid cells with abundant amphophilic-to-eosinophilic cytoplasm, large vesicular nuclei, and frequently prominent nucleoli."[69] The tumors *(Print pagebreak 959)* have high mitotic counts (median of 23 mitoses per 10 high-power fields), frequent atypical mitoses, necrosis, and infiltration of adjacent structures such as muscle or adipose tissue.[69] Epithelioid RMSs have diffuse desmin expression, focal myogenin expression, and coexpression of cytokeratins occurring in about 40% of tumors.[68] We are aware of only one epithelioid RMS arising in the eyelids that presented as left upper eyelid swelling with metastasis to the preauricular region in an 84-year-old woman.[70]

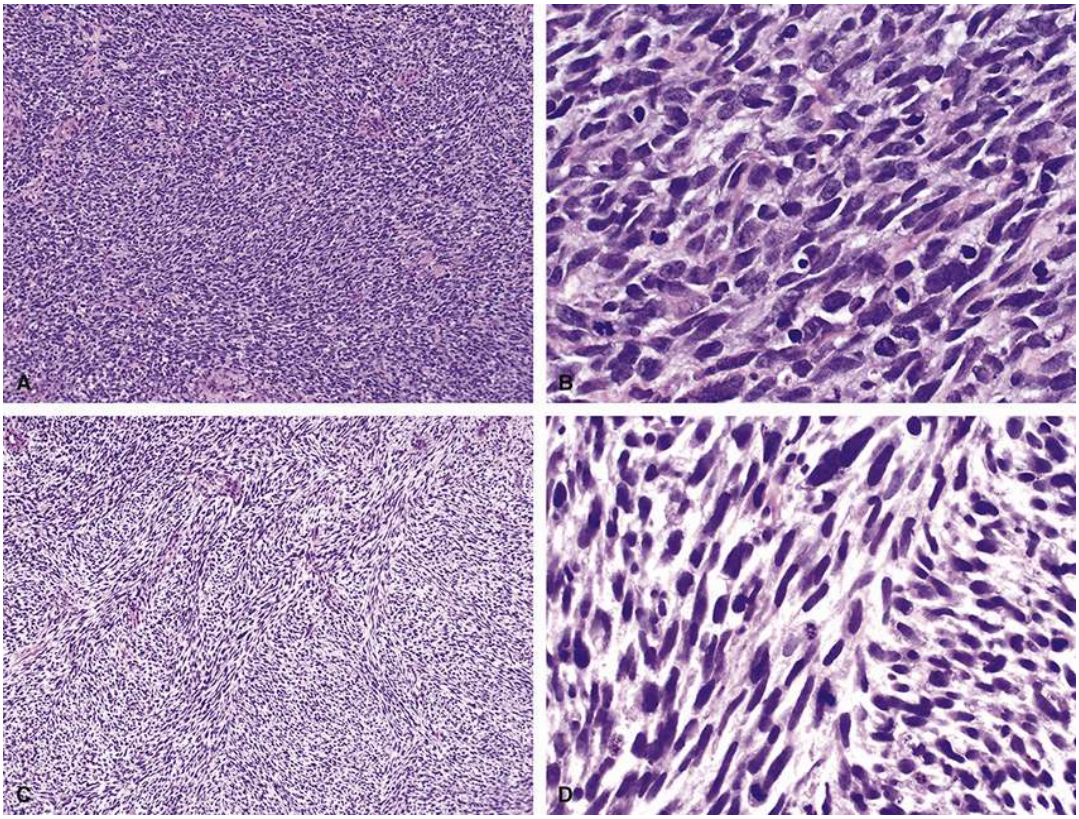

FIGURE 143.3 This embryonal rhabdomyosarcoma arose in the left lower eyelid conjunctiva of a 4-year-old girl. Computed tomography showed 1 cm of preseptal thickening without postseptal involvement. The tumor had two distinct histological features. There were sheets of small basophilic cells with oval nuclei (A and B) and interlacing fascicles of pleomorphic spindle cells (C and D). The tumor cells were immunoreactive using antibodies to desmin, myogenin, and muscle-specific actin. (Photomicrographs are from a microscopic slide distributed by Dr. Norman C. Charles at the 2012 meeting of the Eastern Ophthalmic Pathology Society.)

CHAPTER 144

Sebaceous Carcinoma

Key Points

- Sebaceous carcinoma (SbC) is a rare malignant and potentially lethal tumor derived from the adnexal epithelium of sebaceous glands
- It represents 0.05% of all cutaneous malignancies and about 5% of all malignant neoplasms in the periocular region
- The pathogenesis is unclear but cases have been associated with the Muir-Torre syndrome, with previous radiation, and with UV exposure
- Eyelid and periocular SbC typically present in the sixth to eight decades of life
- The clinical appearance is very diverse, mimicking benign eyelid inflammations and lesions such as chalazion, blepharitis, sarcoidosis, cutaneous horn, and ocular pemphigoid
- SbC lesions may appear as a unilateral, firm, indurated, yellow, flesh-colored, or pink mass
- Treatment is with wide local surgical resection followed by eyelid reconstruction. Radiotherapy is not generally recommended as a primary treatment
- The mortality rate is generally 5% to 10%, and local recurrence rates of 11% to 36% are often seen within 5 years

Sebaceous carcinoma (SbC), or meibomian gland carcinoma, is a rare malignant and potentially lethal tumor derived from the adnexal epithelium of sebaceous glands.[1] It makes up an estimated 0.05% of all cutaneous malignancies[2] and represents about 5% of all malignant neoplasms arising in the periocular region.[3,4,5] In the periocular region, SbC has a tendency for pagetoid spread, a high recurrence rate following treatment, and a significant rate of metastases.[6,7] It may arise in ocular or extraocular sites; however, presumably because the eyelid and periocular tissues contain a high density of sebaceous glands, up to 40% of SbCs arise in eyelid and periocular locations. These tumors typically exhibit a variety of histologic growth patterns and clinical presentations. The diagnosis is frequently delayed with the mean duration from onset to diagnosis ranging from 1 to 2.9 years.[8,9]

Etiology and Pathogenesis

The occurrence of this tumor varies significantly among different ethnic groups. Among populations from China, Japan, Hong Kong, and Singapore, SbC represents as much as 30% to 40% of all periocular malignancies.[10,11,12,13,14] Among Caucasians, SbC accounts for less than 5% of eyelid malignancies.[7,15] No specific causes for these ethnic differences have yet been determined.

While the pathogenesis is unclear, cases of SbC have been associated with the Muir-Torre syndrome (MTS),[16,17] previous radiation in the area of the tumor,[18] or diuretic use.[19] MTS is an autosomal dominant disorder associated with multiple internal malignancies including head and neck, small bowel, and hematologic cancers. As many as 25% to 30% of MTS patients may develop sebaceous tumors, mostly in the periorbital region.[20,21,22,23,24]

Radiation-associated periocular SbC has been described following radiation treatment for retinoblastoma and cavernous hemangioma.[25,26,27] This can be very long term following radiotherapy and in one case was reported 17 years after treatment for retinoblastoma[28] and after more than 40 years affecting all four eyelids following radiotherapy for juvenile facial eczema.[29]

Sung et al[30] described a case of early-onset SbC in a 32-year-old patient who used a UV tanning bed for 9 years, suggesting that UV exposure could be an additional risk factor, but there is little published evidence to support this conclusion. Several recent studies have identified mutations in tumor suppressor genes, including *TP53, RB1,* and the *p16* gene in SbC patients.[31] The *p53* gene has been well studied in several malignancies. This gene promotes either cell cycle arrest, therefore allowing time for DNA repair, or apoptosis.[31] Harris et al[32] found that 67% of SbCs of the eyelid from Asian patients had *p53* mutations. These were point

mutations, rather than tandem mutations, suggesting that they may not be related to UV exposure. The *p53* mutations in eyelid SbC may be caused by UV-independent processes, in contrast to other skin cancers that are associated with UV exposure.[33]

SbC is well known in the literature as a "great masquerader," clinically mimicking other benign and malignant eyelid lesions, such as chalazion and blepharitis, which are frequently the initial misdiagnoses. This raises an interesting question as to the relationship between these lesions and the development of SbC. The relationship between cancer and inflammation has been recognized since the 17th century.[34] There is a small but intriguing literature regarding the relationship between chronic inflammation and the subsequent development of cutaneous malignancies.[35,36,37] There is much evidence that the inflammatory microenvironment can contribute to the development and progression of epithelial skin cancers by contributing to the physical processes of wound *(Print pagebreak 963)* healing and infection,[35] and it has been estimated that as many as 20% of cancers may be initiated by chronic inflammation or persistent infection.[38] Inflammatory-mediated release of various growth factors as well as cytokines and chemokines help to orchestrate tissue repair, but may also serve as promotors of oncogenesis acting on initiators such as accumulated somatic mutations.[36,37,39] Many of the so-called masqueraders of SbC, such as chalazion and blepharitis, are chronic inflammatory lesions. Although there are no reports documenting the evolution of a chalazion or blepharitis to SbC or other malignancies, the relationship between inflammation and cutaneous tumors should be kept in mind.

Clinical Presentation

Eyelid and periocular SbC typically presents in the sixth to eight decades of life, with a mean age of about 65 to 70 years[3,40]; however, studies from Asia have repeatedly shown that SbC occurs a decade earlier in Asians than in Caucasian populations.[10] A recent study has shown that the median age at diagnosis in Asian Indians was 57 years.[10] Rarely, cases in younger age groups have also been described in Caucasians.[30,41] The tumor involves extraocular sites in about 25% of cases, predominantly on the head, trunk, and genitalia. Ocular SbC arises from the meibomian glands of the upper eyelid in 40% to 60% of cases. It can also arise from accessory glands of Zeis along the eyelid margin, in the caruncle, or on the eyebrow. In a series of 60 cases of eyelid SbC, females were involved in 73%, and Caucasians in 95%.[3] In another large series of 1333 cases, Desiato et al reported a female predominance of 60%, with 62% involving the upper eyelid, 32% the lower eyelid, and 5% both.[42]

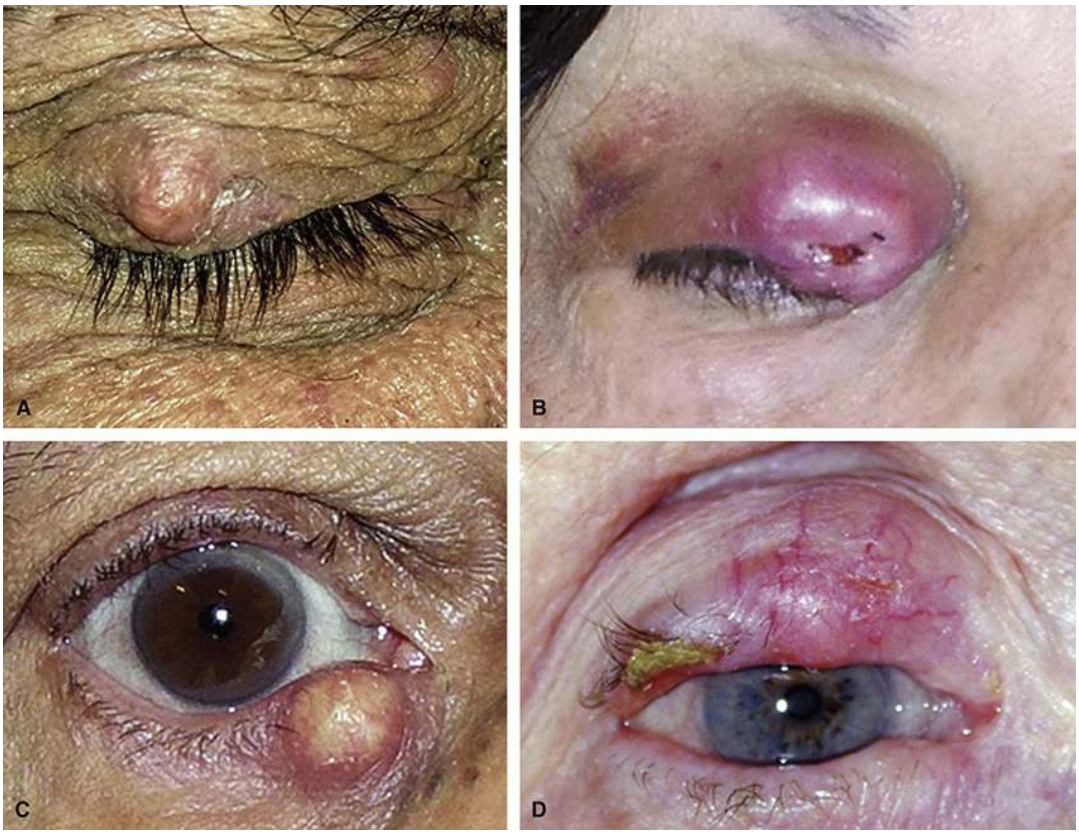

FIGURE 144.1 A-D, Sebaceous carcinoma mimicking benign lesions such as chalazion.

The clinical appearance is very diverse, mimicking a variety of benign eyelid inflammations and lesions such as chalazion, blepharitis, sarcoidosis, and ocular pemphigoid (Figures 144.1 and 144.2).[43,44] Two-thirds of cases are initially misdiagnosed as benign lesions.[3] In cases of unilateral blepharitis or conjunctivitis unresponsive to appropriate treatment, it is essential to rule out SbC. This tumor can also be confused with other malignancies including squamous cell carcinoma (SCC), basal cell carcinoma

(BCC), lymphoma, or Merkel cell carcinoma (Figure 144.3). When SbC arises in the glands of Zeis, it can present as an ulcerated nodule or even a cutaneous horn.[45]

(Print pagebreak 964)

FIGURE 144.2 A-D, Sebaceous carcinoma mimicking inflammatory lesions and blepharitis.

Clinically, SbC appears as a unilateral, firm, indurated, yellow, flesh-colored, or pink mass on the tarsal conjunctiva, caruncle, or eyelid margin, often associated with madarosis and ulceration. The upper eyelid is involved in 75% of eyelid cases. Pagetoid spread is seen in 30% to 80% of cases resulting in diffuse eyelid thickening that can mimic blepharoconjunctivitis.[46] When the conjunctiva is involved, forniceal contraction is often seen, along with invasion of the cornea. SbC can spread to the lacrimal drainage system, and rare orbital invasion has been reported in more advanced cases.[47]

As with other eyelid malignancies, tumor staging is assessed using the TNM definitions in the 8th edition of the American Joint Committee on Cancer (AJCC) recommendations where T1 = ≤10 mm, T2 = >10 mm, T3 = >20 mm but not greater than 30 mm, and T4 is any stage with invasion of adjacent ocular, orbital, or facial structures.[48] Metastasis to regional lymph nodes is common and seen in 10% to 30% of cases.[3,49]

Differential Diagnosis

The differential diagnosis is extensive and includes other malignant tumors such as BCC, SCC, and a variety of benign lesions and inflammations including papilloma, chalazion, blepharitis, ocular cicatricial pemphigoid, cutaneous horns, discoid lupus, and pyogenic granuloma.

A definitive diagnosis requires a high level of suspicion and is best made with a full-thickness eyelid biopsy. Because of the common occurrence of skip lesions and the multicentric nature of this tumor, an adequate wide biopsy is necessary.[3] Pagetoid spread has been reported in 8% to 51% of cases,[50,51] but may not be apparent clinically. Shields et al reported an accurate clinical judgment of conjunctival involvement in only 57.5% of nodular tumor cases.[3] Map biopsies have been advocated to evaluate the conjunctiva for suspected cases of pagetoid spread.[52] However, the accuracy of routine map biopsies has been questioned, and Koreen et al found that 15% of specimens from 144 conjunctival map *(Print pagebreak 965)* biopsies were nondiagnostic due to artifactual epithelial loss, and nondiagnostic specimens were more frequent in patients with extensive pagetoid spread.[53] Immunohistochemical evaluation is important in distinguishing sebaceous carcinoma from other neoplasms.

FIGURE 144.3 A-D, Sebaceous carcinoma with features similar to other eyelid malignancies. (D, Courtesy of Dr. Bita Esmaeli.)

Treatment

After a firm diagnosis is achieved, a systemic workup is undertaken with a multidisciplinary team. Systemic evaluation may include liver function tests, chest X-ray, CT, or PET/CT scanning. AJCC tumor, lymph node, and metastasis staging (TNM) should be performed to help determine the most appropriate management options.[48]

Sentinel lymph node biopsy can be used to assess the draining lymph nodes from the eyelid tumor. It is a well-tolerated procedure and has been recommended for larger tumors greater than 10 mm in size.[54,55] However, false negatives have been reported, and patients with identified lymph node disease have not been shown to have improved survival.[56]

The most important and widely recommended treatment of SbC is wide local surgical resection followed by eyelid reconstruction. Confirmation of clear surgical margins is necessary with intraoperative frozen sections or Mohs micrographic surgery. A surgical margin of 5 to 6 mm is recommended. Where frozen section or Mohs surgery is not available, 5-mm surgical margins are obtained, and reconstruction is delayed until the final paraffin sections are returned.[57,58,59] If pagetoid disease is confirmed, cryotherapy is used if the process is localized. Alternatively mitomycin C can be used for diffuse pagetoid spread. Orbital exenteration may be required if deep orbital involvement is found on imaging[60] but in recent years adjuvant therapies and globe-sparing surgery techniques have reduced the need for exenteration.[3]

Radiotherapy is not generally recommended as a primary treatment for SbC but is effective in achieving tumor control in some patients, or as an adjuvant treatment for locally *(Print pagebreak 966)* advanced tumors, or following orbital exenteration.[61,62] The major adverse effects of radiation therapy are ocular surface disease, dry eyes, keratitis, conjunctivitis, and dermatitis.

Cryotherapy using a double freeze-thaw technique can be used as adjuvant therapy for SbC. It is used after resection for tumors involving locations that are difficult for surgery alone or for tumors with conjunctival pagetoid spread. More importantly, cryotherapy is often applied to the resection edges of the palpebral and bulbar conjunctiva.[60] Adverse effects

include edema, erythema, skin blistering, depigmentation, and madarosis.

Prognosis

Periocular Sbcs are generally more aggressive than Sbcs in extraocular sites, and this is generally attributed to pagetoid spread.[31] Local recurrence rates of 0% to 43% have been reported,[51] often seen within 5 years. The most common risk factors for local recurrence are higher AJCC T stage category, tumor size, tumor location, pagetoid spread, diffuse growth pattern, multicentric origin, and delayed diagnosis. Recently, it has been demonstrated in Asian Indians that age may play a key prognostic factor in SbC.[10] In the older age group, the incidence of tumor recurrence is higher possibly due to immune senescence, while death due to disease, locoregional metastasis, and systemic metastasis is more common in the younger age group, possibly because younger patients have a longer number of years to live which hypothetically causes some micrometastasis to become apparent over the years.[10]

Based on the AJCC 8th Edition classification,[48] nodal metastases are significantly more frequent with advanced T3/T4 stages and associated more with poor tumor differentiation.[63,64] The most common sites for systemic metastases include the lungs, regional lymph nodes, liver, brain, and bone. Important risk factors for recurrence and metastasis include medial canthal involvement, occurrence on both upper and lower eyelids, orbital invasion, longer duration of symptoms >6 months, and tumor size >10 mm.[63] Pagetoid spread, lymphatic invasion, and poor histologic differentiation are also associated with a worse prognosis.[3,61] Tumors originating from the glands of Zeis and those associated with MTS are reported to have a better prognosis.[65,66]

The reported mortality rate for SbC is 4% to 16%,[3,42,51,65] with higher rates associated with wide local excision alone, and rates as low as 4% following Mohs surgery.[66] Risk factors for mortality include medial canthal involvement, tumor diameter >10 mm,[67] and poor histologic differentiation.[68]

Histopathology

SbC may arise from the meibomian glands, glands of Zeiss (the sebaceous glands lubricating the cilia at the lid margin), or sebaceous glands of the caruncle.[69] In the eyelid, SbC arises in the meibomian glands much more often than the glands of Zeiss. Of 97 eyelid tumors in the study by Rao and colleagues, 51 (53%) were of meibomian origin, 10 (10%) were from the glands of Zeiss, 12 (12%) were multicentric arising from both the meibomian glands and glands of Zeiss, and 24 (25%) tumors were of undetermined origin.[70] Ni et al reported the location of 80 eyelid SbCs: 57 (71%) were from the meibomian glands, 20 (25%) involved the meibomian and Zeiss glands, and 3 (4%) arose in glands of Zeiss.[71] In both studies, there were no fatalities in patients with tumors arising from the glands of Zeiss.

Eyelid SbC may have a lobular, comedocarcinoma, papillary, or combined histopathological growth pattern.[72,73] The lobular pattern features well-delimited lobules of varying size that usually have "a peripheral row of basophilic cells with scanty cytoplasm and elongated nuclei."[72] Cleavage artifact between the tumor lobules and the surrounding stroma is common.[72] In our experience, the lobular pattern is by far the most common in eyelid SbCs. Eyelid SbC varies from well- to poorly differentiated tumors (Figures 144.4, 144.5, 144.6), depending on the number of neoplastic cells with sebaceous differentiation. The cells with sebaceous differentiation have abundant, finely vacuolated cytoplasm creating a foamy or frothy appearance.[72] The other neoplastic cells have hyperchromatic nuclei, prominent nucleoli, and abundant basophilic cytoplasm.[72] Sebaceous differentiation is most common in the center of tumor lobules.[72] Moderately differentiated tumors exhibit only "a few foci of highly differentiated sebaceous cells," and poorly differentiated neoplasms show anaplastic cells with only a few cells having foamy cytoplasm.[72] Oil red O stain for lipid within the tumor cells was used in the past to identify sebaceous differentiation,[73] but it has now been supplanted by immunohistochemical staining for adipophilin (Figure 144.6D). Infiltrative features range from minimal to moderate to high, with minimally invasive tumors having well-delineated lobules.[72] Moderately infiltrative tumors have "somewhat smaller lobules than those seen in the minimally invasive infiltrative group, and characteristically they showed extension of infiltrating cords of tumor cells into the stroma."[72] Highly infiltrative eyelid SbCs have only focal lobules with most tumor cells forming infiltrative cords.[72] Both the tumor's degree of differentiation and infiltration correlate with mortality, with poorly differentiated and highly infiltrative tumors having the worst prognosis.[70,72] Spread of carcinoma to the epithelium of the conjunctiva (Figure 144.6), cornea, or eyelid (Figure 144.5) occurs in about 40% of eyelid SbCs.[70,72] Intraepithelial spread of carcinoma may be as single cells or small clusters (pagetoid spread; Figure 144.5E), or there may be diffuse, full-thickness replacement of the epithelium by neoplastic cells (in situ carcinomatous change; Figure 144.6B).[72] Both pagetoid and full-thickness areas of intraepithelial spread are present in about 35% of tumors with intraepithelial involvement.[72] Rarely, intraepithelial SbC may arise in the eyelid conjunctiva without an invasive tumor of the meibomian or Zeiss glands.[74]

The differential diagnosis for periocular SbC includes benign sebaceous tumors such as sebaceoma and sebaceous adenoma, very

rare tumors of the eyelids[75,76,77] that are less *(Print pagebreak 967)* common than SbC.[76] Sebaceomas are well-circumscribed dermal tumors composed mainly of basaloid germinative cells (Figure 113.6).[78,79,80] Greater than 50% basaloid cells is the value usually considered as the cutoff for differentiating sebaceoma from sebaceous adenoma.[79,80] The number of histological sections that should be examined to determine the percentage of basaloid cells is not defined,[80] and there is only moderate interobserver agreement among pathologists for diagnosing sebaceous adenoma and sebaceoma.[81] Well-differentiated (grade 1) SbC may be difficult,[78,80] if not impossible,[81] to discriminate from sebaceous adenoma. An increased mitotic rate,[82] increased nuclear survivin expression,[83] cytological atypia,[40,80] or abnormal mitotic figures[84] favor a diagnosis of carcinoma. We concur that, "If in doubt, any sebaceous tumor should be excised completely."[80]

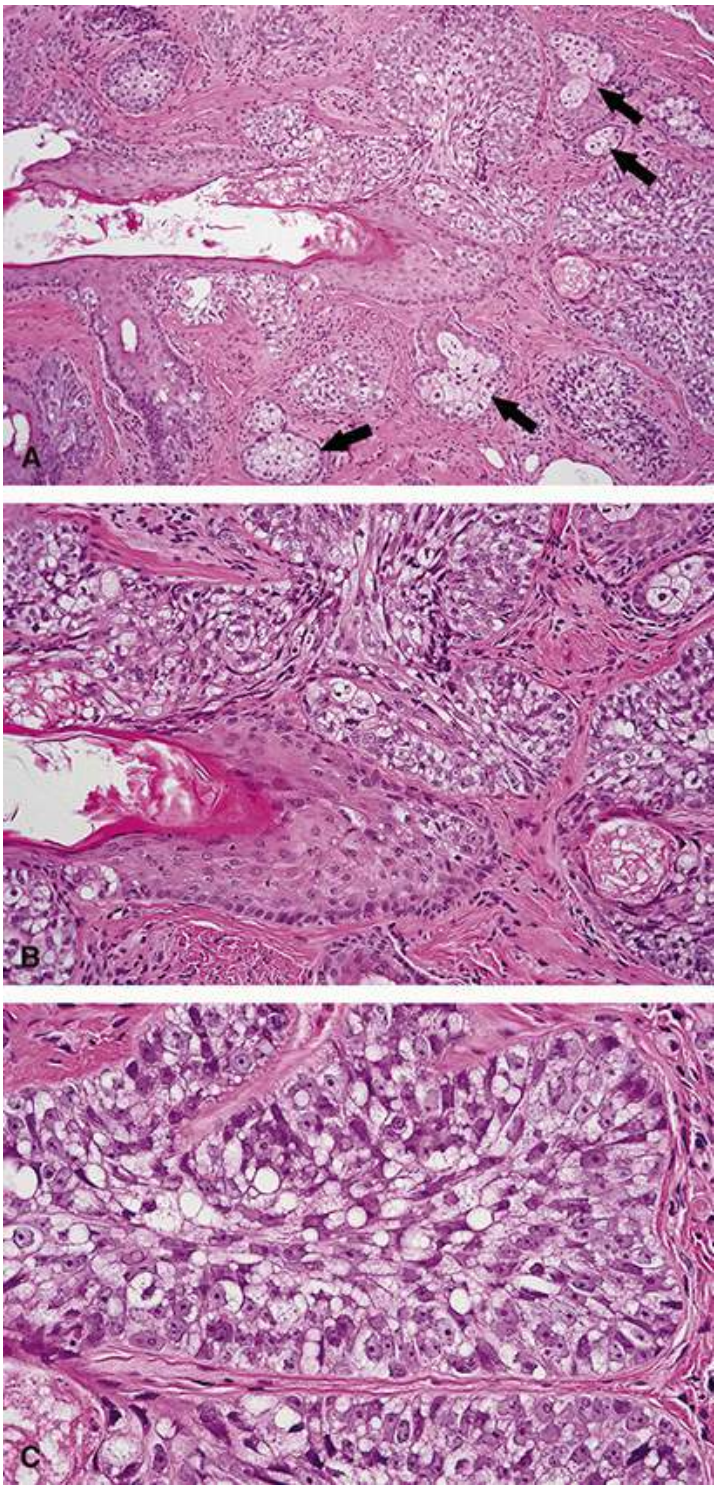

FIGURE 144.4 This well-differentiated (histologic grade 1) sebaceous carcinoma arose in the right lower eyelid meibomian glands of a man in his late 60s. A, Lobules of neoplastic cells are adjacent to a meibomian duct. The neoplastic lobules infiltrate among benign meibomian glands (arrows). B, The tumor lobules have sharp borders, with most cells having sebaceous differentiation. C, Cytoplasmic lipid vacuoles reflect the sebaceous differentiation of the neoplastic cells.

The differential diagnosis of more poorly differentiated SbC includes BCC and SCC, and there have been many attempts to define an immunohistochemical profile to differentiate these neoplasms with conflicting results (Table 144.1, sorted by publication date).[85,86,87,88,89,90,91,92,93,94,95,96,97] Based on our review of the literature and personal experience, we support the use of adipophilin, a protein associated with the surface of lipid droplets,[98] as the best discriminator of SbC from BCC and SCC.[87,92] In the elegant and thorough study by Milman and coworkers, they found "the expression of greater than 5% vacuoles and less than 95% granules to be 100% sensitive and 100% specific in distinguishing sebaceous carcinoma from other periocular and ocular carcinomas."[92]

Pathological staging of eyelid SbC is similar to that of other eyelid carcinomas except for Merkel cell carcinoma.[48] Pathology reports should ideally include factors of prognostic significance, including tumor size; vascular, lymphatic, or orbital invasion; histological grade (differentiation); presence or absence of multicentric origin (if discernible); presence or absence of a highly infiltrative pattern; and the presence or absence of intraepithelial spread.[70]

(Print pagebreak 968)

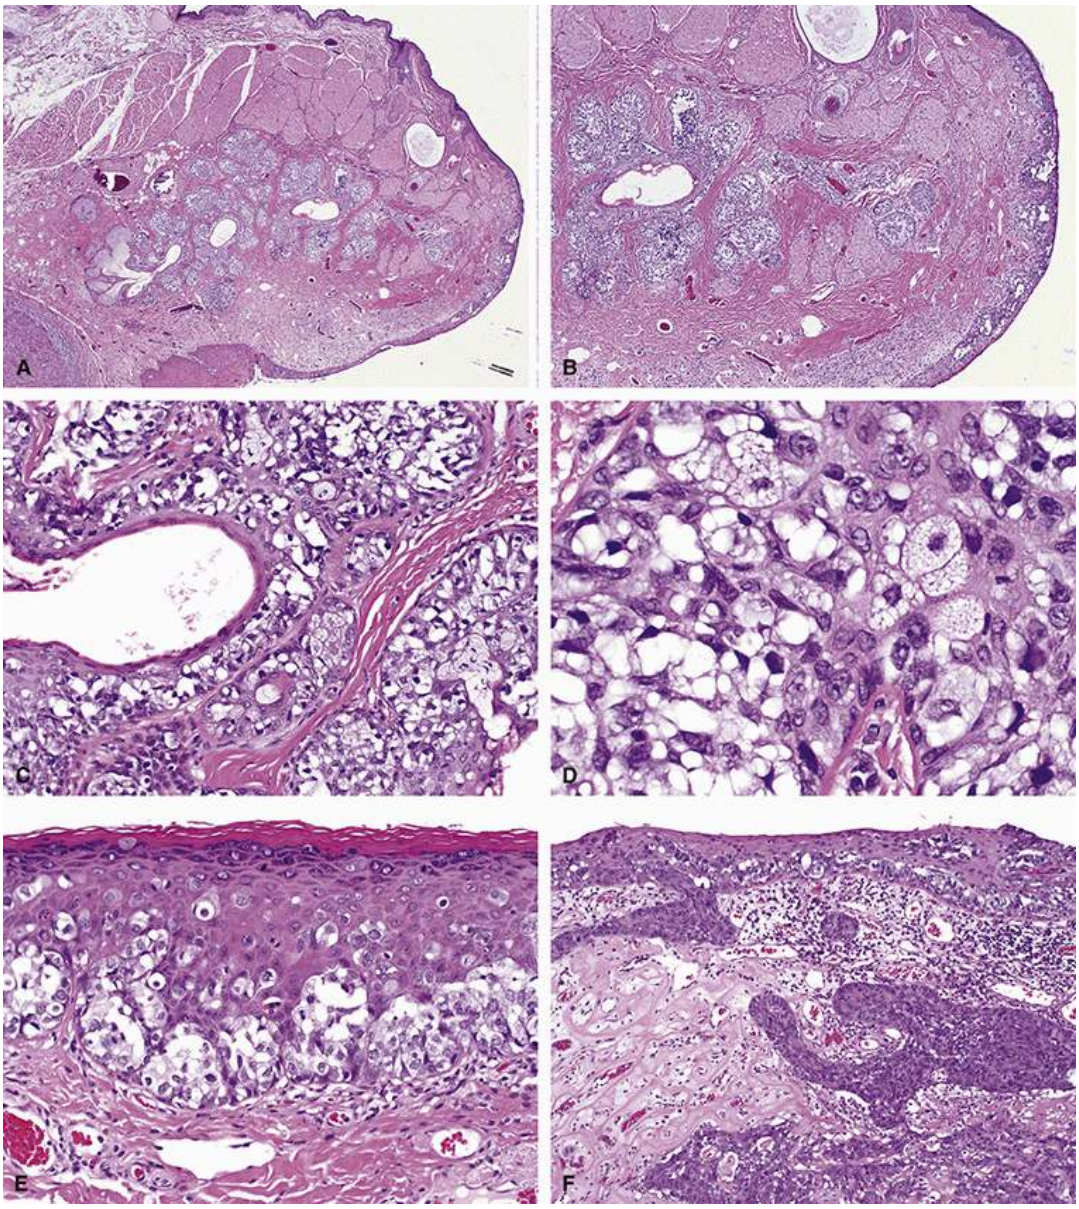

FIGURE 144.5 This well-to moderately differentiated sebaceous carcinoma developed from the right lower eyelid meibomian glands of a man in his early 50s. A, At low magnification, the tumor is in the tarsus around residual meibomian ducts. B, Intraepithelial sebaceous carcinoma extensively involves the eyelid margin. C and D, Tumor in the tarsus is a mixture of cells with sebaceous differentiation and others with minimal or no vacuolation. E, Intraepithelial carcinoma is a mixture of small nests and more superficial individual tumor cells (pagetoid spread). F, This area of the tumor has prominent conjunctival intraepithelial spread over poorly differentiated, moderately infiltrative sebaceous carcinoma that extended into the anterior orbit.

(Print pagebreak 969)(Print pagebreak 970)(Print pagebreak 971)

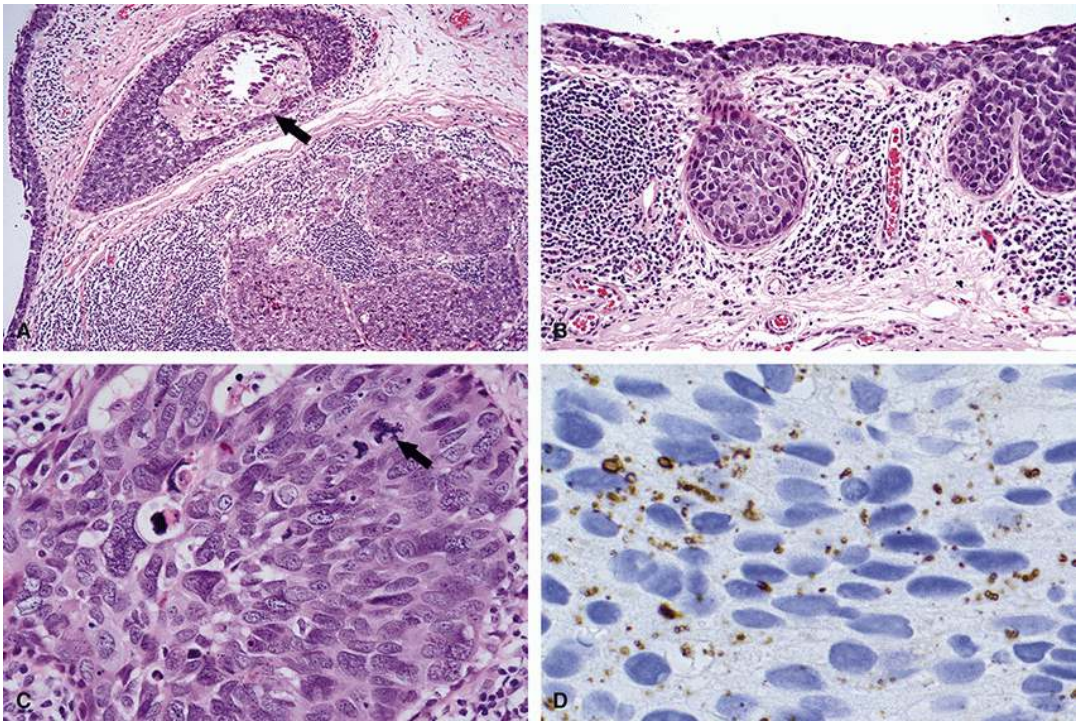

FIGURE 144.6 A man in his late 60s had poorly differentiated sebaceous carcinoma involving the left upper and lower eyelid epidermis and conjunctiva and the bulbar conjunctiva multifocally, with invasive tumor in both eyelids. A, Neoplastic cells replace the conjunctival epithelium and form lobules in the substantia propria. The lobule of invasive tumor at the top left (arrow) has central necrosis with calcification (comedocarcinoma). B, Poorly differentiated neoplastic cells replace the full thickness of the eyelid conjunctival epithelium and push into the substantia propria in several areas. The epithelial basement membrane is intact, indicating that the tumor is not invasive in this area. C, This lobule of invasive tumor has scant sebaceous differentiation and an abnormal mitotic figure (arrow). D, The tumor cells have small vacuoles and granules of staining using antibodies to adipophilin.

CHAPTER 145

Squamous Cell Carcinoma

Key Points

- Squamous cell carcinoma (SCC) is a malignant tumor of the squamous layer of cells of the epidermis, showing keratinocyte differentiation
- It is the second most common malignancy affecting the eyelid skin, accounting for 5% to 10% of such lesions
- The majority of SCCs arise from preexisting lesions such as actinic keratosis, Bowen disease, radiation dermatoses, burn scars, and chronic inflammatory lesions
- 60% to 90% of all SCCs contain mutations in the *p53* cell cycle regulator gene located on chromosome 17p13
- Clinically, SCC appears as a flesh-colored or erythematous, nodule or hyperkeratotic lesion with an indurated border and a central ulcer bed often covered with a thick crust or scale, which may bleed easily
- Mohs micrographic surgery and excisional biopsy with frozen section control are the most important surgical techniques
- Sentinel lymph node biopsy (SLNB) can be a valuable adjunct for the diagnosis of microscopic nodal metastases in some patients
- SCC is associated with local recurrence rates of 5% to 36%, lymph node metastasis in 3% to 24%, perineural invasion in 8% to 24%, and distant metastasis leading to patient death in 2% to 15% of cases

Squamous cell carcinoma (SCC) is a malignant tumor of the squamous layer of cells of the epidermis, showing keratinocyte differentiation. It is the second most common malignancy affecting the eyelid skin, accounting for 5% to 10% of such lesions.[1,2,3,4,5] SCC is much less common than basal cell carcinoma on the eyelids, but it is more aggressive and carries a greater potential for tissue destruction, local invasion, and distant metastatic spread. It may arise de novo where there is no histologic evidence of a preexisting benign lesion or from several premalignant lesions, such as actinic or solar keratosis, intraepidermal carcinoma (Bowen disease), radiation blepharopathy, or xeroderma pigmentosum. This tumor usually affects older individuals and has a predilection for fair-skinned individuals. De novo tumors tend to occur more commonly in younger individuals.[6]

Etiologic factors are similar to other epithelial tumors, such as basal cell carcinoma. Environmental factors that may contribute to its development include ultraviolet radiation (sun exposure), ionizing radiation, arsenic ingestion, hydrocarbons, psoralen plus ultraviolet A (PUVA) therapy for psoriasis, and the human papillomavirus. Intrinsic factors include xeroderma pigmentosum, oculocutaneous albinism, and immunodeficiency.[1,7] Chronic skin dermatoses, ulceration, and scarring also are associated with the development of this tumor.[7] Scarring of the skin is the most common intrinsic factor leading to SCC. In more extensive lesions, lymphatic spread and perineural orbital invasion are possible.

Etiology and Pathogenesis

The majority of SCCs arise from preexisting lesions such as actinic keratosis, Bowen disease, radiation dermatoses, burn scars, and chronic inflammatory lesions.[7] Tumors with no clinical or histologic evidence of a precursor lesion or cutaneous insult are referred to as arising de novo.[8]
This is considered a distinct variant of SCC, primarily occurring in Caucasians in both sun-exposed and sun-protected skin areas.

More than 60% to 90% of all SCCs contain mutations in the *p53* cell cycle regulator gene located on chromosome 17p13 that supports repair of DNA injury and induces apoptosis if the damage is lethal.[1] With *p53* loss by UVB damage, cell proliferation can lead to carcinogenic progression. Other abnormalities of genes regulating tumor suppression and keratinocyte proliferation and differentiation on chromosomes 3, 9, 13, and 17 have been reported.[1]

Clinical Presentation

SCC can present with diverse clinical manifestations ranging from small erythematous scaly patches to very large, ulcerated lesions. It is more common in males where it represents 65% to 75% of cases.[1,9] The age at presentation can be from 30 to 90+ years, with a median of about 65 years. The most common site of eyelid involvement is the lower eyelid, followed by the medial canthus, which together accounts for about 80% of all SCC eyelid tumors.[9] Compared with basal cell carcinoma, squamous cell tumors have a higher tendency toward ulceration and tend to affect the eyelid margin. They often begin as a premalignant lesion, such as actinic keratosis.[6] Early in the course of SCC, lesions can appear erythematous, thickened, and may be associated with loss of lashes (Figure 145.1). As the lesion advances, it can appear as an infiltrative, ulcerated lesion that bleeds easily and may be covered with scales or a thick crust (Figure 145.2). Occasionally, SCC can *(Print pagebreak 975) (Print pagebreak 976)* appear nodular with a central ulceration simulating a basal cell carcinoma, or papillomatous, cystic, pigmented, or even hyperkeratotic (Figure 145.3), and may be masked by an overlying cutaneous horn. Advanced tumors can become more aggressive and can invade the orbit by perineural spread or direct soft tissue extension (Figures 145.3 and 145.4).[10,11,12]

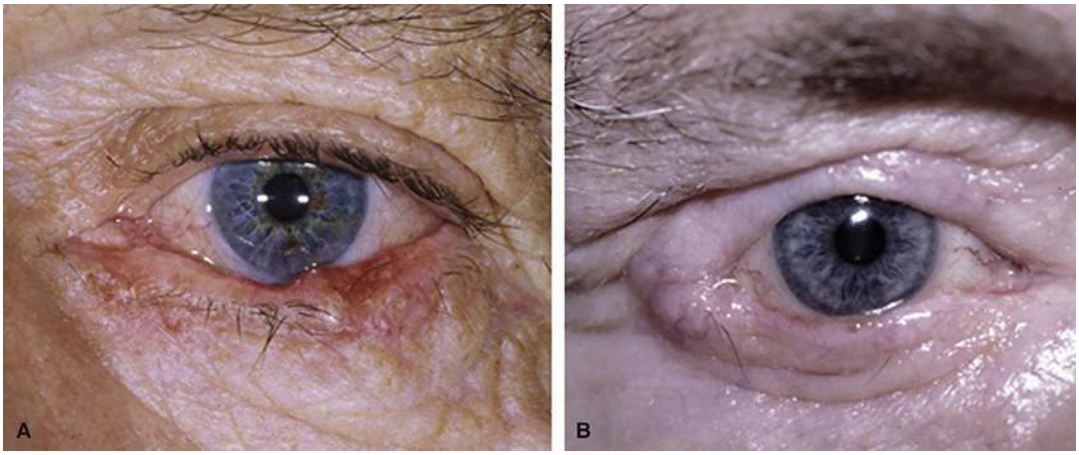

FIGURE 145.1 Early squamous cell carcinoma of the eyelid. A, Localized area of inflammation on the lateral lower eyelid margin. B, Thickening of upper and lower eyelids with complete madarosis.

FIGURE 145.2 Advanced squamous cell carcinoma (SCC). A, Deeply invasive, ulcerated lesion involving the upper and lower eyelids and lateral canthus. B, Ulcerated SCC of the conjunctiva and eyelids. C, SCC completely replacing the conjunctiva and eyelids. D, Multinodular SCC of the lower eyelid extending to the palpebral and bulbar conjunctiva.

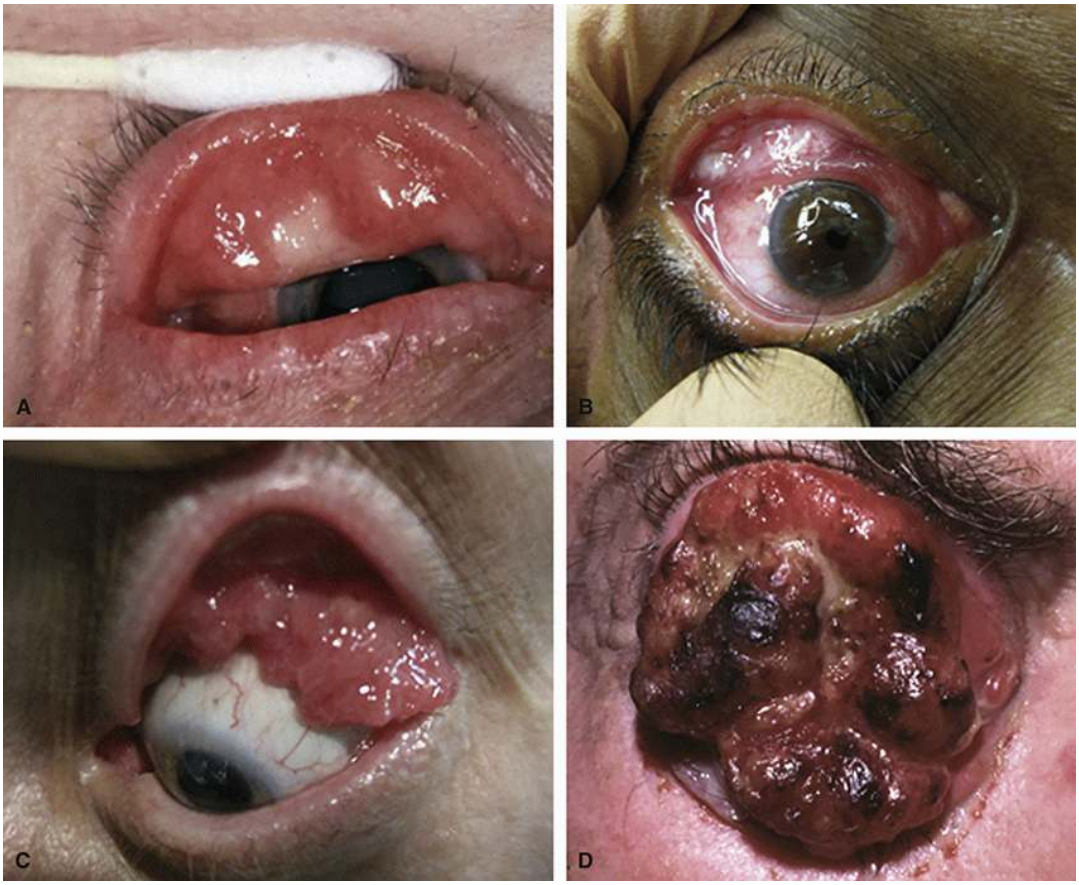

FIGURE 145.3 Conjunctival squamous cell carcinoma (SCC). A, Conjunctival intraepithelial squamous neoplasia (Bowen disease) of the upper eyelid tarsal surface. B, Sessile, minimally elevated SCC arising in the superior bulbar conjunctiva. C, Papillomatous SCC of the superior conjunctiva. D, Extensive conjunctival SCC replacing the globe and invading deeply into the orbit.

Intraepithelial squamous neoplasia, also known as Bowen disease, is a form of SCC that often arises in areas of chronic infection, inflammation, or burns.[6,13] It is confined to the epithelium, but with time it may break through the basement membrane to become invasive SCC. These lesions typically present as slowly enlarging, well-demarcated, vascularized, erythematous plaques with surface crusting or scaling, and they may occur anywhere on a skin surface or on mucosal surfaces. It may become ulcerated with a heaped-up rim. It often spares the basal epidermal layer and typically involves the follicular epithelium. Bowen disease commonly develops on sun-exposed areas of the body and may occur at any age in adults, mostly in patients over 60 years, and rarely before age 30. Although the literature frequently states that females are affected more commonly than males, among 94 cases, Foo et al[14] recorded a slight predominance for males in a ratio of about 1.5:1. When it involves the conjunctiva, it is referred to as conjunctival intraepithelial neoplasia and may present as flat to minimally elevated fleshy, sessile, gelatinous, or papillomatous masses that mostly involve the interpalpebral conjunctiva but may also involve the palpebral conjunctiva (Figure 145.4).[15] Suggested etiologies are similar to SCC and include irradiation, ultraviolet irradiation, radiotherapy, carcinogens such as arsenic, immunosuppression, chronic injury, or dermatoses such as chronic lupus erythematosus. Bowen disease may become invasive in 5% to 19% of cases, and 13% to 20% of those patients may develop distant metastases.[13]

(Print pagebreak 977)

FIGURE 145.4 Unusual presentations of squamous cell carcinoma (SCC) on the eyelids. A, A nodular lesion with a central ulcer crater simulating a basal cell carcinoma. B, Flat erosive plaques of the upper and lower eyelids with crusting and scales. C, SCC with eyelid thickening, madarosis, and crusted exudate. D, Extensive SCC presenting with massive hyperkeratosis and orbital invasion.

Treatment options for Bowen disease include photodynamic therapy, cryotherapy, topical 5-fluorouracil or imiquimod, and surgical excision.[16,17,18,19]

Differential Diagnosis

The differential diagnosis of SCC includes basal cell carcinoma, sebaceous cell carcinoma, Merkel cell carcinoma, Bowen disease, actinic keratosis, keratoacanthoma, inverted follicular keratosis, papilloma, pseudoepitheliomatous hyperplasia, seborrheic keratosis, trichilemmoma, fungal infection, and verruca vulgaris.

Treatment

Diagnosis requires a biopsy for histologic confirmation. Small lesions can be managed by primary excisional biopsy. Larger lesions should be managed with an initial incisional biopsy to establish the diagnosis, followed by more definitive management. A wide variety of treatment options have been employed including surgical and nonsurgical procedures.

Tumor clearance is the ultimate goal of surgery, and Mohs micrographic surgery or excisional biopsy with frozen section control are the most important surgical techniques intended to ensure tumor eradication. Mohs micrographic surgery is the surgical approach of choice and provides the highest cure rate with the most effective preservation of normal tissue.[20,21,22] In a comprehensive evaluation of the literature and analysis of outcomes, Landsbruy et al[23] found a recurrence rate following Mohs excision of 3.0%, marginally lower than any other treatment modality. Excisional biopsy with frozen section control is also an effective way to remove cutaneous tumors and can be performed, in conjunction with reconstruction, in a single surgical setting. The literature pooled recurrence rate using this surgical approach is 5.4%.

Adjuvant therapy is defined as additional lines of treatment, either radiation therapy or systemic treatment options (immunotherapy, epidermal growth factor receptor (EGFR) *(Print pagebreak 978)* inhibitors, chemotherapy and

electrochemotherapy), that are usually given with a curative intent, preferably after complete resection of the primary lesion, and with the aim to reduce the risk of recurrence or metastasis.[3] External beam radiotherapy has not generally been recommended as an initial treatment. However, several reports have shown good results in selected patients, with local control rates of 72% to 90% and 5-year tumor-specific survival rates of 80% to 90%.[24,25,26] It may be more useful in the management of advanced or recurrent lesions in the medial canthal region. Doses are in the range of 4000 to 7000 cGy. Recurrence rates of 3% to 12% with radiation have been reported.

Brachytherapy with iridium-192 interstitial wires has been reported, delivered at total doses of 40 to 70 Gy. Results show that this can achieve good local control rates of 90% to 97%, with excellent cosmetic and functional results comparable to surgery.[27,28]

Cryotherapy has been reported to be safe and effective in treating nonmelanotic skin cancers with 30-year cure rates as high as 99%.[29] Fraunfelder et al[30] reported a recurrence rate of 2% for lesions <10 mm in diameter, which rose to 9.5% for lesions >10 mm. Cryotherapy is more often used to treat nonperiorbital lesions, but when used on the eyelid, notching of the eyelid margin, malpositions of the eyelid such as ectropion, symblepharon formation with fornix foreshortening, and pigmentary changes of the eyelid skin are possible complications.[31]

Recently, a better understanding of SCC mutational burden, and novel discoveries of tumor molecular targets have promoted the use of promising systemic immunotherapeutic agents like the PD-1 inhibiting antibody; cemiplimab.[3,25] However, when compared to radiotherapy, the results of these agents are still suboptimal in metastatic, recurrent, or extensive lesions not amenable to surgery.[25] Imiquimod is a synthetic imidazoquinoline amide derivative that acts as an immune response modifier that activates immune cells via toll-like receptor 7. It biases a T-helper cell-mediated immune response to initiate a cascade leading to the induction of cytokines directed against some cancer cells. Most published reports of this agent in eyelid tumors involve basal cell carcinoma, but some preliminary studies on nonperiorbital SCC have shown it to be less effective than surgery, but more effective than other nonsurgical procedures.[32,33,34]

Sentinel lymph node biopsy (SLNB) can be a valuable adjunct for the diagnosis of microscopic nodal metastases in some patients. Lhote et al[35] reported a rate of positive SLNB of 14%, primarily associated with poorly differentiated tumors, but relapse-free survival and overall survival were not affected by sentinel lymph node status. They suggested that SLNB is not mandatory in the management of SCC and should be used only in patients with higher risk factors, such as poorly differentiated tumors.

Prognosis

SCC is potentially a very aggressive skin tumor.[36] When neglected, it can follow a fulminant course destroying the eye and invading deep into the orbit.[37] It is associated with local recurrence rates of 5% to 36%, lymph node metastasis in 3% to 24%, perineural invasion in 8% to 24%, and distant metastasis leading to patient death in 2% to 15% of cases.[35,38,39,40]

In a study of 594 SCCs, Breuninger et al[41] showed that no tumors smaller than 2 mm in thickness metastasized; lesions between 2 and 6 mm in thickness had a metastatic rate of 4.5%, and tumors >6 mm in depth metastasized at a rate of 15%. Rowe et al[42] showed that poorly differentiated SCC has a much higher rate of metastasis of 32.8% compared with well and moderately differentiated tumors that had a rate of 9.2%. Perineural invasion carries a poor prognosis with higher rates of recurrence up to 47% and of metastasis up to 35% to 80%.[41,42,43,44,45]

Other risk factors for poor prognosis and metastasis include larger tumor size, greater thickness, invasion beyond the subcutaneous fat, poor histologic differentiation, head and neck location, and immunosuppression.[40,42] The rates of lymph node metastasis range from 0% to 24%.[6,39] SCC also has a greater tendency for perineural invasion with extension to the orbit and brain along branches of the trigeminal nerve, reported in 2% to 43% of cases.[8,9,10,39,46,47]

Tumors arising from actinic keratosis appear to have a more favorable prognosis, with a reported metastatic rate of less than 2%.[5,6] De novo SCC tends to be more aggressive in behavior with a rate of regional and distant metastasis of 8% to 14%.[48]

Predisposing Genetic Syndromes

Xeroderma Pigmentosum

As with basal cell carcinoma, xeroderma pigmentosum is associated with a significantly higher risk of cutaneous SCC.[49] This is an autosomal recessive disorder characterized by extreme sensitivity to UV radiation exposure and induced carcinogenesis, leading to a

several thousand-fold increased risk of skin cancer (see Chapter 125). Patients present with photosensitivity, severe sunburns, and chronic skin changes such as actinic damage, poikiloderma, and nonmelanoma skin cancers. The disease can also be associated with mental disability, deafness, and hyporeflexia. Ocular findings include keratitis, iritis, and choroid malignant melanoma. Xeroderma pigmentosum is caused by mutations in nucleotide excision repair (NER) genes that function in identifying and removing UV-induced cutaneous DNA damage.

Dyskeratosis Congenita

Dyskeratosis congenita is a very rare X-linked genetic disorder associated with a significant risk of SCC. Although in most cases the causative mutation is unknown, it has been associated with numerous genetic conditions that are responsible for the maintenance of telomeres, essential for genetic stability, and suppression of cancer development.[49] Patients typically present in childhood and may have mucosal and conjunctival leukoplakia, nail dystrophy, bone marrow dysfunction, cytogenetic instability, reticulate hyperpigmentation, and a predisposition to malignancy. Patients may also have alopecia, premature gray hair, and palmoplantar hyperkeratosis. SCCs often arise from leukoplakic plaques.

(Print pagebreak 979)

Epidermolysis Bullosa

Epidermolysis bullosa is a rare disorder that presents in childhood and results in skin fragility, blistering, and nonhealing wounds. Affected patients are at increased risk of skin cancer. It is associated with several genetic mutations, including those affecting collagen VII and various keratin and integrin genes.[49] There are 4 major types of the disease based on the level of skin cleavage and 30 distinct phenotypic subtypes. SCC often occurs in patients with recessive dystrophic epidermolysis bullosa, in areas with chronic skin blisters, nonhealing wounds, and scars. These are aggressive tumors associated with significant morbidity and mortality.

Histopathology

SCC of the eyelid skin[50,51] resembles that involving other body sites.[52,53] There were 82 cases of SCC (15 in situ SCC and 67 invasive SCC) in Deprez and Uffer's study of 5504 eyelid skin tumors, accounting for 9.3% of the malignant neoplasms.[54] In situ SCC has thickened epidermis with disorganized cytologically atypical keratinocytes involving the entire thickness of the epidermis (Figure 145.5).[13,53,55,56,57] Parakeratosis may be minimal or exuberant with cutaneous horn formation.[57] In situ SCC of the eyelids usually arises in a background of actinic keratosis. The histological appearance of invasive SCC depends on its degree of differentiation, with most tumors classified as well to moderately differentiated.[53] Well-differentiated SCC (Figure 145.6) has enlarged polygonal tumor cells with abundant eosinophilic cytoplasm, dyskeratotic cells with keratin pearl formation, and readily apparent intercellular bridges.[51,55,56,57] Moderately differentiated SCC has less prominent keratinization and more cellular pleomorphism than well-differentiated SCC.[55] Poorly differentiated SCC has tumor cells with markedly enlarged pleomorphic nuclei, frequent mitoses, atypical mitotic figures, and little or no keratinization.[55,56,57] Pathological staging *(Print pagebreak 980)* of eyelid SCC incorporates tumor size, tarsal plate invasion, and invasion of adjacent ocular or orbital structures.[58] SCC variants reported in the eyelid include spindle cell SCC,[50,51] acantholytic (adenoid) SCC,[50,51,59] and basal cell-signet ring SCC.[60] The lesions most frequently misdiagnosed as eyelid cutaneous SCC are sebaceous carcinoma, basal cell carcinoma, seborrheic keratosis, inverted follicular keratosis, pseudoepitheliomatous hyperplasia, adnexal carcinoma, and keratoacanthoma.[4,61]

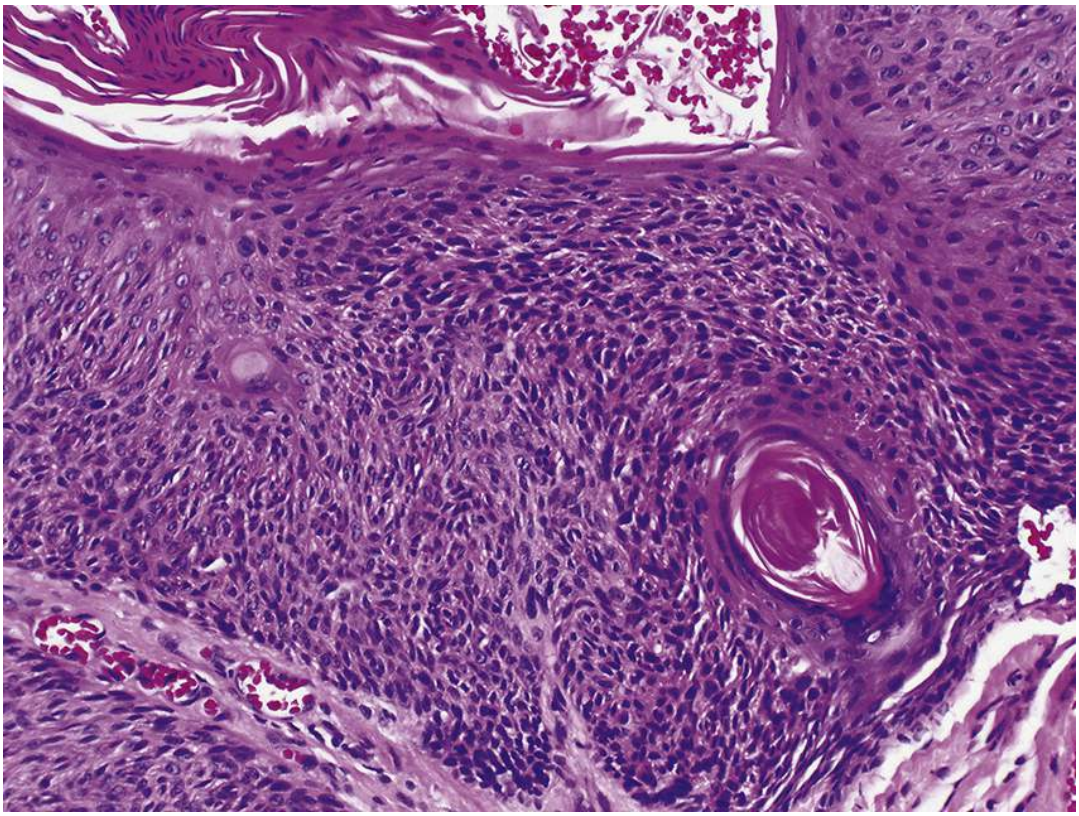

FIGURE 145.5 In situ squamous cell carcinoma arose in a background of actinic keratosis in the right upper eyelid of a man in his early 70s. Cytologically atypical keratinocytes extend through the entire thickened epidermis. The neoplastic cells lack their normal polarity. The surface of the tumor has a layer of parakeratosis.

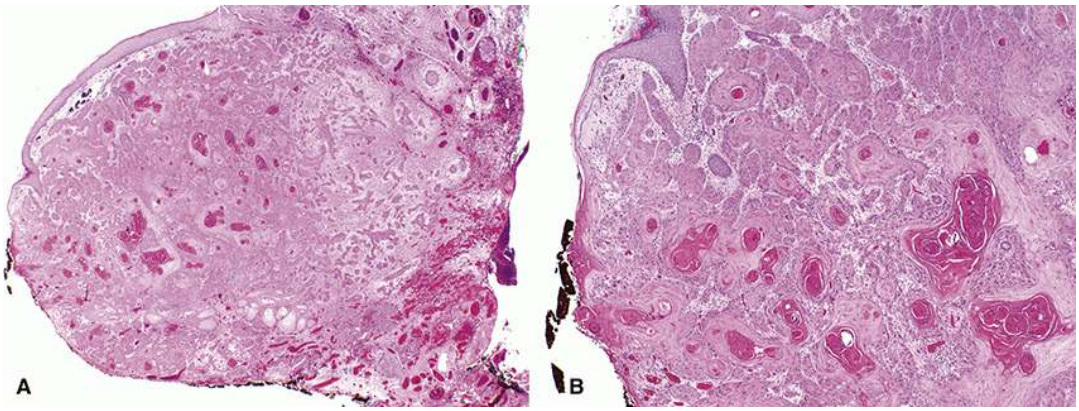

FIGURE 145.6 A, This well-differentiated squamous cell carcinoma (SCC) involved the full thickness of the right lower eyelid in a man who was immunosuppressed following solid organ transplantation. B, The tumor arose along the eyelid margin in an area of in situ SCC. Numerous keratin pearls are evident. C, Squamous cell carcinoma invaded the tarsus with tumor nests adjacent to meibomian glands. D, The tumor cells are pleomorphic with brightly eosinophilic cytoplasm and form keratin pearls, solid nests, and irregular islands. The tumor stroma has an infiltrate of macrophages, lymphocytes, and eosinophils. E, Intercellular bridges are prominent in this tumor island. F, Tumor invades the perineurium and parenchyma of a nerve.

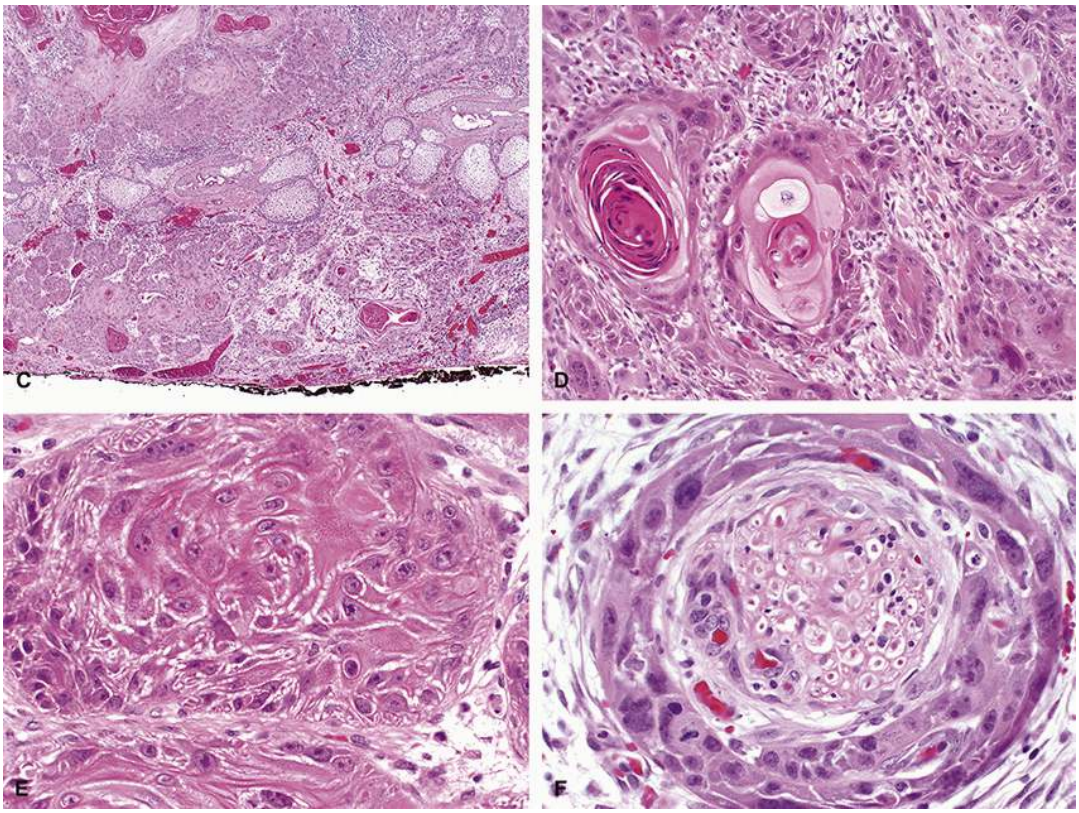

FIGURE 145.6 Continued

There are only rare reports of SCC arising from the palpebral conjunctiva (Figures 145.7 and 145.8),[62,63] including one example of a clear cell SCC.[64] The paucity of reports of palpebral conjunctival SCC prohibit generalizing their histopathological findings, but these tumors will presumably exhibit varying degrees of differentiation similar to bulbar conjunctival SCC.[65]

CHAPTER 146

Trichilemmal Carcinoma

Key Points

- Trichilemmal carcinoma (TC) derives from the outer hair root sheath
- The pathogenesis of TC is not completely understood, but risk factors include UV and ionizing radiation, previous trauma, scars, genetic disorders, and immunosuppression
- Lesions generally present as an asymptomatic tan or flesh-colored solitary, nodular, polypoid, or exophytic lesion, occasionally with ulceration, telangiectasias, and scales
- The recommended treatment of TC is complete surgical excision with wide margins
- Neoadjuvant radiotherapy has been proposed to shrink the tumor before definitive surgical resection, and chemotherapy has been used for distant metastases with limited success
- TC does not usually recur and has a low metastatic potential, but patients with metastasis currently have a poor prognosis

Cutaneous adnexal carcinomas are very rare and represent only 0.005% of all skin tumors.[1] These neoplasms have a heterogeneous origin from different adnexal hair follicle structures and originate from a variety of undifferentiated stem cells.[2] Hair follicle malignancies comprise only 1% of all skin adnexal carcinomas.[3]

Anatomically, the mature hair follicle is divided into several segments distinguished by their vertical position and by their cellular organization and morphology.[4] The deepest portion of the follicle is the bulb, consisting of a central dermal papilla of mesenchymal tissue. This is surrounded by the hair matrix cells of rapidly proliferating keratinocytes that produce the hair shaft. The stem and isthmus are the lowermost and lower portions of the follicle between the bulb and the upper portion called the infundibulum. An inner root sheath is continuous along the bulb and the stem, disappearing at the isthmus, and forms a channel for the growing hair shaft. The outer root sheath is an extension of the epidermal basal layer and envelopes the entire hair follicle. Its lower segment serves as a reservoir of stem cells.

Hair follicle adnexal tumors constitute a large variety of rare benign and malignant neoplasms that arise from the various segments and cellular components of the hair follicle. Trichoblastoma and trichoblastic carcinoma arise from hair germ cells. The hair matrix gives rise to pilomatrixoma (calcifying epithelioma of Malherbe) and pilomatrix carcinoma. Trichilemmoma, proliferating trichilemmal tumors (PTTs), and trichilemmal carcinoma (TC) derive from the outer hair root sheath. Trichofolliculomas are considered to be hamartomas with follicular differentiation, although some authors consider them to represent an abortive differentiation of pluripotent skin cells toward hair follicles.[5]

Currently, there is no generally accepted classification of hair follicle tumors. In 1976, Headington first proposed a classification based on histogenetic features.[6] Mehregan[7] later simplified this into three subgroups: hyperplasias, adenomas, and epitheliomas. More recently, Sia et al[8] published a basic classification of benign and malignant hair follicle tumors according to their cellular origin, as hair germ tumors, hair matrix tumors, and external hair root sheath tumors. In that same report, the authors reviewed 19 previously published case reports of malignant hair follicle tumors occurring in the periorbital region, and among these, there were nine cases of pilomatrix carcinoma, six cases of TC, three cases of malignant proliferating trichilemmal tumor (MPTT), and one case of trichoblastic carcinoma.[8]

The pathogenesis of hair follicle malignant tumors is largely unknown, and it is unclear whether they arise de novo or from preexisting benign lesions. One of the lesions derived from the outer hair root sheath is the trichilemmal (pilar) cyst,[9] which is believed to give rise to PTT with solid/cystic trichilemmal differentiation. Ninety percent of PTTs occur on the scalp, but they have also been found on the forehead, nose, back, chest, abdomen, buttocks, elbow, wrist, mons pubis, and vulva.[10,11] Most patients are female (84%), with a mean age of 65 and a range of 28 to 88 years, and most cases occur in the sixth and seventh decades of life.[9]

Malignant transformation of PTT to MPTT occasionally occurs, heralded by sudden rapid growth,[12,13] an aggressive biologic behavior, and a high rate of recurrence and metastasis. MPTTs are closely related to TCs and occur more commonly in areas with excess hair growth, such as lanugo hair follicles of the bald scalp, and less commonly in areas devoid of nonterminal hair.[14] The gross appearance can range from a smooth mobile nodule to a large lobular or multiple cystic lesion and tends to have more extensive hyperkeratosis and a greater number of cysts compared to TC.

The trichilemmoma is another benign lesion of the outer hair root sheath that is believed to be a precursor of TC.[15] Trichilemmoma is more commonly found on sun-exposed areas of the skin, particularly the face, forehead, and scalp. This distribution is likely related to the higher concentration of skin appendages in these areas.[16] Malignant degeneration may result in TC, first described by Headington in 1976[6] as *(Print pagebreak 985)* "a histologically invasive, cytologically atypical clear cell neoplasm of adnexal keratinocytes that is in continuity with the epidermis and/or follicular epithelium." The existence of TC has been a subject of debate because of its resemblance to clear cell squamous cell carcinoma, but more recent investigations have confirmed its existence as a distinct entity.[17]

Although TC is characterized histologically with features characteristic of malignancy, more benign-appearing lesions can behave aggressively, and malignant-appearing ones can show a relatively benign course.[18] In general, these tumors run an indolent course with a low rate of recurrence following surgical excision and a low metastatic potential. However, despite being commonly regarded as having an indolent clinical course, metastases and multiple recurrences have been reported.[15,19,20,21,22,23,24]

Etiology and Pathogenesis

The pathogenesis of TC and the malignant proliferative trichilemmal tumor is not completely understood. Many risk factors have been identified including UV and ionizing radiation, previous trauma, scars, genetic disorders, and immunosuppression. TCs are usually found on sun-exposed surfaces of elderly patients, suggesting that UV radiation plays a role in their pathogenesis. Chan et al[25] suggested a role for ionizing radiation in a case of TC arising in the supraclavicular region of a patient who had received many chest X-rays and CT scans to this area. Hamman et al[26] summarized 103 reported cases associated with a wide variety of pre-existing conditions. Ko et al[27] reported two cases arising in a burn scar. Reis et al[28] and Mane et al[29] reported cases of TC in young patients with xeroderma pigmentosum. Molecular studies of TC have been very limited, but Ha et al[30] evaluated four patients and found 3 (75%) with *TP53* and *P53* mutations or deletions, 2 (50%) with *TACC3-FGFR3* and *ROS1-GOPC* gene fusions, and isolated cases of *NRAS* and *PTEN* mutations or deletions.

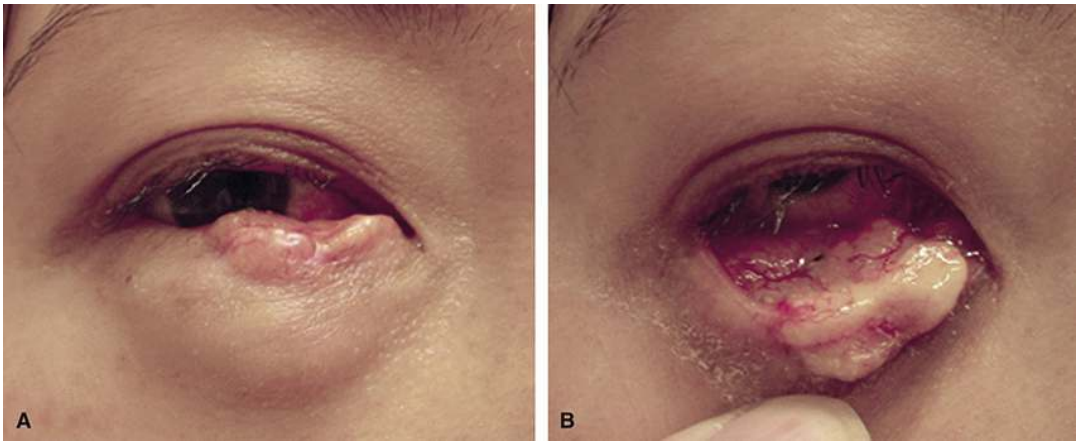

FIGURE 146.1 A, Trichilemmal carcinoma on the lower eyelid margin. B, Same patient as in A, showing the conjunctival surface. (A and B, Courtesy of Dr. Yoon Duck Kim.)

Clinical Presentation

Lesions of TC generally present as a painless tan or flesh-colored solitary, nodular, polypoid, or exophytic lesion, occasionally with ulceration on the face, scalp, and neck[26] (Figure 146.1). It may be associated with madarosis and can have telangiectasias, scales, or rolled borders that resemble basal cell carcinoma, squamous cell carcinoma, keratoacanthoma, or a proliferating pilar cyst.[28,31] Occasionally areas of ulceration and bloody discharge are seen. On presentation, lesions are generally about 2 cm in size but can range from 5 mm to 7.5 cm.[26]

Very few cases of TC have been reported on the eyelid.[26,31,32] Hamman and Jiang[26] reviewed 103 cases of TC from the literature and found 50% on the face. Among these, 18% were on the cheeks, 10% on the forehead, 9% on the nose, 6% on the temple, and 4% on the eyelids. The remaining cases were on the scalp, ears, neck, or elsewhere on the body. The mean age at presentation was

70 years (range 9-93), with less than 5% occurring in patients younger than 40 years.[26] The male to female ratio was about 3:2. Lesions of TC are usually present for less than 1 year before diagnosis, although some lesions have had a reported duration as little as 2 months or as much as 50 years.[33,34]

Differential Diagnosis

The overall clinical appearance is similar to other cutaneous lesions, especially malignancies so that the differential diagnoses of TC includes squamous cell carcinoma, basal cell carcinoma, keratoacanthoma, pilomatrixoma, dermatofibrosarcoma protuberans, cylindroma, angiosarcoma, seborrheic keratosis, chalazion, and epidermoid cyst.[26,35,36,37] The correct diagnosis is usually not suspected until the biopsy and the tumor is differentiated on histopathology.

(Print pagebreak 986)

Treatment

The recommended treatment of TC is complete surgical excision with wide margins.[26,33,34] Recurrences are uncommon but may be seen following incomplete resections. In a review of 103 TC cases from the literature, 35 cases were treated with surgical excision with a mean follow-up of 33 months.[26] A local recurrence was reported in three cases, and two cases experienced three recurrences despite histologically free margins.[26] Although rare, metastatic disease has been reported even after wide local excision.[22] Mohs micrographic surgery may offer better margin control, especially in cosmetically and functionally important areas such as the eyelids. Mohs micrographic surgery also limits excessive excision of healthy tissue.[15,37,38,39,40,41]

Neoadjuvant radiotherapy for hair follicle malignancies has been proposed to shrink the tumor before definitive surgical resection.[39,42] Chemotherapy has been used when distant metastases were found but has been reported to have limited success.[39] Although chemotherapy similar to regimens used for squamous cell carcinoma has been used, there is no established protocol for metastatic TC.

Prognosis

Only a limited number of studies investigating TC are available, so that prognosis is difficult to estimate.[43] Although TC has a low metastatic potential and does not usually recur, local recurrence and deep invasion are possible.[32] Local cervical lymph node and distant metastases have rarely been reported.[21,33,34] But since there is no optimal treatment for TC metastasis, and there is no established chemotherapy regimen for metastatic disease, patients with metastases currently have a poor prognosis.[22] Although supported by limited data, the risk of recurrence and lymph node metastasis appears to be similar to that of squamous cell carcinoma.[43]

Histopathology

The histopathological features of TC[44] are best described in three studies examining 7-10 tumors (Figure 146.2).[19,28,31] Swanson and coworkers studied 10 tumors and noted 7 diagnostic features: (1) TCs are centered on and often expand pilosebaceous units; (2) TCs exhibit varying degrees of cytological atypia but always have nuclear enlargement with hyperchromasia, prominent nucleoli, and mitoses ranging from 4 to 39 per 10 high-power (400×) microscopic fields; (3) tumor cells with palely eosinophilic or clear cytoplasm due to glycogen accumulation usually predominate; (4) there is trichilemmal keratinization with an abrupt transition from neoplastic cells to keratin without a granular layer; (5) tumors have an abrupt interface with the adjacent normal epidermis, i.e., there is not a transitional zone of dysplastic epidermis; (6) neoplasia involved the interfollicular epidermis near the center of the tumors in seven *(Print pagebreak 987)* cases, and seven tumors were ulcerated; and (7) all cases have "conspicuous" dermal actinic elastosis.[19] Boscaino and colleagues studied seven TCs and noted sharply circumscribed lobular neoplasms in continuity with the epidermis, neoplastic cells with clear glycogen-rich cytoplasm, trichilemmal keratinization, and high mitotic rates.[31] The basal layer of neoplastic lobules "showed a tendency toward palisading and was associated with a prominent basement membrane."[31] Four of the tumors were intraepithelial, and three were invasive.[31] Reis and collaborators examined eight invasive tumors, and all TCs had invasive lobules and strands composed mainly of polygonal cells with glycogen-rich clear cytoplasm, trichilemmal keratinization, many mitoses, and nuclear atypia varying from mild to severe.[28] The tumors all displayed multiple connections with the overlying epidermis with replacement by neoplastic cells.[28] TCs lack immunoreactivity for carcinoembryonic antigen[28,31] and S100 protein.[28] Expressions of cytokeratins 1, 10, 14, and 17 suggest differentiation toward follicular infundibulum.[45]

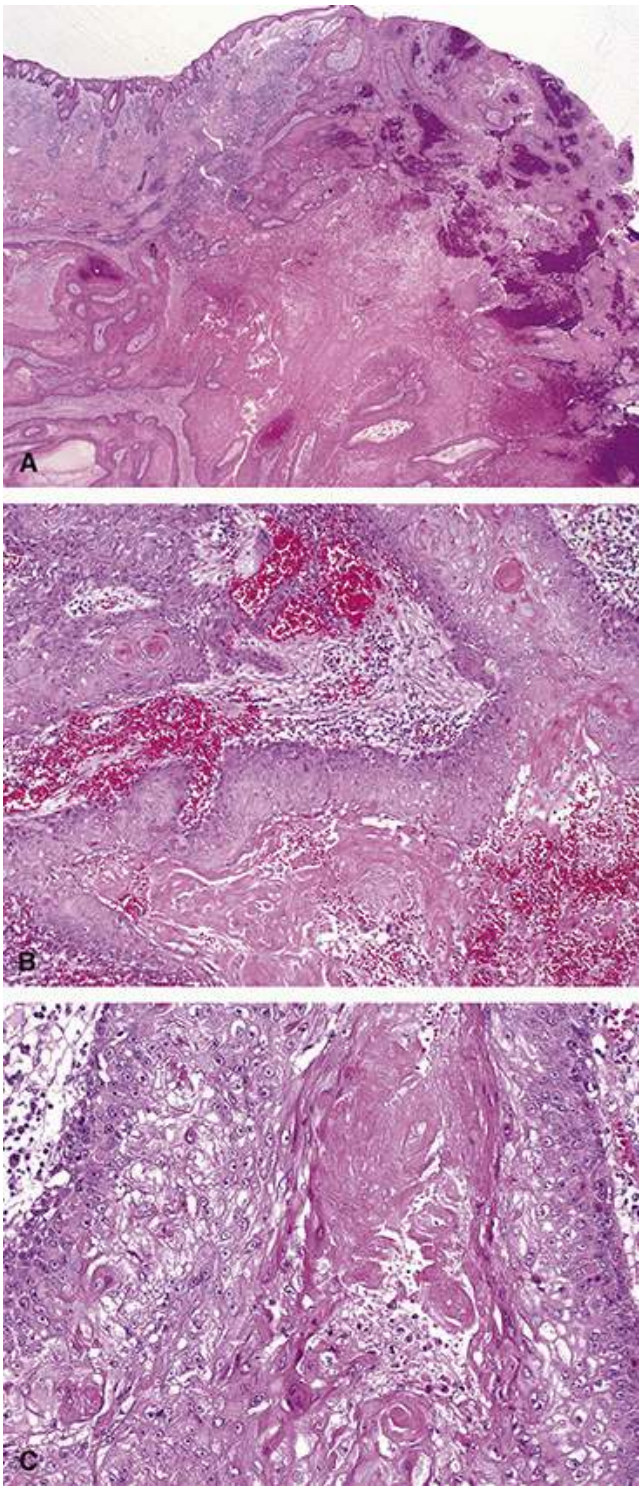

FIGURE 146.2 A, Trichilemmal carcinoma of the scalp showing an abrupt transition from the normal epidermis to an ulcerated, hemorrhagic, invasive tumor composed of lobules and interconnecting cords. B, The interdigitating tumor cords are in a desmoplastic and hemorrhagic stroma. Tumor cells with pale eosinophilic or clear cytoplasm due to abundant cytoplasmic glycogen predominate. The tumor cords have areas of keratinization. C, Tumor cells with clear cytoplasm are evident at higher magnification. Trichilemmal keratinization features an abrupt transition from neoplastic cells to keratin without a granular layer.

CHAPTER 147

Undifferentiated Pleomorphic Sarcoma (Malignant Fibrous Histiocytoma)

Key Points

- Undifferentiated pleomorphic sarcoma (UPS) describes a soft tissue tumor of primitive mesenchymal origin that involves deep skeletal muscle, fascia, and adipose tissue
- The pathogenesis is unclear, but translocations and gene fusions common in the pathogenesis of other sarcomas have not been found to play a role in the pathogenesis of UPS
- Ionizing radiation appears to be an etiologic factor, and has been reported following radiotherapy for breast carcinoma, malignant lymphoma, cervical carcinoma, and brain tumors
- Clinically, UPS presents as a rapidly enlarging, painless soft tissue swelling and a palpable brownish indurated mass that may be ulcerated with deep invasion of muscles, nerves, periosteum, and bone
- The primary treatment is radical surgical excision with wide margins along with dissection of regional lymph nodes
- Radiotherapy and chemotherapy are of limited benefit
- The recurrence rate is high and 28% may develop distant metastasis with an overall 5-year survival between 35% and 70%

Undifferentiated pleomorphic sarcoma (UPS) was established as a distinct entity by Kauffman and Stout in 1961.[1] It has most often been referred to in the literature as malignant fibrous histiocytoma (MFH) and less frequently as a malignant solitary fibrous tumor. In recent years it has been considered to represent a heterogeneous group of undifferentiated neoplasms. In 2002, the World Health Organization (WHO) declassified MFH as a diagnostic entity and renamed it "undifferentiated pleomorphic sarcoma."[2] This terminology has been supported by evidence suggesting that these tumors represent a final common pathway in tumors progressing toward undifferentiation.[3,4,5,6] However, the term "malignant fibrous histiocytoma" is still commonly used in the literature.

UPS describes a group of soft tissue tumors of primitive mesenchymal origin that involve deep skeletal muscle, fascia, and adipose tissue.[7] However, it can also rarely involve many other tissues such as the heart, pancreas, stomach, and maxillary sinuses. It is the most common soft tissue sarcoma of adulthood but also can be seen in young adults and children, although it is rare in patients younger than 20 years old.[8,9,10,11] Ten percent of these tumors occur on the head and neck, and although it is well known in the orbit,[12,13,14] it only rarely affects the eyelids. When it is seen in the eyelid, it is usually either secondarily extended from an orbital lesion or occurs as a simultaneous independent occurrence. Less than a dozen cases of primary UPS of the eyelid have been described to date,[15,16,17,18,19,20,21,22] and one case of a locally aggressive fibrous histiocytoma was reported in the medial canthus.[23] UPS is also occasionally reported in the conjunctiva.[24]

Etiology and Pathogenesis

Soft tissue sarcomas comprise a large heterogeneous group of tumors that often exhibit aggressive behavior with high morbidity and mortality. Many sarcomas arise due to chromosomal aberrations or mutations in mesenchymal progenitor cells. However, the exact cellular origin of most of these tumors remains uncertain.[25] Genetic abnormalities in sarcomas are common and are divided into two types. The first includes tumors that are characterized by specific genetic mutations, simple karyotypes, and translocations that can result in the formation of fusion genes that can alter the regulatory proteins or transcription factors in tumor cells and contribute to tumorigenesis.[26] The second type includes sarcomas with no specific mutations or chromosomal aberrations, but instead involves complex karyotypes with copy number genetic losses of tumor suppressor genes and amplification of proto-oncogenes that favor oncogenesis.[27] Interestingly, a variety of translocations and gene fusions common in the pathogenesis of other sarcomas have not

been found to play a role in the pathogenesis of UPS.[26,28]

A well-known etiologic factor for UPS is ionizing radiation, and this has been reported following radiotherapy for breast carcinoma, malignant lymphoma, cervical carcinoma, and brain tumors.[29] The most common radiation-induced sarcomas (RIS) are osteogenic sarcoma (36.4%) and UPS (33.3%).[29] The mechanisms resulting in the oncogenesis of RIS involve damage to DNA that results in genomic instability.[30] Radiotherapy has been used in the treatment of head and neck neoplasms, but radiation-induced secondary sarcomas in this region are uncommon, and the annual incidence has been estimated to be only 0.06% to 0.17%,[31,32] compared to an incidence of 1.6% reported for the entire body.[33] Nevertheless, UPS of the head and neck has been described after irradiation for nasopharyngeal tumors and retinoblastoma.[34,35,36,37,38,39,40]

(Print pagebreak 990)

Clinical Presentation

The age at presentation for UPS can range from childhood to the ninth decade (range, 6-87 years), with a mean of about 67 years.[41] For eyelid lesions, the few reported cases range in age from 70 to 90 years. The duration of symptoms is variable from 1 month to 20 years (mean = 31 months) for benign fibrous histiocytoma to 1 month to 5 months (mean = 3.4 months) for malignant UPS.[7] Overall, UPS shows a high histologic grade, and 90% have deep invasion at the time of presentation.[42] Eyelid and periorbital involvement are rare with less than a dozen cases reported.[16,17,18,19,20,21,22,23,24,34] Females are involved more frequently than males with a F:M ratio of 4:2.

Presentation is typically with a rapidly enlarging, painless soft tissue swelling and a palpable brownish indurated mass on the eyelid or conjunctiva (Figures 147.1 and 147.2), and that may rarely be ulcerated. There may be deep invasion of muscles, nerves, periosteum, and bone, or even extension into the orbit.

FIGURE 147.1 Large nodular undifferentiated pleomorphic sarcoma on the lower eyelid mucocutaneous border. (Courtesy of Dr. Timothy Sullivan.)

FIGURE 147.2 Undifferentiated pleomorphic sarcoma arising in the palpebral conjunctiva. (Reprinted with permission from Gounder P, Lamb M, Vinciullo C, de Sousad JL. Malignant fibrous histiocytoma masquerading as pyogenic granuloma. *Orbit*. 2017;36:122-123.)

Differential Diagnosis

Clinically, UPS has been confused with inflamed pterygium, juvenile xanthogranuloma, nodular fasciitis, foreign body granuloma, solitary fibrous tumor, leiomyoma, keratoacanthoma, amelanotic melanoma, and squamous cell carcinoma.[15,16,17,18,19,20,21,22,23,24] Pterygia are typically slowly enlarging vascular pink, triangular, or wing-shaped conjunctival lesions, more frequently on the nasal side that can extend onto the cornea. Juvenile xanthogranulomas are often multiple dome-shaped, pink to red papules or nodules that usually progress to a brown or yellowish color and may have telangiectasias or a scaly surface. Nodular fasciitis presents as rapidly growing, firm subcutaneous or submucosal lesions along fascia and occurs in younger patients in the 20 to- 40-year range.

The main histologic differential diagnoses of UPS extending in the superficial subcutis and dermis include spindle cell carcinoma, spindle cell malignant melanoma, leiomyosarcoma, fibrosarcoma, and malignant schwannoma. Other entities such as Kaposi sarcoma, dermal nodular fasciitis, and metastases may also be confused with this tumor.

Treatment

As with most sarcomas, the histologic grade of UPS is important in predicting the biologic behavior of the tumor and for planning the most appropriate management.[43,44,45,46] Kamat et al[42] reported 100% of 55 UPS to be high grade. The primary treatment for such lesions is radical surgical excision with wide margins along with dissection of regional lymph nodes.[41] Clear margins of resection are the most important factor in preventing a recurrence. In a series of 2084 microscopic resection margins of localized soft tissue tumors, positive margins nearly doubled the risk of local recurrence, metastasis, and disease-related death.[47] Wide surgical margins are associated with a better prognosis and reduced recurrence rates.[44,48,49] However, in the head and neck region, an adequate surgical margin is often limited because of the need to preserve tissue for a functional reconstruction, particularly in the periocular area. For this reason, histologically controlled surgical excision can be important. Although Mohs surgery has been advocated for UPS, and some investigators have reported lower recurrence rates than seen with wide surgical resection,[50,51,52,53] other studies showed no added benefit with Mohs surgery compared with wide margin resection.

Adjuvant radiotherapy UPS has been reported to reduce the rate of local recurrence.[43,54,55,56] However, several reports failed to show any added benefit for overall survival from the addition of radiotherapy.[41,42] Chemotherapy has limited use in the treatment of periocular UPS and has not been associated with improved recurrence or survival rates.[42,57,58]

(Print pagebreak 991)

Prognosis

In a series of 36 cases of UPS, regardless of treatment, the recurrence rate was 47% over 3 years, and 28% developed distant metastasis.[41] There was no benefit from Mohs microsurgery or adjunctive radiotherapy compared with wide surgical resection alone. The overall 5-year survival for UPS has been reported to be between 35% and 70%, depending upon several prognostic factors.[7,43,44,46,59,60] Metastasis is seen in about 40% of cases, with the lung as the most common site.[43,45,61,62,63]

The most important prognostic factors that correlate with survival include tumor grade, depth of invasion, tumor size, metastatic status, patient age, and histologic subtype.[64,65,66] Favorable prognostic factors include age less than 60 years, tumor size less than 5 cm, superficial location, low histologic grade, and the absence of metastatic disease.

Histopathology

Undifferentiated soft tissue sarcoma (USTS) is the current World Health Organization term encompassing undifferentiated spindle cell sarcoma, UPS, and undifferentiated round cell sarcoma.[67] Diagnosis of USTS requires “the absence of any morphological or immunohistochemical feature of specific differentiation; demonstrated absence of distinctive molecular aberration.”[67] Diagnosis of UPS, a subtype of USTS, thus requires the exclusion of pleomorphic leiomyosarcoma, pleomorphic rhabdomyosarcoma, dedifferentiated liposarcoma, extraskeletal osteosarcoma, and metastatic carcinoma and melanoma.[68,69] In the dermatopathology literature, UPS includes the entities termed “atypical fibroxanthoma,” “superficial UPS,” and “pleomorphic dermal sarcoma” when the tumor is superficial, while neoplasms arising deep to the dermal fascia are classified as UPS or deep UPS.[70,71]

UPS has variable architectural patterns ranging from patternless to storiform to fascicular (Figures 147.3 and 147.4), with frequent transitions between storiform and pleomorphic areas.[72] Tumor cells may be pleomorphic spindle cells (Figure 147.3), plump fibroblast-like cells, or multinucleated giant cells with hyperchromatic irregular nuclei and brightly eosinophilic cytoplasm (Figure 147.4).[72] There may be numerous typical and atypical mitotic figures.[72] UPS may have focal myxoid change, a hemangiopericytoma-like vascular pattern, and there may rarely be metaplastic osteoid or chondroid.[72] The stroma may feature xanthoma cells and chronic inflammatory cells.[72] UPS may have focal immunoreactivity for smooth muscle actin or cytokeratins, but the staining should not be diffuse.[72] Tumor cells typically lack immunoreactivity for the smooth muscle markers desmin and h-caldesmon; the skeletal muscle markers myogenin and MyoD1; the liposarcoma markers MDM2 and CDK4; the extraskeletal marker SATB2; the melanoma markers S100 protein and SOX10; and cytokeratins.[68] UPS is negative for CD34 expression characteristic of solitary fibrous tumor and dermatofibrosarcoma protuberans. UPS's histological *(Print pagebreak 992)* grading incorporates tumor differentiation (score 3 for undifferentiated sarcomas), mitotic count, and the amount of tumor necrosis.[73,74] Pleomorphic dermal sarcoma, the superficial analog of UPS, shares histological and immunohistochemical features with UPS (Figure 147.5).[70,71,75,76] Deeper depth of invasion,[70,76] the presence of lymphatic or vascular invasion,[70] and positive resection margins[76] are predictors of a poorer prognosis in atypical fibroxanthoma/pleomorphic dermal sarcoma.

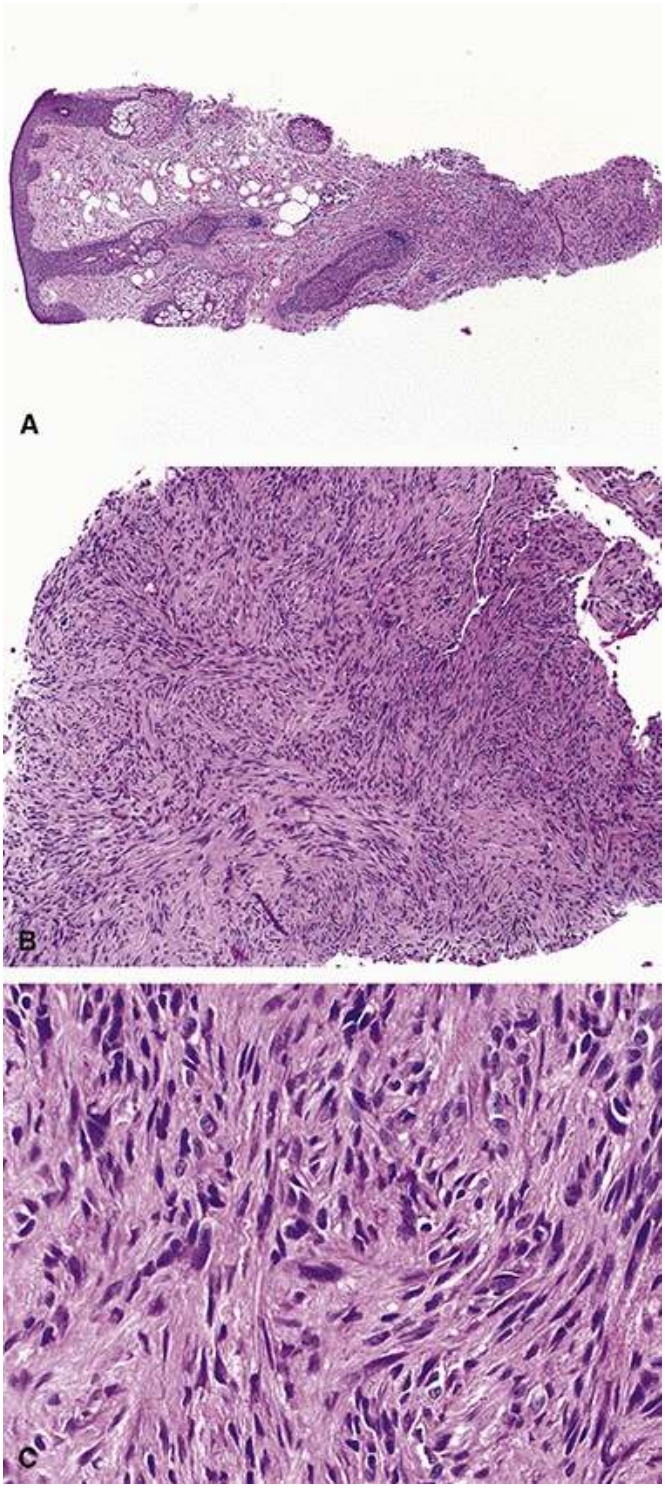

FIGURE 147.3 This undifferentiated pleomorphic sarcoma (UPS) formed a 1-cm diameter, mobile, subcutaneous nodule in the lateral right upper eyelid beneath the eyebrow of a woman in her middle 50s. Following the biopsy, the nodule was completely excised by Mohs micrographic surgery; there has been no recurrence after 10 years. A, The UPS is centered in the subcutaneous tissue on the right side of the photomicrograph. B, The tumor cells form fascicles with a storiform pattern. C, Pleomorphic plump fibroblasts form the fascicles. The tumor cells lacked any immunohistochemical markers for differentiation leading to the diagnosis of UPS.

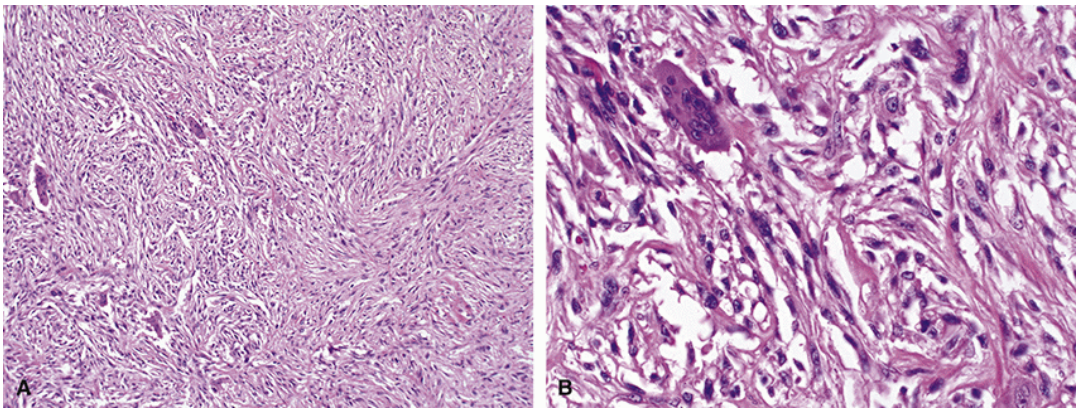

FIGURE 147.4 This undifferentiated pleomorphic sarcoma arose in the right superomedial orbit and recurred following biopsy and Mohs micrographic surgery. Orbitotomy with attempted resection had positive surgical margins, and orbital exenteration was subsequently performed. The tumor recurred following orbital exenteration, and the patient died with metastatic disease. A, The orbital tumor has a storiform pattern with numerous multinucleated giant tumor cells. B, Plump spindle cells with multinucleated giant cells having brightly eosinophilic cytoplasm compose the tumor. The tumor cells lacked immunophenotypic evidence of differentiation.

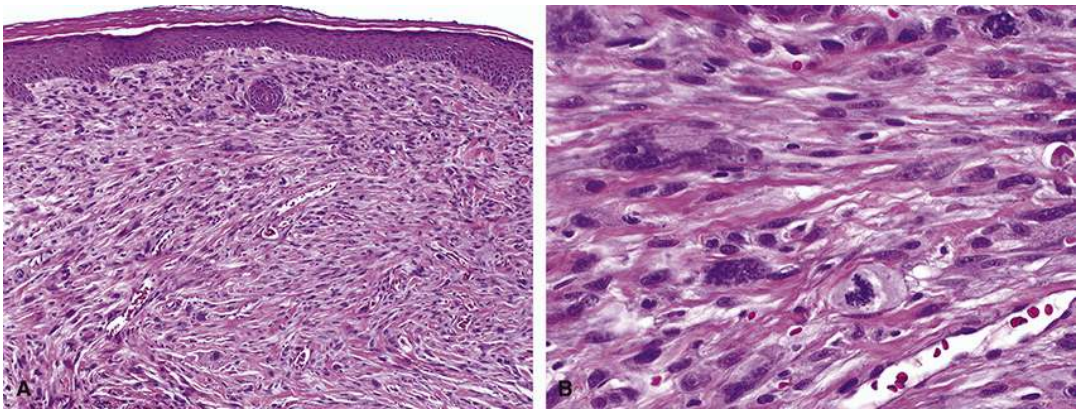

FIGURE 147.5 This atypical fibroxanthoma/dermal pleomorphic sarcoma (superficial undifferentiated pleomorphic sarcoma) arose on the frontal scalp of an octogenarian man. A, Plump spindle tumor cells are in the superficial reticular dermis, replace the papillary dermis, and abut the epidermis. B, The tumor has many multinucleated giant tumor cells. An atypical mitotic figure is at the right of a multinucleated giant cell.
